THE PHARMACOLOGICAL BASIS OF
THERAPEUTICS

THIRTEENTH EDITION

Notice

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

Contents

Contributors ix
Preface xv
Acknowledgments xvii

Section I

General Principles 1

1. Drug Invention and the Pharmaceutical Industry..... 3
Suzanne M. Rivera and Alfred Goodman Gilman
2. Pharmacokinetics: The Dynamics of Drug Absorption,
Distribution, Metabolism, and Elimination 13
Iain L. O. Buxton
3. Pharmacodynamics: Molecular Mechanisms of Drug Action..... 31
Donald K. Blumenthal
4. Drug Toxicity and Poisoning..... 55
Michelle A. Erickson and Trevor M. Penning
5. Membrane Transporters and Drug Response 65
Kathleen M. Giacomini and Yuichi Sugiyama
6. Drug Metabolism 85
Frank J. Gonzalez, Michael Coughtrie, and Robert H. Tukey
7. Pharmacogenetics 101
Dan M. Roden

Section II

Neuropharmacology 113

8. Neurotransmission: The Autonomic and Somatic Motor
Nervous Systems 115
Thomas C. Westfall, Heather Macarthur, and David P. Westfall
9. Muscarinic Receptor Agonists and Antagonists 149
Joan Heller Brown, Katharina Brandl, and Jürgen Wess
10. Anticholinesterase Agents..... 163
Palmer Taylor
11. Nicotine and Agents Acting at the Neuromuscular
Junction and Autonomic Ganglia 177
Ryan E. Hibbs and Alexander C. Zambon
12. Adrenergic Agonists and Antagonists 191
Thomas C. Westfall, Heather Macarthur, and David P. Westfall
13. 5-Hydroxytryptamine (Serotonin) and Dopamine 225
David R. Sibley, Lisa A. Hazelwood, and Susan G. Amara
14. Neurotransmission in the Central Nervous System 243
R. Benjamin Free, Janet Clark, Susan Amara, and David R. Sibley
15. Drug Therapy of Depression and Anxiety Disorders 267
James M. O'Donnell, Robert R. Bies, and Richard C. Shelton
16. Pharmacotherapy of Psychosis and Mania 279
Jonathan M. Meyer
17. Pharmacotherapy of the Epilepsies..... 303
Misty D. Smith, Cameron S. Metcalf, and Karen S. Wilcox
18. Treatment of Central Nervous System
Degenerative Disorders 327
Erik D. Roberson
19. Hypnotics and Sedatives..... 339
S. John Mihic, Jody Mayfield, and R. Adron Harris

20. Opioids, Analgesia, and Pain Management..... 355
Tony Yaksh and Mark Wallace
21. General Anesthetics and Therapeutic Gases 387
**Hemal H. Patel, Matthew L. Pearn, Piyush M. Patel,
and David M. Roth**
22. Local Anesthetics 405
William A. Catterall and Kenneth Mackie
23. Ethanol..... 421
**S. John Mihic, George F. Koob, Jody Mayfield,
and R. Adron Harris**
24. Drug Use Disorders and Addiction 433
Charles P. O'Brien

Section III

Modulation of Pulmonary, Renal, and Cardiovascular Function 443

25. Drugs Affecting Renal Excretory Function 445
Edwin K. Jackson
26. Renin and Angiotensin..... 471
Randa Hilal-Dandan
27. Treatment of Ischemic Heart Disease..... 489
Thomas Eschenhagen
28. Treatment of Hypertension..... 507
Thomas Eschenhagen
29. Therapy of Heart Failure 527
Thomas Eschenhagen
30. Antiarrhythmic Drugs..... 547
Bjorn C. Knollmann and Dan M. Roden
31. Treatment of Pulmonary Arterial Hypertension 573
Dustin R. Fraidenburg, Ankit A. Desai, and Jason X.-J. Yuan
32. Blood Coagulation and Anticoagulant, Fibrinolytic, and
Antiplatelet Drugs..... 585
Kerstin Hogg and Jeffrey I. Weitz
33. Drug Therapy for Dyslipidemias..... 605
Holly E. Gurgle and Donald K. Blumenthal

Section IV

Inflammation, Immunomodulation, and Hematopoiesis 619

34. Introduction to Immunity and Inflammation..... 621
Nancy Fares-Frederickson and Michael David
35. Immunosuppressants and Tolerogens..... 637
Alan M. Krensky, Jamil R. Azzi, and David A. Hafler
36. Immune Globulins and Vaccines 655
Roberto Tinoco and James E. Crowe, Jr.
37. Lipid-Derived Autacoids: Eicosanoids and
Platelet-Activating Factor..... 673
Emer M. Smyth, Tilo Grosser, and Garret A. FitzGerald
38. Pharmacotherapy of Inflammation, Fever, Pain, and Gout..... 685
Tilo Grosser, Emer M. Smyth, and Garret A. FitzGerald

39. Histamine, Bradykinin, and Their Antagonists 711
Randal A. Skidgel
40. Pulmonary Pharmacology 727
Peter J. Barnes
41. Hematopoietic Agents: Growth Factors, Minerals, and Vitamins 751
Kenneth Kaushansky and Thomas J. Kipps

Section V

Hormones and Hormone Antagonists 769

42. Introduction to Endocrinology:
 The Hypothalamic-Pituitary Axis 771
Mark E. Molitch and Bernard P. Schimmer
43. Thyroid and Antithyroid Drugs 787
Gregory A. Brent and Ronald J. Koenig
44. Estrogens, Progestins, and the Female Reproductive Tract 803
Ellis R. Levin, Wendy S. Vitek, and Stephen R. Hammes
45. Androgens and the Male Reproductive Tract 833
Peter J. Snyder
46. Adrenocorticotrophic Hormone, Adrenal Steroids, and the Adrenal Cortex 845
Bernard P. Schimmer and John W. Funder
47. Endocrine Pancreas and Pharmacotherapy of Diabetes Mellitus and Hypoglycemia 863
Alvin C. Powers and David D'Alessio
48. Agents Affecting Mineral Ion Homeostasis and Bone Turnover 887
Thomas D. Nolin and Peter A. Friedman

Section VI

Gastrointestinal Pharmacology 907

49. Pharmacotherapy for Gastric Acidity, Peptic Ulcers, and Gastroesophageal Reflux Disease 909
Keith A. Sharkey and Wallace K. MacNaughton
50. Gastrointestinal Motility and Water Flux, Emesis, and Biliary and Pancreatic Disease 921
Keith A. Sharkey and Wallace K. MacNaughton
51. Pharmacotherapy of Inflammatory Bowel Disease 945
Wallace K. MacNaughton and Keith A. Sharkey

Section VII

Chemotherapy of Infectious Diseases 955

52. General Principles of Antimicrobial Therapy 957
Tawanda Gumbo
53. Chemotherapy of Malaria 969
Joseph M. Vinetz
54. Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections 987
Dawn M. Wetzel and Margaret A. Phillips
55. Chemotherapy of Helminth Infections 1001
Jennifer Keiser, James McCarthy, and Peter Hotez
56. Sulfonamides, Trimethoprim-Sulfamethoxazole, Quinolones, and Agents for Urinary Tract Infections 1011
Conan MacDougall

57. Penicillins, Cephalosporins, and Other β -Lactam Antibiotics 1023
Conan MacDougall
58. Aminoglycosides 1039
Conan MacDougall
59. Protein Synthesis Inhibitors and Miscellaneous Antibacterial Agents 1049
Conan MacDougall
60. Chemotherapy of Tuberculosis, *Mycobacterium avium* Complex Disease, and Leprosy 1067
Tawanda Gumbo
61. Antifungal Agents 1087
P. David Rogers and Damian J. Krysan
62. Antiviral Agents (Nonretroviral) 1105
Edward P. Acosta
63. Treatment of Viral Hepatitis (HBV/HCV) 1119
Jennifer J. Kiser and Charles W. Flexner
64. Antiretroviral Agents and Treatment of HIV Infection 1137
Charles W. Flexner

Section VIII

Pharmacotherapy of Neoplastic Disease 1159

65. General Principles in the Pharmacotherapy of Cancer 1161
Anton Wellstein
66. Cytotoxic Drugs 1167
Anton Wellstein, Giuseppe Giaccone, Michael B. Atkins, and Edward A. Sausville
67. Pathway-Targeted Therapies: Monoclonal Antibodies, Protein Kinase Inhibitors, and Various Small Molecules 1203
Anton Wellstein, Giuseppe Giaccone, Michael B. Atkins, and Edward A. Sausville
68. Hormones and Related Agents in the Therapy of Cancer 1237
Claudine Isaacs, Anton Wellstein, and Anna T. Riegel

Section IX

Special Systems Pharmacology 1249

69. Ocular Pharmacology 1251
Jeffrey D. Henderer and Christopher J. Rapuano
70. Dermatological Pharmacology 1271
Matthew J. Sewell, Craig N. Burkhardt, and Dean S. Morrell
71. Environmental Toxicology: Carcinogens and Heavy Metals 1297
Michael C. Byrns and Trevor M. Penning

Appendices

- I. Principles of Prescription Order Writing and Patient Compliance 1317
Iain L. O. Buxton
- II. Design and Optimization of Dosage Regimens: Pharmacokinetic Data 1325
Kenneth E. Thummel, Danny D. Shen, and Nina Isoherranen

Index 1379

Contributors

Edward P. Acosta, PharmD

Professor and Director, Division of Clinical Pharmacology
University of Alabama at Birmingham School of Medicine
Birmingham, Alabama

Susan G. Amara, PhD

Scientific Director
National Institute of Mental Health
National Institutes of Health
Bethesda, Maryland

Michael B. Atkins, MD

Professor of Oncology and Medicine
Georgetown University, School of Medicine
Washington DC

Jamil Azzi, MD, FAST

Assistant Professor of Medicine
Transplantation Research Center
Harvard Medical School
Boston, Massachusetts

Peter J. Barnes, DM, DSc, FRCP, FMedSci, FRS

Professor and Head of Respiratory Medicine
National Heart & Lung Institute
Imperial College, London

Robert R. Bies, PharmD, PhD

Associate Professor
School of Pharmacy and Pharmaceutical Sciences
University at Buffalo
The State University of New York
Buffalo, New York

Donald K. Blumenthal, PhD

Associate Professor of Pharmacology & Toxicology
College of Pharmacy
University of Utah
Salt Lake City, Utah

Katharina Brandl, PhD

Assistant Professor of Pharmacy
University of California San Diego
Skaggs School of Pharmacy and Pharmaceutical Sciences
La Jolla, California

Gregory A. Brent, MD

Professor of Medicine and Physiology
Geffen School of Medicine
University of California
Los Angeles, California

Joan Heller Brown, PhD

Professor and Chair of Pharmacology
University of California
San Diego, California

Craig N. Burkhart, MD

Associate Professor of Dermatology, School of Medicine
University of North Carolina
Chapel Hill, North Carolina

Iain L. O. Buxton, PharmD

Foundation Professor and Chair
Department of Pharmacology
University of Nevada, Reno School of Medicine
Reno, Nevada

Michael C. Byrns, PhD

Associate Professor of Environmental Health
Illinois State University
Normal, Illinois

William A. Catterall, PhD

Professor and Chair of Pharmacology
University of Washington School of Medicine
Seattle, Washington

Janet A. Clark, PhD

Director, Office of Fellowship Training
Intramural Research Program
National Institute of Mental Health
National Institutes of Health
Bethesda, Maryland

Michael W. H. Coughtrie, PhD

Professor and Dean
Faculty of Pharmaceutical Sciences
University of British Columbia
Vancouver, Canada

James E. Crowe, Jr.

Professor of Pediatrics, Pathology, Microbiology and Immunology
Director, Vanderbilt Vaccine Center
Vanderbilt University Medical Center
Nashville, Tennessee

David D'Alessio, MD

Professor, Department of Medicine
Director, Division of Endocrinology
Duke University Medical Center
Durham, North Carolina

Michael David, PharmD, PhD

Professor of Biology and Moores Cancer Center
University of California, San Diego
La Jolla, California

Ankit A. Desai, MD

Assistant Professor of Medicine
University of Arizona
Tucson, Arizona

Michelle Erickson, PhD

Research Assistant Professor of Gerontology and Geriatric
Medicine, School of Medicine
University of Washington
Seattle, Washington

Thomas Eschenhagen, MD

Professor of Pharmacology and Toxicology
Chair of Pharmacology
University Medical Center Hamburg Eppendorf
Hamburg, Germany

Nancy Fares-Frederickson, PhD

Division of Biology and Moores Cancer Center
University of California, San Diego
La Jolla, California

Garret A. FitzGerald, MD

Professor of Medicine, Pharmacology and Translational Medicine
and Therapeutics;
Chair of Pharmacology
University of Pennsylvania School of Medicine
Philadelphia, Pennsylvania

Charles W. Flexner, MD

Professor of Medicine, Pharmacology and Molecular
Sciences, and International Health
The Johns Hopkins University School of Medicine and
Bloomberg School of Public Health
Baltimore, Maryland

Dustin R. Fraidenburg, MD

Assistant Professor of Medicine
University of Illinois at Chicago
Chicago, Illinois

R. Benjamin Free, PhD

Staff Scientist, Molecular Neuropharmacology Section
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, Maryland

Peter A. Friedman, PhD

Professor of Pharmacology and Chemical Biology, and
of Structural Biology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

John W. Funder, AC, MD, BS, PhD, FRACP

Professor of Medicine, Prince Henry's Institute
Monash Medical Centre
Clayton, Victoria, Australia

Giuseppe Giaccone, MD, PhD

Professor of Medical Oncology and Pharmacology
Georgetown University
Washington DC

Kathleen M. Giacomini, PhD

Professor of Bioengineering and Therapeutic Sciences,
School of Pharmacy
University of California
San Francisco, California

Alfred G. Gilman, MD, PhD (deceased)

Professor (Emeritus) of Pharmacology
University of Texas Southwestern Medical School
Dallas, Texas

Frank J. Gonzalez, PhD

Chief, Laboratory of Metabolism
Center for Cancer Research, National Cancer Institute
Bethesda, Maryland

Tilo Grosser, MD

Research Associate Professor of Pharmacology
Institute for Translational Medicine and Therapeutics
University of Pennsylvania
Philadelphia, Pennsylvania

Tawanda Gumbo, MD

Director, Center for Infectious Diseases Research and
Experimental Therapeutics
Baylor Research Institute
Baylor University Medical Center
Dallas, Texas

Holly Gurgle, PharmD, BCACP, CDE

Assistant Professor (Clinical) of Pharmacotherapy
College of Pharmacy
University of Utah
Salt Lake City, Utah

David A. Hafler, MD

William S. and Lois Stiles Edgerly Professor of Neurology and
Immunobiology
Chairman, Department of Neurology
Yale School of Medicine
New Haven, Connecticut

Stephen R. Hammes, MD, PhD

Professor of Medicine, Chief of Endocrinology and Metabolism
School of Medicine and Dentistry
University of Rochester
Rochester, New York

R. Adron Harris, PhD

Professor of Neuroscience and Pharmacology
Waggoner Center for Alcohol and Addiction Research
University of Texas
Austin, Texas

Lisa A. Hazelwood, PhD

Principal Research Scientist, Liver Disease and Fibrosis, AbbVie
North Chicago, Illinois

Jeffrey D. Henderer, MD

Professor of Ophthalmology
Dr. Edward Hagop Bedrossian Chair of Ophthalmology
Lewis Katz School of Medicine at Temple University
Philadelphia, Pennsylvania

Ryan E. Hibbs, PhD

Assistant Professor of Neuroscience
University of Texas Southwestern Medical School
Dallas, Texas

Randa Hilal-Dandan, PhD

Lecturer in Pharmacology
University of California
San Diego, California

Peter J. Hotez, MD, PhD

Professor of Pediatrics and Molecular Virology & Microbiology
Texas Children's Hospital Endowed Chair in Tropical Pediatrics
Dean, National School of Tropical Medicine
Baylor College of Medicine
Houston, Texas

Claudine Isaacs, MD, FRCPC

Professor of Medicine and Oncology
Georgetown University, School of Medicine
Washington DC

Nina Isoherranen, PhD

Professor of Pharmaceutics, School of Pharmacy
University of Washington
Seattle, Washington

Edwin K. Jackson, PhD

Professor of Pharmacology and Chemical Biology
University of Pittsburgh School of Medicine
Pittsburgh, Pennsylvania

Kenneth Kaushansky, MD

Dean, School of Medicine and Senior Vice President of Health Sciences
SUNY Stony Brook
New York, New York

Jennifer Keiser, PhD

Professor of Neglected Tropical Diseases
Swiss Tropical and Public Health Institute
Basel, Switzerland

Thomas J. Kipps, MD, PhD

Professor of Medicine, Moores Cancer Center
University of California
San Diego, California

Jennifer J. Kiser, PharmD

Associate Professor, Pharmaceutical Sciences
University of Colorado
Denver, Colorado

Ronald J. Koenig, MD, PhD

Professor of Metabolism, Endocrinology and Diabetes
Department of Internal Medicine
University of Michigan Health System
Ann Arbor, Michigan

George F. Koob, PhD

Director, National Institute on Alcohol Abuse and Alcoholism
National Institutes of Health
Rockville, Maryland

Alan M. Krensky, MD

Vice Dean
Professor of Pediatrics and Microbiology & Immunology
Feinberg School of Medicine
Northwestern University
Chicago, Illinois

Ellis R. Levin, MD

Professor of Medicine; Chief of Endocrinology
Diabetes and Metabolism
University of California, Irvine, and Long Beach
VA Medical Center
Long Beach, California

VA-San Diego Healthcare System
San Diego, California

Piyush M. Patel, MD, FRCPC

Professor of Anesthesiology
University of California, San Diego
VA-San Diego Healthcare System
San Diego, California

Matthew L. Pearn, MD

Associate Professor of Anesthesiology
University of California, San Diego
VA-San Diego Healthcare System
San Diego, California

Trevor M. Penning, PhD

Professor of Systems Pharmacology & Translational Therapeutics
Director, Center of Excellence in Environmental Toxicology
School of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Margaret A. Phillips, PhD

Professor of Pharmacology
University of Texas Southwestern Medical School
Dallas, Texas

Alvin C. Powers, MD

Professor of Medicine, Molecular Physiology and Biophysics
Director, Vanderbilt Diabetes Center
Chief, Division of Diabetes, Endocrinology, and Metabolism
Vanderbilt University School of Medicine
Nashville, Tennessee

Christopher J. Rapuano, MD

Director, Cornea Service and Refractive Surgery
Wills Eye Hospital
Philadelphia, Pennsylvania

Anna T. Riegel, PhD

Professor of Oncology and Pharmacology
Georgetown University, School of Medicine
Washington DC

Suzanne M. Rivera, PhD, MSW

Assistant Professor of Bioethics
Case Western Reserve University
Cleveland, Ohio

Erik D. Roberson, MD, PhD

Associate Professor of Neurology and Neurobiology
Co-Director, Center for Neurodegeneration and
Experimental Therapeutics
University of Alabama at Birmingham
Birmingham, Alabama

Dan M. Roden, MD

Professor of Medicine, Pharmacology, and Biomedical Informatics
Senior Vice President for Personalized Medicine
Vanderbilt University Medical Center
Nashville, Tennessee

P. David Rogers, PharmD, PhD, FCCP

First Tennessee Endowed Chair of Excellence in Clinical Pharmacy
Vice-Chair for Research
Director, Clinical and Experimental Therapeutics
Co-Director, Center for Pediatric Pharmacokinetics and Therapeutics
Professor of Clinical Pharmacy and Pediatrics
University of Tennessee College of Pharmacy
Memphis, Tennessee

David M. Roth, MD, PhD

Professor of Anesthesiology
University of California, San Diego
VA-San Diego Healthcare System
San Diego, California

Edward A. Sausville, MD, PhD

Professor of Medicine; Adjunct Professor, Pharmacology &
Experimental Therapeutics
University of Maryland School of Medicine
Baltimore, Maryland

Matthew J. Sewell, MD

Pediatric Dermatology Fellow
Department of Dermatology
University of North Carolina
Chapel Hill, North Carolina

Bernard P. Schimmer, PhD

Professor (Emeritus) of Pharmacology and Toxicology
University of Toronto
Ontario, Canada

Keith A. Sharkey, PhD, CAGF, FCAHS

Professor of Physiology and Pharmacology
Cumming School of Medicine
University of Calgary
Calgary, Alberta, Canada

Richard C. Shelton, MD

Professor, Department of Psychiatry and Behavioral Neurobiology
The University of Alabama at Birmingham
Birmingham, Alabama

Danny Shen, PhD

Professor of Pharmaceutics, School of Pharmacy
University of Washington
Seattle, Washington

David R. Sibley, PhD

Senior Investigator, Molecular Neuropharmacology Section
National Institute of Neurological Disorders & Stroke
National Institutes of Health
Bethesda, Maryland

Randal A. Skidgel, PhD

Professor of Pharmacology
College of Medicine, University of Illinois-Chicago
Chicago, Illinois

Misty D. Smith, PhD

Research Assistant Professor, Department of
Pharmacology & Toxicology;
Research Assistant Professor, School of Dentistry
Co-Investigator, Anticonvulsant Drug Development Program
University of Utah
Salt Lake City, Utah

Emer M. Smyth, PhD

Director, Cancer Research Alliances
Assistant Dean for Cancer Research
Assistant Professor, Pathology and Cell Biology
Herbert Irving Comprehensive Cancer Center
Columbia University Medical Center
New York, New York

Peter J. Snyder, MD

Professor of Medicine
University of Pennsylvania
Philadelphia, Pennsylvania

Yuichi Sugiyama, PhD

Head of Sugiyama Laboratory
RIKEN Innovation Center
RIKEN Yokohama
Yokohama, Japan

Palmer Taylor, PhD

Sandra & Monroe Trout Professor of Pharmacology,
School of Medicine
Dean Emeritus, Skaggs School of Pharmacy and
Pharmaceutical Sciences
University of California
San Diego, California

Kenneth E. Thummel, PhD

Professor and Chair, Department of Pharmaceutics
University of Washington
Seattle, Washington

Roberto Tinoco, PhD

Research Assistant Professor
Infectious and Inflammatory Diseases Center
Sanford Burnham Prebys Medical Discovery Institute
La Jolla, California

Robert H. Tukey, PhD

Professor of Pharmacology and Chemistry/Biochemistry
University of California
San Diego, California

Joseph M. Vinetz, MD

Professor of Medicine, Division of Infectious Diseases
University of California
San Diego, California

Wendy Vitek, MD

Assistant Professor of Obstetrics and Gynecology
University of Rochester School of Medicine and Dentistry
Rochester, New York

Mark S. Wallace, MD

Professor of Clinical Anesthesiology
University of California
San Diego, California

Jeffrey I. Weitz, MD, FRCP(C), FACP

Professor of Medicine
Biochemistry and Biomedical Sciences McMaster University
Executive Director, Thrombosis & Atherosclerosis
Research Institute
Hamilton, Ontario, Canada

Anton Wellstein, MD, PhD

Professor of Oncology and Pharmacology
Georgetown University, School of Medicine
Washington DC

Jürgen Wess, PhD

Chief, Molecular Signaling Section
Lab. of Bioorganic Chemistry
National Institute of Diabetes and Digestive and Kidney Diseases
Bethesda, Maryland

David P. Westfall, PhD

Professor (Emeritus) of Pharmacology
University of Nevada School of Medicine
Reno, Nevada

Thomas C. Westfall, PhD

Professor and Chair Emeritus, Department of Pharmacology
and Physiology
Saint Louis University School of Medicine
St. Louis, Missouri

Dawn M. Wetzel, MD, PhD

Assistant Professor of Pediatrics (Division of Infectious Diseases)
and Pharmacology
University of Texas Southwestern Medical Center
Dallas, Texas

Karen S. Wilcox, PhD

Professor and Chair, Department of Pharmacology
Director, Anticonvulsant Drug Development Program
University of Utah
Salt Lake City, Utah

Kerstin de Wit, MD

Department of Medicine
Divisions of Emergency and Haematology
McMaster University, Canada;
Thrombosis and Emergency Physician
Hamilton Health Sciences
Hamilton, Ontario, Canada

Tony L. Yaksh, PhD

Professor of Anesthesiology and Pharmacology
University of California, San Diego
La Jolla, California

Jason X.-J. Yuan, MD, PhD

Professor of Medicine and Physiology;
Chief, Division of Translational and Regenerative Medicine
University of Arizona
Tucson, Arizona

Alexander C. Zambon, PhD

Assistant Professor of Biopharmaceutical Sciences
Keck Graduate Institute
Claremont, California

Preface

The first edition of this book appeared in 1941, the product of a collaboration between two friends and professors at Yale, Louis Goodman and Alfred Gilman. Their purpose, stated in the preface to that edition, was to correlate pharmacology with related medical sciences, to reinterpret the actions and uses of drugs in light of advances in medicine and the basic biomedical sciences, to emphasize the applications of pharmacodynamics to therapeutics, and to create a book that would be useful to students of pharmacology and to physicians. We continue to follow these principles in the 13th edition.

The 1st edition was quite successful despite its high price, \$12.50, and soon became known as the “blue bible of pharmacology.” The book was evidence of the deep friendship between its authors, and when the Gilmans’ son was born in 1941, he was named Alfred Goodman Gilman. World War II and the relocation of both authors—Goodman to Utah, Gilman to Columbia—postponed a second edition until 1955. The experience of writing the second edition during a period of accelerating basic research and drug development persuaded the authors to become editors, relying on experts whose scholarship they trusted to contribute individual chapters, a pattern that has been followed ever since.

Alfred G. Gilman, the son, served as an associate editor for the 5th edition (1975), became the principal editor for the 6th (1980), 7th (1985), and 8th (1990) editions, and consulting editor for the 9th and 10th editions that were edited by Lee Limbird and Joel Hardman. After an absence in the 11th edition, Al Gilman agreed to co-author the introductory chapter in the 12th edition. His final contribution to G&G, a revision of that chapter, is the first chapter in this edition, which we dedicate to his memory.

A multi-authored text of this sort grows by accretion, posing challenges to editors but also offering 75 years of wisdom, memorable pearls, and flashes of wit. Portions of prior editions persist in the current edition, and we have given credit to recent former contributors at the end of each chapter. Such a text also tends to grow in length with each edition, as contributors add to existing text and as pharmacotherapy advances. To keep the length manageable and in a single volume, Dr. Randa

Hilal-Dandan and I prepared a shortened version of each chapter and then invited contributors to add back old material that was essential and to add new material. We also elected to discard the use of extract (very small) type and to use more figures to explain signaling pathways and mechanisms of drug action. Not wanting to favor one company’s preparation of an agent over that of another, we have ceased to use trade names except as needed to refer to drug combinations or to distinguish multiple formulations of the same agent with distinctive pharmacokinetic or pharmacodynamic properties. Counter-balancing this shortening are five new chapters that reflect advances in the therapeutic manipulation of the immune system, the treatment of viral hepatitis, and the pharmacotherapy of cardiovascular disease and pulmonary artery hypertension.

Editing such a book brings into view a number of overarching issues: Over-prescribing of antibiotics and their excessive use in agricultural animal husbandry continues to promote the development of antimicrobial resistance; the application of CRISPR/cas9 will likely provide new therapeutic avenues; global warming and the sheer size of the human population require medical scientists and practitioners to promote remedial and preventive action based on data, not ideology.

A number of people have made invaluable contributions to the preparation of this edition. My thanks to Randa Hilal-Dandan and Bjorn Knollmann for their editorial work; to Harriet Lebowitz of McGraw-Hill, who guided our work, prescribed the updated style, and kept the project moving to completion; to Vastavikta Sharma of Cenveo Publishers Services, who oversaw the copy editing, typesetting, and preparation of the artwork; to Nelda Murri, our consulting pharmacist, whose familiarity with clinical pharmacy is evident throughout the book; to James Shanahan, publisher at McGraw-Hill, for supporting the project; and to the many readers who have written to critique the book and offer suggestions.

- “Me Too” Versus True Innovation: The Pace of New Drug Development

The first edition of *Goodman & Gilman*, published in 1941, helped to organize the field of pharmacology, giving it intellectual validity and an academic identity. That edition began: “The subject of pharmacology is a broad one and embraces the knowledge of the source, physical and chemical properties, compounding, physiological actions, absorption, fate, and excretion, and therapeutic uses of drugs. A *drug* may be broadly defined as any chemical agent that affects living protoplasm, and few substances would escape inclusion by this definition.” This General Principles section provides the underpinnings for these definitions by exploring the processes of drug invention, development, and regulation, followed by the basic properties of the interactions between the drug and biological systems: *pharmacodynamics*, *pharmacokinetics* (including drug transport and metabolism), and *pharmacogenomics*, with a brief foray into *drug toxicity and poisoning*. Subsequent sections deal with the use of drugs as therapeutic agents in human subjects.

Use of the term *invention* to describe the process by which a new drug is identified and brought to medical practice, rather than the more conventional term *discovery*, is intentional. Today, useful drugs are rarely discovered hiding somewhere waiting to be found. The term *invention* emphasizes the process by which drugs are sculpted and brought into being based on experimentation and optimization of many independent properties; there is little serendipity.

From Early Experiences With Plants to Modern Chemistry

The human fascination—and sometimes infatuation—with chemicals that alter biological function is ancient and results from long experience with and dependence on plants. Because most plants are root bound, many of them produce harmful compounds for defense that animals have learned to avoid and humans to exploit (or abuse).

Earlier editions of this text described examples: the appreciation of coffee (caffeine) by the prior of an Arabian convent, who noted the behavior

of goats that gamboled and frisked through the night after eating the berries of the coffee plant; the use of mushrooms and the deadly nightshade plant by professional poisoners; of belladonna (“beautiful lady”) to dilate pupils; of the Chinese herb ma huang (containing ephedrine) as a circulatory stimulant; of curare by South American Indians to paralyze and kill animals hunted for food; and of poppy juice (opium) containing morphine (from the Greek *Morpheus*, the God of dreams) for pain relief and control of dysentery. Morphine, of course, has well-known addicting properties, mimicked in some ways by other problematic (“recreational”) natural products—nicotine, cocaine, and ethanol.

Although terrestrial and marine organisms remain valuable sources of compounds with pharmacological activities, drug invention became more allied with synthetic organic chemistry as that discipline flourished over the past 150 years, beginning in the dye industry. Dyes are colored compounds with selective affinity for biological tissues. Study of these interactions stimulated Paul Ehrlich to postulate the existence of chemical receptors in tissues that interacted with and “fixed” the dyes. Similarly, Ehrlich thought that unique receptors on microorganisms or parasites might react specifically with certain dyes and that such selectivity could spare normal tissue. Ehrlich’s work culminated in the invention of arsphenamine in 1907, which was patented as “salvarsan,” suggestive of the hope that the chemical would be the salvation of humankind. This and other organic arsenicals were used for the chemotherapy of syphilis until the discovery of penicillin. The work of Gerhard Domagk demonstrated that another dye, prontosil (the first clinically useful sulfonamide), was dramatically effective in treating streptococcal infections, launching the era of antimicrobial chemotherapy.

The collaboration of pharmacology with chemistry on the one hand and with clinical medicine on the other has been a major contributor to the effective treatment of disease, especially since the middle of the 20th century.

Sources of Drugs

Small Molecules Are the Tradition

With the exception of a few naturally occurring hormones (e.g., insulin), most drugs were small organic molecules (typically <500 Da) until

*Deceased, December 23, 2015. AGG served on the Board of Directors of Regeneron Pharmaceuticals, Inc., a potential conflict of interest.

siRNAs: small interfering RNAs

recombinant DNA technology permitted synthesis of proteins by various organisms (bacteria, yeast) and mammalian cells. The usual approach to invention of a small-molecule drug is to screen a collection of chemicals ("library") for compounds with the desired features. An alternative is to synthesize and focus on close chemical relatives of a substance known to participate in a biological reaction of interest (e.g., congeners of a specific enzyme substrate chosen to be possible inhibitors of the enzymatic reaction), a particularly important strategy in the discovery of anticancer drugs.

Drug discovery in the past often resulted from serendipitous observations of the effects of plant extracts or individual chemicals on animals or humans; today's approach relies more on high-throughput screening of libraries containing hundreds of thousands or even millions of compounds for their capacity to interact with a specific molecular target or elicit a specific biological response. Ideally, the target molecules are of human origin, obtained by transcription and translation of the cloned human gene. The potential drugs that are identified in the screen ("hits") are thus known to react with the human protein and not just with its relative (ortholog) obtained from the mouse or another species.

Among the variables considered in screening are the "drugability" of the target and the stringency of the screen in terms of the concentrations of compounds that are tested. *Drugability* refers to the ease with which the function of a target can be altered in the desired fashion by a small organic molecule. If the protein target has a well-defined binding site for a small molecule (e.g., a catalytic or allosteric site), chances are excellent that hits will be obtained. If the goal is to employ a small molecule to mimic or disrupt the interaction between two proteins, the challenge is much greater.

From Hits to Leads

Initial hits in a screen are rarely marketable drugs, often having modest affinity for the target and lacking the desired specificity and pharmacological properties. Medicinal chemists synthesize derivatives of the hits, thereby defining the structure-activity relationship and optimizing parameters such as affinity for the target, agonist/antagonist activity, permeability across cell membranes, absorption and distribution in the body, metabolism, and unwanted effects.

This approach was driven largely by instinct and trial and error in the past; modern drug development frequently takes advantage of determination of a high-resolution structure of the putative drug bound to its target. X-ray crystallography offers the most detailed structural information if the target protein can be crystallized with the lead drug bound to it. Using techniques of molecular modeling and computational chemistry, the structure provides the chemist with information about substitutions likely to improve the "fit" of the drug with the target and thus enhance the affinity of the drug for its target. Nuclear magnetic resonance (NMR) studies of the drug-receptor complex also can provide useful information (albeit usually at lower resolution), with the advantage that the complex need not be crystallized.

The holy grail of this approach to drug invention is to achieve success entirely through computation. Imagine a database containing detailed chemical information about millions of chemicals and a second database containing detailed structural information about all human proteins. The computational approach is to "roll" all the chemicals over the protein of interest to find those with high-affinity interactions. The dream becomes bolder if we acquire the ability to roll the chemicals that bind to the target of interest over all other human proteins to discard compounds that have unwanted interactions. Finally, we also will want to predict the structural and functional consequences of a drug binding to its target (a huge challenge), as well as all relevant pharmacokinetic properties of the molecules of interest. Indeed, computational approaches have suggested new uses for old drugs and offered explanations for recent failures of drugs in the later stages of clinical development (e.g., torcetrapib; see Box 1-2) (Xie et al., 2007, 2009).

Large Molecules Are Increasingly Important

Protein therapeutics were uncommon before the advent of recombinant DNA technology. Insulin was introduced into clinical medicine for the treatment of diabetes following the experiments of Banting and Best in 1921. Insulins purified from porcine or bovine pancreas are active in humans, although antibodies to the foreign proteins are occasionally problematic. Growth hormone, used to treat pituitary dwarfism, exhibits more stringent species specificity. Only the human hormone could be used after purification from pituitary glands harvested during autopsy, and such use had its dangers—some patients who received the human hormone developed Creutzfeldt-Jakob disease (the human equivalent of mad cow disease), a fatal degenerative neurological disease caused by prion proteins that contaminated the drug preparation. Thanks to gene cloning and the production of large quantities of proteins by expressing the cloned gene in bacteria or eukaryotic cells, protein therapeutics now use highly purified preparations of human (or humanized) proteins. Rare proteins can be produced in quantity, and immunological reactions are minimized. Proteins can be designed, customized, and optimized using genetic engineering techniques. Other types of macromolecules may also be used therapeutically. For example, antisense oligonucleotides are used to block gene transcription or translation, as are siRNAs.

Proteins used therapeutically include hormones; growth factors (e.g., erythropoietin, granulocyte colony-stimulating factor); cytokines; and a number of monoclonal antibodies used in the treatment of cancer and autoimmune diseases (Chapters 34–36 and 67). Murine monoclonal antibodies can be "humanized" (by substituting human for mouse amino acid sequences). Alternatively, mice have been engineered by replacement of critical mouse genes with their human equivalents, such that they make completely human antibodies. Protein therapeutics are administered parenterally, and their receptors or targets must be accessible extracellularly.

Targets of Drug Action

Early drugs came from observation of the effects of plants after their ingestion by animals, with no knowledge of the drug's mechanism or site of action. Although this approach is still useful (e.g., in screening for the capacity of natural products to kill microorganisms or malignant cells), modern drug invention usually takes the opposite approach, starting with

a statement (or hypothesis) that a certain protein or pathway plays a critical role in the pathogenesis of a certain disease, and that altering the protein's activity would be effective against that disease. Crucial questions arise:

- Can one find a drug that will have the desired effect against its target?
- Does modulation of the target protein affect the course of disease?
- Does this project make sense economically?

The effort expended to find the desired drug will be determined by the degree of confidence in the answers to the last two questions.

Is the Target Druggable?

The druggability of a target with a low-molecular-weight organic molecule relies on the presence of a binding site for the drug that exhibits considerable affinity and selectivity.

If the target is an enzyme or a receptor for a small ligand, one is encouraged. If the target is related to another protein that is known to have, for example, a binding site for a regulatory ligand, one is hopeful. However, if the known ligands are large peptides or proteins with an extensive set of contacts with their receptor, the challenge is much greater. If the goal is to disrupt interactions between two proteins, it may be necessary to find a “hot spot” that is crucial for the protein-protein interaction, and such a region may not be detected. Accessibility of the drug to its target also is critical. Extracellular targets are intrinsically easier to approach, and, in general, only extracellular targets are accessible to macromolecular drugs.

Has the Target Been Validated?

The question of whether the target has been validated is obviously a critical one. A negative answer, frequently obtained only retrospectively, is a common cause of failure in drug invention (Box 1–1). Modern techniques of molecular biology offer powerful tools for validation of potential drug targets, to the extent that the biology of model systems resembles human biology. Genes can be inserted, disrupted, and altered in mice. One can thereby create models of disease in animals or mimic the effects of long-term disruption or activation of a given biological process. If, for example, disruption of the gene encoding a specific enzyme or receptor has a beneficial effect in a valid murine model of a human disease, one may believe that the potential drug target has been validated. Mutations in humans also can provide extraordinarily valuable information.

For example, loss-of-function mutations in the *PCSK9* gene (encoding proprotein convertase subtilisin/kexin type 9) greatly lower concentrations of LDL cholesterol in blood and reduce the risk of myocardial infarction (Horton et al., 2009; Poirier and Mayer, 2013). Based on these findings, two companies now market antibodies that inhibit the action of *PCSK9*. These antibodies lower the concentration of LDL cholesterol in blood substantially and are essentially additive to the effects of statins; long-term outcome studies are in progress to determine whether the risk of significant cardiovascular events also is reduced. Additional molecules are in the queue.

BOX 1–1 ■ Target Validation: The Lesson of Leptin

Biological systems frequently contain redundant elements or can alter expression of drug-regulated elements to compensate for the effect of the drug. *In general, the more important the function, the greater the complexity of the system.* For example, many mechanisms control feeding and appetite, and drugs to control obesity have been notoriously difficult to find. The discovery of the hormone leptin, which suppresses appetite, was based on mutations in mice that cause loss of either leptin or its receptor; either kind of mutation results in enormous obesity in both mice and people. Leptin thus appeared to be a marvelous opportunity to treat obesity. However, on investigation, it was discovered that obese individuals have high circulating concentrations of leptin and appear insensitive to its action.

Is This Drug Invention Effort Economically Viable?

Drug invention and development is expensive (see Table 1-1), and economic realities influence the direction of pharmaceutical research. For example, investor-owned companies generally cannot afford to develop products for rare diseases or for diseases that are common only in economically underdeveloped parts of the world. Funds to invent drugs targeting rare diseases or diseases primarily affecting developing countries (especially parasitic diseases) often come from taxpayers or wealthy philanthropists.

Additional Preclinical Research

Following the path just described can yield a potential drug molecule that interacts with a validated target and alters its function in the desired fashion. Now, one must consider all aspects of the molecule in question—its affinity and selectivity for interaction with the target; its pharmacokinetic properties (ADME); issues of its large-scale synthesis or purification; its pharmaceutical properties (stability, solubility, questions of formulation); and its safety. One hopes to correct, to the extent possible, any obvious deficiencies by modification of the molecule itself or by changes in the way the molecule is presented for use.

Before being administered to people, potential drugs are tested for general toxicity by long-term monitoring of the activity of various systems in two species of animals, generally one rodent (usually the mouse) and one nonrodent (often the rabbit). Compounds also are evaluated for carcinogenicity, genotoxicity, and reproductive toxicity (see Chapter 4). In vitro and ex vivo assays are used when possible, both to spare animals and to minimize cost. If an unwanted effect is observed, an obvious question is whether it is mechanism based (i.e., caused by interaction of the drug with its intended target) or caused by an off-target effect of the drug, which might be minimized by further optimization of the molecule.

Before the drug candidate can be administered to human subjects in a clinical trial, the sponsor must file an IND application, a request to the U.S. FDA (see “Clinical Trials”) for permission to use the drug for human research. The IND describes the rationale and preliminary evidence for efficacy in experimental systems, as well as pharmacology, toxicology, chemistry, manufacturing, and so forth. It also describes the plan (protocol) for investigating the drug in human subjects. The FDA has 30 days to review the IND application, by which time the agency may disapprove it, ask for more data, or allow initial clinical testing to proceed.

Clinical Trials

Role of the FDA

The FDA is a federal regulatory agency within the U.S. DHHS. It is responsible for protecting the public health by ensuring the safety, efficacy, and security of human and veterinary drugs, biological products, medical devices, our nation's food supply, cosmetics, and products that emit radiation (FDA, 2014). The FDA also is responsible for advancing public health by helping to speed innovations that make medicines and foods more effective, safer, and more affordable and by helping people obtain the accurate, science-based information they need to use medicines and foods to improve their health.

New governmental regulations often result from tragedies. The first drug-related legislation in the U.S., the Federal Food and Drug Act of 1906, was concerned only with the interstate transport of adulterated or misbranded foods and drugs. There were no obligations to establish drug efficacy or safety. This act was amended in 1938 after the deaths of over 100 children from “elixir sulfanilamide,” a solution of sulfanilamide in diethylene glycol, an excellent but highly toxic solvent and an ingredient in antifreeze. The enforcement of the amended act was entrusted to the FDA, which began requiring toxicity studies as well as approval of an NDA (see “The Conduct of Clinical Trials”) before a drug could be promoted and distributed. Although a new drug's safety had to be demonstrated, no proof of efficacy was required.

In the 1960s, thalidomide, a hypnotic drug with no obvious advantages over others, was introduced in Europe. Epidemiological research eventually established that this drug, taken early in pregnancy, was responsible for an epidemic of what otherwise is a relatively rare and severe birth defect, phocomelia, in which limbs are malformed. In reaction to this catastrophe, the U.S. Congress passed the Harris-Kefauver amendments to the Food, Drug, and Cosmetic Act in 1962. These amendments established the requirement for proof of efficacy as well as documentation of relative safety in terms of the risk-to-benefit ratio for the disease entity to be treated (the more serious the disease, the greater the acceptable risk).

Today, the FDA faces an enormous challenge, especially in view of the widely held belief that its mission cannot possibly be accomplished with the resources allocated by Congress. Moreover, harm from drugs that cause unanticipated adverse effects is not the only risk of an imperfect system; harm also occurs when the approval process delays the approval of a new drug with important beneficial effects.

The Conduct of Clinical Trials

Clinical trials of drugs are designed to acquire information about the pharmacokinetic and pharmacodynamic properties of a candidate drug in humans. Efficacy must be proven and an adequate margin of safety established for a drug to be approved for sale in the U.S.

The U.S. NIH identifies seven ethical principles that must be satisfied before a clinical trial can begin:

1. Social and clinical value
2. Scientific validity
3. Fair selection of subjects
4. Informed consent
5. Favorable risk-benefit ratio
6. Independent review
7. Respect for potential and enrolled subjects (NIH, 2011).

The FDA-regulated clinical trials typically are conducted in four phases. Phases I–III are designed to establish safety and efficacy, while phase IV postmarketing trials delineate additional information regarding new indications, risks, and optimal doses and schedules. Table 1–1 and Figure 1–1 summarize the important features of each phase of clinical trials; note the attrition at each successive stage over a relatively long and costly process. When initial phase III trials are complete, the sponsor (usually a pharmaceutical company) applies to the FDA for approval to market the drug; this application is called either an NDA or a BLA. These applications contain comprehensive information, including individual case report forms from the hundreds or thousands of individuals who have received the drug during its phase III testing. Applications are reviewed by teams of

specialists, and the FDA may call on the help of panels of external experts in complex cases.

Under the provisions of the PDUFA (enacted in 1992 and renewed every 5 years, most recently in 2012), pharmaceutical companies now provide a significant portion of the FDA budget via user fees, a legislative effort to expedite the drug approval review process by providing increased resources. The PDUFA also broadened the FDA's drug safety program and increased resources for review of television drug advertising. Under the PDUFA, once an NDA is submitted to the FDA, review typically takes 6–10 months. During this time, numerous review functions are usually performed, including advisory committee meetings, amendments, manufacturing facility inspections, and proprietary name reviews (FDA, 2013a). Before a drug is approved for marketing, the company and the FDA must agree on the content of the “label” (package insert)—the official prescribing information. This label describes the approved indications for use of the drug and clinical pharmacological information, including dosage, adverse reactions, and special warnings and precautions (sometimes posted in a “black box”).

Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. Importantly, the physician is not bound by the package insert; a physician in the U.S. *may* legally prescribe a drug for any purpose that he or she deems reasonable. However, third-party payers (insurance companies, Medicare, and so on) generally will not reimburse a patient for the cost of a drug used for an “off-label” indication unless the new use is supported by a statutorily named compendium (e.g., the AHFS-DI). Furthermore, a physician may be vulnerable to litigation if untoward effects result from an unapproved use of a drug.

Determining “Safe” and “Effective”

Demonstrating efficacy to the FDA requires performing “adequate and well-controlled investigations,” generally interpreted to mean two replicate clinical trials that are usually, but not always, randomized, double blind, and placebo (or otherwise) controlled.

Is a placebo the proper control? The World Medical Association's *Declaration of Helsinki* (World Medical Association 2013) discourages use of placebo controls when an alternative treatment is available for comparison because of the concern that study participants randomized to placebo in such a circumstance would, in effect, be denied treatment during the conduct of the trial.

What must be measured in the trials? In a straightforward trial, a readily quantifiable parameter (a secondary or surrogate end point), thought to be predictive of relevant clinical outcomes, is measured in matched drug- and placebo-treated groups. Examples of surrogate end points include

TABLE 1–1 ■ TYPICAL CHARACTERISTICS OF THE VARIOUS PHASES OF THE CLINICAL TRIALS REQUIRED FOR MARKETING OF NEW DRUGS

PHASE I FIRST IN HUMAN	PHASE II FIRST IN PATIENT	PHASE III MULTISITE TRIAL	PHASE IV POSTMARKETING SURVEILLANCE
10–100 participants	50–500 participants	A few hundred to a few thousand participants	Many thousands of participants
Usually healthy volunteers; occasionally patients with advanced or rare disease	Patient-subjects receiving experimental drug	Patient-subjects receiving experimental drug	Patients in treatment with approved drug
Open label	Randomized and controlled (can be placebo controlled); may be blinded	Randomized and controlled (can be placebo controlled) or uncontrolled; may be blinded	Open label
Safety and tolerability	Efficacy and dose ranging	Confirm efficacy in larger population	Adverse events, compliance, drug-drug interactions
1–2 years	2–3 years	3–5 years	No fixed duration
U.S. \$10 million	U.S. \$20 million	U.S. \$50–100 million	—
Success rate: 50%	Success rate: 30%	Success rate: 25%–50%	—

Figure 1-1 The phases, time lines, and attrition that characterize the invention of new drugs. See also Table 1-1.

LDL cholesterol as a predictor of myocardial infarction, bone mineral density as a predictor of fractures, or hemoglobin A_{1c} as a predictor of the complications of diabetes mellitus. More stringent trials would require demonstration of reduction of the incidence of myocardial infarction in patients taking a candidate drug in comparison with those taking an HMG CoA reductase inhibitor (statin) or other LDL cholesterol-lowering agent or reduction in the incidence of fractures in comparison with those taking a bisphosphonate. Use of surrogate end points significantly reduces cost and time required to complete trials, but there are many mitigating factors, including the significance of the surrogate end point to the disease that the candidate drug is intended to treat.

Some of the difficulties are well illustrated by experiences with ezetimibe, a drug that inhibits absorption of cholesterol from the gastrointestinal tract and lowers LDL cholesterol concentrations in blood, especially when used in combination with a statin. Lowering of LDL cholesterol was assumed to be an appropriate surrogate end point for the effectiveness of ezetimibe to reduce myocardial infarction and stroke, and the drug was approved based on such data. Surprisingly, a subsequent clinical trial (ENHANCE) demonstrated that the combination of ezetimibe and a statin did not reduce intima media thickness of carotid arteries (a more direct measure of subendothelial cholesterol accumulation) compared with the statin alone, despite the fact that the drug combination lowered LDL cholesterol concentrations substantially more than did either drug alone (Kastelein et al., 2008).

Critics of ENHANCE argued that the patients in the study had familial hypercholesterolemia, had been treated with statins for years, and did not have carotid artery thickening at the initiation of the study. Should ezetimibe have been approved? Must we return to measurement of true clinical end points (e.g., myocardial infarction) before approval of drugs that lower cholesterol by novel mechanisms? The costs involved in such extensive and expensive trials must be borne somehow (see below). A follow-up 7-year study involving over 18,000 patients (IMPROVE-IT) vindicated the decision to approve ezetimibe (Jarcho and Keaney, 2015). Taken in conjunction with a statin, the drug significantly reduced the incidence of myocardial infarction and stroke in high-risk patients (Box 1-2).

No drug is totally safe; all drugs produce unwanted effects in at least some people at some dose. Many unwanted and serious effects of drugs occur so infrequently, perhaps only once in several thousand patients, that they go undetected in the relatively small populations (a few thousand) in the standard phase III clinical trial (see Table 1-1). To detect and verify that such events are, in fact, drug-related would require administration of the drug to tens or hundreds of thousands of people during clinical trials, adding enormous expense and time to drug development and delaying access to potentially beneficial therapies. In general, the true spectrum and

incidence of untoward effects become known only after a drug is released to the broader market and used by a large number of people (phase IV, postmarketing surveillance). Drug development costs and drug prices could be reduced substantially if the public were willing to accept more risk. This would require changing the way we think about a pharmaceutical company's liability for damages from an unwanted effect of a drug that was not detected in clinical trials deemed adequate by the FDA. While the concept is obvious, many lose sight of the fact that extremely severe unwanted effects of a drug, including death, may be deemed acceptable if its therapeutic effect is sufficiently unique and valuable. Such dilemmas are not simple and can become issues for great debate.

Several strategies exist to detect adverse reactions after marketing of a drug. Formal approaches for estimation of the magnitude of an adverse drug response include the follow-up or "cohort" study of patients who are receiving a particular drug; the "case-control" study, in which the frequency of drug use in cases of adverse responses is compared to controls; and meta-analysis of pre- and postmarketing studies. Voluntary reporting of adverse events has proven to be an effective way to generate an early signal that a drug may be causing an adverse reaction (Aagard and Hansen, 2009). The primary sources for the reports are responsible, alert physicians; third-party payers (pharmacy benefit managers, insurance companies) and consumers also play important roles. Other useful sources are nurses, pharmacists, and students in these disciplines. In addition, hospital-based pharmacy and therapeutics committees and quality assurance committees frequently are charged with monitoring adverse drug reactions in hospitalized patients. In 2013, the reporting system in the U.S., called *MedWatch*, celebrated its 20th anniversary and announced improvements designed to encourage reporting by consumers (FDA, 2013b). The simple forms for reporting may be obtained 24 hours a day, 7 days a week, by calling 800-FDA-1088; alternatively, adverse reactions

BOX 1-2 ■ A Late Surprise in the Development of a Blockbuster

Torcetrapib elevates high-density lipoprotein (HDL) cholesterol (the "good cholesterol"), and higher levels of HDL cholesterol are statistically associated with (are a surrogate end point for) a lower incidence of myocardial infarction. Surprisingly, clinical administration of torcetrapib caused a significant *increase* in mortality from cardiovascular events, ending a development path of 15 years and \$800 million. In this case, approval of the drug based on this secondary end point would have been a mistake (Cutler, 2007). A computational systems analysis suggested a mechanistic explanation of this failure (Xie et al., 2009).

can be reported directly using the Internet (<http://www.fda.gov/Safety/MedWatch/default.htm>). Health professionals also may contact the pharmaceutical manufacturer, who is legally obligated to file reports with the FDA.

Personalized (Individualized, Precision) Medicine

Drug inventors strive to “fit” the drug to the individual patient. To realize the full potential of this approach, however, requires intimate knowledge of the considerable heterogeneity of both the patient population and the targeted disease process. Why does one antidepressant appear to ameliorate depression in a given patient, while another with the same or very similar presumed mechanism of action does not? Is this a difference in the patient’s response to the drug; in patient susceptibility to the drug’s unwanted effects; in the drug’s ADME; or in the etiology of the depression? By contrast, how much of this variability is attributable to environmental factors and possibly their interactions with patient-specific genetic variability? Recent advances, especially in genetics and genomics, provide powerful tools for understanding this heterogeneity. The single most powerful tool for unraveling these myriad mysteries is the ability to sequence DNA rapidly and economically. The cost of sequencing a human genome has fallen by six orders of magnitude since the turn of the 21st century, and the speed of the process has increased correspondingly. The current focus is on the extraordinarily complex analysis of the enormous amounts of data now being obtained from many thousands of individuals, ideally in conjunction with deep knowledge of their phenotypic characteristics, especially including their medical history.

Readily measured biomarkers of disease are powerful adjuncts to DNA sequence information. Simple blood or other tests can be developed to monitor real-time progress or failure of treatment, and many such examples already exist. Similarly, chemical, radiological, or genetic tests may be useful not only to monitor therapy but also to predict success or failure, anticipate unwanted effects of treatment, or appreciate pharmacokinetic variables that may require adjustments of dosage or choice of drugs. Such tests already play a significant role in the choice of drugs for cancer chemotherapy, and the list of drugs specifically designed to “hit” a mutated target in a specific cancer is growing. Such information is also becoming increasingly useful in the choice of patients for clinical trials of specific agents—thereby reducing the time required for such trials and their cost, to say nothing of better defining the patient population who may benefit from the drug. These important subjects are discussed in detail in Chapter 7, Pharmacogenetics.

Public Policy Considerations and Criticisms of the Pharmaceutical Industry

Drugs can save lives, prolong lives, and improve the quality of people’s lives. However, in a free-market economy, access to drugs is not equitable. Not surprisingly, there is tension between those who treat drugs as entitlements and those who view drugs as high-tech products of a capitalistic society. Supporters of the entitlement position argue that a constitutional right to life should guarantee access to drugs and other healthcare, and they are critical of pharmaceutical companies and others who profit from the business of making and selling drugs. Free-marketers point out that, without a profit motive, it would be difficult to generate the resources and innovation required for new drug development. Given the public interest in the pharmaceutical industry, drug development is both a scientific process and a political one in which attitudes can change quickly. Two decades ago, Merck was named as America’s most admired company by *Fortune* magazine 7 years in a row—a record that still stands. In the 2015 survey of the most admired companies in the U.S., no pharmaceutical company ranked in the top 10.

Critics of the pharmaceutical industry frequently begin from the position that people (and animals) need to be protected from greedy and

unscrupulous companies and scientists (Kassirer, 2005). In the absence of a government-controlled drug development enterprise, our current system relies predominantly on investor-owned pharmaceutical companies that, like other companies, have a profit motive and an obligation to shareholders. The price of prescription drugs causes great consternation among consumers, especially as many health insurers seek to control costs by choosing not to cover certain “brand-name” products (discussed later). Further, a few drugs (especially for treatment of cancer) have been introduced to the market in recent years at prices that greatly exceeded the costs of development, manufacture, and marketing of the product. Many of these products were discovered in government laboratories or in university laboratories supported by federal grants.

The U.S. is the only large country that places no controls on drug prices and where price plays no role in the drug approval process. Many U.S. drugs cost much more in the U.S. than overseas; thus, U.S. consumers subsidize drug costs for the rest of the world, and they are irritated by that fact. The example of new agents for the treatment of hepatitis C infection brings many conflicting priorities into perspective (Box 1–3).

The drug development process is long, expensive, and risky (see Figure 1–1 and Table 1–1). Consequently, drugs must be priced to recover the substantial costs of invention and development and to fund the marketing efforts needed to introduce new products to physicians and patients. Nevertheless, as U.S. healthcare spending continues to rise at an alarming pace, prescription drugs account for only about 10% of total U.S. healthcare expenditures (CDC, 2013), and a significant fraction of this drug cost is for low-priced, nonproprietary medicines. Although the increase in prices is significant in certain classes of drugs (e.g., anticancer agents), the total price of prescription drugs is growing at a slower rate than other healthcare costs. Even drastic reductions in drug prices that would

BOX 1–3 ■ The Cost of Treating Hepatitis C

Infection with hepatitis C virus (HCV) is a chronic disease afflicting millions of people. Some suffer little from this condition; many others eventually develop cirrhosis or hepatocellular carcinoma. Who should be treated? The answer is unknown. Until recently, the treatment of choice for people with genotype 1 HCV involved year-long administration of an interferon (by injection) in combination with ribavirin and a protease inhibitor. Unwanted effects of this regimen are frequent and severe (some say worse than the disease); cure rates range from 50% to 75%. A newer treatment involves an oral tablet containing a combination of sofosbuvir and ledipasvir (see Chapter 63). Treatment usually requires daily ingestion of one tablet, for 8–12 weeks; cure rates exceed 95%, and side effects are minimal.

Controversy surrounds the price of the treatment, about \$1000/d. Some insurers refused to reimburse this high cost, relegating many patients to less-effective, more toxic, but less-expensive treatment. However, these third-party payers have negotiated substantial discounts of the price, based on the availability of a competing product. Is the cost exorbitant? Should insurers, rather than patients and their physicians, be making such important decisions?

Continued and excessive escalation of drug and other healthcare costs will bankrupt the healthcare system. The question of appropriate cost involves complex pharmacoeconomic considerations. What are the relative costs of the two treatment regimens? What are the savings from elimination of the serious sequelae of chronic HCV infection? How does one place value to the patient on the less-toxic and more effective and convenient regimen? What are the profit margins of the company involved? Who should make decisions about costs and choices of patients to receive various treatments? How should we consider cases (unlike that for HCV) for which the benefits are quite modest, such as when a very expensive cancer drug extends life only briefly? One astute observer (and an industry critic of many drug prices) summarized the situation as follows: “great, important problem; wrong example.”

severely limit new drug invention would not lower the overall healthcare budget by more than a few percent.

Are profit margins excessive among the major pharmaceutical companies? There is no objective answer to this question. Pragmatic answers come from the markets and from company survival statistics. The U.S. free-market system provides greater rewards for particularly risky and important fields of endeavor, and many people agree that the rewards should be greater for those willing to take the risk. The pharmaceutical industry is clearly one of the more risky:

- The costs to bring products to market are enormous.
- The success rate is low (accounting for much of the cost).
- Accounting for the long development time, effective patent protection for marketing a new drug is only about a decade (see Intellectual Property and Patents), requiring every company to completely reinvent itself on roughly a 10-year cycle.
- Regulation is stringent.
- Product liability is great.
- Competition is fierce.
- With mergers and acquisitions, the number of companies in the pharmaceutical world is shrinking.

Many feel that drug prices should be driven more by their therapeutic impact and their medical need, rather than by simpler free-market considerations; there is movement in this direction. Difficulties involve estimation or measurement of value, and there are many elements in this equation (Schnipper et al., 2015). There is no well-accepted approach to answer the question of value.

Who Pays?

The cost of prescription drugs is borne by consumers (“out of pocket”), private insurers, and public insurance programs such as Medicare, Medicaid, and the SCHIP. Recent initiatives by major retailers and mail-order pharmacies run by private insurers to offer consumer incentives for purchase of generic drugs have helped to contain the portion of household expenses spent on pharmaceuticals; however, more than one-third of total retail drug costs in the U.S. are paid with public funds—tax dollars.

Healthcare in the U.S. is more expensive than everywhere else, but it is not, on average, demonstrably better than everywhere else. One way in which the U.S. system falls short is with regard to healthcare access. Although the Patient Protection and Affordable Care Act of 2010 has reduced the percentage of Americans without health insurance to a historic low, practical solutions to the challenge of providing healthcare for all who need it must recognize the importance of incentivizing innovation.

Intellectual Property and Patents

Drug invention produces intellectual property eligible for patent protection, protection that is enormously important for innovation. As noted in 1859 by Abraham Lincoln, the only U.S. president to ever hold a patent (for a device to lift boats over shoals), by giving the inventor exclusive use of his or her invention for a limited time, the patent system “added the fuel of interest to the fire of genius in the discovery and production of useful things (Lincoln, 1859).” The U.S. patent protection system provides protection for 20 years from the time the patent is filed. During this period, the patent owner has exclusive rights to market and sell the drug. When the patent expires, equivalent nonproprietary products can come on the market; a generic product must be therapeutically equivalent to the original, contain equal amounts of the same active chemical ingredient, and achieve equal concentrations in blood when administered by the same routes. These generic preparations are sold much more cheaply than the original drug and without the huge development costs borne by the original patent holder.

The long time course of drug development, usually more than 10 years (see Figure 1–1), reduces the time during which patent protection functions as intended. The Drug Price Competition and Patent Term Restoration Act of 1984 (Public Law 98-417, informally called the Hatch-Waxman Act) permits a patent holder to apply for extension of a patent term to compensate for delays in marketing caused by FDA approval processes;

nonetheless, the average new drug brought to market now enjoys only about 10–12 years of patent protection. Some argue that patent protection for drugs should be shortened, so that earlier generic competition will lower healthcare costs. The counterargument is that new drugs would have to bear even higher prices to provide adequate compensation to companies during a shorter period of protected time. If that is true, lengthening patent protection would actually permit lower prices. Recall that patent protection is worth little if a superior competitive product is invented and brought to market.

Bayh-Dole Act

The Bayh-Dole Act (35 U.S.C. § 200) of 1980 created strong incentives for federally funded scientists at academic medical centers to approach drug invention with an entrepreneurial spirit. The act transferred intellectual property rights to the researchers and their respective institutions (rather than to the government) to encourage partnerships with industry that would bring new products to market for the public's benefit. While the need to protect intellectual property is generally accepted, this encouragement of public-private research collaborations has given rise to concerns about conflicts of interest by scientists and universities (Kaiser, 2009).

Biosimilars

As noted previously, the path to approval of a chemically synthesized small molecule that is identical to an approved compound whose patent protection has expired is relatively straightforward. The same is not true for large molecules (usually proteins), which are generally derived from a living organism (e.g., eukaryotic cell or bacterial culture). Covalent modification of proteins (e.g., glycosylation) or conformational differences may influence pharmacokinetics, pharmacodynamics, immunogenicity, or other properties, and demonstration of therapeutic equivalence may be a complex process.

The Biologics Price Competition and Innovation Act was enacted as part of the Patient Protection and Affordable Care Act in 2010. The intent was to implement an abbreviated licensure pathway for certain “similar” biological products. *Biosimilarity* is defined to mean “that the biological product is highly similar to a reference product notwithstanding minor differences in clinically inactive components” and that “there are no clinically meaningful differences between the biological product and the reference product in terms of the safety, purity, and potency of the product.” In general, an application for licensure of a biosimilar must provide satisfactory data from analytical studies, animal studies, and a clinical study or studies. The interpretation of this language has involved seemingly endless discussion, and hard-and-fast rules seem unlikely.

Drug Promotion

In an ideal world, physicians would learn all they need to know about drugs from the medical literature, and good drugs would thereby sell themselves. Instead, we have print advertising and visits from salespeople directed at physicians and extensive direct-to-consumer advertising aimed at the public (in print, on the radio, and especially on television). There are roughly 80,000 pharmaceutical sales representatives in the U.S. who target about 10 times that number of physicians. This figure is down from about 100,000 in 2010, and the decline is likely related to increased attention to real and actual conflicting interests caused by their practices. It has been noted that college cheerleading squads are attractive sources for recruitment of this sales force. The amount spent on promotion of drugs approximates or perhaps even exceeds that spent on research and development. Pharmaceutical companies have been especially vulnerable to criticism for some of their marketing practices.

Promotional materials used by pharmaceutical companies cannot deviate from information contained in the package insert. In addition, there must be an acceptable balance between presentation of therapeutic claims for a product and discussion of unwanted effects. Nevertheless, direct-to-consumer advertising of prescription drugs remains controversial and is permitted only in the U.S. and New Zealand. Canada allows a modified form of advertising in which either the product or the indication can be mentioned, but not both. Physicians frequently succumb with misgivings to patients' advertising-driven requests for specific medications.

The counterargument is that patients are educated by such marketing efforts and in many cases will then seek medical care, especially for conditions (e.g., depression) that they may have been denying (Avery et al., 2012).

The major criticism of drug marketing involves some of the unsavory approaches used to influence physician behavior. Gifts of value (e.g., sports tickets) are now forbidden, but dinners where drug-prescribing information is presented by non-sales representatives are widespread. Large numbers of physicians are paid as “consultants” to make presentations in such settings. The acceptance of any gift, no matter how small, from a drug company by a physician is now forbidden at many academic medical centers and by law in several states. In 2009, the board of directors of PhRMA adopted an enhanced Code on Interactions With Healthcare Professionals that prohibits the distribution of noneducational items, prohibits company sales representatives from providing restaurant meals to healthcare professionals (although exceptions are granted when a third-party speaker makes the presentation), and requires companies to ensure that their representatives are trained about laws and regulations that govern interactions with healthcare professionals.

Concerns About Global Injustice

Because development of new drugs is so expensive, private-sector investment in pharmaceutical innovation has focused on products that will have lucrative markets in wealthy countries such as the U.S., which combines patent protection with a free-market economy. Accordingly, there is concern about the degree to which U.S. and European patent protection laws have restricted access to potentially lifesaving drugs in developing countries.

To lower costs, pharmaceutical companies increasingly test their experimental drugs outside the U.S. and the E.U., in developing countries where there is less regulation and easier access to large numbers of patients. According to the U.S. DHHS, there has been a 2000% increase in foreign trials of U.S. drugs over the past 25 years. When these drugs are successful in obtaining marketing approval, consumers in the countries where the trials were conducted often cannot afford them. Some ethicists have argued that this practice violates the justice principle articulated in the Belmont Report (DHHS, 1979, p10), which states that “research should not unduly involve persons from groups unlikely to be among the beneficiaries of subsequent applications of the research.” A counterargument is that the conduct of trials in developing nations also frequently brings needed medical attention to underserved populations. This is another controversial issue.

Product Liability

Product liability laws are intended to protect consumers from defective products. Pharmaceutical companies can be sued for faulty design or manufacturing, deceptive promotional practices, violation of regulatory requirements, or failure to warn consumers of known risks. So-called failure-to-warn claims can be made against drug makers even when the product is approved by the FDA. With greater frequency, courts are finding companies that market prescription drugs directly to consumers responsible when these advertisements fail to provide an adequate warning of potential adverse effects.

Although injured patients are entitled to pursue legal remedies, the negative effects of product liability lawsuits against pharmaceutical companies may be considerable. First, fear of liability may cause pharmaceutical companies to be overly cautious about testing, thereby delaying access to the drug. Second, the cost of drugs increases for consumers when pharmaceutical companies increase the length and number of trials they perform to identify even the smallest risks and when regulatory agencies increase the number or intensity of regulatory reviews. Third, excessive liability costs create disincentives for development of so-called orphan drugs, pharmaceuticals that benefit a small number of patients. Should pharmaceutical companies be liable for failure to warn when all of the rules were followed and the product was approved by the FDA but the unwanted effect was not detected because of its rarity or another confounding factor? The only way to find “all” of the unwanted effects that a drug may have is to market

it—to conduct a phase IV “clinical trial” or observational study. This basic friction between risk to patients and the financial risk of drug development does not seem likely to be resolved except on a case-by-case basis, in the courts.

The U.S. Supreme Court added further fuel to these fiery issues in 2009 in the case *Wyeth v. Levine*. A patient (Levine) suffered gangrene of an arm following inadvertent arterial administration of the antinausea drug promethazine. She subsequently lost her hand. The healthcare provider had intended to administer the drug by so-called intravenous push. The FDA-approved label for the drug *warned against*, but did not prohibit, administration by intravenous push. The state court and then the U.S. Supreme Court held both the healthcare provider *and the company* liable for damages. Specifically, the Vermont court found that Wyeth had inadequately labeled the drug. This means that FDA approval of the label does not protect a company from liability or prevent individual states from imposing regulations more stringent than those required by the federal government.

“Me Too” Versus True Innovation: The Pace of New Drug Development

Me-too drug is a term used to describe a pharmaceutical that is usually structurally similar to a drug already on the market. Other names used are *derivative medications*, *molecular modifications*, and *follow-up drugs*. In some cases, a me-too drug is a different molecule developed deliberately by a competitor company to take market share from the company with existing drugs on the market. When the market for a class of drugs is especially large, several companies can share the market and make a profit. Other me-too drugs result coincidentally from numerous companies developing products simultaneously without knowing which drugs will be approved for sale (Box 1–4).

There are valid criticisms of me-too drugs. First, an excessive emphasis on profit may stifle true innovation. Of the 487 drugs approved by the FDA between 1998 and 2003, only 67 (14%) were considered by the FDA to be NMEs. Between 1998 and 2011, on average only 24 NMEs were approved by the FDA’s CDER. Second, some me-too drugs are more expensive than the older versions they seek to replace, increasing the costs of healthcare without corresponding benefit to patients. Nevertheless, for some patients, me-too drugs may have better efficacy or fewer side effects or promote compliance with the treatment regimen. For example, the me-too that can be taken once a day rather than more frequently is convenient and promotes compliance. Some me-too drugs add great value from a business and medical point of view. Atorvastatin was the seventh statin to be introduced to market; it subsequently became the best-selling drug in the world.

Critics argue that pharmaceutical companies are not innovative and do not take risks, and, further, that medical progress is actually slowed by their excessive concentration on me-too products. Figure 1–2 summarizes a few of the facts behind this and other arguments. Clearly, only a modest number of NMEs, about two dozen a year, achieved FDA approval in the years 1980 to 2011, with the exception of the several-year spike in approvals following the introduction of PDUFA. Yet, from 1980 to 2010, the industry’s annual investment in research and development grew from

BOX 1–4 ■ A Not-So-New Drug

Some me-too drugs are only slightly altered formulations of a company’s own drug, packaged and promoted as if really offering something new. An example is the heartburn medication esomeprazole, marketed by the same company that makes omeprazole. Omeprazole is a mixture of two stereoisomers; esomeprazole contains only one of the isomers and is eliminated less rapidly. Development of esomeprazole created a new period of market exclusivity, although generic versions of omeprazole are marketed, as are branded congeners of omeprazole/esomeprazole. Both omeprazole and esomeprazole are now available over the counter—narrowing the previous price difference.

Figure 1–2 The cost of drug invention is rising. Is productivity? Each horizontal black line shows the average annual number of NMEs or BLAs for the time period bracketed by the line's length.

\$2 billion to \$50 billion. This disconnect between research and development investment and new drugs approved occurred at a time when combinatorial chemistry was blooming, the human genome was being sequenced, highly automated techniques of screening were being developed, and new techniques of molecular biology and genetics were offering novel insights into the pathophysiology of human disease.

In recent years, there has been a modest increase in approval of NMEs (inhibitors of a number of protein kinases) and new biologics (numerous therapeutic antibodies) (see Figure 1–2). A continued increase in productivity will be needed to sustain today's pharmaceutical companies as they face waves of patent expirations. There are strong arguments that development of much more targeted, individualized drugs, based on a new generation of molecular diagnostic techniques and improved understanding of disease in individual patients, will improve both medical care and the survival of pharmaceutical companies.

Finally, many of the advances in genetics and molecular biology are still new, particularly when measured in the time frame required for drug development. One can hope that modern molecular medicine will sustain the development of more efficacious and more specific pharmacological treatments for an ever-wider spectrum of human diseases.

THERAPEUTIC DRUG MONITORING

The human body restricts access to foreign molecules; therefore, to reach its target within the body and have a therapeutic effect, a drug molecule must cross a number of restrictive barriers en route to its target site. Following administration, the drug must be absorbed and then distributed, usually via vessels of the circulatory and lymphatic systems; in addition to crossing membrane barriers, the drug must survive metabolism (primarily hepatic) and elimination (by the kidney and liver and in the feces). ADME, the absorption, distribution, metabolism, and elimination of drugs, are the processes of *pharmacokinetics* (Figure 2–1). Understanding these processes and their interplay and employing pharmacokinetic principles increase the probability of therapeutic success and reduce the occurrence of adverse drug events.

The absorption, distribution, metabolism, and excretion of a drug involve its passage across numerous cell membranes. Mechanisms by which drugs cross membranes and the physicochemical properties of molecules and membranes that influence this transfer are critical to understanding the disposition of drugs in the human body. The characteristics of a drug that predict its movement and availability at sites of action are its molecular size and structural features, degree of ionization, relative lipid solubility of its ionized and nonionized forms, and its binding to serum and tissue proteins. Although physical barriers to drug movement may be a single layer of cells (e.g., intestinal epithelium) or several layers of cells and associated extracellular protein (e.g., skin), the plasma membrane is the basic barrier.

Passage of Drugs Across Membrane Barriers

The Plasma Membrane Is Selectively Permeable

The plasma membrane consists of a bilayer of amphipathic lipids with their hydrocarbon chains oriented inward to the center of the bilayer to form a continuous hydrophobic phase, with their hydrophilic heads

oriented outward. Individual lipid molecules in the bilayer vary according to the particular membrane and can move laterally and organize themselves into microdomains (e.g., regions with sphingolipids and cholesterol, forming lipid rafts), endowing the membrane with fluidity, flexibility, organization, high electrical resistance, and relative impermeability to highly polar molecules. Membrane proteins embedded in the bilayer serve as structural anchors, receptors, ion channels, or transporters to transduce electrical or chemical signaling pathways and provide selective targets for drug actions. Far from being a sea of lipids with proteins floating randomly about, membranes are ordered and compartmented (Suetsugu et al., 2014), with structural scaffolding elements linking to the cell interior. Membrane proteins may be associated with caveolin and sequestered within caveolae, be excluded from caveolae, or be organized in signaling domains rich in cholesterol and sphingolipid not containing caveolin or other scaffolding proteins.

Modes of Permeation and Transport

Passive diffusion dominates transmembrane movement of most drugs. However, carrier-mediated mechanisms (*active transport* and *facilitated diffusion*) play important roles (Figure 2–2; Figure 5–4).

Passive Diffusion

In passive transport, the drug molecule usually penetrates by diffusion along a concentration gradient by virtue of its solubility in the lipid bilayer. Such transfer is directly proportional to the magnitude of the concentration gradient across the membrane, to the lipid:water partition coefficient of the drug, and to the membrane surface area exposed to the drug. At steady state, the concentration of the unbound drug is the same on both sides of the membrane if the drug is a nonelectrolyte. For ionic compounds, the steady-state concentrations depend on the electrochemical gradient for the ion and on differences in pH across the membrane, which will influence the state of ionization of the molecule disparately on either

side of the membrane and can effectively trap ionized drug on one side of the membrane.

Influence of pH on Ionizable Drugs

Many drugs are weak acids or bases that are present in solution as both the lipid-soluble, diffusible nonionized form and the ionized species that is relatively lipid insoluble and poorly diffusible across a membrane. Among the common ionizable groups are carboxylic acids and amino groups (primary, secondary, and tertiary; quaternary amines hold a permanent positive charge). The transmembrane distribution of a weak electrolyte is influenced by its pK_a and the pH gradient across the membrane. The pK_a is the pH at which half the drug (weak acid or base electrolyte) is in its

ionized form. The ratio of nonionized to ionized drug at any pH may be calculated from the Henderson-Hasselbalch equation:

$$\log \frac{[\text{protonated form}]}{[\text{unprotonated form}]} = pK_a - \text{pH} \quad (\text{Equation 2-1})$$

Equation 2-1 relates the pH of the medium around the drug and the drug's acid dissociation constant (pK_a) to the ratio of the protonated (HA or BH^+) and unprotonated (A^- or B) forms, where

describes the dissociation of an acid, and

describes the dissociation of the protonated form of a base.

At steady state, an acidic drug will accumulate on the more basic side of the membrane and a basic drug on the more acidic side. This phenomenon, known as *ion trapping*, is an important process in drug distribution with potential therapeutic benefit (Perletti et al., 2009). Figure 2-3 illustrates this effect and shows the calculated values for the distribution of a weak acid between the plasma and gastric compartments.

One can take advantage of the effect of pH on transmembrane partitioning to alter drug excretion. In the kidney tubules, urine pH can vary over a wide range, from 4.5 to 8. As urine pH drops (as $[H^+]$ increases), weak acids (A^-) and weak bases (B) will exist to a greater extent in their protonated forms (HA and BH^+); the reverse is true as pH rises, where A^- and B will be favored. Thus, alkaline urine favors excretion of weak acids; acid urine favors excretion of weak bases. Elevation of urine pH (by giving sodium bicarbonate) will promote urinary excretion of weak acids such as aspirin ($pK_a \sim 3.5$) and urate ($pK_a \sim 5.8$). Another useful consequence of a drug's being ionized at physiological pH is illustrated by the relative lack of sedative effects of second-generation histamine H_1 antagonists (e.g., loratadine): Second-generation antihistamines are ionized molecules (less lipophilic, more hydrophilic) that cross the BBB poorly compared to first-generation agents such as diphenhydramine, which are now used as sleep aids.

Carrier-Mediated Membrane Transport

Proteins in the plasma membrane mediate transmembrane movements of many physiological solutes; these proteins also mediate transmembrane movements of drugs and can be targets of drug action. Mediated transport

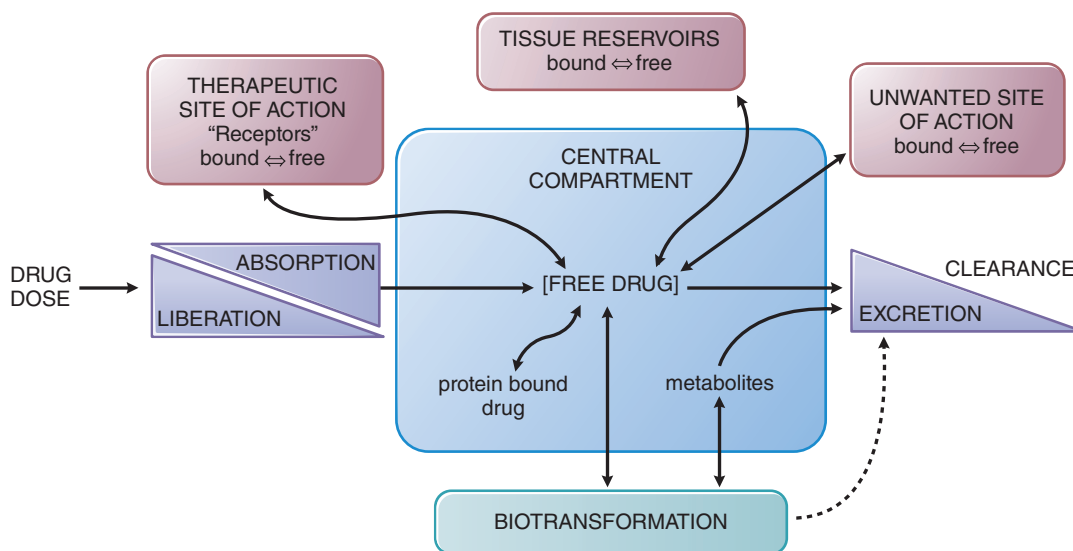

Figure 2-1 The interrelationship of the absorption, distribution, binding, metabolism, and excretion of a drug and its concentration at its sites of action. Possible distribution and binding of metabolites in relation to their potential actions at receptors are not depicted.

Figure 2-2 Drugs move across membrane and cellular barriers in a variety of ways. See details in Figures 5-1 through 5-5.

is broadly characterized as *facilitated diffusion* or *active transport* (see Figure 2-2; Figure 5-4). Membrane transporters and their roles in drug response are presented in detail in Chapter 5.

Facilitated Diffusion. *Facilitated diffusion* is a carrier-mediated transport process in which the driving force is simply the electrochemical gradient of the transported solute; thus, these carriers can facilitate solute movement either in or out of cells, depending on the direction of the electrochemical gradient. The carrier protein may be highly selective for a specific conformational structure of an endogenous solute or a drug whose rate of transport by passive diffusion through the membrane would otherwise be quite slow. For instance, the organic cation transporter OCT1 (SLC22A1) facilitates the movement of a physiologic solute, thiamine, and also of drugs, including metformin, which is used in treating type 2 diabetes. Chapter 5 describes OCT1 and other members of the human SLC superfamily of transporters.

Active Transport. *Active transport* is characterized by a direct requirement for energy, capacity to move solute against an electrochemical gradient, saturability, selectivity, and competitive inhibition by cotransported compounds. Na^+, K^+ -ATPase is an important example of an active transport mechanism that is also a therapeutic target of digoxin in the treatment of heart failure (Chapter 29). A group of primary active transporters, the ABC family, hydrolyze ATP to export substrates across membranes. For example, the P-glycoprotein, also called ABCB1 and MDR1, exports bulky neutral or cationic compounds from cells; its physiologic substrates include steroid hormones such as testosterone and progesterone. MDR1 exports many drugs as well, including digoxin, and a great variety of other agents (see Table 5-4). P-glycoprotein in the enterocyte

limits the absorption of some orally administered drugs by exporting compounds into the lumen of the GI tract subsequent to their absorption. ABC transporters perform a similar function in the cells of the BBB, effectively reducing net accumulation of some compounds in the brain. By the same mechanism, P-glycoprotein also can confer resistance to some cancer chemotherapeutic agents (see Chapters 65-68).

Members of the SLC superfamily can mediate secondary active transport using the electrochemical energy stored in a gradient (usually Na^+) to translocate both biological solutes and drugs across membranes. For instance, the $\text{Na}^+/\text{Ca}^{2+}$ exchange protein (SLC8) uses the energy stored in the Na^+ gradient established by Na^+, K^+ -ATPase to export cytosolic Ca^{2+} and maintain it at a low basal level, about 100 nM in most cells. SLC8 is thus an *antiporter*, using the inward flow of Na^+ to drive an outward flow of Ca^{2+} ; SLC8 also helps to mediate the positive inotropic effects of digoxin and other cardiac glycosides that inhibit the activity of Na^+, K^+ -ATPase and thereby reduce the driving force for the extrusion of Ca^{2+} from the ventricular cardiac myocyte. Other SLC cotransporters are *symporters*, in which driving force ion and solute move in the same direction. The CNT1 (SLC28A1), driven by the Na^+ gradient, moves pyrimidine nucleosides and the cancer chemotherapeutic agents gemcitabine and cytarabine into cells. DAT, NET, and SERT, transporters for the neurotransmitters dopamine, norepinephrine, and serotonin, respectively, are secondary active transporters that also rely on the energy stored in the transmembrane Na^+ gradient, symporters that coordinate movement of Na^+ and neurotransmitter in the same direction (into the neuron); they are also the targets of CNS-active agents used in therapy of depression. Members of the SLC superfamily are active in drug transport in the GI tract, liver, and kidney, among other sites.

Paracellular Transport

In the vascular compartment, paracellular passage of solutes and fluid through intercellular gaps is sufficiently large that passive transfer across the endothelium of capillaries and postcapillary venules is generally limited by blood flow. Capillaries of the CNS and a variety of epithelial tissues have tight junctions that limit paracellular movement of drugs (Spector et al., 2015).

Figure 2-3 Influence of pH on the distribution of a weak acid ($\text{pK}_a = 4.4$) between plasma and gastric juice separated by a lipid barrier. A weak acid dissociates to different extents in plasma (pH 7.4) and gastric acid (pH 1.4): The higher pH facilitates dissociation; the lower pH reduces dissociation. The uncharged form, HA, equilibrates across the membrane. Blue numbers in brackets show relative equilibrium concentrations of HA and A^- , as calculated from Equation 2-1.

Drug Absorption, Bioavailability, and Routes of Administration

Absorption and Bioavailability

Absorption is the movement of a drug from its site of administration into the central compartment (see Figure 2-1). For solid dosage forms, absorption first requires dissolution of the tablet or capsule, thus liberating the drug. Except in cases of malabsorption syndromes, the clinician is concerned primarily with bioavailability rather than absorption (Tran et al., 2013).

Bioavailability describes the fractional extent to which an administered dose of drug reaches its site of action or a biological fluid (usually the systemic circulation) from which the drug has access to its site of action. A drug given orally must be absorbed first from the GI tract, but net absorption may be limited by the characteristics of the dosage form, by the drug's physicochemical properties, by metabolic attack in the intestine, and by transport across the intestinal epithelium and into the portal circulation. The absorbed drug then passes through the liver, where metabolism and biliary excretion may occur before the drug enters the systemic circulation. Accordingly, less than all of the administered dose may reach the systemic circulation and be distributed to the drug's sites of action. If the metabolic or excretory capacity of the liver and the intestine for the drug is large, bioavailability will be reduced substantially (*first-pass effect*). This decrease in availability is a function of the anatomical site from which absorption takes place; for instance, intravenous administration generally permits all of the drug to enter the systemic circulation. Other anatomical, physiological, and pathological factors can influence bioavailability (described further in this chapter), and the choice of the route of drug administration must be based on an understanding of these conditions. We can define bioavailability F as:

$$F = \frac{\text{Quantity of drug reaching systemic circulation}}{\text{Quantity of drug administered}} \quad (\text{Equation 2-2})$$

where $0 < F \leq 1$.

Factors modifying bioavailability apply as well to prodrugs that are activated by the liver, in which case availability results from metabolism that produces the form of the active drug.

Routes of Administration

Some characteristics of the major routes employed for systemic drug effect are compared in Table 2-1.

Oral Administration

Oral ingestion is the most common method of drug administration. It also is the safest, most convenient, and most economical. Its disadvantages include limited absorption of some drugs because of their physical

characteristics (e.g., low water solubility or poor membrane permeability), emesis as a result of irritation to the GI mucosa, destruction of some drugs by digestive enzymes or low gastric pH, irregularities in absorption or propulsion in the presence of food or other drugs, and the need for cooperation on the part of the patient. In addition, drugs in the GI tract may be metabolized by the enzymes of the intestinal microbiome, mucosa, or liver before they gain access to the general circulation.

Absorption from the GI tract is governed by factors such as surface area for absorption; blood flow to the site of absorption; the physical state of the drug (solution, suspension, or solid dosage form); its aqueous solubility; and the drug's concentration at the site of absorption. For drugs given in solid form, the rate of dissolution may limit their absorption. Because most drug absorption from the GI tract occurs by passive diffusion, absorption is favored when the drug is in the nonionized, more lipophilic form. Based on the pH-partition concept (see Figure 2-3), one would predict that drugs that are weak acids would be better absorbed from the stomach (pH 1-2) than from the upper intestine (pH 3-6), and vice versa for weak bases. However, the surface area of the stomach is relatively small, and a mucus layer covers the gastric epithelium. By contrast, the villi of the upper intestine provide an extremely large surface area (~200 m²). Accordingly, the rate of absorption of a drug from the intestine will be greater than that from the stomach even if the drug is predominantly ionized in the intestine and largely nonionized in the stomach. Thus, any factor that accelerates gastric emptying (recumbent position right side) will generally increase the rate of drug absorption, whereas any factor that delays gastric emptying will have the opposite effect. The gastric emptying rate is influenced by numerous factors, including the caloric content of food; volume, osmolality, temperature, and pH of ingested fluid; diurnal and interindividual variation; metabolic state (rest or exercise); and the ambient temperature. Gastric emptying is influenced in women by the effects of estrogen (i.e., compared to men, emptying is slower for premenopausal women and those taking estrogen replacement therapy).

Drugs that are destroyed by gastric secretions and low pH or that cause gastric irritation sometimes are administered in dosage forms with an enteric coating that prevents dissolution in the acidic gastric contents. Enteric coatings are useful for drugs that can cause gastric irritation and for presenting a drug such as mesalamine to sites of action in the ileum and colon (see Figure 51-4).

TABLE 2-1 ■ SOME CHARACTERISTICS OF COMMON ROUTES OF DRUG ADMINISTRATION^a

ROUTE AND BIOAVAILABILITY (F)	ABSORPTION PATTERN	SPECIAL UTILITY	LIMITATIONS AND PRECAUTIONS
Intravenous $F = 1$ by definition	Absorption circumvented	Valuable for emergency use	Increased risk of adverse effects
	Potentially immediate effects	Permits titration of dosage	Must inject solutions <i>slowly</i> as a rule
	Suitable for large volumes and for irritating substances, or complex mixtures, when diluted	Usually required for high-molecular-weight protein and peptide drugs	Not suitable for oily solutions or poorly soluble substances
Subcutaneous $0.75 < F < 1$	Prompt from aqueous solution	Suitable for some poorly soluble suspensions and for instillation of slow-release implants	Not suitable for large volumes
	Slow and sustained from repository preparations		Possible pain or necrosis from irritating substances
Intramuscular $0.75 < F < 1$	Prompt from aqueous solution	Suitable for moderate volumes, oily vehicles, and some irritating substances	Precluded during anticoagulant therapy
	Slow and sustained from repository preparations	Appropriate for self-administration (e.g., insulin)	May interfere with interpretation of certain diagnostic tests (e.g., creatine kinase)
Oral ingestion $.05 < F < 1$	Variable, depends on many factors (see text)	Most convenient and economical; usually safer	Requires patient compliance
			Bioavailability potentially erratic and incomplete

^aSee text for more complete discussion and for other routes.

Controlled-Release Preparations. The rate of absorption of a drug administered as a tablet or other solid oral dosage form is partly dependent on its rate of dissolution in GI fluids. This is the basis for *controlled-release*, *extended-release*, *sustained-release*, and *prolonged-action* pharmaceutical preparations that are designed to produce slow, uniform absorption of the drug for 8 h or longer. Potential advantages of such preparations are reduction in the frequency of administration compared with conventional dosage forms (often with improved compliance by the patient), maintenance of a therapeutic effect overnight, and decreased incidence and intensity of undesired effects (by dampening of the peaks in drug concentration) and nontherapeutic blood levels of the drug (by elimination of troughs in concentration) that often occur after administration of immediate-release dosage forms. Controlled-release dosage forms are most appropriate for drugs with short half-lives ($t_{1/2} < 4$ h) or in select patient groups, such as those receiving antiepileptic or antipsychotic agents (Bera, 2014).

Sublingual Administration. Absorption from the oral mucosa has special significance for certain drugs despite the fact that the surface area available is small. Venous drainage from the mouth is to the superior vena cava, thus bypassing the portal circulation. As a consequence, a drug held sublingually and absorbed from that site is protected from rapid intestinal and hepatic first-pass metabolism. For example, sublingual nitroglycerin (see Chapter 27) is rapidly effective because it is nonionic, has high lipid solubility, and is not subject to the first-pass effect prior to reaching the heart and arterial system.

Parenteral Injection

Parenteral (i.e., not via the GI tract) injection of drugs has distinct advantages over oral administration. In some instances, parenteral administration is essential for delivery of a drug in its active form, as in the case of monoclonal antibodies. Availability usually is more rapid, extensive, and predictable when a drug is given by injection; the effective dose can be delivered more accurately to a precise dose; this route is suitable for the loading dose of medications prior to initiation of oral maintenance dosing (e.g., digoxin). In emergency therapy and when a patient is unconscious, uncooperative, or unable to retain anything given by mouth, parenteral therapy may be necessary. Parenteral administration also has disadvantages: Asepsis must be maintained, especially when drugs are given over time (e.g., intravenous or intrathecal administration); pain may accompany the injection; and it is sometimes difficult for patients to perform the injections themselves if self-medication is necessary.

The major routes of parenteral administration are intravenous, subcutaneous, and intramuscular. Absorption from subcutaneous and intramuscular sites occurs by simple diffusion along the gradient from drug depot to plasma. The rate is limited by the area of the absorbing capillary membranes and by the solubility of the substance in the interstitial fluid. Relatively large aqueous channels in the endothelial layer account for the indiscriminate diffusion of molecules regardless of their lipid solubility. Larger molecules, such as proteins, slowly gain access to the circulation by way of lymphatic channels. Drugs administered into the systemic circulation by any route, excluding the intra-arterial route, are subject to possible first-pass elimination in the lung prior to distribution to the rest of the body. The lungs also serve as a filter for particulate matter that may be given intravenously and provide a route of elimination for volatile substances.

Intravenous. Factors limiting absorption are circumvented by intravenous injection of drugs in aqueous solution because bioavailability is complete ($F = 1.0$) and distribution is rapid. Also, drug delivery is controlled and achieved with an accuracy and immediacy not possible by any other procedures. Certain irritating solutions can be given only in this manner because the drug, when injected slowly, is greatly diluted by the blood.

There are advantages and disadvantages to intravenous administration. Unfavorable reactions can occur because high concentrations of drug may be attained rapidly in plasma and tissues. There are therapeutic circumstances for which it is advisable to administer a drug by bolus injection (e.g., tissue plasminogen activator) and other circumstances where slower or prolonged administration of drug is advisable (e.g., antibiotics).

Intravenous administration of drugs warrants careful determination of dose and close monitoring of the patient's response; once the drug is injected, there is often no retreat. Repeated intravenous injections depend on the ability to maintain a patent vein. Drugs in an oily vehicle, those that precipitate blood constituents or hemolyze erythrocytes, and drug combinations that cause precipitates to form *must not* be given intravenously.

Subcutaneous. Injection into a subcutaneous site can be done only with drugs that are not irritating to tissue; otherwise, severe pain, necrosis, and tissue sloughing may occur. The rate of absorption following subcutaneous injection of a drug often is sufficiently constant and slow to provide a sustained effect. Moreover, altering the period over which a drug is absorbed may be varied intentionally, as is accomplished with insulin for injection using particle size, protein complexation, and pH. The incorporation of a vasoconstrictor agent in a solution of a drug to be injected subcutaneously also retards absorption. Absorption of drugs implanted under the skin in a solid pellet form occurs slowly over a period of weeks or months; some hormones (e.g., contraceptives) are administered effectively in this manner.

Intramuscular. Absorption of drugs in aqueous solution after intramuscular injection depends on the rate of blood flow to the injection site and can be relatively rapid. Absorption may be modulated to some extent by local heating, massage, or exercise. Generally, the rate of absorption following injection of an aqueous preparation into the deltoid or vastus lateralis is faster than when the injection is made into the gluteus maximus. The rate is particularly slower for females after injection into the gluteus maximus, a feature attributed to the different distribution of subcutaneous fat in males and females and because fat is relatively poorly perfused. Slow, constant absorption from the intramuscular site results if the drug is injected in solution in oil or suspended in various other repository (depot) vehicles.

Intra-arterial. Occasionally, a drug is injected directly into an artery to localize its effect in a particular tissue or organ, such as in the treatment of liver tumors and head and neck cancers. Diagnostic agents sometimes are administered by this route (e.g., technetium-labeled human serum albumin). Inadvertent intra-arterial administration can cause serious complications and requires careful management (Sen et al., 2005).

Intrathecal. The BBB and the blood-CSF barrier often preclude or slow the entrance of drugs into the CNS, reflecting the activity of P-glycoprotein (MDRI) and other transporters to export xenobiotics from the CNS. Therefore, when local and rapid effects of drugs on the meninges or cerebrospinal axis are desired, as in spinal anesthesia, drugs sometimes are injected directly into the spinal subarachnoid space. Brain tumors (Calias et al., 2014) or serious CNS infections (Imberti et al., 2014) also may be treated by direct intraventricular drug administration, increasingly through the use of specialized long-term indwelling reservoir devices. Injections into the CSF and epidural space are covered in chapters on analgesia and local anesthesia (Chapters 20 and 22, respectively).

Pulmonary Absorption

Gaseous and volatile drugs may be inhaled and absorbed through the pulmonary epithelium and mucous membranes of the respiratory tract. Access to the circulation is rapid by this route because the lung's surface area is large. In addition, solutions of drugs can be atomized and the fine droplets in air (aerosol) inhaled. Advantages are the almost instantaneous absorption of a drug into the blood, avoidance of hepatic first-pass loss, and in the case of pulmonary disease, local application of the drug at the desired site of action (see Chapters 21 and 40), as in the use of inhaled nitric oxide for pulmonary hypertension in term and near-term infants and adults (see Chapter 31).

Topical Application

Mucous Membranes. Drugs are applied to the mucous membranes of the conjunctiva, nasopharynx, oropharynx, vagina, colon, urethra, and urinary bladder primarily for their local effects. Absorption from these sites is generally excellent and may provide advantages for immunotherapy because vaccination of mucosal surfaces using mucosal vaccines

provides the basis for generating protective immunity in both the mucosal and systemic immune compartments.

Eye. Topically applied ophthalmic drugs are used primarily for their local effects (see Chapter 69). The use of drug-loaded contact lenses and ocular inserts allows drugs to be better placed where they are needed for direct delivery.

Skin: Transdermal Absorption. Absorption of drugs able to penetrate the intact skin is dependent on the surface area over which they are applied and their lipid solubility (see Chapter 70). Systemic absorption of drugs occurs much more readily through abraded, burned, or denuded skin. Toxic effects result from absorption through the skin of highly lipid-soluble substances (e.g., a lipid-soluble insecticide in an organic solvent). Absorption through the skin can be enhanced by suspending the drug in an oily vehicle and rubbing the resulting preparation into the skin. Hydration of the skin with an occlusive dressing may be used to facilitate absorption. Controlled-release topical patches are increasingly available, with nicotine for tobacco-smoking withdrawal, scopolamine for motion sickness, nitroglycerin for angina pectoris, testosterone and estrogen for replacement therapy, various estrogens and progestins for birth control, and fentanyl for pain relief.

Rectal Administration

Approximately 50% of the drug that is absorbed from the rectum will bypass the liver, thereby reducing hepatic first-pass metabolism. However, rectal absorption can be irregular and incomplete, and certain drugs can cause irritation of the rectal mucosa. Rectal administration may be desirable, as in the use of opioids in hospice care.

Novel Methods of Drug Delivery

Drug-eluting stents and other devices are being used to target drugs locally to maximize efficacy and minimize systemic exposure. Recent advances in drug delivery include the use of biocompatible polymers and nanoparticles for drug delivery (Yohan and Chithrani, 2014).

Bioequivalence

Drug products are considered to be pharmaceutical equivalents if they contain the same active ingredients and are identical in strength or concentration, dosage form, and route of administration. Two pharmaceutically equivalent drug products are considered to be *bioequivalent* when the rates and extents of bioavailability of the active ingredient in the two products are not significantly different under suitable and identical test conditions. Generic versus brand name prescribing is further discussed in connection with drug nomenclature and the choice of drug name in writing prescription orders (see Appendix I). Courts have not always found generic and brand name drugs to be legally equivalent (see Chapter 1).

Distribution of Drugs

Not All Tissues Are Equal

Following absorption or systemic administration into the bloodstream, a drug distributes into interstitial and intracellular fluids as functions of the physicochemical properties of the drug, the rate of drug delivery to individual organs and compartments, and the differing capacities of

those regions to interact with the drug. Cardiac output, regional blood flow, capillary permeability, and tissue volume affect the rate of delivery and amount of drug distributed into tissues (Table 2-2 and Figure 2-4). Initially, liver, kidney, brain, and other well-perfused organs receive most of the drug; delivery to muscle, most viscera, skin, and fat is slower. This second distribution phase may require minutes to several hours before the concentration of drug in tissue is in equilibrium with that in blood. The second phase also involves a far larger fraction of body mass (e.g., muscle) than does the initial phase and generally accounts for most of the extravascular distribution. With exceptions such as the brain, diffusion of drug into the interstitial fluid occurs rapidly because of the highly permeable nature of the capillary endothelium. Thus, tissue distribution is determined by the partitioning of drug between blood and the particular tissue.

Binding to Plasma Proteins

Many drugs circulate in the bloodstream bound to plasma proteins. Albumin is a major carrier for acidic drugs; α_1 -acid glycoprotein binds basic drugs. Nonspecific binding to other plasma proteins generally occurs to a much smaller extent. The binding is usually reversible. In addition, certain drugs may bind to proteins that function as specific hormone carrier proteins, such as the binding of estrogen or testosterone to sex hormone-binding globulin or the binding of thyroid hormone to thyroxine-binding globulin.

The fraction of total drug in plasma that is bound is determined by the drug concentration, the affinity of binding sites for the drug, and the concentration of available binding sites. For most drugs, the therapeutic range of plasma concentrations is limited; thus, the extent of binding and the unbound fraction are relatively constant. The extent of plasma protein binding also may be affected by disease-related factors (e.g., hypoalbuminemia). Conditions resulting in the acute-phase reaction response (e.g., cancer, arthritis, myocardial infarction, Crohn's disease) lead to elevated levels of α_1 -acid glycoprotein and enhanced binding of basic drugs. Changes in protein binding caused by disease states and drug-drug interactions are clinically relevant mainly for a small subset of so-called high-clearance drugs of narrow therapeutic index that are administered intravenously, such as lidocaine. When changes in plasma protein binding occur in patients, unbound drug rapidly equilibrates throughout the body and only a transient significant change in unbound plasma concentration will occur. Only drugs that show an almost-instantaneous relationship between free plasma concentration and effect (e.g., antiarrhythmics) will show a measurable effect. Thus, unbound plasma drug concentrations will exhibit significant changes only when either drug input or clearance of unbound drug occurs as a consequence of metabolism or active transport. A more common problem resulting from competition of drugs for plasma protein-binding sites is misinterpretation of measured concentrations of drugs in plasma because most assays do not distinguish free drug from bound drug. Competition for plasma protein-binding sites may cause one drug to elevate the concentration of one bound less avidly.

Binding of a drug to plasma proteins limits its concentration in tissues and at its site of action because only unbound drug is in equilibrium across membranes. Accordingly, after distribution equilibrium is achieved, the concentration of unbound drug in intracellular water is the same as that in plasma except when carrier-mediated active transport is involved. Binding of a drug to plasma protein limits the drug's glomerular filtration and may also limit drug transport and metabolism.

TABLE 2-2 ■ DISTRIBUTION OF BLOOD FLOW IN 70-KG MALE AT REST

	KIDNEYS	HEART	LIVER	BRAIN	SKELETAL MUSCLE	FAT	REMAINDER	Σ
Blood Flow (mL/min)	1100	250	1700	800	900	250	500	5500
Mass (kg)	0.3	0.3	2.6	1.3	34	10	21.5	70
Flow/Mass (mL/min/kg)	3667	833	654	615	26	25	23	
% Cardiac Output	20	4.5	31	14.5	16.4	4.5	9.1	100

Figure 2-4 *Redistribution.* Curves depict the distribution of the barbiturate anesthetic thiopental into different body compartments following a single rapid intravenous dose. Note breaks and changes of scale on both axes. The drug level at thiopental's site of action in the brain closely mirrors the plasma level of the drug. The rate of accumulation in the various body compartments depends on regional blood flow; the extent of accumulation reflects the differing capacities of the compartments and the steady but slow effect of elimination to reduce the amount of drug available. Emergence from the anesthetic influence of this single dose of thiopental relies on redistribution, not on metabolism. The drug will partition out of tissue depots as metabolism and elimination take their course. Depletion of compartments will follow the same order as accumulation, as a function of their perfusion.

Tissue Binding

Many drugs accumulate in tissues at higher concentrations than those in the extracellular fluids and blood. Tissue binding of drugs usually occurs with cellular constituents such as proteins, phospholipids, or nuclear proteins and generally is reversible. A large fraction of drug in the body may be bound in this fashion and serve as a reservoir that prolongs drug action in that same tissue or at a distant site reached through the circulation. Such tissue binding and accumulation also can produce local toxicity (e.g., renal and ototoxicity associated with aminoglycoside antibiotics).

CNS, the BBB, and CSF

The brain capillary endothelial cells have continuous tight junctions; therefore, drug penetration into the brain depends on transcellular rather than paracellular transport. The unique characteristics of brain capillary endothelial cells and pericapillary glial cells constitute the BBB. At the choroid plexus, a similar blood-CSF barrier is present, formed by epithelial cells that are joined by tight junctions. The lipid solubility of the nonionized and unbound species of a drug is therefore an important determinant of its uptake by the brain; the more lipophilic a drug, the more likely it is to cross the BBB. In general, the BBB's function is well maintained; however, meningeal and encephalic inflammation increase local permeability. Drugs may also be imported to and exported from the CNS by specific transporters (see Chapter 5).

Bone

The tetracycline antibiotics (and other divalent metal-ion chelating agents) and heavy metals may accumulate in bone by adsorption onto the bone crystal surface and eventual incorporation into the crystal lattice. Bone

can become a reservoir for the slow release of toxic agents such as lead or radium; their effects thus can persist long after exposure has ceased. Local destruction of the bone medulla also may result in reduced blood flow and prolongation of the reservoir effect as the toxic agent becomes sealed off from the circulation; this may further enhance the direct local damage to the bone. A vicious cycle results, whereby the greater the exposure to the toxic agent, the slower is its rate of elimination. The adsorption of drug onto the bone crystal surface and incorporation into the crystal lattice have therapeutic advantages for the treatment of osteoporosis.

Fat as a Reservoir

Many lipid-soluble drugs are stored by physical solution in the neutral fat. In obese persons, the fat content of the body may be as high as 50%, and even in lean individuals, fat constitutes 10% of body weight; hence, fat may serve as a reservoir for lipid-soluble drugs. Fat is a rather stable reservoir because it has a relatively low blood flow.

Redistribution

Termination of drug effect after withdrawal of a drug usually is by metabolism and excretion but also may result from redistribution of the drug from its site of action into other tissues or sites. Redistribution is a factor in terminating drug effect primarily when a highly lipid-soluble drug that acts on the brain or cardiovascular system is administered rapidly by intravenous injection or inhalation. Such is the case of the intravenous anesthetic thiopental, a lipid-soluble drug. Because blood flow to the brain is high and thiopental readily crosses the BBB, thiopental reaches its maximal concentration in brain rapidly after its intravenous injection. Subsequently, the plasma and brain concentrations decrease as thiopental redistributes to other tissues, such as muscle and, finally, adipose tissue.

This redistribution is the mechanism by which thiopental anesthesia is terminated (see Figure 2–4) because its clearance is rather slow (elimination $t_{1/2}$ after a single dose is 3–8 h). The concentration of the drug in brain follows that of the plasma because there is little binding of the drug to brain constituents. Thus, both the onset and the termination of thiopental anesthesia are relatively rapid, and both are related directly to the concentration of drug in the brain.

Placental Transfer of Drugs

The transfer of drugs across the placenta is of critical importance because drugs may cause anomalies in the developing fetus; thus, the burden for evidenced-based drug use in pregnancy is paramount (see Appendix I). Lipid solubility, extent of plasma binding, and degree of ionization of weak acids and bases are important general determinants in drug transfer across the placenta. The placenta functions as a selective barrier to protect the fetus against the harmful effects of drugs. Members of the ABC family of transporters limit the entry of drugs and other xenobiotics into the fetal circulation via vectorial efflux from the placenta to the maternal circulation (see Figure 2–2 and Chapter 5). The fetal plasma is slightly more acidic than that of the mother (pH 7.0–7.2 vs. 7.4), so that ion trapping of basic drugs occurs. The view that the placenta is an absolute barrier to drugs is inaccurate, in part because a number of influx transporters are also present. The fetus is to some extent exposed to all drugs taken by the mother. The Food and Drug Administration categorizes the relative safety of drugs that may be used in pregnant women (see Appendix I).

Metabolism of Drugs

A Few Principles of Metabolism and Elimination

The many therapeutic agents that are lipophilic do not pass readily into the aqueous environment of the urine. The metabolism of drugs and other xenobiotics into more hydrophilic metabolites is essential for their renal elimination from the body, as well as for termination of their biological and pharmacological activity.

From the point of view of pharmacokinetics, the following are the three essential aspects of drug metabolism:

- **First-order kinetics.** For most drugs in their therapeutic concentration ranges, the amount of drug metabolized per unit time is proportional to the plasma concentration of the drug (C_p) and the fraction of drug removed by metabolism is constant (i.e., first-order kinetics).
- **Zero-order kinetics.** For some drugs, such as ethanol and phenytoin, metabolic capacity is saturated at the concentrations usually employed, and drug metabolism becomes zero order; that is, a constant amount of drug is metabolized per unit time. Zero-order kinetics can also occur at high (toxic) concentrations as drug-metabolizing capacity becomes saturated.
- **Inducible biotransforming enzymes.** The major drug-metabolizing systems are inducible, broad-spectrum enzymes with some predictable genetic variations. Drugs that are substrates in common for a metabolizing enzyme may interfere with each other's metabolism, or a drug may induce or enhance metabolism of itself or other drugs.

In general, drug-metabolizing reactions generate more polar, inactive metabolites that are readily excreted from the body. However, in some cases, metabolites with potent biological activity or toxic properties are generated. Many of the enzyme systems that transform drugs to inactive metabolites also generate biologically active metabolites of endogenous compounds, as in steroid biosynthesis. The biotransformation of drugs occurs primarily in the liver and involves *phase 1 reactions* (oxidation, reduction, or hydrolytic reactions and the activities of CYPs) and *phase 2 reactions* (conjugations of the phase 1 product with a second molecule) and a few other reactions. Other organs with significant drug-metabolizing capacity include the GI tract, kidneys, and lungs. Drug-metabolizing enzymes, especially CYPs, are inducible by some drugs and inhibited by drugs and competing substrates. Chapter 6 covers drug metabolism at length. Knowing which CYP metabolizes a given drug and which other drugs may affect that metabolism is crucial to good drug therapy.

Prodrugs; Pharmacogenomics

Prodrugs are pharmacologically inactive compounds that are converted to their active forms by metabolism. This approach can maximize the amount of the active species that reaches its site of action. Inactive prodrugs are converted rapidly to biologically active metabolites, often by the hydrolysis of an ester or amide linkage. Such is the case with a number of ACE inhibitors employed in the management of high blood pressure. Enalapril, for instance, is relatively inactive until converted by esterase activity to the diacid enalaprilat (see Chapters 6 and 26).

For a number of therapeutic areas, clinical pharmacogenomics, the study of the impact of genetic variations or genotypes of individuals on their drug response or drug metabolism, allows for improved treatment of individuals or groups (Ramamoorthy et al., 2015; Zhang et al., 2015; see Chapter 7).

Excretion of Drugs

Drugs are eliminated from the body either unchanged or as metabolites. Excretory organs, the lung excluded, eliminate polar compounds more efficiently than substances with high lipid solubility. Thus, lipid-soluble drugs are not readily eliminated until they are metabolized to more polar compounds. The kidney is the most important organ for excreting drugs and their metabolites. Renal excretion of unchanged drug is a major route of elimination for 25%–30% of drugs administered to humans. Substances excreted in the feces are principally unabsorbed orally ingested drugs or drug metabolites either excreted in the bile or secreted directly into the intestinal tract and not reabsorbed. Excretion of drugs in breast milk is important not because of the amounts eliminated (which are small) but because the excreted drugs may affect the nursing infant (also small, and with poorly developed capacity to metabolize xenobiotics). Excretion from the lung is important mainly for the elimination of anesthetic gases (see Chapter 21).

Renal Excretion

Excretion of drugs and metabolites in the urine involves three distinct processes: glomerular filtration, active tubular secretion, and passive tubular reabsorption (Figure 2–5). The amount of drug entering the tubular lumen by filtration depends on the glomerular filtration rate and the extent of plasma binding of the drug; only unbound drug is filtered. In the proximal renal tubule, active, carrier-mediated tubular secretion also may add drug to the tubular fluid (see Chapters 5 and 25). Drug from the tubular lumen may be reabsorbed back into the systemic circulation. In the renal tubules, especially on the distal side, the nonionized forms of weak acids and bases undergo net passive reabsorption. Because the tubular cells are less permeable to the ionized forms of weak electrolytes, passive reabsorption of these substances depends on the pH. When the tubular urine is made more alkaline, weak acids are largely ionized and are excreted more rapidly and to a greater extent; conversely, acidification of the urine will reduce fractional ionization and excretion of weak acids. Effects of changing urine pH are opposite for weak bases. In the treatment of drug poisoning, the excretion of some drugs can be hastened by appropriate alkalization or acidification of the urine (see Figure 2–3 and Chapter 4).

In neonates, renal function is low compared with body mass but matures rapidly within the first few months after birth. During adulthood, there is a slow decline in renal function, about 1% per year, so that in elderly patients a substantial degree of functional impairment may be present, and medication adjustments are often needed.

Biliary and Fecal Excretion

Transporters present in the canalicular membrane of the hepatocyte (see Figure 5–6) actively secrete drugs and metabolites into bile. Ultimately, drugs and metabolites present in bile are released into the GI tract during the digestive process. Subsequently, the drugs and metabolites can be reabsorbed into the body from the intestine, which, in the case of conjugated metabolites such as glucuronides, may require enzymatic hydrolysis

Figure 2-5 Renal drug handling. Drugs may be filtered from the blood in the renal glomerulus, secreted into the proximal tubule, reabsorbed from the distal tubular fluid back into the systemic circulation, and collected in the urine. Membrane transporters (OAT, OCT, MDR1, and MRP2, among others) mediate secretion into the proximal tubule (see Figures 5-12 and 5-13 for details). Reabsorption of compounds from the distal tubular fluid (generally acidic) is pH sensitive: Ionizable drugs are subject to ion trapping, and altering urinary pH to favor ionization can enhance excretion of charged species (see Figure 2-2).

by the intestinal microflora. Such *enterohepatic recycling*, if extensive, may prolong significantly the presence of a drug (or toxin) and its effects within the body prior to elimination by other pathways. To interrupt enterohepatic cycling, substances may be given orally to bind metabolites excreted in the bile (for instance, see bile acid sequestrants and ezetimibe, Chapter 33). Biliary excretions and unabsorbed drug are excreted in the feces.

Excretion by Other Routes

Excretion of drugs into sweat, saliva, and tears is quantitatively unimportant. Because milk is more acidic than plasma, basic compounds may be slightly concentrated in this fluid; conversely, the concentration of acidic compounds in the milk is lower than in plasma. Nonelectrolytes (e.g., ethanol and urea) readily enter breast milk and reach the same concentration as in plasma, independent of the pH of the milk (Rowe et al., 2015). Breast milk can also contain heavy metals from environmental exposures. The administration of drugs to breastfeeding women carries the general caution that the suckling infant will be exposed to some extent to the medication or its metabolites. Although excretion into hair and skin is quantitatively unimportant, sensitive methods of detection of drugs in these tissues have forensic significance.

Clinical Pharmacokinetics

Clinical pharmacokinetics relate the pharmacological effects of a drug and concentration of the drug in an accessible body compartment (e.g., in blood or plasma) as these change in time. In most cases, the concentration of drug at its sites of action will be related to the concentration of drug in the systemic circulation (see Figure 2-1). The pharmacological effect

that results may be the clinical effect desired or an adverse or toxic effect. Clinical pharmacokinetics attempts to provide

- a quantitative relationship between dose and effect, and
- a framework within which to interpret measurements of drug concentration in biological fluids and their adjustment through changes in dosing for the benefit of the patient.

The importance of pharmacokinetics in patient care is based on the improvement in therapeutic efficacy and the avoidance of unwanted effects that can be attained by application of its principles when dosage regimens are chosen and modified.

The following are the four most important parameters governing drug disposition:

1. *Bioavailability*, the fraction of drug absorbed as such into the systemic circulation.
2. *Volume of distribution*, a measure of the apparent space in the body available to contain the drug based on how much is given versus what is found in the systemic circulation.
3. *Clearance*, a measure of the body's efficiency in eliminating drug from the systemic circulation.
4. *Elimination $t_{1/2}$* , a measure of the rate of removal of drug from the systemic circulation.

Clearance

Clearance is the most important concept to consider when designing a rational regimen for long-term drug administration. The clinician usually wants to maintain steady-state concentrations of a drug within a *therapeutic window* or range associated with therapeutic efficacy and a minimum of toxicity for a given agent. Assuming complete bioavailability, the steady-state concentration of drug in the body will be achieved when the rate of drug elimination equals the rate of drug administration. Thus,

$$\text{Dosing rate} = CL \cdot C_{ss} \quad (\text{Equation 2-3})$$

where CL is clearance of drug from the systemic circulation, and C_{ss} is the steady-state concentration of drug. When the desired steady-state concentration of drug in plasma or blood is known, the rate of clearance of drug will dictate the rate at which the drug should be administered.

Knowing the clearance of a drug is useful because its value for a particular drug usually is constant over the range of concentrations encountered clinically. This is true because metabolizing enzymes and transporters usually are not saturated; thus, the absolute rate of elimination of the drug is essentially a linear function of its concentration in plasma (first-order kinetics), where a *constant fraction* of drug in the body is eliminated per unit of time. If mechanisms for elimination of a given drug become saturated, the kinetics approach zero order (the case for ethanol and high doses of phenytoin), in which case a *constant amount* of drug is eliminated per unit of time.

With first-order kinetics, clearance CL will vary with the concentration of drug (C), often according to Equation 2-4:

$$CL = \frac{v_m}{(K_m + C)} \quad (\text{Equation 2-4})$$

where K_m represents the concentration at which half the maximal rate of elimination is reached (in units of mass/volume), and v_m is equal to the maximal rate of elimination (in units of mass/time). Thus, clearance is derived in units of volume cleared of drug/time. This equation is analogous to the Michaelis-Menten equation for enzyme kinetics.

Clearance of a drug is its rate of elimination by all routes normalized to the concentration of drug C in some biological fluid where measurement can be made:

$$CL = \text{Rate of elimination}/C \quad (\text{Equation 2-5})$$

Thus, when clearance is constant, the rate of drug elimination is directly proportional to drug concentration. Clearance indicates the volume of

biological fluid such as blood or plasma from which drug would have to be completely removed to account for the clearance per unit of body weight (e.g., mL/min per kg). Clearance can be defined further as blood clearance CL_b , plasma clearance CL_p , or clearance based on the concentration of unbound drug CL_u , depending on the measurement made (C_b , C_p , or C_u). Clearance of drug by several organs is additive. Elimination of drug from the systemic circulation may occur as a result of processes that occur in the kidney, liver, and other organs. Division of the rate of elimination by each organ by a concentration of drug (e.g., plasma concentration) will yield the respective clearance by that organ. Added together, these separate clearances will equal systemic clearance:

$$CL_{\text{renal}} + CL_{\text{hepatic}} + CL_{\text{other}} = CL \quad (\text{Equation 2-6})$$

Any significant alteration in renal or hepatic function can result in decreased clearance for those drugs with high renal or hepatic clearance. Systemic clearance may be determined at steady state by using Equation 2-3. For a single dose of a drug with complete bioavailability and first-order kinetics of elimination, systemic clearance may be determined from mass balance and the integration of Equation 2-5 over time:

$$CL = \text{Dose}/AUC \quad (\text{Equation 2-7})$$

AUC is the total area under the curve that describes the measured concentration of drug in the systemic circulation as a function of time (from zero to infinity), as in Figure 2-9.

Examples of Clearance

The plasma clearance for the antibiotic cephalexin is 4.3 mL/min/kg, with 90% of the drug excreted unchanged in the urine. For a 70-kg man, the clearance from plasma would be 301 mL/min, with renal clearance accounting for 90% of this elimination. In other words, the kidney is able to excrete cephalexin at a rate such that the drug is completely removed (cleared) from about 270 mL of plasma every minute (renal clearance = 90% of total clearance). Because clearance usually is assumed to remain constant in a medically stable patient (e.g., no acute decline in kidney function), the rate of elimination of cephalexin will depend on the concentration of drug in the plasma (see Equation 2-5).

The β adrenergic receptor antagonist propranolol is cleared from the blood at a rate of 16 mL/min/kg (or 1600 mL/min in a 100-kg man), almost exclusively by the liver. Thus, the liver is able to remove the amount of propranolol contained in 1600 mL of blood in 1 min, roughly equal to total hepatic blood (see Table 2-2). In fact, the plasma clearance of some drugs exceeds the rate of blood flow to this organ. Often, this is so because the drug partitions readily into and out of red blood cells (rbc), and the rate of drug delivered to the eliminating organ is considerably higher than expected from measurement of its concentration in plasma. The relationship between plasma clearance (subscript p) and blood clearance (subscript b; all components of blood) at steady state is given by

$$\frac{CL_p}{CL_b} = \frac{C_b}{C_p} = 1 + H \left[\frac{C_{rbc}}{C_p} - 1 \right] \quad (\text{Equation 2-8})$$

Clearance from the blood therefore may be estimated by dividing the plasma clearance by the drug's blood-to-plasma concentration ratio, obtained from knowledge of the hematocrit ($H = 0.45$) and concentration ratio of red cells to plasma. In most instances, the blood clearance will be less than liver blood flow (1.5–1.7 L/min) or, if renal excretion also is involved, the sum of the blood flows to each eliminating organ. For example, the plasma clearance of the immunomodulator tacrolimus, about 2 L/min, is more than twice the hepatic plasma flow rate and even exceeds the organ's blood flow despite the fact that the liver is the predominant site of this drug's extensive metabolism. However, after taking into account the extensive distribution of tacrolimus into red cells, its clearance from the blood is only about 63 mL/min, and it is actually a drug with a rather low clearance, not a high-clearance agent as might be expected from the

plasma clearance value alone. Clearance from the blood by metabolism can exceed liver blood flow, and this indicates extrahepatic metabolism. In the case of the β_1 receptor antagonist esmolol, the blood clearance value (11.9 L/min) is greater than cardiac output (~5.5 L/min) because the drug is metabolized efficiently by esterases present in red blood cells.

A further definition of clearance is useful for understanding the effects of pathological and physiological variables on drug elimination, particularly with respect to an individual organ. The rate of presentation of drug to the organ is the product of blood flow Q and the arterial drug concentration C_A , and the rate of exit of drug from the organ is the product of blood flow and the venous drug concentration C_V . The difference between these rates at steady state is the rate of drug elimination by that organ:

$$\begin{aligned} \text{Rate of elimination} &= Q \cdot C_A - Q \cdot C_V \\ &= Q(C_A - C_V) \end{aligned} \quad (\text{Equation 2-9})$$

Dividing Equation 2-8 by the concentration of drug entering the organ at elimination, C_A , yields an expression for clearance of the drug by the organ in question:

$$CL_{\text{organ}} = Q \left[\frac{C_A - C_V}{C_A} \right] = Q \cdot E \quad (\text{Equation 2-10})$$

The expression $(C_A - C_V)/C_A$ in Equation 2-10 can be referred to as the extraction ratio E of the drug. While not employed in general medical practice, calculations of a drug's extraction ratio(s) are useful for modeling the effects of disease of a given metabolizing organ on clearance and in the design of ideal therapeutic properties of drugs in development.

Hepatic Clearance

For a drug that is removed efficiently from the blood by hepatic processes (metabolism or excretion of drug into the bile), the concentration of drug in the blood leaving the liver will be low, the extraction ratio will approach unity, and the clearance of the drug from blood will become limited by hepatic blood flow. Drugs that are cleared efficiently by the liver (e.g., drugs with systemic clearances > 6 mL/min/kg, such as diltiazem, imipramine, lidocaine, morphine, and propranolol) are restricted in their rate of elimination not by intrahepatic processes but by the rate at which they can be transported in the blood to the liver.

Pharmacokinetic models indicate that when the capacity of the eliminating organ to metabolize the drug is large in comparison with the rate of presentation of drug to the organ, clearance will approximate the organ's blood flow. By contrast, when the drug-metabolizing capacity is small in comparison with the rate of drug presentation, clearance will be proportional to the unbound fraction of drug in blood and the drug's intrinsic clearance, where intrinsic clearance represents drug binding to components of blood and tissues or the intrinsic capacity of the liver to eliminate a drug in the absence of limitations imposed by blood flow (Guner and Bowen, 2013).

Renal Clearance

Renal clearance of a drug results in its appearance in the urine. In considering the clearance of a drug from the body by the kidney, glomerular filtration, secretion, reabsorption, and glomerular blood flow must be considered (see Figure 2-5). The rate of filtration of a drug depends on the volume of fluid that is filtered in the glomerulus and the concentration of unbound drug in plasma (because drug bound to protein is not filtered). The rate of secretion of drug into the tubular fluid will depend on the drug's intrinsic clearance by the transporters involved in active secretion as affected by the drug's binding to plasma proteins, the degree of saturation of these transporters, the rate of delivery of the drug to the secretory site, and the presence of drugs that can compete for these transporters. In addition, one must consider processes of drug reabsorption from the tubular fluid back into the bloodstream. The influences of changes in protein binding, blood flow, and the functional state of nephrons will affect renal clearance.

Aspirin demonstrates the interplay among these processes. Aspirin has a bimodal effect on the renal handling of uric acid: High doses of aspirin (>3 g/d) are uricosuric (probably by blocking urate reabsorption), while low dosages (1–2 g/d) cause uric acid retention (probably via inhibiting urate secretion). Low-dose aspirin, indicated for the prophylaxis of cardiovascular events, can cause changes in renal function and uric acid handling in elderly patients.

Distribution

Volume of Distribution

The volume of distribution V relates the amount of drug in the body to the concentration of drug C in the blood or plasma, depending on the fluid measured. This volume does not necessarily refer to an identifiable physiological volume but rather to the fluid volume that would be required to contain all of the drug in the body at the same concentration measured in the blood or plasma:

$$\text{Amount of drug in body}/V = C$$

or

$$V = \text{Amount of drug in body}/C \quad (\text{Equation 2-11})$$

View V as an imaginary volume because for many drugs V exceeds the known volume of any and all body compartments (Box 2-1). For example, the value of V for the highly lipophilic antimalarial chloroquine is some 15,000 L, whereas the volume of total-body water is about 42 L in a 70-kg male.

For drugs that are bound extensively to plasma proteins but are not bound to tissue components, the volume of distribution will approach that of the plasma volume because drug bound to plasma protein is measurable in the assay of most drugs. In contrast, certain drugs have high volumes of distribution even though most of the drug in the circulation is bound to albumin because these drugs are also sequestered elsewhere.

The volume of distribution defined in Equation 2-11 considers the body as a single homogeneous compartment. In this one-compartment model, all drug administration occurs directly into the central compartment, and distribution of drug is instantaneous throughout the volume V . Clearance of drug from this compartment occurs in a first-order fashion, as defined in Equation 2-5; that is, the amount of drug eliminated per unit of time depends on the amount (concentration) of drug in the body compartment at that time. Figure 2-6A and Equation 2-9 describe the

decline of plasma concentration with time for a drug introduced into this central compartment:

$$C = \left[\frac{\text{Dose}}{V} \right] [e^{-kt}] \quad (\text{Equation 2-12})$$

where k is the rate constant for elimination that reflects the fraction of drug removed from the compartment per unit of time. This rate constant is inversely related to the $t_{1/2}$ of the drug [$kt_{1/2} = \ln 2 = 0.693$]. The idealized one-compartment model does not describe the entire time course of the plasma concentration. Certain tissue reservoirs can be distinguished from the central compartment, and the drug concentration appears to decay in a manner that can be described by multiple exponential terms (Figure 2-6B).

Rates of Distribution

In many cases, groups of tissues with similar perfusion-to-partition ratios all equilibrate at essentially the same rate such that only one apparent phase of distribution is seen (rapid initial decrease in concentration of intravenously injected drug, as in Figure 2-6B). It is as though the drug starts in a “central” volume (see Figure 2-1), which consists of plasma and tissue reservoirs that are in rapid equilibrium, and distributes to a “final” volume, at which point concentrations in plasma decrease in a log-linear fashion with a rate constant of k (see Figure 2-6B). The multicompartment model of drug disposition can be viewed as though the blood and highly perfused lean organs such as heart, brain, liver, lung, and kidneys cluster as a single central compartment, whereas more slowly perfused tissues such as muscle, skin, fat, and bone behave as the final compartment (the tissue compartment).

If blood flow to certain tissues changes within an individual, rates of drug distribution to these tissues also will change. Changes in blood flow may cause some tissues that were originally in the “central” volume to equilibrate sufficiently more slowly so they appear only in the “final” volume. This means that central volumes will appear to vary with disease states that cause altered regional blood flow (such as would be seen in cirrhosis of the liver). After an intravenous bolus dose, drug concentrations in plasma may be higher in individuals with poor perfusion (e.g., shock) than they would be if perfusion were better. These higher systemic concentrations may in turn cause higher concentrations (and greater effects) in tissues such as brain and heart, whose usually high perfusion has not been reduced. Thus, the effect of a drug at various sites of action can vary depending on perfusion of these sites.

Multicompartment Volumes

In multicompartment kinetics, a volume of distribution term is useful especially when the effect of disease states on pharmacokinetics is to be determined. The volume of distribution at steady state V_{ss} represents the volume in which a drug would appear to be distributed during steady state if the drug existed throughout that volume at the same concentration as that in the measured fluid (plasma or blood). V_{ss} also may be appreciated as shown in Equation 2-13, where V_c is the volume of distribution of drug in the central compartment and V_T is the volume term for drug in the tissue compartment:

$$V_{ss} = V_c + V_T \quad (\text{Equation 2-13})$$

Steady-State Concentration

Equation 2-3 (Dosing rate = $CL \cdot C_{ss}$) indicates that a steady-state concentration eventually will be achieved when a drug is administered at a constant rate. At this point, drug elimination (the product of clearance and concentration; Equation 2-5) will equal the rate of drug availability. This concept also extends to regular intermittent dosage (e.g., 250 mg of drug every 8 h). During each interdose interval, the concentration of drug rises with absorption and falls by elimination. At steady state, the entire cycle is repeated identically in each interval (Figure 2-7). Equation 2-3 still applies for intermittent dosing, but it now describes the average

BOX 2-1 ■ V Values May Exceed Any Physiological Volume

For many drugs, Equation 2-11 will give V values that exceed any physiological volume. For example, if 500 μg of the cardiac glycoside digoxin were added into the body of a 70-kg subject, a plasma concentration of about 0.75 ng/mL would be observed. Dividing the amount of drug in the body by the plasma concentration yields a volume of distribution for digoxin of about 667 L, or a value about 15 times greater than the total-body volume of a 70-kg man. In fact, digoxin distributes preferentially to muscle and adipose tissue and binds to its specific receptors, the Na^+, K^+ -ATPase, leaving a very small amount of drug in the plasma to be measured. A drug's volume of distribution therefore can reflect the extent to which it is present in extravascular tissues and not in the plasma.

Thus, V may vary widely depending on the relative degrees of binding to high-affinity receptor sites, plasma and tissue proteins, the partition coefficient of the drug in fat, and accumulation in poorly perfused tissues. The volume of distribution for a given drug can differ according to a patient's age, gender, body composition, and presence of disease. Total-body water of infants younger than 1 year of age, for example, is 75%–80% of body weight, whereas that of adult males is 60% and that of females is 55%.

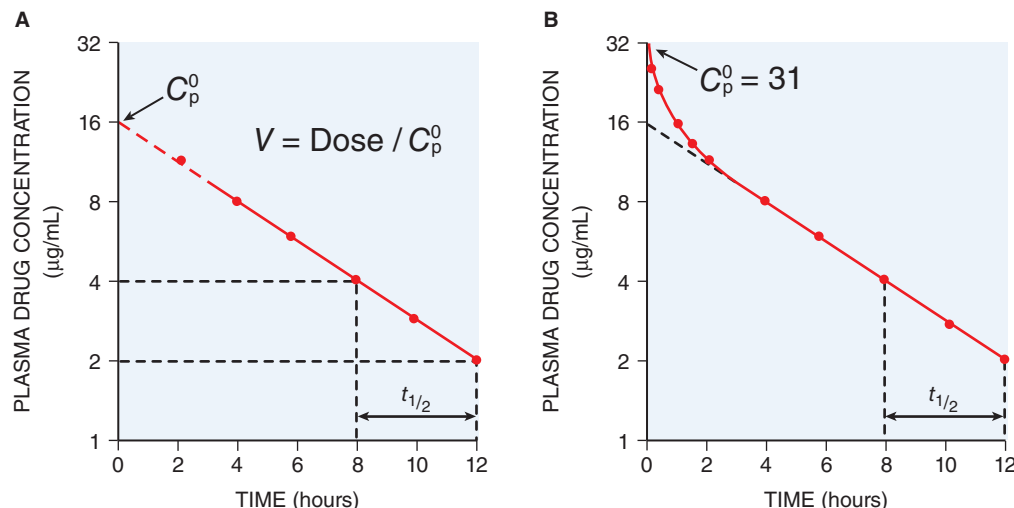

Figure 2-6 Plasma concentration-time curves following intravenous administration of a drug (500 mg) to a 70-kg patient. **A.** Drug concentrations are measured in plasma at 2-hour intervals following drug administration. The semilogarithmic plot of plasma concentration C_p versus time suggests that the drug is eliminated from a single compartment by a first-order process (see Equation 2-12) with a $t_{1/2}$ of 4 h ($k = 0.693/t_{1/2} = 0.173 \text{ h}^{-1}$). The volume of distribution V may be determined from the value of C_p obtained by extrapolation to zero-time. Volume of distribution (see Equation 2-11) for the one-compartment model is 31.3 L, or 0.45 L/kg ($V = \text{dose}/C_p^0$). The clearance for this drug is 90 mL/min; for a one-compartment model, $CL = kV$. **B.** Sampling before 2 h indicates that the drug follows multiexponential kinetics. The terminal disposition $t_{1/2}$ is 4 h, clearance is 84 mL/min (see Equation 2-7), and V_{ss} is 26.8 L (see Equation 2-13). The initial or “central” distribution volume for the drug ($V = \text{dose}/C_p^0$) is 16.1 L. The example indicates that multicompartment kinetics may be overlooked when sampling at early times is neglected. In this particular case, there is only a 10% error in the estimate of clearance when the multicompartment characteristics are ignored. For many drugs, multicompartment kinetics may be observed for significant periods of time, and failure to consider the distribution phase can lead to significant errors in estimates of clearance and in predictions of appropriate dosage.

steady-state drug concentration during an interdose interval. Note the extension of this idea to derive \bar{C}_{ss} during continuous intravenous drug infusion, as explained in the legend to Figure 2-7.

Half-Life

The $t_{1/2}$ is the time it takes for the plasma concentration to be reduced by 50%. For the one-compartment model of Figure 2-6A, $t_{1/2}$ may be determined readily by inspection of the data and used to make decisions about drug dosage. However, as indicated in Figure 2-6B, drug concentrations in plasma often follow a multicomponent pattern of decline.

Half-Life, Volume of Distribution, and Clearance

When using pharmacokinetics to calculate drug dosing in disease, note that $t_{1/2}$ changes as a function of both clearance and volume of distribution:

$$t_{1/2} \cong 0.693 \cdot V_{ss}/CL \quad (\text{Equation 2-14})$$

This $t_{1/2}$ reflects the decline of systemic drug concentrations during a dosing interval at steady state as depicted in Figure 2-7.

Terminal Half-Life

With prolonged dosing (or with high drug concentrations), a drug may penetrate beyond the central compartment into “deep” or secondary body compartments that equilibrate only slowly with the plasma. When the infusion or dosing stops, the drug will be initially cleared from plasma as expected but will eventually drop to a point at which net diffusion from the secondary compartments begins, and this slow equilibration will produce a prolongation of the half-life of the drug, referred to as the terminal half-life.

Steady-State $t_{1/2}$ and Terminal $t_{1/2}$ Compared

Examples of drugs with marked differences in terminal $t_{1/2}$ versus steady-state $t_{1/2}$ are gentamicin and indomethacin. Gentamicin has a $t_{1/2}$ of 2–3 h following a single administration, but a terminal $t_{1/2}$ of 53 h because drug accumulates in spaces such as kidney parenchyma (where this accumulation can result in toxicity). Biliary cycling probably is responsible for the 120-h terminal value for indomethacin (compared

to the steady-state value of 2.4 h). Intravenous anesthetics provide a good example; many have context-sensitive half-times; these agents, with short half-times after single intravenous doses, exhibit longer half-times in proportion to the duration of exposure when used in maintenance anesthesia (see Figure 21-2).

Clearance is the measure of the body’s capacity to eliminate a drug; thus, as clearance decreases, owing to a disease process, for example, $t_{1/2}$ will increase as long as the volume of distribution remains unchanged; alternately, the volume of distribution may change but CL remains constant or a combination of the two changes. For example, the $t_{1/2}$ of diazepam increases with increasing age; however, this does not reflect a change in clearance but rather a change in the volume of distribution. Similarly, changes in protein binding of a drug (e.g., hypoalbuminemia) may affect its clearance as well as its volume of distribution, leading to unpredictable changes in $t_{1/2}$ as a function of disease. The $t_{1/2}$ defined in Equation 2-14 provides an approximation of the time required to reach steady state after a dosage regimen is initiated or changed (e.g., four half-lives to reach ~ 94% of a new steady state).

Extent and Rate of Absorption

Bioavailability

It is important to distinguish between the amount of drug that is administered and the quantity of drug that ultimately reaches the systemic circulation. Dissolution and absorption of drug may be incomplete; some drug may be destroyed prior to entering the systemic circulation, especially by hepatic first-pass metabolism. The first-pass effect is extensive for many oral medications that enter the portal vein and pass directly to the liver. The fraction of a dose F that is absorbed and escapes first-pass elimination measures the drug’s bioavailability; thus, $0 < F \leq 1$ (see Equation 2-2).

For some drugs, extensive first-pass metabolism greatly reduces their effectiveness or precludes their use as oral agents (e.g., lidocaine, propranolol, naloxone, and glyceryl trinitrate). For other agents, the extent of absorption may be very low, thereby reducing bioavailability. When drugs are administered by a route that is subject to significant first-pass loss or incomplete absorption, the equations presented previously that contain

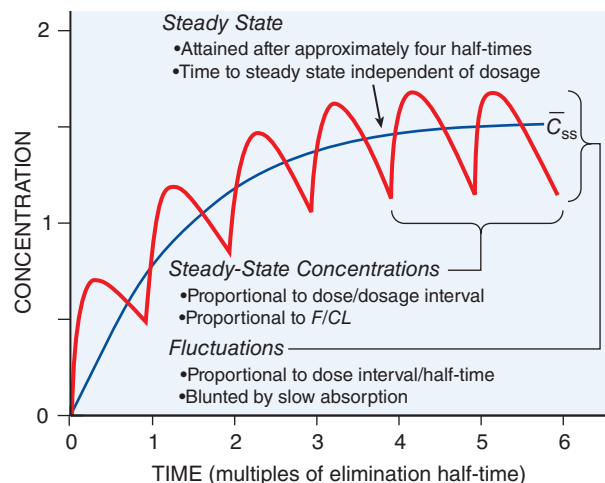

Figure 2-7 Fundamental pharmacokinetic relationships for repeated administration of drugs. The red line is the pattern of drug accumulation during repeated administration of a drug at intervals equal to its elimination half-time. With instantaneous absorption, each dose would add 1 concentration unit to C_p at the time of administration, and then half of that would be eliminated prior to administration of the next dose, resulting in the oscillation of C_p between 1 and 2 after four or five elimination half-times. However, this more realistic simulation uses a rate of drug absorption that is not instantaneous but is 10 times as rapid as elimination; drug is eliminated throughout the absorption process, blunting the maximal blood level achieved after each dose. With repeated administration, C_p achieves steady state, oscillating around the blue line at 1.5 units. The blue line depicts the pattern during administration of equivalent dosage by continuous intravenous infusion. Curves are based on the one-compartment model. Average drug concentration at steady state \bar{C}_{ss} is:

$$\bar{C}_{ss} = \frac{F \cdot \text{dose}}{CL \cdot T} = \frac{F \cdot \text{dosing rate}}{CL}$$

where the dosing rate is the dose per time interval and is dose/T , F is the fractional bioavailability, and CL is clearance. Note that substitution of infusion rate for $[F \cdot \text{dose}/T]$ provides the concentration maintained at steady state during continuous intravenous infusion ($F = 1$ with intravenous administration).

the terms *dose* or *dosing rate* (see Equations 2-3, 2-7, and 2-12) also must include the bioavailability term F such that the available dose or dosing rate is used (Box 2-2). For example, Equation 2-2 is modified to

$$F \cdot \text{Dosing rate} = CL \cdot C_{ss} \quad (\text{Equation 2-15})$$

where the value of F is between 0 and 1.

Rate of Absorption

The rate of absorption can be important with a drug given as a single dose, such as a sleep-inducing medication that must act in a reasonable time

BOX 2-2 ■ Poor Absorption Notwithstanding, Some Agents With Low Bioavailability Are Effective Orally

The value of F varies widely for drugs administered by mouth, and successful therapy can still be achieved for some drugs with F values as low as 0.03 (e.g., etidronate and aliskiren). Aliskiren is the first orally applicable direct renin inhibitor approved for treatment of hypertension; its bioavailability is 2.6%. Etidronate, a bisphosphonate used to stabilize bone matrix in the treatment of Paget's disease and osteoporosis, has a similarly low bioavailability of 0.03, meaning that only 3% of the drug appears in the bloodstream following oral dosing. In these cases, therapy using oral administration is still useful, although the administered dose of the drug per kilogram is larger than would be given by injection.

frame and achieve an effective blood level that is maintained for an appropriate duration. However, with periodic and repeated dosing, the rate of drug absorption does not, in general, influence the average steady-state concentration of the drug in plasma, provided the drug is stable before it is absorbed; the rate of absorption may, however, still influence drug therapy. If a drug is absorbed rapidly (e.g., a dose given as an intravenous bolus) and has a small "central" volume, the concentration of drug initially will be high. It will then fall as the drug is distributed to its "final" (larger) volume (see Figure 2-6B). If the same drug is absorbed more slowly (e.g., by slow infusion), a significant amount of the drug will be distributed while it is being administered, and peak concentrations will be lower and will occur later. Controlled-release oral preparations are designed to provide a slow and sustained rate of absorption to produce smaller fluctuations in the plasma concentration-time profile during the dosage interval compared with more immediate-release formulations. Because the beneficial, nontoxic effects of drugs are based on knowledge of an ideal or desired plasma concentration range, maintaining that range while avoiding large swings between peak and trough concentrations can improve therapeutic outcome.

Nonlinear Pharmacokinetics

Nonlinearity in pharmacokinetics (i.e., changes in such parameters as clearance, volume of distribution, and $t_{1/2}$ as a function of dose or concentration of drug) is usually caused by saturation of protein binding, hepatic metabolism, or active renal transport of the drug.

Saturable Protein Binding

As the molar concentration of small drug molecules increases, the unbound fraction eventually also must increase (as all binding sites become saturated when drug concentrations in plasma are in the range of tens to hundreds of micrograms per milliliter). For a drug that is metabolized by the liver with a low intrinsic clearance-extraction ratio, saturation of plasma-protein binding will cause both V and CL to increase as drug concentrations increase; $t_{1/2}$ thus may remain constant (see Equation 2-14). For such a drug, C_{ss} will not increase linearly as the rate of drug administration is increased. For drugs that are cleared with high intrinsic clearance-extraction ratios, C_{ss} can remain linearly proportional to the rate of drug administration. In this case, hepatic clearance will not change, and the increase in V will increase the half-time of disappearance by reducing the fraction of the total drug in the body that is delivered to the liver per unit of time. Most drugs fall between these two extremes.

Saturable Elimination

In the case of saturable elimination, the Michaelis-Menten equation (see Equation 2-4) usually describes the nonlinearity. All active processes are undoubtedly saturable, but they will appear to be linear if values of drug concentrations encountered in practice are much less than K_m for that process (Box 2-3). When drug concentrations exceeds K_m , nonlinear kinetics are observed. Saturable metabolism causes oral first-pass metabolism to be less than expected (higher *fractional bioavailability*), resulting in a greater fractional increase in C_{ss} than the corresponding fractional increase in the rate of drug administration; basically, the rate of drug entry into the systemic circulation exceeds the maximum possible rate of drug metabolism, and elimination becomes zero order. The major consequences of saturation of metabolism or transport are the opposite of those for saturation of protein binding. Saturation of protein binding will lead to increased CL because CL increases as drug concentration increases, whereas saturation of metabolism or transport may decrease CL .

C_{ss} can be computed by substituting Equation 2-4 (with $C = C_{ss}$) into Equation 2-3 and solving for the steady-state concentration:

$$C_{ss} = \frac{\text{Dosing rate} \cdot K_m}{v_m - \text{dosing rate}} \quad (\text{Equation 2-16})$$

As the dosing rate approaches the maximal elimination rate v_m , the denominator of Equation 2-16 approaches zero, and C_{ss} increases disproportionately. Because saturation of metabolism should have no effect on

BOX 2-3 ■ Saturable Metabolism: Phenytoin

The antiseizure medication phenytoin is a drug for which metabolism can become saturated by levels of the drug in the therapeutic range. Factors contributing to this are phenytoin's variable half-life and clearance and an effective concentration that varies and can saturate clearance mechanisms, such that the C_{ss} may be saturating clearance mechanisms or be well above or below that value. The $t_{1/2}$ of phenytoin is 6–24 h. For clearance, K_m (5–10 mg/L) is typically near the lower end of the therapeutic range (10–20 mg/L). For some individuals, especially young children and newborns being treated for emergent seizures, K_m may be as low as 1 mg/L. Consider an extreme case of a 70 kg adult in whom the target concentration (C_{ss}) is 15 mg/L, $K_m = 1$ mg/L, and the maximal elimination rate, v_m , (from Appendix II) is 5.9 mg/kg/day, or 413 mg/day/70 kg. Substituting into Equation 2-16:

$$15 \text{ mg/L} = (\text{dosing rate})(1 \text{ mg/L}) / (413 \text{ mg/day} - \text{dosing rate})$$

$$\text{dosing rate} = 387 \text{ mg/day}$$

In this case, the dosing rate is just below the elimination capacity. If the dosing rate were to vary upward by 10% (to 387 + 38.7 or ~426 mg/day), the dosing rate would exceed the elimination capacity by 13 mg/day and the C_p of phenytoin would begin a slow climb to toxic levels. Conversely, if the dosing rate were to vary downward by 10% (to 387–38.7 or ~348 mg/day), the C_{ss} achieved would be 5.4 mg/L, a drastic reduction to a level below the therapeutic range.

Consider a more common K_m , 8 mg/L, such that the desired C_{ss} of 15 mg/L is farther from saturating the elimination capacity. In a 70 kg subject ($v_m = 413$ mg/day), these data require a dosing rate of only 269 mg/day. An increase in this rate by 10% (to 296 mg/day) would not saturate the elimination capacity but would lead to a $C_{ss} = 20.2$ mg/L. A 10% downward variance in the dosing rate (to 242 mg/day) will produce a $C_{ss} = 11.3$ mg/L, a much less drastic decrease than above and still in the therapeutic range.

Factoring in all the variables, predicting and controlling dosage so precisely (<10% error) can be difficult. Therefore, for patients in whom the target concentration for phenytoin is ≥ 10 times the K_m , alternating between inefficacious therapy and toxicity is common, careful monitoring is essential, and a pharmacokinetic consult to establish or revise dosing may be appropriate.

Other agents exhibiting saturated metabolism at or near the commonly employed concentrations include aspirin, fluoxetine, verapamil, and ethanol.

the volume of distribution, clearance and the relative rate of drug elimination decrease as the concentration increases; therefore, the $\log C_p$ time curve is concave-downward until metabolism becomes sufficiently desaturated such that first-order elimination is observed (Figure 2-8).

Thus, in the region of saturation of metabolism, the concept of a constant $t_{1/2}$ is not applicable. Consequently, changing the dosing rate for a drug with nonlinear metabolism is difficult and unpredictable because the resulting steady state is reached more slowly, and importantly, the effect is disproportionate to the alteration in the dosing rate.

Figure 2-8 compares the effects of first-order and zero-order elimination kinetics on important pharmacokinetic parameters.

Design and Optimization of Dosage Regimens

The Therapeutic Window

The intensity of a drug's effect is related to its concentration (usually C_p) above a minimum effective concentration, whereas the duration of the drug's effect reflects the length of time the drug level is above this value (Figure 2-9). These considerations, in general, apply to both desired and undesired (adverse) drug effects; as a result, a *therapeutic window* exists that reflects a concentration range that provides efficacy without unacceptable toxicity. Following administration of a single dose, a lag period precedes the onset of the drug effect, after which the magnitude of the effect increases to a maximum and then declines; if a subsequent dose is not administered, the effect eventually disappears as the drug is eliminated. This time course reflects changes in the drug's concentration as determined by the pharmacokinetics of its absorption, distribution, and elimination.

Similar considerations apply after multiple dosing associated with long-term therapy, and they determine the amount and frequency of drug administration to achieve an optimal therapeutic effect. *In general, the lower limit of a drug's therapeutic range is approximately equal to the drug concentration that produces about half the greatest possible therapeutic effect, and the upper limit of the therapeutic range is such that no more than 5%–10% of patients will experience a toxic effect.* For some drugs, this may mean that the upper limit of the range is no more than twice the lower limit. Of course, these figures can be highly variable, and some patients may benefit greatly from drug concentrations that exceed the therapeutic range, whereas others may suffer significant toxicity at much lower values (e.g., with digoxin).

For a limited number of drugs, some effect of the drug is easily measured (e.g., blood pressure, blood glucose) and can be used to optimize dosage using a trial-and-error approach. Even in an ideal case, certain

Figure 2-8 Comparative pharmacokinetic parameters with first-order and zero-order elimination. Black lines represent the relationships under first-order kinetics of elimination. Dashed red lines indicate the effects of transitioning to a region of saturated elimination (zero-order kinetics).

Figure 2-9 A. Temporal characteristics of drug effect and relationship to the therapeutic window (e.g., single dose, oral administration). A lag period is present before the plasma drug concentration C_p exceeds the MEC for the desired effect $MEC_{desired}$. Following onset of the response, the intensity of the effect increases as the drug continues to be absorbed and distributed. This reaches a peak, after which drug elimination results in a decline in C_p and in the effect's intensity. Effect disappears when the drug concentration falls below the $MEC_{desired}$. The duration of a drug's action is determined by the time period over which concentrations exceed the $MEC_{desired}$. An MEC also exists for each adverse response ($MEC_{adverse}$), and if the drug concentration exceeds this, toxicity will result. The therapeutic goal is to obtain and maintain concentrations within the therapeutic window for the desired response with a minimum of toxicity. Drug response below the $MEC_{desired}$ will be subtherapeutic; above the $MEC_{adverse}$, the probability of toxicity will increase. The AUC (pale red) can be used to calculate the clearance (see Equation 2-7) for first-order elimination. The AUC is also used as a measure of bioavailability (defined as 100% for an intravenously administered drug). Bioavailability is less than 100% for orally administered drugs, due mainly to incomplete absorption and first-pass metabolism and elimination. Changing drug dosage shifts the curve up or down the C_p scale and is used to modulate the drug's effect, as shown in panel B.

B. Effects of altered absorption, elimination, and dosage and the temporal profile of a single dose administered orally. The bold green curve is the same as that shown in panel A. Increasing the dose (blue line) decreases the lag period and prolongs the drug's duration of effectiveness but at the risk of increasing the likelihood of adverse effects. Unless the drug is nontoxic (e.g., penicillins), increasing the dose is not a useful strategy for extending the duration of action if the increase puts the drug level near $MEC_{adverse}$. Instead, another dose of drug should be given, timed to maintain concentrations within the therapeutic window (see Figure 2-7). An increased rate of absorption of the dose (orange line) reduces the lag period, leads to a higher maximum C_p at an earlier time, but results in a shorter duration of action (time above $MEC_{desired}$). Increasing the rate of elimination of the dose decreases the maximum C_p and reduces the time of $C_p > MEC_{desired}$.

quantitative issues arise, such as how often to change dosage and by how much. These usually can be settled with simple rules of thumb based on the principles presented (e.g., change dosage by no more than 50% and no more often than every three or four half-lives). Alternatively, some drugs have little dose-related toxicity, and maximum efficacy usually is desired. In such cases, doses well in excess of the average required will ensure efficacy (if this is possible) and prolong drug action. Such a "maximal dose" strategy typically is used for penicillins. For many drugs, however, the effects are difficult to measure (or the drug is given for prophylaxis), toxicity and lack of efficacy are both potential dangers, or the therapeutic index is narrow. In these circumstances, doses must be titrated carefully, and drug dosage is limited by toxicity rather than efficacy.

Thus, the therapeutic goal is to maintain steady-state drug levels within the therapeutic window. When the concentrations associated with this desired range are not known, it is sufficient to understand that efficacy and toxicity depend on concentration and how drug dosage and frequency of administration affect the drug level. However, for a small number of drugs for which there is a small (2- to 3-fold) difference between concentrations resulting in efficacy and toxicity (e.g., digoxin, theophylline, lidocaine, aminoglycosides, cyclosporine, tacrolimus, sirolimus, warfarin, and some anticonvulsants), a plasma concentration range associated with effective therapy has been defined. In these cases, a desired (target) steady-state concentration of the drug (usually in plasma) associated with efficacy and minimal toxicity is chosen, and a dosage is computed that is expected to achieve this value. Drug concentrations are subsequently measured, and dosage is adjusted if necessary (described further in the chapter).

Maintenance Dose

In most clinical situations, drugs are administered in a series of repetitive doses or as a continuous infusion to maintain a steady-state concentration of drug associated with the therapeutic window. Calculation of the appropriate maintenance dosage is a primary goal. To maintain the chosen

steady-state or target concentration, the rate of drug administration is adjusted such that the rate of input equals the rate of loss. This relationship is expressed here in terms of the desired target concentration:

$$\text{Dosing rate} = \text{Target } C_p \cdot CL/F \quad (\text{Equation 2-17})$$

If the clinician chooses the desired concentration of drug in plasma and knows the clearance and bioavailability for that drug in a particular patient, the appropriate dose and dosing interval can be calculated (Box 2-4).

Dosing Interval for Intermittent Dosage

In general, marked fluctuations in drug concentrations between doses are not desirable. If absorption and distribution were instantaneous, fluctuations in drug concentrations between doses would be governed entirely by the drug's elimination $t_{1/2}$. If the dosing interval t were chosen to be equal to the $t_{1/2}$, then the total fluctuation would be 2-fold; this is often a tolerable variation. Pharmacodynamic considerations modify this. If a drug is relatively nontoxic such that a concentration many times that necessary for therapy can be tolerated easily, the maximal dose strategy can be used, and the dosing interval can be much longer than the elimination $t_{1/2}$ (for convenience). The $t_{1/2}$ of amoxicillin is about 2 h, but dosing every 2 h would be impractical. Instead, amoxicillin often is given in large doses every 8 or 12 h.

For some drugs with a narrow therapeutic range, it may be important to estimate the maximal and minimal concentrations that will occur for a particular dosing interval. The minimal steady-state concentration $C_{ss, \min}$ may be reasonably determined by:

$$C_{ss, \min} = \frac{F \cdot \text{dose} / V_{ss}}{1 - e^{-kT}} \cdot e^{-kT} \quad (\text{Equation 2-18})$$

where k equals 0.693 divided by the clinically relevant plasma $t_{1/2}$, and T is the dosing interval. The term e^{-kT} is the fraction of the last dose (corrected for bioavailability) that remains in the body at the end of a dosing interval.

BOX 2-4 ■ Calculating Dosage of Digoxin in Heart Failure

Oral digoxin is to be used as a maintenance dose to gradually “digitalize” a 63-year-old, 84-kg patient with congestive heart failure. A steady-state plasma concentration of 0.7–0.9 ng/mL is selected as a conservative target based on prior knowledge of the action of the drug in patients with heart failure to maintain levels at or below the 0.5– to 1.0-ng/mL range (Bauman et al., 2006). This patient’s creatinine clearance CL_{Cr} is given as 56 mL/min/84 kg; knowing that digoxin’s clearance may be estimated by consulting the entry for digoxin in Appendix II: $CL = 0.88 CL_{Cr} + 0.33$ mL/min/kg. Thus,

$$\begin{aligned} CL &= 0.88 CL_{Cr} + 0.33 \text{ mL/min/kg} \\ &= 0.88 \times 56/84 + 0.33 \text{ mL/min/kg} \\ &= 0.92 \text{ mL/min/kg} \end{aligned}$$

For this 84-kg patient:

$$CL = (84 \text{ kg})(0.92 \text{ mL/min/kg}) = 77 \text{ mL/min} = 4.6 \text{ L/h}$$

Knowing that the oral bioavailability of digoxin is 70% ($F = 0.7$) and with a target C_p of 0.75 ng/mL, one can use Equation 2-17 to calculate an appropriate dose rate for this 84-kg patient:

$$\begin{aligned} \text{Dosing rate} &= \text{Target } C_p \cdot CL/F \\ &= [0.75 \text{ ng/mL} \times 77 \text{ mL/min}] \div [0.7] = 82.5 \text{ ng/min} \\ &\text{or } 82.5 \text{ ng/min} \times 60 \text{ min/h} \times 24 \text{ h/d} = 119 \text{ } \mu\text{g/d} \end{aligned}$$

In practice, the dosing rate is rounded to the closest oral dosage size, 0.125 mg/d, which would result in a C_{ss} of 0.79 ng/mL (0.75 \times 125/119, or using Equation 2-15). Digoxin is a well-characterized example of a drug that is difficult to dose, has a low therapeutic index (~2–3), and has a large coefficient of variation for the clearance equation in patients with heart failure (52%); the effective blood level in one patient may be toxic or ineffective in another. Thus, monitoring the clinical status of patients (new or increased ankle edema, inability to sleep in a recumbent position, decreased exercise tolerance), whether accomplished by home health follow-up or regular visits to the clinician, is essential to avoid untoward results (see Chapter 29).

For drugs that follow multiexponential kinetics (administered orally), estimation of the maximal steady-state concentration $C_{ss,max}$ involves a set of parameters for distribution and absorption (Box 2-5). If these terms are ignored for multiple oral dosing, one easily may estimate a maximal steady-state concentration by omitting the e^{-kt} term in the numerator of Equation 2-18 (see Equation 2-19 in Box 2-5). Because of the approximation, the predicted maximal concentration from Equation 2-19 will be greater than that actually observed.

Loading Dose

As noted, repeated administration of a drug more frequently than its complete elimination will result in accumulation of the drug to or around a steady-state level (see Figure 2-7). When a constant dosage is given, reaching a steady-state drug level (the desired therapeutic concentration) will take four to five elimination half-times. This period can be too long when treatment demands a more immediate therapeutic response. In such a case, one can employ a *loading dose*, one or a series of doses given at the onset of therapy with the aim of achieving the target concentration rapidly. The loading dose is calculated as

$$\text{Loading dose} = \text{Target } C_p \cdot V_{ss}/F \quad (\text{Equation 2-21})$$

Consider the case for treatment of arrhythmias with lidocaine, for example. The $t_{1/2}$ of lidocaine is usually 1–2 h. Arrhythmias encountered after myocardial infarction may be life threatening, and one cannot wait

BOX 2-5 ■ Estimating Maximal and Minimal Blood Levels of Digoxin

In the 84-kg patient with congestive heart failure discussed in Box 2-4, an oral maintenance dose of 0.125 mg digoxin per 24 h was calculated to achieve an average plasma concentration of 0.79 ng/mL during the dosage interval. Digoxin has a narrow therapeutic index, and plasma levels ≤ 1.0 ng/mL usually are associated with efficacy and minimal toxicity. What are the maximum and minimum plasma concentrations associated with this regimen? This first requires estimation of digoxin’s volume of distribution based on pharmacokinetic data (Appendix II).

$$\begin{aligned} V_{ss} &= 3.12 CL_{Cr} + 3.84 \text{ L} \cdot \text{kg}^{-1} \\ &= 3.12 \times (56/84) + 3.84 \text{ L} \cdot \text{kg}^{-1} \\ &= 5.92 \text{ L/kg} \end{aligned}$$

or 497 L in this 84-kg patient.

Combining this value with that of digoxin’s clearance provides an estimate of digoxin’s elimination $t_{1/2}$ in the patient (Equation 2-14).

$$\begin{aligned} t_{1/2} &= 0.693 V_{ss} / CL \\ &= \frac{0.693 \times 497 \text{ L}}{4.6 \text{ L/h}} = 75 \text{ h} = 3.1 \text{ days} \end{aligned}$$

Accordingly, the fractional rate constant of elimination k is equal to 0.22 day^{-1} ($0.693/3.1 \text{ days}$). Maximum and minimum digoxin plasma concentrations then may be predicted depending on the dosage interval. With $T = 1 \text{ day}$ (i.e., 0.125 mg given every day),

$$\begin{aligned} C_{ss,max} &= \frac{F \cdot \text{dose} / V_{ss}}{1 - e^{-kT}} \quad (\text{Equation 2-19}) \\ &= \frac{0.7 \times 0.125 \text{ mg} / 497 \text{ L}}{0.2} \\ &= 0.88 \text{ ng/mL} (\sim 0.9 \text{ ng/mL}) \end{aligned}$$

$$\begin{aligned} C_{ss,min} &= C_{ss,max} \cdot e^{-kT} \quad (\text{Equation 2-20}) \\ &= (0.88 \text{ ng/mL})(0.8) = 0.7 \text{ ng/mL} \end{aligned}$$

Thus, the plasma concentrations would fluctuate minimally about the steady-state concentration of 0.79 ng/mL, well within the recommended therapeutic range of 0.5–1.0 ng/mL.

four half-times (4–8 h) to achieve a therapeutic concentration of lidocaine by infusion of the drug at the rate required to attain this concentration. Hence, use of a loading dose of lidocaine in the coronary care unit is standard.

The use of a loading dose also has significant disadvantages. First, the particularly sensitive individual may be exposed abruptly to a toxic concentration of a drug that may take a long time to decrease (i.e., long $t_{1/2}$). Loading doses tend to be large, and they are often given parenterally and rapidly; this can be particularly dangerous if toxic effects occur as a result of actions of the drug at sites that are in rapid equilibrium with plasma. This occurs because the loading dose calculated on the basis of V_{ss} subsequent to drug distribution is at first constrained within the initial and smaller “central” volume of distribution. It is therefore usually advisable to divide the loading dose into a number of smaller fractional doses that are administered over a period of time (Box 2-6). Alternatively, the loading dose should be administered as a continuous intravenous infusion over a period of time using computerized infusion pumps.

BOX 2-6 ■ A Loading Dose of Digoxin

In the 84-kg patient described previously, accumulation of digoxin to an effective steady-state level was gradual when a daily maintenance dose of 0.125 mg was administered (for at least 12.4 days, based on $t_{1/2} = 3.1$ days). A more rapid response could be obtained (if deemed necessary) by using a loading dose strategy and Equation 2-21. Choosing a target C_p of 0.9 ng/mL (the $C_{ss, max}$ calculated in Box 2-5 and below the recommended maximum of 1.0 ng/mL):

$$\text{Loading dose} = 0.9 \text{ ng} \cdot \text{mL}^{-1} \times 497 \text{ L} / 0.7 = 639 \mu\text{g}$$

Using standard dosage sizes, one would use a loading dose of 0.625 mg given in divided doses. To avoid toxicity, this oral loading dose would be given as an initial 0.25-mg dose followed by a 0.25-mg dose 6–8 h later, with careful monitoring of the patient, and the final 0.125-mg dose given another 6–8 h later.

Therapeutic Drug Monitoring

The major use of measured concentrations of drugs (at steady state) is to refine the estimate of CL/F for the patient being treated, using Equation 2-15 as rearranged:

$$CL/F_{\text{patient}} = \text{Dosing rate} / C_{ss}(\text{measured}) \quad (\text{Equation 2-22})$$

The new estimate of CL/F can be used in Equation 2-17 to adjust the maintenance dose to achieve the desired target concentration (Box 2-7).

Practical details associated with therapeutic drug monitoring should be kept in mind. The first of these relates to the time of sampling for measurement of the drug concentration.

The purpose of sampling during supposed steady state is to modify the estimate of CL/F and thus the choice of dosage. Early postabsorptive concentrations do not reflect clearance; they are determined primarily by the rate of absorption, the “central” (rather than the steady-state) volume of distribution, and the rate of distribution, all of which are pharmacokinetic features of virtually no relevance in choosing the long-term maintenance dosage. When the goal of measurement is adjustment of dosage, the sample should be taken just before the next planned dose, when the concentration is at its minimum.

If it is unclear whether efficacious concentrations of drug are being achieved, a sample taken shortly after a dose may be helpful. On the other

BOX 2-7 ■ Adjusting the Dose at Steady State

If a drug follows first-order kinetics, the average, minimum, and maximum concentrations at steady state are linearly related to dose and dosing rate (see Equations 2-15, 2-18, and 2-19). Therefore, the ratio between the measured and desired concentrations can be used to adjust the dose, consistent with available dosage sizes:

$$\frac{C_{ss}(\text{measured})}{C_{ss}(\text{predicted})} = \frac{\text{Dose (previous)}}{\text{Dose (new)}} \quad (\text{Equation 2-23})$$

Consider the previously described patient given 0.125 mg digoxin every 24 h, for example. If the measured minimum (trough) steady-state concentration were found to be 0.35 ng/mL rather than the predicted level of 0.7 ng/mL, an appropriate, practical change in the dosage regimen would be to increase the daily dose by 0.125 mg to 0.25 mg digoxin daily.

hand, if a concern is whether low clearance (as in renal failure) may cause accumulation of drug, concentrations measured just before the next dose will reveal such accumulation and are considerably more useful for this purpose than is knowledge of the maximal concentration.

Determination of both maximal and minimal concentrations is recommended. These two values can offer a more complete picture of the behavior of the drug in a specific patient (particularly if obtained over more than one dosing period) and can better support pharmacokinetic modeling to adjust treatment.

When constant dosage is given, steady state is reached after four to five elimination half-times. If a sample is obtained too soon after dosage is begun, it will not reflect this state and the drug's clearance accurately. Yet, for toxic drugs, if sampling is delayed until steady state, the damage may have been done. In such cases, the first sample should be taken after two $t_{1/2}$ assuming that no loading dose has been given. If the concentration already exceeds 90% of the eventual expected mean steady-state concentration, the dosage rate should be halved, another sample obtained in another two (supposed) $t_{1/2}$, and the dosage halved again if this sample exceeds the target. If the first concentration is not too high, the initial rate of dosage is continued; even if the concentration is lower than expected, it is usually reasonable to await the attainment of steady state in another two estimated $t_{1/2}$ and then to proceed to adjust dosage as described in Box 2-7.

SIGNALING PATHWAYS AND DRUG ACTION

Pharmacodynamic Concepts

Pharmacodynamics is the study of the biochemical, cellular, and physiological effects of drugs and their mechanisms of action. The effects of most drugs result from their interaction with macromolecular components of the organism. The term *drug receptor* or *drug target* denotes the cellular macromolecule or macromolecular complex with which the drug interacts to elicit a cellular or systemic response. Drugs commonly alter the rate or magnitude of an intrinsic cellular or physiological response rather than create new responses. Drug receptors are often located on the surface of cells but may also be located in specific intracellular compartments, such as the nucleus, or in the extracellular compartment, as in the case of drugs that target coagulation factors and inflammatory mediators. Many drugs also interact with *acceptors* (e.g., serum albumin), which are entities that do not directly cause any change in biochemical or physiological response but can alter the pharmacokinetics of a drug's actions.

A large percentage of the new drugs approved in recent years are *therapeutic biologics*, including genetically engineered enzymes and monoclonal antibodies. Going far beyond the traditional concept of a drug are genetically modified viruses and microbes. One recently approved agent for treating melanoma is a genetically modified live oncolytic herpes virus that is injected into tumors that cannot be removed completely by surgery. *Gene therapy products* using viruses as vectors to replace genetic mutations that give rise to lethal and debilitating diseases have already been approved in China and Europe. The next generation of gene therapy products will be those capable of targeted genome editing using antisense oligonucleotides and RNAi and by delivering the CRISPR/Cas9 genome-editing system using viruses or genetically modified microorganisms. These new agents will have pharmacological properties that are distinctly different from traditional small-molecule drugs.

Physiological Receptors

Many drug receptors are proteins that normally serve as receptors for endogenous regulatory ligands. These drug targets are termed *physiological receptors*. Drugs that bind to physiological receptors and mimic the regulatory effects of the endogenous signaling compounds are termed *agonists*. If the drug binds to the same *recognition site* as the endogenous agonist, the drug is said to be a *primary agonist*. *Allosteric* (or *allotopic*) *agonists* bind to a different region on the receptor, referred to as an allosteric or allotopic site. Drugs that block or reduce the action of an agonist are termed *antagonists*. Antagonism generally results from competition with

an agonist for the same or overlapping site on the receptor (a *syntopic interaction*), but can also occur by interacting with other sites on the receptor (*allosteric antagonism*), by combining with the agonist (*chemical antagonism*), or by *functional antagonism* by indirectly inhibiting the cellular or physiological effects of the agonist. Agents that are only partially as effective as agonists are termed *partial agonists*. Many receptors exhibit some constitutive activity in the absence of a regulatory ligand; drugs that stabilize such receptors in an inactive conformation are termed *inverse agonists* (Figure 3–1) (Kenakin, 2004; Milligan, 2003). In the presence of a full agonist, partial and inverse agonists will behave as competitive antagonists.

Specificity of Drug Responses

The strength of the reversible interaction between a drug and its receptor, as measured by the **dissociation constant**, is defined as the *affinity* of one for the other. (By tradition, only rarely will the inverse of the dissociation constant, the association constant, be used, even though both carry the same information.) Both the *affinity* of a drug for its receptor and its *intrinsic activity* are determined by its *chemical structure*. The chemical structure of a drug also contributes to the drug's *specificity*. A drug that interacts with a single type of receptor that is expressed on only a limited number of differentiated cells will exhibit high specificity. Conversely, a drug acting on a receptor expressed ubiquitously throughout the body will exhibit widespread effects.

Many clinically important drugs exhibit a broad (low) specificity because they interact with multiple receptors in different tissues. Such broad specificity might not only enhance the clinical utility of a drug but also contribute to a spectrum of adverse side effects because of off-target interactions. One example of a drug that interacts with multiple receptors is *amiodarone*, an agent used to treat cardiac arrhythmias. Amiodarone also has a number of serious toxicities, some of which are caused by the drug's structural similarity to thyroid hormone and, as a result, its capacity to interact with nuclear thyroid receptors. Amiodarone's salutary effects and toxicities may also be mediated through interactions with receptors that are poorly characterized or unknown.

Some drugs are administered as racemic mixtures of stereoisomers. The stereoisomers can exhibit different pharmacodynamic as well as pharmacokinetic properties. For example, the antiarrhythmic drug *sotalol* is prescribed as a racemic mixture; the D- and L-enantiomers are equipotent as K⁺ channel blockers, but the L-enantiomer is a much more potent β adrenergic antagonist (see Chapter 30). A drug may have

Abbreviations

AAV: adeno-associated virus
AC: adenylyl cyclase
ACE: angiotensin-converting enzyme
ACh: acetylcholine
AChE: acetylcholinesterase
AKAP: A-kinase anchoring protein
AMPA: α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
AngII: angiotensin II
ANP: atrial natriuretic peptide
Apaf-1: apoptotic activating protease factor 1
ASO: antisense oligonucleotide
ATG: autophagy gene
AT₁R: AT₁ receptor
BNP: brain natriuretic peptide
cAMP: cyclic adenosine monophosphate
cAMP-GEF: cAMP-guanine exchange factor
cGMP: cyclic guanosine monophosphate
CNG: cyclic nucleotide-gated channel
CNP: C-type natriuretic peptide
CREB: cAMP response element-binding protein
CRISPR/Cas9: clustered regularly interspersed short palindromic repeats/CRISPR-associated protein 9
DA: dopamine
DAG: diacylglycerol
DMD: Duchenne muscular dystrophy
DRAM: damage-regulated autophagy modulator
4EBP: eukaryotic initiation factor 4e (eif-4E)-binding protein
EC₅₀: half-maximally effective concentration
EGF: epidermal growth factor
eNOS: endothelial NOS (NOS3)
EPAC: exchange protein activated by cAMP
FADD: Fas-associated death domain
FGF: fibroblast growth factor
FKBP12: immunophilin target (binding protein) for tacrolimus (FK506)
FXR: farnesoid X receptor
GABA: γ -aminobutyric acid
GAP: GTPase-activating protein
GC: guanylyl cyclase
GEF: guanine nucleotide exchange factor
GI: gastrointestinal
GPCR: G protein-coupled receptor
GRK: GPCR kinase
HCN: hyperpolarization-activated, cyclic nucleotide-gated channel
HRE: hormone response element
5HT: serotonin
IGF1R: insulinlike growth factor 1 receptor
IKK: I κ B kinase
iNOS: inducible NOS (NOS2)
IP₃: inositol 1,4,5-trisphosphate
IRAK: interleukin-1 receptor-associated kinase
Jak: Janus kinase
JNK: c-Jun N-terminal kinase
K_{ATP}: ATP-dependent K⁺ channel

K_i: affinity of a competitive antagonist
LBD: ligand-binding domain
LDLR: low-density lipoprotein receptor
LXR: liver X receptor
MAO: monoamine oxidase
MAPK: mitogen-activated protein kinase
MHC: major histocompatibility complex
MLCK: myosin light chain kinase
mTOR: mammalian target of rapamycin
MyD88: myeloid differentiation protein 88
NE: norepinephrine
NF- κ B: nuclear factor kappa B
NGF: nerve growth factor
NGG: 5'-(any Nucleotide)-Guanosine-Guanosine-3'
NMDA: N-methyl-D-aspartate
nmDMD: nonsense mutation Duchenne muscular dystrophy
nNOS: neuronal NOS (NOS1)
NO: nitric oxide
NOS: NO synthase
NPR-A: ANP receptor
NPR-B: natriuretic peptide B receptor
NPR-C: natriuretic peptide C receptor
NSAID: nonsteroidal anti-inflammatory drug
PDE: cyclic nucleotide phosphodiesterase
PAM: protospacer-adjacent motif
PDGF: platelet-derived growth factor
PDGF-R: PDGR receptor
PI3K: phosphatidylinositol 3-kinase
PIP₃: phosphatidylinositol 3,4,5-trisphosphate
PK_α: protein kinase α (e.g., PKA)
PKB: protein kinase B (also known as Akt)
PLC: phospholipase C
PPAR: peroxisome proliferator-activated receptor
RGS: regulator of G protein signaling
RIP1: receptor interacting protein 1
RISC: RNA-induced silencing complex
RNAi: RNA interference
RXR: retinoic acid receptor
SERCA: SR Ca²⁺-ATPase
sGC: soluble guanylyl cyclase
sgRNA: single "guide" RNA
siRNA: small interfering RNA
S6K: S6 kinase
SMAC: second mitochondria-derived activator of caspase
SMC: smooth muscle cell
SR: sarcoplasmic reticulum
STAT: signal transducer and activator of transcription
TAK1: transforming growth factor β -activated kinase 1
TCR: T cell receptor
TGF- β : transforming growth factor β
TLR: Toll-like receptor
TNF- α : tumor necrosis factor α
TRADD: TNF receptor-associated death domain
TRAF: TNF receptor-associated factor
TRAIL: TNF-related apoptosis-inducing ligand
TRP: transient receptor potential
VEGF: vascular endothelial growth factor

Figure 3-1 Regulation of the activity of a receptor with conformation-selective drugs. In this model, receptor R can exist in active (R_a) and inactive (R_i) conformations, and drugs binding to one, the other, or both states of R can influence the balance of the two forms of R and the net effect of receptor-controlled events. The ordinate is the activity of the receptor produced by R_a , the active receptor conformation (e.g., stimulation of AC by an activated β adrenergic receptor). If a drug L selectively binds to R_a , it will produce a maximal response. If L has equal affinity for R_i and R_a , it will not perturb the equilibrium between them and will have no effect on net activity; L would appear as a competitive antagonist if it blocks an agonist binding site (see Figure 3-4). If the drug selectively binds to R_i , then the net influence and amount of R_a will be diminished. If L can bind to receptor in an active conformation R_a but also bind to inactive receptor R_i with lower affinity, the drug will produce a partial response; L will be a partial agonist. If there is sufficient R_a to produce an elevated basal response in the absence of ligand (agonist-independent constitutive activity), and L binds to R_i , then that basal activity will be inhibited; L will then be an inverse agonist. Inverse agonists selectively bind to the inactive form of the receptor and shift the conformational equilibrium toward the inactive state. In systems that are not constitutively active, inverse agonists will behave like competitive antagonists, which helps explain that the properties of inverse agonists and the number of such agents previously described as competitive antagonists were only recently appreciated. Receptors that have constitutive activity and are sensitive to inverse agonists include benzodiazepine, histamine, opioid, cannabinoid, dopamine, bradykinin, and adenosine receptors.

multiple mechanisms of action that depend on receptor specificity, the tissue-specific expression of the receptor(s), drug access to target tissues, different drug concentrations in different tissues, pharmacogenetics, and interactions with other drugs.

Chronic administration of a drug may cause a *downregulation* of receptors or *desensitization* of response that can require dose adjustments to maintain adequate therapy. Chronic administration of nitrovasodilators to treat angina results in the rapid development of *complete tolerance*, a process known as *tachyphylaxis*. *Drug resistance* may also develop because of pharmacokinetic mechanisms (i.e., the drug is metabolized more rapidly with chronic exposure), the development of mechanisms that prevent the drug from reaching its receptor (i.e., increased expression of the multidrug resistance transporter in drug-resistant cancer cells; see Chapter 5), or the clonal expansion of cancer cells containing drug-resistant mutations in the drug receptor.

Some drug effects do not occur by means of macromolecular receptors. For instance, aluminum and magnesium hydroxides [$Al(OH)_3$ and $Mg(OH)_2$] reduce gastric acid chemically, neutralizing H^+ with OH^- and raising gastric pH. Mannitol acts osmotically to cause changes in the distribution of water to promote diuresis, catharsis, expansion of circulating volume in the vascular compartment, or reduction of cerebral edema (see Chapter 25). Anti-infective drugs such as antibiotics, antivirals, and antiparasitics achieve specificity by targeting receptors or cell processes that are critical for the growth or survival of the infective agent but are nonessential or lacking in the host organism. Resistance to antibiotics, antivirals, and other drugs can occur through a variety of mechanisms, including mutation of the target receptor, increased expression of enzymes that degrade or increase efflux of the drug from the infective agent, and development of alternative biochemical pathways that circumvent the drug's effects on the infective agent.

Structure-Activity Relationships and Drug Design

The receptors responsible for the clinical effects of many drugs have yet to be identified. Conversely, sequencing of the entire human genome has identified novel genes related by sequence to known receptors, for which endogenous and exogenous ligands are unknown; these are called *orphan receptors*.

Both the affinity of a drug for its receptor and its intrinsic activity are determined by its chemical structure. This relationship frequently is stringent.

Relatively minor modifications in the drug molecule may result in major changes in its pharmacological properties based on altered affinity for one or more receptors. Exploitation of structure-activity relationships has frequently led to the synthesis of valuable therapeutic agents. Because changes in molecular configuration need not alter all actions and effects of a drug equally, it is sometimes possible to develop a congener with a more favorable ratio of therapeutic to adverse effects, enhanced selectivity amongst different cells or tissues, or more acceptable secondary characteristics than those of the parent drug. Therapeutically useful antagonists of hormones or neurotransmitters have been developed by chemical modification of the structure of the physiological agonist.

With information about the molecular structures and pharmacological activities of a relatively large group of congeners, it is possible to use computer analysis to identify the chemical properties (i.e., the *pharmacophore*) required for optimal action at the receptor: size, shape, position, and orientation of charged groups or hydrogen bond donors, and so on. Advances in molecular modeling of organic compounds and the methods for drug target (receptor) discovery and biochemical measurement of the primary actions of drugs at their receptors have enriched the quantitation of structure-activity relationships and its use in drug design (Carlson and McCammon, 2000). Such information increasingly is allowing the optimization or design of chemicals that can bind to a receptor with improved affinity, selectivity, or regulatory effect. Similar structure-based approaches also are used to improve pharmacokinetic properties of drugs, particularly if knowledge of their metabolism is known. Knowledge of the structures of receptors and of drug-receptor complexes, determined at atomic resolution by X-ray crystallography, is even more helpful in the design of ligands and in understanding the molecular basis of drug resistance and circumventing it. Emerging technology in the field of pharmacogenetics (see Chapter 7) is improving our understanding of the nature of and variation in receptors and their impact on pharmacotherapy (Jain, 2004).

Quantitative Aspects of Drug Interactions With Receptors

Receptor occupancy theory assumes that a drug's response emanates from a receptor occupied by the drug, a concept that has its basis in the law of mass action. The *dose-response curve* depicts the observed effect of a drug

Figure 3-2 Graded responses. On the y axis, the response is expressed as a percentage of maximal response plotted as a function of the concentration of drug A present at the receptor (x axis). The hyperbolic shape of the curve in panel A becomes sigmoid when plotted semilogarithmically, as in panel B. The concentration of drug that produces 50% of the maximal response quantifies drug activity and is referred to as the EC_{50} (effective concentration of agonist for 50% response). The range of concentrations needed to fully depict the dose-response relationship ($\sim 3 \log_{10}$ [10] units) is too wide to be useful in the linear format of Figure 3-2A; thus, most dose-response curves use $\log [\text{Drug}]$ on the x axis, as in Figure 3-2B. Dose-response curves presented in this way are sigmoidal in shape and have three noteworthy properties: threshold, slope, and maximal asymptote. These three parameters quantitate the activity of the drug.

as a function of its concentration in the receptor compartment. Figure 3-2 shows a typical dose-response curve, usually plotted as in Figure 3-2B.

Some drugs cause low-dose stimulation and high-dose inhibition. Such U-shaped relationships are said to display *hormesis*. Several drug-receptor systems can display this property (e.g., prostaglandins, endothelin, and purinergic and serotonergic agonists), which may be at the root of some drug toxicities (Calabrese and Baldwin, 2003).

Affinity, Efficacy, and Potency

In general, the drug-receptor interaction is characterized by (1) binding of drug to receptor and (2) generation of a response in a biological system, as illustrated in Equation 3-1, where the drug or ligand is denoted as L and the inactive receptor as R . The first reaction, the reversible formation of the ligand-receptor complex LR , is governed by the chemical property of *affinity*.

LR^* is produced in proportion to $[LR]$ and leads to a *response*. This simple relationship illustrates the reliance of the affinity of the ligand (L) with receptor (R) on both the forward or *association rate* k_{+1} and the reverse or *dissociation rate* k_{-1} . At any given time, the concentration of ligand-receptor complex $[LR]$ is equal to the product of $k_{+1}[L][R]$, the rate of formation of the bimolecular complex LR , minus the product $k_{-1}[LR]$, the rate of dissociation of LR into L and R . At equilibrium (i.e., when $\delta[LR]/\delta t = 0$), $k_{+1}[L][R] = k_{-1}[LR]$. The *equilibrium dissociation constant* K_D is then described by ratio of the off and on rate constants, k_{-1}/k_{+1} .

Thus, at equilibrium,

$$K_D = \frac{[L][R]}{[LR]} = \frac{k_{-1}}{k_{+1}} \quad (\text{Equation 3-2})$$

The *affinity constant* or *equilibrium association constant* K_A is the reciprocal of the equilibrium dissociation constant (i.e., $K_A = 1/K_D$); thus, a *high-affinity drug* has a low K_D and will bind a greater number of a particular receptor at a low concentration than a low-affinity drug. As a practical matter, the affinity of a drug is influenced most often by changes in its off rate (k_{-1}) rather than its on rate (k_{+1}).

Equation 3-2 permits us to describe the *fractional occupancy* f of receptors by agonist L as a function of $[R]$ and $[LR]$:

$$f = \frac{[\text{ligand-receptor complexes}]}{[\text{total receptors}]} = \frac{[LR]}{[R] + [LR]} \quad (\text{Equation 3-3})$$

f can also be expressed in terms of K_A (or K_D) and $[L]$:

$$f = \frac{K_A[L]}{1 + K_A[L]} = \frac{[L]}{1/K_A + [L]} = \frac{[L]}{K_D + [L]} \quad (\text{Equation 3-4})$$

From Equation 3-4, it follows that when the concentration of drug equals the K_D (or $1/K_A$), $f = 0.5$, that is, the drug will occupy 50% of the receptors. When $[L] = K_D$:

$$f = \frac{K_D}{K_D + K_D} = \frac{1}{2} \quad (\text{Equation 3-4A})$$

Equation 3-4 describes only receptor occupancy, not the eventual response that may be amplified by the cell. Because of downstream amplification, many signaling systems can reach a full biological response with only a fraction of receptors occupied.

Potency is defined by example in Figure 3-3. Basically, when two drugs produce equivalent responses, the drug whose dose-response curve (plotted as in Figure 3-3A) lies to the left of the other (i.e., the concentration producing a half-maximal effect [EC_{50}] is smaller) is said to be the more potent.

Efficacy reflects the capacity of a drug to activate a receptor and generate a cellular response. Thus, a drug with high efficacy may be a full agonist, eliciting, at some concentration, a full response. A drug with a lower efficacy at the same receptor may not elicit a full response at any dose (see Figure 3-1). A drug with a low intrinsic efficacy will be a partial agonist. A drug that binds to a receptor and exhibits zero efficacy is an antagonist.

Quantifying Agonism

When the relative potency of two agonists of equal efficacy is measured in the same biological system and downstream signaling events are the same for both drugs, the comparison yields a relative measure of the affinity and efficacy of the two agonists (see Figure 3-3). We often describe agonist response by determining the *half-maximally effective concentration* (EC_{50}) for producing a given effect. We can also compare maximal

Figure 3-3 Two ways of quantifying agonism. A. The relative potency of two agonists (drug X, —; drug Y, —) obtained in the same tissue is a function of their relative affinities and intrinsic efficacies. The EC_{50} of drug X occurs at a concentration that is one-tenth the EC_{50} of drug Y. Thus, drug X is more potent than drug Y. B. In systems where the two drugs do not both produce the maximal response characteristic of the tissue, the observed maximal response is a nonlinear function of their relative intrinsic efficacies. Drug X is more efficacious than drug Y; their asymptotic fractional responses are 100% for drug X and 50% for drug Y.

asymptotes in systems where the agonists do not produce maximal response (Figure 3–3B). The advantage of using maxima is that this property depends solely on efficacy, whereas drug *potency* is a mixed function of both affinity and efficacy.

Quantifying Antagonism

Characteristic patterns of antagonism are associated with certain mechanisms of receptor blockade. One is straightforward *competitive antagonism*, whereby a drug with affinity for a receptor but lacking intrinsic efficacy (i.e., an antagonist) competes with the agonist for the primary binding site on the receptor (Ariens, 1954; Gaddum, 1957). *The characteristic pattern of such antagonism is the concentration-dependent production*

of a parallel shift to the right of the agonist dose-response curve with no change in the maximal response (Figure 3–4A). The magnitude of the rightward shift of the curve depends on the concentration of the antagonist and its affinity for the receptor (Schild, 1957). *A competitive antagonist will reduce the response to zero.*

A *partial agonist* similarly can compete with a “full” agonist for binding to the receptor. However, increasing concentrations of a partial agonist will inhibit response to a finite level characteristic of the intrinsic efficacy of the partial agonist. Partial agonists may be used therapeutically to buffer a response by inhibiting excessive receptor stimulation without totally abolishing receptor stimulation. For example, varenicline is a nicotinic receptor partial agonist used in smoking cessation therapy. Its utility

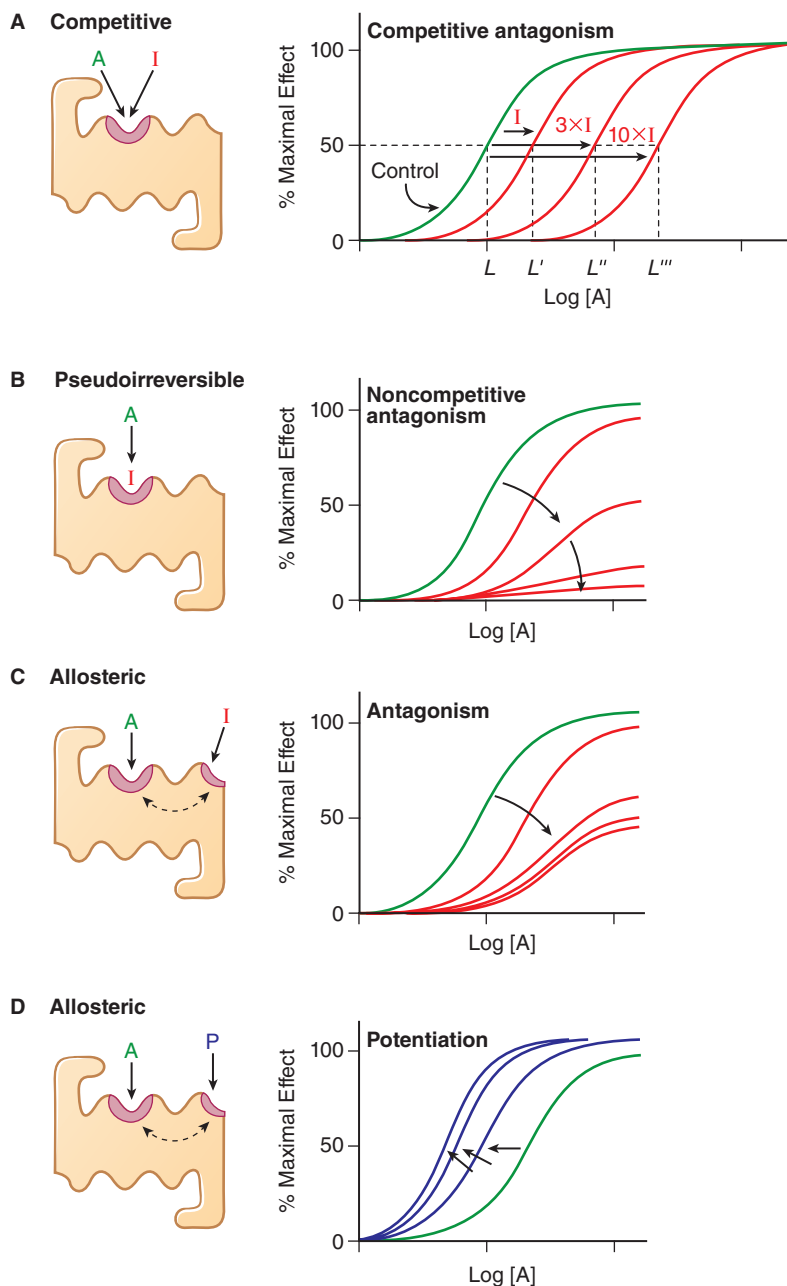

Figure 3–4 Mechanisms of receptor antagonism. In each set of curves, the green curve represents the effect of orthosteric agonist, unmodulated by any antagonist or potentiator. **A.** Competitive antagonism occurs when the agonist **A** and antagonist **I** compete for the same binding site on the receptor. Response curves for the agonist are shifted to the right in a concentration-related manner by the antagonist such that the EC_{50} for the agonist increases (e.g., L versus L' , L'' , and L''') with the concentration of the antagonist. **B.** If the antagonist binds to the same site as the agonist but does so irreversibly or pseudoirreversibly (slow dissociation but no covalent bond), it causes a shift of the dose-response curve to the right, with progressive depression of the maximal response as $[I]$ increases. Allosteric effects occur when an allosteric ligand **I** or **P** binds to a different site on the receptor to either inhibit (**I**) the response (panel C. Increasing concentrations of **I** shift the curves progressively to right and downward.) or potentiate (**P**) the response (panel D. Increasing concentrations of **P** shift the curves progressively to left.). This allosteric effect is saturable; inhibition or potentiation reaches a limiting value when the allosteric site is fully occupied.

derives from the fact that it activates brain nicotinic receptors sufficiently to prevent craving, but blocks the effects of high-dose nicotine delivered by smoking a cigarette.

An antagonist may dissociate so slowly from the receptor that its action is exceedingly prolonged. In the presence of a slowly dissociating antagonist, the maximal response to the agonist will be depressed at some antagonist concentrations (Figure 3-4B). Operationally, this is referred to as *noncompetitive antagonism*, although the molecular mechanism of action cannot be inferred unequivocally from the effect on the dose-response curve. An *irreversible antagonist* competing for the same binding site as the agonist can produce the same pattern of antagonism shown in Figure 3-4B. Noncompetitive antagonism can be produced by an *allosteric* or *allotopic antagonist*, which binds to a site on the receptor distinct from that of the primary agonist, thereby changing the affinity of the receptor for the agonist. *In the case of an allosteric antagonist, the affinity of the receptor for the agonist is decreased by the antagonist* (Figure 3-4C). In contrast, a drug binding at an allosteric site could potentiate the effects of primary agonists (Figure 3-4D); such a drug would be referred to as an *allosteric agonist* or *coagonist* (May et al., 2007).

The affinity of a competitive antagonist (K_i) for its receptor can be determined in radioligand binding assays or by measuring the functional response of a system to a drug in the presence of the antagonist (Cheng, 2004; Cheng and Prusoff, 1973; Limbird, 2005). Measuring a functional response, concentration curves are run with the agonist alone and with the agonist plus an effective concentration of the antagonist (see Figure 3-4A). As more antagonist (I) is added, a higher concentration of the agonist is needed to produce an equivalent response (the half-maximal, or 50%, response is a convenient and accurately determined level of response). *The extent of the rightward shift of the concentration-dependence curve is a measure of the affinity of the inhibitor, and a high-affinity inhibitor will cause a greater rightward shift than a low-affinity inhibitor at the same inhibitor concentration.*

Using Equations 3-3 and 3-4, one may write mathematical expressions of fractional occupancy f of the receptor R by an agonist ligand (L) for the agonist alone [f_{control}] and agonist in the presence of inhibitor [f_{+1}].

For the agonist drug alone, the fractional occupancy is given by Equations 3-3 and 3-4:

$$f_{\text{control}} = \frac{[L]}{[L] + K_D} \quad (\text{Equation 3-5})$$

For the case of agonist plus antagonist, the problem involves two equilibria:

Fractional occupancy by the agonist L in the presence of I is:

$$f_{+1} = \frac{[RL]}{[RL] + [RI] + [R]} \quad (\text{Equation 3-7})$$

Equal fractional occupancies can occur in the absence and presence of a competitive inhibitor, but at different concentrations of agonist. The concentration of agonist needed to achieve a designated fractional occupancy in the presence of antagonist ($[L']$) will be greater than the concentration of agonist needed in the inhibitor's absence ($[L]$). Using the expressions for dissociation constants for the agonist and antagonist ligands (Equations 3-2 and 3-6) and applying a little algebraic tinkering to the righthand side of Equation 3-7, the fractional occupancy in the presence of the competitive inhibitor [f_{+1}] can be expressed in terms of L' , K_D , K_i , and I:

$$f_{+1} = \frac{[L']}{[L'] + K_D \left(1 + \frac{[I]}{K_i} \right)} \quad (\text{Equation 3-8})$$

Assuming that equal responses result from equal fractional receptor occupancies in both the absence and presence of antagonist, one can

set the fractional occupancies equal at experimentally determined agonist concentrations ($[L]$ and $[L']$) that generate equivalent responses, as depicted in Figure 3-4A. Thus,

$$f_{\text{control}} = f_{+1} \quad (\text{Equation 3-9})$$

$$\frac{[L]}{[L] + K_D} = \frac{[L']}{[L'] + K_D \left(1 + \frac{[I]}{K_i} \right)} \quad (\text{Equation 3-10})$$

Simplifying, one obtains

$$\frac{[L']}{[L]} - 1 = \frac{[I]}{K_i} \quad (\text{Equation 3-11})$$

where all values are known except K_i . Thus, one can determine the K_i for a reversible, competitive antagonist without knowing the K_D for the agonist and without needing to define the precise relationship between receptor and response.

Additivity and Synergism: Isobolograms

Drugs with different mechanisms of action are often used in combination to achieve *additive* and *positive synergistic* effects (Figure 3-5). Such positive interactions of two agents may permit use of reduced concentrations of each drug, thereby reducing concentration-dependent adverse effects. *Positive synergism* refers to the *superadditive* effects of drugs used in combination. Drugs used in combination can also demonstrate *negative synergism* or *subadditive effects*, where the efficacy of the drug combination is less than would be expected if the effects were additive. Figure 3-5 is a plot known as an *isobologram*, which shows that a line connecting the EC_{50} values of two drugs, A and B, describes the relative concentrations of each drug that will achieve a half-maximal response *when A and B are used in combination, if the effects of A and B are additive*. Similar lines drawn parallel to the 50% additive line can be used to determine the relative concentrations of A and B required to achieve other responses (e.g., 10%, 20%, 80%, 90%, etc.). If A and B are superadditive (positive synergism), the relative concentrations of A and B needed to achieve a given response will fall below the additive response line. Conversely, if A and B are subadditive (negative synergism), their relative concentrations will lie above the additive response line. The basis for the use of isobolograms in characterizing the effects of drug combinations has been developed and reviewed by Tallarida (2006, 2012).

Pharmacodynamic Variability: Individual and Population Pharmacodynamics

Individuals vary in the magnitude of their response to the same concentration of a single drug, and a given individual may not always respond in the same way to the same drug concentration. Drug responsiveness may change because of disease, age, or previous drug administration. Receptors are dynamic, and their concentrations and functions may be up- or downregulated by endogenous and exogenous factors.

Data on the correlation of drug levels with efficacy and toxicity must be interpreted in the context of the pharmacodynamic variability in the population (e.g., genetics, age, disease, and the presence of coadministered drugs). The variability in pharmacodynamic response in the population may be analyzed by constructing a *quantal concentration-effect curve* (Figure 3-6A). The dose of a drug required to produce a specified effect in 50% of the population is the *median effective dose* (ED_{50} ; see Figure 3-6A). In preclinical studies of drugs, the *median lethal dose* (LD_{50}) is determined in experimental animals (Figure 3-6B). The LD_{50}/ED_{50} ratio is an indication of the *therapeutic index*, a term that reflects how selective the drug is in producing its desired effects versus its adverse effects. A similar term, the *therapeutic window*, is the range of steady-state concentrations of drug that provides therapeutic efficacy with minimal toxicity (Figures 2-9 and 3-7). In clinical studies, the dose, or preferably the concentration, of a drug required to produce toxic effects can be compared with

Figure 3-5 Isobologram showing additivity and synergism of a drug combination. The isobologram shows the line of additivity for a 50% effect obtained with a combination of two drugs (concentrations of drug A are on the x axis, concentrations of drug B are on the y axis) that have similar effects but different mechanisms of action. The intercept of the line of additivity (50% effect) with the x axis is the EC_{50} for A, while the intercept on the y axis is the EC_{50} for B. If the combination of A and B exhibits positive synergism (superadditivity), then the 50% effect with a combination of the two drugs will fall somewhere below the line of additivity, whereas negative synergism (subadditivity) will fall above the line of additivity. Lines of additivity for different percentage effects (e.g., 90% effect) are parallel to the 50% line of additivity. The isobologram can be used to estimate the concentrations of two drugs needed to obtain a given effect when used in combination. For a full explanation of the concept and utility of isoboles, consult Tallarida (2006, 2012).

Figure 3-6 Frequency distribution curves and quantal concentration-effect and dose-effect curves. **A.** Frequency distribution curves. An experiment was performed on 100 subjects, and the effective plasma concentration that produced a quantal response was determined for each individual. The number of subjects who required each dose was plotted, giving a log-normal frequency distribution (purple bars). The normal frequency distribution, when summated, yields the cumulative frequency distribution—a sigmoidal curve that is a quantal concentration-effect curve (red bars, red line). **B.** Quantal dose-effect curves. Animals were injected with varying doses of a drug, and the responses were determined and plotted. The therapeutic index, the ratio of the LD_{50} to the ED_{50} , is an indication of how selective a drug is in producing its desired effects relative to its toxicity. See text for additional explanation.

Figure 3-7 Relation of the therapeutic window of drug concentrations to therapeutic and adverse effects in the population. The ordinate is linear; the abscissa is logarithmic.

the concentration required for therapeutic effects in the population to evaluate the *clinical therapeutic index*. The concentration or dose of drug required to produce a therapeutic effect in most of the population usually will overlap the concentration required to produce toxicity in some of the population, even though the drug's therapeutic index in an individual patient may be large. Thus, a *population therapeutic window* expresses a range of concentrations at which the likelihood of efficacy is high and the probability of adverse effects is low (see Figure 3-7); it does not guarantee efficacy or safety. Therefore, use of the population therapeutic window to optimize the dosage of a drug should be complemented by monitoring appropriate clinical and surrogate markers for drug effect(s) in a given patient.

Factors Modifying Drug Action

Numerous factors contribute to the wide patient-to-patient variability in the dose required for optimal therapy observed with many drugs (Figure 3-8). The effects of these factors on variability of drug pharmacokinetics are described more thoroughly in Chapters 2, 5, 6, and 7.

Drug Interactions and Combination Therapy

Drugs are commonly used in combination with other drugs, sometimes to achieve an additive or synergistic effect, but more often because two or more drugs are needed to treat multiple conditions. When drugs are used

in combination, one cannot assume that their effects are the same as when each agent is administered by itself. Marked alterations in the effects of some drugs can result from coadministration with other agents, including prescription and nonprescription drugs, supplements, and nutraceuticals. Such interactions can cause toxicity or inhibit the drug effect and the therapeutic benefit. Drug interactions always should be considered when unexpected responses to drugs occur. Understanding the mechanisms of drug interactions provides a framework for preventing them.

Drug interactions may be pharmacokinetic (the delivery of a drug to its site of action is altered by a second drug) or pharmacodynamic (the response of the drug target is modified by a second drug). Examples of pharmacokinetic interactions that can enhance or diminish the delivery of drug to its site of action are provided in Chapter 2. In a patient with multiple comorbidities requiring a variety of medications, it may be difficult to identify adverse effects due to medication interactions and to determine whether these are pharmacokinetic, pharmacodynamic, or some combination of interactions.

Combination therapy constitutes optimal treatment of many conditions, including heart failure (see Chapter 29), hypertension (see Chapter 28), and cancer (see Chapters 65–68). However, some drug combinations produce pharmacodynamic interactions that result in adverse effects. For example, nitrovasodilators produce vasodilation via NO-dependent elevation of cGMP in vascular smooth muscle. The pharmacologic effects of sildenafil, tadalafil, and vardenafil result from inhibition of the PDE5 that hydrolyzes cGMP to 5'GMP in the vasculature. Thus, coadministration of an NO donor (e.g., nitroglycerin) with a PDE5 inhibitor can cause potentially catastrophic vasodilation and severe hypotension.

The oral anticoagulant warfarin has a narrow margin between therapeutic inhibition of clot formation and bleeding complications and is subject to numerous important pharmacokinetic and pharmacodynamic drug interactions. Alterations in dietary vitamin K intake may significantly affect the pharmacodynamics of warfarin and mandate altered dosing; antibiotics that alter the intestinal flora reduce the bacterial synthesis of vitamin K, thereby enhancing the effect of warfarin; concurrent administration of NSAIDs with warfarin increases the risk of GI bleeding almost 4-fold compared with warfarin alone. By inhibiting platelet aggregation, aspirin increases the incidence of bleeding in warfarin-treated patients.

Most drugs are evaluated in young and middle-aged adults, and data on their use in children and the elderly are sparse. At the extremes of age, drug pharmacokinetics and pharmacodynamics can be altered, possibly requiring avoidance of selected drugs or substantial alteration in the dose or dosing regimen to safely produce the desired clinical effect. The American Geriatrics Society publishes the Beers Criteria for Potentially Inappropriate Medication Use in Older Adults, an explicit list of drugs that should be avoided in older adults, drugs that should be avoided or be used at lower doses in patients with reduced kidney function, and specific drug-disease and drug-drug interactions that are known to be harmful in older adults (Beers Update Panel, 2015).

Mechanisms of Drug Action

Receptors That Affect Concentrations of Endogenous Ligands

A large number of drugs act by altering the synthesis, storage, release, transport, or metabolism of endogenous ligands such as neurotransmitters, hormones, and other intercellular mediators. For example, some of the drugs acting on adrenergic neurotransmission include α -methyltyrosine (inhibits synthesis of NE), cocaine (blocks NE reuptake), amphetamine (promotes NE release), and selegiline (inhibits NE breakdown by MAO) (see Chapters 8 and 12). There are similar examples for other neurotransmitter systems, including ACh (see Chapters 8 and 10), DA, and 5HT (see Chapters 13–16). Drugs that affect the synthesis and degradation of circulating mediators such as vasoactive peptides (e.g., ACE inhibitors; see Chapter 26) and lipid-derived autoids (e.g., cyclooxygenase inhibitors; see Chapter 37) are also widely used in the treatment of hypertension, inflammation, myocardial ischemia, and heart failure.

Figure 3-8 Factors influencing the response to a prescribed drug dose.

Drug Receptors Associated With Extracellular Processes

Many widely used drugs target enzymes and molecules that control extracellular processes such as thrombosis, inflammation, and immune responses. For instance, the coagulation system is highly regulated and has a number of drug targets that control the formation and degradation of clots, including several coagulation factors (thrombin and factor Xa), antithrombin, and glycoproteins on the surface of platelets that control platelet activation and aggregation (see Chapter 32).

Receptors Utilized by Anti-infective Agents

Anti-infective agents such as antibacterials, antivirals, antifungals, and antiparasitic agents target receptors that are microbial proteins. These proteins are key enzymes in biochemical pathways that are required by the infectious agent but are not critical for the host. Examples of the various mechanisms of action of antibiotics are described in Chapters 52 through 64. A novel approach to preventing infections such as that of the mosquito-borne malaria parasite is to genetically engineer the vector organism to be resistant to infection by the parasite using techniques such as the CRISPR-Cas9 system. Although this approach is just being tested outside the laboratory and must undergo numerous regulatory hurdles before being used on a wide scale, it provides proof of principle that interrupting the life cycle of a parasite in the vector could be as effective as treating the infected host (see Chapter 53).

Receptors That Regulate the Ionic Milieu

A relatively small number of drugs act by affecting the ionic milieu of blood, urine, and the GI tract. The receptors for these drugs are ion pumps and transporters, many of which are expressed only in specialized cells of the kidney and GI tract. Most of the diuretics (e.g., furosemide, chlorothiazide, amiloride) act by directly affecting ion pumps and transporters in epithelial cells of the nephron that increase the movement of Na^+ into the urine or by altering the expression of ion pumps in these cells (e.g., aldosterone). Another therapeutically important target is the H^+ , K^+ -ATPase (proton pump) of gastric parietal cells. Irreversible inhibition of this proton pump by drugs such as esomeprazole reduces gastric acid secretion by 80%–95% (see Chapter 49).

Intracellular Pathways Activated by Physiological Receptors

Signal Transduction Pathways

The largest number of drug receptors are physiological receptors expressed on the surface of cells that transduce extracellular signals to signals within cells that alter cellular processes. Physiological receptors on the surface of cells have two major functions, ligand binding and message propagation (i.e., transmembrane and intracellular signaling). These functions imply the existence of at least two functional domains within the receptor: a *LBD* and an *effector domain*.

The regulatory actions of a receptor may be exerted directly on its cellular target(s), on *effector protein(s)*, or on intermediary cellular signaling molecules called *transducers*. The receptor, its cellular target, and any intermediary molecules are referred to as a *receptor-effector system* or *signal transduction pathway*. Frequently, the proximal cellular effector protein is not the ultimate physiological target but rather is an enzyme, ion channel, or transport protein that creates, moves, or degrades a small molecule (e.g., a cyclic nucleotide, IP_3 , or NO) or ion (e.g., Ca^{2+}) termed a *second messenger*. Second messengers can diffuse in the proximity of their synthesis or release and convey information to a variety of targets that may integrate multiple signals. Even though these second messengers originally were thought of as freely diffusible molecules within the cell, biochemical and imaging studies show that their diffusion and intracellular actions are constrained by *compartmentation*—selective localization of receptor/transducer/effector/signal/signal termination complexes—established by protein-lipid and protein-protein interactions (Baillie, 2009). All cells express multiple forms of proteins designed to localize signaling pathways

by protein-protein interactions; these proteins are termed *scaffolds* or *anchoring proteins* (Carnegie et al., 2009).

Receptors and their associated effector and transducer proteins also act as integrators of information as they coordinate signals from multiple ligands with each other and with the differentiated activity of the target cell. For example, signal transduction systems regulated by changes in cAMP and intracellular Ca^{2+} are integrated in many excitable tissues. In cardiac myocytes, an increase in cellular cAMP caused by activation of β adrenergic receptors enhances cardiac contractility by augmenting the rate and amount of Ca^{2+} delivered to the contractile apparatus; thus, cAMP and Ca^{2+} are positive contractile signals in cardiac myocytes. By contrast, cAMP and Ca^{2+} produce opposing effects on the contraction of SMCs: As usual, Ca^{2+} is a contractile signal; however, activation of β receptor-cAMP-PKA pathway in these cells leads to relaxation through the phosphorylation of proteins that mediate Ca^{2+} signaling, such as MLCK and ion channels that hyperpolarize the cell membrane.

Another important property of physiological receptors is their capacity to significantly amplify a physiological signal. Neurotransmitters, hormones, and other extracellular ligands are often present at the LBD of a receptor in very low concentrations (nanomolar to micromolar levels). However, the effector domain or the signal transduction pathway often contains enzymes and enzyme cascades that catalytically amplify the intended signal. These signaling systems are excellent targets for drugs.

Structural and Functional Families of Physiological Receptors

Receptors for physiological regulatory molecules can be assigned to functional families that share common molecular structures and biochemical mechanisms. Table 3–1 outlines six major families of receptors with examples of their physiological ligands, signal transduction systems, and drugs that affect these systems.

G Protein–Coupled Receptors

The GPCRs comprise a large family of transmembrane receptors (Figure 3–9) that span the plasma membrane as a bundle of seven α helices (Palczewski et al., 2000) (Figure 3–10). Amongst the ligands for GPCRs are neurotransmitters such as ACh, biogenic amines such as NE, all eicosanoids and other lipid-signaling molecules, peptide hormones, opioids, amino acids such as GABA, and many other peptide and protein ligands. GPCRs are important regulators of nerve activity in the CNS and are the receptors for the neurotransmitters of the peripheral autonomic nervous system (GPCR Network; Stevens et al., 2013). Because of their number and physiological importance, GPCRs are the targets for many drugs.

GPCR Subtypes. There are multiple receptor subtypes within families of receptors. Ligand-binding studies initially identified receptor subtypes; molecular cloning has greatly accelerated the discovery and definition of additional receptor subtypes; their expression as recombinant proteins has facilitated the discovery of subtype-selective drugs. The distinction between classes and subtypes of receptors, however, is often arbitrary or historical. The α_1 , α_2 , and β adrenergic receptors differ from each other both in ligand selectivity and in coupling to G proteins (G_q , G_i , and G_s , respectively), yet α and β are considered receptor classes and α_1 and α_2 are considered subtypes. Pharmacological differences amongst receptor subtypes are exploited therapeutically through the development and use of receptor-selective drugs. For example, β_2 adrenergic agonists such as terbutaline are used for bronchodilation in the treatment of asthma in the hope of minimizing cardiac side effects caused by stimulation of the β_1 adrenergic receptor (see Chapter 12). Conversely, the use of β_1 -selective antagonists minimizes the likelihood of bronchoconstriction in patients being treated for hypertension or angina (see Chapters 12, 27, and 28).

Receptor Dimerization. GPCRs undergo both homo- and heterodimerization and possibly oligomerization. Dimerization of receptors may regulate the affinity and specificity of the complex for G proteins and the sensitivity of the receptor to phosphorylation by receptor kinases and the binding of arrestin, events important in termination of the action of agonists and removal of receptors from the cell surface. Dimerization also may permit binding of receptors to other regulatory proteins, such as transcription factors.

TABLE 3-1 ■ PHYSIOLOGICAL RECEPTORS

STRUCTURAL FAMILY	FUNCTIONAL FAMILY	PHYSIOLOGICAL LIGANDS	EFFECTORS AND TRANSDUCERS	EXAMPLE DRUGS
GPCR	β Adrenergic receptors	NE, EPI, DA	G_s ; AC	Dobutamine, propranolol
	Muscarinic cholinergic receptors	ACh	G_i and G_o ; AC, ion channels, PLC	Atropine
	Eicosanoid receptors	Prostaglandins, leukotrienes, thromboxanes	G_s , G_i , and G_q proteins	Misoprostol, montelukast
	Thrombin receptors (PAR)	Receptor peptide	$G_{12/13}$, GEFs	(In development)
Ion channels	Ligand gated	ACh (M_2), GABA, 5HT	Na^+ , Ca^{2+} , K^+ , Cl^-	Nicotine, gabapentin
	Voltage gated	None (activated by membrane depolarization)	Na^+ , Ca^{2+} , K^+ , other ions	Lidocaine, verapamil
Transmembrane enzymes	Receptor tyrosine kinases	Insulin, PDGF, EGF, VEGF, growth factors	SH2 domain and PTB-containing proteins	Herceptin, imatinib
	Membrane bound GC	Natriuretic peptides	cGMP	Nesiritide
	Tyrosine phosphatases	Pleiotrophin, contactins	Tyr-phosphorylated proteins	
Transmembrane, nonenzymes	Cytokine receptors	Interleukins and other cytokines	Jak/STAT, soluble tyrosine kinases	Interferons, anakinra
	Toll-like receptors	Lipopolysaccharide, bacterial products	MyD88, IRAKs, NF- κ B	(In development)
Nuclear receptors	Steroid receptors	Estrogen, testosterone	Coactivators	Estrogens, androgens, cortisol
	Thyroid hormone receptors	Thyroid hormone		Thyroid hormone
	PPAR γ	PPAR γ		Thiazolidinediones
Intracellular enzymes	Soluble GC	NO, Ca^{2+}	cGMP	Nitrovasodilators

G Proteins. GPCRs couple to a family of heterotrimeric GTP-binding regulatory proteins termed *G proteins*. G proteins are signal transducers that convey the information from the agonist-bound receptor to one or more effector proteins. G protein-regulated effectors include enzymes such as AC, PLC, cGMP PDE6, and membrane ion channels selective for Ca^{2+} and K^+ (see Table 3-1 and Figure 3-10).

The G protein heterotrimer consists of a guanine nucleotide-binding α subunit, which confers specific recognition to both receptors and effectors, and an associated dimer of β and γ subunits that helps confer membrane localization of the G protein heterotrimer by prenylation of the γ subunit. In the basal state of the receptor-heterotrimer complex, the α subunit contains bound GDP, and the α -GDP: $\beta\gamma$ complex is bound to the unliganded receptor (Gilman, 1987) (see Figure 3-9). The α subunits fall into four families (G_s , G_p , G_q , and $G_{12/13}$), which are responsible for coupling GPCRs to relatively distinct effectors. The G_s α subunit uniformly activates AC; the G_i α subunit inhibits certain isoforms of AC; the G_q α subunit activates all forms of PLC β ; and the $G_{12/13}$ α subunits couple to GEFs, such as p115RhoGEF for the small GTP-binding proteins Rho and Rac (Etienne-Manneville and Hall, 2002). The signaling specificity of the large number of possible $\beta\gamma$ combinations is not yet clear; nonetheless, it is known that K^+ channels, Ca^{2+} channels, and PI3K are some of the effectors of free $\beta\gamma$ dimer. In the instance of cAMP signaling, endocytosis of GPCRs can prolong aspects of signaling and lend “spatial coding” to distal signaling and regulation of transcription (Irannejad et al., 2015). Figure 3-10 and its legend summarize the basic activation/inactivation scheme for GPCR-linked systems.

Second-Messenger Systems. **Cyclic AMP.** cAMP is synthesized by the enzyme AC; stimulation is mediated by the G_s α subunit, inhibition by the G_i α subunit. There are nine membrane-bound isoforms of AC and one soluble isoform found in mammals (Dessauer et al., 2017; Hanoune and Defer, 2001). cAMP generated by ACs has three major

targets in most cells: the cAMP-dependent PKA; cAMP-regulated GEFs termed EPACs (Cheng et al., 2008; Roscioni et al., 2008); and, via PKA phosphorylation, a transcription factor termed CREB (Mayr and Montminy, 2001; Sands and Palmer, 2008). In cells with specialized functions, cAMP can have additional targets, such as CNG and HCN (Wahl-Schott and Biel, 2009), and cyclic nucleotide-regulated PDEs. For an overview of cyclic nucleotide action and a historical perspective, see Beavo and Brunton (2002).

- **PKA.** The PKA holoenzyme consists of two catalytic (C) subunits reversibly bound to a regulatory (R) subunit dimer to form a heterotrimeric complex (R_2C_2). When AC is activated and cAMP concentrations increase, four cAMP molecules bind to the R_2C_2 complex, two to each R subunit, causing a conformational change in the R subunits that lowers their affinity for the C subunits, resulting in their activation. The active C subunits phosphorylate serine and threonine residues on specific protein substrates. There are multiple isoforms of PKA; molecular cloning has revealed α and β isoforms of both the regulatory subunits (RI and RII), as well as three C subunit isoforms $C\alpha$, $C\beta$, and $C\gamma$. The R subunits exhibit different subcellular localization and binding affinities for cAMP, giving rise to PKA holoenzymes with different thresholds for activation (Taylor et al., 2008). PKA function also is modulated by subcellular localization mediated by AKAPs (Carnegie et al., 2009).
- **PKG.** Stimulation of receptors that raise intracellular cGMP concentrations (see Figure 3-13) leads to the activation of the cGMP-dependent PKG that phosphorylates some of the same substrates as PKA and some that are PKG-specific. Unlike the heterotrimer (R_2C_2) structure of the PKA holoenzyme, the catalytic domain and cyclic nucleotide-binding domains of PKG are expressed as a single polypeptide, which dimerizes to form the PKG holoenzyme.

Protein kinase G exists in two homologous forms, PKG-I and PKG-II. PKG-I has an acetylated N terminus, is associated with the cytoplasm,

Figure 3-9 *The human GPCR superfamily.* Human GPCRs are targeted by about 30% of marketed drugs. This dendrogram, constructed using sequence similarities within the seven-transmembrane region, identifies GPCRs by their names in the UniProt database. There are over 825 human GPCRs, which can be subdivided into the color-coded groups named by the capitalized words on the outer edge of the dendrogram (number of group members in parentheses). These groups can be further subdivided on the basis of sequence similarity. The large Rhodopsin class is subdivided into four broad groups: α , β , δ , and γ . Olfactory receptors constitute the largest fraction of the Rhodopsin class of GPCRs, with 422 members. Receptors on the dendrogram that readers will frequently encounter include AA_{2A}R, A_{2A} adenosine receptor; AC₃M₃ muscarinic acetylcholine receptor; ADR_{B1}, β_1 adrenergic receptor; AG_{TR1}, AT₁ angiotensin receptor; CN_{R1}, CB₁ cannabinoid receptor; CX_{CR4}, CX_{C4} chemokine receptor; DR_{D2}, D₂ dopamine receptor; ED_{NRA}, ET_A endothelin receptor; FP_{R1}, f-Met-Leu-Phe receptor; GC_{GR}, glucagon receptor; GR_{M1}, mGlu_{R1} metabotropic glutamate receptor; HR_{H1}, H₁ histamine receptor; 5HT_{2B}, the 5HT_{2B} serotonin receptor; OP_{RM}, μ opioid receptor; RHO, rhodopsin; SMO, smoothened homolog; S1P_{R1}, S1P₁ sphingosine-1-phosphate receptor, also known as ED_{G1}; TS_{HR}, thyrotropin (TSH) receptor; and VI_{PR1}, V₁ vasoactive intestinal peptide receptor. Details of entries on the dendrogram are available from the GPCR Network (<http://gpcr.usc.edu>). Additional information on GPCRs is available from the IUPHAR/BPS Guide to Pharmacology (<http://www.guidetopharmacology.org>). (Reproduced with permission from Angela Walker, Vsevolod Katrich, and Raymond Stevens of the GPCR Network at the University of Southern California, as created in the Stevens lab by Yekaterina Kadyshevskaya.)

A. Activation by Ligand Binding of GPCR

B. Modulation of Effectors

Figure 3–10 The basic GPCR- G_i protein-effector pathway. In the absence of ligand, the GPCR and G protein heterotrimer form a complex in the membrane with the $G\alpha$ subunit bound to GDP. Following binding of ligand, the receptor and G protein α subunit undergo a conformational change leading to release of GDP, binding of GTP, and dissociation of the complex. The activated GTP-bound $G\alpha$ subunit and the freed $\beta\gamma$ dimer bind to and regulate effectors. The system is returned to the basal state by hydrolysis of the GTP on the α subunit, a reaction that is markedly enhanced by the RGS proteins. Prolonged stimulation of the receptor can lead to downregulation of the receptor. This event is initiated by GRKs that phosphorylate the C-terminal tail of the receptor, leading to recruitment of proteins termed arrestins; arrestins bind to the receptor on the internal surface, displacing G proteins and inhibiting signaling. Detailed descriptions of these signaling pathways are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

and has two isoforms (I α and I β) that arise from alternate splicing. PKG-II has a myristylated N-terminus, is membrane-associated, and can be localized by PKG-anchoring proteins in a manner analogous to that for PKA, although the docking domains of PKA and PKG differ structurally. Pharmacologically important effects of elevated cGMP include modulation of platelet activation and relaxation of smooth muscle (Rybalkin et al., 2003). Receptors linked to cGMP synthesis are covered in a separate section that follows.

- **PDEs.** Cyclic nucleotide PDEs form another family of important signaling proteins whose activities are regulated via the rate of gene transcription as well as by second messengers (cyclic nucleotides or Ca^{2+}) and interactions with other signaling proteins such as β arrestin and PKs. PDEs hydrolyze the cyclic 3',5'-phosphodiester bond in cAMP and cGMP, thereby terminating their action. The PDEs comprise a superfamily with more than 50 different proteins (Conti and Beavo, 2007). The substrate specificities of the different PDEs include those specific for cAMP hydrolysis and for cGMP hydrolysis and some that hydrolyze both cyclic nucleotides. PDEs (mainly PDE3 forms) are drug targets for treatment of diseases such as asthma, cardiovascular diseases such as heart failure, atherosclerotic coronary and peripheral arterial disease, and neurological disorders. PDE5 inhibitors (e.g., sildenafil)

are used in treating chronic obstructive pulmonary disease and erectile dysfunction (Mehats et al., 2002).

- **EPACs.** EPAC, also known as cAMP-GEF, is a novel cAMP-dependent signaling protein that plays unique roles in cAMP signaling. cAMP signaling through EPAC can occur in isolation or in concert with PKA signaling (Schmidt et al., 2013). EPAC serves as a cAMP-regulated GEF for the family of small Ras GTPases (especially the Rap small GTPases), catalyzing the exchange of GTP for GDP, thus activating the small GTPase by promoting formation of the GTP-bound form. Two isoforms of EPAC are known, EPAC1 and EPAC2; they differ in their architecture and tissue expression. Both EPAC isoforms are multidomain proteins that contain a regulatory cAMP-binding domain, a catalytic domain, and domains that determine the intracellular localization of EPAC. Compared to EPAC2, EPAC1 contains an additional N-terminal low-affinity cAMP-binding domain. The expression of EPAC1 and EPAC2 are differentially regulated during development and in a variety of disease states. EPAC2 can promote incretin-stimulated insulin secretion from pancreatic β cells through activation of Rap1 (Figure 47–3). Sulfonylureas, important oral drugs used to treat type II diabetes mellitus, may act in part by activating EPAC2 in β cells and increasing insulin release.

G_q -PLC-DAG/ IP_3 - Ca^{2+} Pathway. Calcium is an important messenger in all cells and can regulate diverse responses, including gene expression, contraction, secretion, metabolism, and electrical activity. Ca^{2+} can enter the cell through Ca^{2+} channels in the plasma membrane (see the Ion Channels section) or be released by hormones or growth factors from intracellular stores. In keeping with its role as a signal, the basal Ca^{2+} level in cells is maintained in the 100-nM range by membrane Ca^{2+} pumps that extrude Ca^{2+} to the extracellular space and a SERCA in the membrane of the ER that accumulates Ca^{2+} into its storage site in the ER/SR.

Hormones and growth factors release Ca^{2+} from its intracellular storage site, the ER, via a signaling pathway that begins with activation of PLC, of which there are two primary forms, PLC β and PLC γ . GPCRs that couple to G_q or G_{12} activate PLC β by activating the $G\alpha$ subunit (see Figure 3–10) and releasing the $\beta\gamma$ dimer. Both the active, G_q -GTP-bound α subunit and the $\beta\gamma$ dimer can activate certain isoforms of PLC β . PLC γ isoforms are activated by tyrosine phosphorylation, including phosphorylation by receptor and nonreceptor tyrosine kinases.

The PLCs are cytosolic enzymes that translocate to the plasma membrane on receptor stimulation. When activated, they hydrolyze a minor membrane phospholipid, phosphatidylinositol-4,5-bisphosphate, to generate two intracellular signals, IP_3 and the lipid DAG. DAG directly activates some members of the PKC family. IP_3 diffuses to the ER, where it activates the IP_3 receptor in the ER membrane, causing release of stored Ca^{2+} from the ER (Patterson et al., 2004). Release of Ca^{2+} from these intracellular stores raises Ca^{2+} levels in the cytoplasm many-fold within seconds and activates Ca^{2+} -dependent enzymes such as some of the PKCs and Ca^{2+} /calmodulin-sensitive enzymes such as one of the cAMP-hydrolyzing PDEs and a family of Ca^{2+} /calmodulin-sensitive PKs (e.g., phosphorylase kinase, MLCK, and CaM kinases II and IV) (Hudmon and Schulman, 2002). Depending on the cell's differentiated function, the Ca^{2+} /calmodulin kinases and PKC may regulate the bulk of the downstream events in the activated cells.

Ion Channels

Changes in the flux of ions across the plasma membrane are critical regulatory events in both excitable and nonexcitable cells. To establish the electrochemical gradients required to maintain a membrane potential, all cells express ion transporters for Na^+ , K^+ , Ca^{2+} , and Cl^- . For example, the Na^+ , K^+ -ATPase expends cellular ATP to pump Na^+ out of the cell and K^+ into the cell. The electrochemical gradients thus established are used by excitable tissues such as nerve and muscle to generate and transmit electrical impulses, by nonexcitable cells to trigger biochemical and secretory events, and by all cells to support a variety of secondary symport and antiport processes (see Figures 2–2 and 5–4).

Passive ion fluxes down cellular electrochemical gradients are regulated by a large family of ion channels located in the membrane. Humans express about 232 distinct ion channels to precisely regulate the flow of Na^+ , K^+ , Ca^{2+} , and Cl^- across the cell membrane (Jegla et al., 2009). Because of their roles as regulators of cell function, these proteins are important drug targets. The diverse ion channel family can be divided into subfamilies based on the mechanisms that open the channels, their architecture, and the ions they conduct. They can also be classified as *voltage-activated*, *ligand-activated*, *store-activated*, *stretch-activated*, and *temperature-activated channels*.

Voltage-Gated Channels. Humans express multiple isoforms of voltage-gated channels for Na^+ , K^+ , Ca^{2+} , and Cl^- ions. In nerve and muscle cells, voltage-gated Na^+ channels are responsible for the generation of robust action potentials that depolarize the membrane from its resting potential of -70 mV up to a potential of $+20$ mV within a few milliseconds. These Na^+ channels are composed of three subunits, a pore-forming α subunit and two regulatory β subunits (Purves et al., 2011). The α subunit is a 260-kDa protein containing four domains that form a Na^+ ion-selective pore by arranging into a pseudotetramer shape. The β subunits are 36-kDa proteins that span the membrane once (Figure 3–11A). Each domain of the α subunit contains six membrane-spanning helices (S1–S6) with an extracellular loop between S5 and S6, termed the pore-forming or P loop; the P loop dips back into the pore and, combined

with residues from the corresponding P loops from the other domains, provides a selectivity filter for the Na^+ ion (see Figure 14–2). Four other helices surrounding the pore (one S4 helix from each of the domains) contain a set of charged amino acids that form the voltage sensor and cause a conformational change in the pore at more positive voltages, leading to opening of the pore and depolarization of the membrane (Figure 11–2). The voltage-activated Na^+ channels in pain neurons are targets for local anesthetics, such as lidocaine and tetracaine, which block the pore, inhibit depolarization, and thus block the sensation of pain (see Chapter 22). They are also the targets of the naturally occurring marine toxins *tetrodotoxin* and *saxitoxin*. Voltage-activated Na^+ channels are also important targets of many drugs used to treat cardiac arrhythmias (see Chapter 30).

Voltage-gated Ca^{2+} channels have a similar architecture to voltage-gated Na^+ channels with a large α subunit (four domains of five membrane-spanning helices) and three regulatory subunits (the β , δ , and γ subunits). Ca^{2+} channels can be responsible for initiating an action potential (as in the pacemaker cells of the heart) but are more commonly responsible for modifying the shape and duration of an action potential initiated by fast voltage-gated Na^+ channels. These channels initiate the influx of Ca^{2+} that stimulates the release of neurotransmitters in the central, enteric, and autonomic nervous systems and that control heart rate and impulse conduction in cardiac tissue (see Chapters 8, 14, and 30). The L-type voltage-gated Ca^{2+} channels are subject to additional regulation via phosphorylation by PKA. Voltage-gated Ca^{2+} channels expressed in smooth muscle regulate vascular tone; the intracellular concentration of Ca^{2+} is critical to regulating the phosphorylation state of the contractile apparatus via the activity of the Ca^{2+} /calmodulin-sensitive MLCK. Ca^{2+} channel antagonists such as nifedipine, diltiazem, and verapamil are effective vasodilators and are widely used to treat hypertension, angina, and certain cardiac arrhythmias (see Chapters 27, 28, and 30).

Voltage-gated K^+ channels are the most numerous and structurally diverse members of the voltage-gated channel family and include the voltage-gated K_v channels, the inwardly rectifying K^+ channel, and the tandem or two-pore domain “leak” K^+ channels (Jegla et al., 2009). The inwardly rectifying channels and the two-pore channels are voltage insensitive, regulated by G proteins and H^+ ions, and greatly stimulated by general anesthetics. Increasing K^+ conductance through these channels drives the membrane potential more negative (closer to the equilibrium potential for K^+); thus, these channels are important in regulating resting membrane potential and restoring the resting membrane at -70 to -90 mV following depolarization.

Ligand-Gated Channels. Channels activated by the binding of a ligand to a specific site in the channel protein have a diverse architecture and set of ligands. Major ligand-gated channels in the nervous system are those that respond to excitatory neurotransmitters such as ACh (Figures 3–11B and 11–1) or glutamate (or agonists such as AMPA and NMDA) and inhibitory neurotransmitters such as glycine or GABA (Purves et al., 2011). Activation of these channels is responsible for the majority of synaptic transmission by neurons both in the CNS and in the periphery (see Chapters 8, 11, and 14). In addition, there are a variety of more specialized ion channels that are activated by intracellular small molecules and are structurally distinct from conventional ligand-gated ion channels. These include ion channels that are formally members of the K_v family, such as the HCN channel expressed in the heart that is responsible for the slow depolarization seen in phase 4 of atrioventricular and sinoatrial nodal cell action potentials (Wahl-Schott and Biel, 2009) (see Chapter 30) and the CNG channel that is important for vision (see Chapter 69). The intracellular small-molecule category of ion channels also includes the IP_3 -sensitive Ca^{2+} channel responsible for release of Ca^{2+} from the ER and the sulfonylurea “receptor” (SUR1) that associates with the K_{ATP} channel to regulate the K_{ATP} in pancreatic β cells. The K_{ATP} channel is the target of oral hypoglycemic drugs such as sulfonylureas and meglitinides that stimulate insulin release from pancreatic β cells and are used to treat type 2 diabetes (see Chapter 47).

The nicotinic ACh receptor is an instructive example of a ligand-gated ion channel. Isoforms of this channel are expressed in the CNS, in

Figure 3-11 Two types of ion channels regulated by receptors and drugs. **A.** A voltage-activated Na⁺ channel with the pore in the closed and open states. The pore-forming P loops are shown in blue, angled into the pore to form the selectivity filter. The S4 helices forming the voltage sensor are shown in orange, with the positively charged amino acids displayed as red dots. **B.** Ligand-gated nicotinic ACh receptor expressed in the skeletal muscle neuromuscular junction. The pore is made up of five subunits, each with a large extracellular domain and four transmembrane helices (one of these subunits is shown at the left of panel **B**). The helix that lines the pore is shown in blue. The receptor is composed of two α subunits and β, γ, and δ subunits. See text for discussion of other ligand-gated ion channels. Detailed descriptions of specific channels are given throughout the text in relation to the therapeutic actions of drugs affecting these channels (see especially Chapters 11, 14, and 22). (Adapted with permission from Purves D et al., eds. *Neuroscience*. 5th ed. Sinauer Associates, Inc., Sunderland, MA, 2011. By permission of Oxford University Press, USA.)

autonomic ganglia, and at the neuromuscular junction (Figures 3-11B and 11-2). The pentameric channel consists of four different subunits (2α, β, δ, γ) in the neuromuscular junction or two different subunits (2α, 3β) in autonomic ganglia (Purves et al., 2011). Each subunit has an identical ACh binding site; the different compositions of the other three subunits between the neuronal and neuromuscular junction receptors account for the ability of competitive antagonists such as rocuronium to inhibit the receptor in the neuromuscular junction without effect on the ganglionic receptor. This property is exploited to provide muscle relaxation during surgery with minimal autonomic side effects (Chapter 11). Each subunit of the receptor contains a large, extracellular N-terminal domain, four membrane-spanning helices (one of which lines the pore in the assembled complex), and an internal loop between helices 3 and 4 that forms the intracellular domain of the channel. The pore opening in the channel measures about 3 nm, whereas the diameter of a Na⁺ or K⁺ ion is only 0.3 nm or less. Accordingly, ligand-gated ion channels do not possess the exquisite ion selectivity found in most voltage-activated channels, and activation of the nicotinic ACh receptor allows passage of both Na⁺ and K⁺ ions.

Transient Receptor Potential Channels. The TRP cation channels are involved in a variety of physiological and pathophysiological sensory processes, including nociception, heat and cold sensation, mechanosensation, and sensation of chemicals such as capsaicin and menthol. The TRP channel superfamily is diverse and consists of 28 channels in six families (Cao et al., 2013; Ramsey et al., 2006; Venkatachalam and Montell, 2007).

The typical TRP channel structure consists of monomers predicted to have six transmembrane helices (S1–S6) with a pore-forming loop between S5 and S6 and large intracellular regions at the amino and carboxyl termini. Most of the functional TRP channels are homotetramers, but heteromultimers are also formed. Genetic mutations in TRP channels are related to channelopathies that are associated with inherited pain syndrome, several different kidney and bladder diseases, and skeletal dysplasias. Agonists and antagonists are being developed and are in clinical trials for a wide variety of indications, including pain, gastroesophageal reflux disorder, respiratory disorders, osteoarthritis, skin disorders, and overactive bladder.

Transmembrane Receptors Linked to Intracellular Enzymes

Receptor Tyrosine Kinases. The receptor tyrosine kinases include receptors for hormones such as insulin; growth factors such as EGF, PDGF, NGF, FGF, VEGF; and ephrins. With the exception of the insulin receptor, which has α and β chains (see Chapter 47), these macromolecules consist of single polypeptide chains with large, cysteine-rich extracellular domains, short transmembrane domains, and an intracellular region containing one or two protein tyrosine kinase domains. Activation of growth factor receptors leads to cell survival, cell proliferation, and differentiation. Activation of the ephrin receptors leads to neuronal angiogenesis, axonal migration, and guidance (Ferguson, 2008).

The inactive state of growth factor receptors is monomeric; binding of ligand induces dimerization of the receptor and cross-phosphorylation of the kinase domains on multiple tyrosine residues (Figure 3–12A). The phosphorylation of other tyrosine residues forms docking sites for the SH2 domains contained in a large number of signaling proteins. There

are over 100 proteins encoded in the human genome containing SH2 domains, and following receptor activation, large signaling complexes are formed on the receptor that eventually lead to cell proliferation.

Molecules recruited to phosphotyrosine-containing proteins by their SH2 domains include PLC γ , the activity of which raises intracellular levels

Figure 3–12 Mechanism of activation of a receptor tyrosine kinase and a cytokine receptor. **A.** Activation of the EGF receptor. The extracellular structure of the unliganded receptor (a) contains four domains (I–IV), which rearrange significantly on binding two EGF molecules. In (b), the conformational changes lead to activation of the cytoplasmic tyrosine kinase domains and tyrosine phosphorylation of intracellular regions to form SH2 binding sites. (c). The adapter molecule Grb2 binds to the phosphorylated tyrosine residues and activates the Ras-MAPK cascade. **B.** Activation of a cytokine receptor. Binding of the cytokine causes dimerization of the receptor and recruits the Jaks to the cytoplasmic tails of the receptor. Jaks transphosphorylate and lead to the phosphorylation of the STATs. The phosphorylated STATs translocate to the nucleus and regulate transcription. There are proteins termed SOCS (suppressors of cytokine signaling) that inhibit the Jak-STAT pathway. **C.** Activation of the mTOR pathway. Signaling via this pathway promotes growth, proliferation, and survival of cells via a complex web of signaling pathways (see Figures 35–2 and 67–4 and Guri and Hall, 2016). mTOR signaling is emerging as a major consideration in immunosuppression and cancer pharmacotherapy, and inhibitors of mTOR signaling are sometimes included as adjunct therapy.

of Ca^{2+} and activates PKC. The α and β isoforms of PI3K contain SH2 domains, dock at the phosphorylated receptor, are activated, and increase the level of PIP_3 and PKB (also known as Akt). PKB can regulate mTOR, which is upstream of various signaling pathways, and the *Bad* protein that is important in apoptosis.

In addition to recruiting enzymes, phosphotyrosine-presenting proteins can interact with SH2 domain-containing adaptor molecules without activity (e.g., Grb2), which in turn attract GEFs such as Sos that can activate the small GTP-binding protein Ras. The small GTP-binding proteins Ras and Rho belong to a large family of small monomeric GTPases. All of the small GTPases are activated by GEFs regulated by a variety of mechanisms and inhibited by GAPs (Etienne-Manneville and Hall, 2002). Activation of members of the Ras family leads in turn to activation of a PK cascade termed the Ras-MAPK pathway. Activation of the MAPK pathway is one of the major routes used by growth factor receptors to signal to the nucleus and stimulate cell growth (Figure 3–12A). Oncogenic mutations that result in constitutively activated growth factor receptors and Ras can also activate the MAPK pathway and drive tumor proliferation. Anticancer agents that target the MAPK pathway and the protein tyrosine kinase activity of oncogenic growth factors are now important agents in treating several forms of cancer (see Chapter 65 and 67).

Jak-STAT Receptor Pathway. Cells express a family of receptors for cytokines such as γ -interferon and hormones such as growth hormone and prolactin, which signal to the nucleus by a more direct manner than the receptor tyrosine kinases. These receptors have no intrinsic enzymatic activity; rather, the intracellular domain binds a separate, intracellular tyrosine kinase termed a Jak. On dimerization induced by ligand binding, Jaks phosphorylate other proteins termed STATs, which translocate to the nucleus and regulate transcription (Figure 3–12B). The entire pathway is termed the Jak-STAT pathway (Gough et al., 2008; Wang et al., 2009). There are four Jaks and six STATs in mammals that, depending on the cell type and signal, combine differentially to activate gene transcription.

Receptor Serine-Threonine Kinases. Protein ligands such as TGF- β activate a family of receptors that are analogous to the receptor tyrosine kinases except that they have a serine-threonine kinase domain in the cytoplasmic region of the protein. There are two isoforms of the monomeric receptor protein, type I (seven forms) and type II (five forms). In the basal state, these proteins exist as monomers; upon binding an agonist ligand, they dimerize, leading to phosphorylation of the kinase domain of the type I monomer, which activates the receptor. The activated receptor then phosphorylates a gene regulatory protein termed a *Smad*. Once phosphorylated by the activated receptor on a serine residue, Smad dissociates from the receptor, migrates to the nucleus, associates with transcription factors, and regulates genes leading to morphogenesis and transformation. There are also inhibitory Smads (the Smad6 and Smad7 isoforms) that compete with the phosphorylated Smads to terminate signaling.

Toll-like Receptors. Signaling related to the innate immune system is carried out by a family of more than 10 single membrane-spanning receptors termed TLRs, which are highly expressed in hematopoietic cells. In a single polypeptide chain, these receptors contain a large extracellular LBD, a short membrane-spanning domain, and a cytoplasmic region termed the TIR domain that lacks intrinsic enzymatic activity. *Ligands for TLRs comprise a multitude of pathogen products, including lipids, peptidoglycans, lipopeptides, and viruses.* Activation of TLRs produces an inflammatory response to the pathogenic microorganisms.

The first step in activation of TLRs by ligands is dimerization, which in turn causes signaling proteins to bind to the receptor to form a signaling complex. Ligand-induced dimerization recruits a series of adaptor proteins, including Mal and MyD88 to the intracellular TIR domain; these proteins in turn recruit the IRAKs. The IRAKs autophosphorylate in the complex and subsequently form a more stable complex with MyD88. The phosphorylation event also recruits TRAF6 to the complex, which facilitates interaction with a ubiquitin ligase that attaches a polyubiquitin molecule to TRAF6. This complex can now interact with TAK1 and the adaptor protein TAB1. TAK1 is a member of the

MAPK family, which activates the NF- κ B kinases; phosphorylation of the NF- κ B transcription factors causes their translocation to the nucleus and transcriptional activation of a variety of inflammatory genes (Gay and Gangloff, 2007).

TNF- α Receptors. The mechanism of action of TNF- α signaling to the NF- κ B transcription factors is similar to that used by TLRs in that the intracellular domain of the receptor has no enzymatic activity. The TNF- α receptor is another membrane monospan protein with an extracellular LBD, a transmembrane domain, and a cytoplasmic domain termed the *death domain*. TNF- α binds a complex composed of TNF receptor 1 and TNF receptor 2. Upon trimerization, the death domains bind the adaptor protein TRADD, which recruits the RIP1 to form a receptor-adaptor complex at the membrane. RIP1 is polyubiquitinated, resulting in recruitment of the TAK1 kinase and the IKK complex to the ubiquitinated molecules (Skaug et al., 2009). The activation loop of IKK is phosphorylated in the complex, eventually resulting in the release of I κ B α from the complex, allowing the p50/p65 heterodimer of the complex to translocate to the nucleus and activate the transcription of inflammatory genes (Ghosh and Hayden, 2008; Hayden and Ghosh, 2008; Kataoka, 2009). While there currently are no drugs that interdict the cytoplasmic portions of the TNF- α signaling pathway, humanized monoclonal antibodies to TNF- α itself, such as *infliximab* and *adalimumab*, are important for the treatment of rheumatoid arthritis and Crohn disease (see Chapters 34, 35, 37, and 51).

Receptors That Stimulate Synthesis of cGMP

The signaling pathways that regulate the synthesis of cGMP in cells include hormonal regulation of transmembrane guanylyl cyclases such as the ANP receptor and the activation of sGC by NO (Figure 3–13). The downstream effects of cGMP are carried out by multiple isoforms of PKG, cGMP-gated ion channels, and cGMP-modulated PDEs that degrade cAMP.

Natriuretic Peptide Receptors: Ligand-Activated Guanylyl Cyclases. The class of membrane receptors with intrinsic enzymatic activity includes the receptors for three small peptide ligands released from cells in cardiac tissues and the vascular system, the natriuretic peptides: ANP, released from atrial storage granules following expansion of intravascular volume or stimulation with pressor hormones; BNP, synthesized and released in large amounts from ventricular tissue in response to volume overload; and CNP, synthesized in the brain and endothelial cells. Like BNP, CNP is not stored in granules; rather, its synthesis and release are increased by growth factors and sheer stress on vascular ECs. The major physiological effects of these hormones are to decrease blood pressure (ANP, BNP), to reduce cardiac hypertrophy and fibrosis (BNP), and to stimulate long-bone growth (CNP). The transmembrane receptors for ANP, BNP, and CNP are ligand-activated guanylyl cyclases. The NPR-A is the molecule that responds to ANP and BNP. The protein is widely expressed and prominent in kidney, lung, adipose, and cardiac and vascular SMCs. ANP and BNP play a role in maintaining the normal state of the cardiovascular system; NPR-A knockout mice develop hypertension and hypertrophic hearts. The synthetic BNP agonist *nesiritide* and the neprilysin inhibitor *sacubitril* (blocks ANP and BNP breakdown) are used in the treatment of acute decompensated heart failure (Chapter 29).

The NPR-B receptor responds to CNP, is widely expressed, and has a physical structure similar to the NPR-A receptor. A role for CNP in bone is suggested by the observation that NPR-B knockout mice exhibit dwarfism. The NPR-C has an extracellular domain similar to those of NPR-A and NPR-B but does not contain the guanylyl cyclase domain. NPR-C has no enzymatic activity and is thought to function as a clearance receptor, removing excess natriuretic peptide from the circulation (Potter et al., 2009).

NO Synthase and Soluble Guanylyl Cyclase. NO is produced locally in cells by forms of the enzyme NOS. NO stimulates sGC to produce cGMP. There are three forms of NOS: nNOS (or NOS1), eNOS (or NOS3), and iNOS (or NOS2). All three forms are widely expressed but are especially important in the cardiovascular system, where they are found in myocytes, vascular smooth muscle cells, endothelial cells, hematopoietic

Figure 3–13 *Cyclic GMP signaling pathways.* Formation of cGMP is regulated by cell surface receptors with intrinsic GC activity and by soluble forms of GC. The cell surface receptors respond to natriuretic peptides such as ANP with an increase in cGMP. sGC responds to NO generated from L-arginine by NOS. Cellular effects of cGMP are carried out by PKG and cGMP-regulated PDEs. In this diagram, NO is produced by a Ca^{2+} /calmodulin–dependent NOS in an adjacent endothelial cell. Detailed descriptions of these signaling pathways are given throughout the text in relation to the therapeutic actions of drugs affecting these pathways.

cells, and platelets. Elevated cell Ca^{2+} , acting via calmodulin, markedly activates nNOS and eNOS; the inducible form is less sensitive to Ca^{2+} , but synthesis of iNOS protein in cells can be induced more than 1000-fold by inflammatory stimuli such as endotoxin, $\text{TNF-}\alpha$, interleukin 1β , and interferon γ .

Nitric oxide synthase produces NO by catalyzing the oxidation of the guanido nitrogen of L-arginine, producing L-citrulline and NO. NO activates sGC, a heterodimer that contains a protoporphyrin-IX heme domain. NO binds to this domain at low nanomolar concentrations and produces a 200- to 400-fold increase in the V_{max} of guanylyl cyclase, leading to an elevation of cellular cGMP (Tsai and Kass, 2009). The cellular effects of cGMP on the vascular system are mediated by a number of mechanisms, but especially by PKG. In vascular smooth muscle, activation of PKG leads to vasodilation by

- Inhibiting IP_3 -mediated Ca^{2+} release from intracellular stores
- Phosphorylating voltage-gated Ca^{2+} channels to inhibit Ca^{2+} influx
- Phosphorylating phospholamban, a modulator of the sarcoplasmic Ca^{2+} pump, leading to a more rapid reuptake of Ca^{2+} into intracellular stores
- Phosphorylating and opening the Ca^{2+} -activated K^+ channel, leading to hyperpolarization of the cell membrane, which closes L-type Ca^{2+} channels and reduces the flux of Ca^{2+} into the cell

Nuclear Hormone Receptors and Transcription Factors

Nuclear hormone receptors comprise a superfamily of 48 receptors that respond to a diverse set of ligands. The nuclear receptor proteins are transcription factors able to regulate the expression of genes controlling numerous physiological processes, such as reproduction, development, and metabolism. Members of the family include receptors for circulating steroid hormones such as androgens, estrogens, glucocorticoids, thyroid hormone, and vitamin D. Other members of the family are receptors for a diverse group of fatty acids, bile acids, lipids, and lipid metabolites (McEwan, 2009).

Examples include the RXR; the LXR (the ligand is 22-OH cholesterol); the FXR (the ligand is chenodeoxycholic acid); and the PPARs α , β , and γ ; 15-deoxy prostaglandin J2 is a possible ligand for PPAR γ ; the cholesterol-lowering fibrates bind to and regulate PPAR α . In the inactive state, receptors for steroids such as glucocorticoids reside in the cytoplasm and translocate to the nucleus on binding ligand. Other members of the family, such as the LXRs and FXRs reside in the nucleus and are activated by changes in the concentration of hydrophobic lipid molecules.

Nuclear hormone receptors contain four major domains in a single polypeptide chain. The N-terminal domain can contain an *activation region* (AF-1) essential for transcriptional regulation, followed by a very conserved region with two zinc fingers that bind to DNA (the *DNA-binding domain*). The N-terminal activation region (AF-1) is subject to regulation by phosphorylation and other mechanisms that stimulate or inhibit transcription. The C-terminal half of the molecule contains a *hinge region* (which can be involved in binding DNA), the domain responsible for binding the hormone or ligand (the LBD), and specific sets of amino acid residues for binding *coactivators* and *corepressors* in a second activation region (AF-2). The LBD is formed from a bundle of 12 helices; ligand binding induces a major conformational change in helix 12 that affects the binding of the coregulatory proteins essential for activation of the receptor-DNA complex (Figure 3–14) (Privalsky, 2004; Tontonoz and Spiegelman, 2008).

When binding to DNA, most of the nuclear hormone receptors act as dimers—some as homodimers, others as heterodimers. Steroid hormone receptors such as the glucocorticoid receptor are commonly homodimers, whereas those for lipids are heterodimers with the RXR receptor. The receptor dimers bind to repetitive DNA sequences, either direct repeat sequences or inverted repeats termed *HREs* that are specific for each type of receptor. The HREs in DNA are found upstream of the regulated genes or in some cases within the regulated genes. An agonist-bound nuclear hormone receptor often activates a large number of genes to carry out a program of cellular differentiation or metabolic regulation. *An important*

Figure 3-14 Activation of nuclear hormone receptors. A nuclear hormone receptor (OR) is shown in complex with the RXR. When an agonist (yellow triangle) and coactivator bind, a conformational change occurs in helix 12 (black bar), and gene transcription is stimulated. If corepressors are bound, activation does not occur. See text for details; see also Figure 6-12.

property of these receptors is that they must bind their ligand, the appropriate HRE, and a coregulator, to regulate their target genes. The activity of the nuclear hormone receptors in a given cell depends not only on the ligand but also on the ratio of coactivators and corepressors recruited to the complex. Coactivators recruit enzymes to the transcription complex that modify chromatin, such as histone acetylase that serves to unravel DNA for transcription. Corepressors recruit proteins such as histone deacetylase, which keeps DNA tightly packed and inhibits transcription.

Apoptosis and Autophagy Pathways

Organ development and renewal requires a balance between cell population survival and expansion versus cell death and removal. One process by which cells are genetically programmed for death is termed *apoptosis*. Defective apoptosis is an important characteristic of many cancers that contributes to both tumorigenesis and resistance to anticancer therapies. *Autophagy* an intracellular degradation pathway that may have evolved before apoptosis, can also lead to programmed cell death. The pharmacological perturbation of these processes could be of importance in many diseases.

Apoptosis

Apoptosis is a highly regulated program of biochemical reactions that leads to cell rounding, shrinking of the cytoplasm, condensation of the nucleus and nuclear material, and changes in the cell membrane that eventually lead to presentation of phosphatidylserine on the outer surface of the cell. Phosphatidylserine is recognized as a sign of apoptosis by macrophages, which engulf and phagocytize the dying cell. During this process, the membrane of the apoptotic cell remains intact, and the cell does not release its cytoplasm or nuclear material. Thus, unlike necrotic cell death, the apoptotic process does not initiate an inflammatory response. Alterations in apoptotic pathways are implicated in cancer, neurodegenerative diseases, autoimmune diseases. Thus, maintaining or restoring normal apoptotic pathways is the goal of major drug development efforts to treat diseases that involve dysregulated apoptotic pathways. Resistance to many cancer chemotherapies is associated with reduced function of apoptotic pathways.

Two major signaling pathways induce apoptosis. Apoptosis can be initiated by external signals that have features in common with those used by ligands such as TNF- α or by an internal pathway activated by DNA damage, improperly folded proteins, or withdrawal of cell survival factors (Figure 3-15). The apoptotic program is carried out by a large family of cysteine proteases termed *caspases*. The caspases are highly specific cytoplasmic proteases that are inactive in normal cells but become activated by apoptotic signals (Bremer et al., 2006; Ghavami et al., 2009).

The external apoptosis signaling pathway can be activated by ligands such as TNF, Fas (also called Apo-1), or TRAIL. The receptors for Fas and TRAIL are transmembrane receptors with no enzymatic activity, similar to the organization of the TNF receptor described previously. On binding TNF, Fas ligand, or TRAIL, these receptors form a receptor dimer,

undergo a conformational change, and recruit adapter proteins to the death domain. The adaptor proteins then recruit RIP1 and caspase 8 to form a complex that results in the activation of caspase 8. Activation of caspase 8 leads to the activation of caspase 3, which initiates the apoptotic program. The final steps of apoptosis are carried out by caspases 6 and 7, leading to degradation of enzymes, structural proteins, and DNA fragmentation characteristic of cell death (Danial and Korsmeyer, 2004; Wilson et al., 2009) (see Figure 3-15).

The internal apoptosis pathway can be activated by signals such as DNA damage, leading to increased transcription of the p53 gene, and involves damage to the mitochondria by proapoptotic members of the Bcl-2 family of proteins. This family includes proapoptotic members such as Bax, Bak, and Bad, which induce damage at the mitochondrial membrane. There are also antiapoptotic Bcl-2 members, such as Bcl-2, Bcl-X, and Bcl-W, which serve to inhibit mitochondrial damage and are negative regulators of the system (Rong and Distelhorst, 2008). When DNA damage occurs, p53 transcription is activated and holds the cell at a cell cycle checkpoint until the damage is repaired. If the damage cannot be repaired, apoptosis is initiated through the proapoptotic Bcl-2 members, such as Bax. Bax is activated, translocates to the mitochondria, overcomes the antiapoptotic proteins, and induces the release of cytochrome *c* and a protein termed the SMAC. SMAC binds to and inactivates the inhibitor of apoptosis proteins (IAPs) that normally prevent caspase activation. Cytochrome *c* combines in the cytosol with another protein, Apaf-1, and with caspase 9. This complex leads to activation of caspase 9 and ultimately to the activation of caspase 3 (Ghobrial et al., 2005; Wilson et al., 2009). Once activated, caspase 3 activates the same downstream pathways as the external pathway described previously, leading to the cleavage of proteins, cytoskeletal elements, and DNA repair proteins, with subsequent DNA condensation and membrane blebbing that eventually lead to cell death and engulfment by macrophages.

Autophagy

Autophagy is a highly regulated, multistep, catabolic pathway in which cellular contents (including aggregate-prone proteins, organelles such as mitochondria and peroxisomes, and infectious agents) are sequestered within double-membrane vesicles known as autophagosomes, then delivered to lysosomes, where fusion occurs and autophagosome contents are degraded by lysosomal proteases (Bento et al., 2016; Hurley and Young, 2017). The functions of autophagy are to remove cell contents that are damaged and provide cells with substrates for energy and biosynthesis under conditions of stress and starvation. Autophagy plays an important protective role in a number of diseases, including neurodegenerative diseases (e.g., Alzheimer, Parkinson, and Huntington diseases) caused by aggregate-prone proteins and certain infectious diseases (*Salmonella typhi* and *Mycobacterium tuberculosis*). Autophagy-related genes may also play a role in tumor suppression, and decreased autophagic capacity is correlated with poor prognosis in brain tumors. However, in breast, ovarian, and prostate cancers, autophagy can function as a tumor

Figure 3–15 Two pathways leading to apoptosis. Apoptosis can be initiated by external ligands such as TNF, Fas, or TRAIL at specific transmembrane receptors (left half of figure). Activation leads to trimerization of the receptor, and binding of adaptor molecules such as TRADD, to the intracellular death domain. The adaptors recruit caspase 8 and activate it, leading to cleavage and activation of the effector caspase, caspase 3, which activates the caspase pathway, leading to apoptosis. Apoptosis can also be initiated by an *intrinsic pathway* regulated by Bcl-2 family members such as Bax and Bcl-2. Bax is activated by DNA damage or malformed proteins via p53 (right half of figure). Activation of this pathway leads to release of cytochrome *c* from the mitochondria, formation of a complex with Apaf-1 and caspase 9. Caspase 9 is activated in the complex and initiates apoptosis through activation of caspase 3. Either the extrinsic or the intrinsic pathway can overwhelm the inhibitor of apoptosis proteins (IAPs), which otherwise keep apoptosis in check.

promoter and may enhance the survival of metastatic cells at sites where nutrients are limited.

Autophagy is a highly conserved process controlled by autophagy-related genes (known as ATGs, AuTophagy genes). More than 30 ATGs have been identified in eukaryotes, and the ATG proteins function at various steps in autophagy, including induction of cargo packaging, vesicle formation, vesicle fusion with lysosomes, and degradation of vesicular contents. Autophagy is primarily regulated by various cellular stress-mediated and growth factor signaling pathways that integrate signaling output via the PI3K-PKB-mTOR pathway (Figure 3–16). Activated mTORC1 inhibits autophagy. Another important regulator of autophagy is the antiapoptotic protein Bcl-2 through its interaction with Beclin-1, an ATG protein. The binding of Bcl-2 to Beclin-1 inhibits autophagy. Phosphorylation of Beclin-1 by JNK1 promotes the dissociation of Beclin-1 from Bcl-2, which promotes autophagy. The ubiquitin-proteasome system is a major protein degradation system that functionally complements autophagy and also regulates autophagy. Ubiquitination of Beclin-1 disrupts its interaction with Bcl-2 and initiates autophagy, but Beclin-1 degradation by the proteasome downregulates autophagy. The tumor suppressor p53 is also a regulator of autophagy through its inhibitory interactions with an ATG on the lysosomal membrane, DRAM.

Receptor Desensitization and Regulation of Receptors

Receptors are almost always subject to feedback regulation by their own signaling outputs. Continued stimulation of cells with agonists generally results in a state of *desensitization* (also referred to as *adaptation*, *refractoriness*, or *downregulation*) such that the effect of continued or repeated

exposure to the same concentration of drug is diminished. This phenomenon, called *tachyphylaxis*, occurs rapidly and is important therapeutically; an example is attenuated response to the repeated use of β adrenergic receptor agonists as bronchodilators for the treatment of asthma (see Chapters 12 and 40).

Desensitization can result from temporary inaccessibility of the receptor to agonist or from fewer receptors being synthesized (e.g., downregulation of receptor number). Phosphorylation of GPCRs by specific GRKs plays a key role in triggering rapid desensitization. Phosphorylation of agonist-occupied GPCRs by GRKs facilitates the binding of cytosolic proteins termed *arrestins* to the receptor, resulting in the uncoupling of G protein from the receptor. The β arrestins recruit proteins, such as PDE4, which limit cAMP signaling, and clathrin and β_2 adaptin, which promote sequestration of receptor from the membrane (*internalization*), thereby providing a scaffold that permits additional signaling steps.

Conversely, *supersensitivity* to agonists also frequently follows chronic reduction of receptor stimulation. As an example, supersensitivity can be noticeable following withdrawal from prolonged receptor blockade (e.g., the long-term administration of β adrenergic receptor antagonists such as metoprolol) or in the case where chronic denervation of a pre-ganglionic fiber induces an increase in neurotransmitter release per pulse and to greater postsynaptic effect, indicating postganglionic neuronal supersensitivity.

Diseases Resulting From Receptor and Pathway Dysfunction

Alteration in receptors and their downstream signaling pathways can be the cause of disease. The loss of a receptor in a highly specialized

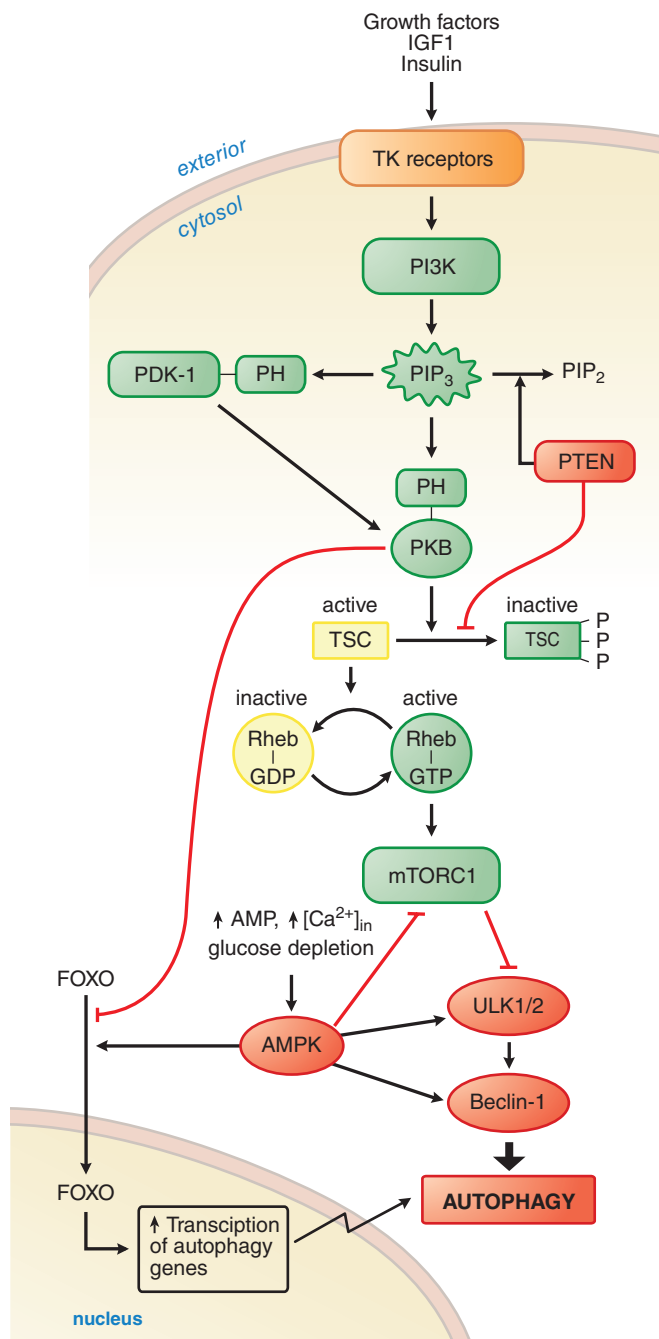

Figure 3-16 Pathways regulating autophagy. Two of the primary regulators of autophagy are growth factor signaling and cellular stress. Growth factor signaling pathways that lead to activation of mTORC1 (green boxes) inhibit autophagy, whereas cellular stress caused by nutrient starvation enhance autophagy through activation of AMPK (red boxes). These pathways not only interact with one another, but also with other pathways including apoptosis pathways as described in the text. See Figure 35-5 for the effect of mTOR inhibitors as immunosuppressants.

signaling system may cause a phenotypic disorder (e.g., deficiency of the androgen receptor and testicular feminization syndrome; see Chapter 45). Deficiencies in widely employed signaling pathways have broad effects, as are seen in myasthenia gravis (due to autoimmune disruption of nicotinic cholinergic receptor function; Chapter 11) and in some forms of insulin-resistant diabetes mellitus (as a result of autoimmune depletion of insulin and interference with insulin receptor function; Chapter 47). The expression of constitutively active, aberrant, or ectopic

receptors, effectors, and coupling proteins potentially can lead to *super-sensitivity*, *subsensitivity*, or *other untoward responses* (Smit et al., 2007). For example, many forms of cancer are now known to arise from mutations that result in constitutive activity of growth factor receptors and downstream signaling enzymes in the Ras-MAPK pathway, or loss of tumor suppressors and other proteins that regulate cell proliferation (see Chapter 67).

Common polymorphisms in receptors and proteins downstream of the receptor can also lead to variability in therapeutic responses in patient populations from different geographic and ethnic origins. An example is the variability in therapeutic response to β blockers in patients with heart failure. African American patients with heart failure do not respond as well to β blockade therapy as do patients of European and Asian descent, and at least part of the lower efficacy in African Americans is attributable to polymorphisms in several components of the myocardial β adrenergic receptor signaling pathway, including β_1 adrenergic receptor polymorphisms that increase its constitutive activity and sensitivity to activation by NE. Interestingly, a GRK5 gain-of-function polymorphism that is more common in African Americans increases the ability of GRK5 to desensitize β_1 receptors and provides a β_1 antiadrenergic effect that increases survival in patients with heart failure not receiving blocker therapy.

Pharmacotherapies That Modify Specific Genes and Their Transcription and Translation

Many hereditary diseases result from mutations in physiologically important proteins that are not receptors or proteins associated with downstream signaling. Until recently, it was difficult or impossible to treat many of these diseases except to provide supportive therapy. However, various gene therapies currently being tested in animal models and humans hold promise of curing or significantly ameliorating the effects of a mutation in a protein that is key to an important physiological process. Examples of diseases that might be treated or cured by gene therapies include DMD, cystic fibrosis, metabolic disorders, and various disorders of the eye.

Approximately 11% of genetic mutations in inherited disease are nonsense mutations that introduce a premature stop codon in the mRNA gene transcript. The first drug approved (in the E.U., but not yet in the U.S.) for the treatment of nmDMD is *ataluren*. This small-molecule drug is thought to act on the ribosome to override the premature stop (nonsense) codon in nonsense mutations, allowing the ribosome to “read through” the transcript and produce normal full-length protein. In the case of nmDMD, ataluren improves synthesis of functional dystrophin, a cytosolic socket protein that is a component of the complex that connects intracellular fibers of a muscle cell with the extracellular matrix. This effect of ataluren modestly improves the symptoms of patients. Ataluren is currently in clinical trials for treatment of other inherited diseases caused by nonsense mutations, including cystic fibrosis (nonsense mutation in the *CFTR* gene) and anaridia (nonsense mutation in the *PAX6* gene).

A different approach to treating diseases resulting from gene mutations is through the use of nucleic acids, including ASOs and RNAi. ASOs are synthetic nucleic acids that are complementary to the mRNA “sense” strand of the disease-causing gene and act by binding to the mRNA, preventing its translation. Examples of ASOs that have been approved include *fomivirsen* for treatment of cytomegalovirus retinitis viral infections of the eye (this agent has been discontinued in the U.S.) and *mipomersen* for treatment of homozygous familial hypercholesterolemia. The target gene for mipomersen is apolipoprotein B100.

Another way to selectively silence gene expression is using siRNA. RNAi is a ubiquitous cellular mechanism for small RNA-guided suppression of gene expression that uses the RISC. The antisense strand of the siRNA guides the RISC to destroy the target mRNA and is protected from degradation by the RISC, resulting in elimination of many copies of the target mRNA and gene knockdown effects that can persist for days to weeks. A number of clinical trials are in progress to treat cancer

Figure 3-17 Interaction of multiple signaling systems regulating vascular SMCs. See text for explanation of signaling and contractile pathways and abbreviations.

using naked siRNAs as well as siRNA delivery systems using adenovirus, liposomes, polymers, and various kinds of nanoparticles.

Perhaps the therapeutic approach with the greatest potential to treat patients with a hereditary disease is the CRISPR/Cas9 genome-editing system using viruses or genetically modified microorganisms. The CRISPR/Cas9 system allows precise and imprecise editing of the genome using sgRNAs that target the Cas9 double-stranded DNA nuclease to specific sites in the genome that contain an adjacent NGG PAM sequence. The CRISPR/Cas9 system allows targeted replacement and modification of disease-causing genes. Recent proof-of-principle experiments in mouse models of DMD demonstrated that CRISPR/Cas9 delivered systemically using AAV vectors can correct disease-causing mutations in the dystrophin gene in young and adult mice. Although there are many technical, regulatory, and ethical hurdles to overcome before genome editing is approved for use in patients, the results of preclinical studies demonstrated the potential impact on treating and curing diseases that previously had no pharmacotherapeutic options.

Physiological Systems Integrate Multiple Signals

Consider the vascular wall of an arteriole (Figure 3-17). Several cell types interact at this site, including vascular smooth muscle cells, endothelial cells, platelets, and postganglionic sympathetic neurons. A variety of physiological receptors and ligands are present, including ligands that cause SMCs to contract (AngII, NE) and relax (NO, BNP, and epinephrine), as well as ligands that alter SMC gene expression (PDGF, AngII, NE, and eicosanoids).

Angiotensin II has both acute and chronic effects on SMCs. Interaction of AngII with AT₁Rs mobilizes stored Ca²⁺ via the G_q-PLC-IP₃-Ca²⁺ pathway. The Ca²⁺ binds and activates calmodulin and its target protein, MLCK. The activation of MLCK results in the phosphorylation of myosin, leading to SMC contraction. Activation of the sympathetic nervous system also regulates SMC tone through release of NE from postganglionic sympathetic neurons. NE binds α₁ adrenergic receptors, which also activate the G_q-PLC-IP₃-Ca²⁺ pathway, resulting in SMC contraction, an effect that is additive to that of AngII.

The contraction of SMCs is opposed by mediators that promote relaxation, including NO, BNP, and catecholamines acting at β₂ adrenergic receptors.

NO is formed in endothelial cells by eNOS when the G_i-PLC-IP₃-Ca²⁺ pathway is activated and by iNOS when that isoform is induced. The NO formed in the endothelium diffuses into SMCs and activates the sGC, which catalyzes the formation of cGMP, which leads to activation of PKG and phosphorylation of proteins in SMCs that reduce intracellular concentrations of Ca²⁺ and thereby promote relaxation. Intracellular concentrations of cGMP are also increased by activation of transmembrane BNP receptors (NPR-A, and to a lesser extent to NPR-B), whose guanylyl cyclase activity is increased when BNP binds.

As a consequence of the variety of pathways that affect arteriolar tone, a patient with hypertension may be treated with one or several drugs that alter signaling through these pathways. Drugs commonly used to treat hypertension include β₁ adrenergic receptor antagonists to reduce secretion of renin (the rate-limiting first step in AngII synthesis); a direct renin inhibitor (aliskiren) to block the rate-limiting step in AngII production; ACE inhibitors (e.g., enalapril) to reduce the concentrations of circulating AngII; AT₁R blockers (e.g., losartan) to block AngII binding to AT₁Rs on SMCs; α₁ adrenergic blockers to block NE binding to SMCs; sodium nitroprusside to increase the quantities of NO produced; or a Ca²⁺ channel blocker (e.g., nifedipine) to block Ca²⁺ entry into SMCs. The β₁ adrenergic receptor antagonists would also block the baroreceptor reflex increase in heart rate and blood pressure elicited by a drop in blood pressure induced by the therapy. ACE inhibitors also inhibit the degradation of a vasodilating peptide, bradykinin (see Chapter 26). Thus, the choices and mechanisms are complex, and the appropriate therapy in a given patient depends on many considerations, including the diagnosed causes of hypertension in the patient, possible side effects of the drug, efficacy in a given patient, and cost.

Signaling Pathways and Drug Action

Throughout this text, cellular signaling pathways figure prominently in explaining the actions of therapeutic agents. Not all pathways have been mentioned or fully explored in this chapter. To aid readers in finding more information on signaling and drug action, Table 3-2 lists relevant figures that appear in other chapters.

TABLE 3-2 ■ SUMMARY: RECEPTOR-SIGNALING PATHWAYS AS SITES OF DRUG ACTION

RECEPTOR/PATHWAY	FIGURE TITLE	FIGURE NUMBER
Drug transport proteins	Major mechanisms by which transporters mediate adverse drug responses	Figure 5-3
CYPs, drug metabolism	Location of CYPs in the cell	Figure 6-2
Nuclear receptors	Induction of drug metabolism by nuclear receptor-mediated signal transduction	Figure 6-13
General neurotransmission	Steps involved in excitatory and inhibitory neurotransmission	Figure 8-3
Exocytosis	Molecular basis of exocytosis: docking and fusion of synaptic vesicles with neuronal membranes	Figure 8-4
Cholinergic neurotransmission	A typical cholinergic neuroeffector junction	Figure 8-6
Adrenergic neurotransmission	A typical adrenergic neuroeffector junction	Figure 8-8
AChE and its inhibition	Steps involved in the hydrolysis of ACh by AChE and in the inhibition and reactivation of the enzyme	Figure 10-2
Transmission at the NMJ	A pharmacologist's view of the motor end plate	Figure 11-4
β Blockers and vasodilation	Mechanisms underlying actions of vasodilating β blockers in blood vessels	Figure 12-4
Serotonergic neurotransmission	A serotonergic synapse	Figure 13-4
Dopaminergic neurotransmission	A dopaminergic synapse	Figure 13-9
Voltage-sensitive cation channels	Voltage-sensitive Na^+ , Ca^{2+} , and K^+ channels	Figure 14-2
Neurotransmission	Transmitter release, action, and inactivation	Figure 14-4
Ligand-gated ion channels	Pentameric ligand-gated ion channels	Figure 14-5
GABA _A receptor	Pharmacologic binding sites on the GABA _A receptor	Figure 14-11
NMDA receptor	Pharmacologic binding sites on the NMDA receptor	Figure 14-12
Glutamate toxicity	Mechanisms contributing to glutamate-induced cytotoxicity/neuronal injury during ischemia-reperfusion-induced glutamate release	Figure 14-13
Histamine signaling	Signal transduction pathways for histamine receptors	Figure 14-14
Cannabinoids in CNS	Anandamide synthesis and signaling	Figure 14-17
Neurotrophin signaling	Neurotrophic factor signaling in the CNS	Figure 14-18
Actions of antidepressants	Sites of action of antidepressants at noradrenergic and serotonergic nerve terminals	Figure 15-1
Na^+ channel	Antiseizure drug-enhanced Na^+ channel inactivation	Figure 17-2
GABA _A receptor/channel	Some antiseizure drugs enhance GABA synaptic transmission	Figure 17-3
T-type Ca^{2+} channel	Antiseizure drug-induced reduction of current through T-type Ca^{2+} channels	Figure 17-4
Dopaminergic signaling	Dopaminergic nerve terminal	Figure 18-1
Endogenous opioid signaling	Receptor specificity of endogenous opioids; effects of receptor activation on neurons.	Figure 20-3
Biased opioid signaling	Biased signaling via opioid receptors	Figure 20-4
Cation signaling	Structure and function of voltage-gated Na^+ channels	Figure 22-2
Local anesthetic action on Na^+ channels	A pharmacologist's view of the interaction of a local anesthetic with a voltage-gated Na^+ channel	Figure 22-3
Aldosterone signaling	Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists	Figure 25-6
ANP signaling	Inter medullary collecting duct Na^+ transport and its regulation	Figure 25-7
V_1 receptor signaling	Mechanism of V_1 receptor-effector coupling	Figure 25-11
V_2 receptor signaling	Mechanism of V_2 receptor-effector coupling	Figure 25-12
Signals regulating renin release	Mechanisms by which the macula densa regulates renin release	Figure 26-4
Signals regulating blood pressure	Principles of blood pressure regulation and its modification by drugs	Figure 28-2
E-C coupling	Cardiac excitation-contraction coupling and its regulation by positive inotropic drugs	Figure 29-6
NO/cGMP signaling in pulmonary hypertension	Stimulators of NO/cGMP signaling	Figure 31-3
cAMP signaling in pulmonary hypertension	Membrane receptor agonists that increase cAMP	Figure 31-4
PLC signaling in pulmonary hypertension	Membrane receptor antagonists that inhibit activation of phospholipase C	Figure 31-5

- Detoxication of the Poisoned Patient
- Enhancing the Elimination of Poisons

RESOURCES FOR INFORMATION ON DRUG TOXICITY AND POISONING

Pharmacology intersects with *toxicology* when the physiological response to a drug is an *adverse effect*. A *poison* is any substance, including any drug, that has the capacity to harm a living organism. *Poisoning* generally implies that damaging physiological effects result from exposure to pharmaceuticals, illicit drugs, or chemicals.

effect can be compared to the LD_1 for lethality (toxic effect), to yield a *margin of safety*.

$$\text{Margin of safety} = \frac{LD_1}{ED_{99}} \quad (\text{Equation 4-2})$$

Dose-Response

Conventional Dose-Response Curves

There is a graded dose-response relationship in an *individual* and a quantal dose-response relationship in the *population* (see Figures 3-2, 3-3, and 3-6). Graded doses of a drug given to an individual usually result in a greater magnitude of response as the dose increases. In a quantal dose-response relationship, the percentage of the population affected increases as the dose is increased; the relationship is quantal in that the effect is judged to be either present or absent in a given individual. This quantal dose-response phenomenon is used to determine the LD_{50} of drugs, as defined in Figure 4-1A.

One can also determine a quantal dose-response curve for the therapeutic effect of a drug to generate ED_{50} , the concentration of drug at which 50% of the population will have the desired response, and a quantal dose-response curve for lethality by the same agent (Figure 4-1B). These two curves can be used to generate a TI, which quantifies the relative safety of a drug:

$$TI = \frac{LD_{50}}{ED_{50}} \quad (\text{Equation 4-1})$$

Clearly, the higher the ratio, the safer the drug.

Values of TI vary widely, from 1-2 to more than 100. Drugs with a low TI must be administered with caution (e.g., the cardiac glycoside digoxin and cancer chemotherapeutic agents). Agents with very high TI (e.g., penicillin) are extremely safe in the absence of a known allergic response in a given patient. Note that use of median doses fails to consider that the slopes of the dose-response curves for therapeutic and lethal (toxic) effects may differ (Figure 4-1). As an alternative the ED_{99} for the therapeutic

Nonmonotonic Dose-Response Curves

Not all dose-response curves follow a typical sigmoidal shape. Three examples of these are shown in Figure 4-2. *U-shaped dose-response curves* can be observed for essential metals and vitamins (Figure 4-2A). At low dose, adverse effects are observed because there is a deficiency of these nutrients to maintain homeostasis. As dose increases, homeostasis is achieved, and the bottom of the U-shaped dose-response curve is reached. As dose increases to surpass the amount required to maintain homeostasis, overdose toxicity can ensue. Thus, adverse effects are seen at both low and high doses.

Some toxicants, such as formaldehyde, are also metabolic by-products for which cells have detoxifying mechanisms. Thus, very low doses of exogenous formaldehyde do not sufficiently exceed levels produced physiologically to elicit a significant adverse response, and do not saturate the detoxifying mechanisms, in this instance, alcohol dehydrogenase (ADH5/GSNOR; Pontel et al., 2015). When these endogenous protective mechanisms are overwhelmed, one will observe a toxic response. Toxicologists represent this type of response as a "hockey stick" (Figure 4-2B), a region of no response followed by an adverse response as the toxicant exceeds the endogenous protective mechanisms and rises sufficiently to cause an adverse response.

Inverted U-shaped dose response curves are observed when receptor downregulation/desensitization occurs following exposure to a ligand or when an additional and distinct negative effect occurs at a concentration beyond that which produces the primary positive effect.

For example, estrogen at high levels can have maximal effects. However, at supraphysiologic levels, the effects of estrogen are reduced, presumably due to downregulation of estrogen receptors. Many endocrine-disrupting chemicals are thought to have inverted U-shaped dose-response curves similar to that of estrogen. Indeed, multiphasic and U-shaped curves are

Abbreviations

ADEs: adverse drug events
ADME: absorption, distribution, metabolism, and elimination
CYP: cytochrome P450
ECG: electrocardiogram
ED₅₀: median effective dose
FDA: U.S. Food and Drug Administration
GI: gastrointestinal
Ig: immunoglobulin
IND: investigational new drug
IRB: institutional review board
LD₅₀: median lethal dose
SSRI: selective serotonin reuptake inhibitor
TI: therapeutic index
WBI: whole-bowel irrigation

common in complex systems in which an administered compound elicits multiple effects, first one effect and then another, possibly opposing, effect as the concentration increases. This phenomenon highlights a necessity for using an extensive dose range and a sufficient response time to ensure detection of the full spectrum of responsiveness and toxicity for a given substance.

Pharmacokinetics Versus Toxicokinetics

Alterations in ADME

Poisoning may significantly alter the functions of ADME (see Chapters 2, 5, and 6), and these alterations can profoundly alter treatment decisions and prognosis. The pharmacokinetics of a drug under circumstances that produce toxicity or excessive exposure are referred to as *toxicokinetics*. Ingesting larger-than-therapeutic doses of a pharmaceutical may prolong its absorption, alter its protein binding and apparent volume of distribution, and change its metabolic fate. When confronted with potential poisoning, two questions should be foremost in the clinician's mind:

- How long will an asymptomatic patient need to be monitored (drug absorption and dynamics)?
- How long will it take an intoxicated patient to get better (drug elimination and dynamics)?

Drug Absorption

Aspirin poisoning is a leading cause of overdose morbidity and mortality as reported to U.S. poison control centers (Bronstein et al., 2008). In therapeutic dosing, aspirin reaches peak plasma concentrations in about 1 h. However, aspirin overdose may cause spasm of the pyloric valve, delaying entry of the drug into the small intestine. Aspirin, especially enteric-coated forms, may coalesce into bezoars, reducing the effective surface area for absorption. Peak plasma salicylate concentrations from aspirin overdose may not be reached for 4–35 h after ingestion (Rivera et al., 2004).

Drug Elimination

Table 4–1 lists some pharmaceuticals notorious for their predilection to have initial symptoms develop *after* a typical 4- to 6-hour emergency medical observation period (Box 4–1).

Types of Therapeutic Drug Toxicity

In therapeutics, a drug typically produces numerous effects, but usually only one is sought as the primary goal of treatment; most of the other effects are undesirable effects for that therapeutic indication. *Side effects* of drugs usually are bothersome but not deleterious. Other undesirable effects may be characterized as toxic effects (Figure 4–3).

Figure 4–1 Dose-response relationships. **A.** The LD₅₀ of a compound is determined experimentally, usually by administration of the chemical to mice or rats (orally or intraperitoneally). The midpoint of the curve representing percentage of population responding (response here is death) versus dose (log scale) represents the LD₅₀, or the dose of drug that is lethal in 50% of the population. The LD₅₀ values for both compounds are the same (~10 mg/kg); however, the slopes of the dose-response curves are quite different. Thus, at a dose equal to one-half the LD₅₀ (5 mg/kg), fewer than 5% of the animals exposed to compound Y would die, but about 25% of the animals given compound X would die. **B.** Depiction of ED and LD. The crosshatched area between the ED₉₁ (10 mg/kg) and the LD₉ (100 mg/kg) gives an estimate of the margin of safety.

Dose-Dependent Reactions

Toxic effects of drugs may be classified as *pharmacological*, *pathological*, or *genotoxic*. Typically, the incidence and seriousness of the toxicity is proportionately related to the concentration of the drug in the body and to the duration of the exposure.

Pharmacological Toxicity. The CNS depression produced by barbiturates is largely predictable in a dose-dependent fashion. The progression of clinical effects goes from anxiolysis to sedation to somnolence to coma. Similarly, the degree of hypotension produced by nifedipine is related to the dose of the drug administered. Tardive dyskinesia (see Chapter 16), an extrapyramidal motor disorder associated with use of antipsychotic medications, seems to be dependent on duration of exposure. Pharmacological toxicity can also occur when the correct dose is given; for example, there is phototoxicity associated with exposure to sunlight in patients treated with tetracyclines, sulfonamides, chlorpromazine, and nalidixic acid.

Pathological Toxicity. Acetaminophen is metabolized to nontoxic glucuronide and sulfate conjugates and to a highly reactive metabolite NAPQI via CYP isoforms. At a therapeutic dose of acetaminophen, NAPQI binds

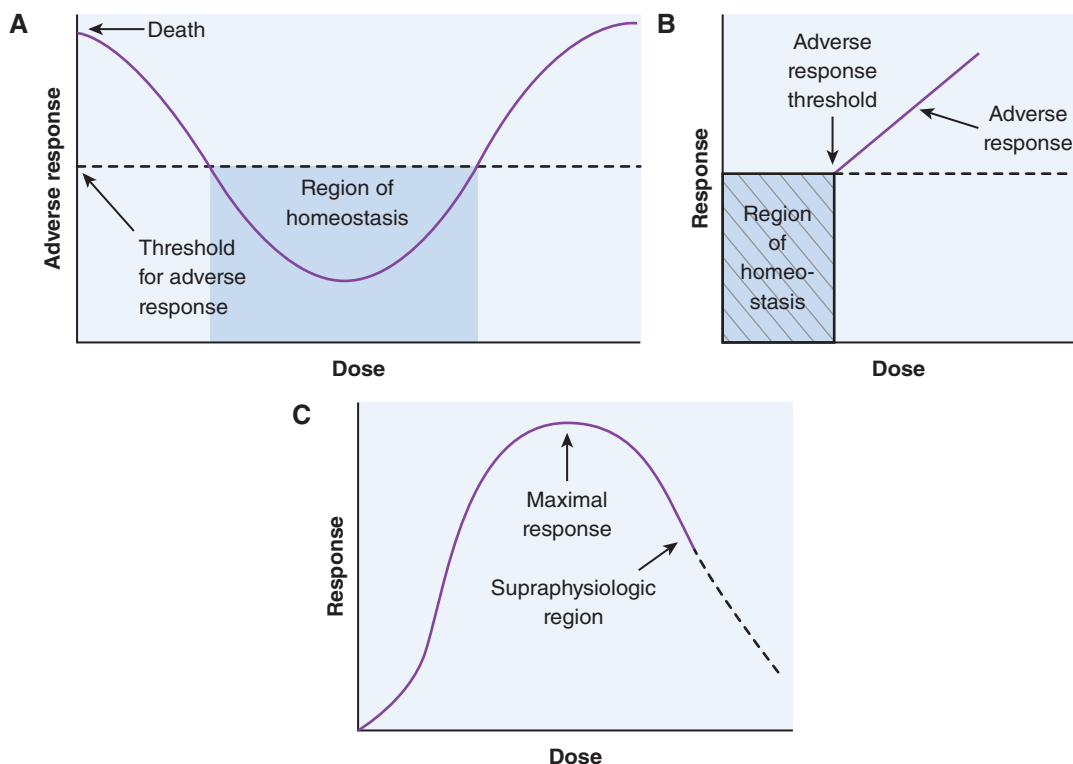

Figure 4-2 Nonmonotonic dose-response relationships. **A.** U-shaped dose-response curve for essential metals and vitamins. **B.** Hockey stick-shaped dose-response curve for toxicants that are also metabolic by-products. **C.** Inverted U-shaped dose-response curve for ligands that downregulate their receptors.

to nucleophilic glutathione, but in acetaminophen overdose, glutathione depletion may lead to the pathological finding of hepatic necrosis due to shunting of NAPQI toward interactions with nucleophilic cellular macromolecules (Figure 4-4).

Genotoxic Effects. Ionizing radiation and many environmental chemicals are known to injure DNA and may lead to mutagenic or carcinogenic toxicities. Many of the cancer chemotherapeutic agents (see Chapters 65–68) may be genotoxic (see Chapters 6 and 7).

Allergic Reactions

An *allergy* is an adverse reaction, mediated by the immune system, that results from previous sensitization to a particular chemical or to one that is structurally similar (see Chapter 34). Allergic responses have been divided into four general categories based on the mechanism of immunological involvement.

TABLE 4-1 ■ DRUGS THAT COMMONLY MANIFEST INITIAL SYMPTOMS MORE THAN 4–6 HOURS AFTER ORAL OVERDOSE^a

Acetaminophen
Aspirin
Illicit drugs in rubber or plastic packages
Monoamine oxidase inhibitors
Sulfonylureas
Sustained-release formulation drugs
Thyroid hormones
Valproic acid
Warfarin-like anticoagulants

^aDrugs coingested with agents having anticholinergic activity, as manifest by diminished GI motility, may also exhibit delayed onset of action.

Type I: Anaphylactic Reactions. Anaphylaxis is mediated by IgE antibodies. The Fc portion of IgE can bind to receptors on mast cells and basophils. If the Fab portion of the antibody molecule then binds an antigen, various mediators (e.g., histamine, leukotrienes, and prostaglandins) are released and cause vasodilation, edema, and an inflammatory response. The main targets of this type of reaction are the GI tract (food allergies), the skin (urticaria and atopic dermatitis), the respiratory system (rhinitis and asthma), and the vasculature (anaphylactic shock). These responses tend to occur quickly after challenge with an antigen to which the individual has been sensitized and are termed *immediate hypersensitivity reactions*.

Type II: Cytolytic Reactions. Type II allergies are mediated by both IgG and IgM antibodies and usually are attributed to their capacity to activate the complement system. The major target tissues for cytolytic reactions are the cells in the circulatory system. Examples of type II allergic responses include penicillin-induced hemolytic anemia, quinidine-induced thrombocytopenic purpura, and sulfonamide-induced granulocytopenia. These autoimmune reactions to drugs usually subside within several months after removal of the offending agent.

Type III: Arthus Reactions. Type III allergic reactions are mediated predominantly by IgG; the mechanism involves the generation of antigen-antibody complexes that subsequently fix complement. The complexes are deposited in the vascular endothelium, where a destructive inflammatory response called *serum sickness* occurs. The clinical symptoms of serum sickness include urticarial skin eruptions, arthralgia or

BOX 4-1 ■ Valproic Acid

After therapeutic dosing, valproic acid has an elimination $t_{1/2}$ of about 14 h. Valproic acid poisoning may lead to coma. In predicting the duration of the coma, it is important to consider that, after overdose, first-order metabolic processes for valproate appear to become saturated, and the apparent elimination $t_{1/2}$ may exceed 30–45 h (Sztajnkrzyer, 2002), putting the patient at risk for a much longer time.

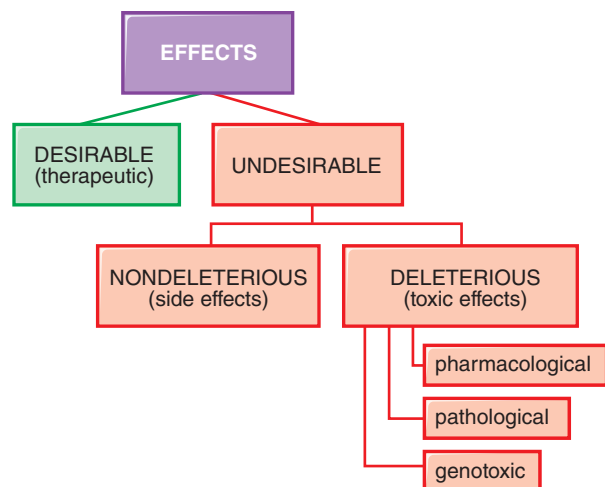

Figure 4-3 Spectrum of the effects of pharmaceuticals.

arthritis, lymphadenopathy, and fever. Several drugs, including commonly used antibiotics, can induce serum sickness-like reactions. These reactions usually last 6–12 days and then subside after the offending agent is eliminated.

Type IV: Delayed Hypersensitivity Reactions. These reactions are mediated by sensitized T lymphocytes and macrophages. When sensitized cells come in contact with antigen, an inflammatory reaction is generated by the production of lymphokines and the subsequent influx of neutrophils and macrophages. An example of type IV or delayed hypersensitivity is the contact dermatitis caused by poison ivy.

Idiosyncratic Reactions and Pharmacogenetic Contributions

Idiosyncrasy is an abnormal reactivity to a chemical that is peculiar to a given individual; the idiosyncratic response may be extreme sensitivity to

low doses or extreme insensitivity to high doses of drugs. A common mechanism is covalent drug binding to serum proteins that leads to the presentation of a foreign hapten, resulting in an immunotoxicological response.

Many interindividual differences in drug responses have a *pharmacogenetic basis* (see Chapter 7). A fraction of black males (~10%) develop a serious hemolytic anemia when they receive primaquine as an antimalarial therapy; this development is due to a genetic deficiency of erythrocyte glucose-6-phosphate dehydrogenase. Polymorphisms in NAT2 lead to a multimodal distribution of isoniazid acetylation and clearance (Figures 60–3 and 60–4). Variability in the anticoagulant response to warfarin is due to polymorphisms in CYP2C9 and VKORC1 (see Figure 7–7, Figure 32–6, and Table 32–2). In addition, CYP3A4 and CYP2D6 metabolize a large number of drugs in the liver (see Figure 6–3). Single nucleotide polymorphic variants in CYP3A4 and CYP2D6 can affect enzyme activity and thus alter drug $t_{1/2}$. Administration of a drug that is a CYP substrate in combination with a drug that is an inhibitor of the same CYP can lead to drug overdose toxicity. Many package inserts for drugs provide prescribing information warning of these drug-drug interactions.

Drug-Drug Interactions

Patients are commonly treated with more than one drug may also be using over-the-counter medications, vitamins, and other “natural” supplements; and may have unusual diets. All of these factors can contribute to drug interactions, a failure of therapy, and toxicity. Figure 4–5 summarizes the mechanisms and types of interactions.

Interaction of Absorption. A drug may cause either an increase or a decrease in the absorption of another drug from the intestinal lumen. Ranitidine, an antagonist of histamine H_2 receptors, raises gastrointestinal pH and may increase the absorption of basic drugs such as triazolam (O’Connor-Semmes et al., 2001). Conversely, the bile acid sequestrant cholestyramine leads to significantly reduced serum concentrations of propranolol (Hibbard et al., 1984).

Interaction of Protein Binding. Many drugs, such as aspirin, barbiturates, phenytoin, sulfonamides, valproic acid, and warfarin, are highly protein bound in the plasma, and it is the free (unbound) drug that produces the clinical effects. These drugs may have enhanced toxicity in overdose if protein-binding sites become saturated in physiological states that lead to hypoalbuminemia, or when displaced from plasma proteins by other drugs (Guthrie et al., 1995).

Interaction of Metabolism. A drug can frequently influence the metabolism of one or several other drugs (see Chapter 6), especially when hepatic CYPs are involved. Acetaminophen is partially transformed by CYP2E1 to the toxic metabolite NAPQI (see Figure 4–4). Intake of ethanol, a potent inducer of CYP2E1, may lead to increased susceptibility to acetaminophen poisoning after overdose (Dart et al., 2006).

Interaction of Receptor Binding. Buprenorphine is an opioid with partial agonist and antagonist receptor activities, commonly used to treat opioid addiction. The drug binds to opiate receptors with high affinity and can prevent euphoria from concomitant use of narcotic drugs of abuse.

Interaction of Therapeutic Action. Aspirin is an inhibitor of platelet aggregation, heparin is an anticoagulant; given together, they may increase risk for bleeding. Sulfonylureas cause hypoglycemia by stimulating pancreatic insulin release, whereas biguanide drugs (e.g., metformin) lead to decreased hepatic glucose production, and these drugs can be used together to control diabetic hyperglycemia.

Such drug interactions are *additive* when the combined effect of two drugs equals the sum of the effect of each agent given alone and *synergistic* when the combined effect exceeds the sum of the effects of each drug given alone. *Potentiation of toxicity* describes the creation of a toxic effect from one drug due to the presence of another drug. *Antagonism* is the interference of one drug with the action of another. *Functional* or *physiological antagonism* occurs when two chemicals produce opposite effects on the same physiological function. *Chemical antagonism*, or *inactivation*, is a reaction between two chemicals to neutralize their effects, such as is seen with chelation therapy. *Dispositional antagonism* is the alteration of

Figure 4-4 Pathways of acetaminophen metabolism and toxicity. The toxic intermediate NAPQI is N-acetyl-*p*-benzoquinoneimine.

Figure 4-5 Mechanisms and classification of drug interactions.

the disposition of a substance (its absorption, biotransformation, distribution, or excretion) so that less of the agent reaches the target organ or its persistence in the target organ is reduced. *Receptor* (meaning receptor, enzyme, drug transporter, ion channel, etc.) *antagonism* is the blockade of the effect of one drug by another drug that competes at the receptor site.

Descriptive Toxicity Testing in Animals

Two main principles or assumptions underlie all descriptive toxicity tests performed in animals.

First, those effects of chemicals produced in laboratory animals, when properly qualified, apply to human toxicity. When calculated on the basis of dose per unit of body surface, toxic effects in human beings usually are encountered in the same range of concentrations as those in experimental animals. On the basis of body weight, human beings generally are more vulnerable than experimental animals.

Second, exposure of experimental animals to toxic agents in high doses is a necessary and valid method to discover possible hazards to human beings who are exposed to much lower doses. This principle is based on the quantal dose-response concept. As a matter of practicality, the number of animals used in experiments on toxic materials usually will be small compared with the size of human populations potentially at risk. For example, 0.01% incidence of a serious toxic effect (such as cancer) represents 25,000 people in a population of 250 million. Such an incidence is unacceptably high. Yet, detecting an incidence of 0.01% experimentally probably would require a minimum of 30,000 animals. To estimate risk at low dosage, large doses must be given to relatively small groups instead. *The validity of the necessary extrapolation is clearly a crucial question.*

Chemicals are first tested for toxicity by estimation of the LD_{50} in two animal species by two routes of administration; one of these is the expected route of exposure of human beings to the chemical being tested. The number of animals that die in a 14-day period after a single dose is recorded. The animals also are examined for signs of intoxication, lethargy, behavioral modification, and morbidity. The chemical is next tested for toxicity by repeat exposure, usually for 90 days. This study is performed most often in two species by the route of intended use or exposure with at least three doses. A number of parameters are monitored during this period, and at the end of the study, organs and tissues are examined by a pathologist.

Long-term or chronic studies are carried out in animals at the same time that clinical trials are undertaken. For drugs, the length of exposure depends somewhat on the intended clinical use. If the drug normally would be used for short periods under medical supervision, as would an antimicrobial agent, a chronic exposure of animals for 6 months might

suffice. If the drug would be used in human beings for longer periods, a study of chronic use for 2 years may be required.

Studies of chronic exposure often are used to determine the carcinogenic potential of chemicals. These studies usually are performed in rats and mice for the average lifetime of the species. Other tests are designed to evaluate teratogenicity (congenital malformations), perinatal and postnatal toxicity, and effects on fertility. Teratogenicity studies usually are performed by administering drugs to pregnant rats and rabbits during the period of organogenesis. *In silico* computational methods of systems chemical biology may soon contribute to such studies.

Safety Pharmacology and Clinical Trials

Fewer than one-third of the drugs tested in clinical trials reach the marketplace. U.S. federal law and ethical considerations require that the study of new drugs in humans be conducted in accordance with stringent guidelines.

Once a drug is judged ready to be studied in humans, an IND application must be filed with the FDA. The IND includes (1) information on the composition and source of the drug; (2) chemical and manufacturing information; (3) all data from animal studies; (4) proposed clinical plans and protocols; (5) the names and credentials of physicians who will conduct the clinical trials; and (6) a compilation of the key data relevant to study the drug in humans made available to investigators and their IRBs.

Testing in humans begins only after sufficient acute and subacute animal toxicity studies have been completed. Chronic safety testing in animals, including carcinogenicity studies, is usually done concurrently with clinical trials. Accumulating and analyzing all necessary data often requires 4–6 years of clinical testing. In each of the three formal phases of clinical trials, volunteers or patients must be informed of the investigational status of the drug as well as the possible risks and must be allowed to decline or to consent to participate and receive the drug. These regulations are based on the ethical principles set forth in the Declaration of Helsinki. In addition, an interdisciplinary IRB at the facility where the clinical drug trial will be conducted must review and approve the scientific and ethical plans for testing in humans. The prescribed phases, time lines, and costs for developing a new drug are presented in Table 1-1 and Figure 1-1.

Epidemiology of Adverse Drug Responses and Pharmaceutical Poisoning

Poisoning can occur in many ways following therapeutic and nontherapeutic exposures to drugs or chemicals (Table 4-2). In the U.S., an estimated 2 million hospitalized patients have serious adverse drug

TABLE 4-2 ■ POTENTIAL SCENARIOS FOR THE OCCURRENCE OF POISONING

Therapeutic drug toxicity

Purposeful administration for self-harm
Purposeful administration to harm another

reactions each year, and about 100,000 suffer fatal adverse drug reactions (Lazarou et al., 1998). Use of good principles of prescribing, as described in Appendix I and Table 4-5, can aid in avoiding such adverse outcomes.

Some toxicities of pharmaceuticals can be predicted based on their known pharmacological mechanism; often, however, the therapeutic toxicity profile of a drug becomes apparent only during the postmarketing period. The Adverse Event Reporting System of the FDA relies on two signals to detect rarer ADEs. First, the FDA requires drug manufacturers to perform postmarketing surveillance of prescription drugs and non-prescription products. Second, the FDA operates a voluntary reporting system (MedWatch, at <http://www.fda.gov/Safety/MedWatch>) available to both health professionals and consumers. Hospitals may also support committees to investigate potential ADEs. Unfortunately, any national data set will likely underestimate the morbidity and mortality attributable to ADEs due to underreporting and the difficulty of estimating the denominator of total patient exposures.

Therapeutic drug toxicity is only a subset of poisoning, as noted in Table 4-2. Misuse and abuse of both prescription and illicit drugs are major public health problems. The incidence of unintentional, non-intentional poisoning is bimodal, primarily affecting exploratory young children, ages 1–5 years, and the elderly. *Intentional* overdose with pharmaceuticals is most common in adolescence and through adulthood. The substances most frequently involved in human exposures and fatalities are presented in Tables 4-3 and 4-4, respectively.

TABLE 4-3 ■ SUBSTANCES MOST FREQUENTLY INVOLVED IN HUMAN POISONING EXPOSURES

SUBSTANCE	%
Analgesics	11.3
Personal care products	7.7
Cleaning substances	7.7
Sedatives/hypnotics/antipsychotics	5.9
Antidepressants	4.4
Antihistamines	4.0
Cardiovascular drugs	4.0
Foreign bodies/toys/miscellaneous	3.9
Pesticides	3.2

In the subset of pediatric exposures (age < 5 years), cosmetic/personal care products and household cleaning products accounted for 25% of cases, followed by analgesics (9.3%), foreign bodies/toys (6.7%), topical preparations (5.8%), vitamins (4.5%), and antihistamines (4.3%).

Cardiovascular drugs	Alcohols
Acetaminophen (alone and in combinations)	SSRIs
Opioids	

As reported in Mowry et al., 2015.

Prevention of Poisoning

Reduction of Medication Errors

Over the past decade, considerable attention has been given to the reduction of medication errors and ADEs. Medication errors can occur in any part of the medication prescribing or use process, whereas ADEs are injuries related to the use or nonuse of medications. It is believed that medication errors are 50–100 times more common than ADEs (Bates et al., 1995). The “five rights” noted in Box 4-2 can serve as a corrective.

In practice, accomplishing a reduction in medication errors involves scrutiny of the systems involved in prescribing, documenting, transcribing, dispensing, administering, and monitoring a therapy, as presented in Appendix I. Good medication use practices have mandatory and redundant checkpoints (Figure 4-6), such as having a pharmacist, a doctor, and a nurse, all review and confirm, prior to the drug’s administration, that an ordered dose of a medication is appropriate for the patient. Several practical strategies can help to reduce medication errors within health care settings (Table 4-5).

Poisoning Prevention in the Home

There are several contexts into which poisoning prevention can be directed (Table 4-2). Depression and suicidal ideation need to be identified and treated. Exposure to hazards in the home, outdoor, and work environments need to be reduced to reasonably achievable levels. Poisoning prevention strategies may be categorized as *passive*, requiring no behavior change on the part of the individual, or *active*, requiring sustained adaptation to be successful. Passive prevention strategies are the most effective (Table 4-6). The incidence of poisoning in children has decreased dramatically over the past four decades, largely due to improved safety packaging of drugs, drain cleaners, turpentine, and other household chemicals; improved medical training and care; and increased public awareness of potential poisons.

Principles of Treatment of Poisoning

When toxicity is expected or occurs, the priorities of poisoning treatment are to

- Maintain vital physiological functions
- Reduce or prevent absorption and enhance elimination to minimize the tissue concentration of the poison
- Combat the toxicological effects of the poison at the effector sites (Box 4-3)

BOX 4-2 ■ Five Principles of Safe Medication

Following the “five rights” of safe medication administration can help practitioners avoid medication errors:

Right drug, right patient, right dose, right route, right time

Figure 4-6 The “Swiss cheese” model of medication error. Several checkpoints typically exist to identify and prevent an adverse drug event, and that adverse event can only occur if holes in several systems align. **A.** One systematic error does not lead to an adverse event because it is prevented by another check in the system. **B.** Several systematic errors can align to allow an adverse event to occur. (Data from Reason J, *Br Med J*, 2000;320:768–770.)

Identification of Clinical Patterns of Toxicity

A medical history may allow for the creation of a list of available medications or chemicals implicated in a poisoning event. Often, an observation of physical symptoms and signs may be the only additional clues to a poisoning diagnosis. Groups of physical signs and symptoms associated with specific poisoning syndromes are known as *toxidromes* (Erickson et al., 2007; Osterhoudt, 2004) (Table 4-7).

The urine drug toxicology test is an immunoassay designed to detect common drugs of abuse, such as amphetamines, barbiturates, benzodiazepines, cannabis, cocaine, and opiates. Acute poisoning with these substances can usually be determined on clinical grounds, and the results of these assays are infrequently available fast enough to guide stabilization. In addition, detection of drugs or their metabolites on a urine immunoassay does not mean that the detected drug is responsible for the currently observed poisoning illness. When ingestion of acetaminophen or aspirin cannot clearly be excluded via the exposure history, serum quantification of these drugs is recommended. An ECG may be useful at detecting heart

TABLE 4-5 ■ BEST PRACTICE RECOMMENDATIONS TO REDUCE MEDICATION ADMINISTRATION ERRORS^a

SHORT TERM

- Maintain unit-dose distribution systems for nonemergency medications
- Have pharmacies prepare intravenous solutions
- Remove inherently dangerous medications (e.g., concentrated KCl) from patient care areas
- Develop special procedures for high-risk drugs
- Improve drug-related clinical information resources
- Improve medication administration education for clinicians
- Educate patients about the safe and accurate use of medications
- Improve access of bedside clinicians to pharmacists

LONG TERM

Implement technology-based safeguards:

- Computerized order entry
- Computerized dose and allergy checking
- Computerized medication tracking
- Use of bar codes or electronic readers for medication preparation and administration

^aSee Massachusetts Coalition for the Prevention of Medical Errors, 2017.

TABLE 4-6 ■ PASSIVE POISONING PREVENTION STRATEGIES AND EXAMPLES

Reduce manufacture/sale of poisons	<i>Withdrawal of phenformin from U.S. pharmaceutical market</i>
Decrease amount of poison in a consumer product	<i>Limiting number of pills in a single bottle of baby aspirin</i>
Prevent access to poison	<i>Using child-resistant packaging</i>
Change product formulation	<i>Removing ethanol from mouthwash</i>

blocks, Na⁺ channel blockade, or K⁺ channel blockade associated with specific medication classes (Table 4-8). Further laboratory analysis should be tailored to the individual poisoning circumstance.

Decontamination of the Poisoned Patient

Poisoning exposures may be by inhalation, by dermal or mucosal absorption, by injection, or by ingestion. The first step in preventing absorption of poison is to stop any ongoing exposure. If necessary, eyes and skin should be washed copiously. GI decontamination prevents or reduces absorption of a substance after it has been ingested. The strategies for GI decontamination are *gastric emptying*, *adsorption of poison*, *WBI*, and *catharsis*. Minimal indications for considering GI decontamination include

- The poison must be potentially dangerous.
- The poison must still be unabsorbed in the stomach or intestine, so it must be soon after ingestion.
- The procedure must be able to be performed safely and with proper technique.

Gastric emptying is rarely recommended anymore (Manoguerra and Cobaugh, 2005), but the administration of activated charcoal and the performance of WBI remain therapeutic options. Gastric emptying reduces drug absorption by about one-third under optimal conditions (American Academy of Clinical Toxicology, 2004; Tenenbein et al., 1987) (see Syrup of Ipecac section that follows).

Adsorption

Adsorption of a poison refers to the binding of a poison to the surface of another substance so that the poison is less available for absorption into

BOX 4-3 ■ Initial Stabilization of the Poisoned Patient

The “ABCDE” mnemonic of emergency care applies to the treatment of acute poisoning:

Airway	Maintain patency
Breathing	Maintain adequate oxygenation and ventilation
Circulation	Maintain perfusion of vital organs
Disability	Assess for CNS dysfunction <i>If neurological disability is noted, consider</i> <ul style="list-style-type: none"> • O₂ administration (check pulse oximetry) • Dextrose administration (check [glucose] in blood) • Naloxone administration (consider empiric trial) • Thiamine (for adult patients receiving dextrose)
Exposure	Assess “toxidrome” (see Table 4-7)

In severe cases, endotracheal intubation, mechanical ventilation, pharmacological blood pressure support, or extracorporeal circulatory support may be necessary and appropriate.

TABLE 4-7 ■ COMMON TOXIDROMES

DRUG CLASS	EXAMPLE(S)	MENTAL STATUS	HR	BP	RR	T	PUPIL SIZE	OTHER
Sympathomimetic	Cocaine Amphetamine	Agitation	↑	↑		↑	↑	Tremor, diaphoresis
Anticholinergic	Diphenhydramine Atropine	Delirium	↑	↑		↑	↑	Ileus, flushing
Cholinergic	Organophosphates	Somnolence Coma			↑		↓	SLUDGE, ^a fasciculation
Opioid	Heroin Oxycodone	Somnolence Coma	↓		↓		↓

^aSLUDGE, muscarinic effects of salivation, lacrimation, urination, defecation, gastric cramping, and emesis.

the body. Fuller's earth has been suggested as an adsorbent for paraquat, Prussian blue binds thallium and cesium, and sodium polystyrene can adsorb lithium. The most common adsorbent used in the treatment of acute drug overdose is activated charcoal.

Activated Charcoal. Charcoal is created through controlled pyrolysis of organic matter and is *activated* through steam or chemical treatment, which increases its internal pore structure and adsorptive surface capacity. The surface of activated charcoal contains carbon moieties that are capable of binding poisons. The recommended dose is typically 0.5–2 g/kg of body weight, up to a maximum tolerated dose of about 75–100 g. As a rough estimate, 10 g of activated charcoal is expected to bind about 1 g of drug. Alcohols, corrosives, hydrocarbons, and metals are not well adsorbed by charcoal. Complications of activated charcoal therapy include vomiting, constipation, pulmonary aspiration, and death. Nasogastric administration of charcoal increases the incidence of vomiting (Osterhoudt et al., 2004) and may increase the risk for pulmonary aspiration. Charcoal should not be given to patients with suspected GI perforation or to patients who may be candidates for endoscopy. Use of activated charcoal in the treatment of poisoning has declined over the last 20 years to 2.1% of cases in 2014 (Mowry et al., 2015).

TABLE 4-8 ■ DIFFERENTIAL POISONING DIAGNOSIS (PARTIAL LISTING) FOR ELECTROCARDIOGRAPHIC MANIFESTATIONS OF TOXICITY

BRADYCARDIA/HEART BLOCK	QRS INTERVAL PROLONGATION	QTc INTERVAL PROLONGATION
Cholinergic agents Physostigmine Neostigmine Organophosphates, Carbamates Sympatholytic agents β Receptor antagonists Clonidine Opioids Other Digoxin Ca ²⁺ channel blockers Lithium	Antiarrhythmia drugs Bupropion Chloroquine Diphenhydramine Lamotrigine Phenothiazines Propranolol Tricyclic antidepressants	See CredibleMeds® QTDrugs List: https://www.crediblemeds.org/new-drug-list/

Whole-Bowel Irrigation

Whole-bowel irrigation involves the enteral administration of large amounts of a high-molecular-weight, iso-osmotic polyethylene glycol electrolyte solution with the goal of passing poison by the rectum before it can be absorbed. Potential candidates for WBI include:

- “body packers” with intestinal packets of illicit drugs
- patients with iron overdose
- patients who have ingested patch pharmaceuticals
- patients with overdoses of sustained-release or bezoar-forming drugs

Polyethylene glycol electrolyte solution is typically administered at a rate of 25–40 mL/kg/h until the rectal effluent is clear and no more drug is being passed. To achieve these high administration rates, a nasogastric tube may be used. WBI is contraindicated in the presence of bowel obstruction or perforation and may be complicated by abdominal distention or pulmonary aspiration.

Cathartics. The two most common categories of simple cathartics are the Mg²⁺ salts, such as magnesium citrate and magnesium sulfate, and the nondigestible carbohydrates, such as sorbitol. The use of simple cathartics has been abandoned as a GI decontamination strategy.

Gastric Lavage. The procedure for gastric lavage involves passing an orogastric tube into the stomach with the patient in the left lateral decubitus position with head lower than feet. After withdrawing stomach contents, 10–15 mL/kg (up to 250 mL) of saline lavage fluid is administered and withdrawn. This process continues until the lavage fluid returns clear. Complications of the procedure include mechanical trauma to the stomach or esophagus, pulmonary aspiration of stomach contents, and vagus nerve stimulation.

Syrup of Ipecac. The alkaloids cephaeline and emetine within syrup of ipecac act as emetics because of both a local irritant effect on the enteric tract and a central effect on the chemoreceptor trigger zone in the area postrema of the medulla. *Based on review of existing evidence, the American Academy of Pediatrics no longer recommends syrup of ipecac as part of its childhood injury prevention program, and the American Academy of Clinical Toxicology dissuades routine use of gastric emptying in the poisoned patient.* As a result, ipecac was administered in only 0.006% of all human poisonings in the U.S. in 2014 (Mowry et al., 2015).

Enhancing the Elimination of Poisons

Once absorbed, the deleterious toxicodynamic effects of some drugs may be reduced by methods that hasten their elimination from the body, as described next.

Manipulating Urinary pH: Urinary Alkalinization

Drugs subject to renal clearance are excreted into the urine by glomerular filtration and active tubular secretion; nonionized compounds may be reabsorbed far more rapidly than ionized polar molecules (see Chapter 2). Weakly acidic drugs are susceptible to “ion trapping” in the urine. Aspirin is a weak acid with a $pK_a = 3.0$. As the pH of the urine increases, more salicylate is in its ionized form at equilibrium, and more salicylic acid diffuses into the tubular lumen of the kidney. Urinary alkalinization is also believed to speed clearance of phenobarbital, chlorpropamide, methotrexate, and chlorophenoxy herbicides. The American Academy of Clinical Toxicologists recommends urine alkalinization as first-line treatment only for moderately severe salicylate poisoning that does not meet criteria for hemodialysis (Proudfoot et al., 2004).

To achieve alkalinization of the urine, 100–150 mEq of sodium bicarbonate in 1 L of 5% dextrose in water (D5W) is infused intravenously at twice the maintenance fluid requirements and then titrated to effect. Hypokalemia should be treated because it will hamper efforts to alkalinize the urine due to H^+K^+ exchange in the kidney. Urine alkalinization is contraindicated in renal failure or if fluid administration may worsen pulmonary edema or congestive heart failure. Acetazolamide is not used to alkalinize urine as it promotes acidemia.

Multiple-Dose Activated Charcoal

Activated charcoal adsorbs drug to its surface and promotes enteral elimination. Multiple doses of activated charcoal can speed elimination of absorbed drug by two mechanisms: Charcoal may interrupt enterohepatic circulation of hepatically metabolized drug excreted in the bile, and charcoal may create a diffusion gradient across the GI mucosa and promote movement of drug from the bloodstream onto the charcoal in the intestinal lumen. Activated charcoal may be administered in multiple doses, 12.5 g/h every 1, 2, or 4 h (smaller doses may be used for children). Charcoal enhances the clearance of many drugs of low molecular weight, small volume of distribution, and long elimination $t_{1/2}$. Multiple-dose activated charcoal is believed to have the highest potential utility in overdoses of carbamazepine, dapsone, phenobarbital, quinine, theophylline, and yellow oleander (American Academy of Clinical Toxicology, 1999; de Silva et al., 2003).

Extracorporeal Drug Removal

The ideal drug amenable to removal by hemodialysis has a low molecular weight, a low volume of distribution, high solubility in water, and minimal protein binding. Hemoperfusion involves passing blood through a cartridge containing adsorbent particles. The most common poisonings for which hemodialysis is sometimes used include salicylate, methanol, ethylene glycol, lithium, carbamazepine, and valproate.

Antidotal Therapies

Antidotal therapy involves antagonism or chemical inactivation of an absorbed poison. Among the most common specific antidotes used are *N*-acetyl-*L*-cysteine for acetaminophen poisoning, opioid antagonists for opioid overdose, and chelating agents for poisoning from certain metal ions. A list of antidotes used is presented in Table 4–9.

The pharmacodynamics of a poison can be altered by competition at a receptor, as in the antagonism provided by naloxone therapy in the setting of heroin overdose. A physiological antidote may use a different cellular mechanism to overcome the effects of a poison, as in the use of glucagon to circumvent a blocked β adrenergic receptor and increase cellular cyclic AMP in the setting of an overdose of a β adrenergic antagonist. Antivenoms and chelating agents bind and directly inactivate poisons. The biotransformation of a drug can also be altered by an antidote; for example, fomepizole will inhibit alcohol dehydrogenase and stop the formation of toxic acid metabolites from ethylene glycol and methanol. Many drugs used in the supportive care of a poisoned patient (anticonvulsants, vasoconstricting agents, etc.) may be considered nonspecific functional antidotes.

The mainstay of therapy for poisoning is good support of the airway, breathing, circulation, and vital metabolic processes of the poisoned patient until the poison is eliminated from the body.

TABLE 4–9 ■ COMMON ANTIDOTES AND THEIR INDICATIONS

ANTIDOTE	POISONING INDICATION(S)
Acetylcysteine	Acetaminophen
Atropine sulfate	Organophosphorus and carbamate pesticides
Benztropine	Drug-induced dystonia
Bicarbonate, sodium	Na^+ channel blocking drugs
Bromocriptine	Neuroleptic malignant syndrome
Calcium gluconate or chloride	Ca^{2+} channel blocking drugs, fluoride
Carnitine	Valproate hyperammonemia
Crotalidae polyvalent immune Fab	North American crotaline snake envenomation
Dantrolene	Malignant hyperthermia
Deferoxamine	Iron
Digoxin immune Fab	Cardiac glycosides
Diphenhydramine	Drug-induced dystonia
Dimercaprol (BAL)	Lead, mercury, arsenic
EDTA, $CaNa_2$	Lead
Ethanol	Methanol, ethylene glycol
Fomepizole	Methanol, ethylene glycol
Flumazenil	Benzodiazepines
Glucagon hydrochloride	β adrenergic antagonists
Hydroxocobalamin hydrochloride	Cyanide
Insulin (high dose)	Ca^{2+} channel blockers
Leucovorin calcium	Methotrexate
Methylene blue	Methemoglobinemia
Naloxone hydrochloride	Opioids
Octreotide acetate	Sulfonylurea-induced hypoglycemia
Oxygen, hyperbaric	Carbon monoxide
Penicillamine	Lead, mercury, copper
Physostigmine salicylate	Anticholinergic syndrome
Pralidoxime chloride (2-PAM)	Organophosphorus pesticides
Pyridoxine hydrochloride	Isoniazid seizures
Succimer (DMSA)	Lead, mercury, arsenic
Thiosulfate, sodium	Cyanide
Vitamin K_1 (phytonadione)	Coumarin, indanedione

Resources for Information on Drug Toxicity and Poisoning

Additional information on poisoning from drugs and chemicals can be found in many dedicated books of toxicology (Flomenbaum et al., 2006; Klaassen, 2013; Olson, 2011; Shannon et al., 2007). A popular computer database for information on toxic substances is POISINDEX® (Micromedex, Inc., Denver, CO). The National Library of Medicine offers information on toxicology and environmental health (<http://sis.nlm.nih.gov/enviro.html>), including a link to TOXNET® (<http://toxnet.nlm.nih.gov/>). Regional poison control centers are a resource for valuable poisoning

information and may be contacted within the U.S. through the national Poison Help hotline: 1-800-222-1222.

Acknowledgment: Curtis D. Klaassen and Kevin Osterhoudt contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

GENETIC VARIATION IN MEMBRANE TRANSPORTERS: IMPLICATIONS FOR CLINICAL DRUG RESPONSE

TRANSPORTERS IN REGULATORY SCIENCES

Membrane transport proteins are present in all organisms. These proteins control the influx of essential nutrients and ions and the efflux of cellular waste, environmental toxins, drugs, and other xenobiotics (Figure 5–1). Consistent with their critical roles in cellular homeostasis, about 2000 genes in the human genome, ~7% of the total number of genes, code for transporters or transporter-related proteins. The functions of membrane transporters may be facilitated (equilibrative, not requiring energy) or active (requiring energy). In considering the transport of drugs, pharmacologists generally focus on transporters from two major superfamilies, ABC and SLC transporters (Nigam, 2015).

Most ABC proteins are primary active transporters, which rely on ATP hydrolysis to actively pump their substrates across membranes. Among the best-recognized transporters in the ABC superfamily are Pgp (encoded by *ABCB1*, also termed *MDR1*) and CFTR (encoded by *ABCC7*).

The SLC superfamily includes genes that encode facilitated transporters and ion-coupled secondary active transporters. Fifty-two SLC families with about 395 transporters have been identified in the human genome (Hediger et al., 2013; Nigam et al., 2015). Many SLC transporters serve as drug targets or in drug absorption and disposition. Widely recognized SLC transporters include SERT and DAT, both targets for antidepressant medications.

absorption and elimination of endogenous substances and xenobiotics, including drugs. Transporters work in concert with drug-metabolizing enzymes to eliminate drugs and their metabolites (Figure 5–2). In addition, transporters in various cell types mediate tissue-specific drug distribution (drug targeting). Conversely, transporters also may serve as protective barriers to particular organs and cell types. For example, Pgp in the BBB protects the CNS from a variety of structurally diverse drugs through its efflux mechanisms.

Pharmacodynamics: Transporters as Drug Targets

Membrane transporters are the targets of many clinically used drugs. SERT (*SLC6A4*) is a target for a major class of antidepressant drugs, the SSRIs. Other neurotransmitter reuptake transporters serve as drug targets for the tricyclic antidepressants, various amphetamines (including amphetamine-like drugs used in the treatment of attention-deficit disorder in children), and anticonvulsants.

These transporters also may be involved in the pathogenesis of neuropsychiatric disorders, including Alzheimer and Parkinson diseases. An inhibitor of the vesicular monoamine transporter VMAT2 (*SLC18A2*), tetrabenazine, is approved for the symptomatic treatment of Huntington disease; the antichorea effect of tetrabenazine appears to relate to its capacity to deplete stores of biogenic amines by inhibiting their uptake into storage vesicles by VMAT2. Transporters that are nonneuronal also may be potential drug targets (e.g., cholesterol transporters in cardiovascular disease, nucleoside transporters in cancers, glucose transporters in metabolic syndromes, and $\text{Na}^+\text{-Cl}^-$ cotransporters in the SLC12 family in hypertension).

Recently, first-in-class drugs that inhibit Na^+ -glucose transporters in the SLC5 family (SGLT1 and SGLT2) have been approved for the

Membrane Transporters in Therapeutic Drug Responses

Pharmacokinetics

Transporters important in pharmacokinetics generally are located in intestinal, renal, and hepatic epithelia, where they function in the selective

Abbreviations

ABC: ATP binding cassette
ABCC: ATP binding cassette family C
ACE inhibitor: angiotensin-converting enzyme inhibitor
AUC: area under the concentration-time curve
BBB: blood-brain barrier
BCRP: breast cancer resistance protein
BSEP: bile salt export pump
CFTR: cystic fibrosis transmembrane regulator
 $CL_{int,all}$: overall hepatic intrinsic clearance
 CL_{met} : metabolic clearance
CPT-11: irinotecan hydrochloride
CSF: cerebrospinal fluid
DA: dopamine
DAT: dopamine transporter
FDA: U.S. Food and Drug Administration
GABA: γ -aminobutyric acid
GAT: GABA reuptake transporter
GSH, GSSG: reduced and oxidized glutathione
HIV: human immunodeficiency virus
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A
5HT: serotonin
 α -KG: α -ketoglutarate
LAT: large amino acid transporter
MAO: monoamine oxidase
MATE1: multidrug and toxin extrusion protein 1
MDMA: 3,4-methylenedioxymethamphetamine
MRP: multidrug resistance protein
NBDs: nucleotide-binding domains
NE: norepinephrine
NET: NE transporter
NME: new molecular entity
NTCP: Na^+ -taurocholate cotransporting polypeptide
OAT1: organic anion transporter 1
OCT1: organic cation transporter 1
OCTN: novel organic cation transporter
PAH: *p*-aminohippurate
PGE₂: prostaglandin E₂
Pgp: P-glycoprotein
PPAR α : peroxisome proliferator-activated receptor α
RAR: retinoic acid receptor
RXR: retinoid X receptor
SERT: serotonin transporter
SLC: solute carrier
SNP: single-nucleotide polymorphism
SXR: steroid X receptor
URAT1: uric acid transporter 1
XOI: xanthine oxidase inhibitor

treatment of type 2 diabetes. These drugs, which include canagliflozin, dapagliflozin, and empagliflozin, reduce renal reabsorption of glucose, thereby facilitating glucose elimination in the kidney. All three are prescribed as second-line therapy for treatment of inadequately controlled diabetes. In addition, lesinurad, a first-in-class drug that targets URAT1 (SLC22A12), was recently approved by the FDA for the treatment of gout when used with an XO; other URAT1 inhibitors are in clinical trial. These drugs are uricosurics and act by selectively inhibiting uric acid reabsorption in the kidney.

Finally, a first-in-class drug, ivacaftor, was recently approved for the treatment of patients with cystic fibrosis who harbor a coding mutation in CFTR (ABCC7), CFTR-G551D. Ivacaftor, termed a potentiator, increases the probability that the mutant chloride channel, CFTR-G551D, remains in the open state. Other drugs in clinical trials for CFTR include

both potentiators and correctors, compounds that enhance trafficking of mutant proteins to the plasma membrane.

Drug Resistance

Membrane transporters play critical roles in the development of resistance to anticancer drugs, antiviral agents, and anticonvulsants. *Decreased uptake of drugs*, such as folate antagonists, nucleoside analogues, and platinum complexes, is mediated by reduced expression of influx transporters required for these drugs to access the tumor. *Enhanced efflux of hydrophobic drugs* is one mechanism of antitumor resistance in cellular assays of resistance. The overexpression of MRP4 is associated with resistance to antiviral nucleoside analogues (Aceti et al., 2015). Pgp (MDR1, ABCB1) and BCRP (ABCG2) can be overexpressed in tumor cells after exposure to cytotoxic anticancer agents and are implicated in resistance to these agents, exporting anticancer drugs, reducing their intracellular concentration, and rendering cells resistant to the drugs' cytotoxic effects. Modulation of MDR1 expression and activity to regulate drug resistance could be a useful adjunct in pharmacotherapy (Gu and Manautou, 2010; He et al., 2011; Toyoda et al., 2008).

Membrane Transporters and Adverse Drug Responses

As controllers of import and export, transporters ultimately control the exposure of cells to chemical carcinogens, environmental toxins, and drugs. Thus, transporters play crucial roles in the cellular activities and toxicities of these agents. Transporter-mediated adverse drug responses generally can be classified into three categories (Figure 5-3):

- Decreased uptake or excretion at clearance organs
- Increased uptake or decreased efflux at target organs
- Altered transport of endogenous compounds at target organs

Transporters expressed in the liver and kidney, as well as metabolic enzymes, are key determinants of drug exposure in the systemic circulation, thereby affecting exposure, and hence toxicity, in all organs (Figure 5-3, top panel). For example, after oral administration of an HMG-CoA reductase inhibitor (e.g., pravastatin), the efficient first-pass hepatic uptake of the drug by the SLC OATP1B1 maximizes the effects of such drugs on hepatic HMG-CoA reductase. Uptake by OATP1B1 also minimizes the escape of these drugs into the systemic circulation, where they can cause adverse responses, such as skeletal muscle myopathy.

Transporters expressed in tissues that may be targets for drug toxicity (e.g., brain) or in barriers to such tissues (e.g., the BBB) can tightly control local drug concentrations and thus control the exposure of these tissues to the drug (Figure 5-3, middle panel). For example, endothelial cells in the BBB are linked by tight junctions, and some efflux transporters are expressed on the blood-facing (luminal) side, thereby restricting the penetration of compounds into the brain. The interactions of loperamide and quinidine are good examples of transporter control of drug exposure at this site. Loperamide is a peripheral opioid used in the treatment of diarrhea and is a substrate of Pgp, which prevents accumulation of loperamide in the CNS. Inhibition of Pgp-mediated efflux in the BBB would cause an increase in the concentration of loperamide in the CNS and potentiate adverse effects. Indeed, coadministration of loperamide and the potent Pgp inhibitor quinidine results in significant respiratory depression, an adverse response to loperamide. Pgp is also expressed in the intestine, where inhibition of Pgp will reduce intestinal efflux of loperamide, increase its systemic concentrations, and contribute to increased concentrations in the CNS.

Drug-induced toxicity sometimes is caused by the concentrative tissue distribution mediated by influx transporters. For example, biguanides (e.g., metformin), used for the treatment of type 2 diabetes mellitus, can produce lactic acidosis, a lethal side effect. Biguanides are substrates of the OCT1 (SLC22A1), which is highly expressed in the liver; of OCT2 (SLC22A2), expressed in the kidney; and of OCT3 (SLC22A3) in adipocytes and skeletal muscle. In experimental animals lacking OCT1,

Figure 5-1 Membrane transporters in pharmacokinetic pathways. Membrane transporters (T) play roles in pharmacokinetic pathways (drug absorption, distribution, metabolism, and excretion), thereby setting systemic drug levels. Drug levels often drive therapeutic and adverse drug effects.

hepatic uptake of biguanides and development of lactic acidosis are greatly reduced. These results indicate that OCT1-mediated hepatic uptake of biguanides and uptake into tissues such as kidney and skeletal muscle mediated by other OCTs play an important role in facilitating tissue concentrations of biguanides and thus the development of lactic acidosis (Wang et al., 2003), which may result from biguanide-induced impairment of mitochondrial function and consequent increased glycolytic flux (Dykens et al., 2008). Biguanides are exported by the MATE1 transporter, and inhibition of this efflux by a variety of drugs, including tyrosine kinase inhibitors, enhances biguanide toxicity (DeCorter et al., 2012).

OAT1 (SLC22A1), OCT1, and OCT2 provide other examples of transporter-related toxicity. OAT1 is expressed mainly in the kidney and is responsible for the renal tubular secretion of anionic compounds. Substrates of OAT1, such as cephaloridine (a β -lactam antibiotic) and adenofovir and cidofovir (antiviral drugs), reportedly cause nephrotoxicity.

Exogenous expression of OCT1 and OCT2 enhances the sensitivities of tumor cells to the cytotoxic effect of oxaliplatin for OCT1 and cisplatin and oxaliplatin for OCT2 (Zhang et al., 2006a). Renal toxicity of cisplatin is modulated by OCT2 present on the basolateral membrane of the proximal tubule as well as by transporters in the SLC47 family, MATE1 (SLC47A1) and MATE2 (SLC47A2), on the apical membrane (Harrach and Ciarimboli, 2015).

Drugs may modulate transporters for endogenous ligands and thereby exert adverse effects (Figure 5-3, bottom panel). For example, bile acids are taken up mainly by NTCP and excreted into the bile by BSEP (*ABCB11*). Bilirubin is taken up by OATP1B1 and conjugated with glucuronic acid; bilirubin glucuronide is excreted into the bile by the MRP2 (*ABCC2*) and transported into the blood by MRP3. Bilirubin glucuronide in the blood undergoes reuptake into the liver by OATP1B1. Inhibition of these transporters by drugs may cause cholestasis or hyperbilirubinemia.

Figure 5-2 Hepatic drug transporters. Membrane transporters (red ovals with arrows) work in concert with phase 1 and phase 2 drug-metabolizing enzymes in the hepatocyte to mediate the uptake and efflux of drugs and their metabolites.

Figure 5-3 Major mechanisms by which transporters mediate adverse drug responses. Three cases are given. The left panel of each case provides a representation of the mechanism; the right panel shows the resulting effect on drug levels. (*Top panel*) Increase in the plasma concentrations of drug due to a decrease in the uptake or secretion in clearance organs (e.g., liver and kidney). (*Middle panel*) Increase in the concentration of drug in toxicological target organs due to enhanced uptake or reduced efflux. (*Bottom panel*) Increase in the plasma concentration of an endogenous compound (e.g., a bile acid) due to a drug inhibiting the influx of the endogenous compound in its eliminating or target organ. The diagram also may represent an increase in the concentration of the endogenous compound in the target organ owing to drug-inhibited efflux of the endogenous compound.

Uptake and efflux transporters determine the plasma and tissue concentrations of endogenous compounds and xenobiotics, thereby influencing the systemic or site-specific toxicity of drugs.

Basic Mechanisms of Membrane Transport

Transporters Versus Channels

Both channels and transporters facilitate the membrane permeation of inorganic ions and organic compounds. In general, channels have two primary states, open and closed, that are stochastic phenomena. Only in the open state do channels appear to act as pores for the selected

ions flowing down an electrochemical gradient. After opening, channels return to the closed state as a function of time. As noted, drugs termed *potentiators* (e.g., ivacaftor) may increase the probability that a channel is in the open state. By contrast, a transporter forms an intermediate complex with the substrate (solute), and a subsequent conformational change in the transporter induces translocation of the substrate to the other side of the membrane. As a consequence, the kinetics of solute movement differ between transporters and channels. Typical turnover rate constants of channels are 10^6 to 10^8 s^{-1} ; those of transporters are, at most, 10^1 to 10^3 s^{-1} . Because a particular transporter forms intermediate complexes with specific compounds (referred to as *substrates*), transporter-mediated membrane transport is characterized by saturability

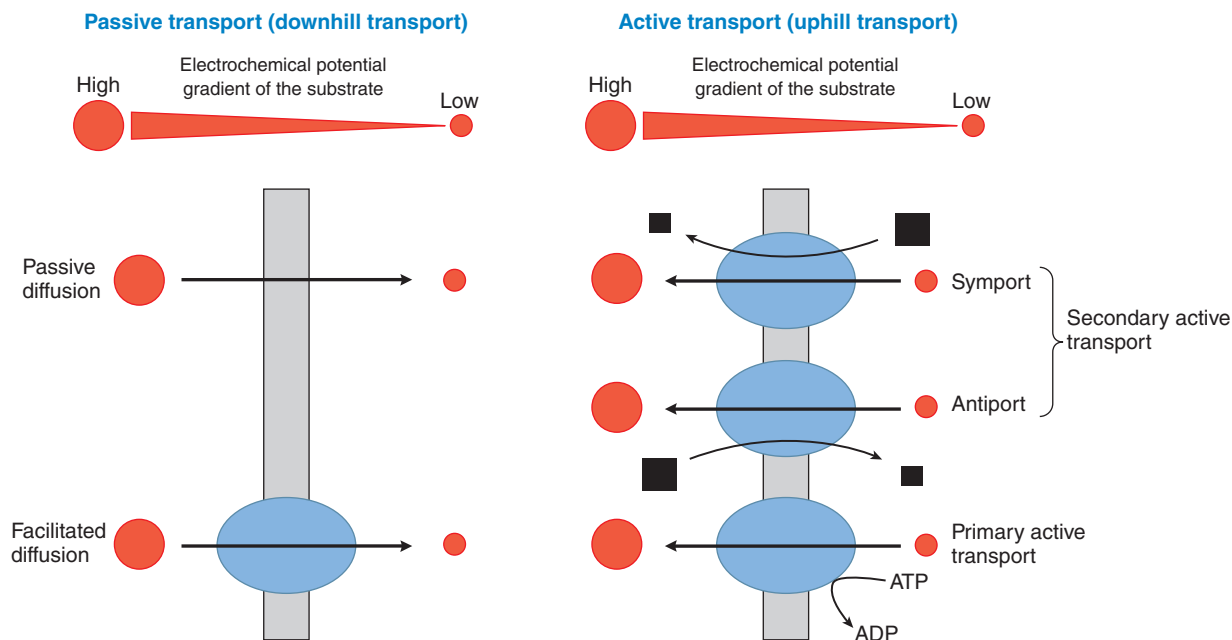

Figure 5-4 Classification of membrane transport mechanisms. Red circles depict the substrate. Size of the circles is proportional to the concentration of the substrate. Arrows show the direction of flux. Black squares represent the ion that supplies the driving force for transport (size is proportional to the concentration of the ion). Blue ovals depict transport proteins.

and inhibition by substrate analogues, as described in the section Kinetics of Transport.

The basic mechanisms involved in solute transport across biological membranes include passive diffusion, facilitated diffusion, and active transport. Active transport can be further subdivided into primary and secondary active transport. These mechanisms are depicted in Figure 5-4.

Passive Diffusion

Simple diffusion of a solute across the plasma membrane consists of three processes: partition from the aqueous to the lipid phase, diffusion across the lipid bilayer, and repartition into the aqueous phase on the opposite side. Passive diffusion of any solute (including drugs) occurs down an electrochemical potential gradient of the solute.

Facilitated Diffusion

Diffusion of ions and organic compounds across the plasma membrane may be facilitated by a membrane transporter. Facilitated diffusion is a form of transporter-mediated membrane transport that does not require energy input. Just as in passive diffusion, the transport of ionized and non-ionized compounds across the plasma membrane occurs down their electrochemical potential gradients. Therefore, steady state will be achieved when the electrochemical potentials of a compound on both sides of the membrane become equal.

Active Transport

Active transport is the form of membrane transport that requires the input of energy. It is the transport of solutes against their electrochemical gradients, leading to the concentration of solutes on one side of the plasma membrane and the creation of potential energy in the electrochemical gradient formed. Active transport plays an important role in the uptake and efflux of drugs and other solutes. Depending on the driving force, active transport can be subdivided into primary active transport in which ATP hydrolysis is coupled directly to solute transport, and secondary active transport, in which transport uses the energy in an existing electrochemical gradient established by an ATP-using process to move a solute uphill against its electrochemical gradient. Secondary active transport is further subdivided into symport and antiport. Symport describes movement of driving ion and transported solute in the same direction. Antiport occurs when the driving ion and the transported solute move in opposite directions, as when the

sodium/calcium exchanger (SLC8A1) transports 3Na^+ into and 1Ca^{2+} out of a cardiac ventricular myocyte (see Figure 5-4).

Primary Active Transport

Membrane transport that directly couples with ATP hydrolysis is called *primary active transport*. ABC transporters are examples of primary active transporters. In mammalian cells, ABC transporters mediate the unidirectional efflux of solutes across biological membranes. Another example of primary active transport that establishes the inward Na^+ gradient and outward K^+ gradient across the plasma membrane, found in all mammalian cells, is the Na^+, K^+ -ATPase.

Secondary Active Transport

In secondary active transport, the transport across a biological membrane of a solute S_1 against its concentration gradient is energetically driven by the transport of another solute S_2 in accordance with its electrochemical gradient. Depending on the transport direction of the solute, secondary active transporters are classified as either symporters or antiporters. For example, using the inwardly directed Na^+ concentration gradient across the plasma membrane that the Na^+, K^+ -ATPase maintains, the inward movement of 3Na^+ can drive the outward movement of 1Ca^{2+} via the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, NCX. This is an example of antiport, or exchange transport, in which the transporter moves S_2 and S_1 in opposite directions. *Symporters*, also termed *cotransporters*, transport S_2 and S_1 in the same direction, as for glucose transport into the body from the lumen of the small intestine by the Na^+ -glucose transporter SGLT1 (see Figure 5-4).

Kinetics of Transport

The flux of a substrate (rate of transport) across a biological membrane via a transporter-mediated process is characterized by saturability. The relationship between the flux v and substrate concentration C in a transporter-mediated process is given by the Michaelis-Menten equation:

$$v = \frac{V_{\max} C}{K_m + C} \quad (\text{Equation 5-1})$$

where V_{\max} is the maximum transport rate and is proportional to the density of transporters on the plasma membrane, and K_m is the Michaelis

constant, which represents the substrate concentration at which the flux is half the V_{\max} value. K_m is an approximation of the dissociation constant of the substrate from the intermediate complex. The K_m and V_{\max} values can be determined by examining the flux at different substrate concentrations. Rearranging Equation 5-1 gives

$$v = -K_m \frac{v}{C} + V_{\max} \quad (\text{Equation 5-2})$$

Plotting v versus v/C provides a convenient graphical method for determining the V_{\max} and K_m values, the Eadie-Hofstee plot (Figure 5-5): The slope is $-K_m$ and the y intercept is V_{\max} .

Transporter-mediated membrane transport of a substrate is also characterized by inhibition by other compounds. The manner of inhibition can be categorized as one of three types: *competitive*, *noncompetitive*, and *uncompetitive*. Competitive inhibition occurs when substrates and inhibitors share a common binding site on the transporter, resulting in an increase in the apparent K_m value in the presence of inhibitor. The flux of a substrate in the presence of a competitive inhibitor is

$$v = \frac{V_{\max} C}{K_m (1 + I/K_i) + C} \quad (\text{Equation 5-3})$$

where I is the concentration of inhibitor, and K_i is the inhibition constant. Noncompetitive inhibition assumes that the inhibitor has an allosteric effect on the transporter, does not inhibit the formation of an intermediate complex of substrate and transporter, but does inhibit the subsequent translocation process.

$$v = \frac{V_{\max} C}{K_m (1 + I/K_i) + C(1 + I/K_i)} \quad (\text{Equation 5-4})$$

Uncompetitive inhibition assumes that inhibitors can form a complex only with an intermediate complex of the substrate and transporter and inhibit subsequent translocation.

$$v = \frac{V_{\max} C}{K_m + C(1 + I/K_i)} \quad (\text{Equation 5-5})$$

Figure 5-5 Eadie-Hofstee plot of transport data. The black lines show the hyperbolic concentration-dependence curve (v vs. C , left panel) and the Eadie-Hofstee transformation of the transport data (v/C vs. v , right panel) for a simple transport system. The blue lines depict transport in the presence of a competitive inhibitor (surmountable inhibition; achieves same V_{\max}). The red lines depict the system in the presence of a noncompetitive inhibitor that effectively reduces the number of transporting sites but leaves the K_m of the functional sites unchanged. Involvement of multiple transporters with different K_m values gives an Eadie-Hofstee plot that is curved and can be resolved into multiple components. Algebraically, the Eadie-Hofstee plot of kinetic data is equivalent to the Scatchard plot of equilibrium binding data (see Chapter 3).

Transporter Structure and Mechanism

Predictions of secondary structure of membrane transport proteins based on hydropathy analysis indicate that membrane transporters in the SLC and ABC superfamilies are multimembrane-spanning proteins. Emerging crystals structures are adding to our ideas of the mechanisms of transport via these proteins.

ABC Transporters

The ABC superfamily includes 49 genes, each containing one or two conserved ABC regions. The core catalytic ABC regions of these proteins bind and hydrolyze ATP, using the energy for uphill transport of their substrates across the membrane. Most ABC transporters in eukaryotes move compounds from the cytoplasm to the cell exterior or into an intracellular compartment (endoplasmic reticulum, mitochondria, peroxisomes). ABC transporters also are found in prokaryotes, where they are involved predominantly in the import of essential compounds that cannot be obtained by passive diffusion (sugars, vitamins, metals, etc.).

ABC transporters have NBDs on the cytoplasmic side. The NBDs are considered the motor domains of ABC transporters and contain conserved motifs (e.g., Walker-A motif, ABC signature motif) that participate in binding and hydrolysis of ATP. Crystal structures of all four full ABC transporters show two NBDs, which are in contact with each other, and a conserved fold. The mechanism, shared by these ABC transporters, appears to involve binding of ATP to the NBDs, which subsequently triggers an outward-facing conformation of the transporters. Dissociation of the hydrolysis products of ATP appears to result in an inward-facing conformation. In the case of drug extrusion, when ATP binds, the transporters open to the outside, releasing their substrates to the extracellular media. On dissociation of the hydrolysis products, the transporters return to the inward-facing conformation, permitting the binding of ATP and substrate (Figure 5-6). Although some ABC superfamily transporters contain only a single ABC motif, they form homodimers (BCRP/ABCG2) or heterodimers (ABCG5 and ABCG8) that exhibit a transport function.

SLC Transporters

The SLC superfamily of transporters comprises a structurally diverse group that includes channels, facilitators, and secondary active

Figure 5-6 Model of ABC transporter function. The transporter accepts a solute molecule at the cytoplasmic membrane surface when its nucleotide NBDs are fully charged with ATP. Sequential hydrolysis of the ATP molecules produces steric change and leads to the translocation and release of the solute at the exterior membrane surface. Exchange of ADP for ATP on both NBDs completes the cycle and restores the system for readiness to transport another solute molecule.

transporters (Hediger et al., 2013). SLC substrates include ionic and nonionic species and a variety of xenobiotics and drugs. Nonetheless, for a number of SLC transporters that are important to pharmacokinetics and pharmacodynamics, there are a few common structural and mechanistic aspects. Human SLC transporters may use an alternating access, the gated pore mechanism, whereby the transporter exposes a single solute binding site interchangeably at either side of the membrane barrier (Figure 5-7).

In general terms, the transporter undergoes a reversible conformational change between the two sides of the membrane during the translocation process. The transport cycle would be as follows: The substrate accesses the substrate binding site on one side of the membrane; substrate binding induces structural changes in the carrier protein, reorienting the opening of the binding site to the opposite side. The substrate dissociates from the transport site, allowing another substrate to be bound and transported in the opposite direction. Such a mechanism requires that binding of different substrates (the “outbound” and “inbound” substrates) that is mutually exclusive; that is, there is a single reorienting binding site. Variations of the model are possible, and some are based on crystal structures of bacterial

homologs of human transporters, where two distinctive protomers are joined in the cytoplasmic side by a connecting loop, supporting a rocker switch mechanism (Figure 5-7).

Vectorial Transport

Asymmetrical transport across a monolayer of polarized cells, such as the epithelial and endothelial cells of brain capillaries, is called *vectorial transport* (Figure 5-8). Vectorial transport is important for the absorption of nutrients and bile acids in the intestine in the intestinal absorption of drugs (from lumen to blood). Vectorial transport also plays a major role in hepatobiliary and urinary excretion of drugs from the blood to the lumen. In addition, efflux of drugs from the brain via brain endothelial cells and brain choroid plexus epithelial cells involves vectorial transport. The ABC transporters mediate only unidirectional efflux, whereas SLC transporters mediate either drug uptake or drug efflux. For lipophilic compounds that have sufficient membrane permeability, ABC transporters alone are able to achieve vectorial transport without the help of influx transporters. For

Figure 5-7 Alternating access models of the transport of two transporters. The gated pore represents the model for SGLT in which the rotation of two broken helices facilitates alternating access of substrates to the intracellular and extracellular sides of the plasma membrane. The rocker switch represents the model by which major facilitator superfamily (MFS) proteins, such as Lac Y, work. This example models a facilitated glucose transporter, GLUT2.

Figure 5–8 *Transepithelial and transendothelial flux.* Transepithelial or transendothelial flux of drugs requires distinct transporters at the two surfaces of the epithelial or endothelial barrier. These are depicted diagrammatically for transport across the small intestine (absorption), the kidney, liver (elimination), and brain capillary endothelial cells that comprise the BBB.

relatively hydrophilic organic anions and cations, coordinated uptake and efflux transporters in the polarized plasma membranes are necessary to achieve the vectorial movement of solutes across an epithelium. A typical configuration involves a primary or secondary active transporter at one membrane and a passive transporter at the other. In this way, common substrates of coordinated transporters are transferred efficiently across the epithelial barrier.

In the liver, a number of transporters with different substrate specificities are localized on the sinusoidal membrane (facing blood). These transporters are involved in the uptake of bile acids, amphipathic organic anions, and hydrophilic organic cations into the hepatocytes. Similarly, ABC transporters on the canalicular membrane (facing bile) export such compounds into the bile. Multiple combinations of uptake (OATP1B1, OATP1B3, OATP2B1) and efflux transporters (MDR1, MRP2, and BCRP) are involved in the efficient transcellular transport of a wide variety of compounds in the liver by using a system called “doubly transfected cells”; these cells express both uptake and efflux transporters on each side. In many cases, overlapping substrate specificities between the uptake transporters (OATP family) and efflux transporters (MRP family) make the vectorial transport of organic anions highly efficient. Similar transport systems also are present in the intestine, renal tubules, and endothelial cells of the brain capillaries (see Figure 5–8).

Transporter expression can be regulated transcriptionally in response to drug treatment and pathophysiological conditions, resulting in induction or downregulation of transporter mRNAs. Type II nuclear receptors, which form heterodimers with the 9-*cis*-retinoic acid receptor (RXR), can regulate transcription of genes for drug-metabolizing enzymes and transporters (see Table 6–4, Figure 6–8, and Urquhart et al., 2007). Such receptors include PXR (NR1I2), CAR (NR1I3), FXR (NR1H4), PPAR α , and RAR. Except for CAR, these are ligand-activated nuclear receptors that, as heterodimers with RXR, bind specific elements in the enhancer regions of target genes. CAR has constitutive transcriptional activity that is antagonized by inverse agonists, such as androsthenol and androstanol, and induced by barbiturates. PXR, also referred to as SXR in humans, is activated by synthetic and endogenous steroids, bile acids, and drugs such as clotrimazole, phenobarbital, rifampicin, sulfapyrazone, ritonavir, carbamazepine, phenytoin, sulfadimidine, paclitaxel, and hyperforin (a constituent of St. John's wort) (Guo and Zhou, 2015). The potency of activators of PXR varies among species, such that rodents are not necessarily a model for effects in humans. There is an overlap of substrates between CYP3A4 and Pgp, and PXR mediates coinduction of CYP3A4 and Pgp, supporting their synergy in efficient detoxification. Recent studies in human hepatocytes treated with an activator of PXR suggested that the expression levels of enzymes in the CYP family are much more highly increased than the levels of transporters in the SLC or ABC families

(Smith et al., 2014). Table 5–1 summarizes the effects of drug activation of type II nuclear receptors on expression of transporters.

DNA methylation is one mechanism underlying the epigenetic control of gene expression. Reportedly, the tissue-selective expression of transporters is achieved by DNA methylation (silencing in the transporter-negative tissues) as well as by transactivation in the transporter-positive tissues. Transporters subjected to epigenetic control include OAT3, URAT1, OCT2, OATP1B2, NTCP, and PEPT2 in the SLC families and MDR1, BCRP, BSEP, and ABCG5/ABCG8 (Imai et al., 2009).

Transporter Superfamilies in the Human Genome

The SLC Superfamily

The SLC superfamily includes 52 families and represents about 395 genes in the human genome, the products of which are membrane-spanning proteins, some of which are associated with genetic diseases (Table 5–2). Myriad substrates, including inorganic and organic ions, interact with SLC transporters. There are highly selective transporters that interact with structurally similar molecules, such as transporters in the SLC18 family that interact with monoamines. On the other hand, there are transporters that accept a broad range of chemically diverse substrates, such as organic ion transporters in the SLC22 family. Unlike ABC transporters that rely on ATP hydrolysis to actively translocate their substrates, SLC transporters are mostly facilitative transporters, although some are secondary active transporters (see Figure 5–4). Knowledge of the superfamily continues to grow; in the past decade, about 100 new human SLC transporters have been identified (Lin et al., 2015).

The physiologic roles of SLC transporters are important and diverse. For example, transporters in the SLC1, SLC3, SLC6, SLC7, SLC25, and SLC36 families, which are expressed in the intestine and kidney, among other organs, transport an array of amino acids critical in protein synthesis and energy homeostasis. Glucose and other sugars interact with transporters in the SLC2, SLC5, and SLC50 families for absorption, elimination, and cellular distribution. Proteins in the SLC11, SLC30, SLC39, and SLC40 families transport zinc, iron, and other metals. Members of the SLC19, SLC46, and SLC52 families transport water-soluble vitamins. Transporters in the SLC6 family move neurotransmitters across the plasma membrane; SLC18 family members transport neurotransmitters into storage vesicles.

Pharmacologically, SLC transporters have been characterized for their role in drug absorption, elimination, and tissue distribution and importantly as mediators of drug-drug interactions. Notably, transporters in the solute carrier organic anion family, SLCO, interact with diverse substrates,

TABLE 5-1 ■ REGULATION OF TRANSPORTER EXPRESSION BY NUCLEAR RECEPTORS IN HUMANS

TRANSPORTER	TRANSCRIPTION FACTOR	LIGAND	EFFECT
MDR1 (Pgp)	PXR	Rifampin	↑ Transcription activity
			↑ Expression in duodenum
			↓ Oral bioavailability of digoxin
			↓ AUC of talinolol
			↑ Expression in primary hepatocyte
	CAR	St John's wort	↑ Expression in duodenum
			↓ Oral bioavailability of digoxin
MRP2	PXR	Rifampin	↑ Expression in duodenum
		Rifampin/hyperforin	↑ Expression in primary hepatocyte
	FXR	GW4064/chenodeoxycholate	↑ Expression in HepG2-FXR
	CAR	Phenobarbital	↑ Expression in hepatocyte
BCR	PXR	Rifampin	↑ Expression in primary hepatocyte
	CAR	Phenobarbital	
MRP3	PXR	Rifampin	↑ Expression in hepatocyte

including statins and antidiabetic drugs. Transporters in the SLC22 family interact with anionic and cationic drugs, including many antibiotics and antiviral agents, to mediate active renal secretion. SLC transporters are increasingly being targeted for treatment of human disease. Over 100 SLC transporters are associated with monogenic disorders and therefore may be usefully targeted in the treatment of rare diseases. Many SNPs in SLC transporters have reached a genome-wide level of significance in association studies of human disease. Notably, polymorphisms in *SLC30A8* are associated with type 1 diabetes mellitus, and polymorphisms in *SLC22A4* and *SLC22A5* are associated with inflammatory bowel disease.

The ABC Superfamily

The seven groups of ABC transporters are essential for many cellular processes, and mutations in at least 13 of the genes for ABC transporters cause or contribute to human genetic disorders (Table 5-3). In addition to conferring multidrug resistance, an important pharmacological aspect of these transporters is xenobiotic export from healthy tissues. In particular, MDR1/*ABCB1*, MRP2/*ABCC2*, and BCRP/*ABCG2* are involved in overall drug disposition.

Tissue Distribution of Drug-Related ABC Transporters

Table 5-4 summarizes the tissue distribution of drug-related ABC transporters in humans along with information about typical substrates. MDR1 (*ABCB1*), MRP2 (*ABCC2*), and BCRP (*ABCG2*) are all expressed in the apical side of the intestinal epithelia, where they serve to pump out xenobiotics, including many orally administered drugs. MRP3 (*ABCC3*) is expressed in the basal side of the epithelial cells.

Key to the vectorial excretion of drugs into urine or bile, ABC transporters are expressed in the polarized tissues of kidney and liver: MDR1, MRP2, BCRP, and MRP4 (*ABCC4*) on the brush border membrane of renal epithelia; MDR1, MRP2, and BCRP on the bile canalicular

membrane of hepatocytes; and MRP3 and MRP4 on the sinusoidal membrane of hepatocytes. Some ABC transporters are expressed specifically on the blood side of the endothelial or epithelial cells that form barriers to the free entrance of toxic compounds into tissues: the BBB (MDR1 and MRP4 on the luminal side of brain capillary endothelial cells), the blood-CSF barrier (MRP1 and MRP4 on the basolateral blood side of choroid plexus epithelia), the blood-testis barrier (MRP1 on the basolateral membrane of mouse Sertoli cells and MDR1 in several types of human testicular cells), and the blood-placenta barrier (MDR1, MRP2, and BCRP on the luminal maternal side and MRP1 on the antiluminal fetal side of placental trophoblasts).

MRP/ABCC Family

The substrates of transporters in the MRP/ABCC family are mostly organic anions. Both MRP1 and MRP2 accept glutathione and glucuronide conjugates, sulfated conjugates of bile salts, and nonconjugated organic anions of an amphipathic nature (at least one negative charge and some degree of hydrophobicity). They also transport neutral or cationic anticancer drugs, such as vinca alkaloids and anthracyclines, possibly by means of a cotransport or symport mechanism with GSH. MRP3 also has a substrate specificity that is similar to that of MRP2 but with a lower transport affinity for glutathione conjugates compared with MRP1 and MRP2. MRP3 is expressed on the sinusoidal side of hepatocytes and is induced under cholestatic conditions. MRP3 functions to return toxic bile salts and bilirubin glucuronides into the blood circulation. MRP4 accepts negatively charged molecules, including cytotoxic compounds (e.g., 6-mercaptopurine and methotrexate), cyclic nucleotides, antiviral drugs (e.g., adefovir and tenofovir), diuretics (e.g., furosemide and trichlormethiazide), and cephalosporins (e.g., ceftizoxime and cefazolin). Glutathione enables MRP4 to accept taurocholate and leukotriene B₄. MRP5 has a narrower substrate specificity and accepts nucleotide analogue and clinically

TABLE 5-2 ■ THE HUMAN SOLUTE CARRIER SUPERFAMILY

GENE	FAMILY	SELECTED DRUG SUBSTRATES	EXAMPLES OF LINKED HUMAN DISEASES
<i>SLC1</i>	Low- K_m glu/neutral aa T		Dicarboxylic aminoaciduria
<i>SLC2</i>	Facilitative GLUT		Fanconi-Bickel syndrome
<i>SLC3</i>	Heavy subunits, heteromeric aa Ts	Melphalan	Classic cystinuria type I
<i>SLC4</i>	Bicarbonate T		Distal renal tubule acidosis
<i>SLC5</i>	Na^+ glucose co-T	Dapagliflozin	Glucose-galactose malabsorption
<i>SLC6</i>	Na^+/Cl^- -dependent neurotransmitter T	Paroxetine, fluoxetine	Cerebral creatine deficiency syndrome
<i>SLC7</i>	Cationic aa T	Melphalan	Lysinuric protein intolerance
<i>SLC8</i>	$\text{Na}^+/\text{Ca}^{2+}$ Exch	$\text{Di-CH}_3\text{-arg}$	
<i>SLC9</i>	Na^+/H^+ Exch	Thiazide diuretics	Hypophosphatemic nephrolithiasis
<i>SLC10</i>	Na^+ bile salt co-T	Benzothiazepines (diltiazem)	Primary bile acid malabsorption
<i>SLC11</i>	H^+ -coupled metal ion T		Hereditary hemochromatosis
<i>SLC12</i>	Electroneutral cation- Cl^- co-T		Gitelman syndrome
<i>SLC13</i>	$\text{Na}^+/\text{SO}_4^{2-}/\text{COO}^-$ co-T	$\text{SO}_4^{2-}/\text{cys}$ conjugates	
<i>SLC14</i>	Urea T		Kidd antigen blood group
<i>SLC15</i>	H^+ -oligopeptide co-T	Valacyclovir	
<i>SLC16</i>	Monocarboxylate T	Salicylate, T_3/T_4 , atorvastatin	Familial hyperinsulinemic hypoglycemia 7
<i>SLC17</i>	Vesicular glu T		Sialic acid storage disease
<i>SLC18</i>	Vesicular amine T	Reserpine	Myasthenic syndromes
<i>SLC19</i>	Folate/thiamine T	Methotrexate	Thiamine-responsive megaloblastic anemia
<i>SLC20</i>	Type III $\text{Na}^+/\text{PO}_4^{3-}$ co-T		
<i>SLC21 (SLCO)</i>	Organic anion T	Pravastatin	Rotor syndrome, hyperbilirubinemia
<i>SLC22</i>	Organic ion T	Pravastatin, metformin	Primary systemic carnitine deficiency
<i>SLC23</i>	Na^+ -dependent ascorbate T	Vitamin C	
<i>SLC24</i>	$\text{Na}^+/(Ca^{2+}-K^+)$ Exch		Congenital stationary night blindness type 1D
<i>SLC25</i>	Mitochondrial carrier		Familial hypertrophic cardiomyopathy
<i>SLC26</i>	Multifunctional anion Exch	Salicylate, ciprofloxacin	Multiple epiphyseal dysplasia 4
<i>SLC27</i>	Fatty acid T		Ichthyosis prematurity syndrome
<i>SLC28</i>	Na^+ -coupled nucleoside T	Gemcitabine, cladribine	
<i>SLC29</i>	Facilitative nucleoside T	Dipyridamole, gemcitabine	
<i>SLC30</i>	Zn efflux		Hyper manganeseemia with dystonia
<i>SLC31</i>	Cu T	Cisplatin	
<i>SLC32</i>	Vesicular inhibitory aa T	Vigabatrin	
<i>SLC33</i>	Acetyl-CoA T		Congenital cataracts
<i>SLC34</i>	Type II $\text{Na}^+/\text{PO}_4^{3-}$ co-T		Hypercalciuric rickets
<i>SLC35</i>	Nucleoside-sugar T		Leukocyte adhesion deficiency II
<i>SLC36</i>	H^+ -coupled aa T	D-Serine, cycloserine	Iminoglycinuria
<i>SLC37</i>	Sugar-phosphate/ PO_4^{3-} Exch		Glycogen storage disease
<i>SLC38</i>	Na^+ -coupled neutral aa T		
<i>SLC39</i>	Metal ion T		Acrodermatitis enteropathica
<i>SLC40</i>	Basolateral Fe T		Hemochromatosis type IV
<i>SLC41</i>	MgtE-like Mg^{2+} T		
<i>SLC42</i>	Rh ammonium T		Rh-null regulator type disease
<i>SLC43</i>	Na^+ -independent L-like aa T	Riboflavin	Oculocutaneous albinism type 4
<i>SLC45</i>	Unknown substrate		Riboflavin deficiency
<i>SLC52</i>	Riboflavin transporter family

TABLE 5-3 ■ THE HUMAN ATP BINDING CASSETTE (ABC) SUPERFAMILY

GENE	FAMILY	NUMBER OF MEMBERS	EXAMPLES OF LINKED HUMAN DISEASES
<i>ABCA</i>	ABC A	12	Tangier disease (defect in cholesterol transport; <i>ABCA1</i>), Stargardt syndrome (defect in retinal metabolism; <i>ABCA4</i>)
<i>ABCB</i>	ABC B	11	Bare lymphocyte syndrome type 1 (defect in antigen presenting; <i>ABCB3</i> and <i>ABCB4</i>), progressive familial intrahepatic cholestasis type 3 (defect in biliary lipid secretion; <i>MDR3/ABCB4</i>), X-linked sideroblastic anemia with ataxia (a possible defect in iron homeostasis in mitochondria; <i>ABCB7</i>), progressive familial intrahepatic cholestasis type 2 (defect in biliary bile acid excretion; <i>BSEP/ABCB11</i>)
<i>ABCC</i>	ABC C	13	Dubin-Johnson syndrome (defect in biliary bilirubin glucuronide excretion; <i>MRP2/ABCC2</i>), pseudoxanthoma (unknown mechanism; <i>ABCC6</i>), cystic fibrosis (defect in Cl^- channel regulation; <i>ABCC7</i>), persistent hyperinsulinemic hypoglycemia of infancy (defect in inwardly rectifying K^+ conductance regulation in pancreatic B cells; <i>SUR1/ABCC8</i>)
<i>ABCD</i>	ABC D	4	Adrenoleukodystrophy (a possible defect in peroxisomal transport or catabolism of very long-chain fatty acids; <i>ABCD1</i>)
<i>ABCE</i>	ABC E	1	
<i>ABCF</i>	ABC F	3	
<i>ABCG</i>	ABC G	5	Sitosterolemia (defect in biliary and intestinal excretion of plant sterols; <i>ABCG5</i> and <i>ABCG8</i>)

TABLE 5-4 ■ ABC TRANSPORTERS INVOLVED IN DRUG ABSORPTION, DISTRIBUTION, AND EXCRETION PROCESSES

NAME TISSUE DISTRIBUTION	SUBSTRATES
MDR1 (ABCB1) Liver, kidney, intestine, BBB, BTB, BPB	Characteristics: Bulky neutral or cationic compounds (many xenobiotics)—etoposide, doxorubicin, vincristine; diltiazem, verapamil; indinavir, ritonavir; erythromycin, ketoconazole; testosterone, progesterone; cyclosporine, tacrolimus; digoxin, quinidine, fexofenadine, loperamide
MRP1 (ABCC1) Ubiquitous	Characteristics: Negatively charged amphiphiles—vincristine (with GSH), methotrexate; GSH conjugate of LTC_4 , ethacrynic acid; glucuronide of estradiol, bilirubin; estrone-3-sulfate; saquinavir; grepafloxacin; folate, GSH, GSSG
MRP2 (ABCC2) Liver, kidney, intestine, BPB	Characteristics: Negatively charged amphiphiles—methotrexate, vincristine; GSH conjugates of LTC_4 , ethacrynic acid; glucuronides of estradiol, bilirubin; tauroolithocholate sulfate; statins, AngII receptor antagonists, temocaprilat; indinavir, ritonavir; GSH, GSSG
MRP3 (ABCC3) Liver, kidney, intestine	Characteristics: Negatively charged amphiphiles—etoposide, methotrexate; GSH conjugates of LTC_4 , PGJ_2 ; glucuronides of estradiol, etoposide, morphine, acetaminophen, hymecromone, harmol; sulfate conjugates of bile salts; glycocholate, taurocholate; folate, leucovorin
MRP4 (ABCC4) Ubiquitous, including BBB and BCSFB	Characteristics: Nucleotide analogues, 6-mercaptopurine, methotrexate; estradiol glucuronide; dehydroepiandrosterone sulfate; cyclic AMP/GMP; furosemide, trichlormethiazide; adefovir, tenofovir; cefazolin, ceftizoxime; folate, leucovorin, taurocholate (with GSH)
MRP5 (ABCC5) Ubiquitous	Characteristics: Nucleotide analogues 6-mercaptopurine; cyclic AMP/GMP; adefovir
MRP6 (ABCC6) Liver, kidney	Characteristics: Doxorubicin, ^a etoposide, ^a GSH conjugate of LTC_4 ; BQ-123 (cyclic penta peptide antagonist at the ETA endothelin receptor)
BCRP(MXR) (ABCG2) Liver, intestine, BBB	Characteristics: Neutral and anionic compounds—methotrexate, mitoxantrone, camptothecins, SN-38, topotecan, imatinib; glucuronides of 4-methylumbelliferone, estradiol; sulfate conjugates of dehydroepiandrosterone, estrone; nitrofurantoin, fluoroquinolones; pitavastatin, rosuvastatin; cholesterol, estradiol, dantrolene, prazosin, sulfasalazine, uric acid, allopurinol, oxypurinol
MDR3 (ABCB4) Liver	Characteristics: Phospholipids
BSEP (ABCB11) Liver	Characteristics: Bile salts
ABCG5, ABCG8 Liver, intestine	Characteristics: Plant sterols

BBB, blood-brain barrier; BTB, blood-testis barrier; BPB, blood-placenta barrier; BCSFB, blood-cerebrospinal fluid barrier; LTC_4 , Leukotriene C; PGJ_2 , prostaglandin J.

^aSubstrates and cytotoxic drugs with increased resistance (cytotoxicity with increased resistance is usually caused by the decreased accumulation of the drugs). Although MDR3 (ABCB4), BSEP (ABCB11), ABCG5, and ABCG8 are not directly involved in drug disposition, their inhibition will lead to unfavorable side effects.

important anti-HIV drugs. No substrates have been identified that explain the mechanism of the MRP6-associated disease pseudoxanthoma.

BCRP/ABCG2

BCRP accepts both neutral and negatively charged molecules, including cytotoxic compounds (e.g., topotecan, flavopiridol, and methotrexate); sulfated conjugates of therapeutic drugs and hormones (e.g., estrogen sulfate); antibiotics (e.g., nitrofurantoin and fluoroquinolones); statins (e.g., pitavastatin and rosuvastatin); and toxic compounds found in normal food [phytoestrogens, (2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine), and pheophorbide A, a chlorophyll catabolite]. In addition, genetic variants in the transporter have been implicated in hyperuricemia and gout and in the disposition of uric acid and the XOIs allopurinol and oxypurinol.

Physiological Roles of ABC Transporters

The physiological significance of the ABC transporters has been amply illustrated by studies involving knockout animals or patients with genetic defects in these transporters. For instance, mice deficient in MDR1 function are viable and fertile and do not display obvious phenotypic abnormalities other than hypersensitivity to the toxicity of drugs. There are equally remarkable data for MRP1, MRP4, BCRP, and BSEP. The lesson is this: Complete absence of these drug-related ABC transporters is not lethal and can remain unrecognized in the absence of exogenous perturbations due to food, drugs, or toxins. However, inhibition of physiologically important ABC transporters (especially those related directly to the genetic diseases described in Table 5–3) by drugs should be avoided to reduce the incidence of drug-induced side effects.

ABC Transporters in Drug Absorption and Elimination

With respect to clinical medicine, MDR1 is the most renowned ABC transporter yet identified. The systemic exposure to orally administered digoxin is decreased by coadministration of rifampin (an MDR1 inducer) and is negatively correlated with the MDR1 protein expression in the human intestine. MDR1 is also expressed on the brush border membrane of renal epithelia, and its function can be monitored using digoxin (> 70% excreted in the urine). MDR1 inhibitors (e.g., quinidine, verapamil, valsopodar, spironolactone, clarithromycin, and ritonavir) all markedly reduce renal excretion of digoxin. Drugs with narrow therapeutic windows (e.g., digoxin, cyclosporine, tacrolimus) should be used with great care if MDR1-based drug-drug interactions are likely.

In the intestine, MRP3 can mediate intestinal absorption in conjunction with uptake transporters. MRP3 mediates sinusoidal efflux in the liver, decreasing the efficacy of the biliary excretion from the blood and excretion of intracellularly formed metabolites, particularly glucuronide conjugates. Thus, dysfunction of MRP3 results in shortening of the elimination $t_{1/2}$. MRP4 substrates also can be transported by OAT1 and OAT3 on the basolateral membrane of the epithelial cells in the kidney. The rate-limiting process in renal tubular secretion is likely the uptake process at the basolateral surface. Dysfunction of MRP4 enhances the renal concentration but has limited effect on the blood concentration.

Transporters Involved in Pharmacokinetics

Drug transporters play a prominent role in pharmacokinetics (see Figure 5–1 and Table 5–4). Transporters in the liver and kidney have important roles in removal of drugs from the blood and hence in metabolism and excretion.

Hepatic Transporters

Hepatic uptake of organic anions (e.g., drugs, leukotrienes, and bilirubin), cations, and bile salts is mediated by SLC-type transporters in the basolateral (sinusoidal) membrane of hepatocytes: OATPs (SLCO), OCTs (SLC22), and NTCP (SLC10A1), respectively. These transporters mediate uptake by either facilitated or secondary active mechanisms.

ABC transporters such as MRP2, MDR1, BCRP, BSEP, and MDR2 in the bile canalicular membrane of hepatocytes mediate the efflux (excretion) of drugs and their metabolites, bile salts, and phospholipids against a steep concentration gradient from liver to bile. This primary active transport is driven by ATP hydrolysis.

Vectorial transport of drugs from the circulating blood to the bile using an uptake transporter (OATP family) and an efflux transporter (MRP2, BCRP) is important for determining drug exposure in the circulating blood and liver. Moreover, there are many other uptake and efflux transporters in the liver (Figure 5–9).

The following examples illustrate the importance of vectorial transport in determining drug exposure in the circulating blood and liver and the role of transporters in drug-drug interactions.

HMG-CoA Reductase Inhibitors

Statins are cholesterol-lowering agents that reversibly inhibit HMG-CoA reductase, which catalyzes a rate-limiting step in cholesterol biosynthesis (see Chapter 33). Most of the statins in their acid form are substrates of hepatic uptake transporters and undergo enterohepatic recirculation (see Figure 5–6). In this process, hepatic uptake transporters such as OATP1B1 and efflux transporters such as MRP2 act cooperatively to produce *bisubstrate vectorial transcellular transport*. The efficient first-pass hepatic uptake of these statins by OATP1B1 helps concentrate them in the liver where they produce their pharmacological effects, thus minimizing their systemic levels and adverse effects in smooth muscle. Genetic polymorphisms of OATP1B1 also affect the function of this transporter (Meyer zu Schwabedissen et al., 2015).

Gemfibrozil

The cholesterol-lowering agent gemfibrozil, a PPAR α activator, can enhance toxicity (myopathy) to several statins by a mechanism that involves transport. Gemfibrozil and its glucuronide inhibit the uptake of the active hydroxy forms of statins into hepatocytes by OATP1B1, resulting in an increase in the plasma concentration of the statin and a concomitant increase in toxicity.

Irinotecan

CPT-11 is a potent anticancer drug, but late-onset GI toxicities, such as severe diarrhea, make this a difficult agent to use safely. After intravenous administration of CPT-11, a carboxylesterase converts the drug to SN-38, an active metabolite. SN-38 is subsequently conjugated with glucuronic acid in the liver. SN-38 and SN-38 glucuronide are then excreted into the bile by MRP2, entering the GI tract and causing adverse effects. The inhibition of MRP2-mediated biliary excretion of SN-38 and its glucuronide by coadministration of probenecid reduces the drug-induced diarrhea in experimental systems and may prove useful in humans (Horikawa et al., 2002). For additional details, see Figures 6–6, 6–8, 6–9.

Bosentan

Bosentan is an endothelin antagonist used to treat pulmonary arterial hypertension. It is taken up in the liver by OATP1B1 and OATP1B3 and subsequently metabolized by CYP2C9 and CYP3A4. Transporter-mediated hepatic uptake can be a determinant of elimination of bosentan, and inhibition of its hepatic uptake by cyclosporine, rifampicin, and sildenafil can affect its pharmacokinetics.

Temocapril and other ACE inhibitors

Temocapril is an ACE inhibitor (see Chapter 26). Its active metabolite, temocaprilat, is excreted both in the bile and in the urine by the liver and kidney, respectively, whereas other ACE inhibitors are excreted mainly by the kidney. A special feature of temocapril among ACE inhibitors is that the plasma concentration of temocaprilat remains relatively unchanged even in patients with renal failure. However, the plasma AUC of enalaprilat and other ACE inhibitors is markedly increased in patients with renal disorders. Temocaprilat is a bisubstrate of the OATP family and MRP2, whereas other ACE inhibitors are not good substrates of MRP2 (although they are taken up into the liver by the OATP family). Taking these findings into consideration, the affinity for MRP2 may dominate in determining the biliary excretion of any series of ACE inhibitors. Drugs that are

Figure 5–9 Transporters in the hepatocyte that function in the uptake and efflux of drugs across the sinusoidal membrane and efflux of drugs into the bile across the canalicular membrane. Arrows show the primary direction of transport. See text for details of the transporters pictured.

excreted into both the bile and urine to the same degree thus are expected to exhibit minimum interindividual differences in their pharmacokinetics.

Angiotensin II Receptor Antagonists

Angiotensin II receptor antagonists are used for the treatment of hypertension, acting on AT_1 receptors expressed in vascular smooth muscle, proximal tubule, adrenal medullary cells, and elsewhere. For most of these drugs, hepatic uptake and biliary excretion are important factors for their pharmacokinetics and pharmacological effects. Telmisartan is taken up into human hepatocytes in a saturable manner, predominantly via OATP1B3 (Ishiguro et al., 2006). On the other hand, both OATPs 1B1 and 1B3 are responsible for the hepatic uptake of valsartan and olmesartan, although the relative contributions of these transporters are unclear. Studies using doubly transfected cells with hepatic uptake transporters and biliary excretion transporters have clarified that MRP2 plays the most important role in the biliary excretion of valsartan and olmesartan.

Repaglinide and Nateglinide

Repaglinide is a meglitinide analogue antidiabetic drug. Although it is eliminated almost completely by the metabolism mediated by CYPs 2C8 and 3A4, transporter-mediated hepatic uptake is one of the determinants of its elimination rate. In subjects with the OATP1B1 (*SLCO1B1*) 521CC genotype, a significant change in the pharmacokinetics of repaglinide was observed (Niemi et al., 2005). Genetic polymorphism in *SLCO1B1* 521T>C results in altered pharmacokinetics of nateglinide, suggesting OATP1B1 is a determinant of its elimination, although it is subsequently metabolized by CYPs 2C9, 3A4, and 2D6 (Zhang et al., 2006b).

Renal Transporters

Organic Cation Transport

Structurally diverse organic cations are secreted in the proximal tubule. Many secreted organic cations are endogenous compounds (e.g., choline, *N*-methylnicotinamide, and DA), and renal secretion helps to eliminate excess concentrations of these substances. Another function of organic cation secretion is ridding the body of xenobiotics, including many positively charged drugs and their metabolites (e.g., cimetidine, ranitidine, metformin, varenicline, and trospium) and toxins from the environment

(e.g., nicotine and paraquat). Organic cations that are secreted by the kidney may be either hydrophobic or hydrophilic. Hydrophilic organic drug cations generally have molecular weights less than 400 Da; a current model for their secretion in the proximal tubule of the nephron is shown in Figure 5–10 involving the transporters described next.

For the transepithelial flux of a compound (e.g., secretion), the compound must traverse two membranes sequentially, the basolateral membrane facing the blood side and the apical membrane facing the tubular lumen. Organic cations appear to cross the basolateral membrane in the human proximal tubule by two distinct transporters in the SLC family 22 (SLC22): OCT2 (*SLC22A2*) and OCT3 (*SLC22A3*). Organic cations are transported across this membrane down an electrochemical gradient.

Transport of organic cations from cell to tubular lumen across the apical membrane occurs through an electroneutral proton–organic cation

Figure 5–10 Organic cation secretory transporters in the proximal tubule. OC^+ , organic cation. See text for details of the transporters pictured.

exchange, which is mediated by transporters in the SLC47 family, which comprises members of the MATE family. Transporters in the MATE family, assigned to the apical membrane of the proximal tubule, appear to play a key role in moving hydrophilic organic cations from tubule cell to lumen. In addition, OCTNs, located on the apical membrane, appear to contribute to organic cation flux across the proximal tubule. In humans, these include *OCTN1* (SLC22A4) and *OCTN2* (SLC22A5). These bifunctional transporters are involved not only in organic cation secretion but also in carnitine reabsorption. In the reuptake mode, the transporters function as Na^+ cotransporters, relying on the inwardly driven Na^+ gradient created by Na^+, K^+ -ATPase to move carnitine from tubular lumen to cell. In the secretory mode, the transporters appear to function as proton–organic cation exchangers. That is, protons move from tubular lumen to cell interior in exchange for organic cations, which move from cytosol to tubular lumen. The inwardly directed proton gradient (tubular lumen \rightarrow cytosol) is maintained by transporters in the SLC9 family, which are Na^+/K^+ exchangers (NHEs, antiporters). Of the two steps involved in secretory transport, transport across the luminal membrane appears to be rate limiting.

OCT2 (SLC22A2). Human, mouse, and rat orthologs of OCT2 are expressed in abundance in human kidney and to some extent in neuronal tissue such as choroid plexus. In the kidney, OCT2 is localized in the proximal and distal tubules and collecting ducts. In the proximal tubule, OCT2 is restricted to the basolateral membrane. OCT2-mediated transport of model organic cations MPP^+ (1-methyl-4-phenylpyridinium) and TEA (tetraethylammonium) is electrogenic, and both OCT2 and OCT1 can support organic cation–organic cation exchange. OCT2 generally accepts a wide array of monovalent organic cations with molecular weights below 400 Da. OCT2 is also present in neuronal tissues; however, monoamine neurotransmitters have low affinities for OCT2.

OCT3 (SLC22A3). The OCT3 gene is located in tandem with genes for OCT1 and OCT2 on chromosome 6. Tissue distribution studies suggest that human OCT3 is expressed in liver, kidney, intestine, placenta, skeletal muscle, and adipose tissue, although in the kidney it appears to be expressed in considerably less abundance than OCT2, and in the liver it is less abundant than OCT1. Like OCT1 and OCT2, OCT3 appears to support electrogenic potential-sensitive organic cation transport. OCT3 plays a role in both the renal elimination and the intestinal absorption of metformin.

OCTN1 (SLC22A4). OCTN1 seems to operate as an organic cation–proton exchanger. OCTN1-mediated influx of model organic cations is enhanced at alkaline pH, whereas efflux is increased by an inwardly directed proton gradient. OCTN1 contains a nucleotide-binding sequence motif, and transport of its substrates appears to be stimulated by cellular ATP. OCTN1 also can function as an organic cation–organic cation exchanger. OCTN1 functions as a bidirectional pH- and ATP-dependent transporter at the apical membrane in renal tubular epithelial cells and appears to be important in renal transport of gabapentin.

OCTN2 (SLC22A5). OCTN2 is a bifunctional transporter; it functions as both an Na^+ -dependent carnitine transporter and an Na^+ -independent OCT. OCTN2 transport of organic cations is sensitive to pH, suggesting that OCTN2 may function as an organic cation exchanger. The transport of *L*-carnitine by OCTN2 is an Na^+ -dependent electrogenic process. Mutations in OCTN2 can result in insufficient renal reabsorption of carnitine and appear to be the cause of primary systemic carnitine deficiency (Tamai, 2013)

MATE1 and MATE2-K (SLC47A1, SLC47A2). Multidrug and toxin extrusion family members MATE1 and MATE2-K interact with structurally diverse hydrophilic organic cations, including the antidiabetic drug metformin, the H_2 antagonist cimetidine, and the anticancer drug topotecan. In addition to cationic compounds, the transporters recognize some anions, including the antiviral agents acyclovir and ganciclovir. The zwitterions cephalixin and cephradine are specific substrates of MATE1. The herbicide paraquat, a bis-quaternary ammonium compound that is nephrotoxic in humans, is a high-affinity substrate of MATE1. Both

MATE1 and MATE2-K have been localized to the apical membrane of the proximal tubule. MATE1, but not MATE2-K, is also expressed on the canalicular membrane of the hepatocyte. These transporters appear to be the long-searched-for organic cation–proton antiporters on the apical membrane of the proximal tubule; that is, an oppositely directed proton gradient can drive the movement of organic cations via MATE1 or MATE2-K. The antibiotics levofloxacin and ciprofloxacin, though potent inhibitors, are not translocated by either MATE1 or MATE2-K.

Polymorphisms of OCTs and MATEs. OCT1 exhibits the greatest number of amino acid polymorphisms, followed by OCT2 and then OCT3. Recent studies suggest that genetic variants of OCT1 and OCT2 are associated with alterations in the renal elimination and response to the antidiabetic drug metformin. MATEs have fewer amino acid polymorphisms; however, recent studies suggested that noncoding region variants of SLC47A1 and SLC47A2 are associated with variation in response to metformin.

Organic Anion Transport

As with organic cation transport, a primary function of organic anion secretion appears to be the removal of xenobiotics from the body. The candidate substrates are structurally diverse and include many weakly acidic drugs (e.g., pravastatin, captopril, PAH, and penicillins) and toxins (e.g., ochratoxin). OATs not only move both hydrophobic and hydrophilic anions but also may interact with cations and neutral compounds.

Figure 5–11 shows a current model for the transepithelial flux of organic anions in the proximal tubule. Two primary transporters on the basolateral membrane mediate the flux of organic anions from interstitial fluid to tubule cell: OAT1 (SLC22A6) and OAT3 (SLC22A8). Energetically, hydrophilic organic anions are transported across the basolateral membrane against an electrochemical gradient, exchanging with intracellular α -ketoglutarate, which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α -ketoglutarate is maintained at least in part by a basolateral Na^+ -dicarboxylate transporter (NaDC3), using the Na^+ gradient established by Na^+, K^+ -ATPase. Transport of low-molecular-weight organic anions by the cloned transporters OAT1 and OAT3 can be driven by α -ketoglutarate; coupled transport of α -ketoglutarate and low-molecular-weight organic anions (e.g., PAH)

Figure 5–11 Organic anion secretory transporters in the proximal tubule. Two primary transporters on the basolateral membrane mediate the flux of OAs from interstitial fluid to tubule cell: OAT1 (SLC22A6) and OAT3 (SLC22A8). Hydrophilic OAs are transported across the basolateral membrane against an electrochemical gradient in exchange with intracellular α -ketoglutarate (α -KG), which moves down its concentration gradient from cytosol to blood. The outwardly directed gradient of α -KG is maintained at least in part by a basolateral Na^+ -dicarboxylate uptake transporter (NaDC3). The Na^+ gradient that drives NaDC3 is maintained by Na^+, K^+ -ATPase.

occurs in isolated basolateral membrane vesicles. The molecular pharmacology and molecular biology of OATs have recently been reviewed (Srimaroeng et al., 2008).

The mechanism responsible for the apical membrane transport of organic anions from tubule cell cytosol to tubular lumen remains controversial. OAT4 may serve as the luminal membrane transporter for organic anions, but the movement of substrates via this transporter can be driven by exchange with a α -ketoglutarate, suggesting that OAT4 may function in the reabsorptive, rather than secretory, flux of organic anions. NaPT1, originally cloned as a phosphate transporter, can support the low-affinity transport of hydrophilic organic anions such as PAH. MRP2 and MRP4, multidrug resistance transporters in the ABCC, can interact with some organic anions and may actively pump them from tubule cell cytosol to tubular lumen.

OAT1 (SLC22A6). Mammalian isoforms of OAT1 are expressed primarily in the kidney, with some expression in brain and skeletal muscle. Immunohistochemical studies suggest that OAT1 is expressed on the basolateral membrane of the proximal tubule in humans, with highest expression in the middle segment, S2 (see Figure 25-1). Based on quantitative PCR, OAT1 is expressed at a third of the level of OAT3. OAT1 exhibits saturable transport of organic anions such as PAH. This transport is transstimulated by other organic anions, including α -ketoglutarate. Thus, the inside negative-potential difference drives the efflux of the dicarboxylate α -ketoglutarate, which in turn supports the influx of monocarboxylates such as PAH. Sex steroids regulate expression of OAT1 in the kidney. OAT1 generally transports low-molecular-weight organic anions, either endogenous (e.g., PGE_2 and urate) or exogenous (ingested drugs and toxins). Some neutral compounds are also transported by OAT1 at a lower affinity (e.g., cimetidine).

OAT2 (SLC22A7). OAT2 is present in both kidney and liver; renal OAT2 is localized to the basolateral membrane of the proximal tubule. OAT2 functions as a transporter for nucleotides, particularly guanine nucleotides such as cyclic GMP, for which it is a bidirectional facilitative transporter (Cropp et al., 2008). Cellular studies indicate that OAT2 functions in both the influx and the efflux of guanine nucleotides. OAT2 transports organic anions such as PAH and methotrexate with low affinity, PGE_2 with high affinity, and some neutral compounds but with lower affinity (e.g., cimetidine).

OAT3 (SLC22A8). Human OAT3 is confined to the basolateral membrane of the proximal tubule. This protein consists of two variants, one of which transports a wide variety of organic anions, including PAH, estrone sulfate, and many drugs (e.g., pravastatin, cimetidine, 6-mercaptopurine, and methotrexate) (Srimaroeng et al., 2008). The longer variant does not support transport. The specificities of OAT3 and OAT1 overlap, although kinetic parameters differ: Estrone sulfate is transported by both but by OAT3 with a much higher affinity; OAT1 transports the H_2 receptor antagonist cimetidine with high affinity.

OAT4 (SLC22A11). Human OAT4 is expressed in placenta and kidney (on the luminal membrane of the proximal tubule). Organic anion transport by OAT4 can be stimulated by transgradients of α -ketoglutarate, suggesting that OAT4 may be involved in the reabsorption of organic anions from tubular lumen into cell (see Figure 5-11). The specificity of OAT4 includes the model compounds estrone sulfate and PAH, as well as zidovudine, tetracycline, and methotrexate. Collectively, emerging studies suggest that OAT4 may be involved not in secretory flux of organic anions but in reabsorption instead.

Other Anion Transporters. URAT1 (SLC22A12) is a kidney-specific transporter confined to the apical membrane of the proximal tubule. URAT1 is primarily responsible for urate reabsorption, mediating electroneutral urate transport that can be transstimulated by Cl^- gradients. NPT1, Na^+ -dependent phosphate transport protein 1 (SLC17A1), is expressed on the luminal membrane of the proximal tubule as well as in the brain. NPT1 transports PAH, probenecid, and penicillin G. It appears to be involved in organic anion efflux from tubule cell to lumen and interacts with uric acid.

MRP2 (ABCC2) is considered to be the primary transporter involved in efflux of many drug conjugates (such as GSH conjugates) across the canalicular membrane of the hepatocyte. MRP2 is also found on the apical membrane of the proximal tubule, where it is thought to play a role in the efflux of organic anions into the tubular lumen. In general, MRP2 transports larger, bulkier compounds than do most of the OATs in the SLC22 family. MRP4 (ABCC4), localized on the apical membrane of the proximal tubule, transports a wide array of conjugated anions, including glucuronides and GSH conjugates. MRP4 appears to interact with methotrexate, cyclic nucleotide analogues, and antiviral nucleoside analogues. BCRP (ABCG2) is localized to the apical membrane of the proximal tubule and duodenum and is involved in uric acid secretion and secretion of the XOIs allopurinol and oxypurinol.

Polymorphisms in OAT1 and OAT3 have been identified in ethnic human subpopulations (see <https://www.pharmgkb.org>). Notably, polymorphisms in ABCG2 have been associated with reduced response to allopurinol and oxypurinol.

Transporters and Pharmacodynamics: Drug Action in the Brain

Biogenic amine neurotransmitters are packaged in vesicles in presynaptic neurons, released in the synapse by fusion of the vesicles with the plasma membrane, and then taken back into the presynaptic neurons or postsynaptic cells (see Chapters 8 and 14). Transporters involved in the neuronal reuptake of the neurotransmitters and the regulation of their levels in the synaptic cleft belong to two major superfamilies, SLC1 and SLC6. Transporters in both families play roles in reuptake of GABA, glutamate, and the monoamine neurotransmitters NE, 5HT, and DA. These transporters may serve as pharmacologic targets for neuropsychiatric drugs. SLC6 family members localized in the brain and involved in the reuptake of neurotransmitters into presynaptic neurons include NET (SLC6A2), DAT (SLC6A3), SERT (SLC6A4), and several GATs (GAT1, GAT2, and GAT3). Each of these transporters appears to have 12 transmembrane (TM) regions and a large extracellular loop with glycosylation sites between TM3 and TM4.

SLC6 family members are secondary active transporters, depending on the Na^+ gradient to transport their substrates into cells. Cl^- is also required, although to a variable extent depending on the family member. Through their reuptake mechanisms, the neurotransmitter transporters in the SLC6A family regulate the concentrations and dwell times of neurotransmitters in the synaptic cleft; the extent of transmitter uptake also influences subsequent vesicular storage of transmitters. Many of these transporters are present in other tissues (e.g., intestine, kidney, and platelets) and may serve other roles. Further, the transporters can function in the reverse direction; that is, the transporters can export neurotransmitters in a Na^{2+} -independent fashion.

GABA Uptake: GAT1 (SLC6A1), GAT3 (SLC6A11), GAT2 (SLC6A13), and BGT1 (SLC6A12)

GAT1 is the most important GABA transporter in the brain, expressed in GABAergic neurons and found largely on presynaptic neurons. GAT1 is abundant in the neocortex, cerebellum, basal ganglia, brainstem, spinal cord, retina, and olfactory bulb. GAT3 is found only in the brain, largely in glial cells. GAT2 is found in peripheral tissues, including the kidney and liver, and within the CNS in the choroid plexus and meninges. Physiologically, GAT1 appears to be responsible for regulating the interaction of GABA at receptors. The presence of GAT2 in the choroid plexus and its absence in presynaptic neurons suggest that this transporter may play a primary role in maintaining the homeostasis of GABA in the CSF. GAT1 is the target of the antiepileptic drug tiagabine (a nipecotic acid derivative), which presumably acts to prolong the dwell time of GABA in the synaptic cleft of GABAergic neurons by inhibiting the reuptake of GABA. A fourth GAT, BGT1, occurs in extrasynaptic regions of the hippocampus and cortex (Madsen et al., 2011).

Catecholamine Uptake: NET (SLC6A2)

NET is found in central and peripheral nervous tissues as well as in adrenal chromaffin tissue. NET colocalizes with neuronal markers, consistent with a role in reuptake of monoamine neurotransmitters. NET provides reuptake of NE (and DA) into neurons, thereby limiting the synaptic dwell time of NE and terminating its actions, salvaging NE for subsequent repackaging. NET serves as a drug target for the antidepressant desipramine, other tricyclic antidepressants, and cocaine. Orthostatic intolerance, a rare familial disorder characterized by an abnormal blood pressure and heart rate response to changes in posture, has been associated with a mutation in NET.

Dopamine Uptake: DAT (SLC6A3)

DAT is located primarily in the brain in dopaminergic neurons. The primary function of DAT is the reuptake of DA, terminating its actions. Although present on presynaptic neurons at the neurosynaptic junction, DAT is also present in abundance along the neurons, away from the synaptic cleft. Physiologically, DAT is involved in functions attributed to the dopaminergic system, including mood, behavior, reward, and cognition. Drugs that interact with DAT include cocaine and its analogues, amphetamines, and the neurotoxin MPTP (methylphenyltetrahydropyridine).

Serotonin Uptake: SERT (SLC6A4)

SERT is responsible for the reuptake and clearance of 5HT in the brain. Like the other SLC6A family members, SERT transports its substrates in a Na⁺-dependent fashion and is dependent on Cl⁻ and possibly on the countertransport of K⁺. Substrates of SERT include 5HT, various tryptamine derivatives, and neurotoxins such as MDMA (ecstasy) and fenfluramine. SERT is the specific target of the SSRI antidepressants (e.g., fluoxetine and paroxetine) and one of several targets of tricyclic antidepressants (e.g., amitriptyline). Genetic variants of SERT have been associated with an array of behavioral and neurological disorders. The precise mechanism by which reduced activity of SERT, caused by either a genetic variant or an antidepressant, ultimately affects behavior, including depression, is not known.

The Blood-Brain Barrier: A Pharmacological View

The CNS is well protected from circulating neurotransmitters, well supplied with necessary nutrients and ions, and able to exclude many toxins, bacteria, and xenobiotics. This careful set of conditions is achieved by a barrier called the BBB. This barrier results from the specialized properties of the microvasculature of the CNS. Functionally, the BBB is partly physical, partly a consequence of selective permeability (export of undesirable molecules and import of necessary molecules), and partly a consequence of the enzymatic destruction of certain permeants by enzymes in the barrier. There are some neurosensory and neurosecretory regions of the brain that lack the barrier: posterior pituitary, median eminence, area postrema, subfornical organ, subcommissural organ, and laminar terminalis.

The *physical part* of the BBB derives from the distinctive structure of the capillary endothelium in the brain and choroid plexus. Unlike the endothelial cells of peripheral microvasculature that have gaps between them that permit flow of water and small molecules to the interstitial space, endothelial cells in the CNS have tight junctions that limit paracellular flow and generally have very low rates of vesicular transport (transcytosis) compared to peripheral endothelium. Moreover, CNS endothelium is wrapped by basement membrane, pericytes, and the pseudopodial processes of astroglia. Lipophilic molecules and gases such as O₂ and CO₂ can readily diffuse across these layers from blood to brain. Hydrophilic molecules (nutrients, ions, charged molecules, many drugs) cannot cross these multiple membrane barriers by diffusion at sufficient rates.

Thus, the system relies on *selective permeability*. For instance, there are transport systems: for ions; for nutrients, many in the SLC family of transport proteins, such as SLC2A1/GLUT1 (glucose), SLC7A1

and SLC7A5/LAT1 (amino acids); for nucleosides; and for metabolic by-products such as lactate and pyruvate (SLC16A1). Members of the SLC22 family (OAT1 and OAT3) play a role in the efflux of xenobiotics from CSF to plasma. There are receptor-mediated transport systems for ferritin and insulin, and there is a low level of transcytosis (caveolin-dependent vesicle trafficking). The endothelial membranes also express exporters that basically prevent molecules such as drugs from crossing the endothelium. There are transporters such as Pgp (ABCB1/MDR1), the well-characterized efflux transporter that extrudes its substrates across the luminal membrane of the brain capillary endothelial cells into the blood, thereby limiting penetration into the brain. There is accumulating evidence for similar roles of BCRP and MRP4. The physiological compounds that need to cross the BBB are able to cross.

There is a *metabolic barrier* for some compounds. For instance, circulating catecholamines are inactivated by MAO in the endothelial cells and endothelial MAO and dopa decarboxylase (aromatic amino acid decarboxylase; see Chapter 8) metabolizes L-dopa to 3,4-dihydroxyphenylacetate (hence the necessity of including a dopa decarboxylase inhibitor when giving L-dopa to treat Parkinson disease). The metabolic barrier enzyme γ -glutamyl transpeptidase cleaves the leukotriene mediator produced by the 5-lipoxygenase pathway, LTC₄, and other glutathione adducts.

What about drug molecules? Once they reach the systemic circulation, delivery to the general region of the brain is not a problem: The brain receives about 15% of cardiac output (see Table 2–2). What about crossing the BBB? Small drugs can diffuse across the BBB as a function of their lipid solubility (oil/water partition coefficient). Thus, anesthetics such as nitrous oxide and thiopental move readily across the BBB. Some drugs may resemble substrates that are transported into the brain (e.g., amino acids, nucleosides) and thereby gain entry. LAT1 (SLC7A5) is involved in the influx of several drugs, such as L-dopa and gabapentin across the BBB. OAT1 and OAT3, which generally play a role in the efflux of drugs from the CSF, mediate the uptake of organic compounds such as β -lactam antibiotics, statins, and H₂ receptor antagonists. Charged and large drugs, on the other hand, generally do not penetrate so easily into the brain. The transport proteins, especially MDRI, BCRP, and MRP4, actively extrude many drugs; clearly, recognition by these transporters is a major disadvantage for a drug used to treat CNS disease.

There are methods of permeation under development: nanoparticles and liposomes containing drugs, drugs adducted to ferritin, and development of drug forms with suitable lipophilicity. Basic biomedical research is advancing our understanding of the role of nuclear receptors in the regulation of drug transporters in the BBB (Chan et al., 2013) and of the development of the BBB and the interaction of its cellular and subcellular components to maintain barrier function (Daneman and Prat, 2015). Kim and Bynoe (2015) reported that activation of the adenosine A_{2A} receptor in an in vitro human brain endothelial barrier model permeabilized the barrier sufficiently to permit passage of T cells and the chemotherapeutic agent gemcitabine. Such studies and techniques may provide progress in putting the control of BBB permeability into the hands of physicians.

The Extended Clearance Concept and Physiologically Based Pharmacokinetic (PBPK) Modeling

Based on the “extended clearance concept,” hepatic clearance consists of some intrinsic processes, such as hepatic uptake PS_1 , backflux from hepatocytes to blood PS_2 , hepatic metabolism CL_{met} , and biliary sequestration PS_3 (Figure 5–12) (Shitara et al., 2006, 2013).

The overall hepatic intrinsic clearance $CL_{int,all}$ is expressed as

$$CL_{int,all} = PS_1 \cdot \frac{CL_{met} + PS_3}{PS_2 + CL_{met} + PS_3} \quad (\text{Equation 5-6})$$

If the sum of the intrinsic clearance of metabolism and biliary sequestration is much larger than the backflux clearance ($PS_2 \ll (CL_{met} + PS_3)$),

Figure 5-12 Extended clearance concept: hepatic uptake, backflux into blood, metabolism, and efflux into bile. The red circles represent parent drugs; the green triangles represent drug metabolites.

$CL_{int,all}$ approximates PS_1 , and uptake is a rate-determining process of the overall hepatic intrinsic clearance. In general, many transporter substrates are efficiently excreted into bile or extensively metabolized rather than fluxed back into blood, so their uptake clearances often determine their overall intrinsic hepatic clearance. Assuming that an orally administered drug is completely absorbed from the small intestine and predominantly cleared by the liver, its blood AUC based on the “well-stirred model” can be described as

$$AUC_{blood} = \frac{Dose}{f_B \cdot CL_{int,all}} = \frac{Dose}{f_B \cdot PS_1 \cdot \frac{CL_{met} + PS_3}{PS_2 + CL_{met} + PS_3}} \quad (\text{Equation 5-7})$$

where f_B represents the unbound fraction in blood.

Figure 5-13 Sensitivity analysis of the effect of functional changes of hepatic uptake clearance PS_1 (A) and biliary excretion clearance PS_3 (B) on the plasma and liver concentrations of pravastatin (Watanabe et al., 2009). These sensitivity analyses were made based on the PBPK model, which connected five sequential liver compartments by blood flow so that this model can be used for drugs exhibiting transporter-mediated high clearance. Plasma and liver concentrations after oral administration (40 mg) were simulated with varying hepatic transport activities over a 1/3- to 3-fold range of the initial values.

The AUC_{liver} is described as (Shitara et al., 2013)

$$\begin{aligned} AUC_{liver} &= \frac{PS_1}{PS_2 + CL_{met} + PS_3} \cdot AUC_{blood} \\ &= \frac{PS_1}{PS_2 + CL_{met} + PS_3} \cdot \frac{Dose}{f_b \cdot PS_1 \cdot \frac{CL_{met} + PS_3}{PS_2 + CL_{met} + PS_3}} \quad (\text{Equation 5-8}) \\ &= \frac{Dose}{f_b \cdot (CL_{met} + PS_3)} \end{aligned}$$

Equations 5-6 through 5-8 suggest that if the uptake clearance PS_1 is decreased, AUC_{blood} is increased in inverse proportion to PS_1 , while AUC_{liver} is not affected. On the other hand, if drug uptake is a rate-determining process of the overall hepatic intrinsic clearance, the decrease in the function of metabolism or biliary sequestration causes the increase in AUC_{liver} but not AUC_{blood} . Therefore, if the molecular targets of pharmacological effect and adverse effect induced by drugs are located inside and outside hepatocytes, respectively, as in the case of statins, decrease in the hepatic uptake clearance of drugs caused by drug-drug interaction or genetic polymorphism of transporters affect mainly adverse effect and not so much pharmacological effect.

To simulate the impact of variations in the transporter activities on the systemic and liver exposure of a statin, which is eliminated mainly via OATP1B1 and MRP2, a PBPK model has been used (Jamei et al., 2014; Watanabe et al., 2009).

In a PBPK model, compartments representing actual tissues are connected by blood flow to predict the time course of drug disposition in the body. A PBPK model allows deep insight into the factors governing the systemic exposure and tissue distribution of drugs and simulates the impact of variations in physiological or drug-dependent parameters on drug disposition. Sensitivity analyses based on the PBPK model indicate that the variation in OATP1B1 activities will have a minimal impact on the therapeutic efficacy but a large impact on the side effect (myopathy) of pravastatin; the opposite will be true for variations in MRP2 activities: a large impact on efficacy, a small impact on the side effect (Watanabe et al., 2009) (Figure 5-13). Such characteristics have been demonstrated for some statins (e.g., simvastatin and rosuvastatin): Pharmacogenomic variation of OATP1B1 activity is associated with the risk of adverse reactions, whereas variation of biliary excretion and intestinal absorption mechanisms result in variation in therapeutic response (Chasman et al., 2012; SEARCH Collaborative Group, 2008).

Genetic Variation in Membrane Transporters: Implications for Clinical Drug Response

There are inherited defects in SLC transporters (see Table 5-2) and ABC transporters (see Table 5-3). Polymorphisms in membrane transporters play roles in drug response and are yielding new insights in pharmacogenetics and pharmacology (see Chapter 7).

Clinical studies have focused on a limited number of transporters, relating genetic variation in membrane transporters to drug disposition and response. For example, two common SNPs in *SLCO1B1* (OATP1B1) are associated with elevated plasma levels of pravastatin (Niemi et al., 2011), a widely used drug for the treatment of hypercholesterolemia (see Chapter 33). Recent studies using genome-wide association methods show that genetic variants in *SLCO1B1* (OATP1B1) predispose patients to risk for muscle toxicity associated with use of simvastatin as well as altered response to selected statins. Other studies indicate that genetic variants in transporters in the SLC22A family are associated with variation in renal clearance and response to various drugs, including the antidiabetic drug metformin (Chen et al. 2013). Responses to the XO1 allopurinol and to rosuvastatin have recently been associated with genetic variants in ABCG2 (BCRP) (Chasman et al., 2012; Wen et al., 2015). For both drugs, a pharmacokinetic mechanism is responsible for the altered pharmacodynamics. Likewise, genetic variants of MRP2 and MRP4 are associated with

drug-related phenotypes (Rungtivasuwan et al., 2015). For example, the disposition of tenofovir, an antiviral agent, has been associated with polymorphisms in both ABCC2 and ABCC4 (MRP2 and MRP4, respectively).

Transporters in Regulatory Sciences

Because of their importance in drug disposition and action, transporters are major determinants of variation in therapeutic and adverse drug reactions. As a result, transporters may mediate drug-drug interactions that result in drug safety issues. A notable example is the interaction between gemfibrozil and cerivastatin. Gemfibrozil glucuronide formed in hepatocytes reduces the hepatic uptake and metabolism of cerivastatin; the result is a high C_p for cerivastatin. Elevated statin levels result in statin-induced myopathies, including rhabdomyolysis, a life-threatening adverse effect. This interaction resulted in the removal of cerivastatin from the market because of deaths due to rhabdomyolysis. The U.S. FDA has issued a draft clinical pharmacology guidance on performing drug-drug interaction studies during clinical drug development (FDA, 2012). The guidance presents information on how to use in vitro data for transporter studies to make decisions about whether to conduct a clinical drug-drug interaction study. For example, if a new molecular entity (NME) inhibits the in vitro uptake of a canonical substrate of OCT2 at clinically relevant (unbound) concentrations, the guidance recommends that the sponsor consider performing a clinical drug-drug interaction study to determine whether the NME inhibits the renal clearance of an OCT2 substrate (e.g., metformin) in vivo. On the other hand, if the NME does not inhibit OCT2-mediated uptake in in vitro assays at therapeutic concentrations, the guidance does not recommend a clinical study. Although only a handful of transporters (OATP1B1, OATP1B3, Pgp, BCRP, OCT2, MATE1, OAT1, and OAT3) are included in the FDA guidance, an increasing number of studies are being performed to identify and characterize transporters that mediate clinical drug-drug interactions.

COPING WITH XENOBIOTICS

THE PHASES OF DRUG METABOLISM

SITES OF DRUG METABOLISM

PHASE 1 REACTIONS

- CYPs: The Cytochrome P450 Superfamily
- Flavin-Containing Monooxygenases
- Hydrolytic Enzymes

PHASE 2 REACTIONS: CONJUGATING ENZYMES

- Glucuronidation
- Sulfation

- Glutathione Conjugation
- N-Acetylation
- Methylation

ROLE OF XENOBIOTIC METABOLISM IN SAFE AND EFFECTIVE USE OF DRUGS

INDUCTION OF DRUG METABOLISM

ROLE OF DRUG METABOLISM IN DRUG DEVELOPMENT

Coping With Xenobiotics

Humans come into contact with thousands of foreign chemicals or xenobiotics (substances foreign to the body) through diet and exposure to environmental contaminants. Fortunately, humans have developed a means to rapidly eliminate xenobiotics so that they do not accumulate in the tissues and cause harm. Plants are a common source of dietary xenobiotics, providing many structurally diverse chemicals, some of which are associated with pigment production and others that are actually toxins (called *phytoalexins*) that protect plants against predators. Poisonous mushrooms are a common example: They have many toxins that are lethal to mammals, including amanitin, gyromitrin, orellanine, muscarine, ibotenic acid, muscimol, psilocybin, and coprine. Animals must be able to metabolize and eliminate such chemicals to consume vegetation. While humans can now choose their dietary sources, a typical animal does not have this luxury and as a result is subject to its environment and the vegetation that exists in that environment. Thus, the ability to metabolize unusual chemicals in plants and other food sources is critical for adaptation to a changing environment and ultimately the survival of animals.

Enzymes that metabolize xenobiotics have historically been called drug-metabolizing enzymes; however, these enzymes are involved in the metabolism of many foreign chemicals to which humans are exposed and are more appropriately called *xenobiotic-metabolizing enzymes*. Myriad diverse enzymes have evolved in animals to metabolize foreign chemicals. Dietary differences among species during the course of evolution could account for the marked species variation in the complexity of the xenobiotic-metabolizing enzymes. Additional diversity within these enzyme systems has also derived from the necessity to “detoxify” a host of endogenous chemicals that would otherwise prove harmful to the organism, such as bilirubin, steroid hormones, and catecholamines. Many of these endogenous biochemicals are detoxified by the same or closely related xenobiotic-metabolizing enzymes.

Drugs are xenobiotics, and the capacity to metabolize and clear drugs involves the same enzymatic pathways and transport systems that are used for normal metabolism of dietary constituents. Indeed, many drugs are derived from chemicals found in plants, some of which have been used in Chinese herbal medicines for thousands of years. Of the prescription drugs in use today for cancer treatment, some are also derived from plants

(see Chapter 68); investigating folkloric claims led to the discovery of most of these drugs. The capacity to metabolize xenobiotics, although largely beneficial, has made development of drugs more time consuming and costly due in part to:

- species differences in expression of enzymes that metabolize drugs and thereby limit the utility of animal models to predict drug effects in humans
- interindividual variations in the capacity of humans to metabolize drugs
- drug-drug interactions involving xenobiotic metabolizing enzymes
- metabolic activation of chemicals to toxic and carcinogenic derivatives

Today, most xenobiotics to which humans are exposed come from sources that include environmental pollution, food additives, cosmetic products, agrochemicals, processed foods, and drugs.

In general, most xenobiotics are lipophilic chemicals; in the absence of metabolism, these would not be efficiently eliminated and thus would accumulate in the body, potentially resulting in toxicity. With few exceptions, all xenobiotics are subjected to one or multiple enzymatic pathways that constitute *phase 1 oxidation* and *phase 2 conjugation*. As a general paradigm, metabolism serves to convert these hydrophobic chemicals into more hydrophilic derivatives that can easily be eliminated from the body through the urine or the bile.

To enter cells and reach their sites of action, drugs generally must possess physical properties that allow them to move down a concentration gradient and across cell membranes. Many drugs are hydrophobic, a property that allows entry via diffusion across lipid bilayers into the systemic circulation and then into cells. With some compounds, transporters on the plasma membrane facilitate entry (see Chapter 5). This property of hydrophobicity renders drugs difficult to eliminate because, in the absence of metabolism, they accumulate in fat and cellular phospholipid bilayers. The xenobiotic-metabolizing enzymes convert drugs and other xenobiotics into derivatives that are more hydrophilic and thus easily eliminated via excretion into the aqueous compartments of the tissues and ultimately into the urine.

Metabolism of a drug can begin even before a drug is absorbed: Gut bacteria represent the first metabolic interface between orally administered drugs and the body. The microbiome of the GI tract can metabolize xenobiotics; interindividual differences in composition of the gut

Abbreviations

ADR:	adverse drug reaction
AUC:	area under the plasma concentration–time curve
AZA:	azathioprine
CAR:	constitutive androstane receptor
CES2:	carboxylesterase 2
COMT:	catechol- <i>O</i> -methyltransferase
CPT-11:	irinotecan
CYP:	cytochrome P450
DPYD:	dihydropyrimidine dehydrogenase
EH:	epoxide hydrolase
FMO:	flavin-containing monooxygenase
GI:	gastrointestinal
GSH and GSSG:	reduced and oxidized glutathione
GST:	glutathione- <i>S</i> -transferase
HGPRT:	hypoxanthine guanine phosphoribosyl transferase
HIF:	hypoxia-inducible factor
HIV:	human immunodeficiency virus
HNMT:	histamine <i>N</i> -methyltransferase
HPPH:	5-(4-hydroxyphenyl)-5-phenylhydantoin
INH:	isonicotinic acid hydrazide (isoniazid)
MAO:	monoamine oxidase
MAPK:	mitogen-activated protein kinase
mEH:	microsomal epoxide hydrolase
6-MP:	6-mercaptopurine
MRP:	multidrug resistance protein
MT:	methyltransferase
NADPH:	nicotinamide adenine dinucleotide phosphate
NAPQI:	<i>N</i> -acetyl- <i>p</i> -benzoquinone imine
NAT:	<i>N</i> -acetyltransferase
NNMT:	nicotinamide <i>N</i> -methyltransferase
PAPS:	3′-phosphoadenosine-5′-phosphosulfate
Per:	Period
Pgp:	P-glycoprotein
PNMT:	phenylethanolamine <i>N</i> -methyltransferase
POMT:	phenol- <i>O</i> -methyltransferase
PPAR:	peroxisome proliferator-activated receptor
PXR:	pregnane X receptor
RXR:	retinoid X receptor
SAM:	<i>S</i> -adenosyl-methionine
sEH:	soluble epoxide hydrolase
SULT:	sulfotransferase
TBP:	TATA box-binding protein
6-TGN:	6-thioguanine nucleotide
TMA:	trimethylamine
TPMT:	thiopurine methyltransferase
TPT:	thiol methyltransferase
UDP-GA:	uridine diphosphate–glucuronic acid
UGT:	uridine diphosphate–glucuronosyltransferase

flora could influence drug action and contribute to differences in drug response. Indeed, diurnal oscillations in GI bacteria and their metabolic capacity, superposed on host clock gene oscillations, appear to affect drug disposition and effect (FitzGerald et al., 2015).

The process of drug metabolism that leads to elimination also plays a major role in diminishing the biological activity of a drug. For example, (*S*)-phenytoin, an anticonvulsant used in the treatment of epilepsy, is virtually insoluble in water. Metabolism by the phase 1 CYPs followed by phase 2 UGT enzymes produces a metabolite that is highly water soluble and readily eliminated from the body (Figure 6–1). Metabolism also terminates the biological activity of the drug. Because conjugates are generally hydrophilic, elimination via the bile or urine is dependent on the

Figure 6–1 Metabolism of phenytoin. In phase 1, CYP facilitates 4-hydroxylation of phenytoin to yield HPPH. In phase 2, the hydroxy group serves as a substrate for UGT, which conjugates a molecule of glucuronic acid using UDP-GA as a cofactor. Together, phase 1 and phase 2 reactions convert a very hydrophobic molecule to a larger hydrophilic derivative that is eliminated via the bile.

actions of many efflux transporters to facilitate transmembrane passage (see Chapter 5).

While xenobiotic-metabolizing enzymes facilitate the elimination of chemicals from the body, paradoxically these same enzymes can also convert certain chemicals to highly reactive, toxic, and carcinogenic metabolites. This occurs when an unstable intermediate is formed that has reactivity toward other compounds found in the cell. Chemicals that can be converted by xenobiotic metabolism to cancer-causing derivatives are called carcinogens. Depending on the structure of the chemical substrate, xenobiotic-metabolizing enzymes can produce electrophilic metabolites that react with nucleophilic cellular macromolecules such as DNA, RNA, and protein. This can cause cell death and organ toxicity. Most drugs and other xenobiotics that cause hepatotoxicity damage mitochondria and lead to hepatocyte death. Reaction of these electrophiles with DNA can sometimes result in cancer through the mutation of genes, such as oncogenes or tumor suppressor genes. It is generally believed that most human cancers are due to exposure to chemical carcinogens.

This potential for carcinogenic activity makes testing the safety of drug candidates of vital importance. Testing for cancer-causing potential is particularly critical for drugs that will be used for the treatment of chronic diseases. Because each species has evolved a unique combination of xenobiotic-metabolizing enzymes, nonprimate models (mostly rodents) cannot be solely used for testing the safety of new drug candidates targeted for human diseases. Nevertheless, testing in rodent models (e.g., mice and rats) can usually identify potential carcinogens. Fortunately, there are no instances of drugs that test negative in rodents but cause cancer in humans, albeit some rodent carcinogens are not associated with human cancer. However, many cytotoxic cancer drugs have the potential

to cause cancer; this risk is minimized by their acute, rather than chronic, use in cancer therapy.

The Phases of Drug Metabolism

Xenobiotic-metabolizing enzymes have historically been categorized as

- *phase 1 reactions*, which include oxidation, reduction, or hydrolytic reactions; or
- *phase 2 reactions*, in which enzymes catalyze the conjugation of the substrate (the phase 1 product) with a second molecule.

The *phase 1 enzymes* lead to the introduction of what are called functional groups, such as $-\text{OH}$, $-\text{COOH}$, $-\text{SH}$, $-\text{O}-$, or NH_2 (Table 6–1). The addition of functional groups does little to increase the water solubility of the drug but can dramatically alter the biological properties of the drug. Reactions carried out by phase 1 enzymes usually lead to the inactivation of a drug. However, in certain instances, metabolism, usually the hydrolysis of an ester or amide linkage, results in bioactivation of a drug. Inactive drugs that undergo metabolism to an active drug are called prodrugs (Huttenen et al., 2011). Examples of prodrugs bioactivated by CYPs are the antitumor drug *cyclophosphamide*, which is bioactivated to a cell-killing electrophilic derivative (see Chapter 66), and the anti-thrombotic agent clopidogrel, which activated to 2-oxo-clopidogrel, which is further metabolized to an irreversible inhibitor of platelet ADP P2Y₁₂ receptors. *Phase 2 enzymes* produce a metabolite with improved water solubility and thereby facilitate the elimination of the drug from the tissue, normally via efflux transporters described in Chapter 5. Thus, in general, phase 1 reactions result in biological inactivation of a drug, and phase 2 reactions facilitate the drug elimination and the inactivation of electrophilic and potentially toxic metabolites produced by oxidation.

Superfamilies of evolutionarily related enzymes and receptors are common in the mammalian genome; the enzyme systems responsible for drug metabolism are good examples. The phase 1 oxidation reactions are carried out by CYPs, FMOs, and EHs. The CYPs and FMOs are composed of superfamilies of enzymes. Each superfamily contains multiple genes. The

phase 2 enzymes include several superfamilies of conjugating enzymes. Among the more important are the GSTs, UGTs, SULTs, NATs, and MTs (Table 6–1).

These conjugation reactions usually require the substrate to have oxygen (hydroxyl or epoxide groups), nitrogen, and sulfur atoms that serve as acceptor sites for a hydrophilic moiety, such as glutathione, glucuronic acid, sulfate, or an acetyl group, that is covalently conjugated to an acceptor site on the molecule. Examine the phase 1 and phase 2 metabolism of phenytoin (Figure 6–1). The oxidation by phase 1 enzymes either adds or exposes a functional group, permitting the products of phase 1 metabolism to serve as substrates for the phase 2 conjugating or synthetic enzymes. In the case of the UGTs, glucuronic acid is delivered to the functional group, forming a glucuronide metabolite that is more water soluble and is targeted for excretion in the urine or bile. When the substrate is a drug, these reactions usually convert the original drug to a form that is not able to bind to its target receptor, thus attenuating the biological response to the drug.

Sites of Drug Metabolism

Xenobiotic-metabolizing enzymes are found in most tissues in the body, with the highest levels located in the GI tract (liver, small and large intestines). The small intestine plays a crucial role in drug metabolism. Orally administered drugs first are exposed to the GI flora, which can metabolize some drugs. During absorption, drugs are exposed to xenobiotic-metabolizing enzymes in the epithelial cells of the GI tract; this is the initial site of drug metabolism. Once absorbed, drugs enter the portal circulation and are taken to the liver, where they can be extensively metabolized (the “first-pass effect”). The liver is the major “metabolic clearinghouse” for both endogenous chemicals (e.g., cholesterol, steroid hormones, fatty acids, and proteins) and xenobiotics. While a portion of active drug escapes metabolism in the GI tract and liver, subsequent passes through the liver result in more metabolism of the parent drug until the agent is eliminated. Thus, drugs that are poorly metabolized remain in the body for longer periods of time, and their pharmacokinetic profiles show much longer elimination half-lives than drugs that are rapidly metabolized.

During drug development, compounds are sought that have a favorable pharmacokinetic profile in which they are eliminated over the course of 24 h after administration. This allows the use of daily single dosing. If a compound with a favorable efficacy cannot be modified to improve its pharmacokinetic profile, twice-a-day or even three times-a-day dosing needs to be used. Other organs that contain significant xenobiotic-metabolizing enzymes include tissues of the nasal mucosa and lung, which play important roles in the metabolism of drugs that are administered through aerosol sprays. These tissues are also the first line of contact with hazardous chemicals that are airborne.

Within the cell, xenobiotic-metabolizing enzymes are found in the intracellular membranes and in the cytosol. The phase 1 CYPs, FMOs, and EHs and some phase 2 conjugating enzymes, notably the UGTs, are all located in the endoplasmic reticulum (ER) of the cell (Figure 6–2). The endoplasmic reticulum consists of phospholipid bilayers organized as tubes and sheets throughout the cytoplasm. This network has an inner lumen that is physically distinct from the rest of the cytosolic components of the cell and has connections to the plasma membrane and nuclear envelope. This membrane localization is ideally suited for the metabolic function of these enzymes: Hydrophobic molecules enter the cell and become embedded in the lipid bilayer, where they come into direct contact with the phase 1 enzymes. Once subjected to oxidation, drugs can be directly conjugated by the UGTs (in the lumen of the endoplasmic reticulum) or by the cytosolic transferases, such as GST and SULT. Glucuronide conjugates must be transported out of the endoplasmic reticulum. The metabolites are transported across the plasma membrane and into the bloodstream, then conveyed to the liver and into the bile through the bile canaliculus, from which they are deposited in the gut (see Figure 5–9).

TABLE 6–1 ■ XENOBIOTIC-METABOLIZING ENZYMES

ENZYMES	REACTIONS
Phase 1 enzymes (CYPs, FMOs, EHs)	
Cytochrome P450s (P450 or CYP)	C and O oxidation, dealkylation, others
Flavin-containing monooxygenases (FMOs)	N, S, and P oxidation
Epoxide hydrolases (EHs)	Hydrolysis of epoxides
Phase 2 “transferases”	
Sulfotransferases (SULT)	Addition of sulfate
UDP-glucuronosyltransferases (UGTs)	Addition of glucuronic acid
Glutathione-S-transferases (GSTs)	Addition of glutathione
N-Acetyltransferases (NATs)	Addition of acetyl group
Methyltransferases (MTs)	Addition of methyl group
Other enzymes	
Alcohol dehydrogenases	Reduction of alcohols
Aldehyde dehydrogenases	Reduction of aldehydes
NADPH-quinone oxidoreductase (NQO)	Reduction of quinones

mEH and sEH, microsomal and soluble epoxide hydrolase, respectively; NADPH, reduced nicotinamide adenine dinucleotide phosphate; UDP, uridine diphosphate.

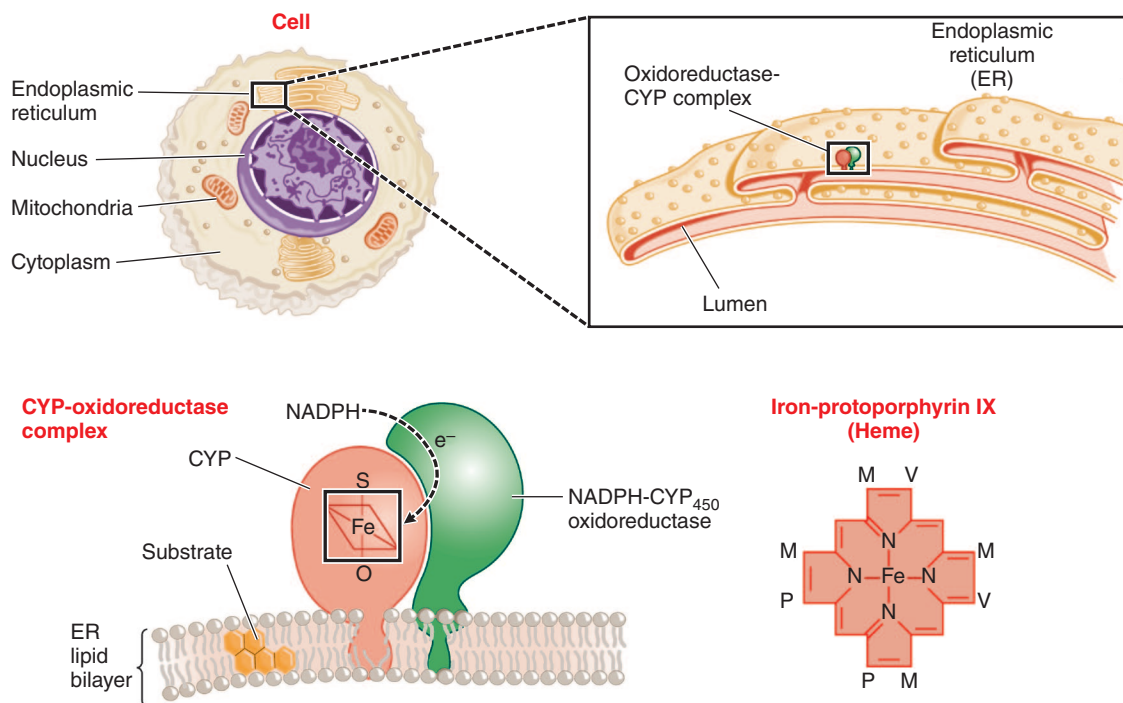

Figure 6-2 Location of CYPs in the cell. Increasingly microscopic levels of detail are shown, sequentially expanding the areas within the black boxes. CYPs are embedded in the phospholipid bilayer of the ER. Most of the enzyme is located on the cytosolic surface of the ER. A second enzyme, NADPH-CYP oxidoreductase, transfers electrons to the CYP where it can, in the presence of O_2 , oxidize xenobiotic substrates, many of which are hydrophobic and dissolved in the ER. A single NADPH-CYP oxidoreductase species transfers electrons to all CYP isoforms in the ER. Each CYP contains a molecule of iron-protoporphyrin IX that functions to bind and activate O_2 . Substituents on the porphyrin ring are methyl (M), propionyl (P), and vinyl (V) groups.

Phase 1 Reactions

CYPs: The Cytochrome P450 Superfamily

The CYPs are a superfamily of enzymes, each of which contains a molecule of heme bound noncovalently to the polypeptide chain (Figure 6-2). Many enzymes that use O_2 as a substrate for their reactions contain heme, and heme is the oxygen-binding moiety in hemoglobin. Heme contains one atom of iron in a hydrocarbon cage that functions to bind O_2 in the active site of the CYP as part of the catalytic cycle of these enzymes. CYPs use O_2 , plus H^+ derived from the cofactor-reduced NADPH, to carry out the oxidation of substrates. The H^+ is supplied through the enzyme NADPH-CYP oxidoreductase. Metabolism of a substrate by a CYP consumes one molecule of O_2 and produces an oxidized substrate and a molecule of H_2O as a by-product. However, for most CYPs, depending on the nature of the substrate, the reaction is “uncoupled,” consuming more O_2 than substrate metabolized and producing what is called activated oxygen or O_2^- . The O_2^- is usually converted to water by the enzyme superoxide dismutase. When elevated, O_2^- , also called a reactive oxygen species (ROS), can cause oxidative stress that is detrimental to cellular physiology and is associated with diseases such as hepatic cirrhosis.

Among the diverse reactions carried out by mammalian CYPs are *N*-dealkylation, *O*-dealkylation, aromatic hydroxylation, *N*-oxidation, *S*-oxidation, deamination, and dehalogenation (Table 6-2). More than 50 individual CYPs have been identified in humans. As a family of enzymes, CYPs are involved in the metabolism of dietary and xenobiotic chemicals, as well as the synthesis of endogenous compounds such as steroids and fatty acid signaling molecules such as epoxyeicosatrienoic acids. CYPs also participate in the production of bile acids from cholesterol.

In contrast to the drug-metabolizing CYPs, the CYPs that catalyze steroid and bile acid synthesis have specific substrate preferences. For example, the CYP that produces estrogen from testosterone, CYP19 or aromatase, can metabolize only testosterone or androstenedione and does not metabolize xenobiotics. Specific inhibitors for aromatase, such as *anastrozole*, have been

developed for use in the treatment of estrogen-dependent tumors (see Chapters 44 and 66).

The synthesis of bile acids from cholesterol occurs in the liver, where, subsequent to CYP-catalyzed oxidation, the bile acids are conjugated with amino acids and transported through the bile duct and gallbladder into the small intestine. Bile acids are emulsifiers that facilitate the elimination of conjugated drugs from the liver and the absorption of fatty acids and vitamins from the diet. In this capacity, more than 90% of bile acids are reabsorbed by the gut and transported back to the hepatocytes. Similar to the steroid biosynthetic CYPs, CYPs involved in bile acid production have strict substrate requirements and do not participate in xenobiotic or drug metabolism.

The CYPs that carry out xenobiotic metabolism have a tremendous capacity to metabolize a large number of structurally diverse chemicals. This is due to multiple forms of CYPs and to the capacity of a single CYP to metabolize many structurally distinct chemicals. There is also significant overlapping substrate specificity among CYPs; a single compound may be metabolized, albeit at different rates, by different CYPs. In addition, CYPs can metabolize a single compound at different positions on the molecule. In contrast to enzymes in the body that carry out highly specific reactions in which there is a single substrate and one or more products or two simultaneous substrates, the CYPs are considered promiscuous in their capacity to bind and metabolize multiple substrates (Table 6-2).

This accommodating property, due to large and fluid substrate-binding sites in the CYP, sacrifices metabolic turnover rates: CYPs metabolize substrates at a fraction of the rate of more typical enzymes involved in intermediary metabolism and mitochondrial electron transfer. As a result, drugs generally have half-lives on the order of 3–30 h, while endogenous compounds have half-lives on the order of seconds or minutes (e.g., dopamine and insulin). Even though CYPs have slow catalytic rates, their activities are sufficient to metabolize drugs that are administered at high concentrations in the body.

This unusual feature of extensive overlapping substrate specificities by the CYPs is one of the underlying reasons for the predominance of

TABLE 6-2 ■ MAJOR REACTIONS INVOLVED IN DRUG METABOLISM

	REACTION	EXAMPLES
I. Oxidative reactions		
N-Dealkylation		Imipramine, diazepam, codeine, erythromycin, morphine, tamoxifen, theophylline, caffeine
O-Dealkylation		Codeine, indomethacin, dextromethorphan
Aliphatic hydroxylation		Tolbutamide, ibuprofen, phenobarbital, meprobamate, cyclosporine, midazolam
Aromatic hydroxylation		Phenytoin, phenobarbital, propranolol, ethinyl estradiol, amphetamine, warfarin
N-Oxidation		Chlorpheniramine, dapsone, meperidine
S-Oxidation		Cimetidine, chlorpromazine, thioridazine, omeprazole
Deamination		Diazepam, amphetamine
II. Hydrolysis reactions		
		Carbamazepine (see Figure 6-4)
		Procaine, aspirin, clofibrate, meperidine, enalapril, cocaine
		Lidocaine, procainamide, indomethacin
III. Conjugation reactions		
Glucuronidation		Acetaminophen, morphine, oxazepam, lorazepam
Sulfation		Acetaminophen, steroids, methyl dopa
Acetylation		Sulfonamides, isoniazid, dapsone, clonazepam
Methylation*		L-dopa, methyl dopa, mercaptopurine, captopril
Glutathionylation		Adriamycin, fosfomycin, busulfan

PAPS, 3'-phosphoadenosine-5' phosphosulfate; PAP, 3'-phosphoadenosine-5'-phosphate; AdoMet, S-adenosylmethionine; AdoHomCys, S-adenosylhomocysteine.

*also for RS-, RN-.

drug-drug interactions. When two coadministered drugs are both metabolized by a single CYP, they compete for binding to the enzyme's active site. This can result in the inhibition of metabolism of one or both of the drugs, leading to elevated plasma levels. If there is a narrow therapeutic index for the drugs, the elevated serum levels may elicit unwanted toxicities. Drug-drug interactions are among the leading causes of ADRs.

The Naming of CYPs

The CYPs, responsible for metabolizing the vast majority of therapeutic drugs, are the most actively studied of the xenobiotic-metabolizing enzymes. CYPs are complex and diverse in their regulation and catalytic activities. Genome sequencing has revealed the existence of 102 putatively functional CYP genes and 88 pseudogenes in the mouse and 57 putatively functional genes and 58 pseudogenes in humans. These genes are grouped, based on amino acid sequence similarity, into a superfamily composed of families and subfamilies with increasing sequence similarity. CYPs are named with the root CYP followed by a number designating the family, a letter denoting the subfamily, and another number designating the CYP form. Thus, CYP3A4 is family 3, subfamily A, and gene number 4.

A Small Number of CYPs Metabolize the Majority of Drugs

A limited number of CYPs (15 in humans) that fall into families 1, 2, and 3 are primarily involved in xenobiotic metabolism. Because a single CYP can metabolize a large number of structurally diverse compounds, these enzymes can collectively metabolize scores of chemicals found in the diet, environment, and pharmaceuticals. In humans, 12 CYPs (CYP1A1, 1A2, 1B1, 2A6, 2B6, 2C8, 2C9, 2C19, 2D6, 2E1, 3A4, and 3A5) are important for metabolism of xenobiotics. The liver contains the greatest abundance of xenobiotic-metabolizing CYPs, thus ensuring efficient first-pass metabolism of drugs. CYPs are also expressed throughout the GI tract and in lower amounts in lung, kidney, and even in the CNS.

The expression of the different CYPs can differ markedly as a result of dietary and environmental exposure to inducers or through interindividual changes resulting from heritable polymorphic differences in gene structure, and tissue-specific expression patterns can affect overall drug metabolism and clearance. The most active CYPs for drug metabolism are those in the CYP2C, CYP2D, and CYP3A subfamilies. CYP3A4, the most abundantly expressed in liver, is involved in the metabolism of over 50% of clinically used drugs (Figure 6-3A). The CYP1A, CYP1B, CYP2A, CYP2B, and CYP2E subfamilies are not significantly involved in the metabolism of therapeutic drugs, but they do catalyze the metabolic activation of many protoxins and procarcinogens to their ultimate reactive metabolites.

There are large differences in levels of expression of each CYP between individuals as assessed by both clinical pharmacologic studies and analysis of expression in human liver samples. This large interindividual variability in CYP expression is due to the presence of genetic polymorphisms and differences in gene regulation (see discussion that follows). Several human CYP genes exhibit polymorphisms, including CYP2A6, CYP2C9, CYP2C19, and CYP2D6. Allelic variants have been found in the CYP1B1 and CYP3A4 genes, but they are present at low frequencies in humans and appear not to have a major role in interindividual levels of expression of these enzymes. However, homozygous mutations in the CYP1B1 gene are associated with primary congenital glaucoma.

Drug-Drug Interactions

Differences in the rate of metabolism of a drug can be due to drug interactions. Most commonly, this occurs when two drugs (e.g., a statin and a macrolide antibiotic or antifungal agent) are coadministered and subjected to metabolism by the same enzyme. Because most of these drug-drug interactions are due to CYPs, it thus becomes important to determine the identity of the CYP that metabolizes a particular drug and to avoid coadministering drugs that are metabolized by the same enzyme. Some drugs can also inhibit CYPs independently of being substrates for a CYP. For example, the common antifungal agent *ketoconazole* is a potent inhibitor of CYP3A4 and other CYPs, and coadministration of *ketoconazole* with the anti-HIV viral protease inhibitors reduces the clearance of the protease inhibitor and increases its plasma concentration and the risk of toxicity.

A. Phase 1 Enzymes

B. Phase 2 Enzymes

Figure 6-3 The fraction of clinically used drugs metabolized by the major phase 1 and phase 2 enzymes. The relative size of each pie section represents the estimated percentage of drugs metabolized by the major phase 1 (A) and phase 2 (B) enzymes, based on studies in the literature. In some cases, more than a single enzyme is responsible for metabolism of a single drug.

Some drugs are CYP inducers that not only can increase their own rates of metabolism but also can induce metabolism of other coadministered drugs (see the following discussion and Figure 6-12). Steroid hormones and herbal products such as St. John's wort can increase hepatic levels of CYP3A4, thereby increasing the metabolism of many orally administered drugs. Drug metabolism can also be influenced by diet. CYP inhibitors and inducers are commonly found in foods, and in some cases these can influence the toxicity and efficacy of a drug. For most drugs, descriptive information found on the package insert lists the CYP that carries out its metabolism and the potential for drug interactions. Components found in grapefruit juice (e.g., naringin, furanocoumarins) are potent inhibitors of CYP3A4, and thus some drug inserts recommend not taking medication with grapefruit juice because it could increase the bioavailability of a drug.

Terfenadine, a once-popular antihistamine, was removed from the market because its metabolism was inhibited by CYP3A4 substrates such as *erythromycin* and grapefruit juice. *Terfenadine* is actually a prodrug that requires oxidation by CYP3A4 to its active metabolite, and at high doses the parent compound caused arrhythmias. Elevated plasma levels of the parent drug resulting from CYP3A4 inhibition caused ventricular tachycardia in some individuals, which ultimately led to the withdrawal of *terfenadine* from the market.

Interindividual differences in drug metabolism are significantly influenced by polymorphisms in CYPs. The CYP2D6 polymorphism has led to the withdrawal of several clinically used drugs (e.g., *debrisoquine* and *perhexiline*) and the cautious use of others that are known CYP2D6 substrates

(e.g., *encainide* and *flecainide* [antiarrhythmics], *desipramine* and *nortriptyline* [antidepressants], and *codeine*).

Flavin-Containing Monooxygenases

The FMOs are another superfamily of phase 1 enzymes involved in drug metabolism. Similar to CYPs, the FMOs are expressed at high levels in the liver and are bound to the endoplasmic reticulum, a site that favors interaction with and metabolism of hydrophobic drug substrates. There are six families of FMOs, with FMO3 the most abundant in liver. FMO3 is able to metabolize nicotine, as well as H_2 -receptor antagonists (*cimetidine* and *ranitidine*), antipsychotics (*clozapine*), and antiemetics (*itopride*). Trimethylamine *N*-oxide (TMAO) occurs in high concentrations, up to 15% by weight, in marine animals, where it acts as an osmotic regulator. In humans, FMO3 normally metabolizes TMAO to TMA, but a genetic deficiency of FMO3 causes the fish-odor syndrome, in which unmetabolized TMAO accumulates in the body and causes a socially offensive fish odor.

FMOs are considered minor contributors to drug metabolism, and they almost always produce benign metabolites. In addition, FMOs are not readily inhibited and are not induced by any of the xenobiotic receptors (see discussion that follows); thus, in contrast to CYPs, FMOs would not be expected to be involved in drug-drug interactions. In fact, this has been demonstrated by comparing the pathways of metabolism of two drugs used in the control of gastric motility: itopride and cisapride. Itopride is metabolized by FMO3; cisapride is metabolized by CYP3A4. As predicted, itopride is less likely to be involved in drug-drug interactions than is cisapride. CYP3A4 participates in drug-drug interactions through induction and inhibition of metabolism, whereas FMO3 is not induced or inhibited by any clinically used drugs. It is possible that FMOs may be important in the development of new drugs. A candidate drug could be designed by introducing a site for FMO oxidation with the knowledge that selected metabolism and pharmacokinetic properties could be accurately calculated for efficient drug-based biological efficacy.

Hydrolytic Enzymes

Two forms of EH carry out hydrolysis of epoxides, most of which are produced by CYPs. The sEH is expressed in the cytosol; mEH is localized to the membrane of the endoplasmic reticulum. Epoxides are highly reactive electrophiles that can bind to cellular nucleophiles found in protein, RNA, and DNA, resulting in cell toxicity and transformation. Thus, EHs participate in the deactivation of potentially toxic metabolites generated by CYPs.

There are a few examples of the influence of mEH on drug metabolism. The antiepileptic drug *carbamazepine* is a prodrug that is converted to its pharmacologically active derivative carbamazepine-10,11-epoxide, by CYP. This metabolite is efficiently hydrolyzed to a dihydrodiol by mEH, resulting in inactivation of the drug (Figure 6-4). Inhibition of mEH can cause an elevation in plasma concentrations of the active metabolite and consequent side effects. The tranquilizer *valnoctamide* and anticonvulsant *valproate* inhibit mEH, resulting in clinically significant drug interactions with carbamazepine. This has led to efforts to develop new antiepileptic drugs, such as *gabapentin* and *levetiracetam*, that are metabolized by CYPs and not by EHs.

In general, the sEH complements the mEH in terms of substrate selectivity, with mEH degrading epoxides on cyclic systems and sEH having a high V_m and low K_m for fatty acid epoxides. Fatty acid epoxides are chemical mediators in the CYP branch of the arachidonic acid cascade. Simplistically, they can be thought of as balancing the generally pro-inflammatory and hypertensive prostaglandins, thromboxanes, and leukotrienes. The epoxides of arachidonic acid and docosahexaenoic acid reduce inflammation, hypertension, and pain but are normally degraded quickly by sEH to vicinal diols that are generally less biologically active (Figure 6-5). Thus, by inhibiting sEH, one can obtain dramatic biological effects. Recent work has focused on pain, where sEH inhibitors reduce both inflammatory and neuropathic pain and synergize with nonsteroidal anti-inflammatory drugs (Kodani and Hammock, 2015). In experimental systems, epoxides of dietary omega-3 and omega-6 fatty acids have anti-inflammatory

Figure 6-4 Metabolism of carbamazepine by CYP and mEH. Carbamazepine is oxidized to the pharmacologically active metabolite carbamazepine-10,11-epoxide by CYP. The epoxide is converted to a trans-dihydrodiol by mEH. This metabolite is biologically inactive and can be conjugated by phase 2 enzymes.

properties, moderating inflammation and autophagy in insulin-sensitive tissues, effects that inhibitors of sEH promote (Lopez-Vicario et al., 2015).

The *carboxylesterases* comprise a superfamily of enzymes that catalyze the hydrolysis of ester- and amide-containing chemicals. These enzymes are found in both the endoplasmic reticulum and the cytosol of many cell types and are involved in detoxification or metabolic activation of various drugs, environmental toxicants, and carcinogens. Carboxylesterases also catalyze the activation of prodrugs to their respective free acids. For example, the prodrug and cancer chemotherapeutic agent *irinotecan* is

Figure 6-5 Production and metabolism of an omega-3 fatty acid epoxide. Fatty acid epoxides, such as the epoxide of the omega-3 fatty acid shown here, have a variety of anti-inflammatory and antinociceptive properties in test systems but are usually evanescent, metabolized to biologically less-active dihydroxy forms by sEH. Inhibition of sEH may promote the salutary effects of these epoxides.

Figure 6-6 Metabolism of irinotecan (CPT-11). The prodrug CPT-11 is initially metabolized by a serum esterase (CES2) to the topoisomerase inhibitor SN-38, which is the active camptothecin analogue that slows tumor growth. SN-38 is then subject to glucuronidation, which results in loss of biological activity and facilitates elimination of SN-38 in the bile.

a camptothecin analogue that is bioactivated by intracellular carboxylesterases to the potent topoisomerase inhibitor SN-38 (Figure 6-6).

Phase 2 Reactions: Conjugating Enzymes

There are a large number of phase 2 conjugating enzymes, all of which are considered to be synthetic in nature because they result in the formation of metabolites with increased molecular mass. Phase 2 reactions also normally terminate the biological activity of the drug, although there are exceptions: For *morphine* and *minoxidil*, glucuronide and sulfate conjugates, respectively, are more pharmacologically active than the parent. The contributions of different phase 2 reactions to drug metabolism are shown in Figure 6-3B.

Two of the phase 2 reactions, glucuronidation and sulfation, result in the formation of metabolites with a significantly increased water-to-lipid partition coefficients. Sulfation and acetylation generally terminate the biological activity of drugs, and the minor change in overall charge increases the aqueous solubility of the metabolite. The enhanced hydrophilicity facilitates metabolite transport into the aqueous compartments of the cell and the body. Characteristic of the phase 2 reactions is the dependency on the catalytic reactions for cofactors (or, more correctly, cosubstrate): UDP-GA for UGT and PAPS for SULTs, which react

with available functional groups on the substrates. The reactive functional groups are often generated by the phase 1 CYPs, although there are many drugs (e.g., *acetaminophen*) for which glucuronidation and sulfation occur directly without prior oxidative metabolism. All of the phase 2 reactions are carried out in the cytosol of the cell, with the exception of glucuronidation, which is localized to the luminal side of the endoplasmic reticulum.

The catalytic rates of phase 2 reactions are significantly faster than the rates of the CYPs. Thus, if a drug is targeted for phase 1 oxidation through the CYPs, followed by a phase 2 conjugation reaction, usually the rate of elimination will depend on the initial (phase 1) oxidation reaction. Because the rate of conjugation is faster and the process leads to an increase in hydrophilicity of the drug, phase 2 reactions are generally considered to ensure efficient elimination and detoxification of most drugs.

Glucuronidation

Among the more important of the phase 2 reactions in drug metabolism is those catalyzed by UGTs (Figure 6-3B). These enzymes catalyze the transfer of glucuronic acid from the cofactor UDP-GA to a substrate to form β -d-glucopyranosiduronic acids (glucuronides), metabolites that are sensitive to cleavage by β -glucuronidase. Glucuronides can be formed via alcoholic and phenolic hydroxyl groups; carboxyl, sulfuryl, and carbonyl moieties; and primary, secondary, and tertiary amines. UGT substrates include many hundreds of chemically unique pharmaceuticals; dietary substances; environmental agents; humoral agents such as circulating hormones (androgens, estrogens, mineralocorticoids, glucocorticoids, thyroxine); bile acids; retinoids; and bilirubin, the end product of heme catabolism.

Examples of glucuronidation reactions are shown in Table 6-2 and Figures 6-1 and 6-6. The structural diversity of the drugs and other xenobiotics that are processed through glucuronidation ensures that most clinically efficacious therapeutic agents will be excreted as glucuronides.

The UGTs are expressed in a highly coordinated tissue-specific and often inducible fashion, with the highest concentration found in the GI tract and liver. Per tissue weight, there are a greater number and higher concentration of the UGTs in the small intestine compared to the liver, so efficient first-pass metabolism plays a role in predicting bioavailability of many orally administered medications. Formation of glucuronides and their increased polarity can result in their passage into the circulation, from which they are excreted into the urine. Alternatively, as xenobiotics enter the liver and are absorbed into hepatocytes, glucuronide formation provides substrates for active transport into the bile canaliculi and ultimate excretion with components of the bile (see Figure 5-9). Many of the glucuronides that are excreted into the bile eventually become substrates for soluble microbial β -glucuronidase in the large intestine, resulting in the formation of free glucuronic acid and the initial substrate. The colon actively absorbs water and a variety of other compounds (see Figure 50-3); depending on its solubility, the glucuronide or the original substrate may be reabsorbed via passive diffusion or by apical transporters in the colon and reenter the systemic circulation. This process, called *enterohepatic recirculation*, can extend the half-life of a xenobiotic that is conjugated in the liver because the compound's ultimate excretion is delayed (see Figures 6-8 and 6-9).

There are 19 human genes that encode the UGT proteins. Nine are encoded by the *UGT1A* locus on chromosome 2q37 (1A1, 1A3, 1A4, 1A5, 1A6, 1A7, 1A8, 1A9, and 1A10), while 10 genes are encoded by the *UGT2* family of genes on chromosome 4q13.2 (2B17, 2B15, 2B10, 2A3, 2B7, 2B11, 2B2, 2B4, 2A1, 2A2, and 2A3). Of these proteins, the major UGTs involved in drug metabolism are UGT1A1, 1A3, 1A4, 1A6, 1A9, and 2B7 (for a list of common UGT drug substrates, see Rowland et al., 2013). Although both families of proteins are associated with metabolism of drugs and xenobiotics, the UGT2 family of proteins appears to have greater specificity for the glucuronidation of endogenous substances.

The *UGT1* locus on chromosome 2 (Figure 6-7) spans nearly 200 kb, with over 150 kb of a tandem array of cassette exonic regions that encode approximately 280 amino acids of the amino terminal portion of the UGT1A proteins. Four exons are located at the 3' end of the locus; these

Figure 6-8 Routes of SN-38 transport and exposure to intestinal epithelial cells. SN-38 is transported into the bile following glucuronidation by liver UGT1A1 and extrahepatic UGT1A7. Following cleavage of luminal SN-38 glucuronide (SN-38G) by bacterial β -glucuronidase, reabsorption into epithelial cells can occur by passive diffusion (indicated by the dashed arrows entering the cell) as well as by apical transporters. Movement into epithelial cells may also occur from the blood by basolateral transporters. Intestinal SN-38 can efflux into the lumen through Pgp and MRP2 and into the blood via MRP1. Excessive accumulation of the SN-38 in intestinal epithelial cells, resulting from reduced glucuronidation, can lead to cellular damage and toxicity. (Modified and reproduced with permission from Tukey RH et al. Pharmacogenomics of human UDP-glucuronosyltransferases and irinotecan toxicity. *Mol Pharmacol*, 2002, 62:446–450. Sulfation

The SULTs, located in the cytosol, conjugate sulfate derived from PAPS to hydroxyl and, less frequently, amine groups of aromatic and aliphatic compounds. Like all of the xenobiotic-metabolizing enzymes, the SULTs metabolize a wide variety of endogenous and exogenous substrates. In humans, 13 SULT isoforms have been identified; based on sequence comparisons, they are classified into the SULT1 (SULT1A1, SULT1A2, SULT1A3/4, SULT1B1, SULT1C2, SULT1C3, SULT1C4, SULT1E1);

SULT2 (SULT2A1, SULT2B1a, SULT2B1b); SULT4 (SULT4A1); and SULT6 (SULT6A1) families. There are major interspecies differences in the expressed complement of SULTs, which makes extrapolation of data on xenobiotic sulfation in animals to humans particularly unreliable.

SULTs play an important role in normal human homeostasis. For example, SULT2B1b is a predominant form expressed in skin, carrying out the catalysis of cholesterol. Cholesterol sulfate is an essential metabolite in regulating keratinocyte differentiation and skin development. SULT2A1 is

Figure 6-9 Cellular targets of SN-38 in the blood and intestinal tissues. Excessive accumulation of SN-38 can lead to blood toxicities, such as leukopenia and neutropenia, as well as damage to the intestinal epithelium. These toxicities are pronounced in individuals who have reduced capacity to form the SN-38 glucuronide, such as patients with Gilbert syndrome. Note the different body compartments and cell types involved. (Modified and reproduced with permission from Tukey RH et al. Pharmacogenomics of human UDP-glucuronosyltransferases and irinotecan toxicity. *Mol Pharmacol*, 2002, 62:446–450. Copyright © 2002 The American Society for Pharmacology and Experimental Therapeutics.)

highly expressed in the fetal adrenal gland, where it produces the large quantities of dehydroepiandrosterone sulfate that are required for placental estrogen biosynthesis during the second half of pregnancy. SULTs 1A3 and 1A4 are highly selective for catecholamines, while estrogens (in particular 17 β -estradiol) are sulfated by SULT1E1. In humans, significant fractions of circulating catecholamines, estrogens, iodothyronines, and DHEA exist in the sulfated form.

Some human SULTs display unique substrate specificities, whereas others are promiscuous. Members of the SULT1 family are the major isoforms involved in xenobiotic metabolism, with SULT1A1 quantitatively and qualitatively the most important in the liver. SULT1A1 displays extensive diversity in its capacity to catalyze the sulfation of a broad variety of structurally heterogeneous xenobiotics with high affinity. The isoforms in the SULT1 family are recognized as phenol SULTs; they catalyze the sulfation of phenolic molecules such as *acetaminophen*, *minoxidil*, and *17 α -ethinyl estradiol*. SULT1B1 is similar to SULT1A1 in its wide range of substrates, although it is much more abundant in the intestine than the liver. Three SULT1C isoforms exist in humans, but little is known of their substrate specificity. In rodents, SULT1C enzymes are capable of sulfating the hepatic carcinogen *N*-OH-2-acetylaminofluorene and are responsible for the bioactivation of this and related carcinogens. Their role in this pathway in humans is not clear. SULT1C enzymes are expressed abundantly in human fetal tissues, yet decline in abundance in adults. SULT1E catalyzes the sulfation of endogenous and exogenous steroids and is localized in liver and in hormone-responsive tissues such as the testis, breast, adrenal gland, and placenta. In the upper GI tract, SULT1A3/4 and SULT1B1 are particularly abundant.

The conjugation of drugs and xenobiotics is considered primarily a detoxification step, ensuring that the metabolites enter the aqueous compartments of the body and are targeted for elimination. However, drug metabolism through sulfation often leads to the generation of chemically reactive metabolites, wherein the sulfate is electron withdrawing and may be heterolytically cleaved, leading to the formation of an electrophilic cation. Most examples of the generation by sulfation of a carcinogenic or toxic response in animal or mutagenicity assays have been documented with chemicals derived from the environment or from heterocyclic arylamine food mutagens generated from well-cooked meat. Thus, it is important to understand whether genetic linkages can be made by associating known human SULT polymorphisms to cancers that are believed to originate from environmental sources. Because SULT1A1 is the most abundant SULT form in human tissues and displays broad substrate specificity, the polymorphic profiles associated with this gene and their associations with various human cancers are of considerable interest.

Gene copy number polymorphisms within the SULT1A1, SULT1A3, and SULT1A4 genes have been identified, which may help explain much of the interindividual variation in the expression and activity of these enzymes. Knowledge of the structure, activities, regulation, and polymorphisms of the SULT superfamily will aid in understanding the linkages between sulfation and cancer susceptibility, reproduction, and development. Structural data, the results of kinetic studies, and molecular dynamics simulations are beginning to provide a picture of the mechanisms by which the SULTs express their unique patterns of substrate specificity (Tibbs et al., 2015).

Glutathione Conjugation

The GSTs catalyze the transfer of glutathione to reactive electrophiles, a function that serves to protect cellular macromolecules from interacting with electrophiles that contain electrophilic heteroatoms ($-O$, $-N$, and $-S$) and in turn protects the cellular environment from damage (Hayes et al., 2005). The cosubstrate in the reaction is glutathione, a tripeptide consisting of γ -glutamic acid, cysteine, and glycine (Figure 6–10). Glutathione exists in the cell in oxidized (GSSG) and reduced (GSH) forms, and the GSH:GSSG ratio is critical in maintaining a cellular environment in the reduced state. In addition to affecting xenobiotic conjugation with GSH, a severe reduction in GSH content can predispose cells to oxidative damage, a state that has been linked to a number of human health issues.

Figure 6–10 Glutathione is a cosubstrate in the conjugation of a xenobiotic (X) by GST.

In the formation of glutathione conjugates, the GST reaction generates a thioether linkage with drug or xenobiotic to the cysteine moiety of the tripeptide. Characteristically, all GST substrates contain an electrophilic atom and are hydrophobic; by nature, they will associate with cellular proteins. Because the concentration of glutathione in cells is usually high, typically 7 $\mu\text{mol/g}$ of liver or in the 10-mM range, many drugs and xenobiotics can react nonenzymatically with glutathione. However, the GSTs have been found to occupy up to 10% of the total hepatocellular protein concentration, a property that ensures efficient conjugation of glutathione to reactive electrophiles. The high concentration of GSTs also provides the cells with a sink of cytosolic protein, a property that facilitates non-covalent and sometimes covalent interactions with compounds that are not substrates for glutathione conjugation. The cytosolic pool of GSTs, once identified as *ligandin*, binds steroids, bile acids, bilirubin, cellular hormones, and environmental toxicants, in addition to complexing with other cellular proteins.

There are in excess of 20 human GSTs, divided into two subfamilies: the *cytosolic* and the *microsomal* forms. The major differences in function between the microsomal and cytosolic GSTs reside in the selection of substrates for conjugation; the cytosolic forms have more importance in the metabolism of drugs and xenobiotics, whereas the microsomal GSTs are important in the endogenous metabolism of leukotrienes and prostaglandins. The cytosolic GSTs are divided into seven classes termed alpha (GSTA1 and 2), mu (GSTM1 through 5), omega (GSTO1), pi (GSTP1), sigma (GSTS1), theta (GSTT1 and GSTT2), and zeta (GSTZ1). Those in the alpha and mu classes can form heterodimers, allowing for a large number of active transferases to form. The cytosolic forms of GST catalyze conjugation, reduction, and isomerization reactions.

The high concentrations of GSH in the cell, as well as the overabundance of GSTs, means that few reactive molecules escape detoxification. Despite the appearance of overcapacity of enzyme and reducing equivalents, there is always concern that some reactive intermediates will escape detoxification and, by nature of their electrophilicity, will bind to cellular components and cause havoc. The potential for such an occurrence is heightened if GSH is depleted or if a specific form of GST is polymorphic and dysfunctional. While it is difficult to deplete cellular GSH levels, therapeutic agents that require large doses to be clinically efficacious have the greatest potential to lower cellular GSH levels.

Acetaminophen, normally metabolized by glucuronidation and sulfation, is also a substrate for oxidative metabolism by CYP2E1 and CYP3A4, which generate the toxic metabolite NAPQI, which, under normal dosing, is readily neutralized through conjugation with GSH. However, an overdose of acetaminophen can deplete cellular GSH levels and thereby increase the potential for NAPQI to interact with other cellular components, resulting in toxicity and cell death. Acetaminophen toxicity is associated with increased levels of NAPQI and hepatic necrosis, although it may be treated in a time- and drug concentration-dependent manner by administration of *N*-acetylcysteine (see Figure 4–4).

All of the GSTs are polymorphic. The mu (GSTM1*0) and theta (GSTT1*0) genotypes express a null phenotype; thus, individuals who are polymorphic at these loci are predisposed to toxicities by agents that are selective substrates for these GSTs. For example, the mutant GSTM1*0 allele is observed in 50% of the Caucasian population and links genetically to human malignancies of the lung, colon, and bladder. Null activity in the *GSTT1* gene associates with adverse side effects and toxicity in cancer chemotherapy with cytostatic drugs; the toxicities result from insufficient clearance of the drugs via GSH conjugation. Expression of the null genotype can be as high as 60% in Chinese and Korean populations. GST polymorphisms may influence efficacies and severity of adverse side effects of drugs.

While the GSTs play an important role in cellular detoxification, their activities in cancerous tissues have been linked to the development of drug resistance toward chemotherapeutic agents that are both substrates and nonsubstrates for the GSTs. Many anticancer drugs are effective because they initiate cell death or apoptosis, which is linked to the activation of MAPKs such as JNK and p38. Investigational studies demonstrated that overexpression of GSTs is associated with resistance to apoptosis and the inhibition of MAPK activity. In a variety of tumors, GSTs are overexpressed, leading to a reduction in MAPK activity and reduced efficacy of chemotherapy. Taking advantage of the relatively high levels of GST in tumor cells, inhibition of GST activity has been exploited as a therapeutic strategy to modulate drug resistance by sensitizing tumors to anticancer drugs. TLK199, a glutathione analogue, is a prodrug that plasma esterases convert to a GST inhibitor, TLK117, which potentiates the toxicity of different anticancer agents (Figure 6–11).

Alternatively, the elevated GST activity in cancer cells has been utilized to develop prodrugs that can be activated by the GSTs to form electrophilic intermediates. For example, TLK286 is a substrate for GST that undergoes a β -elimination reaction, forming a glutathione conjugate and a nitrogen mustard (Figure 6–12) that is capable of alkylating cellular nucleophiles and resulting in antitumor activity (Townsend and Tew, 2003).

N-Acetylation

The cytosolic NATs are responsible for the metabolism of drugs and environmental agents that contain an aromatic amine or hydrazine group. The addition of the acetyl group from the cofactor acetyl-coenzyme A

Figure 6–11 Activation of TLK199 to TLK117, a GST inhibitor.

often leads to a metabolite that is less water soluble because the potential ionizable amine is neutralized by the covalent addition of the acetyl group. NATs are among the most polymorphic of all the human xenobiotic drug-metabolizing enzymes.

The characterization of an acetylator phenotype in humans was one of the first hereditary traits identified and was responsible for the development of the field of pharmacogenetics (see Chapter 7). Following the discovery that isoniazid (isonicotinic acid hydrazide) could be used to treat

Figure 6–12 Generation of the reactive alkylating agent following the conjugation of glutathione to TLK286. GST interacts with the prodrug and GSH analogue TLK286 via a tyrosine in the active site of GST. The GSH portion is shown in blue. The interaction promotes β -elimination and cleavage of the prodrug to a vinyl sulfone and an active alkylating fragment.

tuberculosis, a significant proportion of the patients (5%–15%) experienced toxicities that ranged from numbness and tingling in their fingers to CNS damage. After finding that isoniazid was metabolized by acetylation and excreted in the urine, researchers noted that individuals who had the toxic effects of the drug excreted the largest amount of unchanged drug and the least amount of acetylated isoniazid. Pharmacogenetic studies led to the classification of “rapid” and “slow” acetylators, with the slow phenotype predisposed to toxicity (see Figure 60–4). Purification and characterization of NAT and the eventual cloning of its RNA provided sequence characterization of the gene for slow and fast acetylators, revealing polymorphisms that correspond to the slow acetylator phenotype.

There are two functional NAT genes in humans, *NAT1* and *NAT2*. Over 25 allelic variants of *NAT1* and *NAT2* have been characterized. In individuals in whom acetylation of drugs is compromised, homozygous genotypes for at least two variant alleles are required to predispose a patient to slower drug metabolism. Polymorphism in the *NAT2* gene and its association with the slow acetylation of isoniazid were one of the first completely characterized genotypes shown to affect drug metabolism, thereby linking pharmacogenetic phenotype to a genetic polymorphism. Although nearly as many mutations have been identified in the *NAT1* gene as the *NAT2* gene, the frequency of the slow acetylation patterns is attributed mostly to the polymorphism in the *NAT2* gene.

Some common drug substrates of NAT and their known toxicities are listed in Table 6–4 (see Meisel, 2002, for details). The therapeutic relevance of NAT polymorphisms is in avoiding drug-induced toxicities. The adverse drug response in a slow acetylator resembles a drug overdose; thus, reducing the dose or increasing the dosing interval is recommended. Aromatic amine or hydrazine groups exist in many classes of clinically used drugs, and if a drug is known to be subjected to metabolism through acetylation, determining an individual's phenotype can be important in maximizing a positive therapeutic outcome. For example, *hydralazine*, a once-popular orally active antihypertensive (vasodilator) drug, is metabolized by *NAT2*. The administration of therapeutic doses of hydralazine to a slow acetylator can result in extreme hypotension and tachycardia.

Several known targets for acetylation, such as the sulfonamides, have been implicated in idiosyncratic hypersensitivity reactions; in such instances, an appreciation of a patient's acetylation phenotype is particularly important. Sulfonamides are transformed into hydroxylamines that

interact with cellular proteins, generating haptens that can elicit autoimmune responses, to which slow acetylators are predisposed.

Tissue-specific expression patterns of *NAT1* and *NAT2* have a significant impact on the fate of drug metabolism and the potential for eliciting a toxic episode. *NAT1* is ubiquitously expressed among most human tissues, whereas *NAT2* is found predominantly in liver and the GI tract. Characteristic of both *NAT1* and *NAT2* is the ability to form *N*-hydroxyacetylated metabolites from bicyclic aromatic hydrocarbons, a reaction that leads to the nonenzymatic release of acetyl groups and the generation of highly reactive nitrenium ions. Thus, *N*-hydroxy acetylation is thought to activate certain environmental toxicants. In contrast, direct *N*-acetylation of bicyclic aromatic amines is stable and leads to detoxification. Individuals who are *NAT2* fast acetylators are able to efficiently metabolize and detoxify bicyclic aromatic amines through liver-dependent acetylation. However, slow acetylators (*NAT2* deficient) accumulate bicyclic aromatic amines that become substrates for CYP-dependent *N*-oxidation. These *N*-OH metabolites are eliminated in the urine. In tissues such as bladder epithelium, *NAT1* is highly expressed and can efficiently catalyze the *N*-hydroxy acetylation of bicyclic aromatic amines, a process that leads to deacetylation and the formation of the mutagenic nitrenium ion, especially in *NAT2*-deficient subjects. Epidemiological studies have shown that slow acetylators are predisposed to bladder cancer if exposed environmentally to bicyclic aromatic amines.

Methylation

In humans, drugs and xenobiotics can undergo *O*-, *N*-, and *S*-methylation. Humans express two COMTs, three *N*-methyl transferases, a POMT, a TPMT, and a TMT. All of the MTs exist as monomers and use *S*-adenosylmethionine (AdoMet) as the methyl donor. With the exception of a signature sequence that is conserved among the MTs, there is limited conservation in sequence, indicating that each MT has evolved to display a unique catalytic function. Although the common theme among the MTs is the generation of a methylated product, substrate specificity is high and distinguishes the individual enzymes.

Among the *N*-methyl transferases, NNMT methylates serotonin and tryptophan as well as pyridine-containing compounds such as nicotineamide and nicotine. PNMT is responsible for the methylation of the neurotransmitter norepinephrine to form epinephrine; the HNMT metabolizes drugs containing an imidazole ring. COMT, which exists as two protein

TABLE 6–4 ■ THERAPEUTIC USES AND ADVERSE EFFECTS OF COMMON *N*-ACETYLTRANSFERASE SUBSTRATES

NAT SUBSTRATE	THERAPEUTIC USES	ADVERSE EFFECTS
Acebutolol	Adrenal cortex carcinoma, breast cancer	Drowsiness, weakness, insomnia
Aminogluthethimide	β Blockade, arrhythmias, hypertension	Clumsiness, nausea, dizziness, agranulocytosis
Aminosalicic acid	Ulcerative colitis	Allergic fever, itching, leukopenia
Amrinone	Positive inotrope in heart failure	Thrombocytopenia, arrhythmias
Benzocaine	Local anesthesia	Dermatitis, itching, rash, methemoglobinemia
Caffeine	Neonatal respiratory distress syndrome	Dizziness, insomnia, tachycardia
Clonazepam	Seizures, anxiety	Drowsiness, ataxia, dizziness, slurred speech
Dapsone	Leprosy, dermatitis	Hemolysis, methemoglobinemia, nausea, dermatitis
Hydralazine	Hypertension (acts via vasodilation)	Hypotension, sympathetic baroreceptor reflex effects
Isoniazid	Tuberculosis	Peripheral neuritis, hepatotoxicity
Nitrazepam	Insomnia	Dizziness, somnolence
Phenelzine	Depression (acts via MAO inhibition)	Dizziness, CNS excitation, insomnia, orthostatic hypotension, hepatotoxicity
Procainamide	Ventricular tachyarrhythmia	Hypotension, bradycardia, lupus erythematosus
Sulfonamides	As bacteriostatic agents	Hypersensitivity, acute hemolytic anemia, reversible bone marrow suppression (with AIDS or myelosuppressive chemotherapy)

isoforms generated by alternate exon usage, methylates neurotransmitters containing a catechol moiety, such as dopamine and norepinephrine, as well as methyl dopa and *ecstasy* (3,4-methylenedioxymethamphetamine, MDMA).

From a clinical perspective, the most important MT may be TPMT, which catalyzes the S-methylation of aromatic and heterocyclic sulphydryl compounds, including the thiopurine drugs AZA, 6-MP, and *thioguanine*. AZA and 6-MP are used for the management of inflammatory bowel disease (see Chapter 51), as well as autoimmune disorders such as systemic lupus erythematosus and rheumatoid arthritis. Thioguanine is used in the treatment of acute myeloid leukemia, and 6-MP is used worldwide for the treatment of childhood acute lymphoblastic leukemia (see Chapter 66). Because TPMT is responsible for the detoxification of 6-MP, a genetic deficiency in TPMT can result in severe toxicities in patients taking the drug (see metabolic scheme in Figure 51-5). When given orally at clinically established doses, 6-MP serves as a prodrug that is metabolized by HGPRT to 6-TGNs, which become incorporated into DNA and RNA, resulting in arrest of DNA replication and cytotoxicity.

Toxic side effects arise when a lack of 6-MP methylation by TPMT causes a buildup of 6-MP and the consequent generation of toxic levels of 6-TGNs. The identification of the inactive TPMT alleles and the development of a genotyping test to identify homozygous carriers of the defective allele permit identification of individuals who may be predisposed to the toxic side effects of 6-MP therapy. Simple adjustments in the patient's dosage regimen are a lifesaving intervention for those with TPMT deficiencies.

Role of Xenobiotic Metabolism in Safe and Effective Use of Drugs

Any xenobiotics entering the body must be eliminated through metabolism and excretion via the urine or bile/feces. Mechanisms of metabolism and excretion prevent foreign compounds from accumulating in the body and possibly causing toxicity. In the case of drugs, metabolism normally results in the inactivation of their therapeutic effectiveness and facilitates their elimination. The extent of metabolism can determine the efficacy and toxicity of a drug by controlling its biological half-life. Among the most serious considerations in the clinical use of drugs are ADRs. If a drug is metabolized too quickly, it rapidly loses its therapeutic efficacy. This can occur if specific enzymes involved in metabolism are overly active or are induced by dietary or environmental factors. If a drug is metabolized too slowly, the drug can accumulate in the bloodstream; as a consequence, the plasma clearance of the drug is decreased, the AUC (see Figure 5-3) is elevated, and exposure to the drug may exceed clinically appropriate levels. An increase in AUC often results when specific xenobiotic-metabolizing enzymes are inhibited, which can occur when an individual is taking a combination of different therapeutic agents and one of those drugs targets the enzyme involved in drug metabolism. For example, the consumption of grapefruit juice with drugs taken orally can inhibit intestinal CYP3A4, blocking the metabolism of many of these drugs. The inhibition of specific CYPs in the gut by dietary consumption of grapefruit juice alters the oral bioavailability of many classes of drugs, including certain antihypertensives, immunosuppressants, antidepressants, antihistamines, and the statins, to name a few. Among the components of grapefruit juice that inhibit CYP3A4 are *naringin* and *furanocoumarins*.

While environmental factors can alter the steady-state levels of specific enzymes or inhibit their catalytic potential, these phenotypic changes in drug metabolism are also observed clinically in groups of individuals who are genetically predisposed to ADRs because of pharmacogenetic differences in the expression of xenobiotic-metabolizing enzymes (see Chapter 7). Most of the xenobiotic-metabolizing enzymes display polymorphic differences in their expression, resulting from heritable changes in the structure of the genes. For example, hyperbilirubinemia can result from a reduction in the ability to glucuronidate circulating bilirubin due to a lowered expression of the *UGT1A1* gene (Gilbert syndrome). Drugs that are subject to glucuronidation by UGT1A1, such as the topoisomerase

inhibitor SN-38 (Figures 6-6, 6-8, and 6-9), will display an increased AUC in individuals with Gilbert syndrome because such patients cannot detoxify these drugs. Most cancer chemotherapeutic agents have a narrow therapeutic index, and increases in the circulating levels of the active form due to a deficiency in drug clearance can result in significant toxicities.

Nearly every class of therapeutic agent has been reported to initiate an ADR. In the United States, ADRs annually cost an estimated at \$100 billion and cause over 100,000 deaths. An estimated 56% of drugs associated with ADRs are substrates for xenobiotic-metabolizing enzymes, notably CYPs and UGTs. Because many of the CYPs and UGTs are subject to induction as well as inhibition by drugs, dietary factors, and other environmental agents, these enzymes play an important role in most ADRs. Thus, prior to filing a New Drug Application (NDA), a new drug's route of metabolism must be known. Thus, it is routine practice in the pharmaceutical industry to establish which enzymes are involved in metabolism of a drug candidate and to identify the metabolites and determine their potential toxicity. In consideration of the major role of CYPs in the generation of ADRs, there is likely to be a move to avoid the major oxidative routes of metabolism when developing new small-molecule drugs.

Induction of Drug Metabolism

Xenobiotics can influence drug metabolism by activating transcription and inducing the expression of genes encoding drug-metabolizing enzymes. Thus, a foreign compound may induce its own metabolism, as may certain drugs. One potential consequence of this is a decrease in plasma drug concentration over the course of treatment, resulting in loss of efficacy, as the autoinduced metabolism of the drug exceeds the rate at which new drug enters the body. A list of ligands and the receptors through which they induce drug metabolism is shown in Table 6-5. A particular receptor, when activated by a ligand, can induce the transcription of a battery of target genes. Among these target genes are certain CYPs and drug transporters. Thus, any drug that is a ligand for a receptor that induces CYPs and transporters could lead to drug interactions. Figure 6-13 shows the scheme by which a drug may interact with nuclear receptors to induce its own metabolism.

The aryl hydrocarbon receptor (AHR) is a member of a superfamily of transcription factors with diverse roles in mammals, such as serving a regulatory role in the development of the mammalian CNS and modulating the response to chemical and oxidative stress. This superfamily of transcription factors includes (Period) and Sim (Simple-minded), two transcription factors involved in development of the CNS, and HIF1 α , HIF2 α , and their dimerization partner HIF1 β , which activate genes in response to low cellular O₂ levels.

The AHR induces expression of genes encoding CYP1A1, CYP1A2, and CYP1B1, which are able to metabolically activate chemical carcinogens, including environmental contaminants and carcinogens derived from food. Many of these substances are inert unless metabolized by CYPs. Thus, induction of these CYPs by a drug could potentially result

TABLE 6-5 ■ NUCLEAR RECEPTORS THAT INDUCE DRUG METABOLISM

RECEPTOR	LIGANDS
Aryl hydrocarbon receptor (AHR)	Omeprazole
Constitutive androstane receptor (CAR)	Phenobarbital
Pregnane X receptor (PXR)	Rifampin
Farnesoid X receptor (FXR)	Bile acids
Vitamin D receptor (VDR)	Vitamin D
Peroxisome proliferator-activated receptor (PPARs)	Fibrates
Retinoic acid receptor (RAR)	<i>all-trans</i> -Retinoic acid
Retinoid X receptor (RXR)	<i>9-cis</i> -Retinoic acid

Figure 6–13 Induction of drug metabolism by nuclear receptor-mediated signal transduction. When a drug such as atorvastatin (Ligand) enters the cell, it can bind to a nuclear receptor such as the PXR. The PXR then forms a complex with the RXR, binds to DNA upstream of target genes, recruits coactivator (which binds to the TBP), and activates transcription. Among PXR target genes are *CYP3A4*, which can metabolize the atorvastatin and decrease its cellular concentration. Thus, atorvastatin induces its own metabolism. Atorvastatin undergoes both ortho- and parahydroxylation.

in an increase in the toxicity and carcinogenicity of procarcinogens. For example, *omeprazole*, a proton pump inhibitor used to treat gastric and duodenal ulcers (see Chapter 49), is a ligand for the AHR and can induce *CYP1A1* and *CYP1A2*, with the possible consequences of toxin/carcinogen activation as well as drug-drug interactions in patients receiving agents that are substrates for either of these CYPs.

Another important induction mechanism is due to type 2 nuclear receptors that are in the same superfamily as the steroid hormone receptors. Many of these receptors, identified on the basis of their structural similarity to steroid hormone receptors, were originally termed *orphan receptors* because no endogenous ligands were known to interact with them. Subsequent studies revealed that some of these receptors are activated by xenobiotics, including drugs. The type 2 nuclear receptors of most importance to drug metabolism and drug therapy include PXR, CAR, and PPARs. PXR, discovered because it is activated by the synthetic steroid pregnenolone-16 α -carbonitrile, is also activated by a number of other drugs, including antibiotics (*rifampicin* and *troleandomycin*), Ca²⁺ channel blockers (*nifedipine*), statins (*mevastatin*), antidiabetic drugs (*trogliatone*), HIV protease inhibitors (*ritonavir*), and anticancer drugs (*paclitaxel*).

Hyperforin, a component of St. John's wort, an over-the-counter herbal remedy used for depression, also activates PXR. This activation is thought to be the basis for the increase in failure of oral contraceptives in individuals taking St. John's wort: Activated PXR is an inducer of *CYP3A4*, which can metabolize steroids found in oral contraceptives. PXR also induces the expression of genes encoding certain drug transporters and phase 2 enzymes, including SULTs and UGTs. Thus, PXR facilitates the metabolism and elimination of xenobiotics, including drugs, with notable consequences.

The nuclear receptor CAR was discovered based on its ability to activate genes in the absence of ligand. Steroids such as *androstanol*, the antifungal agent *clotrimazole*, and the antiemetic *meclizine* are inverse agonists that inhibit gene activation by CAR, while the pesticide 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene, the steroid 5- β -pregnane-3,20-dione, and probably other endogenous compounds are agonists that activate gene expression when bound to CAR. Genes induced by CAR include those encoding several CYPs (*CYP2B6*, *CYP2C9*, and *CYP3A4*); various phase 2 enzymes (including GSTs, UGTs, and SULTs); and drug and endobiotic

transporters. *CYP3A4* is induced by both PXR and CAR; thus, its level is highly influenced by a number of drugs and other xenobiotics. In addition to a potential role in inducing the degradation of drugs, including the over-the-counter analgesic acetaminophen, this receptor may function in the control of bilirubin degradation, the process by which the liver decomposes heme.

Clearly, PXR and CAR can bind a great variety of ligands. As with the xenobiotic-metabolizing enzymes, species differences also exist in the ligand specificities of these receptors. For example, rifampicin activates human PXR, but not mouse or rat PXR, while pregnenolone-16 α -carbonitrile preferentially activates the mouse and rat PXR. Paradoxically, meclizine activates mouse CAR but inhibits gene induction by human CAR. These findings further underscore that in some cases studies with rodent model systems do not reflect the response of humans to drugs.

The PPAR family is composed of three members: α , β , and γ . PPAR α is the target for the fibrate class of hyperlipidemic drugs, including the widely prescribed *gemfibrozil* and *fenofibrate*. Activation of PPAR α results in induction of target genes encoding fatty acid-metabolizing enzymes, resulting in lowering of serum triglycerides; in addition, activation of PPAR α induces CYP4 enzymes that carry out the oxidation of fatty acids and drugs with fatty acid-containing side chains, such as *leukotriene* and arachidonate analogues. PPAR γ is the target for the thiazolidinedione class of anti-type 2 diabetic drugs, including *rosiglitazone* and *pioglitazone*. PPAR γ does not induce xenobiotic metabolism.

The UGT genes, in particular UGT1A1, are a target for AHR, PXR, CAR, PPAR α , and Nrf2 (nuclear factor 2 (erythroid-derived 2-like factor), a major transcriptional regulator of cytoprotective genes induced by an antioxidant response). Because the UGTs are abundant in the GI tract and liver, regulation of the UGTs by drug-induced activation of these receptors would be expected to play a role concerning the pharmacokinetic parameters of many orally administered therapeutics.

Role of Drug Metabolism in Drug Development

There are two key elements associated with successful drug development: *efficacy* and *safety*. Both depend on drug metabolism. It is necessary to determine which enzymes metabolize a new drug candidate to predict

whether the compound may cause drug-drug interactions or be susceptible to marked interindividual variation in metabolism due to genetic polymorphisms.

For determination of metabolism, the compound is subjected to analysis by human liver cells or extracts from these cells that contain the drug-metabolizing enzymes. Such studies determine how humans will metabolize a particular drug and, to a limited extent, predict the rate of metabolism. If a CYP is involved, a panel of recombinant CYPs can be used to determine which CYP predominates in the metabolism of the drug. If a single CYP, such as CYP3A4, is found to be the sole CYP that metabolizes a drug candidate, then a decision can be made about the likelihood of drug interactions.

Interactions become a problem when multiple drugs are simultaneously administered, for example, in elderly patients, who on a daily basis may take prescribed anti-inflammatory drugs, cholesterol-lowering drugs, blood pressure medications, a gastric acid suppressant, an anticoagulant, and a number of over-the-counter medications. Ideally, the best drug candidate would be metabolized by several CYPs so that variability in expression levels of one CYP or drug-drug interactions would not significantly affect its metabolism and pharmacokinetics.

Similar studies can be carried out with phase 2 enzymes and drug transporters to predict the metabolic fate of a drug. In addition to the use of recombinant human xenobiotic-metabolizing enzymes in predicting drug metabolism, human receptor-based (PXR and CAR) systems or cell lines expressing these receptors are used to determine whether a particular drug candidate could be a ligand or activator of PXR, CAR, or PPAR α . For example, a drug that activates PXR may result in rapid clearance of other drugs that are CYP3A4 substrates, thus decreasing their bioavailability and efficacy.

Computer-based computational (in silico) prediction of drug metabolism is a prospect for the near future. The structures of several CYPs have been determined, including those of CYPs 2A6, 2C9, and 3A4. These structures may be used to predict metabolism of a drug candidate by fitting the compound to the enzyme's active site and determining oxidation potentials of sites on the molecule. However, the structures, determined by X-ray analysis of crystals of enzyme-substrate complexes, are static, whereas enzymes are flexible; this vital distinction may be limiting. The large size of the CYP active sites, which permits them to metabolize many different compounds, also renders them difficult to model. The potential for modeling ligand or activator interactions with nuclear receptors also exists with limitations similar to those discussed for the CYPs.

Determining the potential for a drug candidate to produce acute toxicity in preclinical studies is vital and routine in drug development. This is typically done by administering the drug candidate to rodents at escalating doses, usually above the predicted human therapeutic dose. For drug candidates proposed for chronic use in humans, such as for lowering serum triglycerides and cholesterol or for treatment of type 2 diabetes, long-term carcinogenicity studies are carried out in rodent models. Signs of toxicity are monitored and organ damage assessed by postmortem pathologies. This process is not high throughput and can be a bottleneck in development of lead compounds.

A new technology of high-throughput screening for biomarkers of toxicity is being adopted for drug development using *metabolomics*. Metabolomics is the systematic identification and quantification of all metabolites

in a given organism or biological sample. Analytical platforms such as ^1H nuclear magnetic resonance and liquid chromatography or gas chromatography coupled to mass spectrometry, in conjunction with chemometric and multivariate data analysis, allow the simultaneous determination and comparison of thousands of chemicals in biological fluids such as serum and urine, as well as the chemical constituents of cells and tissues. This technology can be a screen for drug toxicity in whole-animal systems during preclinical drug development and can obviate the need for time-consuming and expensive necropsies and pathologies on thousands of animals.

Using metabolomics, animals, either treated or not treated with a drug candidate, can be analyzed for the presence of one or more metabolites in urine that correlate with drug efficacy or toxicity. Urine metabolites that are fingerprints for liver, kidney, and CNS toxicity have been identified using known chemical toxicants. Metabolic fingerprints of specific compounds that are elevated in urine can be used to determine, in dose escalation studies, whether a particular drug causes toxicity and can also be employed in early clinical trials to monitor for potential toxicities. Metabolomics can be used to find biomarkers for drug efficacy and toxicity that can be of value in clinical trials to identify responders and nonresponders. Drug metabolism can be studied in whole-animal model systems and in humans to determine the metabolites of a drug or indicate the presence of a polymorphism in drug metabolism that might signal an adverse clinical outcome. Finally, biomarkers developed from experimental metabolomics could eventually be developed for routine monitoring for signs of toxicity in patients receiving pharmacotherapy.

PHARMACOGENETICS IN CLINICAL PRACTICE

It is a given that patients vary in their responses to drug therapy. Some patients derive striking and sustained benefits from drug administration; others may display no benefit, and still others display mild, severe, or even fatal adverse drug reactions (ADRs). Common sources of such variability include noncompliance, medication errors, drug interactions (see Chapter 4 and Appendix I), and genetic factors. *Pharmacogenetics* is the study of the genetic basis for variation in drug response and often implies large effects of a small number of DNA variants. *Pharmacogenomics*, on the other hand, studies larger numbers of variants, in an individual or across a population, to explain the genetic component of variable drug responses. Discovering which variants or combinations of variants have functional consequences for drug effects, validating those discoveries, and ultimately applying them to patient care and to drug discovery are the tasks of modern pharmacogenetics and pharmacogenomics.

Importance of Pharmacogenetics to Variability in Drug Response

An individual's response to a drug depends on the complex interplay among environmental factors (e.g., diet, age, infections, other drugs, exercise level, occupation, exposure to toxins, and tobacco and alcohol use) and genetic factors. Genetic variation may result in altered protein sequence and function or in altered protein levels through regulatory variation. Key genes involved in driving variable drug actions include those encoding drug-metabolizing enzymes, drug transport molecules, the molecular targets with which drugs interact, and a host of other genes that modulate the molecular context within which drugs act, notably genes dysregulated in the disease for which the drug is administered. In some situations, variation in nongermline genomes (e.g., in cancers or in infectious agents) can be critical determinants of variable drug responses.

Drug metabolism is highly heritable, as assessed using drug exposures in monozygotic versus fraternal twins, drug exposures in cell lines from related subjects, or analysis of very large data sets using technologies such as genome-wide genotyping, discussed further in this chapter. Twin studies suggested that up to 75% of the variability in elimination half-lives for metabolized drugs can be heritable. Some drug metabolism traits behave in a conventional “monogenic” fashion with three clearly definable (and separable) groups of drug response phenotypes: heterozygotes as well as major and minor allele homozygotes. The study of these types of responses has helped define key genetic variants that contribute to the striking variability

in responses described in this chapter. However, large effect size single variants are the exception, and for many (most) drug responses, the genetic component of variable responses—although substantial—likely reflects interacting influences of many genetic variants. A major challenge to the field is to accrue large numbers of subjects with well-phenotyped drug responses to enable discovery, and subsequent replication and validation, of multigene effects or of interactions of gene(s) with environmental factors.

Principles of Pharmacogenetics

Phenotype-Driven Terminology

A trait (e.g., the CYP2D6 “poor metabolizer” [PM], as opposed to “extensive metabolizer” [EM]) may be apparent only with nonfunctional alleles on both the maternal and the paternal chromosomes. If the gene is on a nonsex chromosome, the trait is autosomal. The nonfunctional alleles may be the same; the trait is then termed *autosomal recessive*, or different, in which case the subject is a *compound heterozygote*. A trait is deemed *codominant* if heterozygotes exhibit a phenotype that is intermediate to that of homozygotes for the common allele and homozygotes for the variant allele. Many polymorphic traits (e.g., CYP2C19 metabolism of drugs such as clopidogrel and omeprazole) are now recognized to exhibit some degree of codominance; as a result, heterozygotes exhibit metabolizing activity that is intermediate between that of EM and PM subjects.

In some instances, such as clopidogrel, codeine, and irinotecan (described further in this chapter), variants in a single gene produce clearly defined and clinically important differences in drug response. However, these high effect size examples are the exception for two reasons. First, even within a single gene, a vast array of polymorphisms (promoter, coding, noncoding, completely inactivating, or modestly modifying) is possible. Each polymorphism may produce a different effect on gene function and therefore differentially affect a measured trait. Second, even if the designations of recessive, codominant, and dominant are informative for a given gene, their utility in describing the genetic variability that underlies variability in drug response phenotype is diminished because variability is often multigenic.

Types of Genetic Variants

The major types of sequence variation are *single-nucleotide polymorphisms* (SNPs, sometimes termed *single-nucleotide variants*, SNVs), and *insertions or deletions*, which can range in size from a single nucleotide to an entire

Abbreviations

ABCB1: multidrug resistance transporter (P-glycoprotein)
ACE: angiotensin-converting enzyme
ADR: adverse drug reaction
AUC: area under the curve
CBS: cystathionine β -synthase
CF: cystic fibrosis
CNV: copy number variation
cSNP: coding SNP
CYP: cytochrome P450
EGFR: epidermal growth factor receptor
EMR: electronic medical record
FDA: U.S. Food and Drug Administration
FH: familial hypercholesterolemia
GI: gastrointestinal
G6PD: glucose-6-phosphate dehydrogenase
GST: glutathione-S-transferase
GSTM1: glutathione-S-transferase M1
GWAS: genome-wide association study
HIV: human immunodeficiency virus
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A
5HT: 5-hydroxytryptamine, serotonin
indels: insertions or deletions
INR: international normalized ratio
iPSC: induced pluripotent stem cell
LDL: low-density lipoprotein
MAF: minor allele frequency
MDR1: multidrug resistance protein 1
mRNA: messenger RNA
MTHFR: methylenetetrahydrofolate reductase
nsSNP: nonsynonymous SNP
PharmGKB: Pharmacogenomics Knowledgebase
PheWAS: phenome-wide association study
PM: poor metabolizer
RCT: randomized clinical trial
SNP: single-nucleotide polymorphism
SNV: single-nucleotide variant
sSNP: synonymous or sense SNP
TPMT: thiopurine methyltransferase
TYMS: thymidylate synthase
UDP: uridine diphosphate
UGT: UDP-glucuronosyltransferase
UTR: untranslated region
VKORC1: vitamin K epoxide reductase

chromosome; smaller ones are generally termed *indels*, and larger ones are designated CNVs. SNPs are much more common than indels or CNVs (Figure 7-1). The term *polymorphism* was formerly applied to variants occurring at a frequency greater than 1%. However, the application of genome sequencing to large numbers of subjects has made it clear that each individual has more than 10 million sites across their genome at which they differ from some reference sequence (i.e., ~1 variant per 1000 base pairs). While some of these are “common” (>1% frequency), the vast majority are much rarer. For rare variants clearly associated with a genetic disease, the term *mutation* may also be used, but distinguishing between a very rare variant and a mutation may be difficult. Publically available web-based databases (e.g., <http://gnomad.broadinstitute.org>) aggregate sequence data in tens of thousands of subjects and highlight that MAFs may vary strikingly across ancestries (discussed later), and that for the vast majority of variants is much less than 1%.

SNPs

Single-nucleotide polymorphisms

Coding, nonsynonymous
e.g., *TPMT**3A

Coding, synonymous
e.g., *ABCB1* C3435T

Noncoding (promoter, intronic)
e.g., *CYP3A5**3

Indels

Insertions/Deletions

e.g., 68 bp Insertion in *CBS*,
e.g., TA repeat in *UGT1A1*

(TA)₇ TAA
(TA)₆ TAA

CNVs

Copy number variations

Gene Duplications

e.g., *CYP2D6*, up to 13 copies

Large Deletions

e.g., entire *GSTT1* and *GSTM1*

Figure 7-1 Molecular mechanisms of genetic polymorphisms. The most common genetic variants are SNP substitutions. Coding nonsynonymous SNPs result in a nucleotide substitution that changes the amino acid codon (here proline to glutamine), which could change protein structure, stability, or substrate affinities or introduce a stop codon. Coding synonymous SNPs do not change the amino acid codon but may have functional consequences (transcript stability, splicing). Noncoding SNPs may be in promoters, introns, or other regulatory regions that may affect transcription factor binding, enhancers, transcript stability, or splicing. The second major type of polymorphism is indels. SNP indels can have any of the same effects as SNP substitutions: short repeats in the promoter (which can affect transcript amount) or indels that add or subtract amino acids. CNVs involve large segments of genomic DNA that may involve gene duplications (stably transmitted inherited germline gene replication that causes increased protein expression and activity), gene deletions that result in the complete lack of protein production, or inversions of genes that may disrupt gene function. All of these mechanisms have been implicated in common germline pharmacogenetic polymorphisms.

The SNPs in the coding region are termed *cSNPs* and are further classified as *nonsynonymous* (changing the encoded amino acid sequence) or *synonymous* (or *sense*, with no amino acid change). A nucleotide substitution in an *nsSNP* that changes the amino acid codon (e.g., proline [CCG] to glutamine [CAG]) can as a result change protein structure, stability, or substrate affinities. There are 64 trinucleotide codons and only 20 amino acids, so multiple codons encode the same amino acid. Often, substitutions of the third base pair, termed the *wobble position*, in a codon with 3 base pairs, such as the G-to-A substitution in proline (CCG → CCA), do not alter the encoded amino acid. Up to about 10% of SNPs display more than two possible alleles (e.g., a C can be replaced by either an A or a G), so that the same polymorphic site can be associated with amino acid substitutions in some alleles but not others. As discussed in the material that follows, assessing the functional consequences of *nsSNPs*

Figure 7-2 Nomenclature of genomic regions.

can be challenging. SNPs that introduce a premature stop codon, and small indels in a coding region that disrupt the open reading frame and thereby introduce abnormal 3' protein sequences often with early stop codons, are termed *nonsense* variants, and these are thought to be most likely to display abnormal protein function.

Synonymous polymorphisms have been reported to contribute to a phenotypic trait. One example is a polymorphism in *ABCB1*, which encodes MDR1 (also termed P-glycoprotein), an efflux pump that interacts with many clinically used drugs. In *MDR1*, a synonymous polymorphism, C3435T, is associated with various phenotypes, and some evidence indicates that the one of the resulting mRNAs is translated at a slower rate, thereby altering folding of the protein, its insertion into the membrane, and thus its interaction with drugs (Kimchi-Sarfaty et al., 2007).

The vast majority (>97%–99%) of human DNA is noncoding, and the regulatory functions of noncoding sequences are only now being defined. Polymorphisms in noncoding regions may occur in the 3' and 5' untranslated regions, in promoter or enhancer regions, in intronic regions, or in large regions between genes, intergenic regions (for nomenclature guide, see Figure 7-2). Noncoding SNPs in promoter or enhancer sequences are thought to alter DNA binding by regulatory proteins to affect transcription. 3' SNPs may alter binding of microRNAs that affect transcript stability. Noncoding SNPs may also create alternative intron-exon splicing sites, and the altered transcript may have fewer or more exons, or shorter or longer exons, than the wild-type transcript. Large consortia are defining the functions of noncoding DNA: The ENCODE project identifies functional elements (enhancers, promoters, etc.) in genome sequences; and GTEx relates genome sequence variation to tissue-specific variability in gene expression (ENCODE Project Consortium, 2012; GTEx Consortium, 2015).

Like SNPs, indels can be short repeats in the promoter (which can affect transcript amount) or insertions/deletions that add or subtract amino acids in the coding region. The number of TA repeats in the *UGT1A1* promoter affects the quantitative expression of this important glucuronosyltransferase in liver; the most common allele has six repeats and the seven-repeat variant (*UGT1A1**28) decreases *UGT1A1* expression. The frequency of the *28 allele is up to 30%, with up to 10% of subjects (depending on ancestry) being homozygous. Decreased *UGT1A1* transcription can modulate drug actions as described further in the chapter and also accounts for a common form of mild hyperbilirubinemia (Gilbert syndrome; see Table 6-3 and Figure 6-7).

The CNVs appear to occur in about 10% of the human genome and in one study accounted for about 18% of the detected genetic variation in expression of about 15,000 genes in lymphoblastoid cell lines (Stranger et al., 2007). The ultrarapid CYP2D6 metabolizer phenotype arises as a result of *CYP2D6* duplication(s), and individuals with more than 10 functional copies of the gene have been described. A common *GSTM1* polymorphism is caused by a large (50-kb) deletion, and the null allele has a population frequency of 30%–50%. Biochemical studies indicated that livers from homozygous null individuals have only about 50% of the glutathione-conjugating capacity of those with at least one copy of the *GSTM1* gene.

A *haplotype*—a series of alleles found at a linked locus on a chromosome—specifies the DNA sequence variation in a gene or a gene region on one chromosome. For example, consider two SNPs in *ABCB1*. One SNP is a T-to-A base-pair substitution at position 3421, and the other is

a C-to-T change at position 3435. Possible haplotypes would be $T_{3421}C_{3435}$, $T_{3421}T_{3435}$, $A_{3421}C_{3435}$, and $A_{3421}T_{3435}$. For any gene, individuals will have two haplotypes, one maternal and one paternal in origin. A haplotype represents the constellation of variants that occur together for the gene on each chromosome. In some cases, this constellation of variants, rather than the individual variant or allele, may be functionally important. In others, however, a single variant may be functionally important regardless of other linked variants within the haplotype(s).

Linkage disequilibrium is the term used to describe the situation in which genotypes at the two loci are not independent of one another. With complete linkage disequilibrium, genotype at one site is a perfect predictor of genotype at the linked site. Patterns of linkage disequilibrium are population specific, and as recombination occurs, linkage disequilibrium between two alleles will decay and linkage equilibrium will result. Linkage disequilibrium has been enabling for genome-wide association studies because genotyping at a small number of SNPs (“tag SNPs”) in linkage disequilibrium with many others can capture common variation across regions.

Ancestral Diversity

Polymorphisms differ in their frequencies within human populations and have been classified as either cosmopolitan or population (or race and ethnic) specific. *Cosmopolitan polymorphisms* are those polymorphisms present in all ethnic groups and are likely to be ancient, having arisen before migrations of humans from Africa, although present-day frequencies may differ among ancestral groups. The presence of *ancestry-specific polymorphisms* is consistent with geographical isolation of human populations. These polymorphisms probably arose in isolated populations and then reached a certain frequency because they are either advantageous in some way (positive selection) or neutral to a population. Individuals descended from multiple ancestries may display haplotype structures and allele frequencies intermediate between their parents. In the U.S., African Americans have the highest number of population-specific polymorphisms (and the smallest haplotype blocks) in comparison to European Americans, Mexican Americans, and Asian Americans.

Pharmacogenetic Study Design Considerations

There are many important considerations for the conduct of an experiment designed to identify sources of genetic variation contributing to variable drug responses. These include material to be studied (e.g., cells, organs, human subjects); the subjects' genetic backgrounds; the presence of confounders such as diet or variable experimental conditions; the selection of variants to be studied (ranging from a single high-likelihood candidate SNP to “agnostic” approaches that interrogate the whole genome); the methods used for genotyping and quality control; statistical analysis considerations, including effect size estimates and consideration of ancestry; and replication of findings.

Pharmacogenetic Traits

A *pharmacogenetic trait* is any measurable or discernible trait associated with a drug. Some traits reflect the beneficial or adverse effect of a drug in a patient; lowering of blood pressure or reduction in tumor size are examples. These have the disadvantage that they reflect many genetic and

nongenetic influences, but the advantage that they indicate a drug's clinical effects. Other traits represent drug response "endophenotypes," measures that may more directly reflect the action of a drug in a biologic system and thus be more amenable to genetic study but may be removed from the whole patient or a whole population. Examples of the latter include enzyme activity, drug or metabolite levels in plasma or urine, or drug-induced changes in gene expression patterns.

A variant drug metabolizer phenotype can be inferred from genotype data or in some cases directly measured by administering a "probe drug" (one thought to be metabolized by a single pathway) and measuring drug and metabolite concentrations. For example, one method to determine *CYP2D6* metabolizer status is to measure the urinary ratio of parent drug to metabolite after a single oral dose of the *CYP2D6* substrate dextromethorphan. Similarly, mephenytoin can be used as a probe drug for *CYP2C19* metabolizer phenotype. An important caveat is that other drugs can interfere with this assessment: If dextromethorphan is given with a potent inhibitor of *CYP2D6*, such as quinidine or fluoxetine, the phenotype may be consistent with or a "phenocopy of" the poor metabolizer genotype, even though the subject carries wild-type *CYP2D6* alleles. In this case, the assignment of a *CYP2D6* poor metabolizer phenotype would not be accurate. Another pharmacogenetic endophenotype, the erythromycin breath test (for *CYP3A* activity), can sometimes be unstable within a subject, indicating that the phenotype is highly influenced by nongenetic or multigenic factors. *Most pharmacogenetic traits are multigenic rather than monogenic* (Figure 7–3), and considerable effort is being made to identify the important polymorphisms that influence variability in drug response.

Genotyping

Most genotyping methods use DNA extracted from somatic, diploid cells, usually white blood cells or buccal cells. This "germline" DNA is extremely stable if appropriately extracted and stored, and the DNA sequence is generally (but likely not totally) invariant throughout an individual's lifetime. Any genotyping result should be subject to standard and rigorous quality control, which may include inspection of source genotyping experimental data, exclusion of SNPs with a high genotyping failure rate, exclusion of

subjects in which many SNP analyses failed, assessment of Hardy-Weinberg equilibrium, and ensuring the absence of important substructure (e.g., many related individuals) in a general population study. *Hardy-Weinberg* equilibrium is maintained when mating within a population is random and there is no natural selection effect on the variant. Such assumptions are described mathematically when the proportions of the population that are observed to be homozygous for the variant genotype (q^2), homozygous for the wild-type genotype (p^2), and heterozygous ($2p \cdot q$) are not significantly different from that predicted from the overall allele frequencies (p = frequency of wild-type allele; q = frequency of variant allele) in the population. A deviation from Hardy-Weinberg equilibrium (i.e., from the rule that $p^2 + 2pq + q^2 = 1$) suggests a specific survival disadvantage for a particular genotype or a genotyping or other experimental error.

Candidate Gene Versus Genome-Wide Approaches

A candidate gene study uses what is known about a drug (e.g., its metabolism, transport, or mechanism of action) to test the hypothesis that variants in the underlying genes account for variable drug response phenotypes. Variants may be chosen because they are common, known (or thought) to be functional, or tag haplotype blocks. After assays are developed for a set of such variants, statistical methods are used to relate genotype to phenotype. There are several databases that contain information on polymorphisms in human genes (Table 7–1); these databases allow the investigator to search by gene for reported polymorphisms. Some of the databases, such as PharmGKB, include phenotypic as well as genotypic data.

Large-Scale "Agnostic" Approaches

While the candidate gene approach has the intuitive appeal that known drug response pathways are studied, it has the drawback of looking only in regions of known biologic activity. Indeed, candidate genetic studies for susceptibility to common diseases have a remarkably high rate of failure to replicate, and this has been attributed to naïveté about the polygenic nature of most traits, small sizes with underpowering, and a "winner's curse" in which only positive results are published (Ioannidis et al., 2001). It has been argued that, unlike common disease studies, precedent has shown that drug responses may indeed reflect large effect sizes of a small

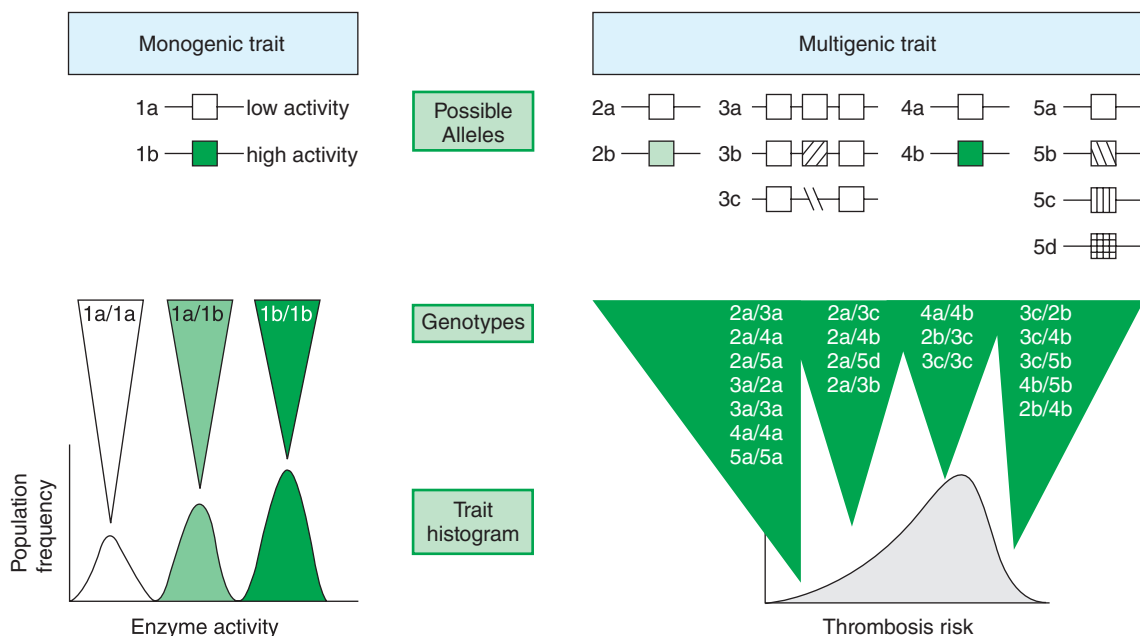

Figure 7–3 Monogenic versus multigenic pharmacogenetic traits. Possible alleles for a monogenic trait (upper left), in which a single gene has a low-activity (1a) and a high-activity (1b) allele. The population frequency distribution of a monogenic trait (bottom left), here depicted as enzyme activity, may exhibit a trimodal frequency distribution among low activity (homozygosity for 1a), intermediate activity (heterozygote for 1a and 1b), and high activity (homozygosity for 1b). This is contrasted with multigenic traits (e.g., an activity influenced by up to four different genes, genes 2 through 5), each of which has two, three, or four alleles (a through d). The population histogram for activity is unimodal skewed, with no distinct differences among the genotypic groups. Multiple combinations of alleles coding for low activity and high activity at several of the genes can translate into low-, medium-, and high-activity phenotypes.

Broad Institute Software	www.broadinstitute.org/data-software-and-tools	Software tools for the analysis of genetic studies

number of genes, but these limitations should nevertheless be borne in mind in the conduct of these studies.

An alternate approach to the candidate gene approach is a GWAS, in which genotypes at more than 500,000 SNP sites (generally tagging haplotype blocks across the genome) are compared across a continuous trait or between cases and controls (e.g., those with or without a therapeutic response or an ADR). A GWAS requires large numbers of subjects, must consider the appropriate statistical approaches to minimize type I (false-positive) errors, and, if successful, identifies loci of interest that require further investigation to identify causative variants and the underlying biology. While associations identified by GWASs generally have modest effect sizes (odds ratios < 2), even with very low *P* values, pharmacogenetic GWASs provide some exceptions; for example, a GWAS in 51 cases of flucloxacillin-induced hepatotoxicity and 282 controls identified risk SNPs in the HLA-B locus with an odds ratio greater than 80 (Daly et al., 2009). Not all pharmacogenetic GWASs have successfully identified signals with this strength, but the approach has some promise and is increasingly used (Karnes et al., 2015; Mosley et al., 2015; Motsinger-Reif et al., 2013; Van Driest et al., 2015).

The GWAS analyses have also provided strong support for candidate gene studies that implicate variants in *CYP2C9* and *VKORC1* in warfarin dose requirement (Cooper et al., 2008; Takeuchi et al., 2009; see Figure 32–6 and Table 32–2) and variants in *CYP2C19* in clopidogrel clinical response (Shuldiner et al., 2009). Newer genotyping platforms can capture both rare coding region variants and tags for common haplotype blocks, and the availability of increasing amounts of sequence data allows reasonable inferences (by a statistical method called imputation) of up to 10 million genotypes from a GWAS genotyping experiment.

While single experimental approaches can suggest a relationship between variable drug responses and a variant in a specific locus or gene, the use of multiple complementary approaches provides the strongest evidence supporting such relationships. One method is to establish that putative variants do in fact display altered function in an *in vitro* system, as discussed in the material that follows. Another approach is to integrate genotype data (by GWAS) with other large-scale measures of gene function, such as the abundance of mRNAs (transcriptomics) or proteins (proteomics). This has the advantage that the abundance of signal may itself directly reflect some of the relevant genetic variation. One such study identified six loci at which exposure to simvastatin in cell lines changed gene expression, and variants in one of these genes, glycine amidinotransferase, was associated with simvastatin myotoxicity in a clinical trial (Mangravite et al., 2013). However, both mRNA and protein expression are highly influenced by choice of tissue type, which may not be available; for example, it may not be feasible to obtain biopsies of brain tissue for studies of CNS toxicity. The GTEx project described previously couples

whole-genome sequence to mRNA transcript levels across multiple tissues and should enable further such studies.

Large-scale coupling of genotypes to phenotypes in EMR systems with associated DNA biobanks represents another potential resource for pharmacogenomic studies. One interesting approach using such biobanks is to turn the GWAS paradigm “on its head” and to ask with what human phenotype is a particular genetic variant associated. This PheWAS can be used to replicate a GWAS result or to identify entirely new associations (Denny et al., 2013) and has been used to “repurpose” (suggest new indications for) marketed drugs (Rastegar-Mojarad et al., 2015).

Functional Studies of Polymorphisms

Once a gene or a locus modulating a drug response phenotype is identified, a major challenge is to establish which coding or regulatory variants contribute. Comparative genomics and functional studies of individual polymorphisms *in vitro* and in animal models are commonly used approaches. Precedents from Mendelian diseases suggest that the variants with the greatest potential effect sizes are rare nonsense variants or missense variants that drastically alter evolutionarily conserved residues. For example, studies of variants in membrane transporters and ion channels suggested that those conferring with the greatest change in function are at low allele frequencies and change an evolutionarily conserved amino acid residue. These data indicate that SNPs that alter evolutionarily conserved residues are most deleterious. For example, substitution of a charged amino acid (Arg) for a nonpolar, uncharged amino acid (Cys) is more likely to affect function than substitution of residues that are more chemically similar (e.g., Arg to Lys). The data also suggest that rare nsSNPs are more likely to alter function than common ones.

The link between Mendelian disease and variant drug responses is highlighted by the fact that one of the first pharmacogenetic examples to be discovered was G6PD deficiency, an X-linked monogenic trait that results in severe hemolytic anemia in individuals after ingestion of fava beans or various drugs, including many antimalarial agents. G6PD is normally present in red blood cells and regulates levels of the antioxidant glutathione. Antimalarials such as primaquine increase red blood cell fragility in individuals with G6PD deficiency, leading to profound hemolytic anemia; the trait is more common in African Americans. The severity of the deficiency syndrome varies among individuals and is related to the amino acid variant in G6PD. The severe form of G6PD deficiency is associated with changes at residues that are highly conserved across evolutionary history. *The information in Table 7–2 on genetic polymorphisms influencing drug response at the end of the chapter can be used as a guide for prioritizing polymorphisms in candidate gene association studies.*

With increasing application of exome or whole-genome sequencing in populations, millions of DNA variants are being identified, and methods

to establish their function are evolving. One approach uses computational algorithms to identify potentially deleterious amino acid substitutions. Earlier methods (e.g., BLOSUM62, SIFT, and PolyPhen) use sequence comparisons across multiple species to identify and score substitutions, especially at highly conserved residues. More recent approaches use structural predictions (Kircher et al., 2014) or integrate multiple predictors (e.g., CADD). While these programs are becoming increasingly sophisticated, they have not yet reached the point that they can substitute for experimental verification.

The functional activity of amino acid variants for many proteins can be studied in isolation, in cellular assays, or in animal models. A traditional step in a cellular study of a nonsynonymous variant is to isolate the variant gene or to construct the variant by site-directed mutagenesis, express it in cells, and compare its functional activity (enzymatic activity, transport kinetics, ion channel gating, etc.) to that of the reference or most common form of the protein (Figure 7–4). Figure 7–5 shows an example of how the combination of population studies, in vitro functional assays, and in silico simulations can be integrated to identify a variant that modulates the risk of drug-induced arrhythmias.

The SNPs identified in GWAS as associated with clinical phenotypes, including drug response phenotypes, have largely been in noncoding regions. An example of profound functional effect of a noncoding SNP is provided by *CYP3A5*; a common noncoding intronic SNP in *CYP3A5* accounts for its polymorphic expression in humans. The SNP accounting for variation in *CYP3A5* protein creates an alternative splice site, resulting

Figure 7–4 Simulated concentration-dependence curves for the common genetic form of an enzyme and two nonsynonymous variants. Compared to the common form of the enzyme, variant A exhibits an increased K_m , likely reflecting an altered substrate-binding site of the protein by the substituted amino acid. Variant B exhibits the same K_m as the common form but a reduced maximum rate of metabolism of the substrate (V_{max}). Because these measurements were made on cell extracts, the reduced V_{max} may be due to a reduced expression level of the enzyme. If similar data were obtained with purified protein, then the reduced activity of variant B could be ascribed to a structural alteration in the enzyme that affects its maximal catalytic rate but not its affinity for the substrate under these assay conditions.

Figure 7–5 Functional evaluation of an ion channel variant. A population study implicated an nsSNP resulting in D85N in *KCNE1* as a modulator of the risk for arrhythmias when blockers of the *KCNH2* K^+ channel are administered to patients (Kääb et al., 2012). *KCNE1* encodes a function-modifying subunit for a different cardiac K^+ channel (encoded by *KCNQ1*), and the ion currents generated at a range of voltages by heterologous coexpression of *KCNQ1* plus the wild-type or mutant *KCNE1* are shown in A and B, respectively. While there are subtle differences in activation kinetics and overall current amplitude, it is not clear whether these are functionally important. C. Results of numerical action potential simulations incorporating either the experimentally determined wild-type or variant K^+ current. At baseline (black and green tracings), there is no difference in computed action potential duration. However, when drug block of the *KCNH2* K^+ channel is superimposed and the stimulation rate is slowed (orange tracings), an arrhythmogenic afterpotential (arrow) is seen with the mutant but not the wild-type *KCNE1*. Taken together, these functional data therefore provide support for the population study. (Data from Drs. Al George and Yoram Rudy.)

in not only a transcript with a larger exon 3 but also the introduction of an early stop codon (Figure 7–6). The nonfunctional allele is more common in subjects of European ancestry compared to those of African ancestry; as a result, CYP3A5 activity is lower in individuals expressing the noncoding intronic SNP (i.e., for a given dose of a drug that is a substrate of CYP3A5, concentrations of the drug will be higher in Europeans). Increased rates of transplant rejection in subjects of African descent may reflect decreased plasma concentrations of the antirejection drug tacrolimus, a substrate for CYP3A5 (the higher activity form lacking the noncoding intronic SNP) (Birdwell et al., 2012).

Two new technologies appear poised to revolutionize functional studies. The first is the ability to generate iPSCs from any individual and then use the cells to generate specific cell types (hepatocytes, cardiomyocytes, neurons, etc.), thereby enabling studies of that individual's cellular physiology. The second is rapid and efficient genome editing using CRISPR/cas9 in iPSCs or any other cell system (see Chapter 3). Multiple exciting applications of genome-editing technology, from rapid generation of genetically modified animals to curing genetic disease in humans, are

being explored. Genome editing holds the promise that the function of individual coding or noncoding variants, alone or in combination, can be rapidly assessed in cellular systems.

Pharmacogenetic Phenotypes

Candidate genes for therapeutic and adverse response can be divided into three categories:

- those modifying drug disposition (*pharmacokinetic*)
- those altering the function of the molecules with which drugs interact to produce their beneficial or adverse effects (*receptor/target*)
- those altering the broad *biologic milieu* in which the drugs interact with target molecules, including the changes associated with the diseases for which the drug is being prescribed

This section summarizes important examples of each type but cannot be all inclusive. Web-based resources such as PharmGKB (Table 7–1) can be consulted for specific genes, variants, drugs, and diseases.

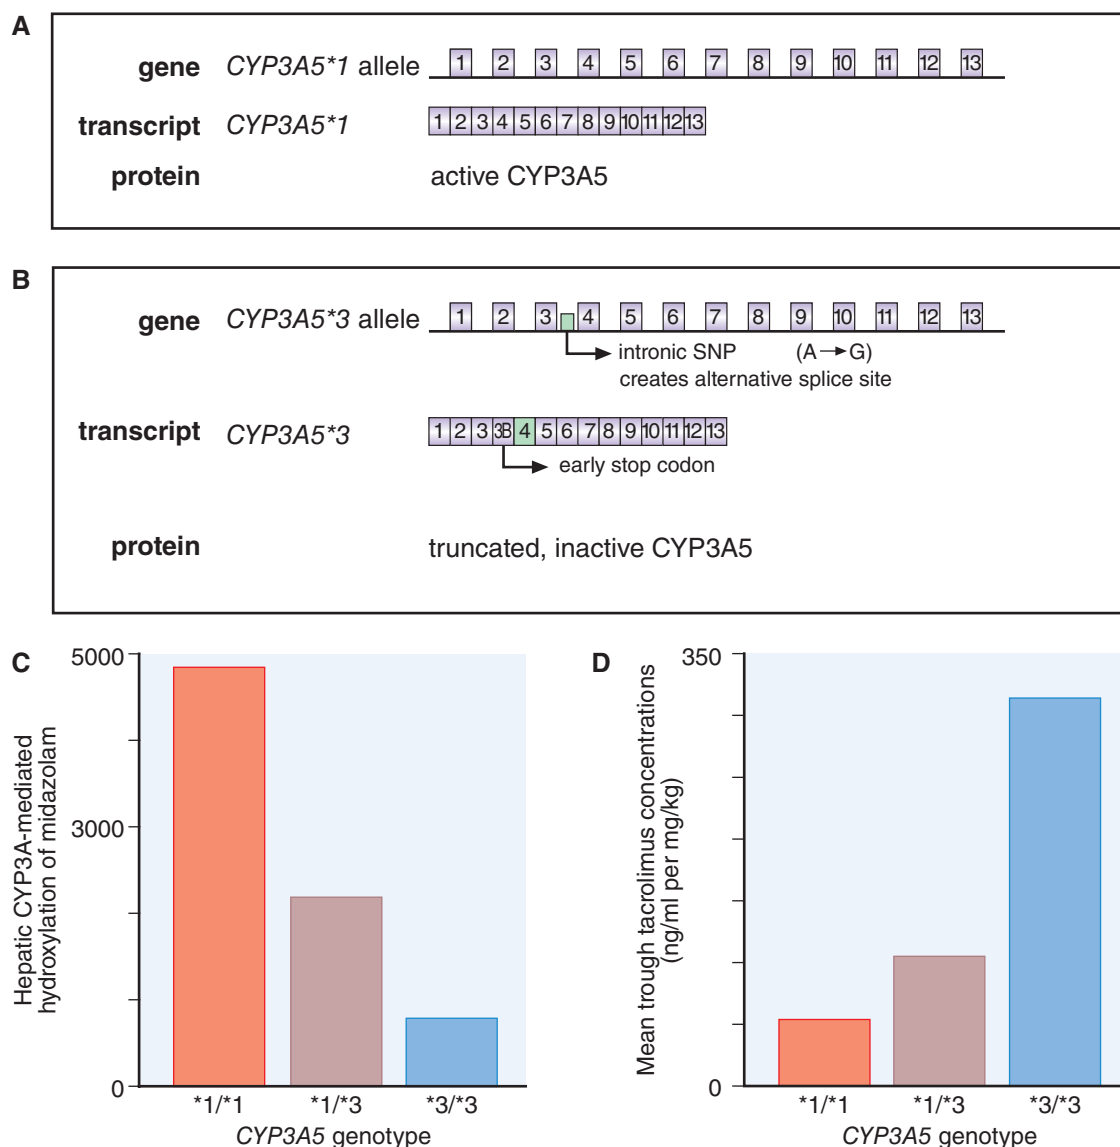

Figure 7–6 An intronic SNP can affect splicing and account for polymorphic expression of CYP3A5. A common polymorphism (A > G) in intron 3 of CYP3A5 defines the genotypes associated with the wild-type CYP3A5*1 allele or the variant nonfunctional CYP3A5*3 allele. This intronic SNP creates an alternative splice site that results in the production of an alternative CYP3A5 transcript carrying an additional intron 3B (B), with an early stop codon and truncated CYP3A5 protein. The wild-type gene (more common in African than Caucasian or Asian populations) results in production of active CYP3A5 protein (A); the *3 variant results in a truncated and inactive protein. Thus, metabolism of CYP3A5 substrates is diminished in vitro (C), and blood concentrations of such substrates (medications) are higher in vivo (D) for those with the *3 than the *1 allele. (Data from Haufroid et al., 2004; Kuehl et al., 2001; Lin et al., 2002.)

Germline variability in genes that encode determinants of the pharmacokinetics of a drug, in particular metabolizing enzymes and transporters, affect drug concentrations and are therefore major determinants of therapeutic and adverse drug response (at the end of the chapter, see Table 7–2 on genetic polymorphisms influencing drug response). A particularly high-risk situation is a drug with a narrow therapeutic margin eliminated by a single pathway: Loss of function in that pathway can lead to drastic increases in drug concentrations (and decreases in metabolite concentrations) with attendant loss of efficacy and an increased likelihood of ADRs (Roden and Stein, 2009). The loss of function can be genetic or can arise as a result of drug interactions or dysfunction of excretory organs (e.g., renal failure will elevate plasma concentrations of renally excreted drugs unless dosages are reduced).

CYP2C9-mediated metabolism of the more active *S*-enantiomer of warfarin is an example. Individuals with the loss of function *3 allele require lower steady-state warfarin dosages and are at increased risk of bleeding (Aithal et al., 1999; Kawai et al., 2014; see also Table 32–2). When multiple enzymes and transporters are involved in the pharmacokinetics of a drug, single variants are unlikely to produce large clinical effects.

Another high-risk situation is a drug that requires bioactivation to achieve pharmacological effect. Individuals with increased or decreased bioactivation, because of genetic variants or drug interactions, are at risk for variant drug responses. Clopidogrel, bioactivated by CYP2C19, and tamoxifen, bioactivated by CYP2D6, are examples (see Table 7–2 and Figure 6–3A). PM subjects homozygous for a common loss function variant in *CYP2C19* display decreased antiplatelet effects and increased stent thrombosis during clopidogrel treatment (Mega et al., 2010; Shuldiner et al., 2009). In heterozygotes (~20%) receiving clopidogrel, adequate antiplatelet effects can be achieved by increasing the dose, whereas in homozygotes (2%–3%) an alternate antiplatelet drug should be used because even large dose increases do not affect platelet function. Other loss-of-function variants (notably *3) are common in Chinese and Japanese populations. Several proton pump inhibitors, including omeprazole and lansoprazole, are inactivated by CYP2C19. Thus, PM patients have higher exposure to active parent drug, a greater pharmacodynamic effect (higher gastric pH), and a higher probability of ulcer cure than heterozygotes or homozygous wild-type individuals.

A variation on this theme is the use of codeine (a prodrug bioactivated to morphine by CYP2D6). In PMs, analgesia is absent. Perhaps more

important, excess morphine is generated in ultrarapid metabolizers, and death due to respiratory arrest has been reported (Ciszkowski et al., 2009). A large number of medications (estimated at 15%–25% of all medicines in use) are substrates for CYP2D6.

The *UGT1A1**28 variant, encoding the 7-TA reduced function *UGT1A1* promoter mentioned previously, has been associated with higher levels of the active metabolite SN-38 of the cancer chemotherapeutic agent *irinotecan* (see Chapter 66), and this increased concentration has been associated with an increased risk of serious toxicities (see Figures 6–6, 6–8, and 6–9).

Drug Receptor/Target Alterations

Warfarin exerts its anticoagulant effect by interfering with the synthesis of vitamin K–dependent clotting factors, and the target molecule with which warfarin interacts to exert this effect is encoded by *VKORC1*, an enzyme in the vitamin K cycle (Figure 7–7). Rare coding region variants in the gene lead to partial or complete warfarin resistance; interestingly, these variants are common (5% allele frequency) in Ashkenazi patients and may account for high dosage requirements in carrier subjects. The *VKORC1* promoter includes common variants that strongly modulate its expression; in subjects with reduced expression, lower steady-state warfarin doses are required. These variants are more common in Asian subjects than in Caucasians or Africans. Inherited variation in *CYP2C9* and *VKORC1* account for more than 50% of the variability in warfarin doses needed to achieve the desired coagulation level. *VKORC1* is one example of how both rare and common variants in genes encoding drug targets can exert important effects on drug actions.

In some instances, highly penetrant variants with profound functional consequences may cause disease phenotypes that confer negative selective pressure; more subtle variations in the same genes can be maintained in the population without causing disease but nonetheless causing variation in drug response. For example, rare loss-of-function mutations in *MTHFR* cause severe mental retardation, cardiovascular disease, and a shortened life span. Conversely, the 677C→T SNP causes an amino acid substitution that is maintained in the population at a high frequency (40% allele frequency in most white populations) and is associated with modestly lower *MTHFR* activity (~30% less than the 677C allele) and modest but significantly elevated plasma homocysteine concentrations (~25% higher). This polymorphism does not alter drug pharmacokinetics but does appear to modulate pharmacodynamics by

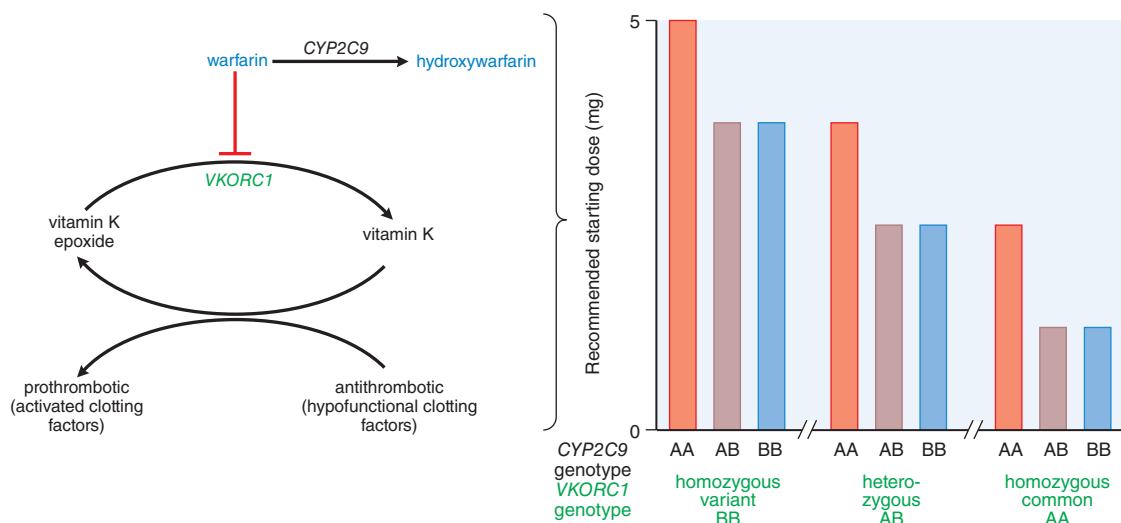

Figure 7–7 Pharmacogenetics of warfarin dosing. Warfarin is metabolized by CYP2C9 to inactive metabolites and exerts its anticoagulant effect partly via inhibition of VKORC1, an enzyme necessary for reduction of inactive to active vitamin K. Common polymorphisms in both genes, CYP2C9 and VKORC1, have an effect on warfarin pharmacokinetics and pharmacodynamics, respectively, to affect the population mean therapeutic doses of warfarin necessary to maintain the desired degree of anticoagulation (often measured by the INR blood test) and minimize the risk of too little anticoagulation (thrombosis) or too much anticoagulation (bleeding). See also Figure 32–6 and Table 32–2. (Data from Caraco et al., 2008; Schwarz et al., 2008; Wen et al., 2008.)

predisposing to GI toxicity to the antifolate drug methotrexate in stem cell transplant recipients.

Like warfarin, methotrexate's clinical effects are dependent on a number of polymorphisms affecting metabolism, transport, drug modifiers, and drug targets. Several of the direct targets (dihydrofolate reductase, purine transformylases, and TYMS) are also subject to common polymorphisms. A polymorphic indel in *TYMS* (two vs. three repeats of a 28-base pair sequence in the enhancer) affects the amount of enzyme expression in both normal and tumor cells. The *TYMS* polymorphism can affect both toxicity and efficacy of anticancer agents (e.g., fluorouracil and methotrexate) that target TYMS. Thus, the genetic contribution to variability in the pharmacokinetics and pharmacodynamics of methotrexate cannot be understood without assessing genotypes at a number of different loci.

Other examples of drug target variants affecting drug response are presented in Table 7–2 at the end of the chapter. Serotonin receptor polymorphisms have been implicated as predictors of responsiveness to antidepressants and of the overall risk of depression. β adrenergic receptor polymorphisms have been linked to asthma responsiveness, changes in renal function following ACE inhibitors, sinus heart rate following β blockers, and the incidence of atrial fibrillation during β blocker therapy. The degree of lowering of LDL by statins has been linked to polymorphisms in HMG-CoA reductase, the statin target (see Chapter 31). Ion channel polymorphisms have been linked by both candidate gene and exome sequencing approaches to a risk of cardiac arrhythmias in the presence and absence of drug triggers (Kääb et al., 2012; Weeke et al., 2014).

Modifiers of the Biologic Milieu

The *MTHFR* polymorphism is linked to homocysteinemia, which in turn affects thrombosis risk. The risk of drug-induced thrombosis is dependent not only on the use of prothrombotic drugs but also on environmental and genetic predisposition to thrombosis, which may be affected by germline polymorphisms in *MTHFR*, factor V, and prothrombin. These polymorphisms do not directly act on the pharmacokinetics or pharmacodynamics of prothrombotic drugs such as glucocorticoids, estrogens, and asparaginase but may modify the risk of the phenotypic event (thrombosis) in the presence of the drug. Likewise, polymorphisms in ion channels (e.g., *KCNQ1*, *KCNE1*, *KCNE2*) that are not themselves the targets of drugs that prolong QT intervals may affect the duration of the baseline QT interval and the overall risk of cardiac arrhythmias; this may in turn increase risk of long QT arrhythmias seen with antiarrhythmics and a number of other “noncardiovascular” drugs (e.g., macrolide antibiotics, antihistamines).

Cancer as a Special Case

Cancer appears to be a disease of genomic instability. In addition to the underlying variation in the germline of the host, tumor cells exhibit somatically acquired mutations, some of which generate mutant protein kinases that are drivers for the development of cancer. Thus, tumor sequencing is becoming standard of care for choosing among anticancer drugs in certain settings (see Chapters 65–68).

For example, patients with lung cancer with activating mutations in *EGFR*, encoding the epidermal growth factor receptor, display increased responses to the EGFR inhibitor gefitinib (Maemondo et al., 2010). Thus, the EGFR is altered, and patients with the activating mutation have, in treatment terms, a distinct pharmacogenetic category of lung cancer. The Her2 antibody trastuzumab can produce cardiomyopathy in all exposed patients. Patients with breast cancer whose tumors express the Her2 antigen may benefit from trastuzumab, whereas those whose tumors do not express Her2 do not benefit but are nevertheless susceptible to cardiomyopathy. Similarly, only patients with melanoma whose tumors express the mutant BRAF V600E respond to vemurafinib; interestingly, vemurafinib may also be effective in other tumors (thyroid cancer, hairy cell leukemia) that express BRAF V600E. Some genetic alterations affect both tumor and host: The presence of two instead of three copies of a *TYMS* enhancer repeat polymorphism not only increases the risk of host toxicity but also increases the chance of tumor susceptibility to TYMS inhibitors (Evans and McLeod, 2003).

Genomics as a Pathway to Identification of New Drug Targets

The identification of genetic pathways in normal physiology and in disease can provide important clues to new drug targets. Seminal studies of patients with the rare disease FH identified HMG-CoA reductase as the key rate-limiting enzyme in LDL cholesterol biosynthesis; now, inhibitors of that enzyme (the statins) are among the most effective and widely used medications in cardiovascular therapy (see Chapter 33). PCSK9 contributes to the degradation of LDL receptors, which are responsible for removing LDL cholesterol from the circulation; an increase in PCSK9 activity results in reduction of LDL receptor function and an increase in LDL cholesterol. One rare cause of FH is gain-of-function mutations in *PCSK9*. Conversely, work in the Dallas Heart Study showed that individuals carrying nonsense mutations in *PCSK9* had lower LDL cholesterol values and decreased risk for coronary artery disease compared to noncarriers (Cohen et al., 2006). This result, in turn, identified PCSK9 as a potential drug target. In 2015, two antibodies that target PCSK9, alirocumab and evolocumab, were approved by the FDA for clinical use in FH and other lipid disorders. These PCSK9 inhibitors prevent degradation of LDL receptors and enhance their recycling to the hepatocyte membrane, thereby facilitating removal of LDL cholesterol and lowering blood LDL cholesterol levels (see Figure 33–4).

In a similar fashion, new drug targets have been identified by work showing that rare loss-of-function variants in *APOC3* lower triglycerides and reduce the risk of coronary artery disease (Stitzel et al., 2014), and loss-of-function variants in *SLC30A8* reduce risk for type 2 diabetes (Flannick et al., 2014). Patients homozygous for *SCN9A* loss-of-function variants are pain insensitive (Cox et al., 2006); inhibitors of *SCN9A* might be useful analgesics. Hundreds of mutations in the chloride transporter encoded by *CFTR* cause CF, but through diverse mechanisms. Ivacaftor partially corrects abnormal gating of certain rare variants of *CFTR* (G551D and others), while lumacaftor improves cell surface expression of the most common variant, $\Delta F508$. Ivacaftor (Ramsey et al., 2011) and the ivacaftor/lumacaftor combination (Wainwright et al., 2015) improve symptoms and outcomes in patients with CF; both agents have now been approved in genotyped patients.

Pharmacogenetics in Clinical Practice

The increasing understanding of genetic contributors to variable drug actions raises questions of how these data might be used by healthcare providers to choose among drugs, doses, and dosing regimens. One approach is point-of-care testing, in which genotyping is ordered at the time of drug prescription; platforms that reliably deliver relevant genotypes rapidly (often in less than an hour) now make such approaches feasible. However, one difficulty in this approach is that each drug requires a separate assay. An alternate approach envisions genotyping at multiple loci relevant for responses to large numbers of drugs, embedding this information in each patient's EMR, and using clinical decision support to advise on drug selection and dosing when a relevant drug is prescribed to a patient with a variant genotype. This approach is being tested in a number of “early adopter” sites (Pulley et al., 2012; Rasmussen-Torvik et al., 2014).

There are several barriers that must be addressed if such an approach is to become widely adopted. First, the evidence linking a variant to a variable drug response must be solid, the variable outcome must be clinically important, and some form of genetically guided advice should be provided (choose another drug, choose another dose, etc.). Drug gene pairs such as *CYP2C19**2/clopidogrel or *CYP2C9**3/warfarin may fall into this category; the Clinical Pharmacogenomics Implementation Consortium provides guidelines on such advice by genotype across multiple drugs (Relling and Klein, 2011). Second, the strength of the evidence supporting a genotype-specific prescribing strategy varies. The strongest level of evidence comes from RCTs, in which a clinically important, genotype-guided treatment strategy is compared to a standard of care. Using this approach, genotyping for HLA-B*57:01 has been shown to eliminate the risk for severe skin reactions (such as

the Stevens-Johnson syndrome) during treatment with the antiretroviral agent abacavir (Mallal et al., 2008). A number of trials have studied the utility of genotyping for *CYP2C9* and *VKORC1* variants during warfarin therapy. The main outcome metric has been duration of drug exposure in therapeutic range during the first 30–90 days of therapy; the results have been inconsistent, with none showing a huge effect (Kimmel et al., 2013; Pirmohamed et al., 2013). These studies have few bleeding events, but EMR-based case-control studies looking at this problem have

implicated variants in *CYP2C9* or *CYP4F2* as risk alleles (Kawai et al., 2014; Roth et al., 2014). Nonrandomized study designs are weaker than RCTs, but performing RCTs to target small subsets of patients carrying uncommon variants may not be feasible.

Acknowledgment: Mary V. Relling and Kathleen M. Giacomini contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

TABLE 7-2 ■ EXAMPLES OF GENETIC POLYMORPHISMS INFLUENCING DRUG RESPONSE

GENE PRODUCT (GENE)	DRUGS ^a	RESPONSES AFFECTED
Drug metabolism and transport		
CYP2C9	Tolbutamide, warfarin, ^a phenytoin, nonsteroidal anti-inflammatory	Anticoagulant effect of warfarin
CYP2C19	Mephenytoin, omeprazole, voriconazole, ^a hexobarbital, mephobarbital, propranolol, proguanil, phenytoin, clopidogrel	Peptic ulcer response to omeprazole; cardiovascular events after clopidogrel
CYP2D6	β blockers, antidepressants, antipsychotics, codeine, debrisoquine, atomoxetine, ^a dextromethorphan, encainide, flecainide, fluoxetine, guanoxan, <i>N</i> -propylajmaline, perhexiline, phenacetin, phenformin, propafenone, sparteine, tamoxifen	Tardive dyskinesia from antipsychotics, narcotic side effects, codeine efficacy, imipramine dose requirement, β-blocker effect; breast cancer recurrence after tamoxifen
CYP3A4/3A5/3A7	Macrolides, cyclosporine, tacrolimus, Ca ²⁺ channel blockers, midazolam, terfenadine, lidocaine, dapsone, quinidine, triazolam, etoposide, teniposide, lovastatin, alfentanil, tamoxifen, steroids	Efficacy of immunosuppressive effects of tacrolimus
Dihydropyrimidine dehydrogenase	Fluorouracil, capecitabine ^a	5-Fluorouracil toxicity
<i>N</i> -acetyltransferase (NAT2)	Isoniazid, hydralazine, sulfonamides, amonafide, procainamide, dapsone, caffeine	Hypersensitivity to sulfonamides, amonafide toxicity, hydralazine-induced lupus, isoniazid neurotoxicity
Glutathione transferases (GSTM1, GSTT1, GSTP1)	Several anticancer agents	Decreased response in breast cancer, more toxicity and worse response in acute myelogenous leukemia
Thiopurine methyltransferase (TPMT)	Mercaptopurine, ^a thioguanine, ^a azathioprine ^a	Thiopurine toxicity and efficacy, risk of second cancers
UDP-glucuronosyl-transferase (UGT1A1)	Irinotecan, ^a bilirubin	Irinotecan toxicity
P-glycoprotein (ABCB1)	Natural product anticancer drugs, HIV protease inhibitors, digoxin	Decreased CD4 response in HIV-infected patients, decreased digoxin AUC, drug resistance in epilepsy
UGT2B7	Morphine	Morphine plasma levels
Organic anion transporter (SLC01B1)	Statins, methotrexate, ACE inhibitors	Statin plasma levels, myopathy; methotrexate plasma levels, mucositis
Catechol- <i>O</i> -methyltransferase	Levodopa	Enhanced drug effect
Organic cation transporter (SLC22A1, OCT1)	Metformin	Pharmacologic effect and pharmacokinetics
Organic cation transporter (SLC22A2, OCT2)	Metformin	Renal clearance
Novel organic cation transporter (SLC22A4, OCTN1)	Gabapentin	Renal clearance
CYP2B6	Cyclophosphamide	Ovarian failure

(Continued)

TABLE 7-2 ■ EXAMPLES OF GENETIC POLYMORPHISMS INFLUENCING DRUG RESPONSE (CONTINUED)

GENE PRODUCT (GENE)	DRUGS ^a	RESPONSES AFFECTED
Targets and receptors		
Angiotensin-converting enzyme (ACE)	ACE inhibitors (e.g., enalapril)	Renoprotective effects, hypotension, left ventricular mass reduction, cough
Thymidylate synthase	5-Fluorouracil	Colorectal cancer response
Chemokine receptor 5 (CCR5)	Antiretrovirals, interferon	Antiviral response
β ₂ adrenergic receptor (ADBR2)	β ₂ -Antagonists (e.g., albuterol, terbutaline)	Bronchodilation, susceptibility to agonist-induced desensitization, cardiovascular effects (e.g., increased heart rate, cardiac index, peripheral vasodilation)
β ₁ adrenergic receptor (ADBR1)	β ₁ -Antagonists	Blood pressure and heart rate after β ₁ antagonists
5-Lipoxygenase (ALOX5)	Leukotriene receptor antagonists	Asthma response
Dopamine receptors (D ₂ , D ₃ , D ₄)	Antipsychotics (e.g., haloperidol, clozapine, thioridazine, nemonapride)	Antipsychotic response (D ₂ , D ₃ , D ₄), antipsychotic-induced tardive dyskinesia (D ₃) and acute akathisia (D ₃), hyperprolactinemia in females (D ₂)
Estrogen receptor α	Estrogen hormone replacement therapy	High-density lipoprotein cholesterol
Serotonin transporter (5HTT)	Antidepressants (e.g., clomipramine, fluoxetine, paroxetine, fluvoxamine)	Clozapine effects, 5HT neurotransmission, antidepressant response
Serotonin receptor (5HT _{2A})	Antipsychotics	Clozapine antipsychotic response, tardive dyskinesia, paroxetine antidepressant response, drug discrimination
HMG-CoA reductase	Pravastatin	Reduction in serum cholesterol
Vitamin K oxidoreductase (VKORC1)	Warfarin ^a	Anticoagulant effect, bleeding risk
Corticotropin-releasing hormone receptor (CRHR1)	Glucocorticoids	Bronchodilation, osteopenia
Ryanodine receptor (RYR1)	General anesthetics	Malignant hyperthermia
Modifiers		
Adducin	Diuretics	Myocardial infarction or strokes, blood pressure
Apolipoprotein E	Statins (e.g., simvastatin), tacrine	Lipid lowering; clinical improvement in Alzheimer disease
Human leukocyte antigen	Abacavir, carbamazepine, phenytoin	Hypersensitivity reactions
G6PD deficiency	Rasburicase, ^a dapsone ^a	Methemoglobinemia
Cholesteryl ester transfer protein	Statins (e.g., pravastatin)	Slowing atherosclerosis progression
Ion channels (HERG, KvLQT1, Mink, MiRP1)	Erythromycin, cisapride, clarithromycin, quinidine	Increased risk of drug-induced torsades de pointes, increased QT interval (Roden, 2003, 2004)
Methylguanine-methyltransferase	DNA methylating agents	Response of glioma to chemotherapy
Parkin	Levodopa	Parkinson disease response
MTHFR	Methotrexate	GI toxicity (Ulrich et al., 2001)
Prothrombin, factor V	Oral contraceptives	Venous thrombosis risk
Stromelysin-1	Statins (e.g., pravastatin)	Reduction in cardiovascular events and in repeat angioplasty
Inosine triphosphatase	Azathioprine, mercaptopurine	Myelosuppression
Vitamin D receptor	Estrogen	Bone mineral density

Chapter 8

Neurotransmission: The Autonomic and Somatic Motor Nervous Systems

Thomas C. Westfall, Heather Macarthur, and David P. Westfall

ANATOMY AND GENERAL FUNCTIONS

- Differences Between Autonomic and Somatic Nerves
- Divisions of the Peripheral Autonomic System
- Comparison of Sympathetic, Parasympathetic, and Motor Nerves

NEUROCHEMICAL TRANSMISSION

- Evidence for Neurohumoral Transmission
- Steps Involved in Neurotransmission
- Cholinergic Transmission
- Adrenergic Transmission

PHARMACOLOGICAL CONSIDERATIONS

- Interference With the Synthesis or Release of the Transmitter
- Promotion of Release of the Transmitter
- Agonist and Antagonist Actions at Receptors
- Interference With the Destruction of the Transmitter

OTHER AUTONOMIC NEUROTRANSMITTERS

- Cotransmission in the Autonomic Nervous System
- Nonadrenergic, Noncholinergic Transmission by Purines
- Signal Integration and Modulation of Vascular Responses by Endothelium-Derived Factors: NO and Endothelin

Anatomy and General Functions

The autonomic nervous system, also called the *visceral, vegetative, or involuntary nervous system*, is distributed widely throughout the body and regulates autonomic functions that occur without conscious control. In the periphery, it consists of nerves, ganglia, and plexuses that innervate the heart, blood vessels, glands, other visceral organs, and smooth muscle in various tissues.

Differences Between Autonomic and Somatic Nerves

- The *efferent nerves* of the autonomic nervous system supply all innervated structures of the body except skeletal muscle, which is served by *somatic nerves*.
- The most distal synaptic junctions in the autonomic reflex arc occur in *ganglia* that are entirely *outside the cerebrospinal axis*. Somatic nerves contain no peripheral *ganglia*, and the synapses are located entirely *within the cerebrospinal axis*.
- Many autonomic nerves form extensive peripheral plexuses; such networks are absent from the somatic system.
- Postganglionic autonomic nerves generally are *nonmyelinated*; motor nerves to skeletal muscles are *myelinated*.
- When the spinal efferent nerves are interrupted, smooth muscles and glands generally retain some level of spontaneous activity, whereas the *denervated* skeletal muscles are paralyzed.

Sensory Information: Afferent Fibers and Reflex Arcs

Afferent fibers from visceral structures are the first link in the reflex arcs of the autonomic system. With certain exceptions, such as local axon reflexes, most visceral reflexes are mediated through the CNS.

Visceral Afferent Fibers. Information on the status of the visceral organs is transmitted to the CNS through two main sensory systems: the *cranial nerve (parasympathetic) visceral sensory system* and the *spinal (sympathetic) visceral afferent system*. The cranial visceral sensory system carries mainly mechanoreceptor and chemosensory information, whereas the afferents of the spinal visceral system principally convey sensations related to temperature and tissue injury of mechanical, chemical, or thermal origin.

Cranial visceral sensory information enters the CNS by four cranial nerves: the trigeminal (V), facial (VII), glossopharyngeal (IX), and vagus

(X) nerves. These four cranial nerves transmit visceral sensory information from the internal face and head (V); tongue (taste, VII); hard palate and upper part of the oropharynx (IX); and carotid body, lower part of the oropharynx, larynx, trachea, esophagus, and thoracic and abdominal organs (X), with the exception of the pelvic viscera. The pelvic viscera are innervated by nerves from the second through fourth sacral spinal segments. The visceral afferents from these four cranial nerves terminate topographically in the STN (Altschuler et al., 1989).

Sensory afferents from visceral organs also enter the CNS from the spinal nerves. Those concerned with muscle chemosensation may arise at all spinal levels, whereas sympathetic visceral sensory afferents generally arise at the thoracic levels where sympathetic preganglionic neurons are found. Pelvic sensory afferents from spinal segments S2–S4 enter at that level and are important for the regulation of sacral parasympathetic outflow. In general, visceral afferents that enter the spinal nerves convey information concerned with temperature as well as nociceptive visceral inputs related to mechanical, chemical, and thermal stimulation. The primary pathways taken by ascending spinal visceral afferents are complex (Saper, 2002). An important feature of the ascending pathways is that they provide collaterals that converge with the cranial visceral sensory pathway at virtually every level (Saper, 2000).

The neurotransmitters that mediate transmission from sensory fibers have not been characterized unequivocally. Substance P and CGRP, present in afferent sensory fibers, dorsal root ganglia, and the dorsal horn of the spinal cord, likely communicate nociceptive stimuli from the periphery to the spinal cord and higher structures. SST, VIP, and CCK also occur in sensory neurons (Hökfelt et al., 2000). ATP appears to be a neurotransmitter in certain sensory neurons (e.g., the urinary bladder). Enkephalins, present in interneurons in the dorsal spinal cord (within the *substantia gelatinosa*), have antinociceptive effects both pre- and postsynaptically to inhibit the release of substance P and diminish the activity of cells that project from the spinal cord to higher centers in the CNS. The excitatory amino acids glutamate and aspartate also play major roles in transmission of sensory responses to the spinal cord. These transmitters and their signaling pathways are reviewed in Chapter 14.

Central Autonomic Connections

There probably are no purely autonomic or somatic centers of integration, and extensive overlap occurs. Somatic responses always are accompanied by visceral responses and vice versa. Autonomic reflexes

Abbreviations

AA: arachidonic acid
AAADC: aromatic L-amino acid decarboxylase
 α -BTX: α -bungarotoxin
AC: adenylyl cyclase
ACh: acetylcholine
AChE: acetylcholinesterase
AD: aldehyde dehydrogenase
ADH: alcohol dehydrogenase
anti-ChE: anti-cholinesterase
AP: action potential
AR: aldehyde reductase
AV: atrioventricular
CaM: calmodulin
CCK: cholecystokinin
CGRP: calcitonin gene-related peptide
ChAT: choline acetyl transferase
CHT1: Choline transporter
CNS: central nervous system
COMT: catechol-O-methyltransferase
CSF: cerebrospinal fluid
DA: dopamine
DAG: diacylglycerol
DAT: DA transporter
D β H: dopamine β -hydroxylase
DOMA: 3,4-dihydroxymandelic acid
DOPEG: 3,4-dihydroxyphenyl glycol
DOPGAL: dihydroxyphenylglycolaldehyde
ENS: enteric nervous system
ENT: extraneuronal transporter
EPI: epinephrine
EPP: end-plate potential
EPSP: excitatory postsynaptic potential
ET: endothelin
GABA: γ -aminobutyric acid
GI: gastrointestinal
GRK: G protein-coupled receptor kinase
GPCR: G protein-coupled receptor
HR: heart rate
5HT: serotonin (5-hydroxytryptamine)
HVA: homovanillic acid
IP₃: inositol 1,4,5-trisphosphate
IPSP: inhibitory postsynaptic potential
KO: knockout
mAChR: muscarinic acetylcholine receptor
MAO: monoamine oxidase
MAPK: mitogen-activated protein kinase
mepps: miniature end-plate potentials
MOPEG: 3-methyl,4-hydroxyphenylglycol
MOPGAL: monohydroxyphenylglycolaldehyde
nAChR: nicotinic ACh receptor
NANC: nonadrenergic, noncholinergic
NE: norepinephrine (noradrenaline)
NET: norepinephrine transporter
NMJ: neuromuscular junction (of skeletal muscle)
NO: nitric oxide
NOS: nitric oxide synthase
NPY: neuropeptide Y
NSF: N-ethylmaleamide sensitive factor
PACAP: pituitary adenylyl cyclase-activating peptide
PG: prostaglandin, as in PGE₂
PK: protein kinase, as in PKA

PL₂: phospholipase, as in PLA₂, PLC, etc.
PNMT: phenylethanolamine-N-methyltransferase
PTX: pertussis toxin
rNTPase: releasable nucleotidase
SA: sinoatrial
SERT: serotonin transporter
SLC: solute carrier
SNAP: soluble NSF attachment protein, synaptosome-associated protein
SNARE: SNAP receptor
SST: somatostatin
STN: solitary tract nucleus
TH: tyrosine hydroxylase
VACht: vesicular ACh transporter
VAT: vesicle-associated transporter
VIP: vasoactive intestinal polypeptide
VMA: vanillyl mandelic acid
VMAT2: vesicular uptake transporter

can be elicited at the level of the spinal cord. They clearly are demonstrable in experimental animals or humans with spinal cord transection and are manifested by sweating, blood pressure alterations, vasomotor responses to temperature changes, and reflex emptying of the urinary bladder, rectum, and seminal vesicles. Extensive central ramifications of the autonomic nervous system exist above the level of the spinal cord. For example, integration of the control of respiration in the medulla oblongata is well known. The hypothalamus and the STN generally are regarded as principal loci of integration of autonomic nervous system functions, which include regulation of body temperature, water balance, carbohydrate and fat metabolism, blood pressure, emotions, sleep, respiration, and reproduction. Signals are received through ascending spinobulbar pathways, the limbic system, neostriatum, cortex, and to a lesser extent other higher brain centers. Stimulation of the STN and the hypothalamus activates bulbospinal pathways and hormonal output to mediate autonomic and motor responses (Andresen and Kunze, 1994) (see Chapter 14). The hypothalamic nuclei that lie posteriorly and laterally are sympathetic in their main connections, whereas parasympathetic functions evidently are integrated by the midline nuclei in the region of the tuber cinereum and by nuclei lying anteriorly.

Highly integrated patterns of response generally are organized at a hypothalamic level and involve autonomic, endocrine, and behavioral components. More limited patterned responses are organized at other levels of basal forebrain, brainstem, and spinal cord.

Divisions of the Peripheral Autonomic System

On the efferent side, the autonomic nervous system consists of two large divisions: (1) the *sympathetic or thoracolumbar outflow* and (2) the *parasympathetic or craniosacral outflow*. Figure 8-1 schematically summarizes the arrangement of the principal parts of the peripheral autonomic nervous system.

The neurotransmitter of all preganglionic autonomic fibers, most postganglionic parasympathetic fibers, and a few postganglionic sympathetic fibers is ACh. Some postganglionic parasympathetic nerves use NO as a neurotransmitter and are termed *nitergic* (Toda and Okamura, 2003). The majority of the postganglionic sympathetic fibers are *adrenergic*, in which the transmitter is NE (also called noradrenaline). The terms *cholinergic* and *adrenergic* describe neurons that liberate ACh or NE, respectively. Not all the transmitters of the primary afferent fibers, such as those from the mechano- and chemoreceptors of the carotid body and aortic arch, have been identified conclusively. Substance P and glutamate may mediate many afferent impulses; both are present in high concentrations in the dorsal spinal cord.

Figure 8-1 The autonomic nervous system. Schematic representation of the autonomic nerves and effector organs based on chemical mediation of nerve impulses. Yellow (—), cholinergic; red (—), adrenergic; dotted blue (---), visceral afferent; solid lines, preganglionic; broken lines, postganglionic. The rectangle at right shows the finer details of the ramifications of adrenergic fibers at any one segment of the spinal cord, the path of the visceral afferent nerves, the cholinergic nature of somatic motor nerves to skeletal muscle, and the presumed cholinergic nature of the vasodilator fibers in the dorsal roots of the spinal nerves. The asterisk (*) indicates that it is not known whether these vasodilator fibers are motor or sensory or where their cell bodies are situated.

The cells that give rise to the preganglionic fibers of the sympathetic nervous system division lie mainly in the intermediolateral columns of the spinal cord and extend from the first thoracic to the second or third lumbar segment. The axons from these cells are carried in the anterior (ventral) nerve roots and synapse, with neurons lying in sympathetic ganglia outside the cerebrospinal axis. Sympathetic ganglia are found in three locations: paravertebral, prevertebral, and terminal.

The 22 pairs of paravertebral sympathetic ganglia form the lateral chains on either side of the vertebral column. The ganglia are connected to each other by nerve trunks and to the spinal nerves by *rami communicantes*. The white rami are restricted to the segments of the thoracolumbar outflow; they carry the preganglionic myelinated fibers that exit the spinal cord by the anterior spinal roots. The gray rami arise from the ganglia and carry postganglionic fibers back to the spinal nerves for distribution to sweat glands and pilomotor muscles and to blood vessels of skeletal muscle and skin. The prevertebral ganglia lie in the abdomen and the pelvis near the ventral surface of the bony vertebral column and consist mainly of the celiac (solar), superior mesenteric, aorticorenal, and inferior mesenteric ganglia. The terminal ganglia are few in number, lie near the organs they innervate, and include ganglia connected with the urinary bladder and rectum and the cervical ganglia in the region of the neck. In addition, small intermediate ganglia lie outside the conventional vertebral chain, especially in the thoracolumbar region. They are variable in number and location but usually are in proximity to the communicating rami and the anterior spinal nerve roots.

Preganglionic fibers issuing from the spinal cord may synapse with the neurons of more than one sympathetic ganglion. Their principal ganglia of termination need not correspond to the original level from which the preganglionic fiber exits the spinal cord. Many of the preganglionic fibers from the fifth to the last thoracic segment pass through the paravertebral ganglia to form the splanchnic nerves. Most of the splanchnic nerve fibers do not synapse until they reach the celiac ganglion; others directly innervate the adrenal medulla.

Postganglionic fibers arising from sympathetic ganglia innervate visceral structures of the thorax, abdomen, head, and neck. The trunk and the limbs are supplied by the sympathetic fibers in spinal nerves. The prevertebral ganglia contain cell bodies whose axons innervate the glands and smooth muscles of the abdominal and the pelvic viscera. Many of the upper thoracic sympathetic fibers from the vertebral ganglia form terminal plexuses, such as the cardiac, esophageal, and pulmonary plexuses. The sympathetic distribution to the head and the neck (vasomotor, pupillodilator, secretory, and pilomotor) is by means of the cervical sympathetic chain and its three ganglia. All postganglionic fibers in this chain arise from cell bodies located in these three ganglia. All preganglionic fibers arise from the upper thoracic segments of the spinal cord, there being no sympathetic fibers that leave the CNS above the first thoracic level.

Pharmacologically, anatomically, and embryologically, the chromaffin cells of the adrenal medulla resemble a collection of postganglionic sympathetic nerve cells. Typical preganglionic fibers that release ACh innervate these chromaffin cells, stimulating the release of EPI (also called adrenaline), in distinction to the NE released by postganglionic sympathetic fibers.

Parasympathetic Nervous System

The parasympathetic nervous system consists of preganglionic fibers that originate in the CNS and their postganglionic connections. The regions of central origin are the midbrain, the medulla oblongata, and the sacral part of the spinal cord. The midbrain, or tectal, outflow consists of fibers arising from the Edinger-Westphal nucleus of the third cranial nerve and going to the ciliary ganglion in the orbit. The medullary outflow consists of the parasympathetic components of the VII, IX, and X cranial nerves.

The fibers in the VII (facial) cranial nerve form the chorda tympani, which innervates the ganglia lying on the submaxillary and sublingual glands. They also form the greater superficial petrosal nerve, which innervates the sphenopalatine ganglion. The autonomic components of the IX (glossopharyngeal) cranial nerve innervate the otic ganglia. Postganglionic

parasympathetic fibers from these ganglia supply the sphincter of the iris (pupillary constrictor muscle), the ciliary muscle, the salivary and lacrimal glands, and the mucous glands of the nose, mouth, and pharynx. These fibers also include vasodilator nerves to these same organs. Cranial nerve X (vagus) arises in the medulla and contains preganglionic fibers, most of which do not synapse until they reach the many small ganglia lying directly on or in the viscera of the thorax and abdomen. In the intestinal wall, the vagal fibers terminate around ganglion cells in the myenteric and submucosal plexuses. *Thus, in the parasympathetic branch of the autonomic nervous system, preganglionic fibers are very long, whereas postganglionic fibers are very short.* The vagus nerve also carries a far greater number of afferent fibers (but apparently no pain fibers) from the viscera into the medulla. The parasympathetic sacral outflow consists of axons that arise from cells in the second, third, and fourth segments of the sacral cord and proceed as preganglionic fibers to form the pelvic nerves (*nervi erigentes*). They synapse in terminal ganglia lying near or within the bladder, rectum, and sexual organs. The vagal and sacral outflows provide motor and secretory fibers to thoracic, abdominal, and pelvic organs (see Figure 8–1).

Enteric Nervous System

The processes of mixing, propulsion, and absorption of nutrients in the GI tract are controlled locally through a restricted part of the peripheral nervous system called the ENS. The ENS comprises components of the sympathetic and parasympathetic nervous systems and has sensory nerve connections through the spinal and nodose ganglia (see Chapter 46 and Furness et al., 2014). The ENS is involved in sensorimotor control and thus consists of both afferent sensory neurons and a number of motor nerves and interneurons that are organized principally into two nerve plexuses: the myenteric (Auerbach) plexus and the submucosal (Meissner) plexus. The myenteric plexus, located between the longitudinal and circular muscle layers, plays an important role in the contraction and relaxation of GI smooth muscle. The submucosal plexus is involved with secretory and absorptive functions of the GI epithelium, local blood flow, and neuroimmune activities.

Parasympathetic preganglionic inputs are provided to the GI tract via the vagus and pelvic nerves. ACh released from *preganglionic neurons* activates nAChRs on postganglionic neurons within the enteric ganglia. Excitatory preganglionic input activates both excitatory and inhibitory motor neurons that control processes such as muscle contraction and secretion/absorption. *Postganglionic sympathetic nerves* also synapse with intrinsic neurons and generally induce relaxation. Sympathetic input is excitatory (contractile) at some sphincters. Information from afferent and preganglionic neural inputs to the enteric ganglia is integrated and distributed by a network of interneurons. ACh is the primary neurotransmitter providing excitatory inputs between interneurons, but other substances, such as ATP (via postjunctional P2X receptors), substance P (by NK₁ receptors), and 5HT (via 5HT₃ receptors) are also important in mediating integrative processing via interneurons.

The muscle layers of the GI tract are dually innervated by excitatory and inhibitory motor neurons, with cell bodies primarily in the myenteric ganglia. ACh is a primary excitatory motor neurotransmitter released from postganglionic neurons. ACh activates M₂ and M₃ receptors in postjunctional cells to elicit motor responses. Pharmacological blockade of mAChRs does not block all excitatory neurotransmission, however, because neuropeptides (neurokinin A and substance P) are also coreleased by excitatory motor neurons and contribute to postjunctional excitation. Inhibitory motor neurons in the GI tract regulate motility events such as accommodation, sphincter relaxation, and descending receptive relaxation. Inhibitory responses are elicited by a purine derivative (either ATP or β -nicotinamide adenine dinucleotide) acting at postjunctional P2Y₁ receptors) and NO. Inhibitory neuropeptides, such as VIP and PACAP, may also be released from inhibitory motor neurons under conditions of strong stimulation.

In general, motor neurons do not directly innervate smooth muscle cells in the GI tract. Nerve terminals make synaptic connections with the interstitial cells of Cajal (ICCs), and these cells make electrical connections (gap junctions) with smooth muscle cells (Ward et al., 2000).

Thus, the ICCs are the receptive, postjunctional transducers of inputs from enteric motor neurons, and loss of these cells has been associated with conditions that appear to be neuropathies. ICCs have all of the major receptors and effectors necessary to transduce both excitatory and inhibitory neurotransmitters into postjunctional responses (Chen et al., 2007).

Comparison of Sympathetic, Parasympathetic, and Motor Nerves

Differences among somatic motor, sympathetic, and parasympathetic nerves are shown schematically in Figure 8–2. To summarize:

- The *sympathetic* system is distributed to effectors throughout the body, whereas *parasympathetic* distribution is much more limited.
- A *preganglionic sympathetic fiber* may traverse a considerable distance of the sympathetic chain and pass through several ganglia before it finally synapses with a postganglionic neuron; also, its terminals make contact with a large number of postganglionic neurons. The *parasympathetic*

system has terminal ganglia very near or within the organs innervated and is generally more circumscribed in its influences.

- The cell bodies of *somatic motor neurons* reside in the ventral horn of the spinal cord; the axon divides into many branches, each of which innervates a single muscle fiber; more than 100 muscle fibers may be supplied by one motor neuron to form a motor unit. At each NMJ, the axonal terminal loses its myelin sheath and forms a terminal arborization that lies in apposition to a specialized surface of the muscle membrane, termed the *motor end plate* (see Figure 11–3). Reciprocal trophic signals between muscle and nerve regulate the development of the NMJ (Witzemann, 2006).
- Ganglionic organization can differ among the different types of nerves and locales. In some organs innervated by the parasympathetic branch, a 1:1 relationship between the number of preganglionic and postganglionic fibers has been suggested. In sympathetic ganglia, one ganglion cell may be supplied by several preganglionic fibers, and the ratio of preganglionic axons to ganglion cells may be 1:20 or more; this organization

Figure 8–2 Comparative features of somatic motor nerves and efferent nerves of the autonomic nervous system. The principal neurotransmitters, ACh and NE, are shown in red. The receptors for these transmitters, nicotinic (N) and muscarinic (M) cholinergic receptors, α and β adrenergic receptors, are shown in green. Somatic nerves innervate skeletal muscle directly at a specialized synaptic junction, the motor end plate, where ACh activates N_m receptors. Autonomic nerves innervate smooth muscles, cardiac tissue, and glands. Both parasympathetic and sympathetic systems have ganglia, where ACh is released by the preganglionic fibers; ACh acts on N_n receptors on the postganglionic nerves. ACh is also the neurotransmitter at cells of the adrenal medulla, where it acts on N_n receptors to cause release of EPI and NE into the circulation. ACh is the dominant neurotransmitter released by postganglionic parasympathetic nerves and acts on muscarinic receptors. The ganglia in the parasympathetic system are near or within the organ being innervated, with generally a one-to-one relationship between pre- and postganglionic fibers. NE is the principal neurotransmitter of postganglionic sympathetic nerves, acting on α or β adrenergic receptors. Autonomic nerves form a diffuse pattern with multiple synaptic sites. In the sympathetic system, the ganglia are generally far from the effector cells (e.g., within the sympathetic chain ganglia). Preganglionic sympathetic fibers may make contact with a large number of postganglionic fibers.

permits diffuse discharge of the sympathetic system. The ratio of preganglionic vagal fibers to ganglion cells in the myenteric plexus has been estimated as 1:8000.

A Few Details About Innervation

The terminations of the postganglionic autonomic fibers in smooth muscle and glands form a rich plexus, or terminal reticulum. The terminal reticulum (sometimes called the *autonomic ground plexus*) consists of the final ramifications of the postganglionic sympathetic, parasympathetic, and visceral afferent fibers, all of which are enclosed within a frequently interrupted sheath of satellite or Schwann cells. At these interruptions, varicosities packed with vesicles are seen in the efferent fibers. Such varicosities occur repeatedly but at variable distances along the course of the ramifications of the axon.

“Protoplasmic bridges” occur between the smooth muscle fibers themselves at points of contact between their plasma membranes. They are believed to permit the direct conduction of impulses from cell to cell without the need for chemical transmission. These structures have been termed *nexuses*, or *tight junctions*, and they enable the smooth muscle fibers to function as a syncytial unit.

Sympathetic ganglia are extremely complex anatomically and pharmacologically (see Chapter 11). The preganglionic fibers lose their myelin sheaths and divide repeatedly into a vast number of end fibers with diameters ranging from 0.1 to 0.3 μm ; except at points of synaptic contact, they retain their satellite cell sheaths. The vast majority of synapses are

axodendritic. Apparently, a given axonal terminal may synapse with multiple dendritic processes.

Responses of Effector Organs to Autonomic Nerve Impulses. In many instances, the sympathetic and parasympathetic neurotransmitters can be viewed as physiological or functional antagonists (Table 8–1). Most viscera are innervated by both divisions of the autonomic nervous system, and their activities on specific structures may be either discrete and independent or integrated and interdependent. The effects of sympathetic and parasympathetic stimulation of the heart and the iris show a pattern of functional antagonism in controlling heart rate and pupillary aperture, respectively, whereas their actions on male sexual organs are complementary and are integrated to promote sexual function.

From the responses of the various effector organs to autonomic nerve impulses and the knowledge of the intrinsic autonomic tone, one can predict the actions of drugs that mimic or inhibit the actions of these nerves.

General Functions of the Autonomic Nervous System. The autonomic nervous system is the primary regulator of the constancy of the internal environment of the organism.

The sympathetic system and its associated adrenal medulla are not essential to life in a controlled environment, but the lack of sympathoadrenal functions becomes evident under circumstances of stress. In the absence of the sympathetic system, body temperature cannot be regulated when environmental temperature varies; the concentration of glucose in blood does not rise in response to urgent need; compensatory vascular

HISTORICAL PERSPECTIVE

The earliest concrete proposal of a neurohumoral mechanism was made shortly after the turn of the 20th century. Lewandowsky and Langley independently noted the similarity between the effects of injection of extracts of the adrenal gland and stimulation of sympathetic nerves. In 1905, T. R. Elliott, while a student with Langley at Cambridge, postulated that sympathetic nerve impulses release minute amounts of an EPI-like substance in immediate contact with effector cells. He considered this substance to be the chemical step in the process of transmission. He also noted that long after sympathetic nerves had degenerated, the effector organs still responded characteristically to the hormone of the adrenal medulla. Langley suggested that effector cells have excitatory and inhibitory “receptive substances,” and that the response to EPI depended on which type of substance was present. In 1907, Dixon, impressed by the correspondence between the effects of the alkaloid muscarine and the responses to vagal stimulation, advanced the concept that the vagus nerve liberated a muscarine-like substance that acted as a chemical transmitter of its impulses. In the same year, Reid Hunt described the actions of ACh and other choline esters. In 1914, Dale investigated the pharmacological properties of ACh and other choline esters and distinguished its nicotine-like and muscarine-like actions. Intrigued with the remarkable fidelity with which this drug reproduced the responses to stimulation of parasympathetic nerves, he introduced the term *parasympathomimetic* to characterize its effects. Dale also noted the brief duration of action of this chemical and proposed that an esterase in the tissues rapidly splits ACh to acetic acid and choline, thereby terminating its action.

The studies of Loewi, begun in 1921, provided the first direct evidence for the chemical mediation of nerve impulses by the release of specific chemical agents. Loewi stimulated the vagus nerve of a perfused (donor) frog heart and allowed the perfusion fluid to come in contact with a second (recipient) frog heart used as a test object. The recipient frog heart was found to respond, after a short lag, in the same way as the donor heart. It thus was evident that a substance was liberated from the first organ that slowed the rate of the second. Loewi referred to this chemical substance as *Vagusstoff* (“vagus substance,” “parasympathin”);

subsequently, Loewi and Navratil presented evidence to identify it as ACh. Loewi also discovered that an accelerator substance similar to EPI and called *Acceleranstoff* was liberated into the perfusion fluid in summer, when the action of the sympathetic fibers in the frog’s vagus, a mixed nerve, predominated over that of the inhibitory fibers. Feldberg and Kraye demonstrated in 1933 that the cardiac “vagus substance” also is ACh in mammals.

In the same year as Loewi’s discovery, Cannon and Uridil reported that stimulation of the sympathetic hepatic nerves resulted in the release of an EPI-like substance that increased blood pressure and heart rate. Subsequent experiments firmly established that this substance is the chemical mediator liberated by sympathetic nerve impulses at neuroeffector junctions. Cannon called this substance “sympathin.” In many of its pharmacological and chemical properties, sympathin closely resembled EPI, but also differed in certain important respects. As early as 1910, Barger and Dale noted that the effects of sympathetic nerve stimulation were reproduced more closely by the injection of sympathomimetic primary amines than by that of EPI or other secondary amines. The possibility that demethylated EPI (NE) might be sympathin had been advanced repeatedly, but definitive evidence for its being the sympathetic nerve mediator was not obtained until specific assays were developed for the determination of sympathomimetic amines in extracts of tissues and body fluids. In 1946, von Euler found that the sympathomimetic substance in highly purified extracts of bovine splenic nerve resembled NE by all criteria used (von Euler, 1946).

We now know that NE is the predominant sympathomimetic substance in the postganglionic sympathetic nerves of mammals and is the adrenergic mediator liberated by their stimulation. NE, its immediate precursor DA, and its *N*-methylated derivative EPI also are neurotransmitters in the CNS (see Chapter 14). As for ACh, in addition to its role as the transmitter of most postganglionic parasympathetic fibers and of a few postganglionic sympathetic fibers, ACh functions as a neurotransmitter in three additional classes of nerves: preganglionic fibers of both the sympathetic and the parasympathetic systems, motor nerves to skeletal muscle, and certain neurons within the CNS.

TABLE 8-1 ■ RESPONSES OF EFFECTOR ORGANS TO AUTONOMIC NERVE IMPULSES

ORGAN SYSTEM	SYMPATHETIC EFFECT ^a	ADRENERGIC RECEPTOR SUBTYPE ^b	PARASYMPATHETIC EFFECT ^a	CHOLINERGIC RECEPTOR SUBTYPE ^b

^aResponses are designated + to +++ to provide an approximate indication of the importance of sympathetic and parasympathetic nerve activity in the control of the various organs and functions listed.

^bAdrenergic receptors: α_1 , α_2 and subtypes thereof; β_1 , β_2 , β_3 . Cholinergic receptors: nicotinic (N); muscarinic (M), with subtypes 1–4. The receptor subtypes are described more fully in Chapters 9 and 12 and in Tables 8–2, 8–3, 8–6, and 8–7. When a designation of subtype is not provided, the nature of the subtype has not been determined unequivocally. Only the principal receptor subtypes are shown. Transmitters other than ACh and NE contribute to many of the responses.

^cIn the human heart, the ratio of β_1 to β_2 is about 3:2 in atria and 4:1 in ventricles. While M₂ receptors predominate, M₃ receptors are also present (Wang et al., 2004).

^dThe predominant α_1 receptor subtype in most blood vessels (both arteries and veins) is α_{1A} , although other α_1 subtypes are present in specific blood vessels. The α_{1D} is the predominant subtype in the aorta (Michelotti et al., 2000).

^eDilation predominates in situ owing to metabolic autoregulatory mechanisms.

^fOver the usual concentration range of physiologically released circulating EPI, the β receptor response (vasodilation) predominates in blood vessels of skeletal muscle and liver; β receptor response (vasoconstriction) predominates in blood vessels of other abdominal viscera. The renal and mesenteric vessels also contain specific dopaminergic receptors whose activation causes dilation.

^gSympathetic cholinergic neurons cause vasodilation in skeletal muscle beds, but this is not involved in most physiological responses.

^hThe endothelium of most blood vessels releases NO, which causes vasodilation in response to muscarinic stimuli. However, unlike the receptors innervated by sympathetic cholinergic fibers in skeletal muscle blood vessels, these muscarinic receptors are not innervated and respond only to exogenously added muscarinic agonists in the circulation.

ⁱWhile adrenergic fibers terminate at inhibitory β receptors on smooth muscle fibers and at inhibitory β receptors on parasympathetic (cholinergic) excitatory ganglion cells of the myenteric plexus, the primary inhibitory response is mediated via enteric neurons through NO, P2Y receptors, and peptide receptors.

^jUterine responses depend on stages of menstrual cycle, amount of circulating estrogen and progesterone, and other factors.

^kPalms of hands and some other sites (“adrenergic sweating”).

^lThere is significant variation among species in the receptor types that mediate certain metabolic responses. All three β adrenergic receptors have been found in human fat cells. Activation of β_3 receptors produces a vigorous thermogenic response as well as lipolysis. The significance is unclear. Activation of β receptors also inhibits leptin release from adipose tissue.

responses to hemorrhage, oxygen deprivation, excitement, and exercise are lacking; and resistance to fatigue is lessened. Sympathetic components of instinctive reactions to the external environment are lost, and other serious deficiencies in the protective forces of the body are discernible. The sympathetic system normally is continuously active, the degree of activity varying from moment to moment and from organ to organ, adjusting to a constantly changing environment. The sympathoadrenal system can discharge as a unit. Heart rate is accelerated; blood pressure rises; blood flow is shifted from the skin and splanchnic region to the skeletal muscles; blood glucose rises; the bronchioles and pupils dilate; and the organism is better prepared for “fight or flight.” Many of these effects result primarily from or are reinforced by the actions of EPI secreted by the adrenal medulla.

The *parasympathetic system* is organized mainly for discrete and localized discharge. Although it is concerned primarily with conservation of energy and maintenance of organ function during periods of minimal activity, its elimination is not compatible with life. The parasympathetic system slows the heart rate, lowers the blood pressure, stimulates GI movements and secretions, aids absorption of nutrients, protects the retina from excessive light, and empties the urinary bladder and rectum.

Neurochemical Transmission

Nerve impulses elicit responses in smooth, cardiac, and skeletal muscles; exocrine glands; and postsynaptic neurons by liberating specific chemical neurotransmitters.

Evidence for Neurohumoral Transmission

The concept of neurohumoral transmission or chemical neurotransmission was developed primarily to explain observations relating to the transmission of impulses from postganglionic autonomic fibers to effector cells. Evidence supporting this concept includes the following:

- demonstration of the presence of a physiologically active compound and its biosynthetic enzymes at appropriate sites;
- recovery of the compound from the perfusate of an innervated structure during periods of nerve stimulation but not (or in greatly reduced amounts) in the absence of stimulation;
- demonstration that the compound is capable of producing responses identical to responses to nerve stimulation; and
- demonstration that the responses to nerve stimulation and to the administered compound are modified in the same manner by various drugs, usually competitive antagonists

While these criteria are applicable for most neurotransmitters, including NE and ACh, there are now exceptions to these general rules. For instance, NO has been found to be a neurotransmitter, in a few postganglionic parasympathetic nerves; in NANC neurons in the periphery; in the ENS; and in the CNS. However, NO is not stored in neurons and released by exocytosis. Rather, it is synthesized when needed and readily diffuses across membranes.

Neurotransmission in the peripheral nervous system and CNS once was believed to conform to the hypothesis that each neuron contains only one transmitter substance. However, we now find that synaptic transmission may be mediated by the release of more than one neurotransmitter. Additional peptides, such as enkephalin, substance P, NPY, VIP, and SST; purines such as ATP and adenosine; and small molecules such as NO have been found in nerve endings along with the “classical” biogenic amine neurotransmitters. These additional substances can depolarize or hyperpolarize nerve terminals or postsynaptic cells. For example, enkephalins are found in postganglionic sympathetic neurons and adrenal medullary chromaffin cells. VIP is localized selectively in peripheral cholinergic neurons that innervate exocrine glands, and NPY is found in sympathetic nerve endings. These observations suggest that synaptic transmission in many instances may be mediated by the release of more than one neurotransmitter (see the next section).

Steps Involved in Neurotransmission

The sequence of events involved in neurotransmission is of particular importance because pharmacologically active agents modulate the individual steps.

Axonal Conduction

Conduction refers to the passage of an electrical impulse along an axon or muscle fiber. At rest, the interior of the typical mammalian axon is about 70 mV negative to the exterior. In response to depolarization to a threshold level, an action potential is initiated at a local region of the membrane. The action potential consists of two phases. Following depolarization that induces an open conformation of the channel, the *initial phase* is caused by a rapid increase in the permeability and inward movement of Na^+ through voltage-sensitive Na^+ channels, and a rapid depolarization from the resting potential continues to a positive overshoot. The *second phase* results from the rapid inactivation of the Na^+ channel and the delayed opening of a K^+ channel, which permits outward movement of K^+ to terminate the depolarization. Although not important in axonal conduction, Ca^{2+} channels in other tissues (e.g., L-type Ca^{2+} channels in heart) contribute to the action potential by prolonging depolarization by an inward movement of Ca^{2+} . This influx of Ca^{2+} also serves as a stimulus to initiate intracellular events (Catterall, 2000), and Ca^{2+} influx is important in excitation-exocytosis coupling (transmitter release).

The transmembrane ionic currents produce local circuit currents such that adjacent resting channels in the axon are activated, and excitation of an adjacent portion of the axonal membrane occurs, leading to propagation of the action potential without decrement along the axon. The region that has undergone depolarization remains momentarily in a refractory state.

With the exception of the local anesthetics, few drugs modify axonal conduction in the doses employed therapeutically. The puffer fish poison, *tetrodotoxin*, and a close congener found in some shellfish, *saxitoxin*, selectively block axonal conduction by blocking the voltage-sensitive Na^+ channel and preventing the increase in Na^+ permeability associated with the rising phase of the action potential. In contrast, *batrachotoxin*, an extremely potent steroidal alkaloid secreted by a South American frog, produces paralysis through a selective increase in permeability of the Na^+ channel, which induces a persistent depolarization. Scorpion toxins are peptides that also cause persistent depolarization by inhibiting the inactivation process (Catterall, 2000). Na^+ and Ca^{2+} channels are discussed in more detail in Chapters 11, 14, and 22.

Junctional Transmission

The term *transmission* refers to the passage of an impulse across a synaptic or neuroeffector junction. The arrival of the action potential at the axonal terminals initiates a series of events that trigger transmission of an excitatory or inhibitory biochemical message across the synapse or neuroeffector junction. These events, diagrammed in Figures 8–3, 8–4, and 8–5, are the following:

1. *Storage and release of transmitter.* The nonpeptide (small-molecule) neurotransmitters, such as biogenic amines, are largely synthesized in the region of the axonal terminals and stored there in synaptic vesicles. Neurotransmitter transport into storage vesicles is driven by an electrochemical gradient generated by the vesicular proton pump (vesicular ATPase) (Figures 8–5 and 8–6). Synaptic vesicles cluster in discrete areas underlying the presynaptic plasma membrane, termed *active zones*, often aligning with the tips of postsynaptic folds. Proteins in the vesicular membrane (e.g., synapsin, synaptophysin, synaptogyrin) are involved in development and trafficking of the storage vesicle to the active zone. The processes of priming, docking, fusion, and exocytosis involve the interactions of proteins in the vesicular and plasma membranes and the rapid entry of extracellular Ca^{2+} and its binding to synaptotagmins (Figure 8–4).

Life Cycle of a Storage Vesicle; Molecular Mechanism of Exocytosis. Fusion of the storage vesicle and plasma membrane involves formation of a multiprotein complex that includes proteins in

Figure 8-3 Steps involved in excitatory and inhibitory neurotransmission. **1.** The nerve AP consists of a transient self-propagated reversal of charge on the axonal membrane. (The internal potential E_i goes from a negative value, through zero potential, to a slightly positive value, primarily through increases in Na^+ permeability, and then returns to resting values by an increase in K^+ permeability.) When the AP arrives at the presynaptic terminal, it initiates release of the excitatory or inhibitory transmitter. Depolarization at the nerve ending and entry of Ca^{2+} initiate docking and then fusion of the synaptic vesicle with the membrane of the nerve ending. Some of the SNARE proteins involved in docking and fusion are shown. Figures 8-4 and 8-5 show some additional details of the life cycle of neurotransmitter storage vesicle and exocytosis. **2.** Interaction of the excitatory transmitter with postsynaptic receptors produces a localized depolarization, the EPSP, through an increase in permeability to cations, most notably Na^+ . The inhibitory transmitter causes a selective increase in permeability to K^+ or Cl^- , resulting in a localized hyperpolarization, the IPSP. **3.** The EPSP initiates a conducted AP in the postsynaptic neuron; this can be prevented, however, by the hyperpolarization induced by a concurrent IPSP. The transmitter is dissipated by enzymatic destruction, by reuptake into the presynaptic terminal or adjacent glial cells, or by diffusion. Depolarization of the postsynaptic membrane can permit Ca^{2+} entry if voltage-gated Ca^{2+} channels are present.

the membrane of the synaptic vesicle, proteins embedded in the inner surface of the plasma membrane, and several cytosolic components. These proteins are referred to as SNARE proteins. Through the assembly of these proteins, vesicles draw near the membrane (priming, docking), spatially prepared for the next step, which the entry of Ca^{2+} initiates. When Ca^{2+} enters with the action potential, fusion and exocytosis occur rapidly. After fusion, the chaperone ATPase NSF and its SNAP adapters catalyze dissociation of the SNARE complex. Figures 8-4 and 8-5 depict this life cycle. Figure 8-4 shows some details of the assembly of the SNARE protein complex leading to fusion and exocytosis of neurotransmitter. The isoforms of the participating proteins may differ in different neurotransmitter systems, but the general mechanism seems to be conserved.

During the resting state, there is continual slow release of isolated quanta of the transmitter; this produces electrical responses (*miniature end-plate potentials* or *mepps*) at the postjunctional membrane that are associated with the maintenance of the physiological responsiveness of the effector organ. A low level of spontaneous activity within the motor units of skeletal muscle is particularly important because skeletal muscle lacks inherent tone.

The action potential causes the synchronous release of several hundred quanta of neurotransmitter. In the fusion/exocytosis process, the contents of the vesicles, including enzymes and other proteins, are discharged to the synaptic space. Synaptic vesicles may either fully exocytose with complete fusion or form a transient, nanometer-size pore that closes after transmitter has escaped, “kiss-and-run” exocytosis. In full-fusion exocytosis, the pit formed by the vesicle’s fusing with the plasma membrane is clathrin-coated and retrieved from the membrane via endocytosis and transported to an endosome for full recycling. During kiss-and-run exocytosis, the

pore closes, and the vesicle is immediately and locally recycled for reuse in neurotransmitter repackaging (Alabi and Tsien, 2013; Südhof, 2014).

Modulation of Transmitter Release. A number of autocrine and paracrine factors may influence the exocytotic process, including the released neurotransmitter itself. Adenosine, DA, glutamate, GABA, prostaglandins, and enkephalins influence neurally mediated release of neurotransmitters. Receptors for these factors exist in the membranes of the soma, dendrites, and axons of neurons (Miller, 1998; Westfall, 2004): *Soma-dendritic receptors*, when activated, primarily modify functions of the soma-dendritic region, such as protein synthesis and generation of action potentials. *Presynaptic receptors*, when activated, modify functions of the terminal region, such as synthesis and release of transmitters.

Two main classes of presynaptic receptors have been identified on most neurons: *Heteroreceptors* are presynaptic receptors that respond to neurotransmitters, neuromodulators, or neurohormones released from adjacent neurons or cells. For example, NE can influence the release of ACh from parasympathetic neurons by acting on α_{2A} , α_{2B} , and α_{2C} receptors, whereas ACh can influence the release of NE from sympathetic neurons by acting on M_2 and M_4 receptors. *Autoreceptors* are receptors located on or close to axon terminals of a neuron through which the neuron’s own transmitter can modify transmitter synthesis and release (see Figures 8-6 and 8-8). For example, NE released from sympathetic neurons may interact with α_{2A} and α_{2C} receptors to inhibit neurally released NE. Similarly, ACh released from parasympathetic neurons may interact with M_2 and M_4 receptors to inhibit neurally released ACh.

2. Interaction of the transmitter with postjunctional receptors and production of the postjunctional potential. The transmitter diffuses across the

Figure 8-4 Molecular basis of exocytosis: docking and fusion of synaptic vesicles with neuronal membranes. **1.** Vesicular docking in the active zone: Munc18 binds to syntaxin 1, stabilizing the neuronal membrane SNARE proteins. **2.** Priming I: Syntaxin assembles with SNAP25, allowing for the vesicle SNARE protein synaptobrevin to bind to the complex. **3.** Priming II: Complexin binds to the SNARE complex and allows for the vesicular synaptotagmin to bind Ca^{2+} that drives the full fusion process. **4.** Fusion pore opening: Synaptotagmin interacts with the SNARE complex and binds Ca^{2+} , permitting pore fusion and exocytosis of neurotransmitter. Other components, not shown, are the vesicular GTP-binding Rab3/27; the linking proteins Munc13, RIM, and RIM-BP; and tethering to the Ca^{2+} channel. **5.** Return to ground state: After fusion, the chaperone ATPase NSF and its SNAP adapters catalyze dissociation of the SNARE-complex. For a more detailed view of this process, see Südhof (2014).

synaptic or junctional cleft and combines with specialized receptors on the postjunctional membrane; this often results in a localized increase in the ionic permeability, or conductance, of the membrane. With certain exceptions (noted in the following discussion), one of three types of permeability change can occur:

- Generalized increase in the permeability to cations (notably Na^{+} but occasionally Ca^{2+}), resulting in a localized depolarization of the membrane, that is, an EPSP.
- Selective increase in permeability to anions, usually Cl^{-} , resulting in stabilization or actual hyperpolarization of the membrane, which constitutes an IPSP.
- Increased permeability to K^{+} . Because the K^{+} gradient is directed out of the cell, hyperpolarization and stabilization of the membrane potential occur (an IPSP).

Electric potential changes associated with the EPSP and IPSP at most sites are the results of passive fluxes of ions down their concentration gradients. The changes in channel permeability that cause these potential changes are specifically regulated by the specialized postjunctional receptors for the neurotransmitter that initiates the response (see Figures 8-6, 8-8, and 11-4 and Chapter 14). These receptors may be clustered on the effector cell surface, as seen at the NMJs of skeletal muscle and other discrete synapses, or distributed more uniformly, as observed in smooth muscle. These *high-conductance, ligand-gated ion channels* usually permit

passage of Na^{+} or Cl^{-} ; K^{+} and Ca^{2+} are involved less frequently. In the presence of an appropriate neurotransmitter, the channel opens rapidly to a high-conductance state, remains open for about a millisecond, and then closes. A short square-wave pulse of current is observed as a result of the channel's opening and closing. The summation of these microscopic events gives rise to the EPSP.

The ligand-gated channels belong to a superfamily of ionotropic receptor proteins that includes the nicotinic, glutamate, and certain 5HT₃ and purine receptors, which conduct primarily Na^{+} , cause depolarization, and are excitatory; and GABA acid and glycine receptors, which conduct Cl^{-} , cause hyperpolarization, and are inhibitory. Neurotransmitters also can modulate the permeability of K^{+} and Ca^{2+} channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed between them by G proteins (see Chapter 3).

The nicotinic, GABA, glycine, and 5HT₃ receptors are closely related, whereas the glutamate and purinergic ionotropic receptors have distinct structures (see Figure 11-1 and Chapter 14). Neurotransmitters also can modulate the permeability of K^{+} and Ca^{2+} channels indirectly. In these cases, the receptor and channel are separate proteins, and information is conveyed between them by G proteins. Other receptors for neurotransmitters act by influencing the synthesis of intracellular second messengers and do not necessarily cause a change in membrane potential. The most widely documented examples of receptor regulation of second-messenger systems are the activation or inhibition of adenylyl cyclase to modulate

Figure 8-5 *Life cycle of a synaptic vesicle.* A mature storage vesicle, replete with transmitter, is translocated to the perimembrane space (*active zone*) (1). Once in the active zone (2), the vesicle undergoes docking and priming (see Figure 8-4), as proteins from the cytosol and the vesicular and plasma membranes (SNARE proteins) interact to tether the vesicle in a prefusion stage. The rapid entry of Ca^{2+} via voltage-sensitive channels located in the active zone (3) activates the calcium sensor synaptotagmin and initiates the process of fusion and exocytosis of the vesicular contents into the synaptic space (4). After transmitter release, the vesicle is endocytosed, the SNARE protein complex is disassembled by the action of the chaperone ATPase NSF and its SNAP adaptors, and the empty vesicle is recycled, either trafficked directly back into use (5) or routed through an early endosomal pathway (5'). In either event, the vesicular ATPase is at work, promoting H^{+} uptake to establish the gradient that drives transmitter uptake and repletion of the vesicle (6). For a more detailed view of the exocytotic process, see Südhof (2014). Secreted neuropeptides are stored in larger, dense core vesicles (see text). Their secretory process is similar; however, there are no uptake transporters for peptide neurotransmitters; rather, vesicles containing releasable peptides are formed in the trans-Golgi network of the nerve cell body and transported to the release site by molecular motors (kinesins, F-actin, etc.); nonsecreted vesicle components are recycled. Park and Loh (2008), Heaslip et al. (2014), and Salogiannis and Reck-Peterson (2016) have reviewed aspects of the transport of such vesicles.

cellular cAMP concentrations and the increase in cytosolic concentrations of Ca^{2+} that results from release of the ion from internal stores by inositol trisphosphate (see Chapter 3).

3. *Initiation of postjunctional activity.* If an EPSP exceeds a certain threshold value, it initiates a propagated action potential in a postsynaptic neuron or a muscle action potential in skeletal or cardiac muscle by activating voltage-sensitive channels in the immediate vicinity. In certain smooth muscle types in which propagated impulses are minimal, an EPSP may increase the rate of spontaneous depolarization, cause Ca^{2+} release, and enhance muscle tone; in gland cells, the EPSP initiates secretion through Ca^{2+} mobilization. An IPSP, which is found in neurons and smooth muscle but not in skeletal muscle, will tend to oppose excitatory potentials simultaneously initiated by other neuronal sources. Whether a propagated impulse or other response ensues depends on the summation of all the potentials.
4. *Destruction or dissipation of the transmitter.* When impulses can be transmitted across junctions at frequencies up to several hundred per second, there must be an efficient means of disposing of the transmitter following each impulse. At cholinergic synapses involved in rapid neurotransmission, high and localized concentrations of AChE are available for this purpose. When AChE activity is inhibited, removal of the transmitter is accomplished principally by diffusion. Under these circumstances, the effects of released ACh are potentiated and prolonged (see Chapter 10).

Rapid termination of NE occurs by a combination of simple diffusion and reuptake by the axonal terminals of most of the released

NE. Termination of the action of amino acid transmitters results from their active transport into neurons and surrounding glia. Peptide neurotransmitters are hydrolyzed by various peptidases and dissipated by diffusion.

5. *Nonelectrogenic functions.* The activity and turnover of enzymes involved in the synthesis and inactivation of neurotransmitters, the density of presynaptic and postsynaptic receptors, and other characteristics of synapses are controlled by trophic actions of neurotransmitters or other trophic factors released by the neuron or target cells.

Cholinergic Transmission

The neurochemical events that underlie cholinergic neurotransmission are summarized in Figure 8-6.

Synthesis and Storage of ACh

Two enzymes, choline acetyltransferase and AChE, are involved in ACh synthesis and degradation, respectively.

Choline Acetyltransferase. *Choline acetyltransferase* catalyzes the synthesis of ACh—the acetylation of choline with acetyl CoA. Choline acetyltransferase is synthesized within the perikaryon and then is transported along the length of the axon to its terminal. Axonal terminals contain a large number of mitochondria, where acetyl CoA is synthesized. Choline is taken up from the extracellular fluid into the axoplasm by active transport. The final step in the synthesis occurs within the cytoplasm, following which most of the ACh is sequestered within synaptic vesicles. Although moderately potent inhibitors of choline acetyltransferase exist, they have no

Figure 8–6 A typical cholinergic neuroeffector junction. The synthesis of ACh in the varicosity depends on the uptake of choline via a Na^+ -dependent carrier, CHT1, that hemicholinium can block. The enzyme ChAT catalyzes the synthesis of ACh from choline and the acetyl moiety of acetyl CoA. ACh is transported into the storage vesicle by VACHT, which can be inhibited by vesamicol. ACh is stored in vesicles (along with other potential cotransmitters, such as ATP and VIP, at certain neuroeffector junctions). Release of ACh and any cotransmitters occurs via exocytosis (the stages are itemized along the gray arrow), triggered by Ca^{2+} entry via a voltage-sensitive Ca^{2+} channel in response to membrane depolarization, as described in Figures 8–3, 8–4, and 8–5. Exocytotic release of ACh at the NMJ can be blocked by botulinum toxins, the active fragments of which are endopeptidases that cleave synaptobrevin, an essential member of the SNARE proteins that mediate docking/priming/exocytosis. Once released, ACh can interact with the muscarinic receptors (M), which are GPCRs, or nicotinic receptors (N), which are ligand-gated ion channels, to produce the characteristic response of the postsynaptic cell. ACh also can act on presynaptic mAChRs or nAChRs to modify its own release. The action of ACh is terminated by extracellular metabolism to choline and acetate by AChE, which is associated with synaptic membranes.

therapeutic utility, in part because the rate-limiting step in ACh biosynthesis is the uptake of choline.

Choline and Choline Transport. The availability of choline is critical to the synthesis of ACh. Choline must be derived primarily from the diet (there is little *de novo* synthesis of choline in cholinergic neurons) or, secondarily, from recycling of choline. Once ACh is released from cholinergic neurons in response to an action potential, ACh is hydrolyzed by AChE to acetate and choline. Much of the choline is taken up at cholinergic nerve terminals and reused for ACh synthesis. Under many circumstances, this reuptake and availability of choline appear to be rate limiting in ACh synthesis. There are three mammalian transport systems for choline; all three are transmembrane proteins with multiple TM segments; all are inhibited by hemicholinium but at distinct concentrations in the same order as their affinities for choline (Haga, 2014):

- The high-affinity ($4\text{-}\mu\text{M}$) choline transporter CHT1 (SLC5A7) present on presynaptic membranes of cholinergic neurons. This transporter is a member of the SLC5 family of solute carrier proteins that

includes Na^+ -glucose cotransporters and shares about 25% homology with those transporters (Haga, 2014). Choline transport by CHT1 is Na^+ and Cl^- dependent. This system provides choline for ACh synthesis and is the high-affinity hemicholinium-binding protein ($K_i = 0.05\text{ }\mu\text{M}$).

- A low-affinity ($40\text{-}\mu\text{M}$), Na^+ -independent transporter, CTL1 (SLC44A), which is widely distributed and appears to supply choline for phospholipid synthesis (e.g., phosphatidyl choline, sphingomyelin).
- A lower-affinity ($100\text{-}\mu\text{M}$) Na^+ -independent transporter, OCT2 (SLC22A2), a nonspecific organic cation secretory transporter found in renal proximal tubules (see Figures 5–8 and 5–9), hepatocytes, the choroid plexus, the luminal membrane of brain endothelium, and synaptic vesicles from cholinergic neurons. Its role in neurons remains to be clarified.

In model systems, CHT1 localizes mainly to intracellular organelles, including transmitter storage vesicles; neural activity increases the fraction of CHT1 in the plasma membrane, and phosphorylation by PKC enhances internalization (Haga, 2014).

Storage of ACh. ACh is transported into synaptic vesicles by the VACHT (a solute carrier protein, SLC18A3) using the potential energy of a proton electrochemical gradient that a vacuolar ATPase establishes, such that the transport of protons out of the vesicle is coupled to uptake of ACh into the vesicle and against a concentration gradient. The process is inhibited by the noncompetitive and reversible inhibitor *vesamicol*, which does not affect the vesicular ATPase (Figure 8–6). The gene for choline acetyltransferase and the vesicular transporter are found at the same locus, with the transporter gene positioned in the first intron of the transferase gene. Hence, a common promoter regulates the expression of both genes (Eiden, 1998).

There appear to be two types of vesicles in cholinergic terminals: electron-lucent vesicles (40–50 nm in diameter) and dense-cored vesicles (80–150 nm). The core of the vesicles contains both ACh and ATP, at a ratio of about 11:1, which are dissolved in the fluid phase with metal ions (Ca^{2+} and Mg^{2+}) and a proteoglycan called vesiculín. Vesiculín, negatively charged and thought to sequester the Ca^{2+} or ACh, is bound within the vesicle, with the protein moiety anchoring it to the vesicular membrane. In some cholinergic terminals, there are peptides, such as VIP, that act as *cotransmitters*. The peptides usually are located in the dense-cored vesicles.

Estimates of the ACh content of synaptic vesicles range from 1000 to over 50,000 molecules per vesicle, with a single motor nerve terminal containing 300,000 or more vesicles. In addition, an uncertain but possibly significant amount of ACh is present in the extravascular cytoplasm. Recording the electrical events associated with the opening of single channels at the motor end plate during continuous application of ACh has permitted estimation of the potential change induced by a single molecule of ACh (3×10^{-7} V); from such calculations, it is evident that even the lower estimate of the ACh content per vesicle (1000 molecules) is sufficient to account for the magnitude of the miniature end-plate potentials.

Release of ACh. Exocytotic release of ACh and cotransmitters (e.g., ATP, VIP) occurs on depolarization of the nerve terminals. Depolarization of the terminals allows the entry of Ca^{2+} through voltage-gated Ca^{2+} channels and promotes fusion of the vesicular membrane with the plasma membrane, allowing exocytosis to occur, as described previously and in Figure 8–6.

Two pools of ACh appear to exist. One pool, the “depot” or “readily releasable” pool, consists of vesicles located near the plasma membrane of the nerve terminals; these vesicles contain newly synthesized transmitter. Depolarization of the terminals causes these vesicles to release ACh rapidly or readily. The other pool, the “reserve pool,” seems to replenish the readily releasable pool and may be required to sustain ACh release during periods of prolonged or intense nerve stimulation.

Botulinum toxin blocks ACh release by interfering with the machinery of transmitter release. The active fragments of botulinum toxins are endopeptidases; the SNARE proteins are their substrates. There are eight isoforms of botulinum toxin, each cleaving a specific site on SNARE proteins. Tetanus toxins act similarly, but in the CNS. The active fragments of these toxins cleave synaptobrevin and block exocytosis in specific sets of neurons (inhibitory neurons in the CNS for tetanus, the NMJ for botulinum).

Acetylcholinesterase. At the NMJ, immediate hydrolysis of ACh by AChE reduces lateral diffusion of the transmitter and activation of adjacent receptors. Rapid release of ACh onto the nAChRs of the motor end plate, followed by rapid hydrolysis of the neurotransmitter, spatially limits receptor activation and facilitates rapid control of responses. The time required for hydrolysis of ACh at the NMJ is less than a millisecond. Chapter 10 presents details of the structure, mechanism, and inhibition of AChE.

AChE is found in cholinergic neurons and is highly concentrated at the postsynaptic end plate of the NMJ. BuChE (butyrylcholinesterase, also called pseudocholinesterase) is virtually absent in neuronal elements of the central and peripheral nervous systems. BuChE is synthesized primarily in the liver and is found in liver and plasma; its likely physiological function is the hydrolysis of ingested esters from plant sources. AChE and BuChE typically are distinguished by the relative rates of ACh and butyrylcholine hydrolysis and by effects of selective inhibitors (see Chapter 10).

Almost all pharmacological effects of the anti-ChE agents are due to the inhibition of AChE, with the consequent accumulation of endogenous ACh in the vicinity of the nerve terminal. Distinct but single genes encode AChE and BuChE in mammals; the diversity of molecular structure of AChE arises from alternative mRNA processing (Taylor et al., 2000).

Numerous reports suggest that AChE plays roles in addition to its classical function in terminating impulse transmission at cholinergic synapses. Nonclassical functions of AChE might include hydrolysis of ACh in a nonsynaptic context, action as an adhesion protein involved in synaptic development and maintenance or as a bone matrix protein, involvement in neurite outgrowth, and acceleration of the assembly of A β peptide into amyloid fibrils (Silman and Sussman, 2005).

Characteristics of Cholinergic Transmission at Various Sites

There are marked differences amongst various sites of cholinergic transmission with respect to architecture and fine structure, the distributions of AChE and receptors, and the temporal factors involved in normal function. In skeletal muscle, for example, the junctional sites occupy a small, discrete portion of the surface of the individual fibers and are relatively isolated from those of adjacent fibers; in the superior cervical ganglion, about 100,000 ganglion cells are packed within a volume of a few cubic millimeters, and both the presynaptic and the postsynaptic neuronal processes form complex networks.

Skeletal Muscle. At the NMJ, ACh stimulates the nicotinic receptor’s intrinsic channel, which opens for about 1 ms, admitting about 50,000 Na^{+} ions. The channel-opening process is the basis for the localized depolarizing EPP within the end plate, which triggers the muscle action potential and leads to contraction. The amount of ACh (10^{-17} mol) required to elicit an EPP following its microiontophoretic application to the motor end plate of a rat diaphragm muscle fiber is equivalent to that recovered from each fiber following stimulation of the phrenic nerve.

Following sectioning and degeneration of the motor nerve to skeletal muscle or of the postganglionic fibers to autonomic effectors, there is a marked reduction in the threshold doses of the transmitters and of certain other drugs required to elicit a response; that is, denervation supersensitivity occurs. In skeletal muscle, this change is accompanied by a spread of the receptor molecules from the end-plate region to the adjacent portions of the sarcoplasmic membrane, which eventually involves the entire muscle surface. Embryonic muscle also exhibits this uniform sensitivity to ACh prior to innervation. Hence, innervation represses the expression of the receptor gene by the nuclei that lie in extrajunctional regions of the muscle fiber and directs the subsynaptic nuclei to express the structural and functional proteins of the synapse.

Autonomic Effector Cells. Stimulation or inhibition of autonomic effector cells occurs on activation of muscarinic ACh receptors (discussed below). In this case, the effector is coupled to the receptor by a G protein (Chapter 3). In contrast to skeletal muscle and neurons, smooth muscle and the cardiac conduction system sinoatrial (SA) node, atrium, AV node, and the His-Purkinje system) normally exhibit intrinsic activity, both electrical and mechanical, that is modulated but not initiated by nerve impulses.

In the basal condition, unitary smooth muscle exhibits waves of depolarization or spikes that are propagated from cell to cell at rates considerably slower than the action potential of axons or skeletal muscle. The spikes apparently are initiated by rhythmic fluctuations in the membrane resting potential. Application of ACh (0.1 to 1 μM) to isolated intestinal muscle causes the membrane potential to become less negative and increases the frequency of spike production, accompanied by a rise in tension. A primary action of ACh in initiating these effects through muscarinic receptors is probably partial depolarization of the cell membrane brought about by an increase in Na^{+} and, in some instances, Ca^{2+} conductance. ACh also can produce contraction of some smooth muscles when the membrane has been depolarized completely by high concentrations of K^{+} , provided that Ca^{2+} is present. Hence, ACh stimulates ion fluxes across membranes or mobilizes intracellular Ca^{2+} to cause contraction.

In the heart, spontaneous depolarizations normally arise from the SA node. In the cardiac conduction system, particularly in the SA and AV

nodes, stimulation of the cholinergic innervation or the direct application of ACh causes inhibition, associated with hyperpolarization of the membrane and a marked decrease in the rate of depolarization. These effects are due, at least in part, to a selective increase in permeability to K^+ .

Autonomic Ganglia. The primary pathway of cholinergic transmission in autonomic ganglia is similar to that at the NMJ of skeletal muscle. The initial depolarization is the result of activation of nAChRs, which are ligand-gated cation channels with properties similar to those found at the NMJ. Several secondary transmitters or modulators either enhance or diminish the sensitivity of the postganglionic cell to ACh (see Figure 11–5).

Prejunctional Sites. ACh release is subject to complex regulation by mediators, including ACh itself acting on M_2 and M_4 autoreceptors, and activation of heteroreceptors (e.g., NE acting on α_{2A} and α_{2C} adrenergic receptors) or substances produced locally in tissues (e.g., NO) (Philipp and Hein, 2004; Wess et al., 2007). ACh-mediated inhibition of ACh release following activation of M_2 and M_4 autoreceptors is a physiological negative-feedback control mechanism. At some neuroeffector junctions (e.g., the myenteric plexus in the GI tract or the cardiac SA node), sympathetic and parasympathetic nerve terminals often lie juxtaposed to each other. There, opposing effects of NE and ACh result not only from the opposite effects of the two neurotransmitters on the smooth muscle or cardiac cells but also from the inhibition of ACh release by NE or inhibition of NE release by ACh acting on heteroreceptors on parasympathetic or sympathetic terminals.

Inhibitory heteroreceptors on parasympathetic terminals include adenosine A_1 receptors, histamine H_3 receptors, opioid receptors, and α_{2A} and α_{2C} adrenergic receptors. The parasympathetic nerve terminal varicosities also may contain additional heteroreceptors that could respond by inhibition or enhancement of ACh release by locally formed autacoids, hormones, or administered drugs.

Extraneuronal Sites. All elements of the cholinergic system are functionally expressed independently of cholinergic innervation in numerous nonneuronal cells. These *nonneuronal cholinergic* systems can both modify and control phenotypic cell functions such as proliferation, differentiation, formation of physical barriers, migration, and ion and water movements.

The widespread synthesis of ACh in nonneuronal cells has changed the thinking that ACh acts only as a neurotransmitter. Each component of the cholinergic system in nonneuronal cells can be affected by pathophysiological conditions. Dysfunctions of nonneuronal cholinergic systems may be involved in the pathogenesis of diseases (e.g., inflammatory processes) (Wessler and Kirkpatrick, 2008).

HISTORICAL PERSPECTIVE

Sir Henry Dale noted that the various esters of choline elicited responses that were similar to those of either nicotine or muscarine depending on the pharmacological preparation. A similarity in response also was noted between muscarine and nerve stimulation in those organs innervated by the craniosacral divisions of the autonomic nervous system. Thus, Dale suggested that ACh or another ester of choline was a neurotransmitter in the autonomic nervous system; he also stated that the compound had dual actions, which he termed a “nicotine action” (*nicotinic*) and a “muscarine action” (*muscarinic*).

The capacities of tubocurarine and atropine to block nicotinic and muscarinic effects of ACh, respectively, provided further support for the proposal of two distinct types of cholinergic receptors. Although Dale had access only to crude plant alkaloids of then-unknown structure from *Amanita muscaria* and *Nicotiana tabacum*, this classification remains the primary subdivision of cholinergic receptors. Its utility has survived the discovery of several distinct subtypes of nicotinic and muscarinic receptors.

Cholinergic Receptors and Signal Transduction

Nicotinic receptors are ligand-gated ion channels whose activation always causes a rapid (millisecond) increase in cellular permeability to Na^+ and Ca^{2+} , depolarization, and excitation. *Muscarinic receptors* are GPCRs. Responses to muscarinic agonists are slower; they may be either excitatory or inhibitory, and they are not necessarily linked to changes in ion permeability. The muscarinic and nicotinic receptors for ACh belong to two different families whose features are described in Chapters 9 and 11, respectively.

Subtypes of nAChRs. The nAChRs exist at the skeletal NMJ, autonomic ganglia, adrenal medulla, and CNS and in nonneuronal tissues. The nAChRs are composed of five homologous subunits organized around a central pore (see Table 8–2 and Figure 11–2). In general, the nAChRs are further divided into two groups:

- *Muscle type* (N_m), found in the vertebrate skeletal muscle, where they mediate transmission at the NMJ
- *Neuronal type* (N_n), found mainly throughout the peripheral nervous system, CNS, and nonneuronal tissues

Neuronal nAChRs are widely distributed in the CNS and are found at presynaptic, perisynaptic, and postsynaptic sites. At pre- and perisynaptic sites, nAChRs appear to act as autoreceptors or heteroreceptors to regulate the release of several neurotransmitters (ACh, DA, NE, glutamate, and 5HT) at diverse sites in the brain (Albuquerque et al., 2009).

Muscle-Type nAChRs. In fetal muscle prior to innervation, in adult muscle after denervation, and in fish electric organs, the nAChR subunit stoichiometry is $(\alpha 1)_2\beta 1\gamma\delta$, whereas in adult muscle the γ subunit is replaced by ϵ to give the $(\alpha 1)_2\beta 1\epsilon\delta$ stoichiometry (Table 8–2). The γ/ϵ and δ subunits are involved together with the $\alpha 1$ subunits in forming the ligand-binding sites and in the maintenance of cooperative interactions between the $\alpha 1$ subunit. Different affinities to the two binding sites are conferred by the presence of different non- α subunits. Binding of ACh to the $\alpha\gamma$ and $\alpha\delta$ sites is thought to induce a conformational change predominantly in the $\alpha 1$ subunits that interacts with the transmembrane region to cause channel opening.

Neuronal-Type nAChRs. Neuronal nAChRs are widely expressed in peripheral ganglia, the adrenal medulla, numerous areas of the brain, and nonneuronal cells, such as epithelial cells and cells of the immune system. To date, nine α ($\alpha 2$ – $\alpha 10$) and three β ($\beta 2$ – $\beta 4$) subunit genes have been cloned. The $\alpha 7$ – $\alpha 10$ subunits are found either as homopentamers (of five $\alpha 7$, $\alpha 8$, and $\alpha 9$ subunits) or as heteropentamers of $\alpha 7$, $\alpha 8$, and $\alpha 9/\alpha 10$. By contrast, the $\alpha 2$ – $\alpha 6$ and $\beta 2$ – $\beta 4$ subunits form heteropentamers usually with $(\alpha x)_2(\beta y)_3$ stoichiometry. The $\alpha 5$ and $\beta 3$ subunits do not appear to be able to form functional receptors when expressed alone or in paired combinations with α or β subunits, respectively (Kalamida et al., 2007).

The precise function of many of the neuronal nAChRs in the brain is not known; they appear to act more as synaptic modulators, the molecular diversity of the subunits putatively resulting in numerous nAChR subtypes with different physiological properties. Neuronal nAChRs are widely distributed in the CNS and are found at presynaptic, perisynaptic, and postsynaptic sites. At pre- and perisynaptic sites, nAChRs appear to act as autoreceptors or heteroreceptors to regulate the release of several neurotransmitters (ACh, DA, NE, glutamate, and 5HT) at sites throughout the brain (Exley and Cragg, 2008). The synaptic release of a particular neurotransmitter can be regulated by different neuronal-type nAChR subtypes in different CNS regions. For instance, DA release from striatal and thalamic DA neurons can be controlled by the $\alpha 4\beta 2$ subtype or both $\alpha 4\beta 2$ and $\alpha 6\beta 2\beta 3$ subtypes, respectively. In contrast, glutamatergic neurotransmission is regulated everywhere by $\alpha 7$ nAChRs (Kalamida et al., 2007).

Subtypes of Muscarinic Receptors. In mammals, there are five distinct subtypes of mAChRs, each produced by a different gene. These variants have distinct anatomic locations in the periphery and CNS and differing chemical specificities. The mAChRs are GPCRs (see Table 8–3 and Chapter 9), present in virtually all organs, tissues, and cell types (Table 8–3

TABLE 8-2 ■ CHARACTERISTICS OF SUBTYPES OF NICOTINIC ACETYLCHOLINE RECEPTORS (NACHRS)

RECEPTOR (Primary Receptor Subtype) ^a	MAIN SYNAPTIC LOCATION	MEMBRANE RESPONSE	MOLECULAR MECHANISM	AGONISTS	ANTAGONISTS
Skeletal Muscle (N_m) ($\alpha 1$) ₂ $\beta 1\epsilon\delta$ adult ($\alpha 1$) ₂ $\beta 1\gamma\delta$ fetal	Skeletal neuromuscular junction (postjunctional)	Excitatory; end-plate depolarization; skeletal muscle contraction	Increased cation permeability (Na^+ ; K^+)	ACh Nicotine Succinylcholine	Atracurium Vecuronium <i>d</i> -Tubocurarine Pancuronium α -Conotoxin α -Bungarotoxin
Peripheral neuronal (N_n) ($\alpha 3$) ₂ ($\beta 4$) ₃	Autonomic ganglia; adrenal medulla	Excitatory; depolarization; firing of postganglion neuron; depolarization and secretion of catecholamines	Increased cation permeability (Na^+ ; K^+)	ACh Nicotine Epibatidine Dimethylphenyl-piperazinium	Trimethaphan Mecamylamine
CNS neuronal ($\alpha 4$) ₂ ($\beta 4$) ₃ (α -BTX-insensitive)	CNS; pre- and postjunctional	Pre- and postsynaptic excitation; prejunctional control of transmitter release	Increased cation permeability (Na^+ ; K^+)	Cytosine, epibatidine Anatoxin A	Mecamylamine DHbE Erysodine Lophotoxin
($\alpha 7$) ₅ (α -BTX-sensitive)	CNS; pre- and postsynaptic	Pre- and postsynaptic excitation; prejunctional control of transmitter release	Increased permeability (Ca^{2+})	Anatoxin A	Methyllycaconitine α -Bungarotoxin α -Conotoxin ImI

^aNine α ($\alpha 2$ – $\alpha 10$) and three β ($\beta 2$ – $\beta 4$) subunits have been identified and cloned in human brain, which combine in various conformations to form individual receptor subtypes. The structure of individual receptors and the subtype composition are incompletely understood. Only a finite number of naturally occurring functional nAChR constructs have been identified. DHbE, dihydro- β -erythroidine.

and Chapter 9). Most cell types have multiple mAChR subtypes, but certain subtypes often predominate in specific sites (Wess et al., 2007). For example, the M_2 receptor is the predominant subtype in the heart and in CNS neurons is mostly located presynaptically, whereas the M_3 receptor is the predominant subtype in the detrusor muscle of the bladder (Dhein et al., 2001; Fetscher et al., 2002).

In the periphery, mAChRs mediate the classical muscarinic actions of ACh in organs and tissues innervated by parasympathetic nerves, although receptors may be present at sites that lack parasympathetic innervation (e.g., most blood vessels). In the CNS, mAChRs are involved in regulating a large number of cognitive, behavioral, sensory, motor, and autonomic functions. Owing to the lack of specific muscarinic agonists and antagonists that demonstrate selectivity for individual mAChRs and the fact that most organs and tissues express multiple mAChRs, it has been a challenge to assign specific pharmacological functions to distinct mAChRs. The development of gene-targeting techniques in mice has been helpful in defining specific functions (Table 8–3) (Wess et al., 2007).

The functions of mAChRs are mediated by interactions with G proteins. The M_1 , M_3 , and M_5 subtypes couple through $G_{q/11}$ to stimulate the PLC-IP₃/DAG- Ca^{2+} pathway, leading to activation of PKC and Ca^{2+} -sensitive enzymes. Activation of M_1 , M_3 , and M_5 receptors can also cause the activation of PLA₂, leading to the release of arachidonic acid and consequent eicosanoid synthesis; these effects of M_1 , M_3 , and M_5 mAChRs are generally secondary to elevation of intracellular Ca^{2+} . Stimulated M_2 and M_4 cholinergic receptors couple to G_i and G_o , with resulting inhibition of adenylyl cyclase, leading to a decrease in cellular cAMP, activation of inwardly rectifying K^+ channels, and inhibition of voltage-gated Ca^{2+} channels (van Koppen and Kaiser, 2003). The functional consequences of these effects are hyperpolarization and inhibition of excitable membranes. In the myocardium, inhibition of adenylyl cyclase and activation of K^+ conductances account for the negative inotropic and chronotropic effects of ACh. In addition, heterologous systems may produce different receptor-transducer-effector interactions (Nathanson, 2008).

Following activation by classical or allosteric agonists, mAChRs can be phosphorylated by a variety of receptor kinases and second-messenger

regulated kinases; the phosphorylated mAChR subtypes then can interact with β -arrestin and possibly other adapter proteins. As a result, mAChR signaling pathways may be differentially altered. Agonist activation of mAChRs also may induce receptor internalization and downregulation (van Koppen and Kaiser, 2003). Muscarinic AChRs can also regulate other signal transduction pathways that have diverse effects on cell growth, survival, and physiology, such as MAPK, phosphoinositide-3-kinase, RhoA, and Rac1 (Nathanson, 2008).

Changes in mAChR levels and activity have been implicated in the pathophysiology of numerous major diseases in the CNS and in the autonomic nervous system (Table 8–3). Phenotypic analysis of mAChR-mutant mice as well as the development of selective agonists and antagonists has led to a wealth of new information regarding the physiological and potential pathophysiological roles of the individual mAChR subtype (Langmead et al., 2008; Wess et al., 2007).

Adrenergic Transmission

Norepinephrine (NE) is the principal transmitter of most sympathetic postganglionic fibers and of certain tracts in the CNS; DA is the predominant transmitter of the mammalian extrapyramidal system and of several mesocortical and mesolimbic neuronal pathways; and EPI is the major hormone of the adrenal medulla. Collectively, these three amines are called *catecholamines*. Drugs affecting these endogenous amines and their actions are used in the treatment of hypertension, mental disorders, and a variety of other conditions. The details of these interactions and of the pharmacology of the sympathomimetic amines themselves can be found in subsequent chapters. The basic physiological, biochemical, and pharmacological features are presented here.

Synthesis of Catecholamines

The steps in the synthesis of catecholamines and the characteristics of the enzymes involved are shown in Figure 8–7 and Table 8–4. Tyrosine is sequentially 3-hydroxylated and decarboxylated to form DA. DA is β -hydroxylated to yield NE, which is *N*-methylated in chromaffin tissue to give EPI. The enzymes involved have been identified, cloned, and characterized

TABLE 8-3 ■ CHARACTERISTICS OF MUSCARINIC ACETYLCHOLINE RECEPTOR (mAChRs) SUBTYPES

RECEPTOR	CELLULAR AND TISSUE LOCATION ^a	CELLULAR RESPONSE ^b	FUNCTIONAL RESPONSE ^c	DISEASE RELEVANCE
M ₁	CNS; most abundant in cerebral cortex, hippocampus, striatum, and thalamus Autonomic ganglia Glands (gastric and salivary) Enteric nerves	Couples by G _{q/11} to activate PLC-IP ₃ -Ca ²⁺ -PKC pathway Depolarization and excitation (↑ sEPSP) Activation of PLD ₂ , PLA ₂ ; ↑AA	Increased cognitive function (learning and memory) Increased seizure activity Decrease in dopamine release and locomotion Increase in depolarization of autonomic ganglia Increase in secretions	Alzheimer disease Cognitive dysfunction Schizophrenia
M ₂	Widely expressed in CNS, hindbrain, thalamus, cerebral cortex, hippocampus, striatum, heart, smooth muscle, autonomic nerve terminals	Couples by G _i /G _o (PTX sensitive) Inhibition of AC, ↓ cAMP Activation of inwardly rectifying K ⁺ channels Inhibition of voltage-gated Ca ²⁺ channels Hyperpolarization and inhibition	Heart: SA node: slowed spontaneous depolarization; hyperpolarization, ↓ HR AV node: decrease in conduction velocity Atrium: ↓ refractory period, ↓ contraction Ventricle: slight ↓ contraction Smooth muscle: ↑ Contraction Peripheral nerves: Neural inhibition via autoreceptors and heteroreceptor ↓ Ganglionic transmission. CNS: Neural inhibition ↑ Tremors; hypothermia; analgesia	Alzheimer disease Cognitive dysfunction Pain
M ₃	Widely expressed in CNS (<other mAChRs), cerebral cortex, hippocampus Abundant in smooth muscle and glands Heart	Couples by G _{q/11} to activate PLC-IP ₃ /DAG-Ca ²⁺ -PKC pathway Depolarization and excitation (↑ sEPSP) Activation of PLD ₂ , PLA ₂ ; ↑AA	Smooth muscle: ↑ Contraction (predominant in some, e.g., bladder) Glands: ↑ Secretion (predominant in salivary gland) Increases food intake, body weight, fat deposits Inhibition of DA release Synthesis of NO	Chronic obstructive pulmonary disease (COPD) Urinary incontinence Irritable bowel disease
M ₄	Preferentially expressed in CNS, particularly forebrain, also striatum, cerebral cortex, hippocampus	Couples by G _i /G _o (PTX sensitive) Inhibition of AC, ↓ cAMP Activation of inwardly rectifying K ⁺ channels Inhibition of voltage-gated Ca ²⁺ channels Hyperpolarization and inhibition	Autoreceptor- and heteroreceptor-mediated inhibition of transmitter release in CNS and periphery Analgesia; cataleptic activity Facilitation of DA release	Parkinson disease Schizophrenia Neuropathic pain
M ₅	Substantia nigra Expressed in low levels in CNS and periphery Predominant mAChR in neurons in VTA and substantia nigra	Couples by G _{q/11} to activate PLC-IP ₃ -Ca ²⁺ -PKC pathway Depolarization and excitation (↑ sEPSP) Activation of PLD ₂ , PLA ₂ ; ↑AA	Mediator of dilation in cerebral arteries and arterioles (?) Facilitates DA release Augmentation of drug-seeking behavior and reward (e.g., opiates, cocaine)	Drug dependence Parkinson disease Schizophrenia

^aMost organs, tissues, and cells express multiple mAChRs.^bM₁, M₃, and M₅ mAChRs appear to couple to the same G proteins and signal through similar pathways. Likewise, M₂ and M₄ mAChRs couple through similar G proteins and signal through similar pathways.^cDespite the fact that in many tissues, organs, and cells multiple subtypes of mAChRs coexist, one subtype may predominate in producing a particular function; in others, there may be equal predominance.

VTA, ventral tegmentum area.

Figure 8-7 Steps in the enzymatic synthesis of dopamine, norepinephrine and epinephrine. The enzymes involved are shown in red; essential cofactors in italics. The final step occurs only in the adrenal medulla and in a few epinephrine-containing neuronal pathways in the brainstem.

(Nagatsu, 2006). Table 8-4 summarizes some of the important characteristics of the four enzymes. These enzymes are not completely specific; consequently, other endogenous substances, as well as certain drugs, are also substrates. For example, 5HT can be produced from 5-hydroxy-L-tryptophan by aromatic L-amino acid decarboxylase (or dopa decarboxylase). Dopa decarboxylase also converts dopa into DA (Chapter 13) and methyl dopa to α -methyl dopamine, which in turn is converted by D β H to methyl norepinephrine.

The hydroxylation of tyrosine by TH is the rate-limiting step in the biosynthesis of catecholamines (Zigmond et al., 1989). This enzyme is activated following stimulation of sympathetic nerves or the adrenal medulla. The enzyme is a substrate for PKA, PKC, and CaM kinase; phosphorylation is associated with increased hydroxylase activity. In addition, there is a delayed increase in TH gene expression after nerve stimulation. These mechanisms serve to maintain the content of catecholamines in response to increased transmitter release. TH also is subject to feedback inhibition by catechol compounds.

Deficiency of TH has been reported in humans and is characterized by generalized rigidity, hypokinesia, and low CSF levels of NE and DA metabolites HVA and 3-methoxy-4-hydroxyphenylethylene glycol (Wevers et al., 1999). TH knockout is embryonically lethal in mice, presumably because the loss of catecholamines results in altered cardiac function. Interestingly, residual levels of DA are present in these mice. Tyrosinase may be an alternate source for catecholamines, although tyrosinase-derived catecholamines are clearly not sufficient for survival (Carson and Robertson, 2002).

Deficiency of D β H in humans is characterized by orthostatic hypotension, ptosis of the eyelids, retrograde ejaculation, and elevated plasma levels of DA. In the case of D β H-deficient mice, there is about 90% embryonic mortality (Carson and Robertson, 2002).

Our understanding of the cellular sites and mechanisms of synthesis, storage, and release of catecholamines derives from studies of sympathetically innervated organs and the adrenal medulla. Nearly all the NE content of innervated organs is confined to the postganglionic sympathetic fibers; it disappears within a few days after section of the nerves. In the adrenal medulla, catecholamines are stored in chromaffin granules (Aunis, 1998). These vesicles contain extremely high concentrations of catecholamines (~21% dry weight), ascorbic acid, and ATP, as well as specific proteins, such as chromogranins, D β H, and peptides, including enkephalin and neuropeptide Y. Vasostatin 1, the N-terminal fragment of chromogranin A, has been found to have antibacterial and antifungal activity (Lugardon et al., 2000), as have other chromogranin A fragments, such as chromogranin, vasostatin II, prochromacin, and chromacins I and II (Taupenot et al., 2003). Two types of storage vesicles are found in sympathetic nerve terminals: large dense-core vesicles corresponding to chromaffin granules and small dense-core vesicles containing NE, ATP, and membrane-bound D β H.

The main features of the mechanisms of synthesis, storage, and release of catecholamines at an adrenergic neuroeffector junction and their modifications by drugs are summarized in Figure 8-8 and its legend. The *adrenal medulla* has two distinct catecholamine-containing cell types: those with NE and those with primarily EPI. The latter cell population contains the enzyme PNMT. In these cells, the NE formed in the granules leaves these structures and is methylated in the cytoplasm to EPI. EPI then reenters the chromaffin granules, where it is stored until released. EPI accounts for about 80% of the catecholamines of the adrenal medulla and NE about 20%.

A major factor that controls the rate of synthesis of EPI, and hence the size of the store available for release from the adrenal medulla, is the level of glucocorticoids secreted by the adrenal cortex. The intra-adrenal portal vascular system carries the corticosteroids directly to the adrenal medullary chromaffin cells, where they induce the synthesis of PNMT (Figure 8-7). The activities of both TH and D β H also are increased in the adrenal medulla when the secretion of glucocorticoids is stimulated (Viskupic et al., 1994). Thus, any stress that persists sufficiently to evoke an enhanced secretion of corticotropin mobilizes the appropriate hormones of both the adrenal cortex (predominantly cortisol in humans) and medulla (EPI). This remarkable relationship is present only in certain mammals, including humans, in which the adrenal chromaffin cells are enveloped entirely by steroid-secreting cortical cells. PNMT is expressed in mammalian tissues such as brain, heart, and lung, leading to extra-adrenal EPI synthesis (Ziegler et al., 2002).

In addition to de novo synthesis, NE stores in the terminal portions of the adrenergic fibers are replenished by reuptake and restoration of NE following its release (see discussion in the following material).

Storage, Release, and Reuptake of Catecholamines; Termination of Action

Storage. NE, ATP, and NPY are stored frequently in the same nerve endings.

Catecholamines. Catecholamines are stored in vesicles, thereby ensuring their regulated release, protecting them from metabolism by cellular enzymes, and preventing their leakage out of the neuron. The vesicular monoamine transporter VMAT2, a vesicular membrane protein, moves

TABLE 8-4 ■ ENZYMES FOR SYNTHESIS OF CATECHOLAMINES

ENZYME	OCCURRENCE	SUBCELLULAR DISTRIBUTION	COFACTORS	SUBSTRATE SPECIFICITY	COMMENTS
TH	Widespread	Cytoplasm	tetrahydrobiopterin (BH ₄), O ₂ , Fe ²⁺	Specific for L-tyrosine	Rate-limiting step. Inhibition can deplete NE.
AAADC	Widespread	Cytoplasm	Pyridoxal PO ₄	Nonspecific	Inhibition does not alter tissue NE and EPI appreciably.
DβH	Widespread	Synaptic vesicles	Ascorbate, O ₂ (DβH contains Cu)	Nonspecific	Inhibition can ↓ NE and EPI levels.
PNMT	Largely in adrenal gland	Cytoplasm	S-adenosyl methionine (SAM) as (CH ₃ donor)	Nonspecific	Inhibition can ↓ adrenal EPI/NE; regulated by glucocorticoids.

NE and other catecholamines from the cytosol into neuronal storage vesicles (Chaudhry et al., 2008). VMAT2 is driven by a pH gradient established by an ATP-dependent proton translocase in the vesicular membrane; for each molecule of amine taken up, two H⁺ ions are extruded. VMAT2 is a member of the SLC protein superfamily and is designated SLC18A. Monoamine transporters in the SLC18 family are relatively promiscuous and transport DA, NE, EPI, and 5HT, as well as metaiodobenzylguanidine, which can be used to image chromaffin cell tumors (Schuldiner, 1994). *Reserpine* inhibits monoamine transport into storage vesicles and ultimately leads to depletion of catecholamine from sympathetic nerve endings and in the brain.

ATP. ATP is an essential component of catecholamine storage; the capacity of ATP and catecholamines to form relatively stable complexes apparently facilitates accumulation of high concentrations of neurotransmitter within the adrenergic storage granule. The granule accumulates ATP via another vesicular nucleotide carrier, VNUT, a member of the SLC superfamily. VNUT is a Na⁺/anion cotransporter, designated as SLC17A9 (see Chapter 5). The frequency and quantal size of exocytotic release mirror VNUT activity (Estévez-Herrera et al., 2016). Thus, vesicular ATP has multiple actions beyond its role as a cellular energy source and energy storage molecule: Vesicular ATP facilitates vesicular storage of high concentrations of catecholamines and, when released with the vesicular contents, acts as a transmitter at purinergic receptors (Burnstock et al., 2015).

Neuropeptide Y. NPY, a peptide with 36 amino acids, is synthesized in the endoplasmic reticulum, first as a 97-amino-acid precursor, prepro-NPY, that is processed by three steps of proteolysis and a final C-terminal amidation; the resultant NPY₁₋₃₆ is stored in large, dense-core vesicles that may also contain NE. NE and ATP are more generally stored in smaller dense-core vesicles, but NPY, ATP, and NE are often coreleased following nerve stimulation, albeit in proportions that change with the pattern and intensity of stimulation (Westfall, 2004). NPY is abundant in the brain and is a powerful orexigenic. In the peripheral nervous system, NPY occurs in sympathetic nerves and adrenal chromaffin cells; it can also be found in platelets, endothelium, and the GI tract and is inducible in the immune system (Hirsch et al., 2012).

Release. Details of excitation-secretion coupling in sympathetic neurons and adrenal medulla are becoming known and are summarized in Figures 8-3 and 8-8. The triggering event is the entry of Ca²⁺, which results in the exocytosis of the granular contents, including the catecholamine, ATP, some neuroactive peptides (e.g., NPY) or their precursors, chromogranins, and DβH. The various SNARE proteins (e.g., SNAP-25, syntaxin, and synaptobrevin) described for exocytosis of ACh are also involved here (Figures 8-3 through 8-6).

Reuptake and Termination of Action. Following its release from a sympathetic nerve varicosity, NE interacts with presynaptic and postsynaptic membrane receptors. Adrenergic fibers can sustain the output of NE during prolonged periods of stimulation without exhausting their supply, provided that synthesis and reuptake of the transmitter are unimpaired. Acute regulation of transmitter synthesis involving activation of TH and DβH has been described previously in this chapter. Recycling of transmitter is

also essential, and this is provided by reuptake, restorage, and reuse of transmitter. *The actions of catecholamines are terminated by reuptake into the nerve and postjunctional cells and to a smaller extent by diffusion out of the synaptic cleft.* Two distinct carrier-mediated transport systems are involved in reuptake (see Figure 8-8; Table 8-5):

- **NET:** This transporter, previously called *uptake 1*, moves NE across the neuronal membrane from the extracellular fluid to the cytoplasm. NET has a higher affinity for NE than for EPI (see Table 8-5). NET is a member of an SLC family of similar transporters and is designated as SLC6A2. This family of proteins transports amino acids and their derivatives into cells using cotransport of extracellular Na⁺ as a driving force for substrate translocation against chemical gradients (see Chapter 5). The SLC6A monoamine transporters include NET, DAT (SLC6A3), and SERT (SLC6A4).
- **ENT:** This transporter, previously called *uptake 2*, is an organic cation transporter, OCT3, designated as SLC22A3. OCT3 facilitates passive transmembrane movement of organic anions down their electrochemical gradients, including the movement of catecholamines into nonneuronal cells. Compared to NET, it has a lower affinity for catecholamines, favors EPI over NE and DA, has a higher maximum uptake rate for catecholamines, is not Na⁺ dependent, and has a different profile for pharmacological inhibition. The synthetic β adrenergic receptor agonist isoproterenol is not a substrate for this system. OCT3 activity is altered by MAPK and Ca²⁺-CaM signaling (Roth et al., 2012). In addition to catecholamines, OCT3 can transport a wide variety of other organic cations, including 5HT, histamine, choline, spermine, guanidine, and creatinine, as can the closely related OCT1 and OCT2. The characteristics and locations of the nonneuronal transporters are summarized in Table 8-5.

For NE released by neurons, uptake by NET is more important than uptake by ENT. Sympathetic nerves as a whole remove about 87% of released NE by NET, compared with 5% by extraneuronal uptake (ENT) and 8% by diffusion to the circulation. In contrast, clearance of circulating catecholamines, such as those released from the adrenal medulla, is primarily by nonneuronal mechanisms, with liver and kidney accounting for over 60% of the clearance of circulating catecholamines. Because VMAT2 has a much higher affinity for NE than does MAO, over 70% of recaptured NE is resequenced into storage vesicles (Eisenhofer, 2001).

The NET is also present in the adrenal medulla, the liver, and the placenta, whereas DAT is present in the stomach, pancreas, and kidney (Eisenhofer, 2001). These plasma membrane transporters appear to have greater substrate specificity than does VMAT2. NET and DAT are targets for drugs such as cocaine and tricyclic antidepressants (e.g., imipramine); selective 5HT reuptake inhibitors such as fluoxetine inhibit SERT. Inhibitors of OCT3 include normetanephrine (an O-methylated metabolite of NE; see Figure 8-9), Pharmacological probes of OCT3 include corticosterone (an inhibitor), and the substrates metformin and cimetidine; the interaction of substrates and inhibitors at renal OCT3 can lead to adverse drug effects (see Chapter 5).

Figure 8–8 A typical adrenergic neuroeffector junction. Tyrosine is transported into the varicosity and is converted to DOPA by TH and DOPA to DA by the action of AAADC. DA is taken up into the vesicles of the varicosity by a transporter, VMAT2, that can be blocked by reserpine. Cytoplasmic NE also can be taken up by this transporter. DA is converted to NE within the vesicle via the action of DβH. NE is stored in vesicles along with other cotransmitters, NPY and ATP, depending on the particular neuroeffector junction. Release of the transmitters occurs via exocytosis, a process activated by depolarization of the varicosity, which allows entry of Ca²⁺ through voltage-dependent Ca²⁺ channels and the interaction of numerous docking and fusion proteins located in the vesicle and the neuronal cell membrane, as described in Figures 8–3, 8–4, and 8–5. In this schematic representation, NE, NPY, and ATP are stored in the same vesicles. Different populations of vesicles, however, may preferentially store different proportions of the cotransmitters. Once in the synapse, NE can interact with α and β adrenergic receptors (GPCRs) to produce the responses characteristic of the particular postsynaptic cell. The α and β receptors also can be located presynaptically, via which NE can either diminish (α₂) or facilitate (β) its own release and that of the cotransmitters. The principal mechanism by which NE is cleared from the synapse is via a cocaine-sensitive neuronal uptake transporter, NET. Once transported into the cytosol, NE can be re-stored in the vesicle or metabolized by MAO. NPY produces its effects by activating NPY receptors (also GPCRs), of which there are at least five types (Y₁ through Y₅). NPY can modify its own release and that of the other transmitters via presynaptic Y₂ receptors. NPY action is terminated by the actions of peptidases. ATP produces its effects by activating P2X receptors (ligand-gated ion channels) or P2Y receptors. There are multiple subtypes of both P2X and P2Y receptors. As with other cotransmitters, ATP can act prejunctionally to modify its own release via receptors for ATP or via its metabolic breakdown to adenosine that acts on P₁ (adenosine) receptors. ATP is cleared from the synapse primarily by rNTPases and by cell-fixed ectonucleotidases.

The use of selective inhibitors of NET in animal and human studies and data from analysis of mice with targeted deletions (KO) of the NET and DAT genes reveal the impact of these uptake systems. The NET-KO and DAT-KO animals exhibit increased extracellular levels and decreased intracellular levels of NE despite increased or unaltered neurotransmitter synthesis (Xu et al., 2000; Gainetdinov and Caron, 2003). NET-KO mice also display marked behavioral alterations (Xu et al., 2000) and show characteristic hemodynamic changes (e.g., excessive tachycardia and increased blood pressure during sympathetic activation with wakefulness and activity), whereas resting mean arterial pressure and heart rate are maintained at nearly normal levels, most likely because of increased central sympathoinhibition (Keller et al., 2004). A coding mutation in humans (A457P in TM9) reduces NET activity and yields marked hemodynamic changes and orthostatic intolerance. When expressed in a heterologous cell line, the mutation resulted in a 98% loss of NET function compared with the wild-type transporter

(Shannon et al., 2000). Furthermore, when coexpressed with wild-type NET, the A457P mutant exerts a dominant negative effect on wild-type NET, likely reflecting transporter oligomerization (Hahn et al., 2003), providing an explanation for the phenotype observed in heterozygous carriers. Another human variant of NET with an F528C mutation displays increased membrane expression of NET associated with increased NE uptake compared with wild-type NET (Hahn et al., 2005); this variant may be associated with an increased incidence of depression (Haenisch et al., 2009).

Certain sympathomimetic drugs (e.g., ephedrine and tyramine) produce some of their effects indirectly by displacing NE from the nerve terminals to the extracellular fluid, where it then acts at receptor sites of the effector cells. The mechanisms by which these drugs release NE from nerve endings are complex. All such agents are substrates for NET. As a result of their uptake by NET, they make carrier available at the inner surface of the membrane for the outward transport of NE ("facilitated exchange diffusion"). In addition,

TABLE 8-5 ■ CHARACTERISTICS OF PLASMA MEMBRANE TRANSPORTERS FOR ENDOGENOUS CATECHOLAMINES

TYPE OF TRANSPORTER	SUBSTRATE SPECIFICITY	TISSUE	REGION/CELL TYPE	INHIBITORS
Neuronal				
NET	DA > NE > EPI	All sympathetically innervated tissue	Sympathetic nerves	Desipramine Cocaine Nisoxetine
		Adrenal medulla	Chromaffin cells	
		Liver	Capillary endothelial cells	
		Placenta	Syncytiotrophoblast	
DAT	DA > NE > EPI	Kidney	Endothelium	Cocaine Imazindol
		Stomach	Parietal and endothelial cells	
		Pancreas	Pancreatic duct	
Nonneuronal				
OCT1	DA > EPI >> NE	Liver	Hepatocytes	Isocyanines Corticosterone
		Intestine	Epithelial cells	
		Kidney (not human)	Distal tubule	
OCT2	DA >> NE > EPI	Kidney	Medullary proximal and distal tubules	Isocyanines Corticosterone
		Brain	Glial cells of DA-rich regions, some nonadrenergic neurons	
ENT (OCT3)	EPI >> NE > DA	Liver	Hepatocytes	Isocyanines Corticosterone O-methyl-isoproterenol
		Brain	Glial cells, others	
		Heart	Myocytes	
		Blood vessels	Endothelial cells	
		Kidney	Cortex, proximal and distal tubules	
		Placenta	Syncytiotrophoblasts (basal membrane)	
		Retina	Photoreceptors, ganglion amacrine cells	

these amines are able to mobilize NE stored in the vesicles by competing for the vesicular uptake process (VMAT2).

The actions of indirect-acting sympathomimetic amines are subject to *tachyphylaxis*. For example, repeated administration of tyramine results in rapidly decreasing effectiveness, whereas repeated administration of NE does not reduce effectiveness and, in fact, reverses the tachyphylaxis to tyramine. These phenomena have not been explained fully. One hypothesis is that the pool of neurotransmitter available for displacement by these drugs is small relative to the total amount stored in the sympathetic nerve ending. This pool is presumed to reside close to the plasma membrane, and the NE of such vesicles may be replaced by the less-potent amine following repeated administration of the latter substance. In any case, neurotransmitter release by displacement is not associated with the release of D β H and does not require extracellular Ca²⁺; thus, it is presumed not to involve exocytosis.

Prejunctional Regulation of NE Release. The release of the three sympathetic cotransmitters can be modulated by prejunctional autoreceptors and heteroreceptors. Following their release from sympathetic terminals, all three cotransmitters—NE, NPY, and ATP—can feed back on prejunctional receptors to inhibit the release of each other (Westfall, 2004; Westfall et al., 2002). The most thoroughly studied have been prejunctional α_2 adrenergic receptors. The α_{2A} and α_{2C} adrenergic receptors are the principal prejunctional receptors that inhibit sympathetic neurotransmitter release, whereas the α_{2B} adrenergic receptors also may inhibit transmitter release at selected sites. Antagonists of this receptor, in turn, can enhance the electrically evoked release of sympathetic neurotransmitter. NPY, acting on Y₂ receptors, and ATP-derived adenosine, acting on P1 receptors, also can inhibit sympathetic neurotransmitter release. Activation of numerous heteroreceptors on sympathetic nerve varicosities can inhibit the release of sympathetic neurotransmitters; these include M₂

and M₄ muscarinic, 5HT, PGE₂, histamine, enkephalin, and DA receptors. Enhancement of sympathetic neurotransmitter release can be produced by activation of β_2 adrenergic receptors, angiotensin AT₂ receptors, and nAChRs. All of these receptors can be targets for agonists and antagonists (Kubista and Boehm, 2006).

Metabolism of Catecholamines. Uptake of released catecholamine terminates the neurotransmitter's effects at the synaptic junction. Following uptake, catecholamines can be metabolized (in neuronal and nonneuronal cells) or re-stored in vesicles (in neurons). Two enzymes are important in the initial steps of metabolic transformation of catecholamines—MAO and COMT.

MAO and COMT. MAO metabolizes transmitter that is released within the nerve terminal or that is in the cytosol as a result of reuptake and has not yet reached the safety of the storage vesicle. COMT, particularly in the liver, plays a major role in the metabolism of endogenous circulating and administered catecholamines. The importance of neuronal reuptake of catecholamines is shown by observations that inhibitors of uptake (e.g., cocaine and imipramine) potentiate the effects of the neurotransmitter; inhibitors of MAO and COMT have less effect.

Both MAO and COMT are distributed widely throughout the body, including the brain; their highest concentrations are in the liver and the kidney. However, little or no COMT is found in sympathetic neurons. In the brain, there is no significant COMT in presynaptic terminals, but it is found in some postsynaptic neurons and glial cells. In the kidney, COMT is localized in proximal tubular epithelial cells, where DA is synthesized and is thought to exert local diuretic and natriuretic effects.

There are distinct differences in the localizations of the two enzymes; MAO is associated chiefly with the outer surface of mitochondria,

Figure 8–9 Metabolism of catecholamines. NE and EPI are first oxidatively deaminated to a short-lived intermediate (DOPGAL) by MAO. DOPGAL then undergoes further metabolism to more stable alcohol- or acid-deaminated metabolites. AD metabolizes DOPGAL to DOMA, while AR metabolizes DOPGAL to DOPEG. Under normal circumstances, DOMA is a minor metabolite, with DOPEG being the major metabolite produced from NE and EPI. Once DOPEG leaves the major sites of its formation (sympathetic nerves; adrenal medulla), it is converted to MOPEG by COMT. MOPEG is then converted to the unstable aldehyde (MOPGAL) by ADH and finally to VMA by AD. VMA is the major end product. Another route for the formation of VMA is conversion of NE or EPI into normetanephrine or metanephrine by COMT in either the adrenal medulla or extraneuronal sites, with subsequent metabolism to MOPGAL and thence to VMA. Catecholamines are also metabolized by *sulfotransferases*. AD, aldehyde dehydrogenase; ADH, alcohol dehydrogenase; AR, aldehyde reductase; COMT, catechol-*O*-methyltransferase; DOMA, 3,4-dihydroxymandelic acid; DOPEG, 3,4-dihydroxyphenyl glycol; DOPGAL, dihydroxyphenylglycolaldehyde; MAO, monoamine oxidase; MOPEG, 3-methyl,4-hydroxyphenylglycol; MOPGAL, monohydroxyphenylglycol aldehyde; VMA, vanillyl mandelic acid.

including those within the terminals of sympathetic or central noradrenergic neuronal fibers, whereas COMT is largely cytosolic, except in the chromaffin cells of the adrenal medulla, where COMT is membrane bound. These factors are of importance both in determining the primary metabolic pathways followed by catecholamines in various circumstances and in explaining the effects of certain drugs. The physiological substrates for COMT include L-dopa, all three endogenous catecholamines (DA, NE, and EPI), their hydroxylated metabolites, catecholestrogens, ascorbic acid, and dihydroxyindolic intermediates of melanin (Männistö and Kaakkola, 1999).

Two different isozymes of MAO (MAO-A and MAO-B) are found in widely varying proportions in different cells in the CNS and in peripheral tissues. In the periphery, MAO-A is located in the syncytiotrophoblast layer of term placenta and liver, whereas MAO-B is located in platelets, lymphocytes, and liver. In the brain, MAO-A is located in all regions containing catecholamines, with the highest abundance in the locus ceruleus. MAO-B, on the other hand, is found primarily in regions that are known to synthesize and store 5HT. MAO-B is most prominent not only in the nucleus raphe dorsalis but also in the posterior hypothalamus and in glial

cells in regions known to contain nerve terminals. MAO-B is also present in osteocytes around blood vessels (Abell and Kwan, 2001).

Many MAO inhibitors are not selective for MAO-A or MAO-B, and these nonselective agents (e.g., phenelzine, tranylcypromine, and isocarboxazid) enhance the bioavailability of tyramine contained in many foods; tyramine-induced NE release from sympathetic neurons may lead to markedly increased blood pressure (hypertensive crisis). Drugs with selectivity for MAO-B (e.g., selegiline, rasagiline, pargyline) or reversible inhibitors of MAO-A (e.g., moclobemide) are less likely to cause this potential interaction (Volz and Gleiter, 1998; Wouters, 1998).

Inhibitors of MAO activity can cause an increase in the concentration of NE, DA, and 5HT in the brain and other tissues accompanied by a variety of pharmacological effects. No striking pharmacological action in the periphery can be attributed to the inhibition of COMT. However, the COMT inhibitors entacapone and tocaptopone are efficacious in the therapy of Parkinson disease (Chong and Mersfelder, 2000, and Chapter 18).

The Metabolic Pathway (Figure 8–9). There is ongoing passive leakage of catecholamines from vesicular storage granules of sympathetic neurons

and adrenal medullary chromaffin cells. As a consequence, most metabolism of catecholamines takes place in the same cells where the amines are synthesized and stored. VMAT2 effectively sequesters about 90% of the amines leaking into the cytoplasm back into storage vesicles; about 10% escapes sequestration and is metabolized (Eisenhofer et al., 2004).

Sympathetic nerves contain MAO but not COMT, and this MAO catalyzes only the first step of a two-step reaction. MAO converts NE or EPI into a short-lived intermediate, DOPGAL, which undergoes further metabolism in a second step catalyzed by another group of enzymes forming more stable alcohol- or acid-deaminated metabolites. Aldehyde dehydrogenase metabolizes DOPGAL to DOMA, while aldehyde reductase metabolizes DOPGAL to DOPEG. In addition to aldehyde reductase, a related enzyme, aldose reductase, can reduce a catecholamine to its corresponding alcohol. This latter enzyme is present in sympathetic neurons and adrenal chromaffin cells. Under normal circumstances, DOMA is an insignificant metabolite of NE and EPI, with DOPEG being the main metabolite produced by deamination in sympathetic neurons and adrenal medullary chromaffin cells.

Once it leaves the sites of formation (sympathetic neurons, adrenal medulla), DOPEG is converted to MOPEG by COMT. Thus, most MOPEG comes from extraneuronal O-methylation of DOPEG produced in and diffusing rapidly from sympathetic neurons into the extracellular fluid. MOPEG is then converted to VMA by the sequential actions of alcohol and aldehyde dehydrogenases. MOPEG is first converted to the unstable aldehyde metabolite MOPGAL and then to VMA, with VMA being the major end product of NE and EPI metabolism. Another route for the formation of VMA is conversion by COMT of NE and EPI into normetanephrine and metanephrine, respectively, followed by deamination to MOPGAL and thence to VMA. This is now thought to be only a minor pathway, as indicated by the size of the arrows on Figure 8–9.

In contrast to sympathetic neurons, adrenal medullary chromaffin cells contain both MAO and COMT, the COMT mainly as the membrane-bound form. This isoform of COMT has a higher affinity for catecholamines than does the soluble form found in most other tissues (e.g., liver and kidney). In adrenal medullary chromaffin cells, leakage of NE and EPI from storage vesicles leads to substantial intracellular production of the O-methylated metabolites normetanephrine and metanephrine. In humans, over 90% of circulating metanephrine and 25%–40% of circulating normetanephrine are derived from catecholamines metabolized within adrenal chromaffin cells.

The sequence of cellular uptake and metabolism of catecholamines in extraneuronal tissues contributes only modestly (~25%) to the total metabolism of endogenously produced NE in sympathetic neurons or the adrenal medulla. However, extraneuronal metabolism is an important mechanism for the clearance of circulating and exogenously administered catecholamines.

Classification of Adrenergic Receptors

Adrenergic receptors are broadly classified as either α or β , with subtypes within each group (Table 8–6). The original subclassification was based on the rank order of agonist potency:

- EPI \geq NE \gg isoproterenol for α adrenergic receptors.
- Isoproterenol $>$ EPI \geq NE for β adrenergic receptors.

Elucidation of the characteristics of these receptors and the biochemical and physiological pathways they regulate has increased our understanding of the seemingly contradictory and variable effects of catecholamines on various organ systems. Although structurally related (discussed further in the chapter), different receptors regulate distinct physiological processes by controlling the synthesis or mobilization of a variety of second messengers.

Raymond Ahlquist and the Functional Definition of α and β Receptors. Based on studies of the capacities of EPI, NE, and related agonists to regulate various physiological processes, Ahlquist (1948) proposed the existence of more than one adrenergic receptor. It was known that adrenergic agents could cause either contraction or relaxation of smooth

muscle depending on the site, the dose, and the agent chosen. For example, NE was known to have potent excitatory effects on smooth muscle and correspondingly low activity as an inhibitor; isoproterenol displayed the opposite pattern of activity. EPI could both excite and inhibit smooth muscle. Thus, Ahlquist proposed the designations α and β for receptors on smooth muscle where catecholamines produce excitatory and inhibitory responses, respectively (an exception was the gut, which generally is relaxed by activation of either α or β receptors). He developed the rank orders of potency that define α and β receptor-mediated responses, as noted above. This initial classification was corroborated by the finding that certain antagonists produced selective blockade of the effects of adrenergic nerve impulses and sympathomimetic agents at α receptors (e.g., phenoxybenzamine), whereas others produced selective β receptor blockade (e.g., propranolol).

α and β Receptor Subtypes. Subsequent to Ahlquist's functional description of α and β receptors, adrenergic pharmacologists used increasingly sophisticated probes, tools, and methods to elucidate subtypes of α and β receptors. The β receptors were subclassified as β_1 (e.g., those in the myocardium) and β_2 (smooth muscle and most other sites), reflecting the finding that EPI and NE essentially are equipotent at β_1 sites, whereas EPI is 10–50 times more potent than NE at β_2 sites. Antagonists that discriminate between β_1 and β_2 receptors were subsequently developed (Chapter 12). Cloning confirmed that these β subtypes are products of different genes, and a human gene that encodes a third β receptor (designated β_3) was isolated (Emorine et al., 1989). Because the β_3 receptor is about 10-fold more sensitive to NE than to EPI and is relatively resistant to blockade by antagonists such as propranolol, the β_3 receptor may mediate responses to catecholamine at sites with “atypical” pharmacological characteristics (e.g., adipose tissue, which expresses all three β receptor subtypes). Animals treated with β_3 receptor agonists exhibit a vigorous thermogenic response as well as lipolysis (Robidoux et al., 2004). Polymorphisms in the β_3 receptor gene may be related to risk of obesity or type 2 diabetes in some populations (Arner and Hoffstedt, 1999), and Weyer and colleagues (1999) suggested that β_3 receptor-selective agonists may be beneficial in treating these disorders. The existence of a fourth β adrenergic receptor, β_4 was proposed but no such receptor has been cloned; rather, the “ β_4 receptor” seems to be an affinity state of the β_1 adrenergic receptor rather than a distinct new protein (Gherbi et al., 2015; Hieble, 2007).

There is also heterogeneity among α adrenergic receptors. The initial distinction was based on functional and anatomic considerations: NE and other α adrenergic agonists profoundly inhibit the release of NE from neurons (Westfall, 1977) (Figure 8–8); conversely, certain α receptor antagonists markedly increase NE release when sympathetic nerves are stimulated. This feedback-inhibitory effect of NE on its release from nerve terminals is mediated by α receptors that are pharmacologically distinct from the classical postsynaptic α receptors. Accordingly, these presynaptic α adrenergic receptors were designated α_2 , whereas the postsynaptic “excitatory” α receptors were designated α_1 (Langer, 1997). Compounds such as clonidine are more potent agonists at α_2 than at α_1 receptors; by contrast, phenylephrine and methoxamine selectively activate postsynaptic α_1 receptors.

Although there is little evidence to suggest that α_1 adrenergic receptors function presynaptically in the autonomic nervous system, α_2 receptors are present at postjunctional or nonjunctional sites in several tissues. For example, stimulation of postjunctional α_2 receptors in the brain is associated with reduced sympathetic outflow from the CNS and appears to be responsible for a significant component of the antihypertensive effect of drugs such as clonidine (Chapter 12). Thus, the anatomic concept of prejunctional α_2 and postjunctional α_1 adrenergic receptors has been abandoned in favor of a pharmacological and functional classification (Tables 8–6 and 8–7).

Cloning revealed additional heterogeneity of both α_1 and α_2 adrenergic receptors (Bylund, 1992). There are three pharmacologically defined α_1 receptors (α_{1A} , α_{1B} , and α_{1D}) with distinct sequences and tissue distributions and three cloned subtypes of α_2 receptors (α_{2A} , α_{2B} , and α_{2C}) (Table 8–6). A fourth type of α_1 receptor, α_{1L} , has been defined on the basis

^aAt least three subtypes each of α_1 and α_2 adrenergic receptors are known, but distinctions in their mechanisms of action have not been clearly defined.

^bIn some species (e.g., rat), metabolic responses in the liver are mediated by α_1 adrenergic receptors, whereas in others (e.g., dog) β_2 adrenergic receptors are predominantly involved. Both types of receptors appear to contribute to responses in human beings.

^c β Receptor coupling to cell signaling can be more complex. In addition to coupling to G_s to stimulate AC, β_2 receptors can activate signaling via a GRK/ β -arrestin pathway. β_2 and β_3 receptors can couple to both G_s and G_i in a manner that may reflect agonist stereochemistry. See also Chapter 12.

^dMetabolic responses in tissues with atypical pharmacological characteristics (e.g., adipocytes) may be mediated by β_3 receptors. Most β receptor antagonists (including propranolol) do not block these responses.

of a low affinity for the selective antagonists prazosin and 5-methyl urapidil but a high affinity for tamsulosin and silodosin. This phenotype could be of physiological significance; the α_{1L} profile has been identified in myriad tissues across a number of species, where it appears to regulate smooth muscle contractility in the vasculature and lower urinary tract. Despite intense efforts, the α_{1L} adrenergic receptor has not been cloned; currently, it is viewed as a second phenotype originating from the α_{1A} receptor gene (Hieble, 2007; Yoshiki et al., 2013). Distinct pharmacological phenotypes of the α_{1B} receptor have also been described (Yoshiki et al., 2014).

Owing to the lack of sufficiently subtype-selective ligands, the precise physiological function and therapeutic potential of the subtypes of adrenergic receptors have not been elucidated fully. Genetic approaches using transgenic and receptor knockout experiments in mice (discussed further in the chapter) have advanced our understanding. These mouse models have been used to identify and localize particular receptor subtypes and to describe the pathophysiological relevance of individual adrenergic receptor subtypes (Philipp and Hein, 2004; Tanoue et al., 2002a, 2002b; Xiao et al., 2006).

Molecular Basis of Adrenergic Receptor Function

Structural Features. All adrenergic receptors are GPCRs that link to heterotrimeric G proteins. Structurally, there are similarities in the regions for ligand binding and modulation by intracellular protein kinases (Figure 8–10). The coding region of each of the three β adrenergic receptor genes and the three α_2 adrenergic receptor genes is contained in a single exon, whereas each of the three α_1 adrenergic receptor genes has a single large intron separating regions that encode the body of the receptor from those that encode the seventh transmembrane domain and carboxy terminus (Dorn, 2010). Each major receptor type shows preference for a particular class of G proteins, that is, α_1 to G_q , α_2 to G_s , and β to G_s (see Table 8–6). The responses that follow receptor activation result from G protein-mediated effects on the generation of second messengers and on the activity of ion channels (see Chapter 3). The signaling pathways overlap broadly with those discussed for muscarinic ACh receptors.

α Adrenergic Receptors. The α_1 receptors (α_{1A} , α_{1B} , and α_{1D}) and the α_2 receptors (α_{2A} , α_{2B} , and α_{2C}) are heptahelical proteins that couple differentially to a variety of G proteins to regulate smooth muscle contraction, secretory pathways, and cell growth (see Table 8–6). Within the membrane-spanning domains, the three α_1 adrenergic receptors share about 75% identity in amino acid residues, as do the three α_2 receptors, but the α_1 and α_2 subtypes are no more similar than are the α and β subtypes (~30%–40%).

α_1 Adrenergic Receptors. Stimulation of α_1 receptors activates the G_q -PLC β -IP $_3$ /DAG-Ca $^{2+}$ pathway and results in the activation of PKC and other Ca $^{2+}$ and CaM-sensitive pathways, such as CaM kinases, with sequelae depending on cell differentiation (e.g., contraction of vascular smooth muscle, stimulation of growth in smooth muscles and hypertrophy in cardiac myocytes, and activation of endothelial NOS in vascular

endothelium) (see Chapter 3). PKC phosphorylates many substrates, including membrane proteins such as channels, pumps, and ion exchange proteins (e.g., Ca $^{2+}$ -transport ATPase). α_1 Receptor stimulation of PLA $_2$ leads to the release of free arachidonate, which is then metabolized by cyclooxygenase (yielding prostaglandins) and lipoxygenase (yielding leukotrienes) (see Chapter 37); PLD hydrolyzes phosphatidylcholine to yield phosphatidic acid, which can yield diacylglycerol, a cofactor for PKC activation. PLD is an effector for ADP-ribosylating factor, suggesting that PLD may play a role in membrane trafficking. In most smooth muscles, the increased concentration of intracellular Ca $^{2+}$ causes contraction (see Figure 3–17). In contrast, the increased concentration of intracellular Ca $^{2+}$ following α_1 stimulation of GI smooth muscle causes hyperpolarization and relaxation by activation of Ca $^{2+}$ -dependent K $^{+}$ channels. Stimulation of α_1 receptors can activate p38/p42/p44, PI3K, JNK, and others to affect cell growth and proliferation, albeit in receptor subtype-specific and tissue-specific manners.

The α_{1A} receptor is the predominant receptor causing vasoconstriction in many vascular beds, including the following arteries: mammary, mesenteric, splenic, hepatic, omental, renal, pulmonary, and epicardial coronary. It is also the predominant subtype in the vena cava and the saphenous and pulmonary veins (Michelotti et al., 2000). Together with the α_{1B} receptor subtype, it promotes cardiac growth and structure. The α_{1B} receptor subtype is the most abundant subtype in the heart, whereas the α_{1D} receptor subtype is the predominant receptor causing vasoconstriction in the aorta. There is evidence to support the idea that α_{1B} receptors mediate behaviors such as reaction to novelty and exploration and are involved in behavioral sensitizations and in the vulnerability to addiction (see Chapter 24).

In addition to their traditional localization in the plasma membrane, α_1 receptors have nuclear localization signals (as do β receptors and receptors for endothelin and angiotensin) and have been found on the nuclear membrane of adult mouse cardiac myocytes, where they activate intranuclear signaling and appear to play a cardioprotective role (Wu and O'Connell, 2015).

α_2 Adrenergic Receptors. The α_2 receptors couple to a variety of effectors (Tan and Limbird, 2005). Inhibition of adenylyl cyclase activity was the first effect observed, but in some systems the enzyme actually is stimulated by α_2 adrenergic receptors, either by G_i $\beta\gamma$ subunits or by weak direct stimulation of G_s . The physiological significance of these last processes is not currently clear. The α_2 receptors activate G protein-gated K $^{+}$ channels, resulting in membrane hyperpolarization. In some cases (e.g., cholinergic neurons in the myenteric plexus), this may be Ca $^{2+}$ dependent, whereas in others (e.g., muscarinic ACh receptors in atrial myocytes) it results from direct interaction of $\beta\gamma$ subunits with K $^{+}$ channels. The α_2 receptors also can inhibit voltage-gated Ca $^{2+}$ channels; this is mediated by G_o . Other second-messenger systems linked to α_2 receptor activation include acceleration of Na $^{+}$ /H $^{+}$ exchange, stimulation of PLC β_2 activity and arachidonic

Figure 8–10 Structural features of adrenergic receptor subtypes. All of the adrenergic receptors are hepta-spanning GPCRs. A representative of each type is shown; each type has three subtypes: α_{1A} , α_{1B} , and α_{1D} ; α_{2A} , α_{2B} , and α_{2C} ; and β_1 , β_2 , and β_3 . The principle effector systems affected by α_1 , α_2 and β receptors are depicted in Table 8–6. ψ indicates a site for N-glycosylation.

acid mobilization, increased phosphoinositide hydrolysis, and increased intracellular availability of Ca^{2+} . The last is involved in the smooth muscle-contracting effect of α_2 adrenergic receptor agonists. In addition, the α_2 receptors activate MAPKs via mechanisms dependent on both the α and $\beta\gamma$ components of G_i , with involvement of protein tyrosine kinases and small GTPases (Goldsmith and Dhanasekaran, 2007). These pathways are reminiscent of pathways activated by tyrosine kinase activities of growth factor receptors. The α_{2A} and α_{2C} receptors play a major role in inhibiting NE release from sympathetic nerve endings and suppressing sympathetic outflow from the brain, leading to hypotension (Kable et al., 2000).

Thus, depending on subtype, the major biological effects of α_2 adrenergic receptors can be on platelet aggregation, regulation of sympathetic outflow from the CNS, reuptake of NE from within peripheral sympathetic nerve synapses, insulin secretion and lipolysis, or, to a limited extent, vasoconstriction (Gavras and Gavras, 2001). Similar studies with knockout mice have been carried out as was done with α_1 adrenergic receptors.

In the CNS, α_{2A} receptors, which appear to be the dominant adrenergic receptor, probably mediate the antinociceptive effects, sedation, hypothermia, hypotension, and behavioral actions of α_2 agonists (Lakhlani et al., 1997). The α_{2C} receptor occurs in the ventral and dorsal striatum and hippocampus. It appears to modulate DA neurotransmission and various behavioral responses. The α_{2B} receptor is the main receptor mediating α_2 -induced vasoconstriction, whereas the α_{2C} receptor is the predominant receptor inhibiting the release of catecholamines from the adrenal medulla and modulating DA neurotransmission in the brain.

β Adrenergic Receptors

Subtypes. The three β receptor subtypes share about 60% amino acid sequence identity within the putative membrane-spanning domains where the ligand-binding pockets for EPI and NE are found. Based on results of site-directed mutagenesis, individual amino acids in the β_2 receptor that interact with each of the functional groups on the catecholamine agonist molecule have been identified. Figure 8–10 depicts the general hepta-spanning structure of adrenergic receptors and notes some differences in the sizes of the third and fourth intracellular loops.

The β receptors regulate numerous functional responses, including heart rate and contractility, smooth muscle relaxation, and myriad metabolic events in numerous tissues, including skeletal muscle, liver, and adipose tissue (Lynch and Ryall, 2008) (Table 8–1).

β Receptor Signaling. All three of the β receptor subtypes (β_1 , β_2 , and β_3) couple to G_s and activate adenylyl cyclase (Table 8–7). Stimulation of β adrenergic receptors leads to the accumulation of cAMP, activation of the PKA, and altered function of numerous cellular proteins as a result of their phosphorylation (Chapter 3). In addition, G_s subunits can enhance directly the activation of voltage-sensitive Ca^{2+} channels in the plasma membrane of skeletal and cardiac muscle cells.

The β_1 , β_2 , and β_3 receptors can differ in their intracellular signaling pathways and subcellular location (Brodde et al., 2006; Violin and Lefkowitz, 2007; Woo et al., 2009). While the positive chronotropic effects of β_1 receptor activation are clearly mediated by G_s in myocytes, dual coupling of β_2 receptors to G_s and G_i occurs in myocytes from newborn mice. Stimulation of β_2 receptors causes a transient increase in heart rate that is followed by a prolonged decrease. Following pretreatment with pertussis toxin, which prevents activation of G_i , the negative chronotropic effect of β_2 activation is abolished. These specific signaling properties of β receptor subtypes likely result from subtype-selective association with intracellular scaffolding and signaling proteins (Baillie and Houslay, 2005). The β_2 receptors normally are confined to caveolae in cardiac myocyte membranes. The activation of PKA by cAMP and the importance of compartmentation of components of the cAMP pathway are discussed in Chapter 3.

Refractoriness to Catecholamines. Exposure of catecholamine-sensitive cells and tissues to adrenergic agonists causes a progressive diminution in their capacity to respond to such agents. This phenomenon, variously termed *refractoriness*, *desensitization*, or *tachyphylaxis*, can limit the therapeutic efficacy and duration of action of catecholamines and other agents (Chapter 3). An understanding of the mechanisms involved in regulation of

GPCR desensitization and the roles of GRKs and β -arrestins has developed over the last two decades due to the efforts of Lefkowitz and colleagues (Violin and Lefkowitz, 2007) and Houslay and colleagues (Baillie and Houslay, 2005), among others. For a perspective on refractoriness and on the roles of GRKs and β -arrestins in biased agonism, see the discussion that follows.

Desensitization has functional correlates in human health. Long-term exposure to catecholamines can cause cardiac dysfunction and contribute to the course of deterioration in heart failure. Data support the idea that the β_1 receptor is the primary mediator of catecholamine cardiotoxicity (Communal et al., 1999). Studies in genetically manipulated mice indicate that β_1 receptor signaling has greater potential than β_2 receptor signaling to contribute to heart failure.

Desensitization, Downregulation, Sustained Signaling. Catecholamines promote β receptor feedback regulation, that is, desensitization, receptor downregulation, and internalization into endosomes. The β receptors differ in the extent to which they undergo such regulation, with the β_2 receptor being the most susceptible, as described in Chapter 3. Post-stimulatory interactions of the agonist-liganded β_2 receptor with a GRK produces a phosphorylated receptor that readily interacts with β -arrestin, which blocks receptor access to the G protein and directs the receptor toward an endocytotic pathway, thereby reducing the number of receptors available at the cell surface. As a scaffolding protein, β -arrestin can also anchor proteins such as phosphodiesterase 4, which can modulate cAMP accumulation. The β receptor- β -arrestin complexes localize to coated pits and are subsequently internalized reversibly into endosomes (where the receptors may be dephosphorylated; such receptors can reenter the plasma membrane to aid resensitization), some complexes reaching lysosomes, where they are degraded (see Chapter 3). β -Arrestin also serves as an organizing center for the formation of a complex of a phospho-GPCR, a G protein, and β -arrestin, and this complex may provide sustained intracellular signaling from the internalized GPCR (Thomsen et al., 2016).

Biased Agonism and Selective Responsiveness. The original idea that a β adrenergic agonist activates just the G_s -AC-cAMP-PKA pathway is incomplete. Recent data demonstrate differences in downstream signals and events activated by the three β receptors and differences when various ligands activate a single receptor subtype. This concept, termed *biased agonism*, follows from four findings:

- signaling resulting from GPCR activation can be complex and involve a host of pathways
- ligand-activated GPCRs can adopt a multiplicity of conformations
- GRKs and β -arrestins are signal transducers, independently of G proteins
- distinct GRKs are recruited to and phosphorylate receptors based on specific ligand-induced receptor conformations, leading to specific signaling mediated by β -arrestin

A biased agonist stabilizes one or a subset of possible GPCR conformations and thereby activates a subset of all possible responses; these responses may involve signaling mechanisms mediated by β -arrestins through its myriad scaffolding partners. In work leading to the Nobel Prize in 2012, Lefkowitz and colleagues described this “pluridimensionality of β -arrestin-dependent signaling” at GPCRs (Reiter et al., 2012). This idea raises the possibility that one may design biased agonists that have unusually precise specificity. Biased agonism is discussed at greater length in Chapter 20 with regard to mu opioid agonists.

Adrenergic Receptor Polymorphism

Numerous polymorphisms and splice variants of adrenergic receptors continue to be identified. Such polymorphisms in adrenergic receptors could result in altered physiological responses to activation of the sympathetic nervous system, contribute to disease states, and alter the responses to adrenergic agonists or antagonists (Brodde, 2008). Knowledge of the functional consequences of specific polymorphisms could theoretically result in the individualization of drug therapy based on a patient's genetic

makeup and could explain marked interindividual variability within the human population.

α_1 Adrenergic Receptor Polymorphisms. The α_1 adrenergic receptor is abundant in vascular smooth muscle and is implicated in regulating arterial resistance and blood pressure (Rokosh and Simpson, 2002). The α_1 adrenergic receptor polymorphism most often studied in human hypertension is α_{1A} Arg347Cys; the accumulated data so far suggest only a marginal effect of this polymorphism in cardiovascular responses to sympathetic stimulation or human hypertension. There are no functional phenotypes or cardiovascular disease associations reported for the α_{1B} and α_{1D} adrenergic receptors.

α_{2A} Adrenergic Receptor Polymorphisms. As with the α_{1A} adrenergic receptor, there is insufficient evidence supporting a major effect of α_2 receptor polymorphisms in hypertension. Likewise, although there are interesting and provocative studies suggesting an association between α_{2A} , α_{2BA} , and α_{2C} polymorphisms and coronary heart disease, heart failure, and sudden death, these linkages are not yet definitive. In contrast, a convincing role for α_{2A} adrenergic receptor polymorphisms in human type 2 diabetes has been elucidated. Moreover, in mice, deletion of the α_{2A} adrenergic receptor results in enhanced insulin secretion (Fagerholm et al., 2004) and β -cell-specific overexpression of α_{2A} R mimics diabetes (Devedjian et al., 2000).

β_1 Adrenergic Receptor Polymorphisms. Evidence does support the notion that increased cardiomyocyte β_1 receptor signaling by any means, including chronic agonist stimulation (Mobine et al., 2009), increased receptor expression (Dorn et al., 1999; Liggett et al., 2000), or enhanced receptor signaling (Mialet et al., 2003), can ultimately result in cardiac toxicity and contribute to heart failure. On the other hand, β_1 adrenergic receptor polymorphisms do not seem to be major risk factors in human hypertension.

Biochemical, functional, and structural studies in cultured cell expression systems and genetic mouse models indicate that the Gly389Arg β_1 adrenergic receptor exhibits a gain-of-signaling function that can initially improve cardiac contractility but ultimately predisposes to cardiomyopathic decompensation. This abnormally active Arg389 receptor is more sensitive to pharmacological blockade and exhibits distinctive pharmacological properties of different β blockers. This polymorphism may affect heart failure risk or progression, but the β blockers currently in use are sufficient to overcome the subtle differences that polymorphic receptor function may have on heart failure survival (Dorn, 2010).

β_2 Adrenergic Receptor Polymorphisms. Data supporting an interaction between β_2 adrenergic receptor polymorphisms and hypertension are inconclusive and suggest that effects of β_2 adrenergic receptor polymorphisms on blood pressure are modest. Similarly, there is no consensus about β_2 adrenergic receptor polymorphisms and heart disease (Dorn, 2010).

β_3 Adrenergic Receptor Polymorphisms. Polymorphisms of the β_3 adrenergic receptor appear to be associated with diabetes phenotypes, but there have been few clinical cardiac studies (Dorn, 2010).

Localization of Adrenergic Receptors

Presynaptic α_2 and β_2 receptors regulate neurotransmitter release from sympathetic nerve endings. Presynaptic α_2 receptors also may mediate inhibition of release of neurotransmitters other than NE in the central and peripheral nervous systems. Both α_2 and β_2 receptors are located at postsynaptic sites (Table 8–6), such as on many types of neurons in the brain. In peripheral tissues, postsynaptic α_2 receptors are found in vascular and other smooth muscle cells (where they mediate contraction), adipocytes, and various secretory epithelial cells (intestinal, renal, endocrine). Postsynaptic β_2 receptors can be found in the myocardium (where they mediate contraction) as well as on vascular and other smooth muscle cells (where they mediate relaxation), and skeletal muscle (where they can mediate hypertrophy). Indeed, most normal human cell types express β_2 receptors. Both α_2 and β_2 receptors may be situated at sites that are relatively remote from nerve terminals that release NE. Such extrajunctional

receptors typically are found on vascular smooth muscle cells and blood elements (platelets and leukocytes) and may be activated preferentially by circulating catecholamines, particularly EPI.

In contrast, α_1 and β_1 receptors appear to be located mainly in the immediate vicinity of sympathetic adrenergic nerve terminals in peripheral target organs, strategically placed to be activated during stimulation of these nerves. These receptors also are distributed widely in the mammalian brain (Table 8–6).

The cellular distributions of the three α_1 and three α_2 receptor subtypes still are incompletely understood. Studies using *in situ* hybridization with receptor mRNA and receptor subtype-specific antibodies indicate that α_{2A} receptors in the brain may be both pre- and postsynaptic, suggesting that this receptor subtype may also function as a presynaptic autoreceptor in central noradrenergic neurons (Aantaa et al., 1995; Lakhani et al., 1997). Using similar approaches, α_{1A} mRNA was found to be the dominant subtype message expressed in prostatic smooth muscle (Walden et al., 1997).

Pharmacological Considerations

Each step involved in neurotransmission is a potential point of pharmacological intervention. The diagrams of the cholinergic and adrenergic terminals and their postjunctional sites (Figure 8–6 and 8–8) show these points of intervention. Drugs that affect processes involved in the steps of transmission at both cholinergic and adrenergic junctions are summarized in Table 8–7, which lists representative agents that act through the mechanisms below.

Interference With the Synthesis or Release of the Transmitter

Cholinergic

Hemicholinium, a synthetic compound, blocks the transport system by which choline accumulates in the terminals of cholinergic fibers, thus limiting the synthesis of ACh. Vesamicol blocks the transport of ACh into its storage vesicles, thereby preventing repletion of ACh stores following transmitter release and thus reducing ACh available for subsequent release. The site on the presynaptic nerve terminal for block of ACh release by botulinum toxin was discussed previously; death usually results from respiratory paralysis unless patients with respiratory failure receive artificial ventilation. Injected locally, botulinum toxin type A is used in the treatment of certain ophthalmic conditions associated with spasms of ocular muscles (e.g., strabismus and blepharospasm) (Chapter 69) and for a wide variety of unlabeled uses, ranging from treatment of muscle dystonias and palsy (Chapter 11) to cosmetic erasure of facial lines and wrinkles (a modern medical testament to the vanity of human wishes; Chapter 70).

Adrenergic

α -Methyltyrosine (metyrosine) blocks the synthesis of NE by inhibiting TH, the enzyme that catalyzes the rate-limiting step in catecholamine synthesis. This drug occasionally may be useful in treating selected patients with pheochromocytoma. On the other hand, methyl dopa, an inhibitor of aromatic L-amino acid decarboxylase, is—like dopa itself—successively decarboxylated and hydroxylated in its side chain to form the putative “false neurotransmitter” α -methylnorepinephrine. The use of methyl dopa in the treatment of hypertension is discussed in Chapter 28. Bretylium, guanadrel, and guanethidine act by preventing the release of NE by the nerve impulse. However, such agents can transiently stimulate the release of NE because of their capacity to displace the amine from storage sites.

Promotion of Release of the Transmitter

Cholinergic

The ability of pharmacological agents to promote the release of ACh is limited. The latrotoxins from black widow spider venom and stonefish are known to promote neuroexocytosis by binding to receptors on the neuronal membrane.

TABLE 8-7 ■ REPRESENTATIVE AGENTS ACTING AT PERIPHERAL CHOLINERGIC AND ADRENERGIC NEUROEFFECTOR JUNCTIONS

MECHANISM OF ACTION	SYSTEM	AGENTS	EFFECT
1. Interference with synthesis of transmitter	Cholinergic	Choline acetyl transferase inhibitors	Minimal depletion of ACh
	Adrenergic	α -Methyltyrosine (inhibition of tyrosine hydroxylase)	Depletion of NE
2. Metabolic transformation by same pathway as precursor of transmitter	Adrenergic	Methyldopa	Displacement of NE by α -methyl-NE, which is an α_2 agonist, similar to clonidine, that reduces sympathetic outflow from CNS
3. Blockade of transport system at nerve terminal membrane	Cholinergic	Hemicholinium	Block of choline uptake with consequent depletion of ACh
	Adrenergic	Cocaine, imipramine	Accumulation of NE at receptors
4. Blockade of transport system of storage vesicle	Cholinergic	Vesamicol	Block of ACh storage
	Adrenergic	Reserpine	Destruction of NE by mitochondrial MAO and depletion from adrenergic terminals
5. Promotion of exocytosis or displacement of transmitter from storage sites	Cholinergic	Latrotoxins	Cholinomimetic followed by anticholinergic
	Adrenergic	Amphetamine, tyramine	Sympathomimetic
6. Prevention of release of transmitter	Cholinergic	Botulinum toxin (BTX, endopeptidase, acts on synaptobrevin)	Anticholinergic (prevents skeletal muscle contraction)
	Adrenergic	Bretylum, guanadrel	Antiadrenergic
7. Mimicry of transmitter at postjunctional sites	Cholinergic		
	Muscarinic ^a	Methacholine, bethanachol	Cholinomimetic
	Nicotinic ^b	Nicotine, epibatidine, cytisine	Cholinomimetic
	Adrenergic		
	α_1	Phenylephrine	Selective α_1 agonist
	α_2	Clonidine	Sympathomimetic (periphery); reduced sympathetic outflow (CNS)
	α_1, α_2	Oxymetazoline	Nonselective α adrenomimetic
	β_1	Dobutamine	Selective cardiac stimulation (also activates α_1 receptors)
8. Blockade of postsynaptic receptor	β_2	Terbutaline, albuterol, metaproterenol	Selective β_2 receptor agonist (selective inhibition of smooth muscle contraction)
	β_1, β_2	Isoproterenol	Nonselective β agonist
	Cholinergic		
	Muscarinic ^a	Atropine	Muscarinic blockade
	Nicotinic (N_m) ^b	<i>d</i> -Tubocurarine, atracurium	Neuromuscular blockade
	Nicotinic (N_n) ^b	Trimethaphan	Ganglionic blockade
	Adrenergic		
	α_1, α_2	Phenoxybenzamine	Nonselective α receptor blockade (irreversible)
	α_1, α_2	Phentolamine	Nonselective α receptor blockade (reversible)
	α_1	Prazosin, terazosin, doxazosin	Selective α_1 receptor blockade (reversible)
	α_2	Yohimbine	Selective α_2 receptor blockade
	β_1, β_2	Propranolol	Nonselective β receptor blockade
	β_1	Metoprolol, atenolol	Selective β_1 receptor blockade (cardiomyocytes; renal j-g cells)
	β_2	—	Selective β_2 receptor blockade (smooth muscle)

(Continued)

TABLE 8-7 ■ REPRESENTATIVE AGENTS ACTING AT PERIPHERAL CHOLINERGIC AND ADRENERGIC NEUROEFFECTOR JUNCTIONS (CONTINUED)

MECHANISM OF ACTION	SYSTEM	AGENTS	EFFECT
9. Inhibition of enzymatic breakdown of transmitter	Cholinergic	AChE inhibitors edrophonium, neostigmine, pyridostigmine	Cholinomimetic (muscarinic sites) Depolarization blockade (nicotinic sites)
	Adrenergic	Nonselective MAO inhibitors: pargyline, nialamide	Little direct effect on NE or sympathetic response; potentiation of tyramine
		Selective MAO-B inhibitor: selegiline	Adjunct in Parkinson disease
		Peripheral COMT inhibitor: Entacapone	Adjunct in Parkinson disease
		COMT inhibitor: Tolcapone	

The j-g cells are renin-secreting cells in the juxtaglomerular complex of the kidney.

^aAt least five subtypes of muscarinic receptors exist (see Table 8-3). Agonists show little subtype selectivity; several antagonists show partial subtype selectivity (see Chapter 9).

^bTwo subtypes of muscle acetylcholine nicotinic receptors and several subtypes of neuronal receptors have been identified (see Table 8-2).

Adrenergic

Several drugs that promote the release of NE already have been discussed. On the basis of the rate and duration of the drug-induced release of NE from adrenergic terminals, one of two opposing effects can predominate. Tyramine, ephedrine, amphetamine, and related drugs cause a relatively rapid, brief liberation of the transmitter and produce a sympathomimetic effect. On the other hand, reserpine, by blocking the uptake of amines by VMAT2, produces a slow, prolonged depletion of the adrenergic transmitter from adrenergic storage vesicles, where it is largely metabolized by intraneuronal MAO. The resulting depletion of transmitter produces the equivalent of adrenergic blockade. Reserpine also causes the depletion of 5HT, DA, and possibly other, unidentified, amines from central and peripheral sites, and many of its major effects may be a consequence of the depletion of transmitters other than NE.

As discussed previously, deficiencies of TH in humans cause a neurologic disorder (Carson and Robertson, 2002) that can be treated by supplementation with the DA precursor levodopa.

A syndrome caused by congenital DβH deficiency is characterized by the absence of NE and EPI, elevated concentrations of DA, intact baroreceptor reflex afferent fibers and cholinergic innervation, and undetectable concentrations of plasma DβH activity (Carson and Robertson, 2002). Patients with this syndrome have severe orthostatic hypotension, ptosis of the eyelids, and retrograde ejaculations. Dihydroxyphenylserine (L-DOPS) improves postural hypotension in this rare disorder. This therapeutic approach takes advantage of the nonspecificity of aromatic L-amino acid decarboxylase, which synthesizes NE directly from this drug in the absence of DβH (Man in't Veld et al., 1988; Robertson et al., 1991). Despite the restoration of plasma NE in humans with L-DOPS, EPI levels are not restored, leading to speculation that PNMT may require DβH for appropriate functioning (Carson and Robertson, 2002).

Agonist and Antagonist Actions at Receptors

Cholinergic

The nicotinic receptors of autonomic ganglia and skeletal muscle are not identical; they respond differently to certain stimulating and blocking agents, and their pentameric structures contain different combinations of homologous subunits (Table 8-2). *Dimethylphenylpiperazinium* (DMPP) and phenyltrimethylammonium (PTMA) show some selectivity for stimulation of autonomic ganglion cells and muscle motor end plates. Trimethaphan and hexamethonium are relatively selective competitive and noncompetitive ganglionic blocking agents, respectively. Although tubocurarine effectively blocks transmission at both motor end plates and autonomic ganglia, its action at the former site predominates. Succinylcholine, a depolarizing agent, produces selective neuromuscular blockade. Transmission at autonomic ganglia and the adrenal

medulla is complicated further by the presence of muscarinic receptors in addition to the principal nicotinic receptors (see Chapter 11).

Various toxins in snake venoms exhibit a high degree of specificity toward cholinergic receptors. The α-neurotoxins from the Elapidae family interact with the agonist-binding site on the nicotinic receptor. α-Bungarotoxin is selective for the muscle receptor and interacts with only certain neuronal receptors, such as those containing α7 through α9 subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, called the *fasciculins*, inhibits AChE. A third group of toxins, termed the *muscarinic toxins* (MT₁ through MT₄), includes partial agonists and antagonists for muscarinic receptors. Venoms from the Viperidae family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Muscarinic ACh receptors, which mediate the effects of ACh at autonomic effector cells, now can be divided into five subclasses. Atropine blocks all the muscarinic responses to injected ACh and related cholinomimetic drugs whether they are excitatory, as in the intestine, or inhibitory, as in the heart. Newer muscarinic agonists, pirenzepine for M₁, triptamine for M₂, and darifenacin for M₃, show selectivity as muscarinic-blocking agents. Several muscarinic antagonists show sufficient selectivity in the clinical setting to minimize the bothersome side effects seen with the nonselective agents at therapeutic doses (see Chapter 9).

Adrenergic

A vast number of synthetic compounds that bear structural resemblance to the naturally occurring catecholamines can interact with α and β adrenergic receptors to produce sympathomimetic effects (see Chapter 12). Phenylephrine acts selectively at α₁ receptors, whereas clonidine is a selective α₂ adrenergic agonist. Isoproterenol exhibits agonist activity at both β₁ and β₂ receptors. Preferential stimulation of cardiac β₁ receptors follows the administration of dobutamine. Terbutaline exerts relatively selective action on β₂ receptors; it produces effective bronchodilation with minimal effects on the heart. The main features of adrenergic blockade, including the selectivity of various blocking agents for α and β adrenergic receptors, are considered in detail in Chapter 12. Partial dissociation of effects at β₁ and β₂ receptors has been achieved by subtype-selective antagonists, as exemplified by the β₁ receptor antagonists metoprolol and atenolol, which antagonize the cardiac actions of catecholamines while causing somewhat less antagonism at bronchioles. Prazosin and yohimbine are representative of α₁ and α₂ receptor antagonists, respectively; prazosin has a relatively high affinity at α_{2B} and α_{2C} subtypes compared with α_{2A} receptors. Several important drugs that promote the release of NE (e.g., tyramine) or deplete the transmitter (e.g., reserpine) resemble, in their effects, activators or blockers of post-junctional receptors.

Interference With the Destruction of the Transmitter

Cholinergic

The anti-ChE agents (see Chapter 10) constitute a chemically diverse group of compounds, the primary action of which is inhibition of AChE, with the consequent accumulation of endogenous ACh. At the NMJ, accumulation of ACh produces depolarization of end plates and flaccid paralysis. At postganglionic muscarinic effector sites, the response is either excessive stimulation resulting in contraction and secretion or an inhibitory response mediated by hyperpolarization. At ganglia, depolarization and enhanced transmission are observed.

Adrenergic

The reuptake of NE by the adrenergic nerve terminals by means of NET is the major mechanism for terminating NE's transmitter action. Interference with this process is the basis of the potentiating effect of cocaine on responses to adrenergic impulses and injected catecholamines. The antidepressant actions and some of the adverse effects of imipramine and related drugs may be due to a similar action at adrenergic synapses in the CNS (Chapter 15).

Entacapone and tolcapone are nitro catechol-type COMT inhibitors. Entacapone is a peripherally acting COMT inhibitor, whereas tolcapone also inhibits COMT activity in the brain. COMT inhibition has been shown to attenuate levodopa toxicity on dopaminergic neurons and enhance DA's action in the brain of patients with Parkinson disease (Chapter 18). On the other hand, nonselective MAO inhibitors, such as tranylcypromine, potentiate the effects of tyramine and may potentiate effects of neurotransmitters. While most MAO inhibitors used as antidepressants inhibit both MAO-A and MAO-B, selective MAO-A and MAO-B inhibitors are available. Selegiline is a selective and irreversible MAO-B inhibitor that also has been used as an adjunct in the treatment of Parkinson disease.

Other Autonomic Neurotransmitters

ATP and ACh coexist in cholinergic vesicles (Dowdall et al., 1974), and ATP, NPY, and catecholamines are found within storage granules in nerves and the adrenal medulla (see previous discussion). ATP is released along with the transmitters, and it and its metabolites can play significant roles in synaptic transmission in some circumstances (see further discussion). Recently, attention has focused on the growing list of peptides that are found in the adrenal medulla, nerve fibers, or ganglia of the autonomic nervous system or in the structures that are innervated by the autonomic nervous system. This list includes enkephalins, substance P and other tachykinins, SST, gonadotropin-releasing hormone, CCK, CGRP, galanin, PACAP, VIP, chromogranins, and NPY (Hökfelt et al., 2000). Some of the orphan GPCRs discovered in the course of genome-sequencing projects may represent receptors for undiscovered peptides or other cotransmitters.

Cotransmission in the Autonomic Nervous System

There is a large body of literature on cotransmission in the autonomic nervous system. Much of the research in this area has focused on co-release of ATP by adrenergic and cholinergic nerves. Co-release of NPY, VIP, CGRP, substance P, and NO has also been studied. Whether these co-released factors act as neurotransmitters, neuromodulators, or trophic factors remains a topic of debate (Burnstock, 2013, 2015; Mutafova-Yambolieva et al, 2014).

The evidence is substantial that ATP plays a role in sympathetic nerves as a cotransmitter with NE (Silinsky et al., 1998; Westfall et al., 1991, 2002). For example, the rodent vas deferens is supplied with dense sympathetic innervation, and stimulation of the nerves results in a biphasic mechanical response that consists of an initial rapid twitch followed by a sustained contraction. The first phase of the response is mediated by ATP acting on postjunctional P2X receptors, whereas the second phase is mediated mainly by NE acting on α_1 receptors (Sneddon and Westfall,

1984). The cotransmitters apparently are released from the same types of nerves because pretreatment with 6-hydroxydopamine, an agent that specifically destroys adrenergic nerves, abolishes both phases of the neurogenically induced biphasic contraction. Whether ATP and NE originate from the same populations of vesicles within a nerve ending is still open to debate and experimentation (Todorov et al., 1996; Mutafova-Yambolieva et al, 2014; Burnstock, 2015).

Once ATP is released into the neuroeffector junction, some of it is metabolized by extracellularly directed membrane-bound nucleotidases to ADP, AMP, and adenosine (Gordon, 1986). However, the majority of its metabolism occurs by the actions of releasable nucleotidases. There is also evidence that ATP and its metabolites exert presynaptic modulatory effects on transmitter release by P2 receptors and receptors for adenosine. In addition to evidence showing that ATP is a cotransmitter with NE, there is evidence that ATP may be a cotransmitter with ACh in certain postganglionic parasympathetic nerves, such as those in the urinary bladder.

The NPY family of peptides is distributed widely in the central and peripheral nervous systems and consists of three members: NPY, pancreatic polypeptide, and peptide YY. NPY is colocalized and coreleased with NE and ATP in most sympathetic nerves in the peripheral nervous system, especially those innervating blood vessels (Westfall, 2004). There is also convincing evidence that NPY exerts prejunctional modulatory effects on transmitter release and synthesis. Moreover, there are numerous examples of postjunctional interactions that are consistent with a cotransmitter role for NPY at various sympathetic neuroeffector junctions. Thus, NPY, together with NE and ATP, qualifies as the third sympathetic cotransmitter of the sympathetic branch of the autonomic nervous system. Functions of NPY include

- direct postjunctional contractile effects
- potentiation of the contractile effects of the other sympathetic cotransmitters
- inhibitory modulation of the nerve stimulation-induced release of all three sympathetic cotransmitters, including actions on autoreceptors to inhibit its own release

Studies with selective NPY- Y_1 antagonists provided evidence that the principal postjunctional receptor is of the Y_1 subtype, although other receptors are also present at some sites and may exert physiological actions. Studies with selective NPY- Y_2 antagonists suggested that the principal prejunctional receptor is of the Y_2 subtype both in the periphery and in the CNS. There is evidence for a role for other NPY receptors, and clarification awaits the further development of selective antagonists. NPY also can act prejunctionally to inhibit the release of ACh, CGRP, and substance P. In the CNS, NPY exists as a cotransmitter with catecholamine in some neurons and with peptides and mediators in others. A prominent action of NPY is the presynaptic inhibition of the release of various neurotransmitters, including NE, DA, GABA, glutamate, and 5HT, as well as inhibition or stimulation of the release of neurohormones such as gonadotropin-releasing hormone, vasopressin, and oxytocin. Evidence also exists for stimulation of NE and DA release by NPY.

The NPY may use several mechanisms to produce its presynaptic effects, including inhibition of Ca^{2+} channels, activation of K^+ channels, and regulation of the vesicle release complex at some point distal to Ca^{2+} entry. NPY also may play a role in several pathophysiological conditions. The further development of selective NPY agonists and antagonists should enhance understanding about the physiological and pathophysiological roles of NPY.

The pioneering studies of Hökfelt and coworkers, which demonstrated the existence of VIP and ACh in peripheral autonomic neurons, initiated interest in the possibility of peptidergic cotransmission in the autonomic nervous system. Subsequent work has confirmed the frequent association of these two substances in autonomic fibers, including parasympathetic fibers that innervate smooth muscle and exocrine glands and cholinergic sympathetic neurons that innervate sweat glands (Hökfelt et al., 2000).

The role of VIP in parasympathetic transmission has been studied most extensively in the regulation of salivary secretion. The evidence for cotransmission includes the release of VIP following stimulation of the

chorda lingual nerve and the incomplete blockade by atropine of vasodilation when the frequency of stimulation is raised; the last observation may indicate independent release of the two substances, which is consistent with histochemical evidence for storage of ACh and VIP in separate populations of vesicles. Synergism between ACh and VIP in stimulating vasodilation and secretion also has been described. VIP may be involved in parasympathetic responses in the trachea and in the GI tract, where it may facilitate sphincter relaxation.

Nonadrenergic, Noncholinergic (NANC) Transmission by Purines

The smooth muscle of many tissues that are innervated by the autonomic nervous system shows inhibitory junction potentials following stimulation by field electrodes. Because such responses frequently are undiminished in the presence of adrenergic and muscarinic cholinergic antagonists, these observations have been taken as evidence for the existence of NANC transmission in the autonomic nervous system.

Burnstock and colleagues have compiled compelling evidence for the existence of purinergic neurotransmission in the GI tract, genitourinary tract, and certain blood vessels; ATP fulfills all the criteria for a neurotransmitter. In at least some circumstances, primary sensory axons may be an important source of ATP (Burnstock et al., 2015). Although adenosine is generated from the released ATP by ectoenzymes and releasable nucleotidases, its primary function appears to be modulatory by causing feedback inhibition of transmitter release.

Adenosine can be transported from the cell cytoplasm to activate extracellular receptors on adjacent cells. The efficient uptake of adenosine by cellular transporters and its rapid metabolism to inosine or to adenine nucleotides contribute to its rapid turnover. Several inhibitors of adenosine transport and metabolism can influence concentrations of extracellular adenosine and ATP (Sneddon et al., 1999).

The purinergic receptors found on the cell surface may be divided into the adenosine (P1) receptors and the receptors for ATP (P2X and P2Y receptors) (Fredholm et al., 2000). Both P1 and P2 receptors have various subtypes. There are four adenosine receptors (A_1 , A_{2A} , A_{2B} , and A_3) and multiple subtypes of P2X and P2Y receptors throughout the body. The adenosine receptors and the P2Y receptors mediate their responses via G proteins, whereas the P2X receptors are a subfamily of ligand-gated ion channels (Burnstock et al., 2015). Methylxanthines such as caffeine and theophylline preferentially block P1 adenosine receptors (Chapter 40).

Signal Integration and Modulation of Vascular Responses by Endothelium-Derived Factors: NO and Endothelin

The contents of adrenergic storage vesicles are not alone in regulating vascular tone. Many other factors modulate vascular contractility, including kinins, angiotensin, natriuretic peptides, substance P, VIP, CGRP, and eicosanoids, all described elsewhere in this volume. There are additional factors generated by the vascular endothelium that influence vascular reactivity: NO and endothelin.

Furchgott and colleagues demonstrated that an intact endothelium is necessary to achieve vascular relaxation in response to ACh (Furchgott, 1999). This inner cellular layer of the blood vessel now is known to modulate autonomic and hormonal effects on the contractility of blood vessels. In response to a variety of vasoactive agents and physical stimuli, endothelial cells release a short-lived vasodilator termed endothelium-derived relaxing factor, now identified as NO. Less commonly, an endothelium-derived hyperpolarizing factor and endothelium-derived contracting factor are released (Vanhoutte, 1996). Formation of endothelium-derived contracting factor depends on cyclooxygenase activity.

Products of inflammation and platelet aggregation (e.g., 5HT, histamine, bradykinin, purines, and thrombin) exert all or part of their action by stimulating the production of NO. Endothelium-dependent mechanisms of relaxation are important in a variety of vascular beds, including the coronary circulation (Hobbs et al., 1999). Activation of specific GPCRs linking to G_q and the mobilization of Ca^{2+} within endothelial cells

promotes NO production. NO diffuses readily to the underlying smooth muscle and induces relaxation of vascular smooth muscle by activating the soluble form of guanylyl cyclase, which increases cyclic GMP concentrations (Figures 3–13 and 3–17). Nitrovasodilating drugs used to lower blood pressure or to treat ischemic heart disease probably act through conversion to or release of NO (Chapter 27). Certain nerves (termed *nitroergic*) innervating blood vessels and smooth muscles of the GI tract also release NO. NO has a negative inotropic action on the heart.

Alterations in the release or action of NO may affect a number of major clinical situations, such as atherosclerosis (Hobbs et al., 1999; Ignarro et al., 1999). Furthermore, there is evidence suggesting that the hypotension of endotoxemia or that induced by cytokines is mediated by induction of NOS2 (the inducible form of NOS) and the enhanced production of NO; consequently, increased NO production may have pathological significance in septic shock.

Full contractile responses of cerebral arteries also require an intact endothelium. A family of peptides, termed *endothelins*, is stored in vascular endothelial cells. Endothelin contributes to the maintenance of vascular homeostasis by acting via multiple endothelin receptors that are GPCRs (Sokolovsky, 1995; Hilal-Dandan et al., 1997). The release of endothelin-1 (21 amino acids) onto smooth muscle promotes contraction by stimulation of the ET_A receptor. Endothelin antagonists are now employed in treating pulmonary artery hypertension (Chapter 31).

MUSCARINIC RECEPTOR ANTAGONISTS

- Structure-Activity Relationships
- Mechanism of Action
- Pharmacological Effects of Muscarinic Antagonists
- Therapeutic Uses of Muscarinic Receptor Antagonists
- Contraindications and Adverse Effects
- Toxicology of Drugs With Antimuscarinic Properties

Acetylcholine and Its Muscarinic Receptor Target

Muscarinic acetylcholine receptors in the peripheral nervous system are found primarily on autonomic effector cells innervated by postganglionic parasympathetic nerves. Muscarinic receptors are also present in autonomic ganglia and on some cells (e.g., vascular endothelial cells) that, paradoxically, receive little or no cholinergic innervation. Within the CNS, the hippocampus, cortex, and thalamus have high densities of muscarinic receptors.

Acetylcholine, the naturally occurring neurotransmitter for these receptors, has virtually no systemic therapeutic applications because its actions are diffuse, and its hydrolysis, catalyzed by both AChE and plasma butyrylcholinesterase, is rapid. Muscarinic agonists mimic the effects of ACh at these sites. These agonists typically are longer-acting congeners of ACh or natural alkaloids, some of which stimulate nicotinic as well as muscarinic receptors.

The mechanisms of action of endogenous ACh at the postjunctional membranes of the effector cells and neurons that represent different types of cholinergic synapses are discussed in Chapter 8. Cholinergic synapses occur at:

- autonomic effector sites innervated by postganglionic parasympathetic nerves (or, in the sweat glands, by postganglionic sympathetic nerves)
- sympathetic and parasympathetic ganglia and the adrenal medulla, innervated by preganglionic autonomic nerves
- motor end plates on skeletal muscle, innervated by somatic motor nerves
- certain synapses in the CNS (Krnjević, 2004) where ACh can have either pre- or postsynaptic actions

When ACh is administered systemically, it can potentially act at all of these sites; however, as a quaternary ammonium compound, its penetration to the CNS is limited, and the amount of ACh that reaches peripheral areas with low blood flow is limited due to hydrolysis by plasma butyrylcholinesterase.

The actions of ACh and related drugs at autonomic effector sites are referred to as *muscarinic*, based on the observation that the alkaloid muscarine acts selectively at those sites and produces the same qualitative effects as ACh. The muscarinic, or parasympathomimetic, actions of the drugs considered in this chapter are practically equivalent to the parasympathetic effects of ACh listed in Table 8–1. Muscarinic receptors are present in autonomic ganglia and the adrenal medulla but primarily

function to modulate the nicotinic actions of ACh at these sites (Chapter 11). In the CNS, muscarinic receptors are widely distributed and have a role in mediating many important responses. The differences between the actions of ACh and other muscarinic agonists are largely quantitative, with limited selectivity for one organ system or another. All of the actions of ACh and its congeners at muscarinic receptors can be competitively inhibited by atropine.

Properties and Subtypes of Muscarinic Receptors

Muscarinic receptors were characterized initially by analysis of the responses of cells and organ systems in the periphery and the CNS. For example, differential effects of two muscarinic agonists, bethanechol and McN-A-343, on the tone of the lower esophageal sphincter led to the initial designation of muscarinic receptors as M_1 (ganglionic) and M_2 (effector cell) (Goyal and Rattan, 1978). Molecular cloning of muscarinic receptors has identified five distinct gene products (Bonner et al., 1987), now designated as M_1 through M_5 muscarinic receptors (Chapter 8). All of the known muscarinic receptors are G protein–coupled receptors that in turn couple to various cellular effectors (Chapter 3). Although selectivity is not absolute, stimulation of M_1 , M_3 , and M_5 receptors causes hydrolysis of polyphosphoinositides and mobilization of intracellular Ca^{2+} as a consequence of activation of the G_q -PLC pathway, resulting in a variety of Ca^{2+} -mediated responses. In contrast, M_2 and M_4 muscarinic receptors inhibit adenylyl cyclase and regulate specific ion channels via their coupling to the pertussis toxin–sensitive G proteins, G_i and G_o (Chapter 3).

Recent X-ray crystallographic studies convincingly demonstrated that the classical (*orthosteric*) binding site for muscarinic agonists and antagonists is highly conserved among muscarinic receptor subtypes (Haga et al., 2012; Kruse et al., 2012, 2013). The orthosteric binding site consists of a cleft deeply buried within the membrane, formed by conserved amino acid chains located on several of the receptors' seven TM helices (TM1–TM7). A key feature shared by other receptors for biogenic amine ligands is the presence of a charge-charge interaction between the tertiary or quaternary nitrogen of the orthosteric ligands and a conserved TM3 aspartic acid side chain. A feature unique to muscarinic receptors is hydrogen bond interactions between the orthosteric ligand and a TM6 asparagine residue. Agonist binding to the receptor leads to considerable contraction of the ligand-binding pocket, reflecting the relatively small size of muscarinic agonists, as compared to muscarinic antagonists. Because the residues that line the orthosteric binding site are highly conserved among all muscarinic receptors, developing

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
AV: atrioventricular
COPD: chronic obstructive pulmonary disease
eNOS: endothelial NO synthase
HCN: hyperpolarization-activated, cyclic nucleotide-gated (channels)
5HT: serotonin
 I_{Ca-L} : L-type Ca^{2+} current
 I_f : cardiac pacemaker current
 I_{K-ACh} : ACh-activated K^+ current
 M_1, M_2, M_3 : muscarinic receptor subclasses
NO: nitric oxide

orthosteric muscarinic ligands endowed with a high degree of receptor subtype selectivity has proven difficult.

The five muscarinic receptor subtypes are widely distributed in both the CNS and peripheral tissues; most cells express at least two subtypes (Abrams et al., 2006; Wess, 1996; Wess et al., 2007). Identifying the role of a specific subtype in mediating a particular muscarinic response to ACh has been difficult due to the lack of subtype-specific agonists and antagonists. More recently, studies with M_1 – M_3 receptor knockout mice have yielded novel information about the physiological roles of the individual muscarinic receptor subtypes (Kruse et al., 2014; Wess et al., 2007; Table 8–3); these studies demonstrated that multiple receptor subtypes are involved in mediating a specific muscarinic response in most cases. For example, abolition of cholinergic bronchoconstriction, salivation, pupillary constriction, and bladder contraction generally requires deletion of more than one receptor subtype.

Various lines of evidence suggest that muscarinic receptors possess one or more topographically distinct allosteric binding sites formed by amino acid side chains located within the extracellular loops or the outer segments of different transmembrane (TM) helices (Birdsall and Lazareno, 2005; May et al., 2007). Because these regions show a considerable degree of sequence variation among the M_1 – M_3 receptors, considerable progress has been made in developing so-called allosteric modulators that show high selectivity for distinct muscarinic receptor subtypes (Conn et al., 2009, 2014; Gentry et al., 2015). These agents exert their pharmacological actions by altering the affinity or efficacy of orthosteric muscarinic ligands. Positive allosteric modulators (PAMs) enhance orthosteric activity, while negative allosteric modulators (NAMs) inhibit it. Allosteric agents that can directly activate muscarinic receptors are termed *allosteric agonists*. However, these designations are not absolute; they depend on the nature of the orthosteric ligand, receptor subtype under investigation, and assay system used. The remarkable progress that has been made recently in identifying subtype-selective muscarinic allosteric agents may lead to the development of new therapeutic agents with increased efficacy and reduced side effects. Currently, much research is focused on the potential of such agents for the treatment of several severe disorders of the CNS, including Alzheimer disease and schizophrenia.

A recent X-ray structure revealed the molecular details of a PAM–muscarinic receptor complex; the binding pocket for muscarinic PAMs is located just above the orthosteric binding crevice (Kruse et al., 2013). This new structure also illustrates that the bound PAM interferes with the dissociation of the bound orthosteric agonist from the receptor. Another potential strategy for achieving receptor subtype selectivity is the development of hybrid, bitopic orthosteric/allosteric ligands that interact with both the orthosteric binding cavity and an allosteric site (Lane et al., 2013; Mohr et al., 2010). By targeting orthosteric and allosteric sites simultaneously, bitopic ligands achieve both high affinity and receptor subtype selectivity.

Pharmacological Effects of Acetylcholine

The influence of ACh and parasympathetic innervation on various organs and tissues was introduced in Chapter 8; a more detailed description of the effects of ACh is presented here as background for understanding the physiological basis for the therapeutic uses of the muscarinic receptor agonists and antagonists.

Cardiovascular System

Acetylcholine has four primary effects on the cardiovascular system:

- vasodilation
- decrease in heart rate (negative chronotropic effect)
- decrease in the conduction velocity in the AV node (negative dromotropic effect)
- decrease in the force of cardiac contraction (negative inotropic effect)

The negative inotropic effect is of less significance in the ventricles than in the atria. In addition, some of these effects can be obscured by baroreceptor and other reflexes that dampen the direct responses to ACh.

Although ACh rarely is given systemically, its cardiac actions are important because the effects of cardiac glycosides, antiarrhythmic agents, and many other drugs are at least partly due to changes in parasympathetic (vagal) stimulation of the heart; in addition, afferent stimulation of the viscera during surgical interventions can reflexly increase the vagal stimulation of the heart.

The intravenous injection of a small dose of ACh produces a transient fall in blood pressure owing to generalized vasodilation (mediated by vascular endothelial NO), which is usually accompanied by reflex tachycardia. The generalized vasodilation produced by exogenously administered ACh is due to the stimulation of muscarinic receptors, primarily of the M_3 subtype located on vascular endothelial cells. Occupation of these receptors activates the G_q -PLC-IP₃ pathway, leading to Ca^{2+} -calmodulin-dependent activation of endothelial eNOS (NOS3) and production of NO (endothelium-derived relaxing factor) (Moncada and Higgs, 1995), which diffuses to adjacent vascular smooth muscle cells, where it stimulates guanylyl cyclase, thereby promoting relaxation via a cyclic GMP-dependent mechanism (see Figure 3-11; Furchgott, 1999; Ignarro et al., 1999). Baroreceptor or chemoreceptor reflexes or direct stimulation of the vagus can also elicit parasympathetic coronary vasodilation mediated by ACh and the consequent production of NO by the endothelium (Feigl, 1998). If the endothelium is damaged, however, as occurs under various pathophysiological conditions, ACh acts predominantly on M_3 receptors located on the underlying vascular smooth muscle cells, causing vasoconstriction. This capacity to both relax and constrict vessels is shared by many hormones that act via the G_q -PLC-IP₃- Ca^{2+} pathway and for which both endothelial cells and vascular smooth muscle cells express receptors. If the agonist can reach both cell types, each cell type will respond in its differentiated way to an elevation of intracellular Ca^{2+} , endothelium with a stimulation of NO synthase, smooth muscle with contraction.

Acetylcholine has direct effects on cardiac function at doses higher than those required for vasodilation. The cardiac effects of ACh are mediated primarily by M_2 muscarinic receptors (Stengel et al., 2000), which couple to G_i/G_o . Direct effects of ACh include an increase in the I_{K-ACh} due to activation of K-ACh channels, a decrease in the I_{Ca-L} due to inhibition of L-type Ca^{2+} channels, and a decrease in the I_f due to inhibition of HCN (pacemaker) channels (DiFrancesco and Tromba, 1987). ACh acting on M_2 receptors also leads to a G_i -mediated decrease in cyclic AMP, which opposes and counteracts the β_1 adrenergic/ G_s -mediated increase in cyclic AMP, and an inhibition of the release of norepinephrine from sympathetic nerve terminals. The inhibition of norepinephrine release is mediated by presynaptic M_2 and M_3 receptors, which are activated by ACh released from adjacent parasympathetic postganglionic nerve terminals (Trendelenburg et al., 2005). There are also presynaptic M_2 receptors that inhibit ACh release from parasympathetic postganglionic nerve terminals in the human heart (Oberhauser et al., 2001).

In the SA node, each normal cardiac impulse is initiated by the spontaneous depolarization of the pacemaker cells (Chapter 30). At a critical level

(the threshold potential), this depolarization initiates an action potential. ACh slows the heart rate primarily by decreasing the rate of spontaneous depolarization; attainment of the threshold potential and the succeeding events in the cardiac cycle are therefore delayed. Until recently, it was widely accepted that β_1 adrenergic and muscarinic cholinergic effects on heart rate resulted from regulation of the cardiac pacemaker current mentioned previously (1). Unexpected findings made through genetic deletion of HCN4 and pharmacological inhibition of I_f have generated an alternative theory involving a pace-making function for an intracellular Ca^{2+} “clock” (Lakatta and DiFrancesco, 2009) that might mediate effects of ACh on heart rate (Lyashkov et al., 2009).

In the atria, ACh causes hyperpolarization and decreased action potential duration by increasing $I_{\text{K-ACh}}$. ACh also inhibits cyclic AMP formation and norepinephrine release, decreasing atrial contractility. In the AV node, ACh slows conduction and increases the refractory period by inhibiting $I_{\text{Ca-L}}$; the decrement in AV conduction is responsible for the complete heart block that may be observed when large quantities of cholinergic agonists are administered systemically. When parasympathetic (vagal) tone to the resting heart is increased (e.g., by digoxin), the prolonged refractory period of the AV node can reduce the frequency with which aberrant atrial impulses are transmitted to the ventricles and thereby decrease the ventricular rate during atrial flutter or fibrillation.

The ventricular myocardium and His-Purkinje system receive only sparse cholinergic (vagal) innervation (Levy and Schwartz, 1994), and the effects of ACh are smaller than those observed in the atria and nodal tissues. The modest negative inotropic effect of ACh in the ventricle is most apparent when there is concomitant adrenergic stimulation or underlying sympathetic tone (Brodde and Michel, 1999; Levy and Schwartz, 1994; Lewis et al., 2001). Automaticity of Purkinje fibers is suppressed, and the threshold for ventricular fibrillation is increased.

Respiratory Tract

The parasympathetic nervous system plays a major role in regulating bronchomotor tone. A diverse set of stimuli cause reflex increases in parasympathetic activity that contributes to bronchoconstriction. The effects of ACh on the respiratory system include bronchoconstriction, increased tracheobronchial secretion, and stimulation of the chemoreceptors of the carotid and aortic bodies. These effects are mediated primarily by M_3 muscarinic receptors located on bronchial and tracheal smooth muscle (Eglen et al., 1996; Fisher et al., 2004).

Urinary Tract

Parasympathetic sacral innervation causes detrusor muscle contraction, increased voiding pressure, and ureteral peristalsis. These responses are difficult to observe with administered ACh because poor perfusion of visceral organs and rapid hydrolysis by plasma butyrylcholinesterase limit access of systemically administered ACh to visceral muscarinic receptors. Control of bladder contraction apparently is mediated by multiple muscarinic receptor subtypes. Muscarinic stimulation of bladder contraction is mediated primarily by M_3 receptors expressed by detrusor smooth muscle cells. Smooth muscle M_2 receptors also seem to make a

small contribution to this response. M_2 receptors may also cause bladder contractions indirectly by reversing β receptor–cyclic AMP–mediated relaxation of the detrusor muscle (Hegde, 2006; Matsui et al., 2002).

GI Tract

Although stimulation of vagal input to the GI tract increases tone, amplitude of contractions, and secretory activity of the stomach and intestine, such responses are inconsistently seen with administered ACh for the same reasons that urinary tract responses are difficult to observe. As in the urinary tract, M_3 receptors appear to be primarily responsible for mediating cholinergic control of GI motility, but M_2 receptors also contribute to this activity (Matsui et al., 2002).

Secretory Effects

In addition to its stimulatory effects on the tracheobronchial and GI secretions, ACh stimulates secretion from other glands that receive parasympathetic or sympathetic cholinergic innervation, including the lacrimal, nasopharyngeal, salivary, and sweat glands. All of these effects are mediated primarily by M_3 muscarinic receptors (Caulfield and Birdsall, 1998); M_1 receptors also contribute significantly to the cholinergic stimulation of salivary secretion (Gautam et al., 2004).

Eye

When instilled into the eye, ACh produces miosis by contracting the pupillary sphincter muscle and accommodation for near vision by contracting the ciliary muscle; both of these effects are mediated primarily by M_3 muscarinic receptors, but other subtypes may contribute to the ocular effects of cholinergic stimulation.

CNS Effects

While systemically administered ACh has limited CNS penetration, muscarinic agonists that can cross the blood-brain barrier evoke a characteristic cortical arousal or activation response similar to that produced by injection of cholinesterase inhibitors or by electrical stimulation of the brainstem reticular formation. All five muscarinic receptor subtypes are expressed in the brain (Volpicelli and Levey, 2004), and recent studies suggest that muscarinic receptor–regulated pathways may have an important role in cognitive function, motor control, appetite regulation, nociception, and other processes (Wess et al., 2007).

Muscarinic Receptor Agonists

Muscarinic cholinergic receptor agonists can be divided into two groups:

- choline esters, including ACh and several synthetic esters
- the naturally occurring cholinomimetic alkaloids (particularly pilocarpine, muscarine, and arecoline) and their synthetic congeners

Of several hundred synthetic choline derivatives investigated, only methacholine, carbachol, and bethanechol (Figure 9–1) have had clinical applications.

Figure 9–1 Structural formulas of ACh, choline esters, and natural alkaloids that stimulate muscarinic receptors.

TABLE 9-1 ■ PHARMACOLOGICAL PROPERTIES OF CHOLINE ESTERS AND NATURAL ALKALOIDS

	HYDROLYSIS BY AChE	NICOTINIC ACTIVITY
Acetylcholine	+++	++
Methacholine	+	+
Carbachol	–	+++
Bethanechol	–	–
Muscarine	–	–
Pilocarpine	–	–

Methacholine (acetyl- β -methylcholine), the β -methyl analogue of ACh, is a synthetic choline ester that differs from ACh chiefly in its greater duration and selectivity of action. Its action is more prolonged because the added methyl group increases its resistance to hydrolysis by cholinesterases. Its selectivity is reflected in a predominance of muscarinic with only minor nicotinic actions, the former manifest most clearly in the cardiovascular system (Table 9-1).

Carbachol, and its β -methyl analogue, bethanechol, are unsubstituted carbamoyl esters that are almost completely resistant to hydrolysis by cholinesterases; their $t_{1/2}$ values are thus sufficiently long that they become distributed to areas of low blood flow. Carbachol retains substantial nicotinic activity, particularly on autonomic ganglia. Bethanechol has mainly muscarinic actions, with prominent effects on motility of the GI tract and urinary bladder.

The major natural alkaloid muscarinic agonists—muscarine, pilocarpine, and arecoline—have the same principal sites of action as the choline esters. Muscarine acts almost exclusively at muscarinic receptor sites, and the classification of these receptors derives from the actions of this alkaloid. Pilocarpine has a dominant muscarinic action but is a partial rather than full agonist; the sweat glands are particularly sensitive to pilocarpine. Arecoline also acts at nicotinic receptors. Although these naturally occurring alkaloids are of great value as pharmacological tools and muscarine has toxicological significance (discussed further in the chapter), present clinical use is restricted largely to the employment of pilocarpine as a sialagogue and miotic agent (Chapter 69).

HISTORY AND SOURCES

The alkaloid muscarine was isolated from the mushroom *Amanita muscaria* by Schmiedeberg in 1869. Pilocarpine is the chief alkaloid obtained from the leaflets of South American shrubs of the genus *Pilocarpus*. Although the natives had long known that the chewing of leaves of *Pilocarpus* plants caused salivation, the active compound, pilocarpine, was isolated only in 1875 and shown to affect the pupil and sweat and salivary glands. Arecoline is the main alkaloid of areca or betel nuts, which are consumed as a euphoric masticatory mixture by the natives of the Indian subcontinent and East Indies. Hunt and Taveau synthesized and studied methacholine as early as 1911. Carbachol and bethanechol were synthesized and investigated in the 1930s.

ADME

The absorption and distribution of these compounds may be predicted from their structures. Muscarine and the choline esters are quaternary amines; pilocarpine and arecoline are tertiary amines (see examples in Figure 9-1). The choline esters, as quaternary amines, are poorly absorbed following oral administration and have limited ability to cross the blood-brain barrier. Even though these drugs resist hydrolysis, the choline esters are short-acting agents due to rapid renal elimination. Pilocarpine and arecoline, as tertiary amines, are readily absorbed and can cross the

blood-brain barrier. While muscarine is a quaternary amine and is poorly absorbed, it can still be toxic when ingested and can even have CNS effects. The natural alkaloids are primarily eliminated by the kidneys; excretion of the tertiary amines can be accelerated by acidification of the urine to trap the cationic form in the urine.

Therapeutic Uses of Muscarinic Receptor Agonists

Muscarinic agonists are currently used in the treatment of urinary bladder disorders and xerostomia and in the diagnosis of bronchial hyperreactivity. They are also used in ophthalmology as miotic agents and for the treatment of glaucoma. There is growing interest in the use of M_1 agonists in treating the cognitive impairment associated with Alzheimer disease. Other receptor subtypes, including M_2 and M_3 , also appear to be involved in the regulation of cognitive function, at least in animal models (Wess et al., 2007).

Acetylcholine

Although rarely given systemically, ACh is used topically for the induction of miosis during ophthalmologic surgery, instilled into the eye as a 1% solution (Chapter 69).

Methacholine

Methacholine is administered by inhalation for the diagnosis of bronchial airway hyperreactivity in patients who do not have clinically apparent asthma (Crapo et al., 2000). It is available as a powder that is diluted with 0.9% NaCl and administered via a nebulizer. While muscarinic agonists can cause bronchoconstriction and increased tracheobronchial secretions in all individuals, asthmatic patients respond with intense bronchoconstriction and a reduction in vital capacity. The response to methacholine may be exaggerated or prolonged in patients taking β adrenergic receptor antagonists. Contraindications to methacholine testing include severe airflow limitation, recent myocardial infarction or stroke, uncontrolled hypertension, or pregnancy. Emergency resuscitation equipment, oxygen, and medications to treat severe bronchospasm (e.g., β_2 adrenergic receptor agonists for inhalation) should be available during testing.

Bethanechol

Bethanechol primarily affects the urinary and GI tracts. In the urinary tract, bethanechol has utility in treating urinary retention and inadequate emptying of the bladder when organic obstruction is absent, as in postoperative urinary retention, diabetic autonomic neuropathy, and certain cases of chronic hypotonic, myogenic, or neurogenic bladder; catheterization can thus be avoided. When used chronically, 10–50 mg of the drug is given orally three to four times daily; the drug should be administered on an empty stomach (i.e., 1 h before or 2 h after a meal) to minimize nausea and vomiting.

In the GI tract, bethanechol stimulates peristalsis, increases motility, and increases resting lower esophageal sphincter pressure. Bethanechol formerly was used to treat postoperative abdominal distention, gastric atony, gastroparesis, adynamic ileus, and gastroesophageal reflux; more efficacious therapies for these disorders are now available (Chapters 49 and 50).

Carbachol

Carbachol is used topically in ophthalmology for the treatment of glaucoma and the induction of miosis during surgery; it is instilled into the eye as a 0.01%–3% solution (Chapter 69).

Pilocarpine

Pilocarpine hydrochloride is used for the treatment of xerostomia that follows head and neck radiation treatments or that is associated with Sjögren syndrome (Porter et al., 2004; Wiseman and Faulds, 1995), an autoimmune disorder occurring primarily in women in whom secretions, particularly salivary and lacrimal, are compromised. Treatment can enhance salivary secretion, ease of swallowing, and subjective improvement in hydration of the oral cavity provided salivary parenchyma maintains residual function. Side effects typify cholinergic stimulation, with sweating the most

common complaint. The usual dose is 5–10 mg three times daily; the dose should be lowered in patients with hepatic impairment.

Pilocarpine is used topically in ophthalmology for the treatment of glaucoma and as a miotic agent; it is instilled in the eye as a 0.5%–6% solution and also can be delivered via an ocular insert (Chapter 69).

Cevimeline

Cevimeline is a muscarinic agonist that seems to preferentially activate M_1 and M_3 receptors on lacrimal and salivary gland epithelia. The drug has a long-lasting sialogogic action and may have fewer side effects and better patient compliance than pilocarpine (Noaiseh et al., 2014). The usual dose is 30 mg three times daily.

Contraindications, Precautions, and Adverse Effects

Most contraindications, precautions, and adverse effects are predictable consequences of muscarinic receptor stimulation. Thus, important contraindications to the use of muscarinic agonists include asthma, chronic obstructive pulmonary disease, urinary or GI tract obstruction, acid-peptic disease, cardiovascular disease accompanied by bradycardia, hypotension, and hyperthyroidism (muscarinic agonists may precipitate atrial fibrillation in hyperthyroid patients). Common adverse effects include diaphoresis; diarrhea, abdominal cramps, nausea/vomiting, and other GI side effects; a sensation of tightness in the urinary bladder; difficulty in visual accommodation; and hypotension, which can severely reduce coronary blood flow, especially if it is already compromised. These contraindications and adverse effects are generally of limited concern with topical administration for ophthalmic use.

Toxicology

Poisoning from the ingestion of plants containing pilocarpine, muscarine, or arecoline is characterized chiefly by exaggeration of their various parasympathomimetic effects. Treatment consists of the parenteral administration of atropine in doses sufficient to cross the blood-brain barrier and measures to support the respiratory and cardiovascular systems and to counteract pulmonary edema.

Muscarinic Receptor Antagonists

The muscarinic receptor antagonists include

- the naturally occurring alkaloids atropine and scopolamine
- semisynthetic derivatives of these alkaloids, which primarily differ from the parent compounds in their disposition in the body or their duration of action
- synthetic derivatives, some of which show a limited degree of selectivity for certain muscarinic receptor subtypes

Noteworthy agents among the last two categories are homatropine and tropicamide, which have a shorter duration of action than atropine, and methscopolamine, ipratropium, tiotropium, aclidinium, and umecclidinium, which are quaternary amines that do not cross the blood-brain barrier or readily cross membranes. The synthetic derivatives possessing some degree of receptor subtype selectivity include pirenzepine, an M_1 receptor–preferring antagonist, and darifenacin and solifenacin, two M_3 receptor–preferring agents.

Muscarinic antagonists prevent the effects of ACh by blocking its binding to muscarinic receptors on effector cells at parasympathetic (and sympathetic cholinergic) neuroeffector junctions in peripheral ganglia and the CNS. In general, muscarinic antagonists cause little blockade of nicotinic receptors. However, the quaternary ammonium antagonists generally exhibit a greater degree of nicotinic-blocking activity and therefore are more likely to interfere with ganglionic or neuromuscular transmission.

While many effects of muscarinic antagonists can be predicted from an understanding of the physiological responses mediated by muscarinic receptors at parasympathetic and sympathetic cholinergic neuroeffector junctions, paradoxical responses can occur. For example, presynaptic

TABLE 9-2 ■ EFFECTS OF ATROPINE IN RELATION TO DOSE

DOSE (mg)	EFFECTS
0.5	Slight cardiac slowing; some dryness of mouth; inhibition of sweating
1	Definite dryness of mouth; thirst; acceleration of heart, sometimes preceded by slowing; mild dilation of pupils
2	Rapid heart rate; palpitation; marked dryness of mouth; dilated pupils; some blurring of near vision
5	Previous symptoms marked; difficulty in speaking and swallowing; restlessness and fatigue; headache; dry, hot skin; difficulty in micturition; reduced intestinal peristalsis
≥10	Previous symptoms more marked; pulse rapid and weak; iris practically obliterated; vision very blurred; skin flushed, hot, dry, and scarlet; ataxia, restlessness, and excitement; hallucinations and delirium; coma

The clinical picture of a high (toxic) dose of atropine may be remembered by an old mnemonic device that summarizes the symptoms: *Red as a beet, Dry as a bone, Blind as a bat, Hot as firestone, and Mad as a hatter.*

muscarinic receptors of variable subtype are present on postganglionic parasympathetic nerve terminals. Because blockade of presynaptic receptors generally augments neurotransmitter release, the presynaptic effects of muscarinic antagonists may counteract their postsynaptic receptor blockade. Blockade of the modulatory muscarinic receptors in peripheral ganglia represents an additional mechanism for paradoxical responses.

An important consideration in the therapeutic use of muscarinic antagonists is the fact that physiological functions in different organs vary in their sensitivity to muscarinic receptor blockade (Table 9-2). Small doses of atropine depress salivary and bronchial secretion and sweating. With larger doses, the pupil dilates, accommodation of the lens to near vision is inhibited, and vagal effects on the heart are blocked so that the heart rate increases. Larger doses antagonize parasympathetic control of the urinary bladder and GI tract, thereby inhibiting micturition and decreasing intestinal tone and motility. Still larger doses are required to inhibit gastric motility and particularly secretion. Thus, doses of atropine and most related muscarinic antagonists that depress gastric secretion also almost invariably affect salivary secretion, ocular accommodation, micturition, and GI motility. This hierarchy of relative sensitivities is not a consequence of differences in the affinity of atropine for the muscarinic receptors at

HISTORY

The naturally occurring muscarinic receptor antagonists atropine and scopolamine are alkaloids of the belladonna (*Solanaceae*) plants. Preparations of belladonna were known to the ancient Hindus and have long been used by physicians. During the time of the Roman Empire and in the Middle Ages, the deadly nightshade shrub was frequently used to produce an obscure and often-prolonged poisoning, prompting Linnaeus to name the shrub *Atropa belladonna*, after Atropos, the oldest of the three Fates, who cuts the thread of life. The name *belladonna* derives from the alleged use of this preparation by Italian women to dilate their pupils; modern-day fashion models are known to use this same device for visual appeal. Atropine (D,L-hyoscyamine) also is found in *Datura stramonium* (Jamestown or jimson weed). Scopolamine (L-hyoscyne) is found chiefly in *Hyoscyamus niger* (henbane). In India, the root and leaves of jimson weed were burned and the smoke inhaled to treat asthma. British colonists observed this ritual and introduced the belladonna alkaloids into Western medicine in the early 1800s. Atropine was isolated in pure form in 1831.

Figure 9-2 Structural formulas of the belladonna alkaloids and semisynthetic and synthetic analogues. Fesoterodine is converted to an active 5-hydroxymethyl metabolite by esterase activity. CYP2D6 converts tolterodine to the same metabolite. Note that atropine, scopolamine, tolterodine, and fesoterodine each contain an asymmetric carbon atom (indicated by red asterisk); these compounds therefore exist as racemic mixtures. Clinically, only the (R)-enantiomers of tolterodine and fesoterodine are used.

these sites because atropine lacks selectivity toward different muscarinic receptor subtypes. More likely determinants include the degree to which the functions of various end organs are regulated by parasympathetic tone, the “spareness” of receptors and signaling mechanisms, the involvement of intramural neurons and reflexes, and the presence of other regulatory mechanisms.

Most clinically available muscarinic antagonists lack receptor subtype selectivity and their actions differ little from those of atropine, the prototype of the group. Notably, the clinical efficacy of some agents may actually depend on antagonistic actions on two or more receptor subtypes.

Structure-Activity Relationships

An intact ester of tropine and tropic acid (Figure 9-2) is essential for antimuscarinic action because neither the free acid nor the basic alcohol exhibits significant antimuscarinic activity. The presence of a free OH group in the acyl portion of the ester also is important for activity. Quaternary ammonium derivatives of atropine and scopolamine are generally more potent than their parent compounds in both muscarinic- and ganglionic- (nicotinic-) blocking activities when given parenterally. These derivatives are poorly and unreliably absorbed when given orally.

Mechanism of Action

Atropine and related compounds compete with ACh and other muscarinic agonists for the orthosteric ACh site on the muscarinic receptor. The antagonism by atropine is competitive; thus, it is surmountable by ACh if the concentration of ACh at muscarinic receptors is increased sufficiently. Muscarinic receptor antagonists inhibit responses to postganglionic cholinergic nerve stimulation less effectively than they inhibit responses to injected choline esters. The difference may be explained by the fact that release of ACh by cholinergic nerve terminals occurs in close proximity to the receptors, resulting in very high concentrations of the transmitter at the receptors.

Pharmacological Effects of Muscarinic Antagonists

The pharmacological effects of atropine, the prototypical muscarinic antagonist, provide a good background for understanding the therapeutic uses of the various muscarinic antagonists. The effects of other muscarinic antagonists will be mentioned only when they differ significantly from those of atropine. The major pharmacological effects of increasing doses of atropine, summarized in Table 9-2, offer a general guide to the problems associated with administration of this class of agents.

Cardiovascular System

Heart. The main effect of atropine on the heart is to alter the rate. Although the dominant response is tachycardia, there is often a transient bradycardia with average clinical doses (0.4–0.6 mg; Table 9-2). The slowing is modest (4–8 beats per min), occurs with no accompanying changes in blood pressure or cardiac output, and is usually absent after rapid intravenous injection. This unexpected effect has been attributed to the block of presynaptic M_1 muscarinic receptors on parasympathetic postganglionic nerve terminals in the SA node, which normally inhibit ACh release (Wellstein and Pitschner, 1988).

Larger doses of atropine cause progressive tachycardia by blocking M_2 receptors on the SA nodal pacemaker cells, thereby antagonizing parasympathetic (vagal) tone to the heart. The resting heart rate is increased by about 35–40 beats per min in young men given 2 mg of atropine intramuscularly. The maximal heart rate (e.g., in response to exercise) is not altered by atropine. The influence of atropine is most noticeable in healthy young adults, in whom vagal tone is considerable. In infants, the elderly, and patients with heart failure, even large doses of atropine may fail to accelerate the heart.

Atropine can abolish many types of reflex vagal cardiac slowing or asystole, such as that occurring from inhalation of irritant vapors, stimulation of the carotid sinus, pressure on the eyeballs, peritoneal stimulation, or injection of contrast dye during cardiac catheterization. Atropine also prevents or abruptly abolishes bradycardia or asystole caused by choline esters, acetylcholinesterase inhibitors, or other parasympathomimetic drugs, as well as cardiac arrest from electrical stimulation of the vagus.

The removal of vagal tone to the heart by atropine may facilitate AV conduction. Atropine shortens the functional refractory period of the AV node and can increase the ventricular rate in patients who have atrial fibrillation or flutter. In certain cases of second-degree AV block (e.g., Wenckebach AV block) in which vagal activity is an etiological factor (as with digoxin toxicity), atropine may lessen the degree of block. In some patients with complete AV block, the idioventricular rate may be accelerated by atropine; in others, it is stabilized. Atropine may improve the clinical condition of patients with inferior or posterior wall myocardial infarction by relieving severe sinus or nodal bradycardia or AV block.

Circulation. Atropine alone has little effect on blood pressure because most vessels lack significant cholinergic innervation. However, in clinical doses, atropine completely counteracts the peripheral vasodilation and sharp fall in blood pressure caused by choline esters. In toxic and occasionally in therapeutic doses, atropine can dilate cutaneous blood vessels, especially those in the blush area (atropine flush). This may be a compensatory

reaction permitting the radiation of heat to offset the atropine-induced rise in temperature that can accompany inhibition of sweating.

Respiratory System

Although atropine can cause some bronchodilation and decrease in tracheobronchial secretion in normal individuals by blocking parasympathetic (vagal) tone to the lungs, its effects on the respiratory system are most significant in patients with respiratory disease. Atropine can inhibit the bronchoconstriction caused by histamine, bradykinin, and the eicosanoids, which presumably reflects the participation of reflex parasympathetic (vagal) activity in the bronchoconstriction elicited by these agents. The ability to block the indirect bronchoconstrictive effects of these mediators forms the basis for the use of muscarinic receptor antagonists, along with β adrenergic receptor agonists, in the treatment of asthma. Muscarinic antagonists also have an important role in the treatment of chronic obstructive pulmonary disease (Chapter 40).

Atropine inhibits the secretions of the nose, mouth, pharynx, and bronchi and thus dries the mucous membranes of the respiratory tract. This action is especially marked if secretion is excessive and formed the basis for the use of atropine and other muscarinic antagonists to prevent irritating inhalational anesthetics such as diethyl ether from increasing bronchial secretion; newer inhalational anesthetics are less irritating. Muscarinic antagonists are used to decrease the rhinorrhea ("runny nose") associated with the common cold or with allergic and nonallergic rhinitis. Reduction of mucous secretion and mucociliary clearance can, however, result in mucus plugs, a potentially undesirable side effect of muscarinic antagonists in patients with airway disease.

The quaternary ammonium compounds ipratropium, tiotropium, aclidinium, and umecclidinium are used exclusively for their effects on the respiratory tract. Dry mouth is the only frequently reported side effect, as the absorption of these drugs from the lungs or the GI tract is inefficient. In addition, aclidinium has been shown to undergo rapid hydrolysis in plasma to inactive metabolites, thus reducing systemic exposure to the drug (Gavalda et al., 2009). The degree of bronchodilation achieved by these agents is thought to reflect the level of basal parasympathetic tone, supplemented by reflex activation of cholinergic pathways brought about by various stimuli. A therapeutically important property of ipratropium and tiotropium is their minimal inhibitory effect on mucociliary clearance relative to atropine. Hence, the choice of these agents for use in patients with airway disease minimizes the increased accumulation of lower airway secretions encountered with atropine.

Eye

Muscarinic receptor antagonists block the cholinergic responses of the pupillary sphincter muscle of the iris and the ciliary muscle controlling lens curvature (Chapter 69). Thus, these agents dilate the pupil (mydriasis) and paralyze accommodation (cycloplegia). The wide pupillary dilation results in photophobia; the lens is fixed for far vision, near objects are blurred, and objects may appear smaller than they are. The normal pupillary reflex constriction to light or on convergence of the eyes is abolished. These effects are most evident when the agent is instilled into the eye but can also occur after systemic administration of the alkaloids.

Conventional systemic doses of atropine (0.6 mg) have little ocular effect, in contrast to equal doses of scopolamine, which cause evident mydriasis and loss of accommodation. Locally applied atropine produces ocular effects of considerable duration; accommodation and pupillary reflexes may not fully recover for 7–12 days. Other muscarinic receptor antagonists with shorter durations of action are therefore preferred as mydriatics in ophthalmologic practice. Pilocarpine and choline esters (e.g., carbachol) in sufficient concentrations can reverse the ocular effects of atropine.

Muscarinic receptor antagonists administered systemically have little effect on intraocular pressure except in patients predisposed to angle-closure glaucoma, in whom the pressure may occasionally rise dangerously. The rise in pressure occurs when the anterior chamber is narrow and the iris obstructs outflow of aqueous humor into the trabeculae. Muscarinic antagonists may precipitate a first attack in unrecognized

cases of this relatively rare condition. In patients with open-angle glaucoma, an acute rise in pressure is unusual. Atropine-like drugs generally can be used safely in the latter condition, particularly if the glaucoma is being treated appropriately.

GI Tract

Knowledge of the actions of muscarinic receptor agonists on the stomach and intestine led to the use of muscarinic receptor antagonists as antispasmodic agents for GI disorders and to reduce gastric acid secretion in the treatment of peptic ulcer disease.

Motility. Parasympathetic nerves enhance GI tone and motility and relax sphincters, thereby favoring the passage of gastrointestinal contents. In normal subjects and in patients with GI disease, muscarinic antagonists produce prolonged inhibitory effects on the motor activity of the stomach, duodenum, jejunum, ileum, and colon, characterized by a reduction in tone and in amplitude and frequency of peristaltic contractions. Relatively large doses are needed to produce such inhibition, probably because the enteric nervous system can regulate motility independently of parasympathetic control; parasympathetic nerves serve only to modulate the effects of the enteric nervous system. Although atropine can completely abolish the effects of exogenous muscarinic agonists on GI motility and secretion, it does not completely inhibit the GI responses to vagal stimulation. This difference, particularly striking in the effects of atropine on gut motility, can be attributed to the fact that preganglionic vagal fibers innervating the GI tract synapse not only with postganglionic cholinergic fibers, but also with a network of noncholinergic intramural neurons that form the plexuses of the enteric nervous system and utilize neurotransmitters whose effects atropine does not block (e.g., 5HT, dopamine, and various peptides).

Gastric Acid Secretion. Similarly, atropine only partially inhibits the gastric acid secretory responses to vagal activity because vagal stimulation of gastrin secretion is mediated not by ACh but by peptidergic neurons in the vagal trunk that release gastrin-releasing peptide (GRP). GRP stimulates gastrin release from G cells; gastrin can act directly to promote acid secretion by parietal cells and to stimulate histamine release from enterochromaffin-like (ECL) cells (see Figure 49–1). Parietal cells (acid secretors) respond to at least three agonists: gastrin, histamine, and ACh. Atropine will inhibit only the components of acid secretion that result from muscarinic stimulation of parietal cells and from muscarinic stimulation of ECL cells that secrete histamine.

Secretions. Salivary secretion is particularly sensitive to inhibition by muscarinic receptor antagonists, which can completely abolish the copious, watery secretion induced by parasympathetic stimulation. The mouth becomes dry, and swallowing and talking may become difficult. The gastric cells that secrete mucin and proteolytic enzymes are more directly under vagal influence than are the acid-secreting cells, and atropine selectively decreases their secretory function. Although atropine can reduce gastric secretion, the doses required also affect salivary secretion, ocular accommodation, micturition, and GI motility (Table 9–2).

In contrast to most muscarinic receptor antagonists, pirenzepine, which shows some degree of selectivity for M_1 receptors, inhibits gastric acid secretion at doses that have little effect on salivation or heart rate. Because parietal cells primarily express M_3 receptors, perhaps M_1 receptors in intramural ganglia are the primary target of pirenzepine (Eglen et al., 1996). However, this concept has been questioned by the observation that pirenzepine is still able to inhibit carbachol-stimulated gastric acid secretion in M_1 receptor-deficient mice (Aihara et al., 2005). In general, histamine H_2 receptor antagonists and proton pump inhibitors have replaced muscarinic antagonists as inhibitors of acid secretion (Chapter 49).

Other Smooth Muscle

Urinary Tract. Muscarinic antagonists decrease the normal tone and amplitude of contractions of the ureter and bladder and often eliminate drug-induced enhancement of ureteral tone. However, this effect is usually

accompanied by reduced salivation and lacrimation and blurred vision (Table 9–2).

Biliary Tract. Atropine exerts mild antispasmodic action on the gallbladder and bile ducts in humans. However, this effect usually is not sufficient to overcome or prevent the marked spasm and increase in biliary duct pressure induced by opioids. The nitrates are more effective than atropine in this respect.

Sweat Glands and Temperature

Small doses of atropine inhibit the activity of sweat glands innervated by sympathetic cholinergic fibers, and the skin becomes hot and dry. Sweating may be depressed enough to raise the body temperature, but only notably so after large doses or at high environmental temperatures.

CNS

Atropine has minimal effects on the CNS at therapeutic doses, although mild stimulation of the parasympathetic medullary centers may occur. With toxic doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, hallucinations, or delirium (see the discussion of atropine poisoning further in the chapter). With still larger doses, stimulation is followed by depression, leading to circulatory collapse and respiratory failure after a period of paralysis and coma.

In contrast to atropine, scopolamine has prominent central effects at low therapeutic doses; atropine therefore is preferred over scopolamine for most purposes. The basis for this difference is probably the greater permeation of scopolamine across the blood-brain barrier. Scopolamine in therapeutic doses normally causes CNS depression, manifest as drowsiness, amnesia, fatigue, and dreamless sleep, with a reduction in REM sleep. It also causes euphoria and can therefore be subject to abuse. The depressant and amnesic effects formerly were sought when scopolamine was used as an adjunct to anesthetic agents or for preanesthetic medication. However, in the presence of severe pain, the same doses of scopolamine can occasionally cause excitement, restlessness, hallucinations, or delirium. These excitatory effects resemble those of toxic doses of atropine. Scopolamine also is effective in preventing motion sickness, probably by blocking neural pathways from the vestibular apparatus in the inner ear to the emetic center in the brainstem.

ADME

The belladonna alkaloids and the *tertiary* synthetic and semisynthetic derivatives are absorbed rapidly from the GI tract. They also enter the circulation when applied locally to the mucosal surfaces of the body. Absorption from intact skin is limited, although efficient absorption does occur in the postauricular region for some agents (e.g., scopolamine, allowing delivery by transdermal patch). Systemic absorption of inhaled or orally ingested *quaternary* muscarinic receptor antagonists is limited. The quaternary ammonium derivatives of the belladonna alkaloids also penetrate the conjunctiva of the eye less readily, and central effects are lacking because the quaternary agents do not cross the blood-brain barrier. Atropine has a $t_{1/2}$ of about 4 h; hepatic metabolism accounts for the elimination of about half of a dose, and the remainder is excreted unchanged in the urine.

Ipratropium is administered as an aerosol or solution for inhalation, whereas tiotropium is administered as a dry powder. As with most drugs administered by inhalation, about 90% of the dose is swallowed. When inhaled, their action is confined almost completely to the mouth and airways. Most of the swallowed drug appears in the feces. After inhalation, maximal responses usually develop over 30–90 min, with tiotropium having the slower onset. The effects of ipratropium last for 4–6 h; tiotropium's effects persist for 24 h, and the drug is amenable to once-daily dosing.

Therapeutic Uses of Muscarinic Receptor Antagonists

Muscarinic receptor antagonists have been used predominantly to inhibit effects of parasympathetic activity in the respiratory tract, urinary tract, GI tract, eye, and heart. Their CNS effects have resulted in their use in the treatment of Parkinson disease, the management of extrapyramidal

side effects of antipsychotic drugs, and the prevention of motion sickness. The major limitation in the use of the nonselective drugs is often failure to obtain desired therapeutic responses without concomitant side effects. While these usually are not serious, they can be sufficiently disturbing to decrease patient compliance, particularly during long-term administration. To date, selectivity is mainly achieved by local administration (e.g., by pulmonary inhalation or instillation in the eye). The development of allosteric modulators that recognize sites unique to particular receptor subtypes is currently considered an important approach to obtain receptor subtype-selective drugs for the treatment of specific clinical conditions (Conn et al., 2009).

Respiratory Tract

Ipratropium, tiotropium, aclidinium, and umeclidinium are important agents in the treatment of chronic obstructive pulmonary disease; they are less effective in most patients with asthma (see Chapter 40). These agents often are used with inhaled long-acting β_2 adrenergic receptor agonists, although there is little evidence of true synergism.

Ipratropium appears to block all subtypes of muscarinic receptors and accordingly also antagonizes the inhibition of ACh release by presynaptic M_2 receptors on parasympathetic postganglionic nerve terminals in the lung; the resulting increase in ACh release may counteract the drug's blockade of M_3 receptor-mediated bronchoconstriction. In contrast, tiotropium shows some selectivity for M_1 and M_3 receptors. In addition, tiotropium and aclidinium have lower affinities for M_2 receptors and dissociate more slowly from M_3 than from M_2 receptors. This minimizes its presynaptic effect to enhance ACh release (Alagha et al., 2014).

Ipratropium is administered four times daily via a metered-dose inhaler or nebulizer; aclidinium is used twice daily via a dry powder inhaler. Tiotropium and umeclidinium are once-daily medications that can be used for maintenance therapy via a dry powder inhaler in patients with moderate-to-severe disease.

In normal individuals, inhalation of antimuscarinic drugs can provide virtually complete protection against the bronchoconstriction produced by the subsequent inhalation of such irritants as sulfur dioxide, ozone, or cigarette smoke. However, patients with atopic asthma or demonstrable bronchial hyperresponsiveness are less well protected. Although these drugs cause a marked reduction in sensitivity to methacholine in asthmatic subjects, more modest inhibition of responses to challenge with histamine, bradykinin, or $PGF_{2\alpha}$ is achieved, and little protection is afforded against the bronchoconstriction induced by 5HT or leukotrienes. The therapeutic uses of ipratropium and tiotropium are discussed further in Chapter 40.

Ipratropium also is approved by the FDA for use in nasal inhalers for the treatment of the rhinorrhea associated with the common cold or with allergic or nonallergic perennial rhinitis. Although the ability of muscarinic antagonists to reduce nasopharyngeal secretions may provide some symptomatic relief, such therapy does not affect the natural course of the condition. It is probable that the contribution of first-generation antihistamines employed in nonprescription cold medications is due primarily to their antimuscarinic properties, except in conditions with an allergic basis (see Chapters 34 and 39).

Genitourinary Tract

Overactive urinary bladder can be successfully treated with muscarinic receptor antagonists. These agents can lower intravesicular pressure, increase capacity, and reduce the frequency of contractions by antagonizing parasympathetic control of the bladder; they also may alter bladder sensation during filling (Chapple et al., 2005). Muscarinic antagonists can be used to treat enuresis in children, particularly when a progressive increase in bladder capacity is the objective, and to reduce urinary frequency and increase bladder capacity in spastic paraplegia.

The muscarinic receptor antagonists indicated for overactive bladder are oxybutynin, tolterodine, trospium chloride, darifenacin, solifenacin, and fesoterodine. Although some comparison trials have demonstrated small but statistically significant differences in efficacy between these agents (Chapple et al., 2008), the clinical relevance of these differences

remains uncertain. The most important adverse reactions are consequences of muscarinic receptor blockade and include xerostomia, blurred vision, and GI side effects such as constipation and dyspepsia. CNS-related antimuscarinic effects, including drowsiness, dizziness, and confusion, can occur and are particularly problematic in elderly patients. CNS effects appear to be less likely with trospium, a quaternary amine, and with darifenacin and solifenacin; the last two agents show some preference for M_3 receptors and therefore seem to have minimal effects on M_1 receptors in the CNS, which appear to play an important role in memory and cognition (Kay et al., 2006). Adverse effects can limit the tolerability of these drugs with continued use, and patient acceptance declines. Xerostomia is the most common reason for discontinuation.

Oxybutynin, the oldest of the antimuscarinics currently used to treat overactive bladder disorders, is associated with a high incidence of antimuscarinic side effects, particularly xerostomia. In an attempt to increase patient acceptance, oxybutynin is marketed as a transdermal system that is associated with a lower incidence of side effects than the oral immediate- and extended-release formulations; a topical gel formulation of oxybutynin also appears to offer a more favorable side-effect profile. Because of the extensive metabolism of oral oxybutynin by enteric and hepatic CYP3A4, higher doses are used in oral than transdermal administration; the dose may need to be reduced in patients taking drugs that inhibit CYP3A4.

Tolterodine shows selectivity for the urinary bladder in animal models and in clinical studies, resulting in greater patient acceptance; however, the drug binds to all muscarinic receptors with similar affinity. Tolterodine is metabolized by CYP2D6 to 5-hydroxymethyltolterodine, a metabolite that possesses similar activity as the parent drug but differs pharmacokinetically. CYP2D6 is a polymorphic enzyme, with significant variability of expression; thus, the production of the 5-hydroxymethyl metabolite can vary, as can the half-life of the parent drug. In patients who poorly metabolize tolterodine via CYP2D6, the CYP3A4 pathway becomes important in tolterodine elimination. Because it is often difficult to assess which patients will be poor metabolizers, tolterodine doses may need to be reduced in patients taking drugs that inhibit CYP3A4 (dosage adjustments generally are not necessary in patients taking drugs that inhibit CYP2D6). Patients with significant renal or hepatic impairment also should receive lower doses of the drug. Fesoterodine is a prodrug that is rapidly hydrolyzed to the active metabolite of tolterodine by esterases (Figure 9-2) rather than CYP2D6, thereby providing a less variable source of the 5-hydroxymethyl metabolite of tolterodine regardless of CYP2D6 status.

Trospium, a quaternary amine, is as effective as oxybutynin and with better tolerability. It is the only antimuscarinic agent used for overactive bladder that is eliminated primarily by the kidneys; 60% of the absorbed trospium dose is excreted unchanged in the urine, and dosage adjustment is necessary for patients with impaired renal function.

Solifenacin shows some preference for M_3 receptors, giving it a favorable ratio of efficacy to side effect (Chapple et al., 2004). Solifenacin is significantly metabolized by CYP3A4; thus, patients taking drugs that inhibit CYP3A4 should receive lower doses.

Like solifenacin, darifenacin shows some degree of selectivity for M_3 receptors (Caulfield and Birdsall, 1998). It is metabolized by CYP2D6 and CYP3A4; as with tolterodine, the latter pathway becomes more important in patients who poorly metabolize the drug by CYP2D6. Darifenacin doses may need to be reduced in patients taking drugs that inhibit either of these CYPs.

GI Tract

Muscarinic receptor antagonists were once widely used for the management of peptic ulcer. Although they can reduce gastric motility and the secretion of gastric acid, antisecretory doses produce pronounced side effects, such as xerostomia, loss of visual accommodation, photophobia, and difficulty in urination (Table 9-2). As a consequence, patient compliance in the long-term management of symptoms of acid-peptic disease with these drugs is poor. H_2 receptor antagonists and proton pump inhibitors generally are considered to be the current drugs of choice to reduce gastric acid secretion (Chapter 49).

Pirenzepine, a tricyclic drug similar in structure to imipramine, displays a limited degree of selectivity for M_1 receptors (Caulfield and Birdsall, 1998). Telenzepine, an analogue of pirenzepine, has higher potency and similar selectivity for M_1 receptors. Both drugs are used in the treatment of acid-peptic disease in Europe, Japan, and Canada, but not currently in the U.S. At therapeutic doses of pirenzepine, the incidence of xerostomia, blurred vision, and central muscarinic disturbances is relatively low. Central effects are not seen because of the drug's limited penetration into the CNS.

Most studies indicate that pirenzepine (100–150 mg per day) produces about the same rate of healing of duodenal and gastric ulcers as the H_2 receptor antagonists cimetidine or ranitidine; pirenzepine also may be effective in preventing the recurrence of ulcers (Tryba and Cook, 1997). Side effects necessitate drug withdrawal in less than 1% of patients.

Myriad conditions known or supposed to involve increased tone (spasticity) or motility of the GI tract are treated with belladonna alkaloids (e.g., atropine, hyoscyamine sulfate, and scopolamine) alone or in combination with sedatives (e.g., phenobarbital) or antianxiety agents (e.g., chlor-diazepoxide). The belladonna alkaloids and their synthetic substitutes can reduce tone and motility when administered in maximally tolerated doses. M_3 -selective antagonists might achieve more selectivity but are unlikely to be better tolerated, as M_3 receptors also have an important role in the control of salivation, bronchial secretion and contraction, and bladder motility. Glycopyrrolate, a muscarinic antagonist that is structurally unrelated to the belladonna alkaloids, is used to reduce GI tone and motility; as a quaternary amine, it is less likely to cause adverse CNS effects than atropine, scopolamine, and other tertiary amines. Alternative agents for treatment of increased GI motility and its associated symptoms are discussed in Chapter 50.

Diarrhea associated with irritation of the lower bowel, such as mild dysenteries and diverticulitis, may respond to atropine-like drugs, an effect that likely involves actions on ion transport as well as motility. However, more severe conditions such as *Salmonella* dysentery, ulcerative colitis, and Crohn disease respond little, if at all, to muscarinic antagonists.

Dicyclomine hydrochloride is a weak muscarinic receptor antagonist that also has nonspecific direct spasmolytic effects on smooth muscle of the GI tract. It is occasionally used in the treatment of diarrhea-predominant irritable bowel syndrome.

Salivary Secretions

The belladonna alkaloids and synthetic substitutes are effective in reducing excessive salivation, such as drug-induced salivation and that associated with heavy-metal poisoning and Parkinson disease. Glycopyrrolate is a quaternary amine and as mentioned is less likely to penetrate the CNS. Glycopyrrolate (as oral solution) is indicated to reduce drooling (e.g., in patients with Parkinson disease).

Eye

Effects limited to the eye are obtained by topical administration of muscarinic receptor antagonists to produce mydriasis and cycloplegia. Cycloplegia is not attainable without mydriasis and requires higher concentrations or more prolonged application of a given agent. Mydriasis often is necessary for thorough examination of the retina and optic disc and in the therapy of iridocyclitis and keratitis. Homatropine hydrobromide, a semisynthetic derivative of atropine (Figure 9-2), cyclopentolate hydrochloride, and tropicamide are agents used in ophthalmological practice. These agents are preferred to topical atropine or scopolamine because of their shorter duration of action. Additional information on the ophthalmological properties and preparations of these and other drugs is provided in Chapter 69.

Cardiovascular System

The cardiovascular effects of muscarinic receptor antagonists are of limited clinical utility. Generally, these agents are used only in coronary care units for short-term interventions or in surgical settings. They are also sometimes used as an adjunct to stress testing to increase heart rate in the setting of chronotropic incompetence.

Atropine may be considered in the initial treatment of patients with acute myocardial infarction in whom excessive vagal tone causes sinus

bradycardia or AV nodal block. Sinus bradycardia is the most common arrhythmia seen during acute myocardial infarction of the inferior or posterior wall. Atropine may prevent further clinical deterioration in cases of high vagal tone or AV block by restoring heart rate to a level sufficient to maintain adequate hemodynamic status and to eliminate AV nodal block. Dosing must be judicious; doses that are too low can cause a paradoxical bradycardia (described previously), while excessive doses will cause tachycardia that may extend the infarct by increasing the demand for O_2 .

Atropine occasionally is useful in reducing the severe bradycardia and syncope associated with a hyperactive carotid sinus reflex. It has little effect on most ventricular rhythms. In some patients, atropine may eliminate premature ventricular contractions associated with a very slow atrial rate. It also may reduce the degree of AV block when increased vagal tone is a major factor in the conduction defect, such as the second-degree AV block that can be produced by digoxin. Selective M_2 receptor antagonists would be of potential utility in blocking ACh-mediated bradycardia or AV block; however, no such agents are currently available for clinical use.

Autonomic control of the heart is known to be abnormal in patients with cardiovascular disease, especially in heart failure. Patients with heart failure typically exhibit increased sympathetic tone accompanied by vagal withdrawal, both of which may contribute to the progression of disease. While β -blockers have now emerged as standard of care in heart failure, less is known about whether augmentation of vagal tone may be beneficial. Studies in animals suggest that augmenting vagal tone chronically decreases the inflammatory response and prevents adverse cardiac remodeling in heart failure, and early studies in humans support their use. However, the pivotal clinical trials of such therapy remain ongoing as of this writing (Dunlap et al., 2015; Schwartz and De Ferrari, 2011).

CNS

The belladonna alkaloids were among the first drugs to be used in the prevention of motion sickness. Scopolamine is the most effective of these agents for short (4- to 6-h) exposures to severe motion and probably for exposures of up to several days. All agents used to combat motion sickness should be given prophylactically; they are much less effective after severe nausea or vomiting has developed. A transdermal preparation of scopolamine has been shown to be highly effective when used prophylactically for the prevention of motion sickness. The drug, incorporated into a multilayer adhesive unit, is applied to the postauricular mastoid region, an area where transdermal absorption of the drug is especially efficient, resulting in the delivery of about 0.5 mg of scopolamine over 72 h. Xerostomia is common, drowsiness is not infrequent, and blurred vision occurs in some individuals using the scopolamine patch. Mydriasis and cycloplegia can occur by inadvertent transfer of the drug to the eye from the fingers after handling the patch. Rare but severe psychotic episodes have been reported.

Muscarinic receptor antagonists have long been used in the treatment of Parkinson disease, which is characterized by reduced dopaminergic input into the striatum, resulting in an imbalance between striatal muscarinic cholinergic and dopaminergic neurotransmission (see Chapter 18). The striatum, the major input area of the basal ganglia, contains multiple cell types, including cholinergic interneurons, all of which express one or more muscarinic receptor subtypes (Goldberg et al., 2012). Studies with muscarinic receptor mutant mice suggested that the beneficial effects of muscarinic antagonists in the treatment of Parkinson disease are primarily due to the blockade of M_1 and M_4 receptors, resulting in the activation or inhibition, respectively, of specific striatal neuronal subpopulations (Wess et al., 2007).

Muscarinic antagonists can be effective in the early stages of Parkinson disease if tremor is predominant, particularly in young patients. Muscarinic receptor antagonists also are used to treat the extrapyramidal symptoms that commonly occur as side effects of conventional antipsychotic drug therapy (Chapter 16). Certain antipsychotic drugs are relatively potent muscarinic receptor antagonists (Roth et al., 2004) and, perhaps for this reason, cause fewer extrapyramidal side effects.

The muscarinic antagonists used for Parkinson disease and drug-induced extrapyramidal symptoms include benztropine mesylate,

trihexyphenidyl hydrochloride, and biperiden; all are tertiary amines that readily gain access to the CNS.

Anesthesia

Atropine is commonly given to block responses to vagal reflexes induced by surgical manipulation of visceral organs. Atropine or glycopyrrolate are also used to block the parasympathomimetic effects of neostigmine when it is administered to reverse skeletal muscle relaxation after surgery. Serious cardiac arrhythmias have occasionally occurred, perhaps because of the initial bradycardia produced by atropine combined with the cholinomimetic effects of neostigmine.

Anticholinesterase Poisoning

The use of atropine in large doses for the treatment of poisoning by anticholinesterase organophosphorus insecticides is discussed in Chapter 10. Atropine also may be used to antagonize the parasympathomimetic effects of pyridostigmine or other anticholinesterases administered in the treatment of myasthenia gravis. It does not interfere with the salutary effects at the skeletal neuromuscular junction. It is most useful early in therapy, before tolerance to muscarinic side effects of anticholinesterases has developed.

Other Therapeutic Uses

Methscopolamine bromide is a quaternary ammonium derivative of scopolamine and therefore lacks the central actions of scopolamine. Although formerly used to treat peptic ulcer disease, at present it is primarily used in certain combination products for the temporary relief of symptoms of allergic rhinitis, sinusitis, and the common cold.

Homatropine methylbromide, the methyl derivative of homatropine, is less potent than atropine in antimuscarinic activity but four times more potent as a ganglionic blocking agent. Formerly used for the treatment of irritable bowel syndrome and peptic ulcer disease, at present it is primarily used with hydrocodone as an antitussive combination.

Contraindications and Adverse Effects

Most contraindications, precautions, and adverse effects are predictable consequences of muscarinic receptor blockade: xerostomia, constipation, blurred vision, dyspepsia, and cognitive impairment. Important contraindications to the use of muscarinic antagonists include urinary tract obstruction, GI obstruction, and uncontrolled (or susceptibility to attacks of) angle-closure glaucoma. Muscarinic receptor antagonists also are contraindicated (or should be used with extreme caution) in patients with benign prostatic hyperplasia. These adverse effects and contraindications generally are of more limited concern with muscarinic antagonists that are administered by inhalation or used topically in ophthalmology.

Toxicology of Drugs With Antimuscarinic Properties

The deliberate or accidental ingestion of natural belladonna alkaloids is a major cause of poisonings. Many histamine H_1 receptor antagonists, phenothiazines, and tricyclic antidepressants also block muscarinic receptors and, in sufficient dosage, produce syndromes that include features of atropine intoxication. Among the tricyclic antidepressants, protriptyline and amitriptyline are the most potent muscarinic receptor antagonists, with affinities for muscarinic receptors only an order of magnitude less than that of atropine. Because these drugs are administered in therapeutic doses considerably higher than the effective dose of atropine, antimuscarinic effects are often observed clinically (Chapter 15). In addition, overdose with suicidal intent is a danger in the population using antidepressants. Fortunately, most of the newer antidepressants and selective serotonin reuptake inhibitors have more limited anticholinergic properties.

Like the tricyclic antidepressants, many of the older antipsychotic drugs have antimuscarinic effects. These effects are most likely to be observed with the less-potent drugs (e.g., chlorpromazine and thioridazine), which must be given in higher doses. The newer antipsychotic drugs, classified as “atypical” and characterized by their low propensity for inducing extrapyramidal side effects, also include agents that are

potent muscarinic receptor antagonists. In particular, clozapine binds to human brain muscarinic receptors with high affinity (10 nM, compared to 1–2 nM for atropine); olanzapine also is a potent muscarinic receptor antagonist (Roth et al., 2004). Accordingly, xerostomia is a prominent side effect of these drugs. A paradoxical side effect of clozapine is increased salivation and drooling, possibly the result of partial agonist properties of this drug.

Infants and young children are especially susceptible to the toxic effects of muscarinic antagonists. Indeed, cases of intoxication in children have resulted from conjunctival instillation for ophthalmic refraction and other ocular effects. Systemic absorption occurs either from the nasal mucosa after the drug has traversed the nasolacrimal duct or from the GI tract if the drug is swallowed. Poisoning with diphenoxylate-atropine, used to treat diarrhea, has been extensively reported in the pediatric literature. Transdermal preparations of scopolamine used for motion sickness have been noted to cause toxic psychoses, especially in children and in the elderly. Serious intoxication may occur in children who ingest berries or seeds containing belladonna alkaloids. Poisoning from ingestion and smoking of jimson weed is seen with some frequency today.

Table 9–2 shows the oral doses of atropine causing undesirable responses or symptoms of overdosage. These symptoms are predictable results of blockade of parasympathetic innervation. In cases of full-blown atropine poisoning, the syndrome may last 48 h or longer. Intravenous injection of the anticholinesterase agent physostigmine may be used for

confirmation. If physostigmine does not elicit the expected salivation, sweating, bradycardia, and intestinal hyperactivity, intoxication with atropine or a related agent is almost certain. Depression and circulatory collapse are evident only in cases of severe intoxication; the blood pressure declines, convulsions may ensue, respiration becomes inadequate, and death due to respiratory failure may follow after a period of paralysis and coma.

If the poison has been taken orally, begin measures to limit intestinal absorption without delay. For symptomatic treatment, slow intravenous injection of physostigmine rapidly abolishes the delirium and coma caused by large doses of atropine, but carries some risk of overdose in mild atropine intoxication. Because physostigmine is metabolized rapidly, the patient may again lapse into coma within 1–2 h, and repeated doses may be needed (Chapter 10). If marked excitement is present and more specific treatment is not available, a benzodiazepine is the most suitable agent for sedation and for control of convulsions. Phenothiazines or agents with antimuscarinic activity should not be used because their antimuscarinic action is likely to intensify toxicity. Support of respiration and control of hyperthermia may be necessary. Ice bags and alcohol sponges help to reduce fever, especially in children.

Drug Facts for Your Personal Formulary: Muscarinic Receptor Agonists and Antagonists

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Muscarinic Receptor Agonists		
Methacholine	• Diagnosis of bronchial airway hyperreactivity	• Muscarinic effects: GI cramps, diarrhea, nausea, vomiting; lacrimation, salivation, sweating; urinary urgency; vision problems; bronchospasm • Do not use in patients with GI obstruction, urinary retention, asthma/COPD
Carbachol	• Glaucoma (topical administration)	• Systemic muscarinic effects minimal with proper topical application, otherwise similar to methacholine
Bethanechol	• Ileus (postoperative, neurogenic) • Urinary retention	• Similar to methacholine • Take on empty stomach to minimize nausea/vomiting
Pilocarpine	• Glaucoma (topical administration) • Xerostomia due to • Sjögren syndrome • Head and neck irradiation	• Systemic muscarinic effects minimal with proper topical application, otherwise similar to methacholine
Cevimeline	• Xerostomia due to • Sjögren syndrome	• Similar to methacholine
Muscarinic Receptor Antagonists		
Atropine	• Acute symptomatic bradycardia (e.g., AV block) • Cholinesterase inhibitor intoxication • Aspiration prophylaxis	• Antimuscarinic adverse effects: xerostomia, constipation, blurred vision, dyspepsia, and cognitive impairment • Contraindicated in patients with urinary tract obstruction (especially in benign prostatic hyperplasia), GI obstruction, and angle-closure glaucoma
Scopolamine	• Motion sickness	• CNS effects (drowsiness, amnesia, fatigue)
Homatropine, cyclopentolate, tropicamide	• Ophthalmological examination (cycloplegia and mydriasis induction)	• Antimuscarinic adverse effects are minimal with proper topical application
Ipratropium, tiotropium, aclidinium, umeclidinium	• COPD • Rhinorrhea (ipratropium)	• Minimal absorption as quaternary amine \Rightarrow fewer antimuscarinic adverse effects, otherwise similar to atropine
Pirenzepine, telenzepine	• Peptic ulcer disease (not in U.S.)	• Antimuscarinic adverse effects and contraindications similar to atropine
Oxybutynin, trospium, darifenacin, solifenacin, tolterodine, fesoterodine	• Overactive bladder, enuresis, neurogenic bladder	• Antimuscarinic adverse effects and contraindications similar to atropine • CNS-related antimuscarinic effects less likely with trospium (quaternary amine), darifenacin and solifenacin (some selectivity for M_3 receptors), fesoterodine (prodrug of tolterodine), and tolterodine (preference for muscarinic receptors in the bladder)

Drug Facts for Your Personal Formulary: Muscarinic Receptor Agonists and Antagonists (continued)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Muscarinic Receptor Antagonists		
Glycopyrrolate	<ul style="list-style-type: none"> • Duodenal ulcer • Sialorrhea 	<ul style="list-style-type: none"> • Antimuscarinic adverse effects and contraindications similar to atropine • Fewer CNS effects as glycopyrrolate is a quaternary amine and therefore unable to cross the blood-brain barrier
Dicyclomine, hyoscyamine	Diarrhea-predominant irritable bowel syndrome (IBS)	<ul style="list-style-type: none"> • Antimuscarinic adverse effects and contraindications similar to atropine (including constipation-dominant IBS) • Evidence for efficacy is limited
Trihexyphenidyl, benztropine	<ul style="list-style-type: none"> • Parkinson disease 	<ul style="list-style-type: none"> • Antimuscarinic adverse effects and contraindications similar to atropine • Mainly used to treat the tremor in Parkinson disease • Not recommended for elderly or demented patients

Acetylcholinesterase

The hydrolytic activity of AChE terminates the action of ACh at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites (Chapter 8). Drugs that inhibit AChE are called anti-ChEs, since they inhibit both AChE and BChE. BChE is not found in nerve ending synapses but in liver and plasma, where it metabolizes circulating esters. AChE inhibitors cause ACh to accumulate in the vicinity of cholinergic nerve terminals and thus are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central and peripheral nervous systems. In view of the widespread distribution of cholinergic neurons across animal species, it is not surprising that the anti-ChE agents have received extensive application as toxic agents, in the form of agricultural insecticides, pesticides, and potential chemical warfare “nerve gases.” Moreover, several compounds of this class are used therapeutically; others that cross the blood-brain barrier have been approved or are in clinical trials for the treatment of Alzheimer disease.

Prior to World War II, only the “reversible” anti-ChE agents were generally known, of which physostigmine is the prototype (Box 10-1). Shortly before and during World War II, a new class of highly toxic chemicals, the organophosphates, was developed, first as agricultural insecticides and later as potential chemical warfare agents. The extreme toxicity of these compounds was found to be due to their “irreversible” inactivation of AChE, which resulted in prolonged enzyme inhibition. Because the pharmacological actions of both the reversible and irreversible anti-ChE agents are qualitatively similar, they are discussed here as a group. Interactions of anti-ChE agents with other drugs acting at peripheral autonomic synapses and the neuromuscular junction are described in Chapters 9 and 11.

Structure of Acetylcholinesterase

Acetylcholinesterase exists in two general classes of molecular forms: simple homomeric oligomers of catalytic subunits (monomers, dimers, and tetramers) and heteromeric associations of catalytic subunits with structural subunits (Massoulié, 2000; Taylor et al., 2000). The homomeric forms are found as soluble species in the cell, presumably destined for export or for association with the outer membrane of the cell, typically through an attached glycopospholipid. One heteromeric form, largely found in neuronal synapses, is a tetramer of catalytic subunits disulfide-linked to a 20-kDa lipid-linked subunit and localized to the outer surface of the cell

membrane. The other heteromeric form consists of tetramers of catalytic subunits, linked by disulfide bonds to each of three strands of a collagen-like structural subunit. This molecular species, whose molecular mass approaches 10^6 Da, is associated with the basal lamina of neuromuscular junctional areas of skeletal muscle.

BOX 10-1 ■ History

Physostigmine, also called *eserine*, is an alkaloid obtained from the Calabar or ordeal bean, the dried, ripe seed of *Physostigma venenosum*, a perennial plant found in tropical West Africa. This Calabar bean once was used by native tribes of West Africa as an “ordeal poison” in trials for witchcraft, in which guilt was judged by death from the poison, innocence by survival after ingestion of a bean. A pure alkaloid was isolated by Jobst and Hesse in 1864 and named physostigmine. The first therapeutic use of the drug was in 1877 by Laqueur in the treatment of glaucoma, one of its clinical uses today. Karczmar (1970) and Holmstedt (2000) have presented accounts of the history of physostigmine.

After basic research elucidated the chemical basis of the activity of physostigmine, scientists began systematic investigations of a series of substituted aromatic esters of alkyl carbamic acids. Neostigmine was introduced in 1931 for its stimulant action on the GI tract and subsequently was reported to be effective in the symptomatic treatment of myasthenia gravis.

Following the synthesis of about 2000 compounds, Schrader defined the structural requirements for insecticidal activity (and, as learned subsequently, for anti-ChE activity). One compound in this early series, parathion (a phosphorothioate), later became the most widely used insecticide of this class. Malathion, which currently is used extensively, also contains the thionophosphorus bond found in parathion. Prior to and during World War II, the efforts of Schrader's group were directed toward the development of chemical warfare agents. The synthesis of several compounds of much greater toxicity than parathion, such as sarin, soman, and tabun, was kept secret by the German government. Investigators in the Allied countries also followed Lange and Krueger's lead in 1932 in the search for potentially toxic compounds; DFP, synthesized by McCombie and Saunders, was studied most extensively by British and American scientists (Giacobini, 2000).

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
anti-ChE: anticholinesterase
BChE: butyrylcholinesterase
ChE: cholinesterase
CNS: central nervous system
CYP: cytochrome P450
DFP: diisopropyl fluorophosphate (diisopropyl phosphorofluoridate)
EPA: Environmental Protection Agency
FDA: Food and Drug Administration
2-PAM: pralidoxime
PON1: paraoxonase isoform 1
TOCP: triorthocresyl phosphate

Molecular cloning revealed that a single gene encodes vertebrate AChEs (Schumacher et al., 1986; Taylor et al., 2000). However, multiple gene products arise from alternative processing of the mRNA that differ only in their carboxyl termini; the portion of the gene encoding the catalytic core of the enzyme is invariant. Hence, the individual AChE species can be expected to show identical substrate and inhibitor specificities.

A separate, structurally related, gene encodes butyrylcholinesterase, which is synthesized in the liver and is found primarily in plasma (Lockridge, 2015; Lockridge et al., 1987). The cholinesterases define a superfamily of proteins that share a common structural motif, the α , β -hydrolase fold (Cygler et al., 1993). The family includes several esterases, other hydrolases not found in the nervous system, and surprisingly, proteins without

hydrolase activity, such as thyroglobulin and members of the tactin and neuroligin families (Taylor et al., 2000).

The three-dimensional structures of AChEs show the active center to be nearly centrosymmetric to each subunit, residing at the base of a narrow gorge about 20 Å in depth (Bourne et al., 1995; Sussman et al., 1991). At the base of the gorge lie the residues of the catalytic triad: Ser203, His447, and Glu334 in mammals (Figure 10–1). The catalytic mechanism resembles that of other hydrolases; the serine hydroxyl group is rendered highly nucleophilic through a charge-relay system involving the carboxylate anion from glutamate, the imidazole of histidine, and the hydroxyl of serine (Figure 10–2A).

During enzymatic attack of ACh, an ester with trigonal geometry, a tetrahedral intermediate between enzyme and substrate is formed (Figure 10–2A) that collapses to an acetyl enzyme conjugate with the concomitant release of choline. The acetyl enzyme is very labile to hydrolysis, which results in the formation of acetate and active enzyme (Froede and Wilson, 1971; Rosenberry, 1975). AChE is one of the most efficient enzymes known: One molecule of AChE can hydrolyze 6×10^5 ACh molecules per minute; this yields a turnover time of 100 μ sec.

Is AChE Essential?

Knockout mice lacking the gene encoding AChE can survive under highly supportive conditions and with a special diet, but they exhibit continuous tremors and are stunted in growth (Xie et al., 2000). Mice that selectively lack AChE expression in skeletal muscle but have normal or near-normal expression in brain and organs innervated by the autonomic nervous system can reproduce but have tremors and severe compromise of skeletal muscle strength. By contrast, mice with selective reductions of CNS AChE by elimination of the exons encoding alternative spliced regions or expression of the structural subunits influencing expression in brain yield no obvious phenotype. This arises from large adaptive responses and compensatory reductions of ACh synthesis and storage and receptor responses (Camp et al., 2008; Dobbertin et al., 2009).

Figure 10–1 The active center gorge of mammalian AChE, looking from the portal of substrate entry. Bound ACh is shown by the dotted structure depicting its van der Waals radii. The crystal structure of mouse cholinesterase active center, which is virtually identical to human AChE, is shown (Bourne et al., 1995). Included are the side chains of (a) the catalytic triad: Glu334, His447, Ser203 (hydrogen bonds are denoted by the dotted lines); (b) acyl pocket: Phe295 and Phe297; (c) choline subsite: Trp86, Glu202, and Tyr337; and (d) the peripheral site: Trp286, Tyr72, Tyr124, and Asp74. Tyrosines 337 and 449 are further removed from the active center but likely contribute to stabilization of certain ligands. The catalytic triad, choline subsite, and acyl pocket are located at the base of the gorge, while the peripheral site is at the lip of the gorge. The gorge is 18- to 20-Å deep, with its base centrosymmetric to the subunit.

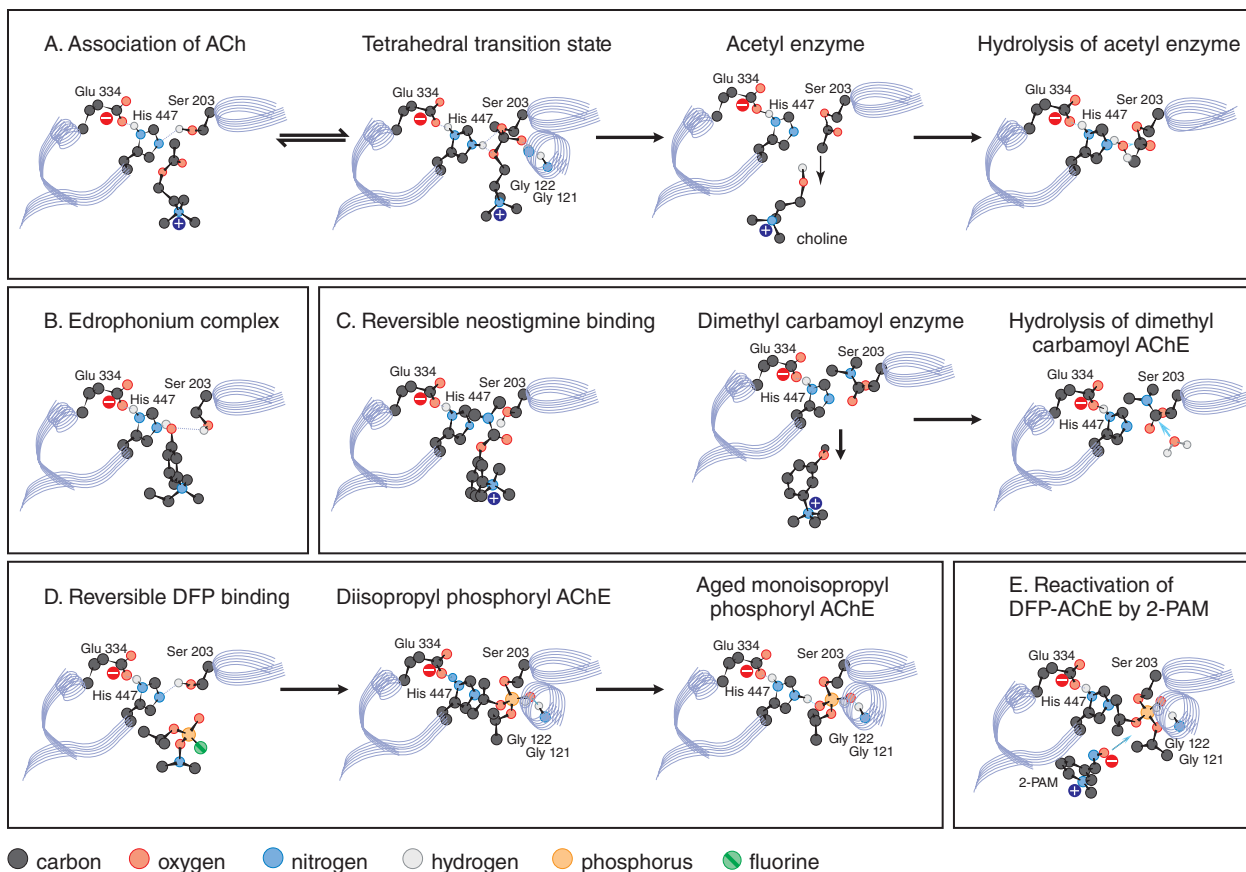

Figure 10-2 Steps involved in the hydrolysis of ACh by AChE and in the inhibition and reactivation of the enzyme. Only the three residues of the catalytic triad shown in Figure 10-1 are depicted. Net charge in a region is represented by red and blue circles containing – or + signs, respectively. The associations and reactions shown are as follows: **A.** ACh catalysis: binding of ACh, formation of a tetrahedral transition state, formation of the acetyl enzyme with liberation of choline, rapid hydrolysis of the acetyl enzyme with return to the original state. **B.** Reversible binding and inhibition by edrophonium. **C.** Neostigmine reaction with and inhibition of AChE: reversible binding of neostigmine, formation of the dimethyl carbamoyl enzyme, slow hydrolysis of the dimethyl carbamoyl enzyme. **D.** DFP reaction and inhibition of AChE: reversible binding of DFP, formation of the diisopropyl phosphoryl enzyme, formation of the aged monoisopropyl phosphoryl enzyme. Hydrolysis of the diisopropyl enzyme is very slow and is not shown. The aged monoisopropyl phosphoryl enzyme is virtually resistant to hydrolysis and reactivation. The tetrahedral transition state of ACh hydrolysis resembles the conjugates formed by the tetrahedral phosphate inhibitors and accounts for their potency. Amide bond hydrogens from Gly121 and Gly122 stabilize the carbonyl and phosphoryl oxygens. **E.** Reactivation of the diisopropyl phosphoryl enzyme by 2-PAM. 2-PAM attack of the phosphorus on the phosphorylated enzyme will form a phospho-oxime with regeneration of active enzyme. The individual steps of phosphorylation reaction and oxime reaction have been characterized by mass spectrometry. (Data from Jennings et al, 2003).

Acetylcholinesterase Inhibitors

Molecular Mechanism of Action of AChE Inhibitors

The mechanisms of action of compounds that typify the three classes of anti-ChE agents are also shown in Figure 10-2.

Three distinct domains on AChE constitute binding sites for inhibitory ligands and form the basis for specificity differences between AChE and butyrylcholinesterase:

- the acyl pocket of the active center;
- the choline subsite of the active center; and
- the peripheral anionic site (Reiner and Radić, 2000; Taylor and Radić, 1994).

Reversible inhibitors, such as edrophonium and tacrine, bind to the choline subsite in the vicinity of Trp86 and Glu202 (Silman and Sussman, 2000) (Figure 10-2B). Edrophonium has a brief duration of action because its quaternary structure facilitates renal elimination, and it binds reversibly to the AChE active center. Additional reversible inhibitors, such as donepezil, bind with higher affinity to the active center gorge. Other reversible inhibitors, such as propidium and the snake peptidic toxin fasciculin, bind to the peripheral anionic site on AChE. This site

resides at the rim of the gorge and is defined by Try286 and Tyr72 and Tyr124 (Figure 10-1).

Drugs that have a carbamoyl ester linkage, such as physostigmine and neostigmine, are hydrolyzed by AChE, but much more slowly than is ACh. The quaternary amine neostigmine and the tertiary amine physostigmine exist as cations at physiological pH. By serving as alternate substrates to ACh (Figure 10-2C), their reaction with the active center serine progressively generates the carbamoylated enzyme. The conjugated carbamoyl moiety resides in the acyl pocket outlined by Phe295 and Phe297. In contrast to the acetyl enzyme, methylcarbamoyl AChE and dimethylcarbamoyl AChE are far more stable (the $t_{1/2}$ for hydrolysis of the dimethylcarbamoyl enzyme is 15–30 min). Sequestration of the enzyme in its carbamoylated form thus precludes the enzyme-catalyzed hydrolysis of ACh for extended periods of time. When administered systemically, the duration of inhibition by the carbamoylating agents is 3–4 h.

The organophosphate inhibitors, such as DFP, serve as true hemisubstrates; the resultant conjugate with the active center serine phosphorylated or phosphonylated is extremely stable (Figure 10-2D). The organophosphorus inhibitors are tetrahedral in configuration, a configuration that resembles the transition state formed in carboxyl ester hydrolysis. Similar to the carboxyl esters, the phosphoryl oxygen binds within the oxyanion hole of the active center. If the alkyl groups in the phosphorylated

enzyme are ethyl or methyl, spontaneous regeneration of active enzyme requires several hours. Secondary (as in DFP) or tertiary alkyl groups further enhance the stability of the phosphorylated enzyme, and significant regeneration of active enzyme usually is not observed. The stability of the phosphorylated enzyme is enhanced through “aging,” which results from the loss of one of the alkyl groups. Hence, the return of AChE activity depends on biosynthesis of new AChE protein.

Thus, the terms *reversible* and *irreversible* as applied to the carbamoyl ester and organophosphate anti-ChE agents are relative terms, reflecting only quantitative differences in rates of decarbamylation or dephosphorylation of the conjugated enzyme. Both chemical classes react covalently with the active center serine in essentially the same manner as does ACh in forming the transient acetyl enzyme.

Chemistry and Structure-Activity Relationships

Structure-activity relationships of anti-ChE agents have been extensively reviewed in the scientific literature. Only agents of general therapeutic or toxicological interest are considered here.

Noncovalent Inhibitors

While these agents interact by reversible and noncovalent association with the active site in AChE, they differ in their disposition in the body and their affinity for the enzyme. Edrophonium, a quaternary drug whose activity is limited to peripheral nervous system synapses, has a moderate affinity for AChE. Its volume of distribution is limited and renal elimination is rapid, accounting for its short duration of action. By contrast,

tacrine and donepezil (Figure 10–3) have higher affinities for AChE, are more hydrophobic, and readily cross the blood-brain barrier to inhibit AChE in the CNS. Partitioning into lipid and higher affinities for AChE account for their longer durations of action.

“Reversible” Carbamate Inhibitors

Drugs of this class that are of therapeutic interest are shown in Figure 10–3. Early studies showed that the essential moiety of the physostigmine molecule was the methylcarbamate of an amine-substituted phenol. The quaternary ammonium derivative neostigmine is a compound of equal or greater potency. Pyridostigmine is a close congener also used in myasthenia gravis patients.

Carbamoylating inhibitors with high lipid solubility (rivastigmine) have longer duration of action, cross the blood-brain barrier, and are used as an alternative in the treatment of Alzheimer disease (Cummings, 2004) (Chapter 18). The carbamate insecticides carbaryl, propoxur, and aldicarb, used extensively as garden insecticides, inhibit AChE with a mechanism identical to other carbamoylating agents. While more reversible and less toxic, symptoms parallel those of organophosphates (Eddleston and Clark, 2011; King and Aaron, 2015).

Organophosphorus Compound

The general formula for the organophosphorus compound class of ChE inhibitors is presented in Table 10–1. A great variety of substituents is possible: R_1 and R_2 may be alkyl, alkoxy, aryloxy, amido, mercaptan, or other groups; and X, the leaving group, typically a conjugate base of a weak acid, is a halide, cyanide, thiocyanate, phenoxy, thiophenoxy, phosphate,

thiocholine, or carboxylate group. For a compilation of the organophosphorus compounds and their toxicity, see Gallo and Lawryk (1991).

Diisopropyl fluorophosphate produces virtually irreversible inactivation of AChE and other esterases by alkylphosphorylation. Its high lipid solubility, low molecular weight, and volatility facilitate inhalation, transdermal absorption, and penetration into the CNS. After desulfuration, the insecticides in current use form the dimethoxy or diethoxyphosphoryl conjugate of AChE.

The “nerve gases”—tabun, sarin, soman, and VX—are among the most potent synthetic toxins known; they are lethal to laboratory animals in nanogram doses. Insidious employment of these agents occurred in the Matsumoto incident and Tokyo subway terrorism attacks in Japan and against civilians by despotic regimes in the Middle East (Council on Foreign Relations, 2013; Dolgin, 2013; King and Aaron, 2015; Nozaki and Aikawa, 1995). While estimates of lethality in Japan amounted to 8 and 10 people killed, in Syria estimates vary, ranging up to 1000 individuals, with over 3000 showing symptoms of organophosphate toxicity. Attacks continued into 2017 with release of sarin vapor from explosive devices. Toxicity results from inhalation and rapid distribution of sarin to the central and peripheral nervous systems. A assassination homicide also occurred in Malaysia in 2017 via slower dermal absorption of VX.

Parathion and methylparathion were widely used as insecticides because of their favorable properties of low volatility and stability in aqueous solution. Acute and chronic toxicity has limited their use, and potentially less-hazardous compounds have replaced them for home and garden use now largely throughout the world. These compounds are inactive in inhibiting AChE *in vitro*; paraoxon is the active metabolite. The phosphoryl oxygen for sulfur substitution is carried out predominantly by hepatic CYPs. This reaction also occurs in the insect, typically with more efficiency. Other insecticides possessing the phosphorothioate structure have been widely employed for agricultural use. These include *diazinon* and *chlorpyrifos*. Use of these agents is restricted because of evidence of chronic toxicity in the newborn animal. They have been banned from indoor and outdoor residential use since 2005.

Malathion also requires replacement of a sulfur atom with oxygen *in vivo*, conferring resistance to mammalian species. Also, this insecticide can be detoxified by hydrolysis of the carboxyl ester linkage by plasma carboxylesterases. Plasma carboxylesterase activity dictates species resistance to malathion: The detoxification reaction is much more rapid in mammals and birds than in insects (Costa et al., 2013). In recent years, malathion has been employed in aerial spraying of relatively populous areas for control of citrus orchard-destructive Mediterranean fruit flies and mosquitoes that harbor and transmit viruses harmful to human beings, such as the West Nile encephalitis virus.

Evidence of acute toxicity from malathion arises primarily with suicide attempts or deliberate poisoning. The lethal dose in mammals is about 1 g/kg. Exposure to the skin results in a small fraction (<10%) systemically absorbed. Malathion is used topically in the treatment of pediculosis (lice) infestations in cases of permethrin resistance (Centers for Disease Control and Prevention, 2015).

Among the quaternary ammonium organophosphorus compounds (group D in Table 10–1), only echothiophate is useful clinically, and its use is limited to ophthalmic administration. Being positively charged, it is not volatile and does not readily penetrate the skin.

Basis for the Pharmacological Effects of ChE Inhibitors

The characteristic pharmacological effects of the anti-ChE agents are due primarily to the prevention of hydrolysis of ACh by AChE at sites of cholinergic transmission. Transmitter thus accumulates, enhancing the response to ACh that is liberated by cholinergic impulses or that is spontaneously released from the nerve ending. Virtually all acute effects of moderate doses of organophosphates are attributable to this action. For example, the characteristic miosis that follows local application of DFP to the eye is not observed after chronic postganglionic denervation of the eye because there is no source from which to release endogenous ACh.

The consequences of enhanced concentrations of ACh at motor end plates are unique to these sites and are discussed below.

Generally, the pharmacological properties of anti-ChE agents can be predicted by knowing those loci where ACh is released physiologically by nerve impulses, the degree of nerve impulse activity, and the responses of the corresponding effector organs to ACh (see Chapter 8). The anti-ChE agents potentially can produce all the following effects:

- stimulation of muscarinic receptor responses at autonomic effector organs;
- stimulation, followed by depression or paralysis, of all autonomic ganglia and skeletal muscle (nicotinic actions); and
- stimulation, with occasional subsequent depression, of pre- and post-synaptic cholinergic receptor sites in the CNS.

At therapeutic doses, several modifying factors are significant. Compounds containing a quaternary ammonium group do not penetrate cell membranes readily; hence, anti-ChE agents in this category are absorbed poorly from the GI tract or across the skin and are excluded from the CNS by the blood-brain barrier after moderate doses. On the other hand, such compounds act preferentially at the neuromuscular junctions of skeletal muscle, exerting their action both as anti-ChE agents and as direct agonists. They have comparatively less effect at autonomic effector sites and ganglia. In contrast, the more lipid-soluble agents are well absorbed after oral administration, have ubiquitous effects at both peripheral and central cholinergic sites, and may be sequestered in lipids for long periods of time. Lipid-soluble organophosphorus agents, such as the chemical warfare agent VX, are well absorbed through the skin, whereas the volatile agents are transferred readily across the alveolar membranes in the lung (King and Aaron, 2015; Storm et al., 2000).

The actions of anti-ChE agents on autonomic effector cells and on cortical and subcortical sites in the CNS, where ACh receptors are largely of the muscarinic type, are blocked by atropine. Likewise, atropine blocks some of the excitatory actions of anti-ChE agents on autonomic ganglia because both nicotinic and muscarinic receptors are involved in ganglionic neurotransmission (Chapter 11).

Effects on Physiological Systems

The sites of action of anti-ChE agents of therapeutic importance are the CNS, eye, intestine, and neuromuscular junction of skeletal muscle; other actions are of toxicological consequence.

Eye

When applied locally to the conjunctiva, anti-ChE agents cause conjunctival hyperemia and constriction of the pupillary sphincter muscle around the pupillary margin of the iris (miosis) and the ciliary muscle (block of accommodation reflex with resultant focusing to near vision). Miosis is apparent in a few minutes and can last several hours to days. Although the pupil may be “pinpoint” in size, it generally contracts further when exposed to light. The block of accommodation is more transient and generally disappears before termination of miosis. Intraocular pressure, when elevated, usually falls as the result of facilitation of outflow of the aqueous humor (Chapter 69).

GI Tract

In humans, neostigmine enhances gastric contractions and increases the secretion of gastric acid. After bilateral vagotomy, the effects of neostigmine on gastric motility are greatly reduced. The lower portion of the esophagus is stimulated by neostigmine; in patients with marked achalasia and dilation of the esophagus, the drug can cause a salutary increase in tone and peristalsis.

Neostigmine also augments motor activity of the small and large bowel; the colon is particularly stimulated. Atony produced by muscarinic receptor antagonists or prior surgical intervention may be overcome, propulsive waves are increased in amplitude and frequency, and movement of intestinal contents is thus promoted. The total effect of anti-ChE agents on intestinal motility probably represents a combination of actions at the ganglion cells of the Auerbach plexus and at the smooth muscle fibers as a

result of the preservation of ACh released by the cholinergic preganglionic and postganglionic fibers, respectively (Chapter 50).

Neuromuscular Junction

Most of the effects of potent anti-ChE drugs on skeletal muscle can be explained adequately on the basis of their inhibition of AChE at neuromuscular junctions. However, there is good evidence for an accessory direct action of neostigmine and other quaternary ammonium anti-ChE agents on skeletal muscle. For example, the intra-arterial injection of neostigmine into chronically denervated muscle, or muscle in which AChE has been inactivated by prior administration of DFP, evokes an immediate contraction, whereas physostigmine does not.

Normally, a single nerve impulse in a terminal motor-axon branch liberates enough ACh to produce a localized depolarization (end-plate potential) of sufficient magnitude to initiate a propagated muscle action potential. The ACh released is rapidly hydrolyzed by AChE, such that the lifetime of free ACh within the nerve-muscle synapse (~200 μ sec) is shorter than the decay of the end-plate potential or the refractory period of the muscle. Therefore, each nerve impulse gives rise to a single wave of depolarization. After inhibition of AChE, the residence time of ACh in the synapse increases, allowing for lateral diffusion and rebinding of the transmitter to multiple receptors. Successive stimulation of neighboring receptors to the release site in the end plate results in a prolongation of the decay time of the end-plate potential. Quanta released by individual nerve impulses are no longer isolated. This action destroys the synchrony between end-plate depolarizations and the development of the muscle action potentials. Consequently, asynchronous excitation and fasciculations of muscle fibers occur. With sufficient inhibition of AChE, depolarization of the end-plate predominates, and blockade due to depolarization ensues (Chapter 11). When ACh persists in the synapse, it also may depolarize the axon terminal, resulting in antidromic firing of the motoneuron; this stimulation contributes to fasciculations that involve the entire motor unit.

Anti-ChE agents will reverse the antagonism caused by competitive neuromuscular blocking agents. By contrast, neostigmine is not effective against the skeletal muscle paralysis caused by succinylcholine, which produces neuromuscular blockade by depolarization; neostigmine will enhance depolarization and the resultant blockade.

Cardiopulmonary System

The cardiovascular actions of anti-ChE agents are complex because they reflect both ganglionic and postganglionic effects of accumulated ACh on the heart and blood vessels and actions in the CNS. The predominant effect on the heart from the peripheral action of accumulated ACh is bradycardia, resulting in a fall in cardiac output. Higher doses usually enhance the fall in blood pressure, as a consequence of effects of anti-ChE agents on the medullary vasomotor centers of the CNS.

Anti-ChE agents augment vagal influences on the heart. This shortens the effective refractory period of atrial muscle fibers and increases the refractory period and conduction time at the sinoatrial and atrioventricular nodes. At the ganglionic level, accumulating ACh initially is excitatory on nicotinic receptors, but at higher concentrations, ganglionic blockade ensues as a result of persistent depolarization of the postsynaptic nerve. The excitatory action on the parasympathetic ganglion cells would tend to reinforce the diminished cardiac output, whereas the opposite sequence results from the action of ACh on sympathetic ganglion cells. Excitation followed by inhibition also is elicited by ACh at the central medullary vasomotor and cardiac centers. All of these effects are complicated further by the hypoxemia resulting from the bronchoconstrictor and secretory actions of increased ACh on the respiratory system; hypoxemia, in turn, can reinforce both sympathetic tone and ACh-induced discharge of epinephrine from the adrenal medulla. Hence, it is not surprising that an increase in heart rate is seen with severe ChE inhibitor poisoning. Hypoxemia probably is a major factor in the CNS depression that appears after large doses of anti-ChE agents.

Actions at Other Sites

Secretory glands that are innervated by postganglionic cholinergic fibers include the bronchial, lacrimal, sweat, salivary, gastric (antral G cells and

parietal cells), intestinal, and pancreatic acinar glands. Low doses of anti-ChE agents augment secretory responses to nerve stimulation, and higher doses actually produce an increase in the resting rate of secretion.

Anti-ChE agents increase contraction of smooth muscle fibers of the bronchioles and ureters, and the ureters may show increased peristaltic activity.

ADME

Physostigmine is absorbed readily from the GI tract, subcutaneous tissues, and mucous membranes. The conjunctival instillation of solutions of the drug may result in systemic effects if measures (e.g., pressure on the inner canthus) are not taken to prevent absorption from the nasal mucosa. Parenterally administered physostigmine is largely destroyed within 2–3 h, mainly by hydrolytic cleavage by plasma esterases.

Neostigmine and pyridostigmine are absorbed poorly after oral administration, such that much larger doses are needed than by the parenteral route. Whereas the effective parenteral dose of neostigmine is 0.5–2 mg, the equivalent oral dose may be 15–30 mg or more. Neostigmine and pyridostigmine are also destroyed by plasma esterases; the half-lives of these drugs are about 1–2 h (Cohan et al., 1976).

Organophosphate anti-ChE agents with the highest risk of toxicity are highly lipid-soluble liquids; others, such as sarin, have high vapor pressures, augmenting their dispersal. The less-volatile agents that are commonly used as agricultural insecticides (e.g., diazinon, malathion) generally are dispersed as aerosols or as dusts adsorbed to an inert, finely particulate material. Consequently, the compounds are absorbed rapidly through the skin and mucous membranes following contact with moisture, by the lungs after inhalation, and by the GI tract after ingestion (Storm et al., 2000).

Following their absorption, most organophosphates are excreted almost entirely as hydrolysis products in the urine. Plasma and liver esterases are responsible for hydrolysis to the corresponding phosphoric and phosphonic acids. However, CYPs are responsible for converting the inactive phosphorothioates containing a phosphorus-sulfur (thiono) bond to phosphorates with a phosphorus-oxygen bond, resulting in their activation. These enzymes also play a role in the inactivation of certain organophosphorus agents, and allelic differences are known to affect rates of metabolism (Furlong, 2007).

The organophosphate anti-ChE agents are hydrolyzed by two families of hepatic enzymes: the carboxylesterases and the paraoxonases (A-esterases). These enzymes are secreted into plasma and scavenge or hydrolyze a large number of organophosphates by cleaving the phosphoester, anhydride, phosphofluoridate, or phosphoryl cyanide bonds. Natural substrates of the paraoxonases appear to be lactones. In addition to catalyzing hydrolysis of organophosphates, the paraoxonase isozyme PON1 associates with high-density lipoproteins and appears to play a role in removing oxidized lipids, thereby exerting a protective effect in atherosclerosis and inflammation (Costa et al., 2013; Harel et al., 2004; Mackness and Mackness, 2015). Wide variations in paraoxonase activity exist among animal species. Young animals are deficient in carboxylesterases and paraoxonases, which may account for age-related toxicities seen in newborn animals and suspected to be a basis for organophosphate toxicity in humans (Padilla et al., 2004).

Plasma and hepatic carboxylesterases (aliesterases) and plasma butyrylcholinesterase are inhibited irreversibly by organophosphates (Costa et al., 2013; Lockridge 2015); their scavenging capacity for organophosphates can afford partial protection against inhibition of AChE in the nervous system. The carboxylesterases also catalyze hydrolysis of malathion and other organophosphates that contain carboxyl-ester linkages, rendering them less active or inactive. Because carboxylesterases are inhibited by organophosphates, toxicity from simultaneous exposure to two organophosphorus insecticides can prove synergistic.

Toxicology

Scope of the Problem

The toxicological aspects of the anti-ChE agents are of practical importance to clinicians. In addition to cases of accidental intoxication from

the use and manufacture of organophosphorus compounds as agricultural insecticides, these agents have been used frequently for homicidal and suicidal purposes. Organophosphates account for as many as 80% of pesticide-related hospital admissions. The World Health Organization documents pesticide toxicity as a widespread global problem associated with over 300,000 deaths a year; most poisonings occur in Southeast Asia (Eddleston and Chowdhury, 2015; Eddleston and Clark, 2011). Occupational exposure occurs most commonly by the dermal and pulmonary routes, while oral ingestion is most common in cases of nonoccupational poisoning.

Sources of Information

In the U.S., the EPA, by virtue of revised risk assessments and the Food Quality Protection Act of 1996, has placed several organophosphate insecticides, including diazinon and chlorpyrifos, on restricted use and phased-out status in consumer products for home and garden use. A primary concern relates to exposure in pregnancy and to infants and children because the developing nervous system may be particularly susceptible to certain of these agents (Eaton et al., 2008). The National Pesticide Information Center (<http://npic.orst.edu/>) and the Office of Pesticide Programs of the EPA (<https://www.epa.gov/pesticides>) provide continuous reviews of the status of organophosphate pesticides, their tolerance reassessments, and revisions of risk assessments through their websites.

Acute Intoxication

Acute intoxication by anti-ChE agents is manifested by muscarinic and nicotinic signs and symptoms and, except for quaternary compounds of low lipid solubility, by signs referable to the CNS. Systemic effects appear within minutes after inhalation of vapors or aerosols, while onset of symptoms is delayed after GI and percutaneous absorption. The duration of toxic symptoms is determined largely by the properties of the compound: its lipid solubility, whether it must be activated to form the oxon, the stability of the organophosphate-AChE bond, and whether “aging” of the phosphorylated enzyme has occurred.

After local exposure to vapors or aerosols or after their inhalation, ocular and respiratory effects generally appear first. Ocular manifestations include marked miosis, ocular pain, conjunctival congestion, diminished vision, ciliary spasm, and brow ache. With acute systemic absorption, miosis may not be evident due to sympathetic discharge in response to hypotension. In addition to rhinorrhea and hyperemia of the upper respiratory tract, respiratory responses consist of tightness in the chest and wheezing caused by the combination of bronchoconstriction and increased bronchial secretion. GI symptoms occur earliest after ingestion and include anorexia, nausea and vomiting, abdominal cramps, and diarrhea. With percutaneous absorption of liquid, localized sweating and muscle fasciculations in the immediate vicinity are generally the earliest symptoms. Severe intoxication is manifested by extreme salivation, involuntary defecation and urination, sweating, lacrimation, penile erection, bradycardia, and hypotension.

Nicotinic actions at the neuromuscular junctions of skeletal muscle usually consist of fatigability and generalized weakness, involuntary twitchings, scattered fasciculations, and eventually severe weakness and paralysis. The most serious consequence is paralysis of the respiratory muscles.

A broad spectrum of effects of acute AChE inhibition on the CNS includes confusion, ataxia, slurred speech, loss of reflexes, Cheyne-Stokes respiration, generalized convulsions, coma, and central respiratory paralysis. Actions on the vasomotor and other cardiovascular centers in the medulla oblongata lead to hypotension.

The time of death after a single acute exposure may range from less than 5 min to nearly 24 h, depending on the dose, route, and agent. The cause of death primarily is respiratory failure, usually accompanied by a secondary cardiovascular component. Peripheral muscarinic and nicotinic as well as central actions all contribute to respiratory compromise; effects include laryngospasm, bronchoconstriction, increased tracheobronchial and salivary secretions, and compromised voluntary control of the diaphragm and intercostal muscles. Blood pressure may fall to alarmingly low levels, and cardiac arrhythmias may result from hypoxemia.

Delayed symptoms appearing after 1–4 days and marked by persistent low blood ChE and severe muscle weakness are termed the *intermediate syndrome* (Lotti, 2002). Delayed neurotoxicity and recurrent seizures also may be evident after severe intoxication (discussed below in “*Reactivation and Disposition*”).

Diagnosis and Treatment

The diagnosis of severe, acute anti-ChE intoxication is made readily from the history of exposure and the characteristic signs and symptoms. In suspected cases of milder acute or chronic intoxication, determination of the ChE activities in erythrocytes and plasma generally will establish the diagnosis (Storm et al., 2000). Although these values vary considerably in the normal population, they usually are depressed well below the normal range before symptoms are evident.

Atropine in sufficient dosage (described further in the chapter) effectively antagonizes the actions at muscarinic receptor sites, including increased tracheobronchial and salivary secretion, bronchoconstriction, and bradycardia. Larger doses are required to get appreciable concentrations of atropine into the CNS. Atropine is virtually without effect against the peripheral neuromuscular compromise, which can be reversed by 2-PAM, a cholinesterase reactivator.

In moderate or severe intoxication with an organophosphorus anti-ChE agent, the recommended adult dose of 2-PAM is 1–2 g, slowly infused intravenously. If weakness is not relieved or if it recurs after 20–60 min, the dose should be repeated. Early treatment is important to ensure that the oxime reaches the phosphorylated AChE while the latter still can be reactivated. Many of the alkylphosphates are extremely lipid soluble, and if extensive partitioning into body fat has occurred and desulfuration is required for inhibition of AChE, toxicity will persist.

General supportive measures also are important, including

- termination of exposure, by removal of the patient or application of a gas mask if the atmosphere remains contaminated, removal and destruction of contaminated clothing, copious washing of contaminated skin or mucous membranes with water, or gastric lavage;
- maintenance of a patent airway, including endobronchial aspiration;
- artificial respiration; administration of O_2 , if required;
- alleviation of persistent convulsions with diazepam (5–10 mg IV); and
- treatment of shock.

Atropine should be given in doses sufficient to cross the blood-brain barrier. Following an initial injection of 2–4 mg, given intravenously if possible, otherwise intramuscularly, 2 mg should be given every 5–10 min until muscarinic symptoms disappear, if they reappear, or until signs of atropine toxicity appear. More than 200 mg may be required on the first day. AChE reactivating agents and mild degree of atropine block then should be maintained for as long as symptoms are evident.

Although the phosphorylated esteratic site of AChE undergoes hydrolytic regeneration at a slow or negligible rate, nucleophilic agents, such as hydroxylamine (NH_2OH), hydroxamic acids ($RCONH-OH$), and oximes ($RCH=NOH$), reactivate the enzyme more rapidly than does spontaneous hydrolysis. Froede and Wilson (1971) reasoned that selective reactivation could be achieved by a site-directed nucleophile, wherein interaction of a quaternary nitrogen with the negative subsite of the active center would place the nucleophile in close apposition to the phosphorus. The oxime is oriented proximally to exert a nucleophilic attack on the phosphorus; a phosphoryloxime is formed, leaving the regenerated enzyme (Figure 10-2E).

Several *bis*-quaternary aldioximes are even more potent as reactivators for insecticide and nerve gas poisoning; examples are obidoxime and HI-6, which are used in Europe as antidotes (Worek and Thiermann, 2013; Steinritz et al., 2016). However, these compounds do not cross the blood-brain barrier, limiting their effectiveness to peripheral nervous system sites only.

Certain phosphorylated AChEs can undergo a fairly rapid process of “aging,” so that within the course of minutes or hours they become completely resistant to the reactivators. Aging is due to the loss of one alkoxy group, leaving a much more stable monoalkyl- or

monoalkoxy-phosphoryl-AChE (Figure 10–2D and 10–2E). Organophosphorus compounds containing tertiary alkoxy groups, such as soman, are more prone to aging than are congeners containing the secondary or primary alkoxy groups. The oximes are not effective in antagonizing the toxicity of the more rapidly hydrolyzing carbamoyl ester inhibitors; since 2-PAM itself has weak anti-ChE activity, it is not recommended for the treatment of overdosage with neostigmine or physostigmine or poisoning with carbamoylating insecticides such as carbaryl.

Reactivation and Disposition

The reactivating action of oximes *in vivo* is most marked at the skeletal neuromuscular junction. Antidotal effects are less striking at autonomic effector sites, and the quaternary ammonium group restricts entry into the CNS (Eddleston et al., 2008; Eddleston and Clark, 2011).

Although high doses or accumulation of oximes can inhibit AChE and cause neuromuscular blockade, they should be given until one can be assured of clearance of the offending organophosphate. Current antidotal therapy for organophosphate exposure resulting from warfare or terrorism includes parenteral atropine, an oxime (2-PAM, HI-6 or obidoxime), and diazepam or midazolam as anticonvulsants (King and Aaron, 2015; Worek and Thiermann, 2013). The oximes and their metabolites are readily eliminated by the kidney.

Parenterally administered human butyrylcholinesterase and recombinant DNA-expressed paraoxonases and phosphotriesterases with selected mutations are under development to scavenge the organophosphate at its portal of entry or plasma before it reaches peripheral and central tissue sites (Cerasoli et al., 2005; Mata et al., 2014; Worek et al., 2014). Because scavenging by butyrylcholinesterase is stoichiometric rather than catalytic, large quantities are required, so a broad spectrum of catalytic activities from other phosphoesterases is sought. Catalytic enzyme scavengers are limited by their slow distribution from intramuscular sites; rapid scavenging by enzymes requires intravenous administration.

Certain fluorine-containing organophosphorus anti-ChE agents (e.g., DFP, mipafox) have the property of inducing delayed neurotoxicity, a property they share with the triarylphosphates, of which TOCP is the classical example. This syndrome first received widespread attention following the demonstration that TOCP, an adulterant of Jamaica ginger, was responsible for an outbreak of thousands of cases of paralysis that occurred in the U.S. during Prohibition.

The clinical picture is that of severe polyneuropathy manifested initially by mild sensory disturbances, ataxia, weakness, muscle fatigue and twitching, reduced tendon reflexes, and tenderness to palpation. In severe cases, the weakness may progress to flaccid paralysis and muscle wasting. Recovery may require several years and may be incomplete.

Toxicity from this organophosphate-induced delayed polyneuropathy is not dependent on inhibition of cholinesterases; instead, a distinct esterase, termed *neurotoxic esterase*, is linked to the lesions (Johnson, 1993). This enzyme has a specificity for hydrophobic esters, but its natural substrate and function remain unknown (Glynn, 2006; Read et al., 2009). Myopathies that result in generalized necrotic lesions and changes in end-plate cytostructure also are found in experimental animals after long-term exposure to organophosphates (De Bleeker et al., 1991).

Therapeutic Uses of AChE Inhibitors

Current use of anti-AChE agents is limited to four conditions in the periphery:

- atony of the smooth muscle of the intestinal tract and urinary bladder
- glaucoma
- myasthenia gravis
- reversal of the paralysis of competitive neuromuscular blocking drugs

Long-acting and hydrophobic ChE inhibitors are the only inhibitors with well-documented efficacy, albeit limited, in the treatment of dementia symptoms of Alzheimer disease. Physostigmine, with its shorter duration of action, is used to treat intoxication by atropine and several

drugs with anticholinergic side effects (discussed further in the chapter); it also is indicated for the treatment of Friedreich or other inherited ataxias. Edrophonium has been used for terminating attacks of paroxysmal supraventricular tachycardia.

Available Therapeutic Agents

The compounds described here are those commonly used as anti-ChE drugs and ChE reactivators in the U.S. Preparations used solely for ophthalmic purposes are described in Chapter 69. Conventional dosages and routes of administration are given in the further discussion of therapeutic applications.

Physostigmine salicylate is available for injection. Physostigmine sulfate ophthalmic ointment and physostigmine salicylate ophthalmic solution also are available. Pyridostigmine bromide is available for oral or parenteral use. Neostigmine bromide is available for oral use. Neostigmine methylsulfate is marketed for parenteral injection. Ambenonium chloride is available for oral use. Tacrine, donepezil, rivastigmine, and galantamine have been approved for the treatment of Alzheimer disease.

Pralidoxime chloride is the only AChE reactivator currently available in the U.S. and can be obtained in a parenteral formulation. HI-6 is available in several European and Near Eastern countries.

AMBENONIUM

PRALIDOXIME (2-PAM)

Paralytic Ileus and Atony of the Urinary Bladder

In the treatment of both paralytic ileus and urinary bladder atony, neostigmine generally is preferred among the anti-ChE agents. Directly acting muscarinic agonists (Chapter 9) are employed for the same purposes.

Neostigmine is used for the relief of abdominal distension and acute colonic pseudo-obstruction from a variety of medical and surgical causes (Ponec et al., 1999). The usual subcutaneous dose of neostigmine methylsulfate for postoperative paralytic ileus is 0.5 mg, given as needed. Peristaltic activity commences 10–30 min after parenteral administration, whereas 2–4 h are required after oral administration of neostigmine bromide (15–30 mg). It may be necessary to assist evacuation with a small low enema or gas with a rectal tube.

When neostigmine is used for the treatment of atony of the detrusor muscle of the urinary bladder, postoperative dysuria is relieved. The drug is used in a similar dose and manner as in the management of paralytic ileus. Neostigmine should not be used when the intestine or urinary bladder is obstructed, when peritonitis is present, when the viability of the bowel is doubtful, or when bowel dysfunction results from inflammatory bowel disease.

Glaucoma and Other Ophthalmologic Indications

Glaucoma is a complex disease characterized by an increase in intraocular pressure that, if sufficiently high and persistent, will damage the optic disc at the juncture of the optic nerve and the retina; irreversible blindness can result. Of the three types of glaucoma—primary, secondary, and congenital—anti-AChE agents are of value in the management of the primary as well as of certain categories of the secondary type (e.g., aphakic glaucoma, following cataract extraction); congenital glaucoma rarely responds to any therapy other than surgery. Primary glaucoma is

subdivided into narrow-angle (acute congestive) and wide-angle (chronic simple) types, based on the configuration of the angle of the anterior chamber where the aqueous humor is reabsorbed.

Narrow-angle glaucoma is nearly always a medical emergency in which drugs are essential in controlling the acute attack, but the long-range management is often surgical (e.g., peripheral or complete iridectomy). Wide-angle glaucoma, on the other hand, has a gradual, insidious onset and is not generally amenable to surgical improvement; in this type, control of intraocular pressure usually is dependent on continuous drug therapy.

Because the cholinergic agonists and ChE inhibitors also block accommodation and induce myopia, these agents produce transient blurring of far vision, limited visual acuity in low light, and loss of vision at the margin when instilled in the eye. With long-term administration of the cholinergic agonists and anti-ChE agents, the compromise of vision diminishes. Nevertheless, other agents without these side effects, such as prostaglandin analogues, β adrenergic receptor antagonists, and carbonic anhydrase inhibitors, have become the primary topical therapies for open-angle glaucoma. AChE inhibitors are held in reserve for the chronic conditions when patients become refractory to the agents mentioned. Topical treatment with long-acting ChE inhibitors such as echothiophate give rise to symptoms characteristic of systemic ChE inhibition. (For a complete account of the use of anti-ChE agents in ocular therapy, see Chapter 69).

Myasthenia Gravis

Myasthenia gravis is a neuromuscular disease of complex genetic etiology characterized by exacerbations and remissions of weakness and marked fatigability of skeletal muscle (Drachman, 1994; Renton et al., 2015).

The relative importance of prejunctional and postjunctional defects in myasthenia gravis was unknown until Patrick and Lindstrom (1973) found that rabbits immunized with nicotinic receptor slowly developed muscular weakness and respiratory difficulties that resembled the symptoms of myasthenia gravis. This animal model prompted intense investigation into whether the natural disease represented an autoimmune response directed toward the ACh receptor. Antireceptor antibodies are detectable in sera of 90% of patients with the disease, although the clinical status of the patient does not correlate precisely with antibody titers (Drachman, 1994). Sequences and the structural location in the α_1 subunit constituting the main immunogenic region are well defined (Lindstrom, 2008).

The picture that emerges is that myasthenia gravis is caused by an autoimmune response primarily to the ACh receptor at the postjunctional end plate. These antibodies reduce the number of receptors detectable either by snake α -neurotoxin-binding assays (Fambrough et al., 1973) or by electrophysiological measurements of ACh sensitivity (Drachman, 1994). Immune complexes along with marked ultrastructural abnormalities appear in the synaptic cleft and enhance receptor degradation through complement-mediated lysis in the end plate.

In a subset of about 10% of patients presenting with a myasthenic syndrome, muscle weakness has a congenital rather than an autoimmune basis. Characterization of biochemical and genetic bases of the congenital condition has demonstrated mutations in the ACh receptor that affect ligand-binding, channel-opening kinetics and durations; receptor biosynthesis; and synaptic location of receptors (Engel et al., 2012; Sine and Engel, 2006). Other mutations occur as a deficiency in the form of AChE that contains the collagen-like tail unit, in presynaptic transporters involved in the uptake of choline, and in vesicular storage of ACh. In this group of patients, identification of the mutation is essential for ascertaining whether a specific pharmacologic treatment is warranted.

Diagnosis

Although the diagnosis of autoimmune myasthenia gravis usually can be made from the history, signs, and symptoms, its differentiation from certain neurasthenic, infectious, endocrine, congenital, neoplastic, and degenerative neuromuscular diseases can be challenging. However, in autoimmune myasthenia gravis, the aforementioned deficiencies and enhancement of muscle strength can be improved dramatically by anti-ChE medication. The edrophonium test for initial diagnosis relies on these

responses. The edrophonium test is performed by rapid intravenous injection of 2 mg of edrophonium chloride, followed 45 sec later by an additional 8 mg if the first dose is without effect. A positive response consists of brief improvement in strength, unaccompanied by lingual fasciculation (which generally occurs in nonmyasthenic patients).

An excessive dose of an anti-ChE drug results in a *cholinergic crisis*. The condition is characterized by weakness resulting from generalized depolarization of the motor end plate; other features result from overstimulation of muscarinic receptors. The weakness resulting from depolarization blockade may resemble myasthenic weakness, which is manifest when anti-ChE medication is insufficient. The distinction is of obvious practical importance because the former is treated by withholding, and the latter by administering, the anti-ChE agent. Detection of antireceptor antibodies in muscle biopsies or plasma is now widely employed to establish the diagnosis.

Treatment of Myasthenia Gravis

Pyridostigmine, neostigmine, and ambenonium are the standard anti-ChE drugs used in the symptomatic treatment of myasthenia gravis. All can increase the response of myasthenic muscle to repetitive nerve impulses, primarily by the preservation of endogenous ACh. Following AChE inhibition, receptors over a greater cross-sectional area of the end plate presumably are exposed to concentrations of ACh that are sufficient for channel opening and production of a postsynaptic end-plate potential.

Unpredictable exacerbations and remissions of the myasthenic state may require adjustment of dosage. Pyridostigmine is available in sustained-release tablets containing a total of 180 mg, of which 60 mg are released immediately and 120 mg are released over several hours; this preparation is of value in maintaining patients for 6- to 8-h periods but should be limited to use at bedtime. Muscarinic cardiovascular and GI side effects of anti-ChE agents generally can be controlled by atropine or other anticholinergic drugs (Chapter 9). However, these anticholinergic drugs mask many side effects of an excessive dose of an anti-ChE agent. In most patients, tolerance develops eventually to the muscarinic effects. Several drugs, including curariform agents and certain antibiotics and general anesthetics, interfere with neuromuscular transmission (Chapter 11); their administration to patients with myasthenia gravis requires proper adjustment of anti-ChE dosage and other precautions.

Other therapeutic measures are essential elements in the management of this disease. Glucocorticoids promote clinical improvement in a high percentage of patients. However, when treatment with steroids is continued over prolonged periods, a high incidence of side effects may result (Chapter 46). Initiation of steroid treatment augments muscle weakness; however, as the patient improves with continued administration of steroids, doses of anti-ChE drugs can be reduced (Drachman, 1994). Other immunosuppressive agents, such as azathioprine and cyclosporine and high-dose cyclophosphamide (Drachman et al., 2008), have also been beneficial in more refractory cases (Chapter 35). Thymectomy should be considered in myasthenia associated with a thymoma or when the disease is not controlled adequately by anti-ChE agents and steroids. Because the thymus contains myoid cells with nicotinic receptors (Schluep et al., 1987), and a predominance of patients have thymic abnormalities, the thymus may be responsible for the initial pathogenesis. It also is the source of autoreactive T-helper cells.

Alzheimer Disease

A deficiency of intact cholinergic neurons, particularly those extending from subcortical areas such as the nucleus basalis, has been observed in patients with progressive dementia of the Alzheimer type (Chapter 18). Using a rationale similar to that in other CNS degenerative diseases, therapy for enhancing concentrations of cholinergic and other neurotransmitters in the CNS has been investigated.

In 1993, the FDA approved tacrine (tetrahydroaminoacridine) for use in mild-to-moderate Alzheimer disease, but a high incidence of enhanced alanine aminotransferase and hepatotoxicity limited the utility of this drug.

Subsequently, donepezil was approved for clinical use and has emerged as the primary agent for treatment in multiple countries (Lee et al., 2015).

Initially, 5-mg doses are administered daily, and if tolerated, doses are increased to 10 mg for mild-to-moderate conditions. Recent clinical trials in moderate-to-severe Alzheimer disease have confirmed benefits for a 23-mg/d sustained release form. Most studies are carried out for periods of 24 weeks, although treatment periods have been extended, usually extending the treatment baseline, but without further improvement or some decline after 6 months. Adverse side effects have been attributed to excessive peripheral cholinergic stimulation and include nasopharyngitis, diarrhea, nausea, and vomiting. Rhabdomyolysis reportedly occurs, requiring discontinuation of the drug. Cotreatment with memantine did not result in significant improvement over the higher-dose donepezil treatment (Howard et al., 2012).

Rivastigmine, a more lipid soluble, longer-acting carbamylating inhibitor, is approved for use in the U.S. and Europe in both oral and skin patch forms. While having similar side effects to other cholinesterase inhibitors, rivastigmine is reported to have shown a higher incidence of fatalities than other cholinesterase inhibitors used in Alzheimer dementias (Ali et al., 2015). It has not been determined whether the increase relates to misuse of the transdermal form of administration. Galantamine is another FDA-approved agent for Alzheimer dementias, acting as a reversible AChE inhibitor with a side-effect profile similar to that of donepezil.

These three cholinesterase inhibitors, which have the requisite affinity and hydrophobicity to cross the blood-brain barrier and exhibit a prolonged duration of action, along with an excitatory amino acid transmitter mimic, memantine, constitute current modes of therapy. These agents are not disease modifying and lack well-documented actions on the pathology of Alzheimer disease. However, the bulk of the evidence indicates that they slow the decline in cognitive function and behavioral manifestation for limited intervals of time (Chapter 18). Associated symptoms, such as depression, may be preferentially delayed (Lu et al., 2009). Current clinical research efforts are directed to synergistic actions of arresting inflammatory processes or neurodegeneration and combining cholinesterase inhibition with selective cholinergic receptor modulation.

Prophylaxis in Cholinesterase Inhibitor Poisoning

Studies in experimental animals have shown that pretreatment with pyridostigmine reduces the incapacitation and mortality associated with nerve agent poisoning, particularly for agents such as soman that show rapid

aging. The first large-scale administration of pyridostigmine to humans occurred in 1990 in anticipation of nerve agent attack in the first Gulf War. At an oral dose of 30 mg every 8 h, the incidence of side effects was around 1%; fewer than 0.1% of the subjects had responses sufficient to warrant discontinuing the drug in the setting of military action (Keeler et al., 1991). Long-term follow-up indicates that veterans of the Gulf War who received pyridostigmine showed a low incidence of a neurologic syndrome, now termed the *Persian Gulf War syndrome*. It is characterized by impaired cognition, ataxia, confusion, myoneuropathy, adenopathy, weakness, and incontinence (Haley et al., 1997).

Controversy still surrounds the basis of Gulf War syndrome or illness, despite multiple reports and reviews by the U.S. Department of Veterans Affairs in 2008 and 2010 and the Institute of Medicine (Committee on Gulf War and Health, 2013; Institute of Medicine, 2013). Although several origins of the syndrome, such as pyridostigmine administration, have been ruled out as unlikely, the constellation of symptoms reflect an interplay of chemical toxicants and psychological factors, encompassing widespread pesticide use, and exposure from postwar demolition bombing of munitions facilities likely containing chemical warfare agents (sarin and mustards). Psychological factors, emerging as post-traumatic stress disorders, have been documented in prolonged wars since the early 20th century.

Intoxication by Anticholinergic Drugs

In addition to atropine and other muscarinic agents, many other drugs, such as the phenothiazines, antihistamines, and tricyclic antidepressants, have central and peripheral anticholinergic activity. Physostigmine is potentially useful in reversing the central anticholinergic syndrome produced by overdose or an unusual reaction to these drugs (Nilsson, 1982). While the effectiveness of physostigmine in reversing anticholinergic side effects has been documented, other toxic effects of the tricyclic antidepressants and phenothiazines (Chapters 15 and 16), such as intraventricular conduction deficits and ventricular arrhythmias, are not reversed by physostigmine. In addition, physostigmine may precipitate seizures; hence, its usually small potential benefit must be weighed against this risk. The use of anti-ChE agents to reverse the effects of competitive neuromuscular blocking agents is discussed in Chapter 11.

Drug Facts for Your Personal Formulary: Anticholinesterase Agents

Drugs	Therapeutic Uses	Major Toxicity and Clinical Pearls
Noncovalent Reversible Inhibitors		
Edrophonium Tacrine Donepezil Propidium Fasciculn Galantamine	<ul style="list-style-type: none"> Edrophonium can be used to diagnose myasthenia gravis Tacrine, donepezil and galantamine used for Alzheimer disease 	<ul style="list-style-type: none"> Edrophonium and tacrine: bind reversibly to choline subsite near Trp86 and Glu202 Edrophonium has a short duration of action because of rapid renal elimination; effects are limited to the peripheral nervous system. Donepezil and tacrine: higher affinity for AChE, more hydrophobic, can cross BBB. Tacrine: high incidence of hepatotoxicity Donepezil binds with higher affinity to the active center gorge of AChE. Propidium & fasciculn: bind peripheral anionic site on AChE
Carbamate Inhibitors		
"Reversible" Carbamate Inhibitors Physostigmine Neostigmine Pyridostigmine Ambenonium Rivastigmine	<ul style="list-style-type: none"> Pyridostigmine, neostigmine and ambenonium are used for treatment of myasthenia gravis Neostigmine is used for paralytic ileus and atony of the urinary bladder Rivastigmine, a very lipid soluble alternative for treating Alzheimer disease Pyridostigmine used prophylactically in nerve gas attacks 	<ul style="list-style-type: none"> Drugs with carbamoyl ester linkage: AChE substrates that block by carbamylation of AChE active center serine, are hydrolyzed slowly; regarded as hemi-substrate blockers Neostigmine and pyridostigmine are poorly absorbed after oral administration Pyridostigmine: available in sustained release tablets; oral dose much higher than parenteral dose Rivastigmine can cross the BBB, has longer duration of action, and is available in oral and epidermal patch formulations

Drug Facts for Your Personal Formulary: Anticholinesterase Agents (continued)

Drugs	Therapeutic Uses	Major Toxicity and Clinical Pearls
Carbamate Inhibitors		
Carbamate insecticides Carbaryl Propoxur Aldicarb	<ul style="list-style-type: none"> Garden insecticides 	<ul style="list-style-type: none"> Symptoms of poisoning resemble those of organophosphates but are more readily reversed and less toxic
Organophosphates		
Echothiophate	<ul style="list-style-type: none"> Treatment of glaucoma 	<ul style="list-style-type: none"> Instilled locally in the eye Stable in aqueous solution
Nerve Agents DFP Tabun Sarin Soman Cyclosarin VX	<ul style="list-style-type: none"> Alkylphosphates are the most potent synthetic toxins React covalently with the active site serine Potent and irreversible inactivators of ChE Recent documented use in terrorism 	<ul style="list-style-type: none"> Form a stable conjugate with the active site serine by phosphorylation/phosphorylation Hydrolyzed by hepatic carboxylesterases and paraoxonases Low MW, hydrophobic, rapidly penetrates into CNS from pulmonary inhalation Tabun, sarin, and cyclosarin are volatile and extremely toxic "nerve gases" VX is absorbed through the skin, has slower onset, but high toxicity 2-PAM and related aldoximes are used to reactivate organophosphate-ChE conjugates Resistance to organophosphate-AChE reactivation is enhanced through "aging" that results from loss of one alkyl group
Pesticides Parathion Methylparathion Malathion Diazinon Chlorpyrifos	<ul style="list-style-type: none"> Insecticides largely agricultural Malathion is used topically in the treatment of pediculosis in cases of permethrin resistance Lethal dose of malathion in mammals is 1g/kg Diazinon and chlorpyrifos are used widely in agriculture 	<ul style="list-style-type: none"> Metabolism of these <i>thion</i> pesticides to the corresponding <i>oxon</i> confers pesticide activity and toxicity, more rapid rate in insects Malathion: detoxified by plasma carboxylesterases, a detoxification reaction that is more rapid in mammals and birds than insects, yielding a further margin of safety
Antidotal therapy for Organophosphate Exposure		
Cholinesterase reactivators 2-PAM HI-6 Obidoxime	<ul style="list-style-type: none"> Quaternary pyridinium aldoxime reactivators indicated for insecticide and nerve gas poisoning Improved agents in development 	<ul style="list-style-type: none"> Reactivates organophosphate-AChE conjugate by attacking the conjugated phosphorus to form phospho-oxime and regenerate the active enzyme Dose is infused IV or IM with autoinjector; dosing should be repeated frequently Early treatment helps insure that the oxime reaches the phosphorylated enzyme prior to complete "aging" Reactivators do not cross the blood-brain barrier and do not reactivate CNS AChE
Anticholinergic agents Atropine	<ul style="list-style-type: none"> Blocks symptoms mediated through muscarinic receptors 	<ul style="list-style-type: none"> Given by parenterally in 2-4mg doses every few min until muscarinic symptoms disappear
Benzodiazepines Diazepam Midazolam	<ul style="list-style-type: none"> Minimize seizures and associated neuronal toxicity 	<ul style="list-style-type: none"> Administered parenterally post-exposure

The Nicotinic Acetylcholine Receptor

The nicotinic ACh receptor mediates neurotransmission postsynaptically at the neuromuscular junction and peripheral autonomic ganglia; in the CNS, it largely modulates release of neurotransmitters from presynaptic sites. The receptor is called the *nicotinic ACh receptor* because both the alkaloid nicotine and the neurotransmitter ACh can stimulate the receptor. Distinct subtypes of nicotinic receptors exist at the neuromuscular junction (N_m), in autonomic ganglia, and in the CNS (the neuronal form, N_n). The binding of ACh to the nicotinic ACh receptor initiates an EPP in muscle or an EPSP in peripheral ganglia by directly mediating cation influx into the postsynaptic cell (see Chapter 8).

Perspective

Classical studies of the actions of curare and nicotine defined the concept of the nicotinic ACh receptor over a century ago and made this the prototypical pharmacological receptor. By taking advantage of specialized structures that have evolved to mediate cholinergic neurotransmission and of natural toxins that block motor activity, nicotinic receptors were isolated and characterized. These accomplishments represent landmarks in the development of molecular pharmacology.

Cholinergic neurotransmission mediates motor activity in marine vertebrates and mammals, and a large number of peptide, terpinoid, and alkaloid toxins that block the nicotinic receptors have evolved to enhance predation or protect plant and animal species from predation (Taylor et al., 2007). Among these toxins are the α -toxins: peptides of about 7 kDa from venoms of the krait, *Bungarus multicinctus*, and varieties of the cobra, *Naja naja*. These toxins potently inhibit neuromuscular transmission, are readily radiolabeled, and provide excellent probes for the nicotinic receptor.

The electrical organs from the aquatic species of *Electrophorus* and *Torpedo* provide rich sources of nicotinic receptor; up to 40% of the surface of the electric organ's membrane is excitable and contains cholinergic receptors, in contrast to vertebrate skeletal muscle, in which motor end plates occupy 0.1% or less of the cell surface. Using the α -toxin probes, the receptor from *Torpedo* was purified, the cDNAs of the subunits were isolated, and the genes were cloned for the multiple receptor subunits from mammalian neurons and muscle (Numa et al., 1983). By simultaneously expressing various permutations of the genes that encode the individual subunits in cellular systems and then measuring binding and the electrophysiological events that result from activation by agonists, researchers have been able to correlate functional properties with details of primary

structures of the receptor subtypes (Changeux and Edelstein, 2005; Karlin, 2002; Sine et al., 2008).

Structure of Nicotinic Receptors

In vertebrates, the nicotinic receptors of skeletal muscle N_m are pentamers composed of four distinct subunits (α , β , γ , and δ) in a stoichiometric ratio of 2:1:1:1 (Changeux and Edelstein, 2005; Karlin, 2002; Unwin, 2005). In mature, innervated muscle end plates, the γ subunit is replaced by ϵ , a closely related subunit. The individual subunits are about 40% identical in their amino acid sequences. The nicotinic receptor is the prototype for other pentameric ligand-gated ion channels, which include the receptors for the inhibitory amino acids (GABA and glycine; Chapter 14) and 5HT₃ receptors (Chapter 13). Each of the subunits in the pentameric receptor has a molecular mass of 40–60 kDa. In each subunit, the amino-terminal approximately 210 residues constitute a large extracellular domain. This is followed by four domains that span the membrane; the region between TM3 and TM4 forms most of the cytoplasmic component (Figure 11–1).

The five subunits of the nicotinic ACh receptor are arranged around a pseudoaxis of symmetry to circumscribe a channel. The resulting receptor is an asymmetrical molecule (16 × 8 nm) of 290 kDa, with the bulk of the non-membrane—spanning domain on the extracellular surface. The receptor is present at high densities (10,000/ μ m²) in junctional areas (i.e., the motor end plate in skeletal muscle and the ventral surface of the *Torpedo* electrical organ). Agonist-binding sites occur at the subunit interfaces; in muscle, only two of the five subunit interfaces, $\alpha\gamma$ and $\alpha\delta$, bind ligands (Figure 11–2). Both of the subunits forming the subunit interface contribute to ligand specificity. Neuronal nicotinic N_n receptors found in ganglia and the CNS also exist as pentamers of one or more types of subunits. Subunit types α_2 through α_{10} and β_2 through β_4 are found in neuronal tissues. Although not all pentameric combinations of α and β subunits lead to functional receptors, the diversity in subunit composition is large and exceeds the capacity of ligands to distinguish subtypes on the basis of their selectivity.

Agonist-mediated changes in ion permeability occur through a cation channel intrinsic to the receptor structure. Measurements of membrane conductance demonstrate rates of ion translocation of 5×10^7 ions/s. The channel is generally nonselective among cations; while highly permeable to Na⁺, K⁺, and in some cases Ca²⁺, the majority of the current is carried by Na⁺ ions. The second of four TM α -helices in each subunit line the ion channel. The agonist-binding site is intimately coupled with the ion channel; in the N_m , simultaneous binding of two agonist molecules results in a rapid conformational change that opens the channel.

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
anti-ChE: anticholinesterase
CNS: central nervous system
EPP: end-plate potential
EPSP: excitatory postsynaptic potential
FDA: Food and Drug Administration
GABA: γ -aminobutyric acid
GI: gastrointestinal
5HT: 5-hydroxytryptamine (serotonin)
IPSP: inhibitory postsynaptic potential
M_x: muscarinic receptor subtype x (x = 1, 2, 3, 4, or 5)
N_m: nicotinic ACh receptor in skeletal muscle
N_n: nicotinic ACh receptor in neurons
NRT: nicotine replacement therapy
TM: transmembrane
VMAT2: vesicular monoamine transporter 2

Transmission at the Neuromuscular Junction

Neuromuscular Blocking Agents

Modern-day neuromuscular blocking agents fall generally into two classes, depolarizing and competitive/nondepolarizing. At present, only a single depolarizing agent, succinylcholine, is in general clinical use; multiple competitive or nondepolarizing agents are available (see Figure 11-3). Neuromuscular blocking agents are most commonly used for facilitating endotracheal intubation and to relax skeletal muscle during surgery.

Chemistry

Early structure-activity studies led to the development of the polymethylene bis-trimethyl-ammonium series (referred to as the methonium compounds, or depolarizing blockers). The most potent of these agents at the neuromuscular junction was the compound with 10 carbon atoms between the quaternary nitrogens: decamethonium (Figure 11-3). The compound with 6 carbon atoms in the chain, hexamethonium, was

HISTORY Curare

In the mid-19th century, Claude Bernard demonstrated that the locus of action of curare was at or near the neuromuscular junction. Curare is a generic term for various South American arrow poisons. The drug has been used for centuries by Indians along the Amazon and Orinoco Rivers for immobilizing and paralyzing wild animals used for food; death results from paralysis of skeletal muscles. The preparation of curare was long shrouded in mystery and was entrusted only to tribal witch doctors. Soon after the discovery of the American continent, European explorers and botanists became interested in curare, and late in the 16th century, samples of the native preparations were brought to Europe. Following the pioneering work of scientist/explorer von Humboldt in 1805, the botanical sources of curare became the object of much field research. The curares from eastern Amazonia come from *Strychnos* species; these and other South American species of *Strychnos* contain chiefly quaternary neuromuscular blocking alkaloids. The Asiatic, African, and Australian species nearly all contain tertiary strychnine-like alkaloids.

Research on curare was accelerated by the work of Gill, who, after prolonged and intimate study of the native methods of preparing curare, brought to the U.S. a sufficient amount of the authentic drug to permit chemical and pharmacological investigations. The modern clinical use of curare apparently dates from 1932, when West employed highly purified fractions in patients with tetanus and spastic disorders. King established the essential structure of tubocurarine in 1935 (Figure 11-3). Griffith and Johnson reported the first trial of curare for promoting muscular relaxation in general anesthesia in 1942.

found to be essentially devoid of neuromuscular blocking activity but particularly effective as a ganglionic blocking agent (see following discussion).

Several structural features distinguish competitive and depolarizing neuromuscular blocking agents. The competitive agents (e.g., tubocurarine, the benzyloisoquinolines, the amino steroids, and the asymmetric mixed-onium chlorofumarates) are relatively bulky, rigid molecules, whereas the depolarizing agents (e.g., decamethonium [no longer marketed in the U.S.] and succinylcholine) generally have more flexible structures that enable free bond rotations. While the distance between

Figure 11-1 Subunit organization of pentameric ligand-gated ion channels and the ACh-binding protein. For each subunit of these pentameric receptors, the amino-terminal region of about 210 amino acids is found at the extracellular surface. It is then followed by four hydrophobic regions that span the membrane (TM1–TM4), leaving the small carboxyl terminus on the extracellular surface. The TM2 region is α -helical, and TM2 regions from each subunit of the pentameric receptor line the internal pore of the receptor. Two disulfide loops at positions 128–142 and 192–193 are found in the α subunit of the nicotinic receptor. The 128–142 motif is conserved in the family of receptors, whereas the vicinal cysteines at 192 and 193 distinguish α subunits and the ACh-binding protein from β , γ , δ , and ϵ in the nicotinic receptor.

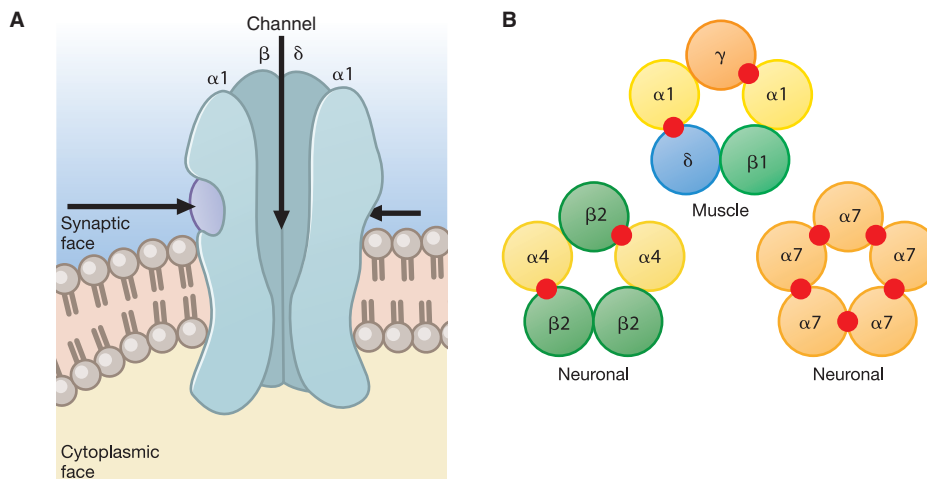

Figure 11-2 Subunit arrangement and molecular structure of the nicotinic ACh receptor. **A.** Longitudinal view of receptor schematic with the γ subunit removed. The remaining subunits, two copies of α , one of β , and one of δ , are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α -helices with slightly bowed structures form the perimeter of the channel and come from the TM2 region of the linear sequence (Figure 11-1). ACh-binding sites, indicated by red arrows, occur at the $\alpha\gamma$ and $\alpha\delta$ (not visible) interfaces. **B.** Nicotinic receptor subunit arrangement, with examples of subunit assembly. Agonist binding sites (red circles) occur at α subunit-containing interfaces. A total of 17 functional receptor isoforms have been observed in vivo, with different ligand specificity, relative $\text{Ca}^{2+}/\text{Na}^{+}$ permeability, and physiological function as determined by their subunit composition. The only isoform found at the neuromuscular junction is that shown here. There are 16 neuronal receptor isoforms found at autonomic ganglia and in the CNS, homo- and heteropentamers of α ($\alpha 2$ – $\alpha 10$) and β ($\beta 2$ – $\beta 4$) subunits.

quaternary groups in the flexible depolarizing agents can vary up to the limit of the maximal bond distance (1.45 nm for decamethonium), the distance for the rigid competitive blockers is typically 1.0 ± 0.1 nm.

Mechanism of Action

Competitive antagonists bind the N_m and thereby competitively block the binding of ACh. The depolarizing agents, such as succinylcholine, depolarize the membrane by opening channels in the same manner as ACh. However, they persist longer at the neuromuscular junction primarily because of their resistance to AChE. The depolarization is thus longer lasting, resulting in a brief period of repetitive excitation that may elicit transient and repetitive muscle excitation (fasciculations), followed by blocking of neuromuscular transmission and flaccid paralysis (called *phase I block*). The block arises because, after an initial opening, perijunctional Na^{+} channels close and will not reopen until the end plate is repolarized. At this point, neural release of ACh results in the binding of ACh to receptors on an already-depolarized end plate. These closed perijunctional channels keep the depolarization signal from affecting downstream channels and effectively shield the rest of the muscle from activity at the motor end plate. This sequence is influenced by such factors as the anesthetic agent used concurrently, the type of muscle, and the rate of drug administration. The characteristics of depolarization and competitive blockade are contrasted in Table 11-1.

Under clinical conditions, with increasing concentrations of succinylcholine and over time, the block may convert slowly from a depolarizing phase I block to a nondepolarizing *phase II block* (Durant and Katz, 1982). While the response to peripheral stimulation during phase II block resembles that of the competitive agents, reversal of phase II block by administration of anti-AChE agents (e.g., with neostigmine) is difficult to predict and should be undertaken cautiously. The characteristics of phase I and phase II blocks are shown in Table 11-2.

Many drugs and toxins block neuromuscular transmission by other mechanisms, such as interference with the synthesis or release of ACh (Figure 8-6), but most of these agents are not employed clinically for neuromuscular blockade. One exception is the group of botulinum toxins, which are administered locally into muscles of the orbit in the management of ocular blepharospasm and strabismus and have been used to control other muscle spasms and to facilitate facial muscle relaxation (Table 8-7 and Chapter 70). This toxin also has been injected into the lower esophageal sphincter to treat achalasia (Chapter 50). The sites of

action and interrelationship of several agents that serve as pharmacological tools are shown in Figure 11-4.

Sequence and Characteristics of Paralysis

Following intravenous injection of an appropriate dose of a *competitive blocking agent*, motor weakness progresses to total flaccid paralysis. Small, rapidly moving muscles such as those of the eyes, jaw, and larynx relax before those of the limbs and trunk. Ultimately, the intercostal muscles and finally the diaphragm are paralyzed, and respiration then ceases. Recovery of muscles usually occurs in the reverse order to that of their paralysis, and thus the diaphragm ordinarily is the first muscle to regain function (Naguib et al., 2015).

After a single intravenous dose (10–30 mg) of the *depolarizing blocking agent* succinylcholine, muscle fasciculations, particularly over the chest and abdomen, occur briefly; then, relaxation occurs within 1 min, becomes maximal within 2 min, and generally disappears within 5 min. Transient apnea usually occurs at the time of maximal effect. Muscle relaxation of longer duration is achieved by continuous intravenous infusion. After infusion is discontinued, the effects of the drug usually disappear rapidly because of its efficient hydrolysis by plasma and hepatic butyrylcholinesterase. Muscle soreness may follow the administration of succinylcholine.

During prolonged depolarization, muscle cells may lose significant quantities of K^{+} and gain Na^{+} , Cl^{-} , and Ca^{2+} . In patients with extensive injury to soft tissues, the efflux of K^{+} following continued administration of succinylcholine can be life threatening. There are many conditions for which succinylcholine administration is contraindicated or should be undertaken with great caution. The change in the nature of the blockade produced by succinylcholine (from phase I to phase II) presents an additional complication with long-term infusions.

Effects in CNS and at Ganglia

Tubocurarine and other quaternary neuromuscular blocking agents are virtually devoid of central effects following ordinary clinical doses because of their inability to penetrate the blood-brain barrier.

Neuromuscular blocking agents show variable potencies in producing ganglionic blockade. Ganglionic blockade by tubocurarine and other stabilizing drugs is reversed or antagonized by anti-ChE agents (e.g., edrophonium, neostigmine, pyridostigmine, etc.).

Clinical doses of tubocurarine produce partial blockade both at autonomic ganglia and at the adrenal medulla, resulting in a fall in blood

pressure and tachycardia. Pancuronium shows less ganglionic blockade at common clinical doses. Atracurium, vecuronium, doxacurium, pipecuronium, mivacurium, and rocuronium are even more selective, showing less ganglionic blockade (Naguib et al., 2015). The maintenance of cardiovascular reflex responses usually is desired during anesthesia. Pancuronium has a vagolytic action, presumably from blockade of muscarinic receptors, which leads to tachycardia.

Of the depolarizing agents, succinylcholine at doses producing neuromuscular relaxation rarely causes effects attributable to ganglionic blockade. However, cardiovascular effects are sometimes observed, probably owing to the successive stimulation of vagal ganglia (manifested by

bradycardia) and sympathetic ganglia (resulting in hypertension and tachycardia).

ADME

Quaternary ammonium neuromuscular blocking agents are poorly absorbed from the GI tract. Absorption is adequate from intramuscular sites. Rapid onset is achieved with intravenous administration. The more potent agents must be given in lower concentrations, and diffusional requirements slow their rate of onset.

When long-acting competitive blocking agents such as D-tubocurarine and pancuronium are administered, blockade may diminish after 30 min

TABLE 11-1 ■ COMPARISON OF COMPETITIVE (D-TUBOCURARINE) AND DEPOLARIZING (DECAMETHONIUM) BLOCKING AGENTS

	D-TUBOCURARINE	DECAMETHONIUM
Effect of D-tubocurarine administered previously	Additive	Antagonistic
Effect of decamethonium administered previously	No effect or antagonistic	Some tachyphylaxis, but may be additive
Effect of anticholinesterase agents on block	Reversal of block	No reversal
Effect on motor end plate	Elevated threshold to acetylcholine; no depolarization	Partial, persisting depolarization
Initial excitatory effect on striated muscle	None	Transient fasciculations
Character of muscle response to indirect tetanic stimulation during <i>partial</i> block	Poorly sustained contraction	Well-sustained contraction

TABLE 11-2 ■ CLINICAL RESPONSES AND MONITORING OF PHASE I AND PHASE II NEUROMUSCULAR BLOCKADE BY SUCCINYLCHOLINE INFUSION

RESPONSE	PHASE I	PHASE II
End-plate membrane potential	Depolarized to -55 mV	Repolarization toward -80 mV
Onset	Immediate	Slow transition
Dose dependence	Lower	Usually higher or follows prolonged infusion
Recovery	Rapid	More prolonged
Train of four and tetanic stimulation	No fade	Fade ^a
Acetylcholinesterase inhibition	Augments	Reverses or antagonizes
Muscle response	Fasciculations → flaccid paralysis	Flaccid paralysis

^aPosttetanic potentiation follows fade.

owing to redistribution of the drug, yet residual blockade and plasma levels of the drug persist. Subsequent doses show diminished redistribution as tissues become saturated. Long-acting agents may accumulate with multiple doses.

The amino steroids contain ester groups that are hydrolyzed in the liver. Typically, the metabolites have about one-half the activity of the parent compound and contribute to the total relaxation profile. Amino steroids of intermediate duration of action, such as vecuronium and rocuronium (Table 11-3), are cleared more rapidly by the liver than is pancuronium. The more rapid decay of neuromuscular blockade with compounds of intermediate duration argues for sequential dosing of these agents rather than administering a single dose of a long-duration neuromuscular blocking agent.

Atracurium is converted to less-active metabolites by plasma esterases and by spontaneous degradation in plasma and tissue (Hofmann elimination). Cisatracurium is also subject to this spontaneous degradation. Because of these alternative routes of metabolism, atracurium and cisatracurium do not exhibit an increased $t_{1/2}$ of elimination in patients with impaired renal function and therefore are good choices in this setting (Fisher et al., 1986; Naguib et al., 2015).

The extremely brief duration of action of succinylcholine is due largely to its rapid hydrolysis by the butyrylcholinesterase synthesized by the liver

and found in the plasma. Among the occasional patients who exhibit prolonged apnea following the administration of succinylcholine or mivacurium, most have an atypical plasma cholinesterase or a deficiency of the enzyme owing to allelic variations, hepatic or renal disease, or a nutritional disturbance; however, in some, the enzymatic activity in plasma is normal (Naguib et al., 2015).

Gantacurium is degraded by two chemical mechanisms, a rapid cysteine adduction and a slower hydrolysis of the ester bond adjacent to the chlorine. Both processes are purely chemical and hence not dependent on enzymatic activities. The adduction process has a $t_{1/2}$ of 1–2 min and is likely the basis for the ultrashort duration of action of gantacurium. Administration of exogenous cysteine, which may have excitotoxic side effects, can accelerate the antagonism of gantacurium-induced neuromuscular blockade (Naguib and Brull, 2009).

Clinical Pharmacology

Choice of Agent

Therapeutic selection of a neuromuscular blocking agent should be based on achieving a pharmacokinetic profile consistent with the duration of the interventional procedure and minimizing cardiovascular compromise or other side effects, with attention to drug-specific modes of elimination in patients with renal or hepatic failure (see Drug Facts Table).

Two characteristics are useful in distinguishing side effects and pharmacokinetic behavior of neuromuscular blocking agents:

- **The chemical nature of the agents (Figure 11-3 and Table 11-3).** Apart from a shorter duration of action, newer agents exhibit greatly diminished frequency of side effects, chiefly ganglionic blockade, block of vagal responses, and histamine release.
- **Duration of drug action.** These agents are categorized as long-, intermediate-, short-, or ultrashort-acting agents. Often, the long-acting agents are the more potent, requiring the use of low doses (Table 11-4). The necessity of administering potent agents at low concentrations delays their onset.

The prototypical amino steroid pancuronium induces virtually no histamine release; however, it blocks muscarinic receptors, an antagonism manifested primarily by vagal blockade and tachycardia. Tachycardia is eliminated in the newer amino steroids vecuronium and rocuronium. The benzylisoquinolines appear to be devoid of vagolytic and ganglionic blocking actions but show a slight propensity to cause histamine release. The unusual metabolism of the prototype compound atracurium and its

TABLE 11-4 ■ DOSING RANGES FOR NEUROMUSCULAR BLOCKING AGENTS

AGENT	INITIATION DOSE (mg/kg)	INTERMITTENT INJECTION (mg/kg)	CONTINUOUS INFUSION (μg/kg/min)

^aNot commercially available in the U.S.^bOff-label use.

congener mivacurium confers special indications for use of these compounds. For example, atracurium's disappearance from the body depends on hydrolysis of the ester moiety by plasma esterases and by a spontaneous or Hofmann degradation (cleavage of the *N*-alkyl portion in the benzylisoquinoline). Hence, two routes for termination of effect are available, both of which remain functional in renal failure. Mivacurium is extremely sensitive to catalysis by cholinesterase or other plasma hydrolases, accounting for its short duration of action. Side effects are not yet fully characterized for gantacurium, but transient adverse cardiovascular effects suggestive of histamine release have been observed at doses over three times the ED₉₅ (Belmont et al., 2004).

Muscle Relaxation

The main clinical use of the neuromuscular blocking agents is as an adjuvant in surgical anesthesia to obtain relaxation of skeletal muscle, particularly of the abdominal wall, to facilitate operative manipulations. With muscle relaxation no longer dependent on the depth of general anesthesia, a much lighter level of anesthesia suffices. Thus, the risk of respiratory and cardiovascular depression is minimized, and postanesthetic recovery is shortened. Neuromuscular blocking agents of short duration often are used to facilitate endotracheal intubation and have been used to facilitate laryngoscopy, bronchoscopy, and esophagoscopy in combination with a general anesthetic agent. Neuromuscular blocking agents are administered parenterally, nearly always intravenously. These agents may be administered by continuous infusion in the intensive care setting for improving chest wall compliance and eliminating ventilator dyssynchrony.

Measurement of Neuromuscular Blockade in Humans

Assessment of neuromuscular block usually is performed by stimulation of the ulnar nerve (Naguib et al., 2015). Responses are monitored from compound action potentials or muscle tension developed in the adductor pollicis (thumb) muscle. Responses to repetitive or tetanic stimuli are most useful for evaluation of blockade of transmission. Rates of onset of blockade and recovery are more rapid in the airway musculature (jaw, larynx, and diaphragm) than in the thumb. Hence, tracheal intubation can be performed before onset of complete block at the adductor pollicis, whereas partial recovery of function of this muscle allows sufficient recovery of respiration for extubation.

Preventing Trauma During Electroshock Therapy

Electroconvulsive therapy of psychiatric disorders occasionally is complicated by trauma to the patient; the seizures induced may cause dislocations or fractures. Inasmuch as the muscular component of the convulsion is not essential for benefit from the procedure, neuromuscular blocking agents, usually succinylcholine, and a short-acting barbiturate, usually methohexital, are employed.

Control of Muscle Spasms and Rigidity

Botulinum toxins and dantrolene act peripherally to reduce muscle contraction; a variety of other agents act centrally to reduce skeletal muscle tone and spasm. IncobotulinumtoxinA, onabotulinumtoxinA, abobotulinumtoxinA, and rimabotulinumtoxinB, by blocking ACh release, produce flaccid paralysis of skeletal muscle and diminished activity of parasympathetic and sympathetic cholinergic synapses. Inhibition lasts from several weeks to 3–4 months, and restoration of function requires nerve sprouting.

Originally approved for the treatment of the ocular conditions of strabismus and blepharospasm and for hemifacial spasms, botulinum toxins have been used to treat spasms and dystonias and spasms associated with the lower esophageal sphincter and anal fissures. Botulinum toxin treatments also have become a popular cosmetic procedure for those seeking a wrinkle-free face. Like the bloom of youth, the reduction of wrinkles is temporary; unlike the bloom of youth, the effect of botulinum toxin can be renewed by readministration. The FDA has issued a safety alert, warning of respiratory paralysis from unexpected spread of the toxin from the site of injection (uses are described in Chapter 70).

Dantrolene inhibits Ca²⁺ release from the sarcoplasmic reticulum of skeletal muscle by limiting the capacity of Ca²⁺ and calmodulin to activate the ryanodine receptor, RYR1. Because of its efficacy in managing

an acute attack of malignant hyperthermia (described separately in the section Adverse Effects), dantrolene has been used experimentally in the treatment of muscle rigidity and hyperthermia in neuroleptic malignant syndrome. Dantrolene is also used in treatment of spasticity and hyperreflexia. With its peripheral action, it causes generalized weakness. Thus, its use should be reserved to nonambulatory patients with severe spasticity. Hepatotoxicity has been reported with chronic use, requiring frequent liver function tests and use of the lowest possible oral dose.

Several agents, many of limited efficacy, have been used to treat spasticity involving the α -motor neurons originating in the brainstem and spinal cord. Agents that act in the CNS at either higher centers or the spinal cord to block spasms, with the objective of increasing functional capacity and relieving discomfort, include baclofen, the benzodiazepines, tizanidine, and cyclobenzaprine. A number of other agents used as muscle relaxants seem to rely on sedative properties and blockade of nociceptive pathways; this group includes carisoprodol (which is metabolized to meprobamate; see Chapter 19); metaxalone; methocarbamol; and orphenadrine. Tetrabenazine is available for treatment of the chorea associated with Huntington disease; the drug is a VMAT2 inhibitor that depletes vesicular stores of dopamine in the CNS (Chapters 8 and 18).

Synergisms and Antagonisms

The comparison of interactions between competitive and depolarizing neuromuscular blocking agents is instructive (Table 11–1) and a good test of one's understanding of the drugs' actions. In addition, many other drugs affect transmission at the neuromuscular junction and thus can affect the choice and dosage of neuromuscular blocking agent used.

Because the anti-ChE agents neostigmine, pyridostigmine, and edrophonium preserve endogenous ACh and also act at the neuromuscular junction, they have been used in the treatment of overdosage with competitive blocking agents. Similarly, on completion of the surgical procedure, many anesthesiologists employ neostigmine or edrophonium to reverse and decrease the duration of competitive neuromuscular blockade. A muscarinic antagonist (atropine or glycopyrrolate) is used concomitantly to prevent stimulation of muscarinic receptors and thereby to avoid slowing of the heart rate. Anti-ChE agents will not reverse depolarizing neuromuscular blockade and, in fact, can enhance it.

Many inhalational anesthetics exert a stabilizing effect on the post-junctional membrane and therefore potentiate the activity of competitive blocking agents. Consequently, when such blocking drugs are used for muscle relaxation as adjuncts to these anesthetics, their doses should be reduced. The rank order of potentiation is desflurane > sevoflurane > isoflurane > halothane > nitrous oxide-barbiturate-opioid or propofol anesthesia (Naguib et al., 2015).

Aminoglycoside antibiotics produce neuromuscular blockade by inhibiting ACh release from the preganglionic terminal (through competition with Ca²⁺) and to a lesser extent by noncompetitively blocking the receptor. The blockade is antagonized by Ca²⁺ salts but only inconsistently by anti-ChE agents (see Chapter 58). The tetracyclines also can produce neuromuscular blockade, possibly by chelation of Ca²⁺. Additional antibiotics that have neuromuscular blocking action, through both presynaptic and postsynaptic actions, include polymyxin B, colistin, clindamycin, and lincomycin. Ca²⁺ channel blockers enhance neuromuscular blockade produced by both competitive and depolarizing antagonists. When neuromuscular blocking agents are administered to patients receiving these agents, dose adjustments should be considered.

Miscellaneous drugs that may have significant interactions with either competitive or depolarizing neuromuscular blocking agents include trimethaphan, lithium, opioid analgesics, procaine, lidocaine, quinidine, phenelzine, carbamazepine, phenytoin, propranolol, dantrolene, azathioprine, tamoxifen, magnesium salts, corticosteroids, digitalis glycosides, chloroquine, catecholamines, and diuretics.

Adverse Effects

The important untoward responses of the neuromuscular blocking agents include prolonged apnea, cardiovascular collapse, those resulting from histamine release, and, rarely, anaphylaxis. Related factors may include alterations in body temperature; electrolyte imbalance, particularly of K⁺;

low plasma butyrylcholinesterase levels, resulting in a reduction in the rate of destruction of succinylcholine; the presence of latent myasthenia gravis or of malignant disease such as small cell carcinoma of the lung with Eaton-Lambert myasthenic syndrome; reduced blood flow to skeletal muscles, causing delayed removal of the blocking drugs; and decreased elimination of the muscle relaxants secondary to hepatic dysfunction (cisatracurium, rocuronium, vecuronium) or reduced renal function (pancuronium). Great care should be taken when administering neuromuscular blockers to dehydrated or severely ill patients. Depolarizing agents can cause rapid release of K^+ from intracellular sites; this may be a factor in production of the prolonged apnea in patients who receive these drugs while in electrolyte imbalance. Succinylcholine-induced hyperkalemia is a life-threatening complication of that drug.

Malignant Hyperthermia. Malignant hyperthermia is a potentially life-threatening event triggered by the administration of certain anesthetics and neuromuscular blocking agents. The clinical features include contracture, rigidity, and heat production from skeletal muscle, resulting in severe hyperthermia (increases of up to $1^\circ\text{C}/5\text{ min}$), accelerated muscle metabolism, metabolic acidosis, and tachycardia. Uncontrolled release of Ca^{2+} from the sarcoplasmic reticulum of skeletal muscle is the initiating event. Although the halogenated hydrocarbon anesthetics (e.g., halothane, isoflurane, and sevoflurane) and succinylcholine alone have been reported to precipitate the response, most of the incidents arise from the combination of depolarizing blocking agent and anesthetic. Susceptibility to malignant hyperthermia, an autosomal dominant trait, is associated with certain congenital myopathies, such as *central core disease*. In the majority of cases, however, no clinical signs are visible in the absence of anesthetic intervention.

Treatment entails intravenous administration of dantrolene, which blocks Ca^{2+} release from the sarcoplasmic reticulum of skeletal muscle (see previous discussion, Control of Muscle Spasms and Rigidity). Rapid cooling, inhalation of 100% O_2 , and control of acidosis should be considered adjunct therapy in malignant hyperthermia.

Respiratory Paralysis. Treatment of respiratory paralysis arising from an adverse reaction or overdose of a neuromuscular blocking agent should be by positive-pressure artificial respiration with O_2 and maintenance of a patent airway until recovery of normal respiration is ensured. With the competitive blocking agents, this may be hastened by the administration of neostigmine methylsulfate (0.5–2 mg IV) or edrophonium (10 mg IV, repeated as required up to a total of 40 mg) (Watkins, 1994). In the case of overdose, a muscarinic cholinergic antagonist (atropine or glycopyrrolate) may be added to prevent undue slowing of the heart (see Synergisms and Antagonisms).

Histamine Release From Mast Cells. Some clinical responses to neuromuscular blocking agents (e.g., bronchospasm, hypotension, excessive bronchial and salivary secretion) appear to be caused by the release of histamine. Succinylcholine, mivacurium, and atracurium cause histamine release, but to a lesser extent than tubocurarine unless administered rapidly. The amino steroids pancuronium, vecuronium, pipecuronium, and rocuronium have even less tendency to release histamine after intradermal or systemic injection (Basta, 1992; Watkins, 1994). Histamine release typically is a direct action of the muscle relaxant on the mast cell rather than anaphylaxis mediated by immunoglobulin E.

Interventional Strategies for Toxic Effects

Neostigmine effectively antagonizes only the skeletal muscular blocking action of the competitive blocking agents and may aggravate such side effects as hypotension or induce bronchospasm. In such circumstances, sympathomimetic amines may be given to support the blood pressure. Atropine or glycopyrrolate is administered to counteract muscarinic stimulation. Antihistamines are definitely beneficial to counteract the responses that follow the release of histamine, particularly when administered before the neuromuscular blocking agent.

Reversal of Effects by Chelation Therapy. Sugammadex, a modified γ -cyclodextrin, is a chelating agent specific for rocuronium and vecuronium. Sugammadex at doses greater than 2 mg/kg is able to reverse neuromuscular blockade from rocuronium within 3 min. Sugammadex clearance is markedly reduced in patients with impaired renal function,

and use of this agent should be avoided. Sugammadex is approved for clinical use in Europe but not yet in the U.S. Side effects include dysgeusia and rare hypersensitivity.

Pediatric and Geriatric Indications and Problems

Because the neuromuscular junction is not fully developed at birth, additional care must be taken in administration of neuromuscular blocking agents to infants and children. Succinylcholine is not safe for routine use in pediatric patients, and its use must be reserved for extreme emergency situations where immediate securing of the airway is necessary and other options for neuromuscular blockade are not available. Competitive blocking agents, however, are commonly used in pediatric patients; generally, dosage is similar to adults but both rate of block onset and clearance are faster. Atracurium is an exception: The dosage and duration of action are not significantly different between children older than 2 years and adults, and the same dose (0.25 to 0.5 mg/kg) can be used among these populations for tracheal intubation. Vecuronium, cisatracurium, rocuronium, and mivacurium are also commonly administered to children for short procedures where only a single intubating dose is required.

There are normal changes at the neuromuscular junction in elderly patients that may affect pharmacodynamics of neuromuscular blocking agents. With aging, the distance between the terminus of the motor neuron and the end plate increases, the end-plate invaginations become flatter, the amount of transmitter per synaptic vesicle decreases, the vesicle release probability is lower, and the density of receptors at the end plate decreases. The end result of these changes is decreased efficiency of neuromuscular transmission. General physiological changes in aging patients, including decreases in body water and muscle, increases in total body fat, and decreases in renal and hepatic function, also contribute to the action of neuromuscular blockers. The dosing of succinylcholine is not significantly altered in the geriatric population. Among the competitive blocking agents, initial dose requirements are unchanged, however, the onset of blockade is delayed in an age-related manner, and block is prolonged. For compounds dependent on the kidney, liver, or both for clearance, such as pancuronium, vecuronium, and rocuronium, plasma clearance times are prolonged by 30%–50% (Naguib et al., 2015). For compounds such as atracurium that are not dependent on hepatic or renal blood flow for their elimination, pharmacodynamics and kinetics are largely unaltered.

Ganglionic Neurotransmission

The Neural Nicotinic Receptor and Postsynaptic Potentials

Neurotransmission in autonomic ganglia involves release of ACh by preganglionic fibers and the rapid depolarization of postsynaptic membranes via the activation of neuronal nicotinic (N_n) receptors by ACh. Unlike the neuromuscular junction, ganglia do not have discrete end plates with focal localization of receptors; rather, the dendrites and nerve cell bodies contain the receptors. The characteristics of nicotinic-receptor channels of the ganglia and the neuromuscular junction are similar. There are multiple nicotinic receptor subunits (e.g., $\alpha 3$, $\alpha 5$, $\alpha 7$, $\beta 2$, and $\beta 4$) in ganglia, with $\alpha 3$ and $\beta 4$ most abundant and important. The ganglionic nicotinic ACh receptors are sensitive to classical blocking agents such as hexamethonium and trimethaphan (see discussion that follows). Measurements of single-channel conductances indicate that the characteristics of nicotinic receptor channels of the ganglia and the neuromuscular junction are similar.

Intracellular recordings from postganglionic neurons indicate that at least four different changes in postsynaptic membrane potential can be elicited by stimulation of the preganglionic nerve (Figure 11–5):

- An initial EPSP (via nicotinic receptors) that may result in an action potential
- An IPSP mediated by M_2 (G_i/G_o -coupled) muscarinic receptors
- A secondary slow EPSP mediated by M_1 (G_q/G_{11} -coupled) muscarinic receptors
- A late, slow EPSP mediated by myriad peptides

Figure 11-5 Postsynaptic potentials recorded from an autonomic postganglionic nerve cell body after stimulation of the preganglionic nerve fiber. The preganglionic nerve releases ACh onto postganglionic cells. The initial EPSP results from the inward Na^+ current (and perhaps Ca^{2+} current) through the nicotinic receptor channel. If the EPSP is of sufficient magnitude, it triggers an action potential spike, which is followed by a slow IPSP, a slow EPSP, and a late, slow EPSP. The slow IPSP and slow EPSP are not seen in all ganglia. The electrical events subsequent to the initial EPSP are thought to modulate the probability that a subsequent EPSP will reach the threshold for triggering a spike. Other interneurons, such as catecholamine-containing SIF cells, and axon terminals from sensory, afferent neurons also release transmitters, which may influence the slow potentials of the postganglionic neuron. A number of cholinergic, peptidergic, adrenergic, and amino acid receptors are found on the dendrites and soma of the postganglionic neuron and the interneurons. The preganglionic fiber releases ACh and peptides; the interneurons store and release catecholamines, amino acids, and peptides; the sensory afferent nerve terminals release peptides. The initial EPSP is mediated through nicotinic (N_n) receptors, the slow IPSP and EPSP through M_2 and M_1 muscarinic receptors, and the late, slow EPSP through several types of peptidergic receptors.

An action potential is generated in the postganglionic neuron when the initial EPSP achieves a threshold potential. The events that follow the initial depolarization (IPSP; slow EPSP; late, slow EPSP) are insensitive to hexamethonium or other N_n antagonists. Electrophysiological and neurochemical evidence suggests that catecholamines participate in the generation of the IPSP. Dopamine and norepinephrine cause hyperpolarization of ganglia; however, in some ganglia IPSPs are mediated by M_2 muscarinic receptors.

The slow EPSP is generated by ACh activation of M_1 muscarinic receptors and is blocked by atropine and M_1 -selective antagonists (see Chapter 9). The slow EPSP has a longer latency and greater duration (10–30 sec) than the initial EPSP. Slow EPSPs result from decreased K^+ conductance, the *M* current that regulates the sensitivity of the cell to repetitive fast-depolarizing events. By contrast, the late, slow EPSP lasts for several minutes and is mediated by peptides released from presynaptic nerve endings or interneurons in specific ganglia (see next section). The peptides and ACh may be coreleased at the presynaptic nerve terminals; the relative stability of the peptides in the ganglion extends its sphere of influence to postsynaptic sites beyond those in the immediate proximity of the nerve ending.

Secondary synaptic events modulate the initial EPSP. A variety of peptides, including gonadotropin-releasing hormone, substance P, angiotensin, calcitonin gene-related peptide, vasoactive intestinal polypeptide, neuropeptide Y, and enkephalins, have been identified in ganglia by immunofluorescence. They appear localized to particular cell bodies, nerve fibers, or small, intensely fluorescent (SIF) cells; are released on nerve stimulation; and are presumed to mediate the late, slow EPSP. Other neurotransmitter substances (e.g., 5HT and GABA) can modify ganglionic transmission.

Ganglionic Stimulating Agents

Drugs that stimulate N_n cholinergic receptors on autonomic ganglia have been essential for analyzing the mechanism of ganglionic function; however, these ganglionic agonists have limited therapeutic use. They can be grouped into two categories. The first group consists of drugs with specificities similar to nicotine: lobeline, tetramethylammonium, and dimethylphenylpiperazinium. Nicotine's excitatory effects on ganglia are rapid in onset, are blocked by ganglionic nicotinic-receptor antagonists, and mimic the initial EPSP. The second group consists of muscarinic receptor agonists such as muscarine, McN-A-343, and methacholine (see Chapter 9); their excitatory effects on ganglia are delayed in onset, blocked by atropine-like drugs, and mimic the slow EPSP.

Nicotine

Nicotine is of considerable medical significance because of its toxicity, presence in tobacco, and propensity for conferring dependence on its users. The chronic effects of nicotine and the untoward effects of the chronic use of tobacco are considered in Chapter 24. Nicotine is one of the few natural liquid alkaloids. It is a colorless, volatile base ($\text{pK}_a = 8.5$) that turns brown and acquires the odor of tobacco on exposure to air.

Mechanism of Action. In addition to the actions of nicotine on a variety of neuroeffector and chemosensitive sites, the alkaloid can both stimulate and desensitize receptors, making nicotine's effects complex and unpredictable. The ultimate response of any one system represents the summation of stimulatory and inhibitory effects of nicotine. Nicotine can increase heart rate by excitation of sympathetic ganglia or by paralysis of parasympathetic cardiac ganglia, and it can slow heart rate by paralysis of sympathetic or stimulation of parasympathetic cardiac ganglia. The effects of the drug on the chemoreceptors of the carotid and aortic bodies and on regions of the CNS also can influence heart rate, as can the compensatory baroreceptor reflexes resulting from changes in blood pressure caused by nicotine. Finally, nicotine can stimulate secretion of epinephrine from the adrenal medulla, which accelerates heart rate and raises blood pressure.

Effects on Physiological Systems

Peripheral Nervous System. The major action of nicotine consists initially of transient stimulation and then a more persistent depression of all autonomic ganglia. Small doses of nicotine stimulate the ganglion cells directly and may facilitate impulse transmission. Following larger doses, the initial stimulation is followed by a blockade of transmission. Whereas stimulation of the ganglion cells coincides with their depolarization, depression of transmission by adequate doses of nicotine occurs both during the depolarization and after it has subsided. Nicotine also possesses a biphasic action on the adrenal medulla: Small doses evoke the discharge of catecholamines; larger doses prevent their release in response to splanchnic nerve stimulation.

The effects of high doses of nicotine on the neuromuscular junction are similar to those on ganglia. However, the stimulant phase is obscured largely by the rapidly developing paralysis. In the latter stage, nicotine also produces neuromuscular blockade by receptor desensitization. At lower concentrations, such as those typically achieved by recreational tobacco use (~200 nM), nicotine's effects reflect its higher affinity for a neuronal nicotinic receptor ($\alpha 4\beta 2$) than for the neuromuscular junction receptor ($\alpha 1\beta 1\gamma\delta$) (Xiu et al., 2009).

Nicotine, like ACh, stimulates a number of sensory receptors. These include mechanoreceptors that respond to stretch or pressure of the skin, mesentery, tongue, lung, and stomach; chemoreceptors of the carotid body; thermal receptors of the skin and tongue; and pain receptors. Prior administration of hexamethonium prevents stimulation of the sensory receptors by nicotine but has little, if any, effect on the activation of sensory receptors by physiological stimuli.

Central Nervous System. Nicotine markedly stimulates the CNS. Low doses produce weak analgesia; higher doses cause tremors, leading to convulsions at toxic doses. The excitation of respiration is a prominent action of nicotine: Large doses act directly on the medulla oblongata, whereas smaller doses augment respiration reflexly by excitation of the chemoreceptors of the carotid and aortic bodies. Stimulation of the CNS with large doses is followed by depression, and death results from failure of respiration owing to both central paralysis and peripheral blockade of the diaphragm and intercostal muscles that facilitate respiration.

Nicotine induces vomiting by both central and peripheral actions. The central component of the vomiting response is due to stimulation of the emetic chemoreceptor trigger zone in the area postrema of the medulla oblongata. In addition, nicotine activates vagal and spinal afferent nerves that form the sensory input of the reflex pathways involved in the act of vomiting. The primary sites of action of nicotine in the CNS are prejunctional, causing the release of other transmitters. The stimulatory and pleasure-reward actions of nicotine appear to result from release of excitatory amino acids, dopamine, and other biogenic amines from various CNS centers (Dorostkar and Boehm, 2008).

Chronic exposure to nicotine in several systems causes a marked increase in the density or number of nicotinic receptors, possibly contributing to tolerance and dependence. Nicotine is thought to act as an intracellular pharmacological chaperone; it is uncharged at physiological pH and readily permeates the plasma membrane. Inside the cell, it upregulates receptor expression by stabilizing nascent subunits in pentamers in the endoplasmic reticulum. Chronic low-dose exposure to nicotine also significantly increases the $t_{1/2}$ of nicotinic receptors on the cell surface (Kuryatov et al., 2005; Srinivasan et al., 2014).

Cardiovascular System. In general, the cardiovascular responses to nicotine are due to stimulation of sympathetic ganglia and the adrenal medulla, together with the discharge of catecholamines from sympathetic nerve endings. Contributing to the sympathomimetic response to nicotine is the activation of chemoreceptors of the aortic and carotid bodies, which reflexly results in vasoconstriction, tachycardia, and elevated blood pressure.

GI Tract. The combined activation of parasympathetic ganglia and cholinergic nerve endings by nicotine results in increased tone and motor activity of the bowel. Nausea, vomiting, and occasionally diarrhea are observed following systemic absorption of nicotine in an individual who has not been exposed to nicotine previously.

Exocrine Glands. Nicotine causes an initial stimulation of salivary and bronchial secretions that is followed by inhibition.

ADME. Nicotine is readily absorbed from the respiratory tract, buccal membranes, and skin. Severe poisoning has resulted from percutaneous absorption. As a relatively strong base, nicotine has limited absorption from the stomach. Intestinal absorption is far more efficient. Nicotine in chewing tobacco, because it is absorbed more slowly than inhaled nicotine, has a longer duration of effect. The average cigarette contains 6–11 mg nicotine and delivers about 1–3 mg nicotine systemically to the smoker; bioavailability can increase as much as 3-fold with the intensity of puffing and technique of the smoker (Benowitz, 1998).

Approximately 80%–90% of nicotine is altered in the body, mainly in the liver but also in the kidney and lung. Cotinine is the major metabolite. The $t_{1/2}$ of nicotine following inhalation is about 2 h. Nicotine and its metabolites are eliminated rapidly by the kidney. The rate of urinary excretion of nicotine diminishes when the urine is alkaline. Nicotine also is excreted in the milk of lactating women who smoke; the milk of heavy smokers may contain 0.5 mg/L.

Acute Adverse Effects. Poisoning from nicotine may occur from accidental ingestion of nicotine-containing insecticide sprays or in children from ingestion of tobacco products. The acutely fatal dose of nicotine for an adult is probably about 60 mg. Smoking tobacco usually contains 1%–2% nicotine. The gastric absorption of nicotine from tobacco taken by mouth is delayed because of slowed gastric emptying, so vomiting caused by the central effect of the initially absorbed fraction may remove much of the tobacco remaining in the GI tract.

The onset of symptoms of acute, severe nicotine poisoning is rapid; they include nausea, salivation, abdominal pain, vomiting, diarrhea, cold sweat, headache, dizziness, disturbed hearing and vision, mental confusion, and marked weakness. Faintness and prostration ensue; the blood pressure falls; breathing is difficult; the pulse is weak, rapid, and irregular; and collapse may be followed by terminal convulsions. Death may result within a few minutes from respiratory failure.

For treating nicotine poisoning, vomiting may be induced, or gastric lavage should be performed. Alkaline solutions should be avoided. A slurry of activated charcoal is then passed through the tube and left in the stomach. Respiratory assistance and treatment of shock may be necessary.

Ganglionic Blocking Agents

There are two categories of agents that block ganglionic nicotinic receptors. The prototype of the first group, nicotine, initially stimulates the ganglia by an ACh-like action and then blocks them by causing persistent depolarization (Volle, 1980). Compounds in the second category (e.g., trimethaphan and hexamethonium) impair transmission. Trimethaphan acts by competition with ACh, analogous to the mechanism of action of curare at the neuromuscular junction. Hexamethonium appears to block the channel after it opens; this action shortens the duration of current flow because the open channel either becomes occluded or closes. Thus, the initial EPSP is blocked, and ganglionic transmission is inhibited. Representative diverse chemicals that block autonomic ganglia without first causing stimulation are shown in Figure 11–6.

Figure 11–6 Ganglionic blocking agents.

TABLE 11-5 ■ USUAL PREDOMINANCE OF SYMPATHETIC OR PARASYMPATHETIC TONE AT VARIOUS EFFECTOR SITES AND CONSEQUENCES OF AUTONOMIC GANGLIONIC BLOCKADE

SITE	PREDOMINANT TONE	EFFECT OF GANGLIONIC BLOCKADE
Arterioles	Sympathetic (adrenergic)	Vasodilation; increased peripheral blood flow; hypotension
Veins	Sympathetic (adrenergic)	Dilation: peripheral pooling of blood; decreased venous return; decreased cardiac output
Heart	Parasympathetic (cholinergic)	Tachycardia
Iris	Parasympathetic (cholinergic)	Mydriasis
Ciliary muscle	Parasympathetic (cholinergic)	Cycloplegia—focus to far vision
Gastrointestinal tract	Parasympathetic (cholinergic)	Reduced tone and motility; constipation; decreased gastric and pancreatic secretions
Urinary bladder	Parasympathetic (cholinergic)	Urinary retention
Salivary glands	Parasympathetic (cholinergic)	Xerostomia
Sweat glands	Sympathetic (cholinergic)	Anhidrosis
Genital tract	Sympathetic and parasympathetic	Decreased stimulation

Ganglionic blocking agents were the first effective therapy for the treatment of hypertension. However, due to the role of ganglionic transmission in both sympathetic and parasympathetic neurotransmission, the anti-hypertensive action of ganglionic blocking agents was accompanied by numerous undesirable side effects. Mecamylamine, a secondary amine with a channel block mechanism similar to hexamethonium, is available as an antihypertensive agent with good oral bioavailability.

Mechanism of Action

Nearly all the physiological alterations observed after the administration of ganglionic blocking agents can be anticipated with reasonable accuracy by a careful inspection of Figure 8-1 and Table 8-1, and by knowing which division of the autonomic nervous system exercises dominant control of various organs (Table 11-5). For example, blockade of sympathetic ganglia interrupts adrenergic control of arterioles and results in vasodilation, improved peripheral blood flow in some vascular beds, and a fall in blood pressure.

Generalized ganglionic blockade also may result in atony of the bladder and GI tract, cycloplegia, xerostomia, diminished perspiration, and, by abolishing circulatory reflex pathways, postural hypotension. These changes represent the generally undesirable features of ganglionic blockade that severely limit the therapeutic efficacy of ganglionic blocking agents.

Cardiovascular Effects

Existing sympathetic tone is a critical determinant of the degree ganglionic blockade will lower blood pressure. Thus, blood pressure may decrease only minimally in recumbent normotensive subjects but may fall markedly in sitting or standing subjects. Postural hypotension limits the use of ganglionic blockers in ambulatory patients. Changes in heart rate following ganglionic blockade depend largely on existing vagal tone. In humans, only mild tachycardia usually accompanies the hypotension, a sign that indicates fairly complete ganglionic blockade. However, a decrease may occur if the heart rate is high initially. Cardiac output often is reduced by ganglionic blocking drugs in patients with normal cardiac function, as a consequence of venodilation, peripheral pooling of blood, and the resulting decrease in venous return. In patients with cardiac failure, ganglionic blockade frequently results in increased cardiac output owing to a reduction in peripheral resistance. In hypertensive subjects, cardiac output, stroke volume, and left ventricular work are diminished. Although total systemic vascular resistance is decreased in patients who receive ganglionic blocking agents, changes in blood flow and vascular resistance of individual vascular beds are variable. Reduction of cerebral blood flow is small unless mean systemic blood pressure falls below 50–60 mm Hg. Skeletal muscle blood flow is unaltered, but splanchnic and renal blood flow decrease.

ADME

The absorption of quaternary ammonium and sulfonium compounds from the enteric tract is incomplete and unpredictable. This is due both to the limited ability of these ionized substances to penetrate cell membranes and to the depression of propulsive movements of the small intestine and gastric emptying. Although the absorption of mecamylamine is less erratic, reduced bowel activity and paralytic ileus are a danger. After absorption, the quaternary ammonium- and sulfonium-blocking agents are confined primarily to the extracellular space and are excreted mostly unchanged by the kidney. Mecamylamine concentrates in the liver and kidney and is excreted slowly in an unchanged form.

Therapeutic Uses; Adverse Effects

Trimethaphan was once used for the induction of controlled hypotension during surgery to reduce bleeding and for the rapid reduction of blood pressure in the treatment of hypertensive emergencies; however, the agent is no longer marketed in the U.S.

Among the milder untoward responses observed are visual disturbances, dry mouth, conjunctival suffusion, urinary hesitancy, decreased potency, subjective chilliness, moderate constipation, occasional diarrhea, abdominal discomfort, anorexia, heartburn, nausea, eructation, and bitter taste and the signs and symptoms of syncope caused by postural hypotension. More severe reactions include marked hypotension, constipation, syncope, paralytic ileus, urinary retention, and cycloplegia.

Nicotine Addiction and Smoking Cessation

As a therapeutic, nicotine is primarily used to aid in smoking cessation. Two goals of the pharmacotherapy of smoking cessation are the reduction of the craving for nicotine and inhibition of the reinforcing effects of smoking. Myriad approaches and drug regimens are used, including NRT, bupropion (a CNS-active nicotinic antagonist; see Chapter 15), and partial agonists of the nicotinic ACh receptor (e.g., varenicline).

Current consensus is that NRT, bupropion, and varenicline all help smokers to quit their smoking habit. Cytisine (not approved for use in Europe or the U.S.) also appears effective. The safety and efficacy of NRT are clear. The highest rates of smoking cessation (~30% success at maintaining abstinence from smoking for 6 months) result from the combination of NRT (e.g., patch plus inhaler) and varenicline (Cahill et al., 2013, 2014).

Nicotine Replacement Therapy

Nicotine replacement therapy is available in several dosage forms to help achieve abstinence from tobacco use. Nicotine is marketed for over-the-counter use as a gum or lozenge or transdermal patch and by prescription

as a nasal spray or vapor inhaler. Different nicotine delivery systems produce different patterns of exposure (see Figure 24–2; St. Helen et al., 2016). The efficacy of these dosage forms in producing abstinence from smoking is enhanced when linked to counseling and motivational therapy (Frishman, 2009; Prochaska and Benowitz 2016).

Varenicline

Varenicline has been recently introduced as an aid to smoking cessation. The drug interacts with nicotinic ACh receptors. In model systems, varenicline is a partial agonist at $\alpha 4\beta 2$ receptors, which is thought to be the principal nicotinic receptor subtype involved in nicotine addiction. Varenicline is a full agonist at the $\alpha 7$ subtype and exhibits weak activity

toward $\alpha 3\beta 2$ - and $\alpha 6$ -containing receptors. The drug is effective clinically; however, it is not benign: The FDA has issued a warning about mood and behavioral changes associated with its use, and there is some evidence of increased cardiovascular risk (Chelladurai and Singh, 2014; Singh et al., 2011).

Cytisine

Cytisine is a plant alkaloid and a partial agonist at nicotinic ACh receptors, with an affinity for the $\alpha 4\beta 2$ subtype. Cytisine is taken orally, has a half-life of about 5 h, and can produce mild GI side effects. In a recent small trial, cytisine was effective in producing effects similar to those of NRT and varenicline (Walker et al., 2014).

Drug Facts for Your Personal Formulary: Agents Acting at the NMJ and Autonomic Ganglia; Antispasmodics; Nicotine

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Nicotinic ACh Receptor Agonists		
Succinylcholine ^{US} (N _m agonist)	Induction of neuromuscular blockade in surgery and during intubation	<ul style="list-style-type: none"> Induces rapid depolarization of motor end plate, inducing phase I block Resistant to and augments AChE inhibition; induces fasciculations, then flaccid paralysis Influenced by anesthetic agent, type of muscle, and rate of administration Leads to phase II block after prolonged use Metabolized by butyrylcholinesterase; not safe for infants and children Contraindications: history of malignant hyperthermia, muscular dystrophy
Dexamethonium (depolarizer)	<ul style="list-style-type: none"> Not used clinically in the U.S. 	
Nicotine (N _n agonist)	<ul style="list-style-type: none"> Smoking cessation 	<ul style="list-style-type: none"> Low dose induces postganglionic depolarization High doses induce ganglionic transmission blockade
Varenicline (N _n [$\alpha 4\beta 2$ subtype])	<ul style="list-style-type: none"> Smoking cessation FDA warning about mood and behavioral changes 	<ul style="list-style-type: none"> Partial nicotinic receptor agonist preventing nicotine stimulation and decreasing craving Potential for neuropsychiatric events, may cause seizures with alcohol use; excreted largely unchanged in urine
Competitive Nicotinic ACh Receptor Antagonists (Nondepolarizing Neuromuscular Blocking Agents)		
D-Tubocurarine ^{a,L}	<ul style="list-style-type: none"> Induction of neuromuscular blockade in surgery and during intubation All neuromuscular blocking agents are administered parenterally 	<ul style="list-style-type: none"> No longer used clinically in the U.S. or Canada Produces partial blockade of ganglionic ACh transmission that can produce hypertension and reflex tachycardia Can induce histamine release
Mivacurium ^S		<ul style="list-style-type: none"> Short acting due to rapid hydrolysis by plasma cholinesterase Use with caution in patients with renal or hepatic insufficiency
Pancuronium ^L		<ul style="list-style-type: none"> Shows antimuscarinic receptor activity Renal and hepatic elimination Vagolytic activity may cause tachycardia, hypertension, and increased cardiac output
Rocuronium ^I		<ul style="list-style-type: none"> Amino steroid Stable in solution More rapid onset than vecuronium and cisatracurium Hepatic elimination
Vecuronium ^I		<ul style="list-style-type: none"> Amino steroid Not stable in solution Hepatic and renal elimination
Metocurine ^{a,L}		<ul style="list-style-type: none"> Three times more potent than tubocurarine Less histamine release
Atracurium ^I		<ul style="list-style-type: none"> Preferred agent for patients with renal failure Susceptible to Hofmann elimination and ester hydrolysis Same dosage for infants > 1 month, children, and adults
Cisatracurium ^I		<ul style="list-style-type: none"> More potent than atracurium, Hofmann elimination, no histamine release (unlike atracurium)
Doxacurium ^{a,L}		<ul style="list-style-type: none"> Renal elimination
Pipecuronium ^{a,L}		<ul style="list-style-type: none"> Hepatic metabolism; renal elimination

Competitive Nicotinic ACh Receptor Antagonists (Nondepolarizing Neuromuscular Blocking Agents) (continued)		
Gantacurium ^{b,US}		<ul style="list-style-type: none">• New compound class; in clinical trial stage• Fastest onset and shortest acting• Metabolism: rapid cysteine adduction, slow ester hydrolysis
Hexamethonium	<ul style="list-style-type: none">• Not used therapeutically	<ul style="list-style-type: none">• N_n receptor antagonist; blocks ganglionic transmission
Trimethaphan	<ul style="list-style-type: none">• Hypertensive crisis• No longer used	<ul style="list-style-type: none">• N_n receptor antagonist; blocks ganglionic transmission
CNS-Active Agents		
Baclofen Benzodiazepines Tizanidine Cyclobenzaprine	<ul style="list-style-type: none">• Control of muscle spasms	<ul style="list-style-type: none">• See Chapter 22
Carisoprodol Metaxalone Methocarbamol Orphenadrine Tetrabenazine	<ul style="list-style-type: none">• Muscle relaxants acting in CNS, having, in general, a depressant effect	<ul style="list-style-type: none">• CYP2C19 metabolizes carisoprodol to largely to meprobamate• Tetrabenazine is a VMAT2 inhibitor and depletes neuronal monoamine stores
Agents That Block ACh Release		
AbobotulinumtoxinA	<ul style="list-style-type: none">• Cervical dystonia• Glabellar lines (moderate to severe)	<ul style="list-style-type: none">• Spread of toxin effect may induce paralysis of nontargeted muscle, rarely if administered carefully• Paralysis of swallowing and respiration can be life threatening
IncobotulinumtoxinA	<ul style="list-style-type: none">• Blepharospasm, cervical dystonia• Glabellar lines (moderate to severe)	
OnabotulinumtoxinA	<ul style="list-style-type: none">• Botox: axillary hyperhidrosis (severe)• Blepharospasm associated with dystonia; cervical dystonia; migraine (chronic) prophylaxis• Overactive bladder; strabismus; upper limb spasticity (severe); urinary incontinence (due to detrusor overactivity associated with a neurologic condition)	
RimabotulinumtoxinB	<ul style="list-style-type: none">• Cervical dystonia	
Inhibitor of Release of Ca ²⁺ From the SR		
Dantrolene	<ul style="list-style-type: none">• Management and prevention of malignant hyperthermia• Treatment of spasticity associated with upper motor neuron disorders (e.g., spinal cord injury, stroke, cerebral palsy, or multiple sclerosis)	<ul style="list-style-type: none">• Hepatic metabolism• Can cause significant hepatotoxicity

Duration of action: ¹long (> 80 min), ²intermediate (~20–80 min), ³short (~15–20 min), ^{US}ultrashort (< ~15 min).

^aNot available in the U.S.

^bGantacurium is in investigational status.

Overview: Actions of Catecholamines and Sympathomimetic Drugs

Most of the actions of catecholamines and sympathomimetic agents can be classified into seven broad types:

1. A *peripheral excitatory action* on certain types of smooth muscle, such as those in blood vessels supplying skin, kidney, and mucous membranes; and on gland cells, such as those in salivary and sweat glands.
2. A *peripheral inhibitory action* on certain other types of smooth muscle, such as those in the wall of the gut, in the bronchial tree, and in blood vessels supplying skeletal muscle.
3. A *cardiac excitatory action* that increases heart rate and force of contraction.
4. *Metabolic actions*, such as an increase in the rate of glycogenolysis in liver and muscle and liberation of free fatty acids from adipose tissue.
5. *Endocrine actions*, such as modulation (increasing or decreasing) of the secretion of insulin, renin, and pituitary hormones.
6. *Actions in the CNS*, such as respiratory stimulation, an increase in wakefulness and psychomotor activity, and a reduction in appetite.
7. *Prejunctional actions* that either inhibit or facilitate the release of neurotransmitters, the inhibitory action being physiologically more important.

Many of these actions and the receptors that mediate them are summarized in Tables 8–1 and 8–6. Not all sympathomimetic drugs show each of the types of action to the same degree; however, many of the differences in their effects are only quantitative. The pharmacological properties of these drugs as a class are described in detail for the prototypical agent, epinephrine (EPI). Appreciation of the pharmacological properties of the drugs described in this chapter depends on an understanding of the classification, distribution, and mechanism of action of α and β adrenergic receptors (Chapter 8).

Classification of Sympathomimetic Drugs

Catecholamines and sympathomimetic drugs are classified as *direct-acting*, *indirect-acting*, or *mixed-acting sympathomimetics* (Figure 12–1). Direct-acting sympathomimetic drugs act directly on one or more of the adrenergic receptors. These agents may exhibit considerable selectivity for a specific receptor subtype (e.g., phenylephrine for α₁, terbutaline for β₂) or may have no or minimal selectivity and act on several receptor types (e.g., EPI for α₁, α₂, β₁, β₂, and β₃ receptors; NE for α₁, α₂, and β₁ receptors).

Indirect-acting drugs increase the availability of NE or EPI to stimulate adrenergic receptors by several mechanisms:

- By releasing or displacing NE from sympathetic nerve varicosities
- By inhibiting the transport of NE into sympathetic neurons (e.g., cocaine), thereby increasing the dwell time of the transmitter at the receptor
- By blocking the metabolizing enzymes, MAO (e.g., pargyline) or COMT (e.g., entacapone), effectively increasing transmitter supply

Drugs that indirectly release NE and also directly activate receptors are referred to as *mixed-acting sympathomimetic drugs* (e.g., ephedrine). A feature of *direct-acting sympathomimetic drugs* is that their responses are not reduced by prior treatment with reserpine or guanethidine, which deplete NE from sympathetic neurons. After transmitter depletion, the actions of direct-acting sympathomimetic drugs actually may increase because the loss of the neurotransmitter induces compensatory changes that upregulate receptors or enhance the signaling pathway. In contrast, the responses of indirect-acting sympathomimetic drugs (e.g., *amphetamine*, *tyramine*) are abolished by prior treatment with reserpine or guanethidine. The cardinal feature of mixed-acting sympathomimetic drugs is that their effects are blunted, but not abolished, by prior treatment with reserpine or guanethidine.

Abbreviations

AAAD: L-aromatic amino acid decarboxylase
ACEI: angiotensin-converting enzyme inhibitor
ADHD: attention-deficit/hyperactivity disorder
AV: atrioventricular
BPH: benign prostatic hyperplasia
CNS: central nervous system
COMT: catechol-O-methyltransferase
COPD: chronic obstructive pulmonary disease
DA: dopamine
ECG: electrocardiogram
EPI: epinephrine
FDA: Food and Drug Administration
GI: gastrointestinal
HDL: high-density lipoprotein
HMG CoA: 3-hydroxy-3-methylglutaryl coenzyme A
5HT: 5-hydroxytryptamine (serotonin)
INE: isoproterenol (Isopropyl NE)
LABA: long-acting β_2 adrenergic agonist
LDL: low-density lipoprotein
MAO: monoamine oxidase
NE: norepinephrine
NET: NE transporter
NPY: neuropeptide Y
PBZ: phenoxybenzamine
PDE: phosphodiesterase
PVR: peripheral vascular resistance
ROS: reactive oxygen species
SA: sinoatrial
VLABA: very long-acting β_2 adrenergic agonist

Because the actions of NE are more pronounced on α and β_1 receptors than on β_2 receptors, many noncatecholamines that release NE have predominantly α receptor-mediated and cardiac effects. However, certain noncatecholamines with both direct and indirect effects on adrenergic receptors show significant β_2 activity and are used clinically for these effects. Thus, ephedrine, although dependent on release of NE for some of its effects, relieves bronchospasm by its action on β_2 receptors in bronchial smooth muscle, an effect not seen with NE. Moreover, some noncatecholamines (e.g., phenylephrine) act primarily and directly on target cells. It therefore is impossible to predict precisely the effects of noncatecholamines solely on their ability to provoke NE release.

Structure-Activity Relationship of Sympathomimetic Amines

β -Phenylethylamine can be viewed as the parent compound of the sympathomimetic amines, consisting of a benzene ring and an ethylamine side chain (parent structure in Table 12-1). The structure permits substitutions to be made on the aromatic ring, the α - and β -carbon atoms, and the terminal amino group to yield a variety of compounds with sympathomimetic activity. NE, EPI, DA, INE, and a few other agents have hydroxyl groups substituted at positions 3 and 4 of the benzene ring. Because *o*-dihydroxybenzene is also known as catechol, sympathomimetic amines with these hydroxyl substitutions in the aromatic ring are termed catecholamines.

Many directly acting sympathomimetic drugs influence both α and β receptors, but the ratio of activities varies among drugs in a continuous spectrum from predominantly α activity (phenylephrine) to predominantly β activity (INE). Despite the multiplicity of the sites of action of sympathomimetic amines, several generalizations can be made (Table 12-1).

Separation of Aromatic Ring and Amino Group

By far the greatest sympathomimetic activity occurs when two carbon atoms separate the ring from the amino group. This rule applies with few exceptions to all types of action.

Substitution on the Amino Group

The effects of amino substitution are most readily seen in the actions of catecholamines on α and β receptors. Increase in the size of the alkyl substituent increases β receptor activity (e.g., INE). NE has, in general, rather feeble β_2 activity; this activity is greatly increased in EPI by the addition of a methyl group. A notable exception is phenylephrine, which has an *N*-methyl substituent but is an α -selective agonist. β_2 -Selective compounds require a large amino substituent, but depend on other substitutions to define selectivity for β_2 rather than for β_1 receptors. In general, the smaller the substitution on the amino group, the greater the selectivity for α activity, although *N*-methylation increases the potency of primary amines. Thus, α activity is maximal in EPI, less in NE, and almost absent in INE.

Substitution on the Aromatic Nucleus

Maximal α and β activity depends on the presence of hydroxyl groups on positions 3 and 4. When one or both of these groups are absent, with no other aromatic substitution, the overall potency is reduced. Phenylephrine is thus less potent than EPI at both α and β receptors, with β_2 activity almost completely absent. Studies of the β adrenergic receptor suggest that the hydroxyl groups on serine residues 204 and 207 probably form hydrogen bonds with the catechol hydroxyl groups at positions 3 and 4, respectively. It also appears that aspartate 113 is a point of electrostatic interaction with the amine group on the ligand. Because the serines are in the fifth membrane-spanning region and the aspartate is in the third (Chapter 8), it is likely that catecholamines bind parallel to the plane of the membrane, forming a bridge between the two membrane spans. However, models involving DA receptors suggest alternative possibilities.

Hydroxyl groups in positions 3 and 5 confer β_2 receptor selectivity on compounds with large amino substituents. Thus, terbutaline and similar compounds relax the bronchial musculature in patients with asthma but cause less direct cardiac stimulation than do the nonselective drugs. The response to noncatecholamines is partly determined by their capacity to release NE from storage sites. These agents thus cause effects that are mostly mediated by α and β_1 receptors because NE is a weak β_2 agonist. Phenylethylamines that lack hydroxyl groups on the ring and the β -hydroxyl group on the side chain act almost exclusively by causing the release of NE from sympathetic nerve terminals.

Because substitution of polar groups on the phenylethylamine structure makes the resultant compounds less lipophilic, unsubstituted or alkyl-substituted compounds cross the blood-brain barrier more readily and have more central activity. Thus, ephedrine, amphetamine, and methamphetamine exhibit considerable CNS activity. As noted, the absence of polar hydroxyl groups results in a loss of direct sympathomimetic activity.

Catecholamines have only a brief duration of action and are ineffective when administered orally because they are rapidly inactivated in the intestinal mucosa and in the liver before reaching the systemic circulation (Chapter 8). Compounds without one or both hydroxyl substituents are not acted on by COMT, and their oral effectiveness and duration of action are enhanced.

Groups other than hydroxyls have been substituted on the aromatic ring. In general, potency at α receptors is reduced, and β receptor activity is minimal; the compounds may even block β receptors. For example, methoxamine, with methoxy substituents at positions 2 and 5, has highly selective α stimulating activity and in large doses blocks β receptors. Albuterol, a β_2 -selective agonist, has a substituent at position 3 and is an important exception to the general rule of low β receptor activity.

Substitution on the α -Carbon Atom

The substitution on the α -carbon atom blocks oxidation by MAO, greatly prolonging the duration of action of noncatecholamines because their degradation depends largely on the action of this enzyme. The duration of action of drugs such as ephedrine or amphetamine is thus measured in hours rather than in minutes. Similarly, compounds with an α -methyl

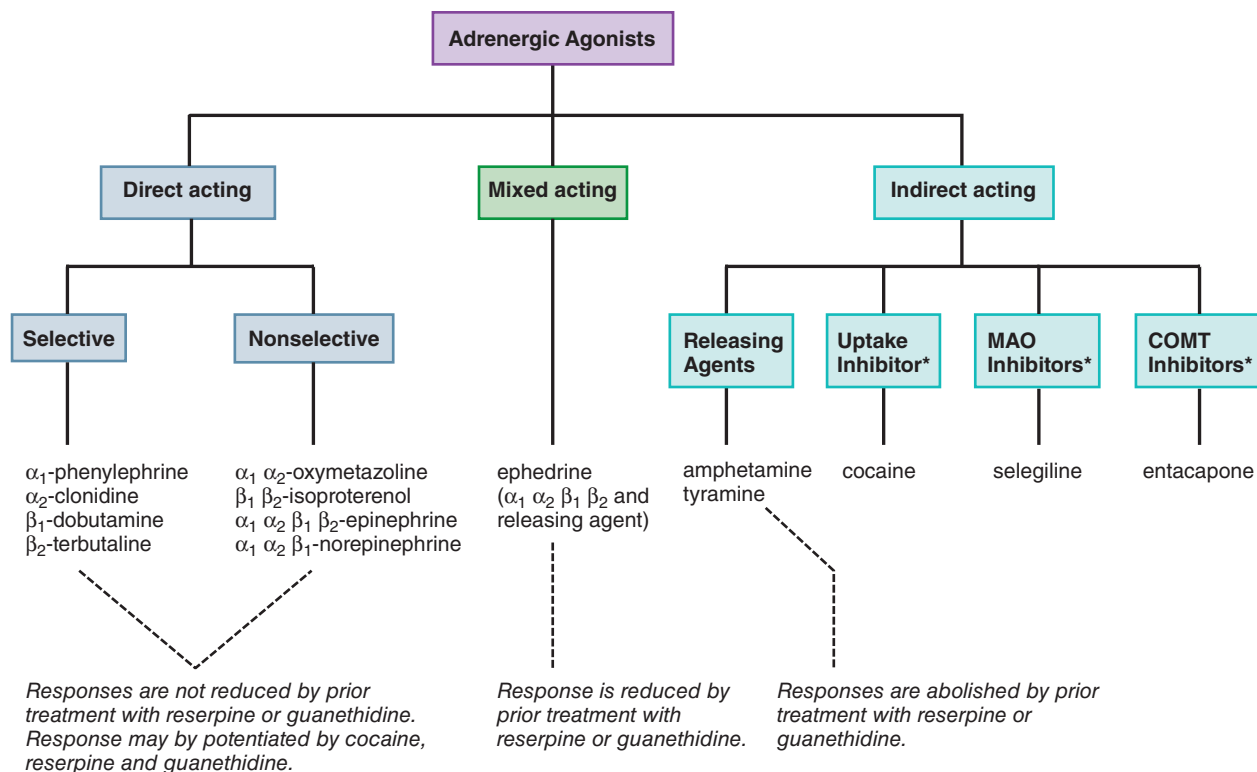

Figure 12-1 Classification of adrenergic receptor agonists (sympathomimetic amines) or drugs that produce sympathomimetic-like effects. For each category, a prototypical drug is shown. (*Not actually sympathetic drugs but produce sympathomimetic-like effects.)

TABLE 12-1 ■ STRUCTURES AND MAIN CLINICAL USES OF IMPORTANT SYMPATHOMIMETIC DRUGS

					MAIN CLINICAL USES							
					α RECEPTOR				β RECEPTOR			CNS

substituent persist in the nerve terminals and are more likely to release NE from storage sites. Agents such as metaraminol exhibit a greater degree of indirect sympathomimetic activity.

Substitution on the β -Carbon Atom

Substitution of a hydroxyl group on the β -carbon generally decreases actions within the CNS, largely because it lowers lipid solubility. However, such substitution greatly enhances agonist activity at both α and β adrenergic receptors. Although ephedrine is less potent than methamphetamine as a central stimulant, it is more powerful in dilating bronchioles and increasing blood pressure and heart rate.

Optical Isomerism

Substitution on either α - or β -carbon yields optical isomers. Levorotatory substitution on the β -carbon confers the greater peripheral activity, so that the naturally occurring *l*-EPI and *l*-NE are at least 10 times more potent than their unnatural *d*-isomers. Dextrorotatory substitution on the α -carbon generally results in a more potent compound. *d*-Amphetamine is more potent than *l*-amphetamine in central but not peripheral activity.

Physiological Basis of Adrenergic Responsiveness

Important factors in the response of any cell or organ to sympathomimetic amines are the density and relative proportion of α and β adrenergic receptors. For example, NE has relatively little capacity to increase bronchial airflow because the receptors in bronchial smooth muscle are largely of the β_2 subtype. In contrast, INE and EPI are potent bronchodilators. Cutaneous blood vessels physiologically express almost exclusively α receptors; thus, NE and EPI cause constriction of such vessels, whereas INE has little effect. The smooth muscle of blood vessels that supply skeletal muscles has both β_2 and α receptors; activation of β_2 receptors causes vasodilation, and stimulation of α receptors constricts these vessels. In such vessels, the threshold concentration for activation of β_2 receptors by EPI is lower than that for α receptors, but when both types of receptors are activated at high concentrations of EPI, the response to α receptors predominates. Physiological concentrations of EPI primarily cause vasodilation.

The ultimate response of a target organ to sympathomimetic amines is dictated not only by the direct effects of the agents but also by the reflex homeostatic adjustments of the organism. One of the most striking effects of many sympathomimetic amines is a rise in arterial blood pressure caused by stimulation of vascular α adrenergic receptors. This stimulation elicits compensatory reflexes that are mediated by the carotid-aortic baroreceptor system. As a result, sympathetic tone is diminished and vagal tone is enhanced; each of these responses leads to slowing of the heart rate. Conversely, when a drug (e.g., a β_2 agonist) lowers mean blood pressure at the mechanoreceptors of the carotid sinus and aortic arch, the baroreceptor reflex works to restore pressure by reducing parasympathetic (vagal) outflow from the CNS to the heart and increasing sympathetic outflow to the heart and vessels. The baroreceptor reflex effect is of special importance for drugs that have little capacity to activate β receptors directly. With diseases such as atherosclerosis, which may impair baroreceptor mechanisms, the effects of sympathomimetic drugs may be magnified.

False-Transmitter Concept

Indirectly acting amines are taken up into sympathetic nerve terminals and storage vesicles, where they replace NE in the storage complex. Phenylethylamines that lack a β -hydroxyl group are retained there poorly, but β -hydroxylated phenylethylamines and compounds that subsequently become hydroxylated in the synaptic vesicle by DA β -hydroxylase are retained in the synaptic vesicle for relatively long periods of time. Such substances can produce a persistent diminution in the content of NE at functionally critical sites. When the nerve is stimulated, the contents of a relatively constant number of synaptic vesicles are released by exocytosis. If these vesicles contain phenylethylamines that are much less potent than NE, activation of postsynaptic α and β receptors will be diminished.

This hypothesis, known as the *false-transmitter concept*, is a possible explanation for some of the effects of MAO inhibitors. Phenylethylamines normally are synthesized in the GI tract as a result of the action of bacterial

tyrosine decarboxylase. The *tyramine* formed in this fashion usually is oxidatively deaminated in the GI tract and the liver, and the amine does not reach the systemic circulation in significant concentrations. However, when a MAO inhibitor is administered, tyramine may be absorbed systemically and transported into sympathetic nerve terminals, where its catabolism again is prevented because of the inhibition of MAO at this site; the tyramine then is β -hydroxylated to octopamine and stored in the vesicles in this form. As a consequence, NE gradually is displaced, and stimulation of the nerve terminal results in the release of a relatively small amount of NE along with a fraction of octopamine. The latter amine has relatively little ability to activate either α or β receptors. Thus, a functional impairment of sympathetic transmission parallels long-term administration of MAO inhibitors.

Despite such functional impairment, patients who have received MAO inhibitors may experience severe hypertensive crises if they ingest cheese, beer, or red wine. These and related foods, which are produced by fermentation, contain a large quantity of tyramine and, to a lesser degree, other phenylethylamines. When GI and hepatic MAO are inhibited, the large quantity of tyramine that is ingested is absorbed rapidly and reaches the systemic circulation in high concentration. A massive and precipitous release of NE can result, causing hypertension severe enough to precipitate a myocardial infarction or a stroke. The properties of various MAO inhibitors (reversible or irreversible; selective or nonselective at MAO-A and MAO-B) are discussed in Chapters 8 and 15.

Endogenous Catecholamines

Epinephrine

Epinephrine (adrenaline) is a potent stimulant of both α and β adrenergic receptors, and its effects on target organs are thus complex. Most of the responses listed in Table 8–1 are seen after injection of EPI, although the occurrence of sweating, piloerection, and mydriasis depends on the physiological state of the subject. Particularly prominent are the actions on the heart and on vascular and other smooth muscle.

Actions on Organ Systems

Effects on Blood Pressure. Epinephrine is one of the most potent vasoconstrictor drugs known. If a pharmacological dose is given rapidly by an intravenous route, it evokes a characteristic effect on blood pressure, which rises rapidly to a peak that is proportional to the dose. The increase in systolic pressure is greater than the increase in diastolic pressure, so that the pulse pressure increases. As the response wanes, the mean pressure may fall below normal before returning to control levels.

The mechanism of the rise in blood pressure due to EPI is a triad of effects:

- a direct myocardial stimulation that increases the strength of ventricular contraction (*positive inotropic action*);
- an increased heart rate (*positive chronotropic action*); and
- vasoconstriction in many vascular beds—especially in the *precapillary resistance vessels* of skin, mucosa, and kidney—along with marked constriction of the veins.

The pulse rate, at first accelerated, may be slowed markedly at the height of the rise of blood pressure by compensatory vagal discharge (baroreceptor reflex). Small doses of EPI (0.1 $\mu\text{g/kg}$) may cause the blood pressure to fall. The depressor effect of small doses and the biphasic response to larger doses are due to greater sensitivity to EPI of vasodilator β_2 receptors than of constrictor α receptors.

Absorption of EPI after subcutaneous injection is slow due to local vasoconstrictor action; the effects of doses as large as 0.5–1.5 mg can be duplicated by intravenous infusion at a rate of 10–30 $\mu\text{g/min}$. There is a moderate increase in systolic pressure due to increased cardiac contractile force and a rise in cardiac output (Figure 12–2). Peripheral resistance decreases, owing to a dominant action on β_2 receptors of vessels in skeletal muscle, where blood flow is enhanced; as a consequence, diastolic pressure usually falls. Because the mean blood pressure is not, as a rule, greatly elevated, compensatory baroreceptor reflexes do not appreciably antagonize the direct cardiac

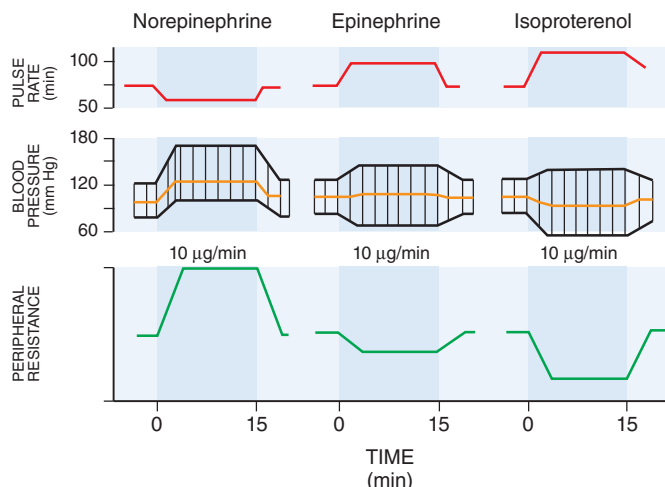

Figure 12-2 Comparative effects of intravenous infusion of NE, EPI, and INE. (Reproduced with permission from Allwood MJ, Cobbold AF, Ginsberg J. Peripheral vascular effects of noradrenaline, isopropyl-noradrenaline, and dopamine. *Br Med Bull.* 1963;19:132–136. With permission from Oxford University Press.)

actions. Heart rate, cardiac output, stroke volume, and left ventricular work per beat are increased as a result of direct cardiac stimulation and increased venous return to the heart, which is reflected by an increase in right atrial pressure. At slightly higher rates of infusion, there may be no change or a slight rise in peripheral resistance and diastolic pressure, depending on the dose and the resultant ratio of α to β responses in the various vascular beds; compensatory reflexes also may come into play. The details of the effects of intravenous infusion of EPI, NE, and INE in humans are compared in Figure 12-2 and of EPI and NE in Table 12-2.

Vascular Effects. In the vasculature, EPI acts chiefly on the smaller arterioles and precapillary sphincters, although veins and large arteries also respond to the drug. Various vascular beds react differently, which results in a substantial redistribution of blood flow. *Injected EPI markedly decreases cutaneous blood flow, constricting precapillary vessels and small venules.* Cutaneous vasoconstriction accounts for a marked decrease in blood flow in the hands and feet. *Blood flow to skeletal muscles is increased by therapeutic doses in humans.* This is due in part to a powerful β_2 -mediated vasodilator action that is only partially counterbalanced by a vasoconstrictor action on the α receptors that also are present in the vascular bed.

The effect of EPI on cerebral circulation is related to systemic blood pressure. In usual therapeutic doses, the drug has relatively little constrictor action on cerebral arterioles. Indeed, autoregulatory mechanisms tend to limit the increase in cerebral blood flow caused by increased blood pressure.

Doses of EPI that have little effect on mean arterial pressure consistently increase renal vascular resistance and reduce renal blood flow by as much as 40%. All segments of the renal vascular bed contribute to the increased resistance. Because the glomerular filtration rate is only slightly and variably altered, the filtration fraction is consistently increased. Excretion of Na^+ , K^+ , and Cl^- is decreased; urine volume may be increased, decreased, or unchanged. Maximal tubular reabsorptive and excretory capacities are unchanged. *The secretion of renin is increased as a consequence of a direct action of EPI on β_1 receptors in the juxtaglomerular apparatus.*

Arterial and venous pulmonary pressures are raised. Although direct pulmonary vasoconstriction occurs, redistribution of blood from the systemic to the pulmonary circulation, due to constriction of the more powerful musculature in the systemic great veins, doubtless plays an important part in the increase in pulmonary pressure. Very high concentrations of EPI may cause pulmonary edema precipitated by elevated pulmonary capillary filtration pressure and possibly by “leaky” capillaries.

Coronary blood flow is enhanced by EPI or by cardiac sympathetic stimulation under physiological conditions. The increased flow, which occurs even with doses that do not increase the aortic blood pressure, is the result

of two factors. The first is the increased relative duration of diastole at higher heart rates (described further in the chapter); this is partially offset by decreased blood flow during systole because of more forceful contraction of the surrounding myocardium and an increase in mechanical compression of the coronary vessels. The increased flow during diastole is further enhanced if aortic blood pressure is elevated by EPI; as a consequence, total coronary flow may be increased. The second factor is a metabolic dilator effect that results from the increased strength of contraction and myocardial O_2 consumption due to the direct effects of EPI on cardiac myocytes. This vasodilation is mediated in part by adenosine released from cardiac myocytes, which tends to override a direct vasoconstrictor effect of EPI that results from activation of α receptors in coronary vessels.

Cardiac Effects. Epinephrine is a powerful cardiac stimulant. It acts directly on the predominant β_1 receptors of the myocardium and of the cells of the pacemaker and conducting tissues; β_2 , β_3 , and α receptors also are present in the heart, although there are considerable species differences. The heart rate increases, and the rhythm often is altered. Cardiac systole is shorter and more powerful, cardiac output is enhanced, and the work of the heart and its oxygen consumption are markedly increased. Cardiac efficiency (work done relative to oxygen consumption) is lessened.

Direct responses to EPI include increases in contractile force, accelerated rate of rise of isometric tension, enhanced rate of relaxation, decreased time to peak tension, increased excitability, acceleration of the rate of spontaneous beating, and induction of automaticity in specialized regions of the heart.

In accelerating the heart, EPI preferentially shortens systole so that the duration of diastole usually is not reduced. Indeed, activation of β receptors increases the rate of relaxation of ventricular muscle. EPI speeds the heart by accelerating the slow depolarization of SA nodal cells that takes place during diastole, that is, during phase 4 of the action potential (Chapter 30). Consequently, the transmembrane potential of the pacemaker cells rises more rapidly to the threshold level of action potential initiation. The amplitude of the action potential and the maximal rate of depolarization (phase 0) also are increased. A shift in the location of the pacemaker within the SA node often occurs, owing to activation of latent pacemaker cells. In Purkinje fibers, EPI also accelerates diastolic depolarization and may activate latent pacemaker cells. These changes do not occur in atrial and ventricular muscle fibers, where EPI has little effect on the stable, phase 4 membrane potential after repolarization. If large doses of EPI are given, premature ventricular contractions occur and may herald more serious ventricular arrhythmias. This rarely is seen with conventional doses in humans, but ventricular extrasystoles, tachycardia, or even fibrillation may be precipitated by release of endogenous EPI when the heart has been sensitized to this action of EPI by certain anesthetics or by myocardial ischemia. The mechanism of induction of these cardiac arrhythmias is not clear.

Some effects of EPI on cardiac tissues are largely secondary to the increase in heart rate and are small or inconsistent when the heart rate is kept constant. For example, the effect of EPI on repolarization of atrial muscle, Purkinje fibers, or ventricular muscle is small if the heart rate is unchanged. When the heart rate is increased, the duration of the action potential is consistently shortened, and the refractory period is correspondingly decreased.

Conduction through the Purkinje system depends on the level of membrane potential at the time of excitation. Excessive reduction of this potential results in conduction disturbances, ranging from slowed conduction to complete block. EPI often increases the membrane potential and improves conduction in Purkinje fibers that have been excessively depolarized.

Epinephrine normally shortens the refractory period of the human AV node by direct effects on the heart, although doses of EPI that slow the heart through reflex vagal discharge may indirectly tend to prolong it. EPI also decreases the grade of AV block that occurs as a result of disease, drugs, or vagal stimulation. Supraventricular arrhythmias are apt to occur from the combination of EPI and cholinergic stimulation. Depression of sinus rate and AV conduction by vagal discharge probably plays a part in EPI-induced ventricular arrhythmias because various drugs that block the vagal effect confer some protection. The actions of EPI in enhancing cardiac automaticity and in causing arrhythmias are effectively antagonized by β receptor antagonists such as propranolol. However, α_1 receptors exist in most regions of the heart, and their activation prolongs the refractory period and strengthens myocardial contractions.

Cardiac arrhythmias have been seen in patients after inadvertent intravenous administration of conventional subcutaneous doses of EPI. Premature ventricular contractions can appear, which may be followed by multifocal ventricular tachycardia or ventricular fibrillation. Pulmonary edema also may occur.

Epinephrine decreases the amplitude of the T wave of the ECG in normal persons. In animals given relatively larger doses, additional effects are seen on the T wave and the ST segment. After decreasing in amplitude, the T wave may become biphasic, and the ST segment can deviate either above or below the isoelectric line. Such ST segment changes are similar to those seen in patients with angina pectoris during spontaneous or EPI-induced attacks of pain. These electrical changes therefore have been attributed to myocardial ischemia. Also, EPI as well as other catecholamines may cause myocardial cell death, particularly after intravenous infusions. Acute toxicity is associated with contraction band necrosis and other pathological changes. Recent interest has

focused on the possibility that prolonged sympathetic stimulation of the heart, such as in congestive cardiomyopathy, may promote apoptosis of cardiomyocytes.

Effects on Smooth Muscles. The effects of EPI on the smooth muscles of different organs and systems depend on the type of adrenergic receptor in the muscle (Table 8–1). In general, EPI relaxes *GI smooth muscle* due to activation of both α and β receptors. Intestinal tone and the frequency and amplitude of spontaneous contractions are reduced. The stomach usually is relaxed and the pyloric and ileocecal sphincters are contracted, but these effects depend on the preexisting tone of the muscle. If tone already is high, EPI causes relaxation; if low, contraction.

The responses of *uterine muscle* to EPI vary with species, phase of the sexual cycle, state of gestation, and dose given. During the last month of pregnancy and at parturition, EPI inhibits uterine tone and contractions. Effects of adrenergic agents and other drugs on the uterus are discussed further in this chapter and in Chapter 44. *EPI relaxes the detrusor muscle of the bladder as a result of activation of β receptors and contracts the trigone and sphincter muscles owing to its α agonist activity.* This can result in hesitancy in urination and may contribute to retention of urine in the bladder. Activation of smooth muscle contraction in the prostate promotes urinary retention.

Respiratory Effects. *Epinephrine has a powerful bronchodilator action,* most evident when bronchial muscle is contracted because of disease, as in bronchial asthma, or in response to drugs or various autacoids. The beneficial effects of EPI in asthma also may arise from inhibition of antigen-induced release of inflammatory mediators from mast cells and to a lesser extent from diminution of bronchial secretions and congestion within the mucosa. *Inhibition of mast cell secretion is mediated by β_2 receptors, while the effects on the mucosa are mediated by α receptors;* however, other drugs, such as glucocorticoids and leukotriene receptor antagonists, have much more profound anti-inflammatory effects in asthma (Chapters 40 and 46).

Effects on the CNS. Because EPI is a polar compound, it penetrates poorly into the CNS and thus is not a powerful CNS stimulant. While the drug may cause restlessness, apprehension, headache, and tremor in many persons, these effects in part may be secondary to the effects of EPI on the cardiovascular system, skeletal muscles, and intermediary metabolism; that is, they may be the result of somatic manifestations of anxiety.

Metabolic Effects. Epinephrine elevates the concentrations of glucose and lactate in blood. *EPI inhibits secretion of insulin through an interaction with α_2 receptors, whereas activation of β_2 receptors enhances insulin secretions; the predominant effect of EPI is inhibition.* *Glucagon secretion is enhanced via activation of β receptors of the α cells of pancreatic islets.* EPI also decreases the uptake of glucose by peripheral tissues, at least in part not only because of its effects on the secretion of insulin, but also possibly due to direct effects on skeletal muscle. Glycosuria rarely occurs. The effect of EPI to stimulate glycogenolysis in most tissues and in most species involves β receptors. EPI raises the concentration of free fatty acids in blood by stimulating β receptors in adipocytes. The result is activation of triglyceride lipase, which accelerates the triglyceride breakdown to free fatty acids and glycerol. The calorogenic action of EPI (increase in metabolism) is reflected in humans by an increase of 20%–30% in O_2 consumption after conventional doses, an effect due mainly to enhanced breakdown of triglycerides in brown adipose tissue, providing an increase in oxidizable substrate (Chapter 8).

Miscellaneous Effects. Epinephrine reduces circulating plasma volume by loss of protein-free fluid to the extracellular space, thereby increasing hematocrit and plasma protein concentration. However, conventional doses of EPI do not significantly alter plasma volume or packed red cell volume under normal conditions, although such doses may have variable effects in the presence of shock, hemorrhage, hypotension, or anesthesia. EPI rapidly increases the number of circulating polymorphonuclear leukocytes, likely due to β receptor-mediated demargination of these cells. EPI accelerates blood coagulation and promotes fibrinolysis.

The effects of EPI on secretory glands are not marked; in most glands, secretion usually is inhibited, partly owing to the reduced blood flow caused by vasoconstriction. EPI stimulates lacrimation and scanty mucus secretion from salivary glands. Sweating and pilomotor activity are minimal after systemic administration of EPI, but occur after intradermal injection of very dilute solutions of either EPI or NE. Such effects are inhibited by a receptor antagonists.

Mydriasis occurs with physiological sympathetic stimulation but not when EPI is instilled into the conjunctival sac of normal eyes. However, EPI usually lowers intraocular pressure, possibly the result of reduced production of aqueous humor due to vasoconstriction and enhanced outflow (Chapter 69).

Although EPI does not directly excite *skeletal muscle*, it facilitates *neuromuscular transmission*, particularly that following prolonged rapid stimulation of motor nerves. In apparent contrast to the effects of a receptor activation at presynaptic nerve terminals in the autonomic nervous system (α_2 receptors), stimulation of α receptors causes a more rapid increase in transmitter release from the somatic motor neuron, perhaps as a result of enhanced influx of Ca^{2+} . These responses likely are mediated by α_1 receptors. These actions may explain in part the ability of EPI (given intra-arterially) to briefly increase strength of the injected limb of patients with myasthenia gravis. EPI also acts directly on white, fast-twitch muscle fibers to prolong the active state, thereby increasing peak tension. Of greater physiological and clinical importance is the capacity of EPI and selective β_2 agonists to increase physiological tremor, at least in part due to β receptor-mediated enhancement of discharge of muscle spindles.

Epinephrine promotes a fall in plasma K^+ , largely due to stimulation of K^+ uptake into cells, particularly skeletal muscle, due to activation of β_2 receptors. This is associated with decreased renal K^+ excretion. These receptors have been exploited in the management of hyperkalemic familial periodic paralysis, which is characterized by episodic flaccid paralysis, hyperkalemia, and depolarization of skeletal muscle. The β_2 -selective agonist albuterol apparently is able to ameliorate the impairment in the ability of the muscle to accumulate and retain K^+ .

The administration of large or repeated doses of EPI or other sympathomimetic amines to experimental animals damages arterial walls and myocardium, even inducing necrosis in the heart that is indistinguishable from myocardial infarction. The mechanism of this injury is not yet clear, but α and β receptor antagonists and Ca^{2+} channel blockers may afford substantial protection against the damage. Similar lesions occur in many patients with pheochromocytoma or after prolonged infusions of NE.

ADME

Epinephrine is not effective after oral administration because it is rapidly conjugated and oxidized in the GI mucosa and liver. Absorption from subcutaneous tissues occurs relatively slowly because of local vasoconstriction. Absorption is more rapid after intramuscular injection. In emergencies, it may be necessary to administer EPI intravenously. When relatively concentrated solutions are nebulized and inhaled, the actions of the drug largely are restricted to the respiratory tract; however, systemic reactions such as arrhythmias may occur, particularly if larger amounts are used.

Epinephrine is rapidly inactivated in the liver by COMT and MAO (see Figure 8–9). Although only small amounts appear in the urine of normal persons, the urine of patients with pheochromocytoma may contain relatively large amounts of EPI, NE, and their metabolites.

Epinephrine is available in a variety of formulations geared for different clinical indications and routes of administration, including self-administration for anaphylactic reactions. EPI is unstable in alkaline solution; when exposed to air or light, it turns pink from oxidation to adrenochrome and then brown from formation of polymers. Injectable EPI is available in solutions of 1, 0.5, and 0.1 mg/mL. A subcutaneous dose ranges from 0.3 to 0.5 mg. The intravenous route is used cautiously if an immediate and reliable effect is mandatory. If the solution is given by vein, it must be adequately diluted and injected very slowly. The dose is seldom as much as 0.25 mg, except for cardiac arrest, when larger doses may be required.

Toxicity, Adverse Effects, and Contraindications

Epinephrine may cause restlessness, throbbing headache, tremor, and palpitations. The effects rapidly subside with rest, quiet, recumbency, and reassurance. More serious reactions include cerebral hemorrhage and cardiac arrhythmias. The use of large doses or the accidental, rapid intravenous injection of EPI may result in cerebral hemorrhage from the sharp rise in blood pressure. Ventricular arrhythmias may follow the administration of EPI. Angina may be induced by EPI in patients with coronary artery disease. *The use of EPI generally is contraindicated in patients who are receiving nonselective β receptor antagonists because its unopposed actions on vascular α_1 receptors may lead to severe hypertension and cerebral hemorrhage.*

Therapeutic Uses

A major use of EPI is to provide rapid, emergency relief of hypersensitivity reactions, including anaphylaxis, to drugs and other allergens. EPI also is used to prolong the action of local anesthetics, presumably by decreasing local blood flow and reducing systemic absorption. (Chapter 22). Its cardiac effects may be of use in restoring cardiac rhythm in patients with cardiac arrest due to various causes. It also is used as a topical hemostatic agent on bleeding surfaces, such as in the mouth or in bleeding peptic ulcers during endoscopy of the stomach and duodenum. Systemic absorption of the drug can occur with dental application. Inhalation of EPI may be useful in the treatment of postintubation and infectious croup.

Norepinephrine

Norepinephrine (levarterenol, *l*-noradrenaline, *l*- β -[3,4-dihydroxyphenyl]- α -aminoethanol) is a major chemical mediator liberated by mammalian *postganglionic sympathetic nerves*. It differs from EPI only by lacking the methyl substitution in the amino group (Table 12–1). NE constitutes 10%–20% of the catecholamine content of human adrenal medulla and as much as 97% in some pheochromocytomas, which may not express the enzyme phenylethanolamine-*N*-methyltransferase.

Pharmacological Properties

The pharmacological actions of NE and EPI are compared in Table 12–2. Both drugs are direct agonists on effector cells, and their actions differ mainly in the ratio of their effectiveness in stimulating α and β_2 receptors. *They are approximately equipotent in stimulating β_1 receptors. NE is a potent α agonist and has relatively little action on β_2 receptors; however, it is somewhat less potent than EPI on the α receptors of most organs.*

Cardiovascular Effects

In response to intravenous infusion of NE in humans (Figure 12–2), *systolic and diastolic pressures, and usually pulse pressure, are increased. Cardiac output is unchanged or decreased, and total peripheral resistance is raised. Compensatory vagal reflex activity slows the heart, overcoming a direct cardioaccelerator action, and stroke volume is increased. The peripheral vascular resistance increases in most vascular beds, and renal blood flow is reduced. NE constricts mesenteric vessels and reduces splanchnic and hepatic blood flow. Coronary flow usually is increased, probably owing both to indirectly induced coronary dilation, as with EPI, and to elevated blood pressure.* Although generally a poor β_2 receptor agonist, NE may increase coronary blood flow directly by stimulating β_2 receptors on coronary vessels. Patients with Prinzmetal variant angina may be supersensitive to the adrenergic vasoconstrictor effects of NE.

Unlike EPI, NE in small doses does not cause vasodilation or lower blood pressure because the blood vessels of skeletal muscle constrict rather than dilate; α adrenergic receptor antagonists therefore abolish the pressor effects but do not cause significant reversal (i.e., hypotension).

Other Effects

Other responses to NE are not prominent in humans. The drug causes hyperglycemia and other metabolic effects similar to those produced by EPI, but these are observed only when large doses are given because NE is not as effective a “hormone” as EPI. Intradermal injection of suitable doses causes sweating that is not blocked by atropine.

Norepinephrine, like EPI, is ineffective when given orally and is absorbed poorly from sites of subcutaneous injection. It is rapidly inactivated in the body by the same enzymes that methylate (COMT) and oxidatively deaminate EPI (MAO). Small amounts normally are found in the urine. The excretion rate may be greatly increased in patients with pheochromocytoma.

Toxicity, Adverse Effects, and Precautions

The untoward effects of NE are similar to those of EPI, although there typically is greater elevation of blood pressure with NE. Excessive doses can cause severe hypertension.

Care must be taken that necrosis and sloughing do not occur at the site of intravenous injection owing to extravasation of the drug. The infusion should be made high in the limb, preferably through a long plastic cannula extending centrally. Impaired circulation at injection sites, with or without extravasation of NE, may be relieved by infiltrating the area with phenolamine, an α receptor antagonist. Blood pressure must be determined frequently during the infusion, particularly during adjustment of the rate of the infusion. Reduced blood flow to organs such as kidney and intestines is a constant danger with the use of NE.

Therapeutic Uses

Norepinephrine is used as a vasoconstrictor to raise or support blood pressure under certain intensive care conditions (discussed further in this chapter).

Droxidopa, a Synthetic Prodrug of Norepinephrine

Droxidopa (L-threo-3,4,-dihydroxyphenylserine) is a synthetic prodrug that is converted by AAAD into NE. It is FDA-approved for the treatment of orthostatic dizziness and light-headedness in adults with symptomatic neurogenic orthostatic hypotension associated with primary autonomic failure and impaired compensatory autonomic reflexes (Keating, 2014). The pharmacological effects of droxidopa are thought to be mediated through NE rather than through the parent drug or other metabolites. Droxidopa can cross the blood-brain barrier, presumably as the substrate of an amino acid transporter.

Dopamine

Dopamine (3,4-dihydroxyphenylethylamine) (Table 12-1) is the immediate metabolic precursor of NE and EPI; it is a central neurotransmitter particularly important in the regulation of movement (Chapters 14, 16, and 18) and possesses important intrinsic pharmacological properties. In the periphery, it is synthesized in epithelial cells of the proximal tubule and is thought to exert local diuretic and natriuretic effects. DA is a substrate for both MAO and COMT and thus is ineffective when administered orally. Classification of DA receptors is described in Chapter 13.

Pharmacological Properties Cardiovascular Effects

The cardiovascular effects of DA are mediated by several distinct types of receptors that vary in their affinity for DA (Chapter 13). At low concentrations, the primary interaction of DA is with vascular D_1 receptors, especially in the renal, mesenteric, and coronary beds. By activating adenylyl cyclase and raising intracellular concentrations of cAMP, D_1 receptor stimulation leads to vasodilation. Infusion of low doses of DA causes an increase in glomerular filtration rate, renal blood flow, and Na^+ excretion. Activation of D_1 receptors on renal tubular cells decreases Na^+ transport by cAMP-dependent and cAMP-independent mechanisms. Increasing cAMP production in the proximal tubular cells and the medullary part of the thick ascending limb of the loop of Henle inhibits the Na^+-H^+ exchanger and the $Na^+,K^+-ATPase$ pump. The renal tubular actions of DA that cause natriuresis may be augmented by the increase in renal blood flow and the small increase in the glomerular filtration rate that follows its administration. The resulting increase in hydrostatic pressure in the peritubular capillaries and reduction in oncotic pressure may contribute to diminished reabsorption of Na^+ by the proximal tubular cells. As a consequence, DA has pharmacologically appropriate effects in the

management of states of low cardiac output associated with compromised renal function, such as severe congestive heart failure.

At higher concentrations, DA exerts a positive inotropic effect on the myocardium, acting on β_1 adrenergic receptors. DA also causes the release of NE from nerve terminals, which contributes to its effects on the heart. Tachycardia is less prominent during infusion of DA than of INE (discussed further in the chapter). DA usually increases systolic blood pressure and pulse pressure and either has no effect on diastolic blood pressure or increases it slightly. Total peripheral resistance usually is unchanged when low or intermediate doses of DA are given, probably because of the ability of DA to reduce regional arterial resistance in some vascular beds, such as mesenteric and renal, while causing only minor increases in others. At high concentrations, DA activates vascular α_1 receptors, leading to more general vasoconstriction.

CNS Effects

Although there are specific DA receptors in the CNS, injected DA usually has no central effects because it does not readily cross the blood-brain barrier.

Precautions, Adverse Reactions, and Contraindications

Before DA is administered to patients in shock, hypovolemia should be corrected by transfusion of whole blood, plasma, or other appropriate fluid. Untoward effects due to overdosage generally are attributable to excessive sympathomimetic activity (although this also may be the response to worsening shock). Nausea, vomiting, tachycardia, anginal pain, arrhythmias, headache, hypertension, and peripheral vasoconstriction may be encountered during DA infusion. Extravasation of large amounts of DA during infusion may cause ischemic necrosis and sloughing. Rarely, gangrene of the fingers or toes has followed prolonged infusion of the drug. DA should be avoided or used at a much reduced dosage if the patient has received a MAO inhibitor. Careful adjustment of dosage also is necessary in patients who are taking tricyclic antidepressants.

Therapeutic Uses

Dopamine is used in the treatment of severe congestive heart failure, particularly in patients with oliguria and low or normal peripheral vascular resistance. The drug also may improve physiological parameters in the treatment of cardiogenic and septic shock. While DA may acutely improve cardiac and renal function in severely ill patients with chronic heart disease or renal failure, there is relatively little evidence supporting long-term benefit in clinical outcome (Marik and Iglesias, 1999).

Dopamine hydrochloride is used only intravenously, preferably into a large vein to prevent perivascular infiltration; extravasation may cause necrosis and sloughing of the surrounding tissue. The use of a calibrated infusion pump to control the rate of flow is necessary. The drug is administered at a rate of 2–5 $\mu\text{g/kg}$ per min; this rate may be increased gradually up to 20–50 $\mu\text{g/kg}$ per min or more as the clinical situation dictates. During the infusion, patients require clinical assessment of myocardial function, perfusion of vital organs such as the brain, and the production of urine. Reduction in urine flow, tachycardia, or the development of arrhythmias may be indications to slow or terminate the infusion. The duration of action of DA is brief, and hence the rate of administration can be used to control the intensity of effect.

Fenoldopam and Dopexamine. Fenoldopam, a benzazepine derivative, is a rapidly acting vasodilator used for not more than 48 h for control of severe hypertension (e.g., malignant hypertension with end-organ damage) in hospitalized patients. Fenoldopam is an agonist for peripheral D_1 receptors and binds with moderate affinity to α_2 adrenergic receptors; it has no significant affinity for D_2 receptors or α_1 or β adrenergic receptors. Fenoldopam is a racemic mixture; the R-isomer is the active component. It dilates a variety of blood vessels, including coronary arteries, afferent and efferent arterioles in the kidney, and mesenteric arteries (Murphy et al., 2001). Fenoldopam must be administered using a calibrated infusion pump; the usual dose rate ranges from 0.01 to 1.6 $\mu\text{g/kg}$ per min.

Less than 6% of an orally administered dose is absorbed because of extensive first-pass formation of sulfate, methyl, and glucuronide

conjugates. The elimination $t_{1/2}$ of intravenously infused fenoldopam is about 10 min. Adverse effects are related to the vasodilation and include headache, flushing, dizziness, and tachycardia or bradycardia.

Dopexamine is a synthetic analogue related to DA with intrinsic activity at DA D_1 and D_2 receptors as well as at β_2 receptors; it may have other effects, such as inhibition of catecholamine uptake (Fitton and Benfield, 1990). It has favorable hemodynamic actions in patients with severe congestive heart failure, sepsis, and shock. In patients with low cardiac output, dopexamine infusion significantly increases stroke volume with a decrease in systemic vascular resistance. Tachycardia and hypotension can occur, but usually only at high infusion rates. Dopexamine is not currently available in the U.S.

β Adrenergic Receptor Agonists

β Adrenergic receptor agonists play a major role only in the treatment of bronchoconstriction in patients with asthma (reversible airway obstruction) or COPD. Minor uses include management of preterm labor, treatment of complete heart block in shock, and short-term treatment of cardiac decompensation after surgery or in patients with congestive heart failure or myocardial infarction. The development of β_2 -selective agonists has resulted in drugs with even more valuable characteristics, including adequate oral bioavailability, lack of α adrenergic activity and relative lack of β_1 adrenergic activity, and thus diminished likelihood of adverse cardiovascular effects.

β Receptor agonists may be used to stimulate the rate and force of cardiac contraction. The chronotropic effect is useful in the emergency treatment of arrhythmias such as torsades de pointes, bradycardia, or heart block (Chapter 30), whereas the inotropic effect is useful when it is desirable to augment myocardial contractility.

Isoproterenol

Isoproterenol (INE, isopropyl norepinephrine, isoprenaline, isopropylarterenol, isopropyl noradrenaline, *d,l*- β -[3,4-dihydroxyphenyl]- α -isopropylaminoethanol) (Table 12-1) is a potent, nonselective β receptor agonist with very low affinity for α receptors. Consequently, INE has powerful effects on all β receptors and almost no action at α receptors.

Pharmacological Actions

The major cardiovascular effects of INE (compared with EPI and NE) are illustrated in Figure 12-2. *Intravenous infusion of INE lowers peripheral vascular resistance*, primarily in skeletal muscle but also in renal and mesenteric vascular beds. *Diastolic pressure falls. Systolic blood pressure may remain unchanged or rise, although mean arterial pressure typically falls. Cardiac output is increased because of the positive inotropic and chronotropic effects of the drug in the face of diminished peripheral vascular resistance.* The cardiac effects of INE may lead to palpitations, sinus tachycardia, and more serious arrhythmias; large doses of INE cause myocardial necrosis in experimental animals.

Isoproterenol relaxes almost all varieties of smooth muscle when the tone is high, an action that is most pronounced on bronchial and GI smooth muscle. INE prevents or relieves bronchoconstriction. Its effect in asthma may be due in part to an additional action to inhibit antigen-induced release of histamine and other mediators of inflammation, an action shared by β_2 -selective stimulants.

ADME

Isoproterenol is readily absorbed when given parenterally or as an aerosol. *It is metabolized by COMT, primarily in the liver but also by other tissues.* INE is a relatively poor substrate for MAO and NET (SLC6A2) and is not taken up by sympathetic neurons to the same extent as are EPI and NE. The duration of action of INE therefore may be longer than that of EPI, but it still is relatively brief.

Therapeutic Uses

Isoproterenol may be used in emergencies to stimulate heart rate in patients with bradycardia or heart block, particularly in anticipation of

inserting an artificial cardiac pacemaker or in patients with the ventricular arrhythmia torsades de pointes. In disorders such as asthma and shock, INE largely has been replaced by other sympathomimetic drugs (see further in this chapter and in Chapter 40).

Adverse Effects

Palpitations, tachycardia, headache, and flushing are common. Cardiac ischemia and arrhythmias may occur, particularly in patients with underlying coronary artery disease.

Dobutamine

Dobutamine resembles DA structurally but possesses a bulky aromatic substituent on the amino group (Table 12-1). The pharmacological effects of dobutamine are due to direct interactions with α and β receptors; its actions do not appear to result from release of NE from sympathetic nerve endings, and they are not exerted by dopaminergic receptors.

Dobutamine possesses a center of asymmetry; both enantiomeric forms are present in the racemate used clinically. The (–) isomer of dobutamine is a potent α_1 agonist and can cause marked pressor responses. In contrast, (+)-dobutamine is a potent α_1 receptor antagonist, which can block the effects of (–)-dobutamine. Both isomers are full agonists at β receptors; the (+) isomer is a more potent β agonist than the (–) isomer by about 10-fold.

Cardiovascular Effects

The cardiovascular effects of racemic dobutamine represent a composite of the distinct pharmacological properties of the (–) and (+) stereoisomers. Compared to INE, dobutamine has relatively more prominent inotropic than chronotropic effects on the heart. Although not completely understood, this useful selectivity may arise because peripheral resistance is relatively unchanged. Alternatively, cardiac α_1 receptors may contribute to the inotropic effect. At equivalent inotropic doses, dobutamine enhances automaticity of the sinus node to a lesser extent than does INE; however, enhancement of AV and intraventricular conduction is similar for both drugs.

In animals, infusion of dobutamine increases cardiac contractility and cardiac output without markedly changing total peripheral resistance; the relatively constant peripheral resistance presumably reflects counterbalancing of α_1 receptor-mediated vasoconstriction and β_2 receptor-mediated vasodilation. Heart rate increases only modestly when dobutamine is administered at less than 20 $\mu\text{g/kg}$ per min. After administration of β receptor antagonists, infusion of dobutamine fails to increase cardiac output, but total peripheral resistance increases, confirming that dobutamine has modest direct effects on α adrenergic receptors in the vasculature.

ADME

Dobutamine has a $t_{1/2}$ of about 2 min; the major metabolites are conjugates of dobutamine and 3-O-methyldobutamine. The onset of effect is rapid. Steady-state concentrations generally are achieved within 10 min of initiation of the infusion by calibrated infusion pump. The rate of infusion required to increase cardiac output typically is between 2.5 and 10 $\mu\text{g/kg}$ per min, although higher infusion rates occasionally are required. The rate and duration of the infusion are determined by the clinical and hemodynamic responses of the patient.

Therapeutic Uses

Dobutamine is indicated for the short-term treatment of cardiac decompensation that may occur after cardiac surgery or in patients with congestive heart failure or acute myocardial infarction. Dobutamine increases cardiac output and stroke volume in such patients, usually without a marked increase in heart rate. Alterations in blood pressure or peripheral resistance usually are minor, although some patients may have marked increases in blood pressure or heart rate. An infusion of dobutamine in combination with echocardiography is useful in the noninvasive assessment of patients with coronary artery disease.

Adverse Effects

Blood pressure and heart rate may increase significantly during dobutamine administration requiring reduction of infusion rate. Patients with

a history of hypertension may exhibit an exaggerated pressor response more frequently. Because dobutamine facilitates AV conduction, patients with atrial fibrillation are at risk of marked increases in ventricular response rates; digoxin or other measures may be required to prevent this from occurring. Some patients may develop ventricular ectopic activity. Dobutamine may increase the size of a myocardial infarct by increasing myocardial O₂ demand, a property common to inotropic agents. The efficacy of dobutamine over a period of more than a few days is uncertain; there is evidence for the development of tolerance.

β_2 -Selective Adrenergic Receptor Agonists

Some of the major adverse effects of β receptor agonists in the treatment of asthma or COPD are caused by stimulation of β_1 receptors in the heart. β_2 -Selective agents have been developed to avoid these adverse effects. This selectivity, however, is not absolute and is lost at high concentrations of these drugs. Moreover, up to 40% of the β receptors in the human heart are β_2 receptors, activation of which can also cause cardiac stimulation (Brodde and Michel, 1999).

A second strategy that has increased the usefulness of several β_2 -selective agonists in the treatment of asthma and COPD has been structural modification that results in lower rates of metabolism and enhanced oral bioavailability. Modifications have included placing the hydroxyl groups at positions 3 and 5 of the phenyl ring or substituting another moiety for the hydroxyl group at position 3. This has yielded drugs such as metaproterenol, terbutaline, and albuterol, which are not substrates for COMT. Bulky substituents on the amino group of catecholamines contribute to potency at β receptors with decreased activity at α receptors and decreased metabolism by MAO.

A final strategy to enhance preferential activation of pulmonary β_2 receptors is the administration by inhalation of small doses of the drug in aerosol form. This approach typically leads to effective activation of β_2 receptors in the bronchi but very low systemic drug concentrations. Consequently, there is less potential to activate cardiac β_1 or β_2 receptors or to stimulate β_2 receptors in skeletal muscle, which can cause tremor and thereby limit oral therapy.

Subcutaneous injection also causes prompt bronchodilation; for an orally administered agent, the peak effect may be delayed for several hours. Administration of β receptor agonists by aerosol (Chapter 40) typically leads to a very rapid therapeutic response, generally within minutes, although some agonists such as *salmeterol* have a delayed onset of action. Aerosol therapy depends on the delivery of drug to the distal airways. This, in turn, depends on the size of the particles in the aerosol and respiratory parameters such as inspiratory flow rate, tidal volume, breath-holding time, and airway diameter. Only about 10% of an inhaled dose actually enters the lungs; much of the remainder is swallowed and ultimately may be absorbed. Successful aerosol therapy requires that each patient master the technique of drug administration. In some patients, particularly children and the elderly, spacer devices may enhance the efficacy of inhalation therapy.

In the treatment of asthma and COPD, β receptor agonists are used to activate pulmonary receptors that relax bronchial smooth muscle and decrease airway resistance. β Receptor agonists also may suppress the release of leukotrienes and histamine from mast cells in lung tissue, enhance mucociliary function, decrease microvascular permeability, and possibly inhibit phospholipase A₂. Airway inflammation also contributes to airway hyperresponsiveness; consequently, the use of anti-inflammatory drugs such as inhaled steroids has primary importance. Most authorities recommend that long-acting β agonists should not be used without concomitant anti-inflammatory therapy in the treatment of asthma (see Chapter 40; Drazen and O'Byrne, 2009; Fanta, 2009).

Short-Acting β_2 Adrenergic Agonists

Metaproterenol. Metaproterenol (called orciprenaline in Europe), along with *terbutaline* and *fenoterol*, belongs to the structural class of resorcinol bronchodilators that have hydroxyl groups at positions 3 and 5 of the phenyl ring (rather than at positions 3 and 4 as in catechols) (Table 12-1).

Consequently, metaproterenol is resistant to methylation by COMT, and a substantial fraction (40%) is absorbed in active form after oral administration. It is excreted primarily as glucuronic acid conjugates. Metaproterenol is considered to be β_2 selective, although it probably is less selective than albuterol or terbutaline and hence is more prone to cause cardiac stimulation. Effects occur within minutes of inhalation and persist for several hours. After oral administration, onset of action is slower, but effects last 3–4 h. Metaproterenol is used for the long-term treatment of obstructive airway diseases and asthma and for treatment of acute bronchospasm (Chapter 40). Side effects are similar to the short- and intermediate-acting sympathomimetic bronchodilators.

Albuterol. Albuterol is a selective β_2 receptor agonist with pharmacological properties and therapeutic indications similar to those of terbutaline. It can be administered by inhalation or orally for the symptomatic relief of bronchospasm.

When administered by inhalation, it produces significant bronchodilation within 15 min, and effects persist for 3–4 h. The cardiovascular effects of albuterol are much weaker than those of INE when doses that produce comparable bronchodilation are administered by inhalation. Oral albuterol has the potential to delay preterm labor. Although rare, CNS and respiratory side effects are sometimes observed.

Albuterol has been made available in a metered-dose inhaler free of CFCs (chlorofluorocarbons). The alternate propellant, HFA (hydrofluoroalkane), is inert in the human airway, but unlike CFCs, it does not deplete stratospheric ozone.

Levalbuterol. Levalbuterol is the *R*-enantiomer of albuterol, a racemate used to treat asthma and COPD. Although originally available only as a solution for a nebulizer, it is now available as a CFC-free metered-dose inhaler. Levalbuterol is β_2 selective and acts like other β_2 adrenergic agonists. In general, levalbuterol has similar pharmacokinetic and pharmacodynamics properties as albuterol.

Pirbuterol. Pirbuterol is a relatively selective β_2 agonist. Its structure differs from that of albuterol by the substitution of a pyridine ring for the benzene ring. Pirbuterol acetate is available for inhalation therapy; dosing is typically every 4–6 h. Pirbuterol is the only preparation available in a breath-activated metered-dose inhaler, a device meant to optimize medication delivery by releasing a spray of medication only on the patient's initiation of inspiration.

Terbutaline. Terbutaline is a β_2 -selective bronchodilator. It contains a resorcinol ring and thus is not a substrate for COMT methylation. It is effective when taken orally or subcutaneously or by inhalation (not marketed for inhalation in the U.S.). Effects are observed rapidly after inhalation or parenteral administration; after inhalation, its action may persist 3–6 h. With oral administration, the onset of effect may be delayed 1–2 h. Terbutaline is used for the long-term treatment of obstructive airway diseases and for treatment of acute bronchospasm; it also is available for parenteral use for the emergency treatment of status asthmaticus (Chapter 40).

Isoetharine. Isoetharine is an older β_2 -selective drug. Its selectivity for β_2 receptors does not approach that of some newer agents. Although resistant to metabolism by MAO, it is a catecholamine and thus is a good substrate for COMT. Consequently, it is used only by inhalation for the treatment of acute episodes of bronchoconstriction. Isoetharine is no longer marketed in the U.S.

Fenoterol. Fenoterol is a β_2 -selective receptor agonist. After inhalation, it has a prompt onset of action, and its effect typically is sustained for 4–6 h. A possible association of fenoterol use with increased deaths from asthma, although controversial (Suisa and Ernst, 1997), has led to its withdrawal from the market. The dysrhythmias and cardiac effects associated with fenoterol are likely due to effects on β_1 adrenergic receptors.

Procaterol. Procaterol is a β_2 -selective receptor agonist. After inhalation, it has a prompt onset of action that is sustained for about 5 h. Procaterol is not available in the U.S.

Long-Acting β_2 Adrenergic Agonists (LABAs)

Salmeterol

Mechanism of Action. Salmeterol is a lipophilic β_2 -selective agonist with a prolonged duration of action (>12 h) and a selectivity for β_2 receptors about 50-fold greater than that of albuterol. Salmeterol provides symptomatic relief and improves lung function and quality of life in patients with COPD. It is as effective as the cholinergic antagonist ipratropium, more effective than theophylline, and has additive effects when used in combination with inhaled ipratropium or oral theophylline. Salmeterol may have anti-inflammatory activity.

ADME. The onset of action of inhaled salmeterol is relatively slow, so it is not suitable monotherapy for acute attacks of bronchospasm. Salmeterol is metabolized by CYP3A4 to α -hydroxy-salmeterol, which is eliminated primarily in the feces.

Clinical Use, Precautions, and Adverse Effects. Salmeterol and formoterol are the agents of choice for nocturnal asthma in patients who remain symptomatic despite anti-inflammatory agents and other standard management.

Salmeterol generally is well tolerated but has the potential to increase heart rate and plasma glucose concentration, to produce tremors, and to decrease plasma K^+ concentration through effects on extrapulmonary β_2 receptors. Salmeterol should not be used more than twice daily (morning and evening) and should not be used to treat acute asthma symptoms, which should be treated with a short-acting β_2 agonist (e.g., *albuterol*) when breakthrough symptoms occur despite twice-daily use of salmeterol (Redington, 2001).

Patients with moderate or severe persistent asthma or COPD benefit from the use of LABAs like salmeterol in combination with an inhaled corticosteroid. For that reason, salmeterol is available in a single formulate combination with the corticosteroid fluticasone. These benefits must be counterbalanced against data, oft-criticized, showing that the addition of a LABA to “usual therapy” was associated with an increased risk of fatal or near-fatal asthmatic attacks, as compared with usual therapy alone. On the other hand, there is a lack of reports of increased asthma mortality among patients taking both a LABA and an inhaled corticosteroid (Fanta, 2009). Nevertheless, the FDA has placed a **black-box warning** in the labeling information for *salmeterol*, *formoterol*, and *arformoterol*. Expert panels (Fanta, 2009) recommend the use of LABAs only for patients in whom inhaled corticosteroids alone either failed to achieve good asthma control or for initial therapy.

Formoterol. Formoterol is a long-acting β_2 -selective receptor agonist. Significant bronchodilation, which may persist for up to 12 h, occurs within minutes of inhalation of a therapeutic dose. It is highly lipophilic and has high affinity for β_2 receptors. Its major advantage over many other β_2 -selective agonists is this prolonged duration of action, which may be particularly advantageous in settings such as nocturnal asthma. Formoterol's sustained action is due to its insertion into the lipid bilayer of the plasma membrane, from which it gradually diffuses to provide prolonged stimulation of β_2 receptors. It is FDA-approved for treatment of asthma and bronchospasm, prophylaxis of exercise-induced bronchospasm, and COPD. It can be used concomitantly with short-acting β_2 agonists, glucocorticoids (inhaled or systemic), and theophylline (Goldsmith and Keating, 2004). Formoterol is also available as a single formulaic combination with the glucocorticoids mometasone or budesonide for treatment of COPD.

Arformoterol. Arformoterol, an enantiomer of formoterol, is a selective LABA that has twice the potency of racemic formoterol. It is FDA-approved for the long-term treatment of bronchoconstriction in patients with COPD, including chronic bronchitis and emphysema (Matera and Cazzola, 2007). It was the first LABA developed as inhalational therapy for use with a nebulizer (Abdelghany, 2007).

Systemic exposure to arformoterol is due to pulmonary absorption, with plasma levels reaching a peak in 0.25–1 h. It is primarily metabolized by direct conjugation to glucuronide or sulfate conjugates and secondarily by O-demethylation by CYP2D6 and CYP2C19. It does not inhibit any of the common CYPs (Fanta, 2009).

Very Long-Acting β_2 Adrenergic Agonists (VLABAs)

Very long-acting β_2 adrenergic agonists have been developed primarily for treating COPD. These drugs are not recommended for treating asthma.

Indacaterol, the first once-daily LABA approved for COPD, is a potent β_2 agonist with high intrinsic efficacy. It has a fast onset of action, appears well tolerated, and is effective in COPD with little tachyphylaxis on continued use. In contrast to salmeterol, indacaterol does not antagonize the bronchorelaxant effect of short-acting β_2 adrenergic agonists.

Olodaterol is also a once-daily, long-acting β_2 agonist approved for use in COPD. It is also offered in combination with tiotropium bromide, an antagonist at M_3 muscarinic receptors.

Vilanterol is a VLABA approved for use in combination with fluticasone. Vilanterol is available in Europe in combination with the long-acting muscarinic antagonist umeclidinium.

Other β_2 -Selective Agonists

Ritodrine. Ritodrine is a β_2 -selective agonist that was developed specifically for use as a uterine relaxant. Its pharmacological properties closely resemble those of the other agents in this group. The pharmacokinetic properties of ritodrine are complex and incompletely defined, especially in pregnant women. Ritodrine is rapidly but incompletely (30%) absorbed following oral administration: The drug may be administered intravenously to selected patients to arrest premature labor. β_2 -Selective agonists may not have clinically significant benefits on perinatal mortality and may actually increase maternal morbidity. Ritodrine is not available in the U.S. See Chapter 44 for the pharmacology of tocolytic agents.

Adverse Effects of β_2 -Selective Agonists

The major adverse effects of β receptor agonists occur as a result of excessive activation of β receptors. Patients with underlying cardiovascular disease are particularly at risk for significant reactions. However, the likelihood of adverse effects can be greatly decreased in patients with lung disease by administering the drug by inhalation rather than orally or parenterally.

Tremor is a relatively common adverse effect of the β_2 -selective receptor agonists. Tolerance generally develops to this effect; it is not clear whether tolerance reflects desensitization of the β_2 receptors of skeletal muscle or adaptation within the CNS. This adverse effect can be minimized by starting oral therapy with a low dose of drug and progressively increasing the dose as tolerance to the tremor develops. Feelings of restlessness, apprehension, and anxiety may limit therapy with these drugs, particularly oral or parenteral administration.

Tachycardia is a common adverse effect of systemically administered β receptor agonists. Stimulation of heart rate occurs primarily by means of β_1 receptors. It is uncertain to what extent the increase in heart rate also is due to activation of cardiac β_2 receptors or to reflex effects that stem from β_2 receptor-mediated peripheral vasodilation. During a severe asthma attack, heart rate actually may decrease during therapy with a β agonist, presumably because of improvement in pulmonary function with consequent reduction in endogenous cardiac sympathetic stimulation. In patients without cardiac disease, β agonists rarely cause significant arrhythmias or myocardial ischemia; however, patients with underlying coronary artery disease or preexisting arrhythmias are at greater risk. The risk of adverse cardiovascular effects also is increased in patients who are receiving MAO inhibitors. In general, at least 2 weeks should elapse between the use of MAO inhibitors and administration of β_2 agonists or other sympathomimetics.

When given parenterally, these drugs also may increase the concentrations of glucose, lactate, and free fatty acids in plasma and decrease the concentration of K^+ . The decrease in K^+ concentration may be especially important in patients with cardiac disease, particularly those taking digoxin and diuretics. In some diabetic patients, hyperglycemia may be worsened by these drugs, and higher doses of insulin may be required. Side effects of LABAs and VLABAs include nasopharyngitis and increase in incidence of pneumonia. As a result of these side effects, postmarketing safety studies are under way.

Large doses of β receptor agonists cause myocardial necrosis in laboratory animals.

β_3 Adrenergic Receptor Agonists

The existence of the β_3 adrenergic receptor subtype was first proposed in the 1970s but was not confirmed until the receptor was cloned in 1989 (Emorine et al., 1989). The β_3 receptor couples to the G_s -cAMP pathway and has a much stronger affinity for NE than EPI. The β_3 receptor displays much lower affinities for classic β antagonists (such as propranolol or atenolol) than do β_1 and β_2 receptors. In humans, the β_3 receptor is expressed in brown adipose tissue, gallbladder, and ileum and to a lesser extent in white adipose tissue and the detrusor muscle of the bladder; there is little expression elsewhere (Berkowitz et al., 1995). To date, the major therapeutic target that has emerged from this field has been the development of β_3 receptor agonists for use in urinary incontinence (Michel, 2016).

Mirabegron is a β_3 adrenergic receptor agonist approved for use against incontinence. Activation of this receptor in the bladder leads to detrusor muscle relaxation and increased bladder capacity. This action prevents voiding and provides relief for those with an overactive bladder and urinary incontinence. Side effects include increased blood pressure, increased incidence of urinary tract infection, and headache. Mirabegron is also a moderate CYP2D6 inhibitor, so care must be taken when prescribing with other drugs metabolized by CYP2D6, such as digoxin, metoprolol, and desipramine.

α Adrenergic Receptor Agonists

α_1 -Selective Adrenergic Receptor Agonists

The major effects of a number of sympathomimetic drugs are due to activation of α adrenergic receptors in vascular smooth muscle. As a result, peripheral vascular resistance is increased, and blood pressure is maintained or elevated. The clinical utility of these drugs is limited to the treatment of some patients with hypotension, including orthostatic hypotension, or shock. *Phenylephrine* and *methoxamine* (discontinued in the U.S.) are direct-acting vasoconstrictors and are selective activators of α_1 receptors. *Mephentermine* and *metaraminol* act both directly and indirectly. Midodrine is a prodrug that is converted, after oral administration, to *desglymidodrine*, a direct-acting α_1 agonist.

Phenylephrine

Phenylephrine is an α_1 -selective agonist; it activates β receptors only at much higher concentrations. The pharmacological effects of phenylephrine are similar to those of methoxamine. The drug causes marked arterial vasoconstriction during intravenous infusion. Phenylephrine also is used as a nasal decongestant and as a mydriatic in various nasal and ophthalmic formulations (see Chapter 69).

Metaraminol

Metaraminol exerts *direct effects* on vascular α adrenergic receptors and acts *indirectly* by stimulating the release of NE. The drug has been used in the treatment of hypotensive states or off-label to relieve attacks of paroxysmal atrial tachycardia, particularly those associated with hypotension (see Chapter 30).

Midodrine

Midodrine is an orally effective α_1 receptor agonist. It is a prodrug, converted to an active metabolite, *desglymidodrine*, which achieves peak concentrations about 1 h after a dose of midodrine. The $t_{1/2}$ of desglymidodrine is about 3 h; its duration of action is about 4–6 h. Midodrine-induced rises in blood pressure are associated with contraction of both arterial and venous smooth muscle. This is advantageous in the treatment of patients with autonomic insufficiency and postural hypotension (McClellan et al., 1998). A frequent complication in these patients is supine hypertension. This can be minimized by administering the drug during periods when the patient will remain upright, avoiding dosing

within 4 h of bedtime, and elevating the head of the bed. Very cautious use of a short-acting antihypertensive drug at bedtime may be useful in some patients. Typical dosing, achieved by careful titration of blood pressure responses, varies between 2.5 and 10 mg three times daily.

α_2 -Selective Adrenergic Receptor Agonists

α_2 -Selective adrenergic agonists are used primarily for the treatment of systemic hypertension. Their efficacy as antihypertensive agents is somewhat surprising, because many blood vessels contain postsynaptic α_2 adrenergic receptors that promote vasoconstriction (Chapter 8). Clonidine, an α_2 -agonist, was developed as a vasoconstricting nasal decongestant; its lowers blood pressure by activating α_2 receptors in the CNS, thereby suppressing sympathetic outflow from the brain.

The α_2 agonists also reduce intraocular pressure by decreasing the production of aqueous humor. Two derivatives of clonidine, apraclonidine and brimonidine, applied topically to the eye, decrease intraocular pressure with little or no effect on systemic blood pressure.

Clonidine

Clonidine is an imidazoline derivative and an α_2 adrenergic agonist.

Mechanisms of Action and Pharmacological Effects. Intravenous infusion of clonidine causes an acute rise in blood pressure because of activation of postsynaptic α_2 receptors in vascular smooth muscle. This transient vasoconstriction (not usually seen with oral administration) is followed by a more prolonged hypotensive response that results from decreased sympathetic outflow from the CNS. The effect appears to result, at least in part, from activation of α_2 receptors in the lower brainstem region. Clonidine also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate. In addition, some of the antihypertensive effects of clonidine may be mediated by activation of presynaptic α_2 receptors that suppress the release of NE, ATP, and NPY from postganglionic sympathetic nerves. Clonidine decreases the plasma concentration of NE and reduces its excretion in the urine.

Does Clonidine Act Via Imidazoline I_1 Receptors?

Studies in knockout animals demonstrated the requirement for a functional α_2 receptor for the hypotensive effect of clonidine. Clonidine and its congeners, as imidazolines, also bind to imidazoline receptors, of which there are three subtypes (I_1 , I_2 , and I_3) that are widely distributed in the body, including the CNS. Activation of the I_1 receptor appears to reduce sympathetic outflow from the CNS. Whether activation of the CNS I_1 imidazoline receptor also plays a role in the hypotensive effects of clonidine and its congeners is a topic of ongoing research. The current hypothesis is that I_1 receptors are upstream from the hypotensive α_2 receptors in the CNS and work in tandem with them, such that activation of the I_1 receptors results in catecholamine release onto the α_2 receptors (Lowry and Brown, 2014; Nikolic and Agbaba 2012), thereby reducing sympathetic outflow and reducing blood pressure.

Clonidine decreases discharges in sympathetic preganglionic fibers in the splanchnic nerve and in postganglionic fibers of cardiac nerves. These effects are blocked by α_2 -selective antagonists such as yohimbine. Clonidine also stimulates parasympathetic outflow, which may contribute to the slowing of heart rate as a consequence of increased vagal tone and diminished sympathetic drive. In addition, some of the antihypertensive effects of clonidine may be mediated by activation of presynaptic α_2 receptors that suppress

the release of NE, ATP, and NPY from postganglionic sympathetic nerves. Clonidine decreases the plasma concentration of NE and reduces its excretion in the urine.

ADME. Clonidine is well absorbed after oral administration, with bioavailability about 100%. Peak concentration in plasma and the maximal hypotensive effect are observed 1–3 h after an oral dose. The elimination $t_{1/2}$ is 6–24 h (mean about 12 h). About half of an administered dose can be recovered unchanged in the urine; the $t_{1/2}$ of the drug may increase with renal failure. A transdermal delivery patch permits continuous administration of clonidine as an alternative to oral therapy. The drug is released at an approximately constant rate for a week; 3–4 days are required to reach steady-state concentrations in plasma. When the patch is removed, plasma concentrations remain stable for about 8 h and then decline gradually over a period of several days; this decrease is associated with a rise in blood pressure.

Therapeutic Uses. Clonidine is used mainly in the treatment of hypertension (see Chapter 27). Clonidine also has apparent efficacy in the off-label treatment of a range of other disorders: in reducing diarrhea in some diabetic patients with autonomic neuropathy; in treating and preparing addicted subjects for withdrawal from narcotics, alcohol, and tobacco (see Chapter 24) by ameliorating some of the adverse sympathetic nervous activity associated with withdrawal and decreasing craving for the drug; and in reducing the incidence of menopausal hot flashes (transdermal application). Acute administration of clonidine has been used in the differential diagnosis of patients with hypertension and suspected pheochromocytoma. Among the other off-label uses of clonidine are atrial fibrillation, ADHD, constitutional growth delay in children, cyclosporine-associated nephrotoxicity, Tourette syndrome, hyperhidrosis, mania, posthepatic neuralgia, psychosis, restless leg syndrome, ulcerative colitis, and allergy-induced inflammatory reactions in patients with extrinsic asthma.

Adverse Effects. The major adverse effects of clonidine are dry mouth and sedation, which may diminish in intensity after several weeks of therapy. Sexual dysfunction also may occur. Marked bradycardia is observed in some patients. These effects of clonidine frequently are related to dose, and their incidence may be lower with transdermal administration of clonidine. About 15%–20% of patients develop contact dermatitis when using the transdermal system. Withdrawal reactions follow abrupt discontinuation of long-term therapy with clonidine in some hypertensive patients (see Chapter 28).

Apraclonidine

Apraclonidine is a relatively selective α_2 receptor agonist that is used topically to reduce intraocular pressure with minimal systemic effects. This agent does not cross the blood-brain barrier and is more useful than clonidine for ophthalmic therapy. Apraclonidine is useful as short-term adjunctive therapy in patients with glaucoma whose intraocular pressure is not well controlled by other pharmacological agents. The drug also is used to control or prevent elevations in intraocular pressure that occur in patients after laser trabeculoplasty or iridotomy (see Chapter 69).

Brimonidine

Brimonidine is a clonidine derivative and α_2 -selective agonist that is administered ocularly to lower intraocular pressure in patients with ocular hypertension or open-angle glaucoma. Unlike apraclonidine, brimonidine can cross the blood-brain barrier and can produce hypotension and sedation, although these CNS effects are slight compared to those of clonidine.

Guanfacine

Guanfacine is an α_2 receptor agonist that is more selective than clonidine for α_2 receptors. Like clonidine, guanfacine lowers blood pressure by activation of brainstem receptors with resultant suppression of sympathetic activity. A sustained-release form is FDA-approved for treatment of ADHD in children aged 6–17 years.

Clinical Use. The drug is well absorbed after oral administration. About 50% of guanfacine appears unchanged in the urine; the rest is metabolized.

The $t_{1/2}$ for elimination ranges from 12 to 24 h. Guanfacine and clonidine appear to have similar efficacy for the treatment of hypertension and a similar pattern of adverse effects. A withdrawal syndrome may occur after the abrupt discontinuation, but it is less frequent and milder than the syndrome that follows clonidine withdrawal; this difference may relate to the longer $t_{1/2}$ of guanfacine.

Guanabenz

Guanabenz is a centrally acting α_2 -agonist that decreases blood pressure by a mechanism similar to those of clonidine and guanfacine. Guanabenz has a $t_{1/2}$ of 4–6 h and is extensively metabolized by the liver. Dosage adjustment may be necessary in patients with hepatic cirrhosis. The adverse effects caused by guanabenz (e.g., dry mouth and sedation) are similar to those seen with clonidine.

Methyldopa

Methyldopa (α -methyl-3,4-dihydroxyphenylalanine) is a centrally acting antihypertensive agent. It is metabolized to α -methylnorepinephrine in the brain, and this compound is thought to activate central α_2 receptors and lower blood pressure in a manner similar to that of clonidine (see Chapter 27).

Tizanidine

Tizanidine is a muscle relaxant used for the treatment of spasticity associated with cerebral and spinal disorders. It is also an α_2 -agonist with some properties similar to those of clonidine.

Moxonidine

Moxonidine is a mixed α_2 receptor and imidazole I_1 receptor agonist. It acts to reduce sympathetic outflow from the CNS and thereby reduces blood pressure. Moxonidine also has analgesic activity, interacts synergistically with opioid agonists, and is used in treating neuropathic pain.

Miscellaneous Sympathomimetic Agonists

Amphetamine

Amphetamine, racemic β phenylisopropylamine (Table 12–1), has powerful CNS stimulant actions in addition to the peripheral α and β actions common to indirect-acting sympathomimetic drugs. Unlike EPI, it is effective after oral administration, and its effects last for several hours.

Cardiovascular System

Amphetamine given orally raises both systolic and diastolic blood pressure. Heart rate often is reflexly slowed; with large doses, cardiac arrhythmias may occur. Cardiac output is not enhanced by therapeutic doses, and cerebral blood flow does not change much. The *l*-isomer is slightly more potent than the *d*-isomer in its cardiovascular actions.

Other Smooth Muscles

In general, smooth muscles respond to amphetamine as they do to other sympathomimetic amines. The contractile effect on the sphincter of the urinary bladder is particularly marked, and for this reason amphetamine has been used in treating enuresis and incontinence. Pain and difficulty in micturition occasionally occur. The GI effects of amphetamine are unpredictable. If enteric activity is pronounced, amphetamine may cause relaxation and delay the movement of intestinal contents; if the gut already is relaxed, the opposite effect may occur. The response of the human uterus varies, but there usually is an increase in tone.

CNS

Amphetamine is one of the most potent sympathomimetic amines in stimulating the CNS. It stimulates the medullary respiratory center, lessens the degree of central depression caused by various drugs, and produces other signs of CNS stimulation. In eliciting CNS excitatory effects, the *d*-isomer (dextroamphetamine) is three to four times more potent than the *l*-isomer. The psychic effects depend on the dose and the mental state and personality of the individual. The main results of an oral dose of 10–30 mg include wakefulness, alertness, and a decreased sense of fatigue; elevation of mood, with increased initiative, self-confidence, and ability to concentrate; often,

elation and euphoria; and increase in motor and speech activities. Performance of simple mental tasks is improved, but, although more work may be accomplished, the number of errors may increase. Physical performance (e.g., in athletes) is improved, and the drug often is abused for this purpose. These effects are variable and may be reversed by overdosage or repeated usage. Prolonged use or large doses are nearly always followed by depression and fatigue. Many individuals given amphetamine experience headache, palpitation, dizziness, vasomotor disturbances, agitation, confusion, dysphoria, apprehension, delirium, or fatigue.

Fatigue and Sleep. In general, amphetamine prolongs the duration of adequate performance before fatigue appears, and the effects of fatigue are at least partly reversed, most strikingly when performance has been reduced by fatigue and lack of sleep. Such improvement may be partly due to alteration of unfavorable attitudes toward the task. However, amphetamine reduces the frequency of attention lapses that impair performance after prolonged sleep deprivation and thus improves execution of tasks requiring sustained attention. The need for sleep may be postponed, but it cannot be avoided indefinitely. When the drug is discontinued after long use, the pattern of sleep may take as long as 2 months to return to normal.

Analgesia. Amphetamine and some other sympathomimetic amines have a small analgesic effect that is not sufficiently pronounced to be therapeutically useful. However, amphetamine can enhance the analgesia produced by opiates.

Respiration. Amphetamine stimulates the respiratory center, increasing the rate and depth of respiration. In normal individuals, usual doses of the drug do not appreciably increase respiratory rate or minute volume. Nevertheless, when respiration is depressed by centrally acting drugs, amphetamine may stimulate respiration.

Appetite. Amphetamine and similar drugs have been used for the treatment of obesity, although the wisdom of this use is at best questionable. Weight loss in obese humans treated with amphetamine is almost entirely due to reduced food intake and only in small measure to increased metabolism. The site of action probably is in the lateral hypothalamic feeding center; injection of amphetamine into this area, but not into the ventromedial region, suppresses food intake. Neurochemical mechanisms of action are unclear but may involve increased release of NE or DA. In humans, tolerance to the appetite suppression develops rapidly. Hence, continuous weight reduction usually is not observed in obese individuals without dietary restriction.

Mechanisms of Action in the CNS

Amphetamine exerts most or all of its effects in the CNS by releasing biogenic amines from their storage sites in nerve terminals. The neuronal DAT and the VMAT2 appear to be two of the principal targets of amphetamine's action (Fleckenstein, 2007; Sitte and Freissmuth, 2015). These mechanisms include amphetamine-induced exchange diffusion, reverse transport, channel-like transport phenomena, and effects resulting from the weakly basic properties of amphetamine. Amphetamine analogues affect monoamine transporters through phosphorylation, transporter trafficking, and the production of reactive oxygen and nitrogen species. These mechanisms may have potential implications for neurotoxicity as well as dopaminergic neurodegenerative diseases (discussed further in the chapter).

The alerting effect of amphetamine, its anorectic effect, and at least a component of its locomotor-stimulating action presumably are mediated by release of NE from central noradrenergic neurons. These effects can be prevented in experimental animals by inhibiting tyrosine hydroxylase and thus catecholamine synthesis. Some aspects of locomotor activity and the stereotyped behavior induced by amphetamine probably are a consequence of the release of DA from dopaminergic nerve terminals, particularly in the neostriatum. Higher doses are required to produce these behavioral effects, and this correlates with the higher concentrations of amphetamine required to release DA from brain slices or synaptosomes in vitro. With still higher doses of amphetamine, disturbances of perception and overt psychotic behavior occur. These effects may be due to release of 5HT from serotonergic neurons and of DA in the mesolimbic system.

In addition, amphetamine may exert direct effects on CNS receptors for 5HT (Chapter 13).

Toxicity and Adverse Effects

The acute toxic effects of amphetamine usually are extensions of its therapeutic actions and as a rule result from overdosage. CNS effects commonly include restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, tenseness, irritability, weakness, insomnia, fever, and sometimes euphoria. Confusion, aggressiveness, changes in libido, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies occur, especially in mentally ill patients. However, these psychotic effects can be elicited in any individual if sufficient quantities of amphetamine are ingested for a prolonged period. Fatigue and depression usually follow central stimulation. Cardiovascular effects are common and include headache, chilliness, pallor or flushing, palpitation, cardiac arrhythmias, anginal pain, hypertension or hypotension, and circulatory collapse. Excessive sweating occurs. GI symptoms include dry mouth, metallic taste, anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Fatal poisoning usually terminates in convulsions and coma, and cerebral hemorrhages are the main pathological findings.

The toxic dose of amphetamine varies widely. Toxic manifestations occasionally occur as an idiosyncratic reaction after as little as 2 mg but are rare with doses less than 15 mg. Severe reactions have occurred with 30 mg, yet doses of 400–500 mg are not uniformly fatal. Larger doses can be tolerated after chronic use of the drug. Treatment of acute amphetamine intoxication may include acidification of the urine by administration of ammonium chloride; this enhances the rate of elimination. Sedatives may be required for the CNS symptoms. Severe hypertension may require administration of sodium nitroprusside or an α adrenergic receptor antagonist.

Chronic intoxication with amphetamine causes symptoms similar to those of acute overdosage, but abnormal mental conditions are more common. Weight loss may be marked. A psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia, is the most common serious effect. Recovery usually is rapid after withdrawal of the drug, but occasionally the condition becomes chronic. In these persons, amphetamine may act as a precipitating factor hastening the onset of incipient schizophrenia.

The abuse of amphetamine as a means of overcoming sleepiness and of increasing energy and alertness should be discouraged. The drug should be used only under medical supervision. The amphetamines are schedule II drugs under federal regulations. The additional contraindications and precautions for the use of amphetamine generally are similar to those described for EPI. Amphetamine use is inadvisable in patients with anorexia, insomnia, asthenia, psychopathic personality, or a history of homicidal or suicidal tendencies.

Dependence and Tolerance

Psychological dependence often occurs when amphetamine or dextroamphetamine is used chronically, as discussed in Chapter 24. Tolerance almost invariably develops to the anorexigenic effect of amphetamines and often is seen also in the need for increasing doses to maintain improvement of mood in psychiatric patients. Tolerance is striking in individuals who are dependent on the drug; a daily intake of 1.7 g without apparent ill effects has been reported. Development of tolerance is not invariable, and cases of narcolepsy have been treated for years without requiring an increase in the initially effective dose.

Therapeutic Uses

Amphetamine is used chiefly for its CNS effects. Dextroamphetamine, with greater CNS action and less peripheral action, is FDA-approved for the treatment of narcolepsy and ADHD (see discussion later in this chapter).

Methamphetamine

Methamphetamine is closely related chemically to amphetamine and ephedrine (Table 12–1). The drug acts centrally to release DA and other biogenic amines and to inhibit neuronal and VMATs as well as MAO.

Small doses have prominent central stimulant effects without significant peripheral actions; somewhat larger doses produce a sustained rise in systolic and diastolic blood pressures, due mainly to cardiac stimulation. Cardiac output is increased, although the heart rate may be reflexly slowed. Venous constriction causes peripheral venous pressure to increase. These factors tend to increase the venous return and thus cardiac output; pulmonary arterial pressure is raised.

Methamphetamine is a schedule II drug under federal regulations and has high potential for abuse (Chapter 24). It is widely abused as a cheap, accessible recreational drug. Illegal production of methamphetamine in clandestine laboratories throughout the U.S. is common. It is used principally for its central effects, which are more pronounced than those of amphetamine and are accompanied by less-prominent peripheral actions (see Therapeutic Uses of Sympathomimetic Drugs).

Methylphenidate

Methylphenidate is a piperidine derivative that is structurally related to amphetamine. Methylphenidate is a mild CNS stimulant with more prominent effects on mental than on motor activities. However, large doses produce signs of generalized CNS stimulation that may lead to convulsions.

The effects of methylphenidate resemble those of the amphetamines. Methylphenidate also shares the abuse potential of the amphetamines and is listed as a schedule II controlled substance in the U.S. Methylphenidate is effective in the treatment of narcolepsy and ADHD (described in the material that follows). Methylphenidate is readily absorbed after oral administration, reaching a peak C_p in about 2 h. The drug is a racemate; its more potent (+) enantiomer has a $t_{1/2}$ of about 6 h; the less-potent (−) enantiomer has a $t_{1/2}$ of approximately 4 h. Concentrations in the brain exceed those in plasma. The main urinary metabolite is a deesterified product, ritalinic acid, which accounts for 80% of the dose. The use of methylphenidate is contraindicated in patients with glaucoma.

Dexmethylphenidate

Dexmethylphenidate is the *d*-threo enantiomer of racemic methylphenidate. It is FDA-approved for the treatment of ADHD and is listed as a schedule II controlled substance in the U.S.

Pemoline

Pemoline is structurally dissimilar to methylphenidate but elicits similar changes in CNS function with minimal effects on the cardiovascular system. It is employed in treating ADHD. It can be given once daily because of its long $t_{1/2}$. Clinical improvement may require treatment for 3–4 weeks. Use of pemoline has been associated with severe hepatic failure. The drug was discontinued in the U.S. in 2006.

Lisdexamphetamine

Lisdexamphetamine is a therapeutically inactive prodrug that is converted primarily in the blood to lysine and *D*-amphetamine, the active component (Childress and Berry, 2012). It is approved for the treatment of ADHD in children, adolescents, and adults. The drug produces mild-to-moderate side effects, including decreased appetite, dizziness, dry mouth, fatigue, headache, insomnia, irritability, nasal congestion, nasal pharyngitis, upper respiratory infection, vomiting, and decreased weight.

Ephedrine

Ephedrine is an agonist at both α and β receptors; in addition, it enhances release of NE from sympathetic neurons and thus is a mixed-acting sympathomimetic (see Table 12–1 and Figure 12–1). Only *l*-ephedrine and racemic ephedrine are used clinically.

ADME and Pharmacological Actions

Ephedrine is effective after oral administration; effects may persist for several hours. Ephedrine is eliminated in the urine largely as unchanged drug, with a $t_{1/2}$ of 3–6 h. The drug stimulates heart rate and cardiac output

and variably increases peripheral resistance; as a result, ephedrine usually increases blood pressure. Stimulation of the α receptors of smooth muscle cells in the bladder base may increase the resistance to the outflow of urine. Activation of β receptors in the lungs promotes bronchodilation. Ephedrine is a potent CNS stimulant.

Therapeutic Uses and Untoward Effects

The use of ephedrine as a bronchodilator in asthmatic patients is less common with the availability of β_2 -selective agonists. Ephedrine has been used to promote urinary continence. Indeed, the drug may cause urinary retention, particularly in men with BPH. Ephedrine also has been used to treat the hypotension that may occur with spinal anesthesia.

Untoward effects of ephedrine include hypertension and insomnia. Tachyphylaxis may occur with repetitive dosing. Usual or higher-than-recommended doses may cause important adverse effects in susceptible individuals, especially in patients with underlying cardiovascular disease that might be unrecognized. Large amounts of herbal preparations containing ephedrine (ma huang, ephedra) are utilized around the world. There can be considerable variability in the content of ephedrine in these preparations, which may result in inadvertent consumption of higher-than-usual doses of ephedrine and its isomers, leading to significant toxicity and death. Thus, the FDA has banned the sale of dietary supplements containing ephedra. In addition, the Combat Methamphetamine Epidemic Act of 2005 regulates the sale of ephedrine, phenylpropanolamine, and pseudoephedrine, which can be used as precursors in the illicit manufacture of amphetamine and methamphetamine.

Other Sympathomimetic Agents

Several sympathomimetic drugs (e.g., propylhexedrine, naphazoline, oxymetazoline, and xylometazoline) are used primarily as vasoconstrictors for local application to the nasal mucous membrane or the eye.

Phenylephrine, pseudoephedrine (a stereoisomer of ephedrine), and phenylpropanolamine are the sympathomimetic drugs that have been used most commonly in oral preparations for the relief of nasal congestion. *Pseudoephedrine* is available without a prescription in a variety of solid and liquid dosage forms. *Phenylpropanolamine* shares the pharmacological properties of ephedrine and is approximately equal in potency except that it causes less CNS stimulation. Due to concern about the possibility that phenylpropanolamine increases the risk of hemorrhagic stroke, the drug is no longer licensed for marketing in the U.S.

Therapeutic Uses of Sympathomimetic Drugs

Shock

Shock is a clinical syndrome characterized by inadequate perfusion of tissues; it usually is associated with hypotension and ultimately with the failure of organ systems. Shock is an immediately life-threatening impairment of delivery of O_2 and nutrients to the organs of the body. Causes of shock include hypovolemia; cardiac failure; obstruction to cardiac output (due to pulmonary embolism, pericardial tamponade, or aortic dissection); and peripheral circulatory dysfunction (sepsis or anaphylaxis). Recent research on shock has focused on the accompanying increased permeability of the GI mucosa to pancreatic proteases, and on the role of these degradative enzymes on microvascular inflammation and multi-organ failure (Delano et al., 2013; Schmid-Schoenbein and Hugli, 2005). The treatment of shock consists of specific efforts to reverse the underlying pathogenesis as well as nonspecific measures aimed at correcting hemodynamic abnormalities. The accompanying fall in blood pressure generally leads to marked activation of the sympathetic nervous system. This, in turn, causes peripheral vasoconstriction and an increase in the rate and force of cardiac contraction. In the initial stages of shock, these mechanisms may maintain blood pressure and cerebral blood flow, although blood flow to the kidneys, skin, and other organs may be decreased, leading to impaired production of urine and metabolic acidosis.

The initial therapy of shock involves basic life support measures. It is essential to maintain blood volume, which often requires monitoring of hemodynamic parameters. Specific therapy (e.g., antibiotics for patients in septic shock) should be initiated immediately. If these measures do not lead to an adequate therapeutic response, it may be necessary to use vasoactive drugs in an effort to improve abnormalities in blood pressure and flow. Many of these pharmacological approaches, while apparently clinically reasonable, are of uncertain efficacy. Adrenergic receptor agonists may be used in an attempt to increase myocardial contractility or to modify peripheral vascular resistance. In general terms, β receptor agonists increase heart rate and force of contraction, α receptor agonists increase peripheral vascular resistance, and DA promotes dilation of renal and splanchnic vascular beds, in addition to activating β and α receptors (Breslow and Ligier, 1991).

Cardiogenic shock due to myocardial infarction has a poor prognosis; therapy is aimed at improving peripheral blood flow. Medical intervention is designed to optimize cardiac filling pressure (preload), myocardial contractility, and peripheral resistance (afterload). Preload may be increased by administration of intravenous fluids or reduced with drugs such as diuretics and nitrates. A number of sympathomimetic amines have been used to increase the force of contraction of the heart. Some of these drugs have disadvantages: INE is a powerful chronotropic agent and can greatly increase myocardial O_2 demand; NE intensifies peripheral vasoconstriction; and EPI increases heart rate and may predispose the heart to dangerous arrhythmias. DA is an effective inotropic agent that causes less increase in heart rate than does INE. DA also promotes renal arterial dilation; this may be useful in preserving renal function. When given in high doses (>10 – 20 $\mu\text{g/kg}$ per min), DA activates α receptors, causing peripheral and renal vasoconstriction. Dobutamine has complex pharmacological actions that are mediated by its stereoisomers; the clinical effects of the drug are to increase myocardial contractility with little increase in heart rate or peripheral resistance.

In some patients in shock, hypotension is so severe that vasoconstricting drugs are required to maintain a blood pressure that is adequate for CNS perfusion. The α agonists such as NE, phenylephrine, metaraminol, mephentermine, midodrine, ephedrine, EPI, DA, and methoxamine all have been used for this purpose. This approach may be advantageous in patients with hypotension due to failure of the sympathetic nervous system (e.g., after spinal anesthesia or injury). However, in patients with other forms of shock, such as cardiogenic shock, reflex vasoconstriction generally is intense, and α receptor agonists may further compromise blood flow to organs such as the kidneys and gut and adversely increase the work of the heart. Indeed, vasodilating drugs such as nitroprusside are more likely to improve blood flow and decrease cardiac work in such patients by decreasing afterload if a minimally adequate blood pressure can be maintained.

The hemodynamic abnormalities in septic shock are complex and poorly understood. Most patients with septic shock initially have low or barely normal peripheral vascular resistance, possibly owing to excessive effects of endogenously produced NO as well as normal or increased cardiac output. If the syndrome progresses, myocardial depression, increased peripheral resistance, and impaired tissue oxygenation occur. The primary treatment of septic shock is antibiotics. Therapy with drugs such as DA or dobutamine is guided by hemodynamic monitoring.

Hypotension

Drugs with predominantly α agonist activity can be used to raise blood pressure in patients with decreased peripheral resistance in conditions such as spinal anesthesia or intoxication with antihypertensive medications. However, hypotension per se is not an indication for treatment with these agents unless there is inadequate perfusion of organs such as the brain, heart, or kidneys. Furthermore, adequate replacement of fluid or blood may be more appropriate than drug therapy for many patients with hypotension.

Patients with orthostatic hypotension (excessive fall in blood pressure with standing) often represent a pharmacological challenge. There are diverse causes for this disorder, including the Shy-Drager syndrome and

idiopathic autonomic failure. Therapeutic approaches include physical maneuvers and a variety of drugs (fludrocortisone, prostaglandin synthesis inhibitors, somatostatin analogues, caffeine, vasopressin analogues, and DA antagonists). A number of sympathomimetic drugs also have been used in treating this disorder. The ideal agent would enhance venous constriction prominently and produce relatively little arterial constriction to avoid supine hypertension. No such agent currently is available. Drugs used in this disorder to activate α_1 receptors include both direct- and indirect-acting agents. Midodrine shows promise in treating this challenging disorder.

Hypertension

Centrally acting α_2 receptor agonists such as clonidine are useful in the treatment of hypertension. Drug therapy of hypertension is discussed in Chapter 28.

Cardiac Arrhythmias

Cardiopulmonary resuscitation in patients with cardiac arrest due to ventricular fibrillation, electromechanical dissociation, or asystole may be facilitated by drug treatment. EPI is an important therapeutic agent in patients with cardiac arrest; EPI and other α agonists increase diastolic pressure and improve coronary blood flow. The α agonists also help to preserve cerebral blood flow during resuscitation. Cerebral blood vessels are relatively insensitive to the vasoconstricting effects of catecholamines, and perfusion pressure is increased. Consequently, during external cardiac massage, EPI facilitates distribution of the limited cardiac output to the cerebral and coronary circulations. The optimal dose of EPI in patients with cardiac arrest is unclear. Once a cardiac rhythm has been restored, it may be necessary to treat arrhythmias, hypotension, or shock.

In patients with paroxysmal supraventricular tachycardias, particularly those associated with mild hypotension, careful infusion of an α agonist (e.g., phenylephrine) to raise blood pressure to about 160 mm Hg may end the arrhythmia by increasing vagal tone. However, this method of treatment has been replaced largely by Ca^{2+} channel blockers with clinically significant effects on the AV node, β antagonists, adenosine, and electrical cardioversion (Chapter 30). A β agonist such as INE may be used as adjunctive or temporizing therapy with atropine in patients with marked bradycardia who are compromised hemodynamically; if long-term therapy is required, a cardiac pacemaker usually is the treatment of choice.

Congestive Heart Failure

At first glance, sympathetic stimulation of β receptors in the heart would appear to be an important compensatory mechanism for maintenance of cardiac function in patients with congestive heart failure. However, the failing heart does not respond well to excess sympathetic stimulation. While β agonists may increase cardiac output in acute emergency settings such as shock, long-term therapy with β agonists as inotropic agents is not efficacious. Indeed, interest has grown in the use of β receptor antagonists in the treatment of patients with congestive heart failure, a topic covered in detail in Chapter 29.

Local Vascular Effects

Epinephrine is used in surgical procedures in the nose, throat, and larynx to shrink the mucosa and improve visualization by limiting hemorrhage. Simultaneous injection of EPI with local anesthetics retards their absorption and increases the duration of anesthesia (Chapter 22). Injection of α agonists into the penis may be useful in reversing priapism, a complication of the use of α receptor antagonists or PDE 5 inhibitors (e.g., sildenafil) in the treatment of erectile dysfunction. Both phenylephrine and oxymetazoline are efficacious vasoconstrictors when applied locally during sinus surgery.

Nasal Decongestion

α Receptor agonists are used as nasal decongestants in patients with allergic or vasomotor rhinitis and in acute rhinitis in patients with upper respiratory infections. These drugs probably decrease resistance to airflow by

decreasing the volume of the nasal mucosa; this may occur by activation of α receptors in venous capacitance vessels in nasal tissues that have erectile characteristics. The receptors that mediate this effect appear to be α_1 receptors. α_2 Receptors may mediate contraction of arterioles that supply nutrition to the nasal mucosa. Intense constriction of these vessels may cause structural damage to the mucosa. A major limitation of therapy with nasal decongestants is loss of efficacy, “rebound” hyperemia, and worsening of symptoms with chronic use or when the drug is stopped. Although mechanisms are uncertain, possibilities include receptor desensitization and damage to the mucosa. Agonists that are selective for α_1 receptors may be less likely to induce mucosal damage.

The α agonists may be administered either orally or topically. Sympathomimetic decongestants should be used with great caution in patients with hypertension and in men with prostatic enlargement; these agents are contraindicated in patients who are taking MAO inhibitors. Topical decongestants are particularly useful in acute rhinitis because of their more selective site of action, but they are apt to be used excessively by patients, leading to rebound congestion. Oral decongestants are much less likely to cause rebound congestion but carry a greater risk of inducing adverse systemic effects. Patients with uncontrolled hypertension or ischemic heart disease generally should avoid the oral consumption of OTC products or herbal preparations containing sympathomimetic drugs.

Asthma

Use of β adrenergic agonists in the treatment of asthma and COPD is discussed in Chapter 40.

Allergic Reactions

Epinephrine is the drug of choice to reverse the manifestations of serious acute hypersensitivity reactions (e.g., from food, bee sting, or drug allergy). A subcutaneous injection of EPI rapidly relieves itching, hives, and swelling of lips, eyelids, and tongue. In some patients, careful intravenous infusion of EPI may be required to ensure prompt pharmacological effects. This treatment may be life-saving when edema of the glottis threatens airway patency or when there is hypotension or shock in patients with anaphylaxis. In addition to its cardiovascular effects, EPI is thought to activate β receptors that suppress the release from mast cells of mediators such as histamine and leukotrienes. Although glucocorticoids and antihistamines frequently are administered to patients with severe hypersensitivity reactions, EPI remains the mainstay. EPI autoinjectors are employed widely for the emergency self-treatment of anaphylaxis.

Ophthalmic Uses

Ophthalmic uses are discussed in Chapter 69.

Narcolepsy and Sleep/Wake Imbalance

Hypocretin neurons activate wake-promoting pathways in the CNS. A deficiency of hypocretin, likely due to autoimmune destruction of hypocretin neurons, produces narcolepsy, a condition of hypersomnia, including excessive daytime sleepiness and attacks of sleep that may occur suddenly under conditions that are not normally conducive to sleep. Hypocretin agonists will likely be available in the future. At present, treatment relies on the fact that monoamine pathways promote wakefulness; thus, current treatments utilize CNS stimulants, including those that enhance transmission in monoamine pathways (Black et al., 2015).

The CNS stimulants modafinil (a mixture of *R*- and *S*-enantiomers) and armodafinil (the *R*-enantiomer of modafinil) are first-line agents for narcolepsy. In the U.S., modafinil is a schedule IV controlled substance. Its mechanism of action in narcolepsy is unclear. Methylphenidate and amphetamines are also used. Therapy with amphetamines is complicated by the risk of abuse and the likelihood of the development of tolerance. Depression, irritability, and paranoia also may occur. Amphetamines may disturb nocturnal sleep, which increases the difficulty of avoiding daytime attacks of sleep in these patients. Armodafinil is also indicated to improve wakefulness in shift workers and to combat excessive sleepiness in patients with obstructive sleep apnea-hypopnea syndrome. See previous sections

for more details on these agents. Some patients respond to tricyclic antidepressants (Chapter 15) or MAO inhibitors (Chapter 8).

Sodium γ -hydroxybutyrate (Na^+ -oxybate) is FDA-approved for treating the sleep/wake imbalance and cataplexy of narcolepsy. The mechanism of action of oxybate is unknown but likely relates to its structural similarity to glutamate and GABA and to actions on NE and DA neurons mediated by GABA_B receptors. Oxybate is a schedule III controlled substance, available through a special program with the manufacturer. Oxybate carries an FDA black-box warning about severe CNS depressants and must be used with great caution (see FDA, 2012).

Weight Reduction

Amphetamine promotes weight loss by suppressing appetite rather than by increasing energy expenditure. Other anorexic drugs include methamphetamine, dextroamphetamine (and a prodrug form, lisdexamfetamine), phentermine, benzphetamine, phendimetrazine, phenmetrazine, diethylpropion, mazindol, phenylpropanolamine, and sibutramine (a mixed adrenergic/serotonergic drug). Phenmetrazine, mazindol, and phenylpropanolamine have been discontinued in the U.S. Available evidence does not support the isolated use of these drugs in the absence of a more comprehensive program that stresses exercise and modification of diet under medical supervision.

The β_3 receptor agonists have remarkable antiobesity and antidiabetic effects in rodents.

Mirabegron (see previous discussion) has some promising effects in humans (Cypess et al., 2015). Use of β_3 agonists in the treatment of obesity remains a possibility for the future (Arch, 2011).

Attention-Deficit/Hyperactivity Disorder

The ADHD syndrome, usually first evident in childhood, is characterized by excessive motor activity, difficulty in sustaining attention, and impulsiveness. Children with this disorder frequently are troubled by difficulties in school, impaired interpersonal relationships, and excitability. Academic underachievement is an important characteristic. A substantial number of children with this syndrome have characteristics that persist into adulthood. Behavioral therapy may be helpful in some patients.

Catecholamines may be involved in the control of attention at the level of the cerebral cortex. A variety of stimulant drugs have been utilized in the treatment of ADHD, and they are particularly indicated in moderate-to-severe cases. Dextroamphetamine has been demonstrated to be more effective than placebo. Methylphenidate is effective in children with ADHD and is the most common intervention (Swanson and Volkow, 2003). Treatment may start with a dose of 5 mg of methylphenidate in the morning and at lunch; the dose is increased gradually over a period of weeks depending on the response as judged by parents, teachers, and the clinician. The total daily dose generally should not exceed 60 mg; because of its short duration of action, most children require two or three doses of methylphenidate each day. The timing of doses is adjusted individually in accordance with rapidity of onset of effect and duration of action.

Methylphenidate, dextroamphetamine, and amphetamine probably have similar efficacy in ADHD and are the preferred drugs in this disorder. Sustained-release preparations of dextroamphetamine, methylphenidate, dexamethylphenidate, and amphetamine, Adderall may be used once daily in children and adults. Lisdexamfetamine can be administered once daily, and a transdermal formulation of methylphenidate is marketed for daytime use. Potential adverse effects of these medications include insomnia, abdominal pain, anorexia, and weight loss, which may be associated with suppression of growth in children. Minor symptoms may be transient or may respond to adjustment of dosage or administration of the drug with meals. Other drugs that have been utilized include tricyclic antidepressants, antipsychotic agents, and clonidine. A sustained-release formulation of guanfacine, an α_2A receptor agonist, has recently been approved for use in children (ages 6–17 years) in treating ADHD (May and Kratochvil, 2010).

Adrenergic Receptor Antagonists

Many types of drugs interfere with the function of the sympathetic nervous system and thus have profound effects on the physiology of sympathetically innervated organs. Several of these drugs are important in clinical medicine, particularly for the treatment of cardiovascular diseases.

The remainder of this chapter focuses on the pharmacology of adrenergic receptor *antagonists*, drugs that inhibit the interaction of NE, epinephrine, and other sympathomimetic drugs with α and β receptors (Figure 12–3). Most of these agents are competitive antagonists; an important exception is phenoxybenzamine, an irreversible antagonist that binds covalently to α receptors.

There are important structural differences amongst the various types of adrenergic receptors, differences that have permitted development of compounds with substantially different affinities for the various receptors. Thus, it is possible to interfere selectively with responses that result from stimulation of the sympathetic nervous system. The selectivity is relative, not absolute. Nonetheless, selective antagonists of β_1 receptors block most actions of epinephrine and NE on the heart, while having less effect on β_2 receptors in bronchial smooth muscle and no effect on responses mediated by α_1 or α_2 receptors.

Detailed knowledge of the autonomic nervous system and the sites of action of drugs that act on adrenergic receptors is essential for understanding the pharmacological properties and therapeutic uses of this important class of drugs. Additional background material is presented in Chapter 8. Agents that block DA receptors are considered in Chapter 13.

α Adrenergic Receptor Antagonists

The α adrenergic receptors mediate many of the important actions of endogenous catecholamines. The α_1 receptors mediate contraction of arterial, venous, and visceral smooth muscle, while the α_2 receptors are involved in suppressing sympathetic output, increasing vagal tone, facilitating platelet aggregation, inhibiting the release of NE and acetylcholine from nerve endings, and regulating metabolic effects (e.g., suppression of insulin secretion and inhibition of lipolysis). The α_2 receptors also mediate contraction of some arteries and veins.

Some of the most important effects of a receptor antagonists observed clinically are on the cardiovascular system. Actions in both the CNS and the periphery are involved; the outcome depends on the cardiovascular status of the patient at the time of drug administration and the relative selectivity of the agent for α_1 and α_2 receptors.

The α receptor antagonists have a wide spectrum of pharmacological specificities and are chemically heterogeneous. Some of these drugs have markedly different affinities for α_1 and α_2 receptors. For example, *prazosin* is much more potent in blocking α_1 than α_2 receptors (i.e., α_1 selective), whereas *yohimbine* is α_2 selective; *phentolamine* has similar affinities for both of these receptor subtypes. More recently, agents that discriminate among the various subtypes of a particular receptor have become available; for example, *tamsulosin* has higher potency at α_{1A} than at α_{1B} receptors. Prior editions of this textbook contain information about the chemistry of a receptor antagonists.

Catecholamines increase the output of glucose from the liver; in humans, this effect is mediated predominantly by β receptors, although α receptors may contribute. The α receptor antagonists therefore may reduce glucose release. Receptors of the α_{2A} subtype facilitate platelet aggregation; the effect of blockade of platelet α_2 receptors in vivo is not clear. Activation of α_2 receptors in the pancreatic islets suppresses insulin secretion; conversely, blockade of pancreatic α_2 receptors may facilitate insulin release (Chapter 47).

α_1 Adrenergic Receptor Antagonists

General Pharmacological Properties

Blockade of α_1 adrenergic receptors inhibits vasoconstriction induced by endogenous catecholamines; vasodilation may occur in both arteriolar resistance vessels and veins. The result is a fall in blood pressure due to decreased peripheral resistance.

The magnitude of such effects depends on the activity of the sympathetic nervous system at the time the antagonist is administered and thus is less in supine than in upright subjects and is particularly marked if there is hypovolemia. For most α receptor antagonists, the fall in blood pressure is opposed by *baroreceptor reflexes* that cause increases in heart rate and cardiac output, as well as fluid retention. These *reflexes* are exaggerated if the antagonist also blocks α_2 receptors on peripheral sympathetic nerve endings, leading to enhanced release of NE and increased stimulation of postsynaptic β_1 receptors in the heart and on juxtaglomerular cells (Chapter 8) (Starke et al., 1989). Although stimulation of α_1 receptors in the heart may cause an increased force of contraction, the importance of blockade at this site in humans is uncertain.

Blockade of α_1 receptors also inhibits vasoconstriction and the increase in blood pressure produced by the administration of a sympathomimetic amine. The pattern of effects depends on the adrenergic agonist that is administered: Pressor responses to phenylephrine can be completely suppressed; those to NE are only incompletely blocked because of residual

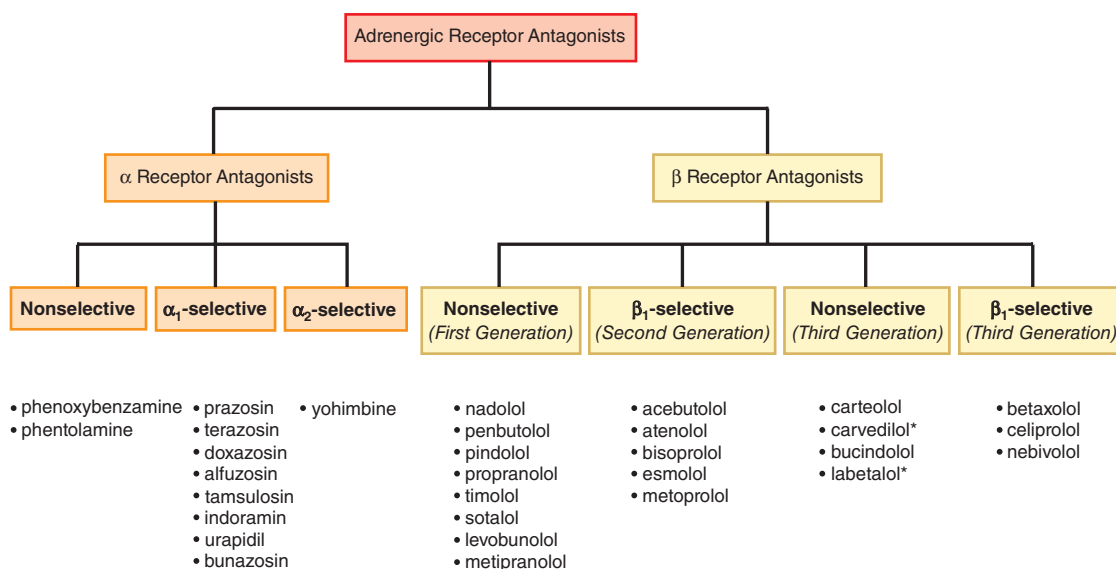

Figure 12-3 Classification of adrenergic receptor antagonists. Drugs marked by an asterisk (*) also block α_1 receptors.

stimulation of cardiac β_1 receptors; and pressor responses to EPI may be transformed to vasodepressor effects because of residual stimulation of β_2 receptors in the vasculature with resultant vasodilation.

Blockade of α_1 receptors can alleviate some of the symptoms of BPH. The symptoms of BPH include a resistance to urine outflow. This results from mechanical pressure on the urethra due to an increase in smooth muscle mass and an α adrenergic receptor-mediated increase in smooth muscle tone in the prostate and neck of the bladder. Antagonism of α_1 receptors permits relaxation of the smooth muscle and decreases the resistance to the outflow of urine. The prostate and lower urinary tract tissues exhibit a high proportion of α_{1A} receptors (Michel and Vrydag, 2006).

Available Agents

Prazosin. Due in part to its greater α_1 receptor selectivity, this class of α receptor antagonists exhibits greater clinical utility and has largely replaced the nonselective haloalkylamine (e.g., phenoxybenzamine) and imidazoline (e.g., phentolamine) α receptor antagonists.

Prazosin is the prototypical α_1 -selective antagonist. The affinity of prazosin for α_1 adrenergic receptors is about 1000-fold greater than that for α_2 adrenergic receptors. Prazosin has similar potencies at α_{1A} , α_{1B} , and α_{1D} subtypes. Interestingly, the drug also is a relatively potent inhibitor of cyclic nucleotide PDEs, and it originally was synthesized for this purpose. Prazosin and the related α receptor antagonists *doxazosin* and *tamsulosin* frequently are used for the treatment of hypertension (Chapter 28).

Pharmacological Effects. The major effects of prazosin result from its blockade of α_1 receptors in arterioles and veins. This leads to a fall in peripheral vascular resistance and in venous return to the heart. Unlike other vasodilating drugs, administration of prazosin usually does not increase heart rate. Because prazosin has little or no α_2 receptor-blocking effect, it probably does not promote the release of NE from sympathetic nerve endings in the heart. Prazosin decreases cardiac preload and has little effect on cardiac output and rate, in contrast to vasodilators such as hydralazine that have minimal dilatory effects on veins. Although the combination of reduced preload and selective α_1 receptor blockade might be sufficient to account for the relative absence of reflex tachycardia, prazosin also may act in the CNS to suppress sympathetic outflow. Prazosin appears to depress baroreflex function in hypertensive patients. Prazosin and related drugs in this class decrease LDLs and triglycerides and increase concentrations of HDLs.

ADME. Prazosin is well absorbed after oral administration, and bioavailability is about 50%–70%. Peak concentrations of prazosin in plasma generally are reached 1–3 h after an oral dose. The drug is tightly bound to plasma proteins (primarily α_1 -acid glycoprotein), and only 5% of the drug is free in the circulation; diseases that modify the concentration of this protein (e.g., inflammatory processes) may change the free fraction. Prazosin is extensively metabolized in the liver, and little unchanged drug is excreted by the kidneys. The plasma $t_{1/2}$ is about 3 h (may be prolonged to 6–8 h in congestive heart failure). The duration of action is approximately 7–10 h in the treatment of hypertension.

The initial dose should be 1 mg, usually given at bedtime so that the patient will remain recumbent for at least several hours to reduce the risk of syncopal reactions that may follow the first dose of prazosin. The dose is titrated upward depending on the blood pressure. A maximal effect generally is observed with a total daily dose of 20 mg in patients with hypertension. In the off-label treatment of BPH, doses from 1 to 5 mg twice daily typically are used.

Terazosin. *Terazosin*, a close structural analogue of prazosin, is less potent than prazosin but retains high specificity for α_1 receptors; terazosin does not discriminate among α_{1A} , α_{1B} , and α_{1D} receptors. The major distinction between the two drugs is in their pharmacokinetic properties.

Terazosin is more soluble in water than is prazosin, and its bioavailability is high (>90%). The $t_{1/2}$ of elimination of terazosin is about 12 h, and its duration of action usually extends beyond 18 h. Consequently, the drug may be taken once daily to treat hypertension and BPH in most patients. Terazosin has been found more effective than finasteride in treatment of BPH (Lepor et al., 1996). *Terazosin* and *doxazosin* induce apoptosis in prostate smooth muscle cells. This apoptosis may lessen the symptoms associated with chronic BPH by limiting cell proliferation. The apoptotic

effect of terazosin and doxazosin appears to be related to the quinazoline moiety rather than α_1 receptor antagonism; tamsulosin, a nonquinazoline α_1 receptor antagonist, does not produce apoptosis (Kyprianou, 2003). Only about 10% of terazosin is excreted unchanged in the urine. An initial first dose of 1 mg is recommended. Doses are slowly titrated upward depending on the therapeutic response. Doses of 10 mg/d may be required for maximal effect in BPH.

Doxazosin. *Doxazosin* is another congener of prazosin and a highly selective antagonist at α_1 receptors. It is nonselective among α_1 receptor subtypes and differs from prazosin in its pharmacokinetic profile.

The $t_{1/2}$ of doxazosin is about 20 h, and its duration of action may extend to 36 h. The bioavailability and extent of metabolism of doxazosin and prazosin are similar. Most doxazosin metabolites are eliminated in the feces. The hemodynamic effects of doxazosin appear to be similar to those of prazosin. Doxazosin should be given initially as a 1-mg dose in the treatment of hypertension or BPH. Doxazosin also may have beneficial actions in the long-term management of BPH related to apoptosis that are independent of α_1 receptor antagonism. Doxazosin is typically administered once daily. An extended-release formulation marketed for BPH is not recommended for the treatment of hypertension.

Alfuzosin. *Alfuzosin* is a quinazoline-based α_1 receptor antagonist with similar affinity at all of the α_1 receptor subtypes. It has been used extensively in treating BPH; it is not approved for treatment of hypertension. Alfuzosin has a $t_{1/2}$ of 3–5 h. Alfuzosin is a substrate of CYP3A4, and the concomitant administration of CYP3A4 inhibitors (e.g., ketoconazole, clarithromycin, itraconazole, ritonavir) is contraindicated. Alfuzosin should be avoided in patients at risk for prolonged QT syndrome. The recommended dosage is one 10-mg extended-release tablet daily to be taken after the same meal each day.

Tamsulosin. *Tamsulosin*, a benzenesulfonamide, is an α_1 receptor antagonist with some selectivity for α_{1A} (and α_{1D}) subtypes compared to the α_{1B} subtype (Kenny et al., 1996). This selectivity may favor blockade of α_{1A} receptors in prostate. Tamsulosin is efficacious in the treatment of BPH with little effect on blood pressure (Beduschi et al., 1998); tamsulosin is not approved for the treatment of hypertension. Tamsulosin is well absorbed and has a $t_{1/2}$ of 5–10 h. It is extensively metabolized by CYPs. Tamsulosin may be administered at a 0.4-mg starting dose; a dose of 0.8 mg ultimately will be more efficacious in some patients. Abnormal ejaculation is an adverse effect of tamsulosin, experienced by about 18% of patients receiving the higher dose.

Silodosin. *Silodosin* exhibits selectivity for the α_{1A} , over the α_{1B} , adrenergic receptor. The drug is metabolized by several pathways; the main metabolite is a glucuronide formed by UGT2B7; coadministration with inhibitors of this enzyme (e.g., probenecid, valproic acid, fluconazole) increases systemic exposure to silodosin. The drug is approved for the treatment of BPH and has lesser effects on blood pressure than the non- α_1 -subtype selective antagonists. Nevertheless, dizziness and orthostatic hypotension can occur. The chief side effect of silodosin is retrograde ejaculation (in 28% of those treated). Silodosin is available as 4-mg and 8-mg capsules.

Adverse Effects

A major potential adverse effect of prazosin and its congeners is the first-dose effect; marked postural hypotension and syncope sometimes are seen 30–90 min after an initial dose of prazosin and 2–6 h after an initial dose of doxazosin.

Syncopal episodes also have occurred with a rapid increase in dosage or with the addition of a second antihypertensive drug to the regimen of a patient who already is taking a large dose of prazosin. The risk of the first-dose phenomenon is minimized by limiting the initial dose (e.g., 1 mg at bedtime), by increasing the dosage slowly, and by introducing additional antihypertensive drugs cautiously.

Because orthostatic hypotension may be a problem during long-term treatment with prazosin or its congeners, it is essential to check standing as well as recumbent blood pressure. Nonspecific adverse effects such as headache, dizziness, and asthenia rarely limit treatment with prazosin.

Hypertension. Prazosin and its congeners have been used successfully in the treatment of essential hypertension (Chapter 28). Pleotropic effects of these drugs improve lipid profiles and glucose-insulin metabolism in patients with hypertension who are at risk for atherosclerotic disease (Deano and Sorrentino, 2012). Catecholamines are also powerful stimulators of vascular smooth muscle hypertrophy, acting by α_1 receptors. To what extent these effects of α_1 antagonists have clinical significance in diminishing the risk of atherosclerosis is not known.

Congestive Heart Failure. α Receptor antagonists have been used in the treatment of congestive heart failure but are not the drugs of choice. Short-term effects of a receptor blockade in these patients are due to dilation of both arteries and veins, resulting in a reduction of preload and afterload, which increases cardiac output and reduces pulmonary congestion. In contrast to results obtained with inhibitors of angiotensin-converting enzyme or a combination of hydralazine and an organic nitrate, prazosin has not been found to prolong life in patients with congestive heart failure.

Benign Prostatic Hyperplasia. In a significant percentage of older men, BPH produces symptomatic urethral obstruction that leads to weak stream, increased urinary frequency, and nocturia. These symptoms are due to a combination of mechanical pressure on the urethra due to the increase in smooth muscle mass and the α_1 receptor-mediated increase in smooth muscle tone in the prostate and neck of the bladder (Kyprianou, 2003). α_1 Receptors in the trigone muscle of the bladder and urethra contribute to the resistance to outflow of urine. Prazosin reduces this resistance in some patients with impaired bladder emptying caused by prostatic obstruction or parasympathetic decentralization from spinal injury.

Finasteride and dutasteride, two drugs that inhibit conversion of testosterone to dihydrotestosterone (Chapter 45) and can reduce prostate volume in some patients, are approved as monotherapy and in combination with α receptor antagonists. α_1 -Selective antagonists have efficacy in BPH owing to relaxation of smooth muscle in the bladder neck, prostate capsule, and prostatic urethra. α_1 -Selective antagonists rapidly improve urinary flow, whereas the actions of finasteride are typically delayed for months. Combination therapy with doxazosin and finasteride reduces the risk of overall clinical progression of BPH significantly more than treatment with either drug alone (McConnell et al., 2003). Tamsulosin at the recommended dose of 0.4 mg daily and silodosin at 0.8 mg are less likely to cause orthostatic hypotension than are the other drugs. The predominant α_1 subtype expressed in the human prostate is the α_{1A} receptor (Michel and Vrydag, 2006). Developments in this area will provide the basis for the selection of α receptor antagonists with specificity for the relevant subtype of α_1 receptor. However, the possibility remains that some of the symptoms of BPH are due to α_1 receptors in other sites, such as bladder, spinal cord, or brain.

Other Disorders. Some studies indicated that prazosin can decrease the incidence of digital vasospasm in patients with Raynaud disease; however, its relative efficacy as compared with Ca^{2+} channel blockers is not known. Prazosin may have some benefit in patients with other vasospastic disorders. Prazosin may be useful for the treatment of patients with mitral or aortic valvular insufficiency, presumably by reducing afterload.

α_2 Adrenergic Receptor Antagonists

Activation of presynaptic α_2 receptors inhibits the release of NE and other cotransmitters from peripheral sympathetic nerve endings. Activation of α_2 receptors in the pontomedullary region of the CNS inhibits sympathetic nervous system activity and leads to a fall in blood pressure; these receptors are a site of action for drugs such as clonidine. *Blockade of α_2 receptors with selective antagonists such as yohimbine thus can increase sympathetic outflow and potentiate the release of NE from nerve endings, leading to activation of α_1 and β_1 receptors in the heart and peripheral vasculature with a consequent rise in blood pressure.* Antagonists that also block α_1 receptors give rise to similar effects on sympathetic outflow and release of NE, but the net increase in blood pressure is prevented by inhibition of vasoconstriction.

Although certain vascular beds contain α_2 receptors that promote contraction of smooth muscle, it is thought that these receptors are preferentially stimulated by circulating catecholamines, whereas α_1 receptors are activated by NE released from sympathetic nerve fibers. In other vascular beds, α_2 receptors reportedly promote vasodilation by stimulating the release of NO from endothelial cells. The physiological role of vascular α_2 receptors in the regulation of blood flow within various vascular beds is uncertain. The α_2 receptors contribute to smooth muscle contraction in the human saphenous vein, whereas α_1 receptors are more prominent in dorsal hand veins. The effects of α_2 receptor antagonists on the cardiovascular system are dominated by actions in the CNS and on sympathetic nerve endings.

Yohimbine

Yohimbine is a competitive antagonist that is selective for α_2 receptors. The compound is an indolealkylamine alkaloid and is found in the bark of the tree *Pausinystalia yohimbe* and in *Rauwolfia* root; its structure resembles that of reserpine. Yohimbine readily enters the CNS, where it acts to increase blood pressure and heart rate; it also enhances motor activity and produces tremors. These actions are opposite to those of clonidine, an α_2 agonist. Yohimbine also antagonizes effects of 5HT. In the past, it was used extensively to treat male sexual dysfunction (Tam et al., 2001). However, the efficacies of PDE5 inhibitors (e.g., sildenafil, vardenafil, and tadalafil) and apomorphine (off-label) have been much more conclusively demonstrated in oral treatment of erectile dysfunction. Some studies suggested that yohimbine may be useful for diabetic neuropathy and in the treatment of postural hypotension. In the U.S., yohimbine can be legally sold as a dietary supplement; however, labeling claims that it will arouse or increase sexual desire or improve sexual performance are prohibited. Yohimbine is approved in veterinary medicine for the reversal of xylazine anesthesia.

Nonselective α Adrenergic Antagonists

Phenoxybenzamine and Phentolamine

Phenoxybenzamine and phentolamine are nonselective α receptor antagonists. Phenoxybenzamine, a haloalkylamine compound, produces an irreversible antagonism, while phentolamine, an imidazoline, produces a competitive antagonism.

Phenoxybenzamine and phentolamine cause a progressive decrease in peripheral resistance due to antagonism of α receptors in the vasculature and an increase in cardiac output that is due in part to reflex sympathetic nerve stimulation. The cardiac stimulation is accentuated by enhanced release of NE from cardiac sympathetic nerve due to antagonism of presynaptic α_2 receptors by these nonselective α blockers. Postural hypotension is a prominent feature with these drugs, and this, accompanied by reflex tachycardia that can precipitate cardiac arrhythmias, severely limits the use of these drugs to treat essential hypertension. The α_1 -selective antagonists, such as prazosin, have replaced the “classical” α -blockers in the management of essential hypertension. Phenoxybenzamine and phentolamine are still marketed for several specialized uses.

Therapeutic Uses. Phenoxybenzamine is used in the treatment of pheochromocytomas, tumors of the adrenal medulla and sympathetic neurons that secrete enormous quantities of catecholamines into the circulation. The usual result is hypertension, which may be episodic and severe. The vast majority of pheochromocytomas are treated surgically; phenoxybenzamine is often used in preparing the patient for surgery. The drug controls episodes of severe hypertension and minimizes other adverse effects of catecholamines, such as contraction of plasma volume and injury of the myocardium. A conservative approach is to initiate treatment with phenoxybenzamine (at a dosage of 10 mg twice daily) 1–3 weeks before the operation. The dose is increased every other day until the desired effect on blood pressure is achieved. The usual daily dose of phenoxybenzamine in patients with pheochromocytoma is 40–120 mg given in two or three divided portions. Prolonged treatment with phenoxybenzamine may be necessary in patients with inoperable or malignant pheochromocytoma. In some patients, particularly those with malignant disease, administration of metyrosine, a competitive inhibitor of tyrosine hydroxylase (the

rate-limiting enzyme in the synthesis of catecholamines), may be a useful adjunct (Chapter 8). β Receptor antagonists also are used to treat pheochromocytoma, *but only after the administration of an α receptor antagonist* (described later in the chapter).

Phentolamine can also be used in short-term control of hypertension in patients with pheochromocytoma. Rapid infusions of phentolamine may cause severe hypotension, so the drug should be administered cautiously. Phentolamine also may be useful to relieve pseudo-obstruction of the bowel in patients with pheochromocytoma.

Phentolamine has been used locally to prevent dermal necrosis after the inadvertent extravasation of an α receptor agonist. The drug also may be useful for the treatment of hypertensive crises that follow the abrupt withdrawal of clonidine or that may result from the ingestion of tyramine-containing foods during the use of nonselective MAO inhibitors. Although excessive activation of α receptors is important in the development of severe hypertension in these settings, there is little information about the safety and efficacy of phentolamine compared with those of other antihypertensive agents in the treatment of such patients. Buccally or orally administered phentolamine may have efficacy in some men with sexual dysfunction.

Phentolamine is FDA-approved for reversing or limiting the duration of soft tissue anesthesia. Sympathomimetics are frequently administered with local anesthetics to slow the removal of the anesthetic by causing vasoconstriction. When the need for anesthesia is over, phentolamine can help reverse it by antagonizing the α receptor-induced vasoconstriction.

Phenoxybenzamine has been used off-label to control the manifestations of autonomic hyperreflexia in patients with spinal cord transection.

Toxicity and Adverse Effects. Hypotension is the major adverse effect of phenoxybenzamine and phentolamine. In addition, reflex cardiac stimulation may cause alarming tachycardia, cardiac arrhythmias, and ischemic cardiac events, including myocardial infarction. Reversible inhibition of ejaculation may occur due to impaired smooth muscle contraction in the vas deferens and ejaculatory ducts. Phentolamine stimulates GI smooth muscle, an effect antagonized by atropine, and also enhances gastric acid secretion due in part to histamine release. Thus, phentolamine should be used with caution in patients with a history of peptic ulcer. Phenoxybenzamine is mutagenic in the Ames test, and repeated administration of this drug to experimental animals causes peritoneal sarcomas and lung tumors.

Additional α Adrenergic Receptor Antagonists

Ergot Alkaloids

The ergot alkaloids were the first adrenergic receptor antagonists to be discovered. Ergot alkaloids exhibit a complex variety of pharmacological properties. To varying degrees, these agents act as partial agonists or antagonists at α receptors, DA receptors, and serotonin receptors. Additional information about the ergot alkaloids can be found in Chapter 13.

Indoramin

Indoramin is a selective, competitive α_1 -selective receptor antagonist that also antagonizes H_1 and 5HT receptors. Indoramin lowers blood pressure with minimal tachycardia. The drug is not available in the U.S.; outside the U.S., indoramin is used for the treatment of hypertension and BPH and in the prophylaxis of migraine. The drug also decreases the incidence of attacks of Raynaud phenomenon. Some of the adverse effects of indoramin include sedation, dry mouth, and failure of ejaculation.

Ketanserin

Although developed as a 5HT receptor antagonist, ketanserin also blocks α_1 receptors. Ketanserin (not available in the U.S.) is discussed in Chapter 13.

Urapidil

Urapidil is a selective α_1 receptor antagonist that has a chemical structure distinct from those of prazosin and related compounds; the drug is not commercially available in the U.S. Blockade of peripheral α_1 receptors appears to be primarily responsible for the hypotension produced by urapidil, although it has actions in the CNS as well.

Bunazosin

Bunazosin is an α_1 -selective antagonist of the quinazoline class that has been shown to lower blood pressure in patients with hypertension. Bunazosin is not available in the U.S.

Neuroleptic Agents

Chlorpromazine, haloperidol, and other neuroleptic drugs of the phenothiazine and butyrophenone types produce significant blockade of both α and D_2 receptors in humans.

β Adrenergic Receptor Antagonists

HISTORICAL PERSPECTIVE

Ahlquist's hypothesis that the effects of catecholamines were mediated by activation of distinct α and β receptors provided the initial impetus for the synthesis and pharmacological evaluation of β receptor antagonists (Chapter 8). The first such selective agent was dichloroisoproterenol, a partial agonist. Sir James Black and his colleagues initiated a program in the late 1950s to develop additional β blockers, with the resulting synthesis and characterization of propranolol.

Overview

Competitive antagonists of β adrenergic receptors, or β blockers, have received enormous clinical attention because of their efficacy in the treatment of hypertension, ischemic heart disease, congestive heart failure, and certain arrhythmias.

The myriad β antagonists can be distinguished by the following properties:

- Relative affinity for β_1 and β_2 receptors
- Intrinsic sympathomimetic activity
- Blockade of α receptors
- Differences in lipid solubility (CNS penetration)
- Capacity to induce vasodilation
- Pharmacokinetic parameters

Propranolol is a competitive β receptor antagonist and remains the prototype to which other β antagonists are compared. Propranolol is a *nonselective β adrenergic receptor antagonist* with equal affinity for β_1 and β_2 adrenergic receptors. Agents such as metoprolol, atenolol, acebutolol, bisoprolol, and esmolol have somewhat greater affinity for β_1 than for β_2 receptors; these are examples of *β_1 -selective antagonists*, even though the selectivity is not absolute. Propranolol is a pure antagonist, and it has no capacity to activate β receptors. Several β blockers (e.g., pindolol and acebutolol) activate β receptors partially in the absence of catecholamines; however, the intrinsic activities of these drugs are less than that of a full agonist such as INE. These partial agonists have *intrinsic sympathomimetic activity*; this slight residual activity may prevent profound bradycardia or negative inotropy in a resting heart. The potential clinical advantage of this property, however, is unclear and may be disadvantageous in the context of secondary prevention of myocardial infarction. Other β receptor antagonists have the property of *inverse agonism* (Chapter 3); these drugs can decrease basal activity of β receptor signaling by shifting the equilibrium of spontaneously active receptors toward an inactive state (see Chapters 3 and 8).

Several β receptor antagonists also have local anesthetic or membrane-stabilizing activity, independent of β blockade. Such drugs include propranolol, acebutolol, and carvedilol. Pindolol, metoprolol, betaxolol, and labetalol have slight membrane-stabilizing effects. Although most β receptor antagonists do not block α adrenergic receptors, labetalol, carvedilol, and bucindolol block both α_1 and β adrenergic receptors. In addition to carvedilol, labetalol, and bucindolol, other β receptor antagonists have vasodilating properties due to mechanisms discussed in the following

material. These include celiprolol, nebivolol, nipradilol, carteolol, betaxolol, bopindolol, and bevantolol (Toda, 2003).

Pharmacological Properties

The pharmacological properties of β receptor antagonists can be deduced and explained largely from knowledge of the responses elicited by the receptors in the various tissues and the activity of the sympathetic nerves that innervate these tissues (Table 8–1). For example, β receptor blockade has relatively little effect on the normal heart of an individual at rest but has profound effects when sympathetic control of the heart is dominant, as during exercise or stress.

The β adrenergic receptor antagonists are classified as non subtype-selective (“first generation”), β_1 selective (“second generation”), and non subtype- or subtype-selective *with additional cardiovascular actions* (“third generation”). These last drugs have additional cardiovascular properties (especially vasodilation) that seem unrelated to β blockade. Table 12–3 summarizes pharmacological and pharmacokinetic properties of β receptor antagonists.

Cardiovascular System. The major therapeutic effects of β receptor antagonists are on the cardiovascular system. It is important to distinguish these effects in normal subjects from those in subjects with cardiovascular disease such as hypertension or myocardial ischemia.

Catecholamines have positive chronotropic and inotropic actions. Conversely, β receptor antagonists slow the heart rate and decrease myocardial contractility, *if there are sympathetic stimuli to antagonize*. When tonic stimulation of β receptors is low, this effect is correspondingly modest. However, when the sympathetic nervous system is activated, as during exercise or stress, β receptor antagonists attenuate the expected rise in heart rate.

Short-term administration of β receptor antagonists decreases cardiac output; peripheral resistance increases in proportion to maintain blood

pressure as a result of blockade of vascular β_2 receptors and compensatory reflexes, such as increased sympathetic nervous system activity, leading to activation of vascular α receptors. However, with long-term use of β antagonists, total peripheral resistance returns to initial values (Mimran and Ducailar, 1988) *or decreases in patients with hypertension* (Man in't Veld et al., 1988). With β antagonists that also are α_1 receptor antagonists, such as labetalol, carvedilol, and bucindolol, cardiac output is maintained with a greater fall in peripheral resistance. This also is seen with β receptor antagonists that are direct vasodilators.

The β receptor antagonists have significant effects on cardiac rhythm and automaticity. Although it had been thought that these effects were due exclusively to blockade of β_1 receptors, β_2 receptors likely also regulate heart rate in humans (Altschuld and Billman, 2000; Brodde and Michel, 1999). The β_3 receptors also have been identified in normal myocardial tissue (Moniotte et al., 2001). Signal transduction for β_3 receptors is complex and includes not only G_s but also G_i/G_o ; stimulation of cardiac β_3 receptors inhibits cardiac contraction and relaxation. The physiological role of β_3 receptors in the heart remains to be established (Morimoto et al., 2004). β Receptor antagonists reduce the sinus rate, decrease the spontaneous rate of depolarization of ectopic pacemakers, slow conduction in the atria and in the AV node, and increase the functional refractory period of the AV node.

Although high concentrations of many β blockers exert a membrane-stabilizing activity, it is doubtful that this is significant at usual therapeutic doses. However, this effect may be important when there is overdosage. *d*-Propranolol may suppress ventricular arrhythmias independently of β receptor blockade.

The cardiovascular effects of β receptor antagonists are most evident during dynamic exercise. In the presence of β receptor blockade, exercise-induced increases in heart rate and myocardial contractility are attenuated. However, the exercise-induced increase in cardiac output is less

TABLE 12–3 ■ PHARMACOLOGICAL/PHARMACOKINETIC PROPERTIES OF β ADRENERGIC RECEPTOR BLOCKING AGENTS

DRUG	MEMBRANE STABILIZING ACTIVITY	INTRINSIC AGONIST ACTIVITY	LIPID SOLUBILITY	EXTENT OF ABSORPTION (%)	ORAL AVAILABILITY (%)	PLASMA $t_{1/2}$ (HOURS)	PROTEIN BINDING (%)

affected because of an increase in stroke volume. The effects of β receptor antagonists on exercise are somewhat analogous to the changes that occur with normal aging. In healthy elderly persons, catecholamine-induced increases in heart rate are smaller than in younger individuals; however, the increase in cardiac output in older people may be preserved because of an increase in stroke volume during exercise. β Blockers tend to decrease work capacity, as assessed by their effects on intense short-term or more prolonged steady-state exertion. Exercise performance may be impaired to a lesser extent by β_1 selective agents than by nonselective antagonists. Blockade of β_2 receptors blunts the increase in blood flow to active skeletal muscle during submaximal exercise and also may attenuate catecholamine-induced activation of glucose metabolism and lipolysis.

Coronary artery blood flow increases during exercise or stress to meet the metabolic demands of the heart. By increasing heart rate, contractility, and systolic pressure, catecholamines increase myocardial O_2 demand. However, in patients with coronary artery disease, fixed narrowing of these vessels attenuates the expected increase in flow, leading to myocardial ischemia. β Receptor antagonists decrease the effects of catecholamines on the determinants of myocardial O_2 consumption. However, these agents may tend to increase the requirement for O_2 by increasing end-diastolic pressure and systolic ejection period. Usually, the net effect is to improve the relationship between cardiac O_2 supply and demand; exercise tolerance generally is improved in patients with angina, whose capacity to exercise is limited by the development of chest pain (Chapter 27).

Antihypertensive Activity. β Receptor antagonists generally do not reduce blood pressure in patients with normal blood pressure. However,

these drugs lower blood pressure in patients with hypertension, but the mechanisms responsible for this important clinical effect are not fully understood. The release of *renin* from the juxtaglomerular cells is stimulated by the sympathetic nervous system by means of β_1 receptors, and this effect is blocked by β receptor antagonists (see Chapter 26). Some investigators have found that the antihypertensive effect of β blockade is most marked in patients with elevated concentrations of plasma renin, compared to patients with low or normal concentrations of renin. However, β receptor antagonists are effective even in patients with low plasma renin.

Presynaptic β receptors enhance the release of NE from sympathetic neurons, and diminished release of NE from β blockade is a possible response. Although β blockers would not be expected to decrease the contractility of vascular smooth muscle, long-term administration of these drugs to hypertensive patients ultimately leads to a fall in peripheral vascular resistance (Man in't Veld et al., 1988). The mechanism for this effect is not known, but this delayed fall in peripheral vascular resistance in the face of a persistent reduction of cardiac output appears to account for much of the antihypertensive effect of these drugs.

Some β receptor antagonists have additional effects that may contribute to their capacity to lower blood pressure. These drugs all produce peripheral vasodilation; at least six properties have been proposed to contribute to this effect, including production of NO, activation of β_2 receptors, blockade of α_1 receptors, blockade of Ca^{2+} entry, opening of K^+ channels, and antioxidant activity (see Table 12-4 and Figure 12-4). These mechanisms appear to contribute to the antihypertensive effects by enhancing hypotension, increasing peripheral blood flow, and decreasing afterload.

Figure 12-4 Mechanisms underlying actions of vasodilating β blockers in blood vessels. AC: adenylyl cyclase; sGC: soluble guanylyl cyclase; NO: nitric oxide; ROS: reactive oxygen species; VGCC: voltage-gated Ca^{2+} channel. (Modified with permission from Toda N. Vasodilating β adrenoreceptor blockers as cardiovascular therapeutics. *Pharmacol Ther*, 2003, 100:215–234. Copyright © Elsevier.)

Nonselective β receptor antagonists inhibit the vasodilation caused by INE and augment the pressor response to EPI. This is particularly significant in patients with pheochromocytoma, in whom β receptor antagonists should be used only after adequate α receptor blockade has been established. This avoids uncompensated α receptor-mediated vasoconstriction caused by EPI secreted from the tumor.

Pulmonary System. Nonselective β receptor antagonists such as propranolol block β_2 receptors in bronchial smooth muscle. This usually has little effect on pulmonary function in normal individuals. However, *in patients with COPD, such blockade can lead to life-threatening bronchoconstriction.* Although β_1 -selective antagonists or antagonists with intrinsic sympathomimetic activity are less likely than propranolol to increase airway resistance in patients with asthma, these drugs should be used only with great caution, if at all, in patients with bronchospastic diseases. Drugs such as celiprolol, with β_1 receptor selectivity and β_2 receptor partial agonism, are of potential promise, although clinical experience is limited.

Metabolic Effects. The β receptor antagonists modify the metabolism of carbohydrates and lipids. Catecholamines promote glycogenolysis and mobilize glucose in response to hypoglycemia. Nonselective β blockers may delay recovery from hypoglycemia in type 1 (insulin-dependent) diabetes mellitus, but infrequently in type 2 diabetes mellitus. In addition to blocking glycogenolysis, β receptor antagonists can interfere with the counterregulatory effects of catecholamines secreted during hypoglycemia by blunting the perception of symptoms such as tremor, tachycardia, and nervousness. Thus, β adrenergic receptor antagonists should be used with great caution in patients with labile diabetes and frequent hypoglycemic reactions. If such a drug is indicated, a β_1 -selective antagonist is preferred because these drugs are less likely to delay recovery from hypoglycemia (DiBari et al., 2003).

The β receptors mediate activation of hormone-sensitive lipase in fat cells, leading to release of free fatty acids into the circulation. This increased flux of fatty acids is an important source of energy for exercising muscle. β Receptor antagonists can attenuate the release of free fatty acids from adipose tissue. Nonselective β receptor antagonists consistently reduce HDL cholesterol, increase LDL cholesterol, and increase triglycerides. In contrast, β_1 -selective antagonists, including celiprolol, carteolol, nebivolol, carvedilol, and bevantolol, reportedly improve the serum lipid profile of dyslipidemic patients. While drugs such as propranolol and atenolol increase triglycerides, plasma triglycerides are reduced with chronic celiprolol, carvedilol, and carteolol (Toda, 2003).

In contrast to classical β blockers, which decrease insulin sensitivity, the vasodilating β receptor antagonists (e.g., celiprolol, nipradilol, carteolol, carvedilol, and dilevalol) increase insulin sensitivity in patients with insulin resistance. Together with their cardioprotective effects, improvement in insulin sensitivity from vasodilating β receptor antagonists may partially counterbalance the hazard from worsened lipid abnormalities associated with diabetes.

When β blockers are required, β_1 -selective or vasodilating β receptor antagonists are preferred. In addition, it may be necessary to use β receptor antagonists in conjunction with other drugs, (e.g., HMG CoA reductase inhibitors) to ameliorate adverse metabolic effects (Dunne et al., 2001).

The β receptor agonists decrease the plasma concentration of K^+ by promoting its uptake, predominantly into skeletal muscle. At rest, an infusion of EPI causes a decrease in the plasma concentration of K^+ . The marked increase in the concentration of EPI that occurs with stress (such as myocardial infarction) may cause hypokalemia, which could predispose to cardiac arrhythmias. The hypokalemic effect of EPI is blocked by an experimental antagonist, ICI 118551, which has a high affinity for β_2 and, to a lesser degree, β_3 receptors. Exercise causes an increase in the efflux of K^+ from skeletal muscle. Catecholamines tend to buffer the rise in K^+ by increasing its influx into muscle. β Blockers negate this buffering effect.

Other Effects. The β receptor antagonists block catecholamine-induced tremor. They also block inhibition of mast cell degranulation by catecholamines.

Adverse Effects and Precautions

Cardiovascular System. β Receptor blockade may cause or exacerbate heart failure in patients with compensated heart failure, acute myocardial infarction, or cardiomegaly. It is not known whether β receptor antagonists that possess intrinsic sympathomimetic activity or peripheral vasodilating properties are safer in these settings. Nonetheless, there is convincing evidence that chronic administration of β receptor antagonists is efficacious in prolonging life in the therapy of heart failure in selected patients (discussed in Chapter 29).

Bradycardia is a normal response to β receptor blockade; however, in patients with partial or complete AV conduction defects, β antagonists may cause life-threatening bradyarrhythmias. Particular caution is indicated in patients who are taking other drugs, such as verapamil or various antiarrhythmic agents, which may impair sinus node function or AV conduction.

Some patients complain of cold extremities while taking β receptor antagonists. Symptoms of peripheral vascular disease may occasionally worsen, or Raynaud phenomenon may develop.

Abrupt discontinuation of β receptor antagonists after long-term treatment can exacerbate angina and may increase the risk of sudden death. There is enhanced sensitivity to β receptor agonists in patients who have undergone long-term treatment with certain β receptor antagonists after the blocker is withdrawn abruptly. This increased sensitivity is evident several days after stopping a β receptor antagonist and may persist for at least 1 week. Such enhanced sensitivity can be attenuated by tapering the dose of the β blocker for several weeks before discontinuation. Supersensitivity to INE also has been observed after abrupt discontinuation of metoprolol, but not of pindolol. This enhanced β responsiveness may result from upregulation of β receptors. The number of β receptors on circulating lymphocytes is increased in subjects who have received propranolol for long periods; pindolol has the opposite effect. For discontinuation of β blockers, it is prudent to decrease the dose gradually and to restrict exercise during this period.

Pulmonary Function. A major adverse effect of β receptor antagonists is caused by blockade of β_2 receptors in bronchial smooth muscle. These receptors are particularly important for promoting bronchodilation in patients with bronchospastic disease, and β_2 blockade may cause a life-threatening increase in airway resistance in such patients. Drugs with selectivity for β_1 receptors or those with intrinsic sympathomimetic activity at β_2 receptors seem less likely to induce bronchospasm. β Blocker drugs should be avoided if at all possible in patients with asthma. However, in selected patients with COPD and cardiovascular disease, the advantages of using β_1 receptor antagonists may outweigh the risk of worsening pulmonary function (Salpeter et al., 2005).

CNS. The adverse effects of β receptor antagonists that are referable to the CNS may include fatigue, sleep disturbances (including insomnia and nightmares), and depression. Interest has focused on the relationship between the incidence of the adverse effects of β receptor antagonists and their lipophilicity; however, no clear correlation has emerged.

Metabolism. β Adrenergic blockade may blunt recognition of hypoglycemia by patients; it also may delay recovery from insulin-induced hypoglycemia. β Receptor antagonists should be used with great caution in patients with diabetes who are prone to hypoglycemic reactions; β_1 -selective agents may be preferable for these patients. The benefits of β receptor antagonists in type 1 diabetes with myocardial infarction may outweigh the risk in selected patients (Thompson, 2013).

Sexual Function and Reproduction. The incidence of sexual dysfunction in men with hypertension who are treated with β receptor antagonists is not clearly defined. Although experience with the use of β adrenergic receptor antagonists in pregnancy is increasing, information about the safety of these drugs during pregnancy still is limited.

Overdosage. The manifestations of poisoning with β receptor antagonists depend on the pharmacological properties of the ingested drug, particularly its β_1 selectivity, intrinsic sympathomimetic activity, and

membrane-stabilizing properties. Hypotension, bradycardia, prolonged AV conduction times, and widened QRS complexes are common manifestations of overdosage. Seizures and depression may occur. Hypoglycemia and bronchospasm can occur. Significant bradycardia should be treated initially with atropine, but a cardiac pacemaker often is required. Large doses of INE or an α receptor agonist may be necessary to treat hypotension. Glucagon, acting through its own G protein-coupled receptor and independently of the β adrenergic receptor, has positive chronotropic and inotropic effects on the heart, and the drug has been useful in some patients who have an overdose of a β receptor antagonist.

Drug Interactions. Aluminum salts, cholestyramine, and colestipol may decrease the absorption of β blockers. Drugs such as phenytoin, rifampin, and phenobarbital, as well as smoking, induce hepatic biotransformation enzymes and may decrease plasma concentrations of β receptor antagonists that are metabolized extensively (e.g., propranolol). Cimetidine and hydralazine may increase the bioavailability of agents such as propranolol and metoprolol by affecting hepatic blood flow. β Receptor antagonists can impair the clearance of lidocaine.

Additive effects on blood pressure by β blockers and other antihypertensive agents often are employed to clinical advantage. However, the antihypertensive effects of β receptor antagonists can be opposed by indomethacin and other nonsteroidal anti-inflammatory drugs (see Chapter 38).

Therapeutic Uses

Cardiovascular Diseases. The β receptor antagonists are used extensively in the treatment of hypertension, angina and acute coronary syndromes, and congestive heart failure (Chapters 27–29). These drugs also are used frequently in the treatment of supraventricular and ventricular arrhythmias (Chapter 30). β Receptor antagonists are used in the treatment of hypertrophic obstructive cardiomyopathy, relieving angina, palpitations, and syncope in patients with this disorder. Efficacy probably is related to partial relief of the pressure gradient along the outflow tract. β Blockers also may attenuate catecholamine-induced cardiomyopathy in pheochromocytoma.

β Blockers are used frequently in the medical management of acute dissecting aortic aneurysm; their usefulness comes from reduction in the force of myocardial contraction and the rate of development of such force. Nitroprusside is an alternative, but when given in the absence of β receptor blockade, it causes an undesirable reflex tachycardia. Chronic treatment with β antagonists may be efficacious in slowing the progression of aortic dilation and its complications in patients with Marfan syndrome, although surgical aortic repair is still warranted as aortic diameter expands; losartan, an ACEI, is showing promise as a more effective treatment (Hiratzka et al., 2010).

Glaucoma. The β receptor antagonists are used in the treatment of chronic open-angle glaucoma (see Chapter 69). These agents decrease the production of aqueous humor, which appears to be the mechanism for their clinical effectiveness.

Other Uses. Many of the signs and symptoms of hyperthyroidism are reminiscent of the manifestations of increased sympathetic nervous system activity. β Receptor antagonists control many of the cardiovascular signs and symptoms of hyperthyroidism and are useful adjuncts to more definitive therapy. In addition, propranolol inhibits the peripheral conversion of thyroxine to triiodothyronine, an effect that may be independent of β receptor blockade (see Chapter 43).

Propranolol, timolol, and metoprolol are effective for the prophylaxis of migraine; these drugs are not useful for treatment of acute attacks of migraine.

Propranolol and other β blockers are effective in controlling acute panic symptoms in individuals who are required to perform in public or in other anxiety-provoking situations. Tachycardia, muscle tremors, and other evidence of increased sympathetic activity are reduced.

β Blockers may be of some value in the treatment of patients undergoing withdrawal from alcohol or those with akathisia. Propranolol and nadolol are efficacious in the primary prevention of variceal

bleeding in patients with portal hypertension caused by cirrhosis of the liver (Bosch, 1998).

Clinical Selection of a β Receptor Antagonist

The various β receptor antagonists that are used for the treatment of hypertension and angina appear to have similar efficacies. Selection of the most appropriate drug for an individual patient should be based on pharmacokinetic and pharmacodynamic differences among the drugs, cost, and whether there are concurrent medical problems. β_1 -Selective antagonists are preferable in patients with bronchospasm, diabetes, peripheral vascular disease, or Raynaud phenomenon. Although no clinical advantage of β receptor antagonists with intrinsic sympathomimetic activity has been clearly established, such drugs may be preferable in patients with bradycardia. In addition, third-generation β antagonists that block α_1 receptors, stimulate β_2 receptors, enhance NO production, block Ca^{2+} entry, open K^+ channels, or possess antioxidant properties may offer therapeutic advantages.

Nonselective β Adrenergic Receptor Antagonists

Propranolol

Propranolol (Table 12–5) interacts with β_1 and β_2 receptors with equal affinity, lacks intrinsic sympathomimetic activity, and does not block α receptors.

ADME. Propranolol is highly lipophilic and almost completely absorbed after oral administration. Much of the drug is metabolized by the liver during its first passage through the portal circulation; only about 25% reaches the systemic circulation. In addition, there is great interindividual variation in the presystemic clearance of propranolol by the liver; this contributes to enormous variability in plasma concentrations (~20-fold) after oral administration of the drug and to the wide dosage range for clinical efficacy. The degree of hepatic extraction of propranolol declines as the dose is increased. The bioavailability of propranolol may be increased by the concomitant ingestion of food and during long-term administration of the drug.

Propranolol readily enters the CNS. Approximately 90% of the drug in the circulation is bound to plasma proteins. It is extensively metabolized, with most metabolites appearing in the urine. One product of hepatic metabolism is 4-hydroxypropranolol, which has some β adrenergic antagonist activity.

Analysis of the distribution of propranolol, its clearance by the liver, and its activity is complicated by the stereospecificity of these processes (Walle et al., 1988). The (–) enantiomers of propranolol and other β -blockers are the active forms. The (–) enantiomer of propranolol appears to be cleared more slowly from the body than is the inactive enantiomer. The clearance of propranolol may vary with hepatic blood flow and liver disease and also may change during the administration of other drugs that affect hepatic metabolism.

Despite its short $t_{1/2}$ in plasma (~4 h), twice-daily administration suffices to produce the antihypertensive effect in some patients. Sustained-release formulations of propranolol maintain therapeutic concentrations of propranolol in plasma throughout a 24-h period. For the treatment of hypertension and angina, the initial oral dose of propranolol generally is 40–80 mg per day. The dose may then be titrated upward until the optimal response is obtained. For the treatment of angina, the dose may be increased at intervals of less than 1 week, as indicated clinically. In hypertension, the full blood pressure response may not develop for several weeks. Typically, doses are less than 320 mg/d. If propranolol is taken twice daily for hypertension, blood pressure should be measured just prior to a dose to ensure that the duration of effect is sufficiently prolonged. Adequacy of β adrenergic blockade can be assessed by measuring suppression of exercise-induced tachycardia (Table 12–5).

Propranolol may be administered intravenously for the management of life-threatening arrhythmias or to patients under anesthesia. Under these circumstances, the usual dose is 1–3 mg, administered slowly (<1 mg/min) with careful and frequent monitoring of blood pressure, ECG, and cardiac

function. If an adequate response is not obtained, a second dose may be given after several minutes. If bradycardia is excessive, atropine should be administered to increase heart rate. A change to oral therapy should be initiated as soon as possible.

Nadolol

Nadolol is a long-acting antagonist with equal affinity for β_1 and β_2 receptors. It is devoid of both membrane-stabilizing and intrinsic sympathomimetic activity. A distinguishing characteristic of nadolol is its relatively long $t_{1/2}$. It can be used to treat hypertension and angina pectoris. Unlabeled uses have included migraine prophylaxis, parkinsonian tremors, and variceal bleeding in portal hypertension.

ADME. Nadolol is very soluble in water and is incompletely absorbed from the gut; its bioavailability is about 35%. Interindividual variability is less than with propranolol. The low lipid solubility of nadolol may result in lower concentrations of the drug in the brain. Nadolol is not extensively metabolized and is largely excreted intact in the urine. The $t_{1/2}$ of the drug in plasma is about 20 h; consequently, it generally is administered once daily. Nadolol may accumulate in patients with renal failure, and dosage should be reduced in such individuals.

Timolol

Timolol is a potent, nonselective β receptor antagonist with no intrinsic sympathomimetic or membrane-stabilizing activity. It is used for hypertension, congestive heart failure, acute myocardial infarction, and migraine prophylaxis. In ophthalmology, timolol has been used in the treatment of open-angle glaucoma and intraocular hypertension. The drug appears to reduce aqueous humor production through blockade of β receptors on the ciliary epithelium.

ADME. Timolol is well absorbed from the GI tract. It is metabolized extensively by CYP2D6 in the liver. Only a small amount of unchanged drug appears in the urine. The $t_{1/2}$ in plasma is about 4 h. The ocular formulation of timolol may be absorbed systemically (Chapter 69) and produce adverse effects in susceptible patients, such as those with asthma or congestive heart failure. The systemic administration of cimetidine with topical ocular timolol increases the degree of β blockade, resulting in a reduction of resting heart rate, intraocular pressure, and exercise tolerance (Ishii et al., 2000). For ophthalmic use, timolol is available combined with other medications (e.g., with dorzolamide or travoprost). Timolol also provides benefits to patients with coronary heart disease: In the acute period after myocardial infarction, timolol produced a 39% reduction in mortality in the Norwegian Multicenter Study.

Pindolol

Pindolol is a nonselective β receptor antagonist with *intrinsic sympathomimetic activity*. It has low membrane-stabilizing activity and low lipid solubility. It is used to treat angina pectoris and hypertension. β -Blockers with slight partial agonist activity may be preferred as antihypertensive agents in individuals with diminished cardiac reserve or a propensity for bradycardia. Nonetheless, the clinical significance of partial agonism has not been substantially demonstrated in controlled trials but may be of importance in individual patients.

ADME. Pindolol is almost completely absorbed after oral administration; the drug has a moderately high bioavailability and plasma $t_{1/2}$ of about 4 h. Approximately 50% of pindolol ultimately is metabolized in the liver; the remainder is excreted unchanged in the urine. Clearance is reduced in patients with renal failure.

β_1 -Selective Adrenergic Receptor Antagonists

Metoprolol

Metoprolol is a β_1 -selective receptor antagonist that is devoid of intrinsic sympathomimetic activity and membrane-stabilizing activity.

ADME. Metoprolol is almost completely absorbed after oral administration, but bioavailability is relatively low (~40%) due to first-pass metabolism. Plasma concentrations of the drug vary widely (up to 17-fold), possibly due to genetically determined differences in the rate of metabolism in the liver by CYP2D6. Only 10% of the administered drug is

recovered unchanged in the urine. The $t_{1/2}$ of metoprolol is 3–4 h, but can increase to 7–8 h in CYP2D6 poor metabolizers who have a 5-fold higher risk for developing adverse effects (Wuttke et al., 2002). An extended-release formulation is available for once-daily administration.

Therapeutic Uses. Metoprolol has been used to treat essential hypertension, angina pectoris, tachycardia, heart failure, and vasovagal syncope and as secondary prevention after myocardial infarction, an adjunct in treatment of hyperthyroidism, and for migraine prophylaxis. For the treatment of hypertension, the usual initial dose is 100 mg/d. The drug sometimes is effective when given once daily, although it frequently is used in two divided doses. Dosage may be increased at weekly intervals until optimal reduction of blood pressure is achieved. Metoprolol generally is used in two divided doses for the treatment of stable angina. For the initial treatment of patients with acute myocardial infarction, an intravenous formulation of metoprolol tartrate is available; oral dosing is initiated as soon as the clinical situation permits. Metoprolol generally is contraindicated for the treatment of acute myocardial infarction in patients with heart rates of less than 45 beats per min, heart block greater than first-degree (PR interval ≥ 0.24 sec), systolic blood pressure less than 100 mm Hg, or moderate-to-severe heart failure.

Atenolol

Atenolol is a β_1 -selective antagonist that is devoid of intrinsic sympathomimetic and membrane-stabilizing activity. Atenolol is very hydrophilic and appears to penetrate the CNS only to a limited extent.

ADME. Atenolol is available in 25-, 50-, and 100-mg oral tablets (initial dose is 50 mg/d). It is incompletely absorbed (~50%) and is excreted largely unchanged in the urine, with elimination $t_{1/2}$ of 5–8 h. The drug accumulates in patients with renal failure, and dosage should be adjusted for patients whose creatinine clearance is less than 35 mL/min.

Therapeutic Uses. Atenolol can be used to treat hypertension, coronary heart disease, arrhythmias, and angina pectoris and to treat or reduce the risk of heart complications following myocardial infarction. Recent meta-analysis and clinical trials demonstrated a lack of benefit compared with placebo or other antihypertensive agents for reduction of stroke, cardiovascular and all-cause, in spite of similar blood pressure reduction compared to other antihypertensive agents (Ripley and Saseen, 2014). Compared with other active treatments, atenolol was associated with increased risk of all-cause mortality, cardiovascular mortality, and stroke and had a neutral effect on myocardial infarction. Atenolol is also used to treat Graves disease until antithyroid medication can take effect. The initial dose of atenolol for the treatment of hypertension usually is 50 mg/d, given once daily. If an adequate therapeutic response is not evident within several weeks, the daily dose may be increased to 100 mg. Atenolol has been shown to be efficacious, in combination with a diuretic, in elderly patients with isolated systolic hypertension. Atenolol causes fewer CNS side effects (depression, nightmares) than most β -blockers and few bronchospastic reactions due to its pharmacological and pharmacokinetic profile (Varon, 2008).

Esmolol

Esmolol is a β_1 -selective antagonist with a rapid onset and a very short duration of action. It has little if any intrinsic sympathomimetic activity and lacks membrane-stabilizing actions. Esmolol is administered intravenously and is used when β blockade of short duration is desired or in critically ill patients in whom adverse effects of bradycardia, heart failure, or hypotension may necessitate rapid withdrawal of the drug. It is a class II antiarrhythmic agent (Chapter 30).

ADME. Esmolol is given by slow intravenous injection. Because esmolol is used in urgent settings where immediate onset of β blockade is warranted, a partial loading dose (500 μ g/kg over 1 min) typically is administered, followed by a continuous infusion of the drug (maintenance dose of 50 μ g/kg/min for 4 min). If an adequate therapeutic effect is not observed within 5 min, the same loading dose is repeated, followed by a maintenance infusion at a higher rate. This may need to be repeated until the desired end point (e.g., lowered heart rate or blood pressure) is approached. The drug

is hydrolyzed rapidly by esterases in erythrocytes and has a $t_{1/2}$ of about 8 min. The $t_{1/2}$ of the carboxylic acid metabolite of esmolol is far longer (~4 h) and will accumulate during prolonged infusion of esmolol. However, this metabolite has very low potency as a β receptor antagonist (1/500 of the potency of esmolol); it is excreted in the urine.

Therapeutic Uses. Esmolol is commonly used in patients during surgery to prevent or treat tachycardia and in the treatment of supraventricular tachycardia. The onset and cessation of β receptor blockade with esmolol are rapid; peak hemodynamic effects occur within 6–10 min of administration of a loading dose, and there is substantial diminution of β -blockade within 20 min of stopping an infusion. Esmolol is particularly useful in severe postoperative hypertension and is a suitable agent in situations where cardiac output, heart rate, and blood pressure are increased. The American Heart Association/American College of Cardiology guidelines recommend against using esmolol in patients already on β blocker therapy, bradycardic patients, and patients with decompensated heart failure, as the drug may compromise their myocardial function (Varon, 2008). Esmolol is generally tolerated well, but it is associated with an increased risk of hypotension that is rapidly reversible (Garnock-Jones, 2012).

Acebutolol

Acebutolol is a β_1 -selective antagonist with some intrinsic sympathomimetic and membrane-stabilizing activity.

ADME. Acebutolol is administered orally (starting dose 200 mg twice daily titrated up to 1200 mg/d). It is well absorbed and undergoes significant first-pass metabolism to an active metabolite, diacetolol, which accounts for most of the drug's activity. Overall bioavailability is 35%–50%. The elimination $t_{1/2}$ of acebutolol typically is about 3 h, but the $t_{1/2}$ of diacetolol is 8–12 h; it is excreted largely in the urine. Acebutolol has lipophilic properties and crosses the blood-brain barrier. It has no negative impact on serum lipids (cholesterol, triglycerides, or HDL).

Therapeutic Uses. Acebutol has been used to treat hypertension, ventricular and atrial cardiac arrhythmias, acute myocardial infarction in high-risk patients, and Smith-Magenis syndrome. The initial dose of acebutolol in hypertension usually is 400 mg/d; it may be given as a single dose, but two divided doses may be required for adequate control of blood pressure. Optimal responses usually occur with doses of 400–800 mg per day (range 200–1200 mg).

Bisoprolol

Bisoprolol is a highly selective β_1 receptor antagonist that lacks intrinsic sympathomimetic or membrane-stabilizing activity (McGavin and Keating, 2002). It has a higher degree of β_1 -selective activity than atenolol, metoprolol, or betaxolol but less than nebivolol. It is approved for the treatment of hypertension.

Bisoprolol generally is well tolerated; side effects include dizziness, bradycardia, hypotension, and fatigue. Bisoprolol is well absorbed following oral administration, with bioavailability of about 90%. It is eliminated by renal excretion (50%) and liver metabolism to pharmacologically inactive metabolites (50%). Bisoprolol has a plasma $t_{1/2}$ of approximately 11–17 h. Bisoprolol can be considered a standard treatment option when selecting a β -blocker for use in combination with ACEIs and diuretics in patients with stable, moderate-to-severe chronic heart failure and in treating hypertension (McGavin and Keating, 2002; Simon et al., 2003). It has also been used to treat arrhythmias and ischemic heart disease. Bisoprolol was associated with a 34% mortality benefit in the CIBIS-II (Cardiac Insufficiency Bisoprolol Study-II).

Betaxolol

Betaxolol is a selective β_1 receptor antagonist with no partial agonist activity and slight membrane-stabilizing properties. Betaxolol is used to treat hypertension, angina pectoris, and glaucoma. The drug is well absorbed with high bioavailability; its elimination $t_{1/2}$ varies from 14 to 22 h. It is usually well tolerated; side effects are mild and transient.

β Adrenergic Receptor Antagonists With Additional Cardiovascular Effects (“Third-Generation” β -Blockers)

In addition to the classical nonselective and β_1 selective adrenergic receptor antagonists, there are drugs that possess vasodilating actions (Toda, 2003). These effects are produced through a variety of mechanisms, including the following:

- α_1 adrenergic receptor blockade (labetalol, carvedilol, bucindolol, bevantolol, nipradilol)
- increased production of NO (celiprolol, nebivolol, carteolol, bopindolol, nipradolol)
- β_2 agonist properties (celiprolol, carteolol, bopindolol)
- Ca^{2+} entry blockade (carvedilol, betaxolol, bevantolol)
- opening of K^+ channels (tilisolol)
- antioxidant action (carvedilol)

These actions are summarized in Table 12–4 and Figure 12–4. Some third-generation β receptor antagonists are not yet available in the U.S. but have undergone clinical trials and are available elsewhere.

Labetalol

Labetalol is representative of a class of drugs that act as competitive antagonists at both α_1 and β receptors. Labetalol has two optical centers, and the formulation used clinically contains equal amounts of the four diastereomers. The pharmacological properties of the drug are complex because each isomer displays different relative activities. The properties of the mixture include selective blockade of α_1 receptors (as compared with the α_2 subtype), blockade of β_1 and β_2 receptors, partial agonist activity at β_2 receptors, and inhibition of neuronal uptake of NE (cocaine-like effect) (Chapter 8). The potency of the mixture for β receptor blockade is 5- to 10-fold that for α_1 receptor blockade.

The pharmacological effects of labetalol have become clearer since the four isomers were separated and tested individually.

- The *R,R* isomer is about four times more potent as a β receptor antagonist than is racemic labetalol and accounts for much of the β blockade produced by the mixture of isomers. As an α_1 antagonist, this isomer is less than 20% as potent as the racemic mixture. The *R,R* isomer has some intrinsic sympathomimetic activity at β_2 adrenergic receptors; this may contribute to vasodilation.
- The *R,S* isomer is almost devoid of both α and β blocking effects.
- The *S,R* isomer has almost no β -blocking activity, yet is about five times more potent as an α_1 blocker than is racemic labetalol.
- The *S,S* isomer is devoid of β blocking activity and has a potency similar to that of racemic labetalol as an α_1 receptor antagonist.

The actions of labetalol on both α_1 and β receptors contribute to the fall in blood pressure observed in patients with hypertension. α_1 Receptor blockade leads to relaxation of arterial smooth muscle and vasodilation, particularly when the patient is upright. The β_1 blockade also contributes to a fall in blood pressure, in part by blocking reflex sympathetic stimulation of the heart. In addition, the intrinsic sympathomimetic activity of labetalol at β_2 receptors may contribute to vasodilation, and the drug may have some direct vasodilating capacity.

Labetalol is available in oral form for therapy of chronic hypertension and as an intravenous formulation for use in hypertensive emergencies. Labetalol has been associated with hepatic injury in a limited number of patients. Labetalol has been recommended as treatment of acute severe hypertension (hypertensive emergency). Its hypotensive action begins within 2–5 min after intravenous administration, reaching its peak at 5–15 min and lasting about 2–4 h. Heart rate is either maintained or slightly reduced, and cardiac output is maintained. Labetalol reduces systemic vascular resistance without reducing total peripheral blood flow. Cerebral, renal, and coronary blood flow is maintained. It can be used in the setting of pregnancy-induced hypertensive crisis because little placental transfer occurs due to the poor lipid solubility of labetalol.

ADME. Although labetalol is completely absorbed from the gut, there is extensive first-pass clearance; bioavailability is about 20%–40% but may be increased by food intake. The drug is rapidly metabolized in the liver; very little unchanged drug is found in the urine. The rate of metabolism of labetalol is sensitive to changes in hepatic blood flow. The elimination $t_{1/2}$ of the drug is about 8 h. The $t_{1/2}$ of the *R,R* isomer of labetalol is approximately 15 h.

Carvedilol

Carvedilol is a third-generation β receptor antagonist that has a unique pharmacological profile. It blocks β_1 , β_2 , and α_1 receptors similarly to labetalol but also has antioxidant and anti-inflammatory properties (Dandona et al., 2007). The antioxidant and anti-inflammatory properties may be beneficial in treating congestive heart failure. The drug has membrane-stabilizing activity but lacks intrinsic sympathomimetic activity.

Carvedilol reduces arterial blood pressure by decreasing vascular resistance and maintaining cardiac output while decreasing sympathetic vascular tone (DiNicolantonio et al., 2015; Zepeda et al., 2012). The hemodynamic effect exerted by carvedilol is similar to that of ACEIs and superior to that of traditional β blockers. Carvedilol is renoprotective and has favorable effects in patients with diabetes or metabolic syndrome. The drug is FDA-approved for use in hypertension, congestive heart failure, and left ventricular dysfunction following myocardial infarction.

Carvedilol possesses two distinct antioxidant properties: It is a chemical antioxidant that can bind to and scavenge ROS, and it can suppress the biosynthesis of ROS and oxygen radicals. Carvedilol is extremely lipophilic and protects cell membranes from lipid peroxidation. It prevents LDL oxidation, which in turn induces the uptake of LDL into the coronary vasculature. Carvedilol also inhibits ROS-mediated loss of myocardial contractility, stress-induced hypertrophy, apoptosis, and the accumulation and activation of neutrophils. *At high doses, carvedilol exerts Ca^{2+} channel-blocking activity.* Carvedilol does not increase β receptor density and does not show a high level of inverse agonist activity (Cheng et al., 2001; Dandona et al., 2007; Keating and Jarvis, 2003).

Carvedilol has been tested in numerous controlled trials (Cleland, 2003; Poole-Wilson et al., 2003). These trials showed that carvedilol improves ventricular function and reduces mortality and morbidity in patients with mild-to-severe congestive heart failure. Several experts recommend it as the standard treatment option in this setting. In addition, carvedilol combined with conventional therapy reduces mortality and attenuates myocardial infarction. In patients with chronic heart failure, carvedilol reduces cardiac sympathetic drive, but it is not clear if blockade of α_1 receptor-mediated vasodilation is maintained over long periods of time.

ADME. Carvedilol is rapidly absorbed following oral administration, with peak plasma concentrations occurring in 1–2 h. It is highly lipophilic and more than 95% protein bound. Hepatic CYPs 2D6 and 2C9 metabolized carvedilol, yielding a $t_{1/2}$ of 7–10 h. Stereoselective first-pass metabolism results in more rapid clearance of *S*(–)-carvedilol than *R*(+)-carvedilol. No significant changes in the pharmacokinetics of carvedilol are seen in elderly patients with hypertension, and no change in dosage is needed in patients with moderate-to-severe renal insufficiency (Cleland, 2003; Keating and Jarvis, 2003). Because of carvedilol's extensive oxidative metabolism by the liver, its pharmacokinetics can be profoundly affected by drugs that induce or inhibit oxidation. These include the inducer rifampin and inhibitors such as cimetidine, quinidine, fluoxetine, and paroxetine.

Bucindolol

Bucindolol is a third-generation *nonselective β adrenergic antagonist with weak α_1 adrenergic blocking properties.*

Bucindolol increases left ventricular systolic ejection fraction and decreases peripheral resistance, thereby reducing afterload. It increases plasma HDL cholesterol but does not affect plasma triglycerides. A large comprehensive clinical trial, the BEST (β Blocker Evaluation of Survival Trial), was terminated early because of a lack of a demonstrable survival benefit with bucindolol versus placebo. Further analysis has demonstrated that polymorphisms in β_1 and α_{2c} receptors predict the effect of bucindolol to prevent new-onset atrial fibrillation and ventricular arrhythmias (Cooper-DeHoff and Johnson, 2016; O'Connor et al., 2012).

Celiprolol

Celiprolol is a third-generation cardioselective β receptor antagonist. It has low lipid solubility and possesses weak vasodilating and bronchodilating effects attributed to *partial selective β_2 -agonist activity* and possibly papaverine-like relaxant effects on smooth muscle (including bronchial). It also has been reported to *antagonize peripheral α_2 adrenergic receptor activity, to promote NO production, and to inhibit oxidative stress.* There is evidence for intrinsic sympathomimetic activity at the β_2 receptor. Celiprolol is devoid of membrane-stabilizing activity. Weak α_2 antagonistic properties are present but are not considered clinically significant at therapeutic doses (Toda, 2003).

Celiprolol reduces heart rate and blood pressure and can increase the functional refractory period of the AV node. Oral bioavailability ranges from 30% to 70%, and peak plasma levels are seen at 2–4 h. It is excreted largely unchanged in the urine and feces. The predominant mode of excretion is renal. Celiprolol is used for treatment of hypertension and angina (Witchitz et al., 2000).

Nebivolol

Nebivolol is a third-generation, long-acting, and highly selective β_1 adrenergic receptor antagonist that stimulates NO-mediated vasodilation via β_3 receptor agonism (Fongemia and Felix-Getzik, 2015). Nebivolol is devoid of intrinsic sympathomimetic effects as well as membrane-stabilizing activity and α_1 receptor blocking properties.

Therapeutic Uses. Nebivolol is approved for treatment of hypertension and has potential utility in the treatment of heart failure with reduced ejection fraction. The drug lowers blood pressure by reducing peripheral vascular resistance and significantly increases stroke volume with preservation of cardiac output and maintains systemic flow and blood flow to target organs. Nebivolol also reduces oxidative stress and may have favorable effects on both carbohydrate and lipid metabolism. These benefits are also observed in the presence of metabolic syndrome, which often copresents with hypertension (Ignarro, 2008).

ADME. Nebivolol is administered as the racemate containing equal amounts of the *d*- and *l*-enantiomers. The *d*-isomer is the active β blocking component; the *l*-isomer is responsible for enhancing production of NO.

Nebivolol undergoes extensive first-pass metabolism, primarily by CYP2D6, yielding a mean terminal $t_{1/2}$ of about 10 h. Active metabolites (e.g., 4-OH nebivolol) contribute to the β -blocking effect of nebivolol. Polymorphisms in the CYP2D6 gene affect nebivolol's metabolism but not its efficacy due to the production of active hydroxylated metabolites (Lefebvre et al., 2007).

Nebivolol is lipophilic, and concomitant administration of chlorthalidone, hydrochlorothiazide, theophylline, or digoxin with nebivolol may reduce its extent of absorption. The NO-dependent vasodilating action of nebivolol and its high β_1 adrenergic receptor selectivity likely contribute to the drug's efficacy and comparative tolerability as an antihypertensive agent (e.g., less fatigue and sexual dysfunction) (Moen and Wagstaff, 2006).

TABLE 12-5 ■ SUMMARY OF ADRENERGIC AGONISTS AND ANTAGONISTS

SUB-CLASS	DRUGS	PROMINENT PRINCIPAL PHARMACOLOGICAL ACTIONS	THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
Direct-acting nonselective agonists					
	Epinephrine (α_1 , α_2 , β_1 , β_2 , β_3)	\uparrow Heart rate; \uparrow blood pressure; \uparrow contractility; slight \downarrow in PVR; \uparrow cardiac output; vasoconstriction (viscera); vasodilation (skeletal muscle); \uparrow blood glucose and lactate	Open-angle glaucoma With local anesthetics to prolong action Anaphylactic shock Complete heart block or cardiac arrest Bronchodilator in asthma	Palpitation Cardiac arrhythmias Cerebral hemorrhage Headache Tremor Restlessness	Not given orally Life saving in anaphylaxis or cardiac arrest
	Norepinephrine (α_1 , α_2 , $\beta_1 \gg \beta_2$)	\uparrow Systolic and diastolic blood pressure; vasoconstriction; \uparrow PVR; direct \uparrow in heart rate and contraction; reflex \downarrow in heart rate	Hypotension	Similar to EPI Hypertension	Not absorbed orally
β Receptor agonists					
Nonselective ($\beta_1 + \beta_2$)	Isoproterenol	\downarrow PVR; \uparrow cardiac output; bronchodilation	Bronchodilator in asthma Complete heart block or cardiac arrest Shock	Palpitations Tachycardia Tachyarrhythmias Headache Flushed skin Cardiac ischemia in patients with coronary artery disease	Intravenous administration Administered by inhalation in asthma
β_1 Selective	Dobutamine	\uparrow Contractility; some \uparrow heart rate; \uparrow AV conduction	Short-term treatment of cardiac decompensation after surgery or patients with congestive heart failure or myocardial infarction	\uparrow Blood pressure and heart rate	Intravenous only Use with caution in patients with hypertension or cardiac arrhythmias
β_2 Selective (intermediate acting)	Albuterol Bitolterol Fenoterol Isoetharine Levalbuterol Metaproterenol Pirbuterol Procaterol Terbutaline	Relaxation of bronchial smooth muscle Relaxation of uterine smooth muscle Activation of other β_2 receptors after systemic administration	Bronchodilators for treatment of asthma and COPD Short-/intermediate-acting drugs for acute bronchospasm	Skeletal muscle tremor Tachycardia and other cardiac effects seen after systemic administration (much less with inhalational use)	Use with caution in patients with cardiovascular disease (reduced by inhalational administration) Minimal side effects

(Continued)

TABLE 12-5 ■ SUMMARY OF ADRENERGIC AGONISTS AND ANTAGONISTS (CONTINUED)

SUB-CLASS	DRUGS	PROMINENT PRINCIPAL PHARMACOLOGICAL ACTIONS	THERAPEUTIC APPLICATIONS	UNTOWARD EFFECTS	COMMENTS
(Long acting)	Formoterol Salmeterol Arformoterol Carniterol Indacaterol Ritodrine	Relaxation of bronchial smooth muscle Relaxation of uterine smooth muscle	Bronchodilators for treatment of COPD Best choice for prophylaxis due to long action Ritodrine, to stop premature labor	Contraindicated in asthma	Long action, favored for prophylaxis
α Receptor agonists					
α ₁ Selective	Methoxamine Phenylephrine Mephentermine Metaraminol Midodrine	Vasoconstriction	Nasal congestion (used topically) Postural hypotension	Hypertension Reflex bradycardia Dry mouth, sedation, rebound hypertension on abrupt withdrawal	Mephentermine and metaraminol also act indirectly to release NE Midodrine, a prodrug activated in vivo
α ₂ Selective	Clonidine Apraclonidine Guanfacine Guanabenz Brimonidine α-Methyldopa	↓ Sympathetic outflow from brain to periphery resulting in ↓ PVR and blood pressure ↓ Nerve-evoked release of sympathetic transmitters ↓ Production of aqueous humor	Adjunctive therapy in shock Hypertension To reduce sympathetic response to withdrawal from narcotics, alcohol, and tobacco Glaucoma		Apraclonidine and brimonidine used topically for glaucoma and ocular hypertension Methyldopa is converted in CNS to α-methyl NE, an effective α ₂ agonist
Indirect acting	Amphetamine Methamphetamine Methylphenidate (releases NE peripherally; NE, DA, 5HT centrally)	CNS stimulation ↑ Blood pressure Myocardial stimulation	Treatment of ADHD Narcolepsy Obesity (rarely)	Restlessness Tremor Insomnia Anxiety Tachycardia Hypertension Cardiac arrhythmias	Schedule II drugs Marked tolerance occurs Chronic use leads to dependence Can result in hemorrhagic stroke in patients with underlying disease Long-term use can cause paranoid schizophrenia
Mixed acting	Dopamine (α ₁ ; α ₂ ; β ₁ ; D ₁ ; releases NE)	Vasodilation (coronary, renal mesenteric beds) ↑ Glomerular filtration rate and natriuresis ↑ Heart rate and contractility ↑ Systolic blood pressure	Cardiogenic shock Congestive heart failure Treatment of acute renal failure	High doses lead to vasoconstriction Restlessness	Important for its ability to maintain renal blood flow Administered intravenously
	Ephedrine (α ₁ ; α ₂ ; β ₁ ; β ₂ ; releases NE)	Similar to epinephrine but longer lasting CNS stimulation	Bronchodilator for treatment of asthma Nasal congestion Treatment of hypotension and shock	Tremor Insomnia Anxiety Tachycardia Hypertension	Administered by all routes Not commonly used

α Blockers					
Nonselective (classical α blockers)	PBZ Phentolamine Tolazoline	↓ PVR and blood pressure Venodilation	Treatment of catecholamine excess (e.g., pheochromocytoma)	Postural hypotension Failure of ejaculation	Cardiac stimulation due to initiation of reflexes and to enhanced release of NE via α ₂ receptor blockade PBZ produces long-lasting α receptor blockade, can block neuronal and extraneuronal uptake of amines
α ₁ Selective	Prazosin Terazosin Doxazosin Trimazosin Alfuzosin Tamsulosin Silodosin	↓ PVR and blood pressure Relax smooth muscles in neck of urinary bladder and in prostate	Primary hypertension Increase urine flow in BPH	Postural hypotension when therapy instituted	Prazosin and related quinazolines are selective for α ₁ receptors Tamsulosin exhibits some selectivity for α _{1A} receptors
β Blockers					
Nonselective (first generation)	Nadolol Penbutolol Pindolol Propranolol Timolol	↓ Heart rate ↓ Contractility ↓ Cardiac output Slow conduction in atria and AV node ↑ Refractory period, AV node Bronchoconstriction Prolonged hypoglycemia ↓ Plasma free fatty acids ↓ HDL cholesterol ↑ LDL cholesterol and triglycerides Hypokalemia	Angina pectoris Hypertension Cardiac arrhythmias Congestive heart failure Pheochromocytoma Glaucoma Hypertrophic obstructive cardiomyopathy Hyperthyroidism Migraine prophylaxis Acute panic symptoms Substance abuse withdrawal Variceal bleeding in portal hypertension	Bradycardia Negative inotropy ↓ Cardiac output Bradyarrhythmias ↓ AV conduction Bronchoconstriction Fatigue Sleep disturbances (insomnia, nightmares) Prolongation of hypoglycemia Sexual dysfunction in men Drug interactions	Effects depend on sympathoadrenal tone Bronchoconstriction (do not use in asthma and COPD) Hypoglycemia (of concern in hypoglycemics and diabetics) Membrane-stabilizing effect (propranolol, and betaxolol) ISA (strong for pindolol; weak for penbutolol, carteolol, and betaxolol)
β ₁ Selective (second generation)	Acebutolol Atenolol Bisoprolol Betaxolol Esmolol Metoprolol	Similar to above but with less adverse effect on bronchial constriction	Similar to above	Similar to above	Effects depend on sympathoadrenal tone Bronchoconstriction effect is less than for non-specific agents but use only with great caution in asthma and COPD
Nonselective (third-generation) vasodilators	Carteolol Carvedilol Bucindolol Labetalol	See text. These agents affect multiple receptor types and signaling pathways. They are used to treat hypertension; carvedilol is also used to treat heart failure. Effects and applications generally resemble those of other β blockers with some α blocking properties: <ul style="list-style-type: none">• α₁ adrenergic receptor blockade (labetalol, carvedilol, bucindolol)			Vasodilation seen in third-generation drugs; multiple mechanisms (see Figure 12–4) Weak ISA for labetalol
β ₁ Selective (third-generation) vasodilators	Celiprolol Nebivolol	<ul style="list-style-type: none">• increased production of NO (celiprolol, nebivolol, carteolol)• β₂ agonist properties (celiprolol, carteolol)• Ca²⁺ entry blockade (carvedilol)• antioxidant action (carvedilol)			Receptor polymorphisms affect response to bucindolol's anti-arrhythmic properties

- Pituitary Gland
- Catecholamine Release
- CNS

DRUGS AFFECTING DOPAMINE SIGNALING

- Dopamine Receptor Agonists
- Dopamine Receptor Antagonists

Introduction

5-Hydroxytryptamine (5HT, serotonin) and DA are neurotransmitters in the CNS and also have prominent peripheral actions. 5HT is found in high concentrations in enterochromaffin cells throughout the GI tract, in storage granules in platelets, and throughout the CNS. The highest concentrations of DA are found in the brain; DA stores are also present peripherally in the adrenal medulla, in the plexuses of the GI, and in the enteric nervous system. Fourteen 5HT receptor subtypes and five DA receptor subtypes have been delineated by structural and pharmacological analyses. The identification of individual receptor subtypes has allowed for the development of subtype-selective drugs and the elucidation of actions of these neurotransmitters at a molecular level. Increasingly, therapeutic goals are being achieved by using drugs that selectively target one or more of the subtypes of 5HT or DA receptors, or that act on a combination of both 5HT and DA receptors.

5-Hydroxytryptamine

In the 1930s, Erspamer began to study the distribution of enterochromaffin cells, which were stained with a reagent for indoles. The highest concentrations of these cells were found in GI mucosa, followed by platelets and the CNS. Soon thereafter, Page and colleagues isolated and chemically characterized a vasoconstrictor substance released from platelets in clotting blood. This substance, named serotonin, was shown to be identical to the indole isolated by Erspamer. Subsequent discovery of the biosynthetic and degradative pathways for 5HT and clinical presentation of patients with carcinoid tumors of intestinal enterochromaffin cells spurred interest in 5HT. In the mid-1950s, the discovery that the pronounced behavioral effects of reserpine are accompanied by a profound decrease in brain 5HT led to the proposal that serotonin may function as a neurotransmitter in the mammalian CNS. Numerous synthetic or naturally occurring congeners of 5HT have pharmacological activity (see Figure 13-1 for chemical

structures). Many of the *N*- and *O*-methylated indoleamines, such as *N,N*-dimethyltryptamine, are hallucinogens. Another close relative of 5HT, melatonin (5-methoxy-*N*-acetyltryptamine), is formed by sequential *N*-acetylation and *O*-methylation (Figure 13-1). Melatonin, not to be confused with the pigment melanin, is the principal indoleamine in the pineal gland, where it serves a role in regulating circadian rhythms and shows promise in the treatment of jet lag and other sleep disturbances, such as insomnia. In that regard, melatonin could be thought of as a pigment of the imagination.

Synthesis and Metabolism of 5HT

Synthesis of 5HT is by a two-step pathway from the essential amino acid tryptophan (Figure 13-2). Tryptophan is actively transported into the brain by LAT1, a heteromeric carrier protein that also transports other large neutral and branched-chain amino acids and some drugs. Levels of tryptophan in the brain are influenced not only by its plasma concentration but also by the plasma concentrations of other amino acids that compete for the transporter. TPH, a mixed-function oxidase that requires molecular O₂ and a reduced pteridine cofactor for activity, is the rate-limiting enzyme in the synthetic pathway. TPH2, a brain-specific isoform of TPH, is entirely responsible for the synthesis of brain 5HT. Brain TPH is not generally saturated with substrate; consequently, the concentration of tryptophan in the brain influences the synthesis of 5HT.

L-5-hydroxytryptophan is converted to 5HT by AADC; AADC is widely distributed and has broad substrate specificity. The synthesized product, 5HT, is accumulated in secretory granules by VMAT2, which can be selectively inhibited by reserpine, thus depleting vesicular stores of monoamine transmitters. Based on its ability to deplete NE or DA, reserpine was once used as an antihypertensive and antipsychotic agent. Stored vesicular 5HT is released by exocytosis from serotonergic neurons in response to an action potential. In the nervous system, the action of released 5HT is terminated via neuronal uptake by a specific SERT, localized in the membrane of serotonergic axon terminals and in the membranes of platelets.

Abbreviations

AADC: aromatic L-amino acid decarboxylase
AC: adenylyl cyclase
ACh: acetylcholine
ADD: attention-deficit disorder
ADHD: attention-deficit/hyperactivity disorder
ALDH: aldehyde dehydrogenase
BBB: blood-brain barrier
CNS: central nervous system
COMT: catechol-O-methyl transferase
CSF: cerebrospinal fluid
DA: dopamine
DAG: diacylglycerol
DAT: dopamine transporter
L-dopa: 3,4-dihydroxyphenylalanine
DOPAC: 3,4-dihydroxyphenylacetic acid
ENT: equilibrative nucleoside transporter
EPI: epinephrine
EPS: extrapyramidal symptoms
FDA: Food and Drug Administration
FSIAD: female sexual interest/arousal disorder
GABA: γ -aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
GSK-3: glycogen synthase kinase 3
5-HIAA: 5-hydroxyindole acetic acid
HSDD: hypoactive sexual desire disorder
5HT: 5-hydroxytryptamine, serotonin
HVA: homovanillic acid
LAT1: L-type amino acid transporter 1
LSD: lysergic acid diethylamide
MAO: monoamine oxidase
MPP⁺: 1-methyl-4-phenylpyridinium
MPTP: 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
MSAA: multifunctional serotonin agonist and antagonist
NE: norepinephrine
NET: norepinephrine transporter
NMDA: N-methyl-D-aspartate
NO: nitric oxide
NSS: neurotransmitter-sodium symporter
OCT: organic cation transporter
6-OHDA: 6-hydroxydopamine
PCPA: para-chlorophenylalanine
PD: Parkinson disease
PFC: prefrontal cortex
PH: phenylalanine hydroxylase
PKC: protein kinase C
PL₂: phospholipase α_2 , as in PLC
RLS: restless leg syndrome
SERT: serotonin transporter
SNRI: serotonin-norepinephrine reuptake inhibitor
SSRI: selective serotonin reuptake inhibitor
TAAR1: trace amine-associated receptor 1
TCA: tricyclic antidepressant
TH: tyrosine hydroxylase
TPH: tryptophan hydroxylase
VMAT2: vesicular monoamine transporter
VNTR: variable number of tandem repeats

Figure 13-1 Structures of representative indolealkylamines.

a nonspecific amine carrier. SERT, the 5HT transporter or reuptake system is specific (see discussion that follows) and can be inhibited by SSRIs that are used to treat depression and other mood disorders.

The principal route of metabolism of 5HT involves oxidative deamination by MAO; the aldehyde intermediate thus formed is converted to 5-HIAA by aldehyde dehydrogenase (see Figure 13-2). An alternative route, reduction of the acetaldehyde to an alcohol, 5-hydroxytryptophol, is normally insignificant. 5-HIAA is actively transported out of the brain by a process that is sensitive to the nonspecific transport inhibitor probenecid. 5-HIAA from brain and peripheral sites of 5HT storage and metabolism is excreted in the urine along with small amounts of 5-hydroxytryptophol sulfate or glucuronide conjugates.

Of the two isoforms of MAO (see Chapter 8), MAO-A preferentially metabolizes 5HT and NE. Selective MAO-A inhibitors increase stores of 5HT and NE and are first-generation antidepressant agents (Chapter 15). MAO-B prefers β -phenylethylamine and benzylamine as substrates; low-dose selegiline is a relatively selective inhibitor of MAO-B. DA and tryptamine are metabolized equally well by both isoforms. Neurons contain both isoforms of MAO, localized primarily in the outer membrane of mitochondria. MAO-B is the principal isoform in platelets, which contain large amounts of 5HT.

Serotonergic Projection Pathways in the Brain

In the CNS, 5HT is almost entirely synthesized by cells located in the raphe nuclei in the brainstem. These neurons exhibit extensive projections throughout the brain and spinal cord. These projections are so extensive that it has been hypothesized that every neuron in the brain may be in synaptic contact with a serotonergic projection fiber (Figure 13-3).

A model of a serotonergic synapse is depicted in Figure 13-4. 5HT released from the nerve terminal activates cell-specific postsynaptic receptors, leading to signal transduction. Presynaptic 5HT receptors also exist on the nerve terminal where they can act to modulate 5HT release. Reuptake of 5HT by the 5HT transporter is the primary mechanism for termination of 5HT action and allows for either vesicular repackaging of transmitter or metabolism.

The 5HT Receptors

Multiple 5HT receptor subtypes mediate serotonin's diverse array of physiologic effects and comprise the largest known neurotransmitter-receptor family (Hoyer et al., 1994). The 5HT receptor subtypes are expressed in distinct but often overlapping patterns and are coupled to different transmembrane signaling mechanisms (Table 13-1). All of the 5HT receptor subtypes are GPCRs, with the exception of the 5HT₃ receptor, which is a ligand-gated ion channel (see Figures 3-11 and 11-1).

This uptake system is the means by which platelets acquire 5HT because they lack the enzymes required for 5HT synthesis. SERT is distinct from VMAT2, which concentrates amines in intracellular storage vesicles and is

Figure 13-2 Synthesis and inactivation of serotonin. Enzymes are identified in red lettering, and cofactors are shown in blue.

The 5HT₁ Receptor Subfamily

- The 5HT₁ receptor family comprises five members, all of which preferentially couple to G_{i/o} and inhibit adenylyl cyclase. 5HT₁ receptors are also known to modulate K⁺ and Ca²⁺ channels.
- The 5HT_{1A} and 5HT_{1B/1D} receptors all act as autoreceptors, either on the cell bodies (5HT_{1A}) or on the axon terminals (5HT_{1B/1D}) (Figure 13-5). Antimigraine triptan drugs are 5HT_{1B/1D} antagonists (see further discussion).
- In early literature, the 5HT_{2C} receptor (see next section) was referred to as the 5HT_{1C} receptor. To avoid confusion, the name 5HT_{1C} is no longer in use (Hoyer et al., 1994).

- The 5HT_{1D} receptors, abundantly expressed in the substantia nigra and basal ganglia, also regulate the firing rate of DA-containing cells and the release of DA at axonal terminals.
- The precise physiological roles of the 5HT_{1E} and 5HT_{1F} receptors are unclear at present.

The 5HT₂ Receptor Subfamily

- The three subtypes of 5HT₂ receptors couple to G_q/G₁₁ proteins and activate PLC-DAG/IP₃-Ca²⁺-PKC pathways (Table 13-1). 5HT_{2A} and 5HT_{2C} receptors also activate phospholipase A₂, promoting the release of arachidonic acid.
- The 5HT_{2A} receptors are broadly distributed in the CNS, primarily in serotonergic terminal areas. High densities are found in several brain structures, including prefrontal, parietal, and somatosensory cortex, as well as in blood platelets and smooth muscle cells. Many antipsychotic drugs inhibit 5HT_{2A} receptors.
- The 5HT_{2C} receptor is the only GPCR that is regulated by RNA editing. Multiple 5HT_{2C} receptor isoforms are generated by RNA editing; extensively edited isoforms have modified G protein-coupling efficiencies (Burns et al., 1997). The 5HT_{2C} receptor has been implicated in the control of CSF production and in feeding behavior and mood.

5HT₃ Receptors

- The 5HT₃ receptor is the only monoamine neurotransmitter receptor that functions as a ligand-gated ion channel.
- The functional 5HT₃ receptor forms pentameric complexes consisting of three distinct subunits; activation of these ligand-gated channels elicits a rapidly desensitizing depolarization, mediated by the gating of cations.
- The 5HT₃ receptors are located on parasympathetic terminals in the GI tract, including vagal and splanchnic afferents. In the CNS, a high density of 5HT₃ receptors occurs in the solitary tract nucleus and the area postrema. 5HT₃ receptors in both the GI tract and the CNS participate in the emetic response, providing a basis for the antiemetic property of the FDA-approved 5HT₃ receptor antagonists, including ondansetron and dolasetron.

5HT₄ Receptors

- The 5HT₄ receptor subtype couples to G_s to activate AC and increase cAMP production.
- In the CNS, 5HT₄ receptors are found on neurons of the superior and inferior colliculi and in the hippocampus. In the GI tract, 5HT₄ receptors are located on neurons of the myenteric plexus and on smooth muscle and secretory cells. Stimulation of the 5HT₄ receptor is thought to evoke secretion and to facilitate the peristaltic reflex. The latter effect may explain the utility of prokinetic benzamides in GI disorders (see Chapter 50).
- Effects of pharmacological manipulation of 5HT₄ receptors on memory and feeding in animal models suggest possible clinical applications in the future.

5HT₅ Receptors

- The 5HT₅ subfamily couples to G_{i/o} to inhibit AC.
- Humans only express a functional 5HT_{5A} receptor, while rodents express both 5HT_{5A} and 5HT_{5B} receptors. The human 5HT_{5B} gene is interrupted by a stop codon leading to a nonfunctional protein product.
- The 5HT_{5A} receptor is expressed widely in the CNS, and its function is linked to circadian rhythms and cognition.

5HT₆ Receptors

- The 5HT₆ receptors couple to G_s to activate AC and increase intracellular cAMP.
- The 5HT₆ receptor is almost exclusively found in the CNS; its abundance in cortical, limbic, and extrapyramidal regions suggests that it is important for motor control and cognition.
- Recent studies have focused on 5HT₆ receptor agonists as a therapeutic modality for cognitive decline in patients with Alzheimer disease.

Figure 13–3 Serotonergic pathways in the brain. Serotonin is produced by several discrete brainstem nuclei, shown here in rostral and caudal clusters. The rostral nuclei, which include the nucleus, dorsal raphe, medial raphe, and raphe pontis, innervate most of the brain, including the cerebellum. The caudal nuclei, which comprise the raphe magnus, raphe pallidus, and raphe obscurus, have more limited projections that terminate in the cerebellum, brainstem, and spinal cord. Together, the rostral and caudal nuclei innervate most of the CNS. (Modified with permission from Nestler EJ et al., eds. *Molecular Neuropharmacology*. McGraw-Hill, New York, 2015.)

5HT₇ Receptors

- The 5HT₇ receptor couples to G_s to activate AC and increase intracellular cAMP. It is widely distributed throughout the CNS.
- Blockade of the 5HT₇ receptor has recently been investigated as a putative therapeutic mechanism to treat depression. 5HT₇ receptors may also play a role in the relaxation of smooth muscle in the GI tract and the vasculature.

The 5HT Transporter

- The actions of 5HT are primarily terminated by SERT, the transport protein responsible for the reuptake of 5HT into serotonergic neurons.
- Encoded by a single gene, SERT possesses 12 membrane-spanning domains and is a member of the NSS family that includes the carriers for DA, NE, GABA, and glycine. SERT is expressed prominently in central serotonin neurons that originate in the raphe nucleus, but is also found in platelets, placenta, lung, gut, enteric nervous system, and adrenal gland.
- SERT couples the transport of serotonin to the movement of Na⁺ into the cell.
- SSRIs such as fluoxetine, paroxetine, citalopram, and sertraline bind to the SERT and inhibit serotonin transport. TCAs and a newer class of SNRIs that includes venlafaxine and duloxetine, block SERT, the NE transporter, or both with varying degrees of selectivity.
- SSRIs and SNRIs are prescribed for major depressive disorder, obsessive-compulsive disorder, panic disorder, generalized anxiety disorder, fibromyalgia and neuropathic pain.

Actions of 5HT in Physiological Systems

Platelets

Platelets differ from other formed elements of blood in expressing mechanisms for uptake, storage, and exocytotic release of 5HT. 5HT is not synthesized in platelets but is taken up from the circulation and stored in secretory granules by active transport, similar to the uptake and storage of serotonin by serotonergic nerve terminals. When platelets make contact with injured endothelium (see Chapter 32), they release substances that promote platelet aggregation; secondarily, they release 5HT (see Figure 13–6). 5HT binds to platelet 5HT_{2A} receptors and elicits

a weak aggregation response that is markedly augmented by the presence of collagen. If the damaged blood vessel is injured to a depth where vascular smooth muscle is exposed, 5HT exerts a direct vasoconstrictor effect, thereby contributing to hemostasis, which is enhanced by locally released autocooids (thromboxane A₂ [TxA₂], kinins, and vasoactive peptides). Conversely, 5HT may interact with endothelial cells to stimulate production of NO and antagonize its own vasoconstrictor action, as well as the vasoconstriction produced by other locally released agents.

Cardiovascular System

The classical response of blood vessels to 5HT is contraction, particularly in the splanchnic, renal, pulmonary, and cerebral vasculatures. 5HT also induces a variety of responses in the heart that are the result of activation of multiple 5HT receptor subtypes, stimulation or inhibition of autonomic nerve activity, or dominance of reflex responses to 5HT. Thus, 5HT has positive inotropic and chronotropic actions on the heart that may be blunted by simultaneous stimulation of afferent nerves from baroreceptors and chemoreceptors. Activation of 5HT₃ receptors on vagus nerve endings elicits the Bezold-Jarisch reflex, causing extreme bradycardia and hypotension. The local response of arterial blood vessels to 5HT also may be inhibitory, the result of the stimulation of endothelial NO production and prostaglandin synthesis and blockade of NE release from sympathetic nerves. Conversely, 5HT amplifies the local constrictor actions of NE, angII, and histamine, which reinforce the hemostatic response to 5HT.

Gastrointestinal Tract

Enterochromaffin cells in the gastric mucosa are the site of the synthesis and most of the storage of 5HT in the body and are the source of circulating 5HT. Motility of gastric and intestinal smooth muscle may be either enhanced or inhibited via signaling mediated by at least five subtypes of 5HT receptors (Table 13–2).

Mechanical stretching augments basal release of enteric 5HT, such as that caused by food and by efferent vagal stimulation. Released 5HT enters the portal vein and is metabolized by hepatic MAO-A. 5HT that survives hepatic oxidation may be captured by platelets or rapidly removed by the endothelium of lung capillaries and inactivated. 5HT released from enterochromaffin cells also acts locally to regulate GI function. 5HT₃ receptors in the GI tract and the CNS participate in the emetic response, providing a basis for the antiemetic property of 5HT₃ receptor antagonists (see Figure 50–5 and Table 50–6). A large series of selective 5HT₃ receptor

Figure 13-4 A serotonergic synapse. Presynaptic and postsynaptic molecular entities involved in the synthesis, release, signaling, and reuptake of serotonin are shown. MAO is shown extracellularly and in mitochondria within serotonergic nerve terminals.

antagonists, the “setrons,” including ondansetron, dolasetron, granisetron, and palonosetron, are used in the treatment of various GI disturbances. All 5HT₃ receptor antagonists are highly efficacious in the treatment of nausea, and alosetron and cilansetron are licensed for treating irritable bowel syndrome.

Inflammation

Acting via the 5HT_{2A} receptor, 5HT exerts a pro-inflammatory influence in acute inflammatory states, including models of airway inflammation and asthma (Nau et al., 2015). These preclinical findings agree with reports of higher expression of 5HT_{2A} receptors in peripheral blood mononuclear cells in patients with a history of asthma as compared to healthy volunteers (Ahangari et al., 2015). This research builds on several decades of analysis linking levels of plasma 5HT to incidents of asthma in human patients (Lechin et al., 2002). While this correlation between the 5HT_{2A} receptor and human inflammatory disease is still preliminary, the findings are compelling and merit additional investigation into the untapped role of 5HT and the 5HT_{2A} receptor in airway inflammation.

CNS

All 5HT receptor subtypes are expressed in the brain, where 5HT influences a multitude of functions, including sleep, cognition, sensory perception, motor activity, temperature regulation, nociception, mood, appetite, sexual behavior, and hormone secretion. The principal cell bodies of 5HT neurons are located in raphe nuclei of the brainstem and project throughout the brain and spinal cord (Figure 13-3). In addition to release at discrete synapses, serotonin release seems to occur at sites of axonal varicosities that do not form distinct synaptic contacts. 5HT released at nonsynaptic varicosities is thought to diffuse to outlying targets, rather than acting on discrete synaptic targets, perhaps acting as a neuromodulator as well as a neurotransmitter (see Chapter 14).

Sleep-Wake Cycle

Control of the sleep-wake cycle is one of the first behaviors in which a role for 5HT was identified. Depletion of 5HT with *p*-chlorophenylalanine, a tryptophan hydroxylase inhibitor, elicits insomnia that is reversed by

TABLE 13-1 ■ SEROTONIN RECEPTOR SUBTYPES^a

^aFor further information on the pharmacological properties of the 5HT subtypes, see IUPHAR/BPS Guide to Pharmacology: <http://www.guidetopharmacology.org/index.jsp>. Abbreviations: 5-CT, 5-carboxamino-tryptamine; DOI, 1-(2,5-dimethoxy-4-iodophenyl) isopropylamine; 8-OH-DPAT, 8-hydroxy-(2-N,N-dipropylamino)-tetraline; MCPP, metachlorophenylpiperazine; others are manufacturers' designations.

the 5HT precursor, 5-hydroxytryptophan. Conversely, treatment with L-tryptophan or with nonselective 5HT agonists accelerates sleep onset and prolongs total sleep time. 5HT antagonists reportedly can increase and decrease slow-wave sleep, probably reflecting interacting or opposing roles for subtypes of 5HT receptors. One relatively consistent finding in humans and in laboratory animals is an increase in slow-wave sleep

following administration of a selective 5HT_{2A/2C} receptor antagonist such as ritanserin.

Aggression and Impulsivity

Serotonin serves a critical role in aggression and impulsivity. Human studies reveal a correlation between low CSF 5-HIAA and violent impulsivity and aggression. Gene knockout mice lacking the 5HT_{1B} receptor exhibit extreme aggression, suggesting either a role for 5HT_{1B} receptors in the development of neuronal pathways important in aggression or a direct role in the mediation of aggressive behavior. A human genetic study identified a point mutation in the gene encoding MAO-A that was associated with extreme aggressiveness and mental retardation (Brunner et al., 1993); this has been confirmed in knockout mice lacking MAO-A (Cases et al., 1995).

Appetite and Obesity

Lorcaserin is a 5HT_{2C} receptor agonist approved for weight loss. The drug is thought to decrease food consumption and promote satiety by selectively activating 5HT_{2C} receptors on anorexigenic proopiomelanocortin neurons in the arcuate nucleus of the hypothalamus. Halogenated amphetamines, which are known to promote the release of 5HT and block its reuptake, are valuable experimental tools; two of them, fenfluramine and dexfenfluramine, were used clinically to reduce appetite; the once-popular diet drug regimen, “fen-phen,” combined fenfluramine and phentermine. Fenfluramine and dexfenfluramine were withdrawn from the U.S. market in the late 1990s after reports of life-threatening heart valve disease and pulmonary hypertension associated with their use. This toxicity was the result of 5HT_{2B} receptor activation (Hutcheson et al., 2011).

Figure 13-5 Two classes of 5HT autoreceptors with differential localizations. Somatodendritic 5HT_{1A} autoreceptors decrease raphe cell firing when activated by 5HT released from axon collaterals of the same or adjacent neurons. The receptor subtype of the presynaptic autoreceptor on axon terminals in the forebrain has different pharmacological properties and has been classified as 5HT_{1D} (in humans) or 5HT_{1B} (in rodents). This receptor modulates the release of 5HT. Postsynaptic 5HT₁ receptors are also indicated.

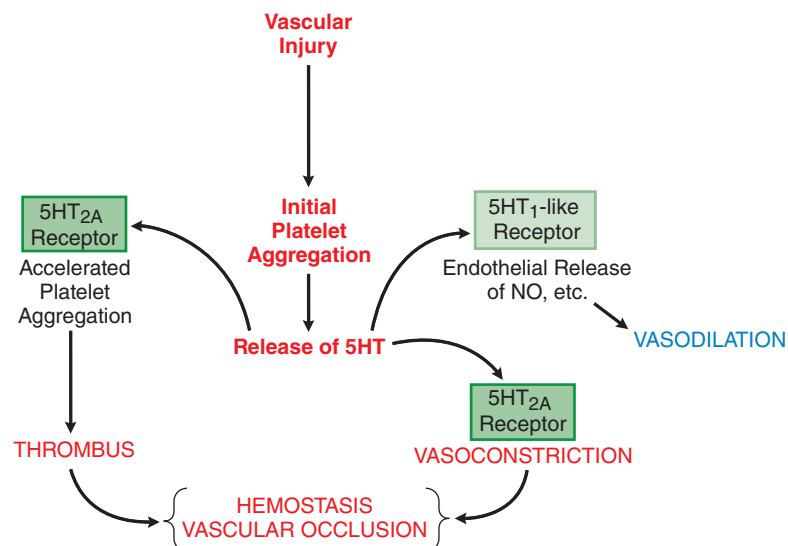

Figure 13–6 The local influences of platelet 5HT. The release of 5HT stored in platelets is triggered by aggregation. The local actions of 5HT include feedback actions on platelets (shape change and accelerated aggregation) mediated by interaction with platelet 5HT_{2A} receptors, stimulation of NO production mediated by 5HT₁-like receptors on vascular endothelium, and contraction of vascular smooth muscle mediated by 5HT_{2A} receptors. These influences act in concert with many other mediators to promote thrombus formation and hemostasis. See Chapter 32 for details of adhesion and aggregation of platelets and factors contributing to thrombus formation and blood clotting.

Drugs Affecting 5HT Signaling

Direct-acting 5HT receptor agonists have widely different chemical structures and diverse pharmacological properties and are used in the pharmacotherapy of a number of disorders (Table 13–3), including anxiety, depression, nausea, disorders of GI motility, and migraine. 5HT is a key mediator in the pathogenesis of migraine. Consistent with the 5HT hypothesis of migraine, 5HT receptor agonists are a mainstay for acute treatment of migraine headaches. The efficacy of antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and as yet undefined environmental and genetic factors.

TABLE 13–2 ■ ACTIONS OF 5HT IN THE GASTROINTESTINAL TRACT

SITE	RESPONSE	RECEPTOR
Enterochromaffin cells	Release of 5HT	5HT ₃
	Inhibition of 5HT release	5HT ₄
Enteric ganglion cells (presynaptic)	Release of ACh	5HT ₄
	Inhibition of ACh release	5HT _{1P} ^a
		5HT _{1A}
Enteric ganglion cells (postsynaptic)	Fast depolarization	5HT ₃
	Slow depolarization	5HT _{1P} ^a
Smooth muscle, intestinal	Contraction	5HT _{2A}
Smooth muscle, stomach fundus	Contraction	5HT _{2B}
Smooth muscle, esophagus	Contraction	5HT ₄

^a5HT_{1P} is an operationally defined serotonergic response in the gut that does not correspond to any known monoamine receptor subtype. 5HT and certain 5HT derivatives are potent and selective agonists. The 5HT_{1P} response may be due to receptor heteromerization resulting in a novel pharmacology.

5HT_{1B/1D} Receptor Agonists: The Triptans

The triptans are indole derivatives that are effective, acute antimigraine agents. Their capacity to decrease the nausea and vomiting of migraine is an important advance in the treatment of the condition. Available compounds include almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, sumatriptan, and zolmitriptan. Sumatriptan for migraine headaches is also marketed in a fixed-dose combination with naproxen. The triptans are effective in the acute treatment of migraine (with or without aura) but are not intended for use in prophylaxis of migraine. Treatment with triptans should begin as soon as possible after onset of a migraine attack. Oral dosage forms of the triptans are the most convenient to use, but they may not be practical in patients experiencing migraine-associated nausea and vomiting.

Sumatriptan

Serotonin

Migraine

Migraine headache afflicts 10%–20% of the population. Although migraine is a specific neurological syndrome, the manifestations vary widely. The principal types are migraine without aura (common migraine); migraine with aura (classic migraine, which includes subclasses of migraine with typical aura, migraine with prolonged aura, migraine aura without headache, and migraine with acute-onset aura), and several rarer types. Premonitory aura may begin as long as 24 h before the onset of pain and often is accompanied by photophobia, hyperacusis, polyuria, and diarrhea and by disturbances of mood and appetite. A migraine attack may last for hours or days and be followed by prolonged pain-free

TABLE 13-3 ■ SEROTONERGIC DRUGS: PRIMARY ACTIONS AND CLINICAL INDICATIONS

RECEPTOR	ACTION	DRUG EXAMPLES	CLINICAL DISORDER
5HT _{1A}	Partial agonist	Buspirone, ipsapirone	Anxiety, depression
5HT _{1D}	Agonist	Sumatriptan	Migraine
5HT _{2A/2C}	Antagonist	Methysergide, risperidone, ketanserin	Migraine, depression, schizophrenia
5HT ₃	Antagonist	Ondansetron	Chemotherapy-induced emesis
5HT ₄	Agonist	Cisapride	GI disorders
SERT (5HT transporter)	Inhibitor	Fluoxetine, sertraline	Depression, obsessive-compulsive disorder, panic disorder, social phobia, posttraumatic stress disorder

intervals. The frequency of migraine attacks is extremely variable. Therapy of migraine headaches is complicated by the variable responses among and within individual patients and by the lack of a firm understanding of the pathophysiology of the syndrome. The efficacy of antimigraine drugs varies with the absence or presence of aura, duration of the headache, its severity and intensity, and possibly undefined environmental and genetic factors.

The pathogenesis of migraine headache is complex, involving both neural and vascular elements. Evidence suggesting that 5HT is a key mediator in the pathogenesis of migraine includes the following:

- Plasma and platelet concentrations of 5HT vary with the different phases of the migraine attack.
- Urinary concentrations of 5HT and its metabolites are elevated during most migraine attacks.
- Migraine may be precipitated by agents (e.g., reserpine and fenfluramine) that release 5HT from intracellular storage sites.

Consistent with the 5HT hypothesis, 5HT receptor agonists have become a mainstay for *acute* treatment of migraine headaches. Treatments for the *prevention* of migraines, such as β adrenergic antagonists and newer antiepileptic drugs, have mechanisms of action that are, presumably, unrelated to 5HT (Mehrotra et al., 2008).

Mechanism of Action

The pharmacological effects of the triptans appear to be limited to the 5HT₁ family of receptors, providing evidence that this receptor subclass plays an important role in the acute relief of a migraine attack. The triptans interact potently with 5HT_{1B} and 5HT_{1D} receptors and have a low or no affinity for other subtypes of 5HT receptors or for α_1 and α_2 adrenergic, β adrenergic, dopaminergic, muscarinic cholinergic, and benzodiazepine receptors. Clinically effective doses of the triptans correlate well with their affinities for both 5HT_{1B} and 5HT_{1D} receptors, supporting the hypothesis that 5HT_{1B} and 5HT_{1D} receptors are the most likely receptors involved in the mechanism of action of acute antimigraine drugs.

The mechanism of the efficacy of 5HT_{1B/1D} agonists in migraine is not resolved. One hypothesis of migraine suggests that unknown events lead to the abnormal dilation of carotid arteriovenous anastomoses in the head and shunting of carotid arterial blood flow, producing cerebral ischemia and hypoxia perceived as migraine pain; activation of 5HT_{1B/1D} receptors may cause constriction of intracranial blood vessels, including arteriovenous anastomoses, closing the shunts and restoring blood flow to the brain. An alternative hypothesis proposes that both 5HT_{1B} and 5HT_{1D} receptors serve as presynaptic autoreceptors that block the release of neurotransmitter or pro-inflammatory neuropeptides at nerve terminals in the perivascular space, which could account for the efficacy of agonists at those receptors in the acute treatment of migraine.

ADME

When given subcutaneously, sumatriptan reaches its peak plasma concentration in about 12 min, and an autoinjector with 6 mg of sumatriptan

is available. Following oral administration of a tablet, sumatriptan has a bioavailability of about 15% and reaches a peak plasma concentration within 1–2 h; oral disintegrating tablets take advantage of sublingual absorption and produce more rapid effects; a nasal spray formulation of sumatriptan has an onset of action of about 15 min. A sumatriptan-naproxen combination tablet is available. An iontophoretic transdermal sumatriptan patch was recently withdrawn from the market. The other, newer triptans (see Drug Facts table) have higher oral bioavailabilities, and reach C_{max} values within 1–3 h after ingestion of a tablet. The agents differ in their affinities for the 5HT_{1B} and 5HT_{1D} receptors, their half-lives and metabolic routes (usually CYP3A4 or MAO-A), and their reliance on the kidney for excretion. These differences, detailed in the Drug Facts table at the end of this chapter, define the likely drug interactions and precautions with age and reduced hepatic and renal function.

Clinical Use

The triptans are effective in the acute treatment of migraine (with or without aura) but are not intended for prophylaxis of migraine. Treatment with triptans should begin as soon as possible after onset of a migraine attack. Oral dosage forms of the triptans are the most convenient to use but may not be practical in patients experiencing migraine-associated nausea and vomiting, for whom injectable and nasal spray formulations are useful. Approximately 70% of individuals report significant headache relief from a 6-mg subcutaneous dose of sumatriptan, a dose that may be repeated once within a 24-h period if the first dose does not relieve the headache. The recommended oral dose of sumatriptan is 25–100 mg, repeatable after 2 h up to a total dose of 200 mg over a 24-h period. When administered by nasal spray, from 5 to 20 mg of sumatriptan is recommended, repeatable after 2 h up to a maximum dose of 40 mg over a 24-h period. The other triptans have distinct dosing requirements as summarized on their FDA-approved package inserts. A recent meta-analysis concluded that eletriptan is the most likely triptan to produce a favorable outcome at the 2-h and 24-h times after administration (Thorlund et al., 2014). The safety of treating more than three or four headaches over a 30-day period with triptans has not been established. No triptan should be used concurrently with (or within 24 h of) an ergot derivative (described in the next section) or another triptan.

Adverse Effects and Contraindications

In general, only minor side effects are seen with the triptans in the acute treatment of migraine. After subcutaneous injection of sumatriptan, patients often experience irritation at the site of injection (transient mild pain, stinging, or burning sensations). The most common side effect of sumatriptan nasal spray is a bitter taste. Triptans can cause paresthesias; asthenia and fatigue; flushing; feelings of pressure, tightness, or pain in the chest, neck, and jaw; drowsiness; dizziness; nausea; and sweating. In the extreme, these agents can cause serotonin syndrome, a consequence of a generalized excess of 5HT at 5HT receptors, especially when used in combination with SSRIs, SNRIs, TCAs, and MAO inhibitors.

Rare but serious cardiac events have been associated with the administration of 5HT₁ agonists, including coronary artery vasospasm, transient myocardial ischemia, atrial and ventricular arrhythmias, and myocardial infarction, predominantly in patients with risk factors for coronary artery disease. The triptans are contraindicated in patients with a history of ischemic or vasospastic coronary artery disease (including history of stroke or transient ischemic attacks), cerebrovascular or peripheral vascular disease, hemiplegic or basilar migraines, other significant cardiovascular diseases, or ischemic bowel diseases. Because triptans may cause an acute, usually small, increase in blood pressure, they also are contraindicated in patients with uncontrolled hypertension. Naratriptan is contraindicated in patients with severe renal or hepatic impairment; rizatriptan should be used with caution in such patients. Eletriptan is contraindicated in hepatic disease. Almotriptan, rizatriptan, sumatriptan, and zolmitriptan are contraindicated in patients who have taken a MAO inhibitor within the preceding 2 weeks, and all triptans are contraindicated in patients with near-term prior exposure to ergot alkaloids, other triptans or 5HT agonists, SSRIs, and SNRIs. The triptans are classified as *pregnancy category C* (i.e., there are no adequate and well-controlled studies in pregnant women; use during pregnancy only if the potential benefit justifies a potential risk to the fetus) and should also be used with caution in nursing mothers; evidence of safety in pregnancy is best with sumatriptan. Källén and Reis (2016) have reviewed drugs for managing pain, including migraine, during pregnancy.

The Ergot Alkaloids

Ergot is the product of a fungus (*Claviceps purpurea*) that grows on rye and other grains. The elucidation of the constituents of ergot and their complex actions was an important chapter in the evolution of modern

pharmacology, even though the very complexity of their actions limits their therapeutic uses. The pharmacological effects of the ergot alkaloids are varied and complex; in general, the effects result from their actions as partial agonists or antagonists at serotonergic, dopaminergic, and adrenergic receptors. All ergot alkaloids can all be considered to be derivatives of the tetracyclic compound 6-methylethylergoline (Table 13–4).

The natural alkaloids of therapeutic interest are amide derivatives of *d*-lysergic acid. Numerous semisynthetic derivatives of the ergot alkaloids have been prepared by catalytic hydrogenation of the natural alkaloids (e.g., dihydroergotamine). The synthetic derivative, bromocriptine (2-bromo- α -ergocryptine), is used to control the secretion of prolactin, a property derived from its DA agonist effect. Other products of this series include LSD, a potent hallucinogen, and methysergide, a serotonin antagonist. LSD interacts with most brain 5HT receptors as an agonist/partial agonist and elicits sensory distortions (especially visual) and hallucinations at doses as low as 1 μ g/kg. Current hypotheses of the mechanism of action of LSD and other hallucinogens focus on 5HT_{2A} receptor-mediated disruption of thalamic gating with sensory overload of the cortex (Nichols, 2016). Of note, positron emission tomography imaging studies revealed that administration of the hallucinogen psilocybin (the active component of “shrooms”) mimics the pattern of brain activation found in schizophrenic patients experiencing hallucinations. This action of psilocybin is blocked by pretreatment with a 5HT_{2A/2C} antagonist. These and other studies have suggested that stimulation of the 5HT_{2A} receptor can lead to hallucinations (Nichols, 2016).

Ergots in the Treatment of Migraine

The multiple pharmacological effects of ergot alkaloids have complicated the determination of their precise mechanism of action in the acute treatment of migraine. The actions of ergot alkaloids at 5HT_{1B/1D} receptors

likely mediate their *acute* antimigraine effects. The use of ergot alkaloids for migraine should be restricted to patients having frequent, moderate migraine or infrequent, severe migraine attacks. Ergot preparations should be administered as soon as possible after the onset of a headache. GI absorption of ergot alkaloids is erratic, perhaps contributing to the large variation in patient response to these drugs. Methysergide (1-methyl-*d*-lysergic acid butanolamide) is an ergot derivative but has very weak vasoconstrictor and oxytocic activity. It interacts with 5HT₁ receptors, but its therapeutic effects appear primarily to reflect blockade of 5HT_{2A} and 5HT_{2C} receptors. Methysergide is used for the prophylactic treatment of migraine and other vascular headaches. A potentially serious complication of prolonged treatment is inflammatory fibrosis, giving rise to various syndromes that include pleuropulmonary fibrosis and coronary and endocardial fibrosis. Usually, the fibrosis regresses after drug withdrawal, although persistent cardiac valvular damage has been reported.

Use of Ergot Alkaloids in Postpartum Hemorrhage

All of the natural ergot alkaloids markedly increase the motor activity of the uterus; however, ergonovine and its semisynthetic derivative methylergonovine have primarily been used as uterine-stimulating agents in obstetrics. As the dose is increased, contractions become more forceful and prolonged, resting tone is dramatically increased, and sustained contracture can result. This characteristic is compatible with their use postpartum or after abortion to control bleeding and maintain uterine contraction. Oxytocin (see Chapter 44) is now the more prevalent agent in controlling postpartum hemorrhage.

Serotonin Receptor Partial Agonists, SSRIs, and MSAAs

Anxiolytic and Antidepressant Agents

Buspirone, gepirone, and ipsapirone are selective partial agonists at 5HT_{1A} receptors. Buspirone has been effective in the treatment of anxiety (see Chapter 15). Buspirone mimics the anxiolytic properties of benzodiazepines but does not interact with GABA_A receptors or display the sedative and anticonvulsant properties of benzodiazepines. The effects of 5HT-active drugs in anxiety and depressive disorders, like the effects of SSRIs, strongly suggest a role for 5HT in the neurochemical mediation of these disorders. Inhibition of neuronal reuptake of 5HT via the 5HT transporter prolongs the dwell time of 5HT in the synapse. SSRIs, such as fluoxetine, potentiate and prolong the action of 5HT released by neuronal activity. When coadministered with L-5-hydroxytryptophan, SSRIs elicit profound activation of serotonergic responses. However, the capacity to enhance serotonergic neurotransmission alone does not explain the antidepressant effectiveness: Uptake inhibition occurs immediately, whereas weeks of treatment are required to achieve clinical efficacy. This has led to the proposal that long-term homeostatic adaptations in brain function underlie the therapeutic effects of this class of antidepressants. SSRIs (citalopram, escitalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline) are the most widely used treatment of major depressive disorder (see Chapter 15). Vilazodone is an SSRI and a partial agonist at the 5HT_{1A} receptor; it is FDA approved in adults for treatment of depression.

5HT and Sexual Dysfunction

One of the most common side effects of SSRIs and SNRIs is sexual dysfunction, such as anorgasmia, erectile dysfunction, diminished libido, and sexual anhedonia. Poor sexual function is one of the most common reasons that patients discontinue taking these medications. The mechanism by which SSRIs/SNRIs cause sexual side effects is not well understood. In contrast, the serotonergic drug flibanserin has recently been approved to treat hypoactive sexual desire disorder (HSDD) in premenopausal women. This disorder is also referred to as female sexual interest/arousal disorder (FSIAD). Flibanserin can increase the number of satisfying sexual events in some, but not all, women with this disorder. Flibanserin is a potent agonist of the 5HT_{1A} receptor and a moderately potent antagonist of the 5HT₂ receptor subfamily; the drug is classified as a MSAA. Flibanserin is also a weak blocker of the D₄ DA receptor. Administration of flibanserin can decrease 5HT levels in the cortex while increasing DA and NE levels.

This redistribution of monoamine levels has been speculated to be the mechanism of the observed response of increased sexual function.

Clinical Manipulation of 5HT Levels: Serotonin Syndrome

Excessive elevation of 5HT levels in the body can cause *serotonin syndrome*, a constellation of symptoms sometimes observed in patients starting new or increased antidepressant therapy or combining an SSRI with an NE reuptake inhibitor or a triptan (for migraine). Symptoms may include restlessness, confusion, shivering, tachycardia, diarrhea, muscle twitches/rigidity, fever, seizures, loss of consciousness, and even death. Serotonin syndrome and its treatment are discussed in Chapter 15.

Dopamine

Dopamine consists of a catechol moiety linked to an ethyl amine, leading to its classification as a catecholamine (Figure 13–7). DA is a polar molecule that does not readily cross the BBB. It is closely related to melanin, a pigment that is formed by oxidation of DA, tyrosine, or L-dopa. Melanin exists in the skin and cuticle and gives the substantia nigra brain region its namesake dark color. Both DA and L-dopa are readily oxidized by nonenzymatic pathways to form cytotoxic reactive oxygen species and quinones. DA- and dopa-quinones form adducts with α -synuclein, a major constituent of Lewy bodies in PD (Chapter 22).

HISTORICAL PERSPECTIVE

Dopamine was first synthesized in 1910. Later that year, Henry Dale characterized the biological properties of DA in the periphery and described it as a weak, adrenaline-like substance. In the 1930s, DA was recognized as a transitional compound in the synthesis of NE and EPI but was believed to be little more than a biosynthetic intermediate. Not until the early 1950s were stores of DA identified in tissues, suggesting that DA had a signaling function of its own. Soon thereafter, Hornykiewicz discovered the DA deficit in Parkinsonian brains, fueling interest in the role of DA in neurological diseases and disorders (Hornykiewicz, 2002).

Synthesis and Metabolism

The biosynthesis and metabolism of DA are summarized in Figure 13–8. Phenylalanine and tyrosine are the precursors of DA. For the most part, mammals convert dietary phenylalanine to tyrosine by phenylalanine hydroxylase. Diminished levels of phenylalanine hydroxylase lead to high levels of phenylalanine, producing a condition known as phenylketonuria, which must be controlled by dietary restrictions to avoid intellectual impairment. Tyrosine crosses readily into the brain through uptake; normal brain levels of tyrosine are typically saturating. Conversion of tyrosine to L-dopa by the tyrosine hydroxylase is the rate-limiting step in the synthesis of DA (as in NE synthesis; see Chapter 8). Once generated, L-dopa is rapidly converted to DA by AADC, the same enzyme that generates 5HT from L-5-hydroxytryptophan. Unlike DA, L-dopa readily crosses the BBB and is converted to DA in the brain, which explains its utility in therapy for PD (see Chapter 18).

Metabolism of DA occurs primarily by MAO in both pre- and postsynaptic elements. MAO acts on DA to generate an inactive aldehyde derivative by oxidative deamination; the aldehyde is subsequently metabolized by

Figure 13–7 The catechol nucleus of catecholamines.

Figure 13–8 Synthesis and inactivation of DA. Enzymes are identified in blue lettering, and cofactors are shown in black letters.

aldehyde dehydrogenase to form DOPAC. DOPAC can be further metabolized by COMT to form HVA. In humans, HVA is the principal metabolite of DA. DOPAC, HVA, and DA are excreted in the urine, where they are readily measured. Levels of DOPAC and HVA are reliable indicators of DA turnover; ratios of these metabolites to DA in CSF serve as accurate representations of brain dopaminergic activity. In addition to metabolizing DOPAC, COMT acts on DA to generate 3-methoxytyramine, which is subsequently converted to HVA by MAO. MAO_B-selective inhibitors, such as selegiline and rasagiline, can increase DA levels and are currently used to treat PD (see Chapter 18). COMT in the periphery also metabolizes L-dopa to 3-O-methyldopa, which then competes with L-dopa for uptake into the CNS (see Figure 18–4). Consequently, L-dopa given in the

treatment of PD must be coadministered with peripheral COMT inhibitors, such as entacapone and tolcapone, to preserve L-dopa and allow sufficient entry into the CNS.

Figure 13–9 summarizes the neurochemical events that underlie DA neurotransmission. In dopaminergic neurons, synthesized DA is packaged into secretory vesicles by VMAT2. Drugs such as reserpine, which inhibit VMAT and deplete DA levels, were once used to treat psychosis. This packaging allows DA to be stored in readily releasable quanta and protects the transmitter from further anabolism or catabolism. By contrast, in adrenergic and noradrenergic cells, DA is not packaged; instead, it is converted to NE by DA β -hydroxylase and, in adrenergic cells, methylated to EPI in cells expressing phenylethanolamine *N*-methyltransferase (Chapter 8).

Synaptically released DA activates postsynaptic receptor subtypes, the expression of which is cell specific, leading to signal transduction via G protein-mediated pathways, although in some cases G protein-independent signaling is possible (see further discussion). DA receptor subtypes are also the targets of many therapeutically employed drugs and pharmacological tool compounds. Specific receptor subtypes of the D₂-like category can also be expressed on the presynaptic nerve terminal, where they regulate the release of DA. Reuptake of released DA by the DA transporter is the primary mechanism for termination of DA action and allows for either vesicular repackaging of transmitter or metabolism.

The DA transporter, DAT, localizes to dendrites, axons, and soma of mesencephalic DA neurons and is also found peripherally in the stomach, pancreas, and lymphocytes. Psychostimulants, such as cocaine, amphetamine, and methamphetamine, induce euphoria and hyperactivity by increasing extracellular DA. Cocaine potentiates DA signaling by acting as a nontransported antagonist of the plasma membrane DAT. However, the actions of amphetamines are more complex; amphetamines are competitive substrates for both the DATs and the VMATs. Amphetamines enter the cell through the DAT, where they displace DA from vesicular stores, causing an accumulation of DA within the neuronal cytoplasm. This resulting increase in cytosolic DA drives the release of DA by a nonvesicular mechanism that involves efflux through the DAT (Sitte et al., 2015). Newer studies also support the idea that amphetamines have additional targets within DA neurons that activate cellular signaling pathways, including G_s-dependent pathways coupled to increases in cAMP and G_{12/13}-dependent pathways coupled to the activation of the small GTPase, RhoA (Wheeler et al., 2015). The trace amine-associated receptor TAAR1, a predominantly intracellular GPCR, is activated by amphetamines, DA, and a variety of drugs and trace amines and has been proposed to mediate some of the intracellular actions of amphetamines (Miller, 2011).

The DA transporter can also serve as a molecular entryway for some neurotoxins, including 6-OHDA and MPP⁺, the neurotoxic metabolite of MPTP. Following uptake into dopaminergic neurons, MPP⁺ and 6-OHDA facilitate intra- and extracellular DA release and generate reactive oxygen species such as superoxide radicals (O₂^{•−}) that cause neuronal death. This selective dopaminergic degeneration mimics PD and serves as an animal model for this disorder.

Dopamine Receptors

Early investigations found that DA increases cAMP levels in both the brain and retina, presumably by activating a DA-sensitive AC enzyme. Subsequent studies revealed the existence of DA receptors not linked to AC activation, suggesting multiple DA receptor subtypes. These were initially categorized as D₁ and D₂ receptors and could be distinguished on the basis of pharmacological properties and physiological function (Kebabian et al., 1979). Molecular biological studies have identified not only genes encoding the biochemically defined D₁ and D₂ receptor subtypes but also genes for additional DA receptors. We now recognize that there are five distinct DA receptors in mammals that are organized into two D₁-like and D₂-like subfamilies. The D₁-like subfamily consists of the D₁ and D₅ receptors; the D₂, D₃, and D₄ subtypes comprise the D₂-like subfamily. Receptors in the D₁-like subfamily (D₁ and D₅) couple to G_s or G_o proteins to activate AC and increase cAMP levels; the D₂-like receptors (D₂, D₃, and D₄) couple to G_i or G_o proteins, which inhibit AC and diminish

Figure 13–9 A dopaminergic synapse. Dopamine is synthesized from tyrosine in the nerve terminal by the sequential actions of TH and AADC. DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA transporter (DAT) or removed by postsynaptic uptake via OCT transporters. Cytosolic DA is subject to degradation by MAO/ALDH in the neuron, and by COMT in non-neuronal cells; the final metabolic product is HVA. See structures in Figure 13–8.

cyclic cAMP production. Activation of $G_{i/o}$ proteins can also directly modulate the activity of certain K^+ and Ca^{2+} channels (Figure 13–10). Signaling of D_2 receptors through β -arrestin-mediated pathways has also been postulated (see following discussion).

Pharmacological agents targeting DA receptors are used in the treatment of numerous neuropsychiatric disorders, including PD, schizophrenia, bipolar disorder, Huntington disease, ADHD, and Tourette syndrome. Like many GPCRs, DA receptors may form homo- and hetero-oligomers and also oligomerize with other GPCRs as well as ligand-gated ion channels (Fuxe et al., 2015). In most cases, the physiological significance of receptor oligomerization remains unclear. For recent in-depth reviews on DA receptor signaling, see the work of Beaulieu and Gainetdinov (2011) and Beaulieu et al. (2015).

The D_1 Receptor

- The D_1 receptor is the most highly expressed of the DA receptors; highest levels of D_1 receptor protein are found within the CNS, but it is also located in the kidney, retina, and cardiovascular system.
- The neostriatum expresses the highest levels of D_1 receptor in the CNS but does not express any detectable G_{α_s} . In this region, the D_1 receptor appears to couple to $G_{\alpha_{olf}}$ to increase levels of cAMP and its downstream effectors.

- The gene for the human D_1 receptor lacks introns.
- In addition to activating G proteins, the D_1 receptor can form hetero-oligomers with ionotropic NMDA glutamate receptors (Chapter 14) to modulate glutamatergic signaling.

The D_2 Receptor

- The D_2 receptor is the second most highly expressed DA receptor and consists of short (D_{2S}) and long (D_{2L}) isoforms that arise from alternative messenger RNA splicing. The D_{2S} isoform is missing 29 amino acids in the third intracellular loop that are present in the D_{2L} variant.
- The D_{2S} and D_{2L} receptors are pharmacologically identical; both couple to G_i or G_o to decrease cAMP production. The D_{2L} receptor is more prevalent and postulated to function postsynaptically. In contrast, the D_{2S} isoform functions as a putative presynaptic autoreceptor that regulates DA synthesis and release.
- The D_2 receptors can signal through $G_{\beta\gamma}$ subunits to regulate a variety of functions, including inwardly rectifying K^+ channels, N-type Ca^{2+} channels, and L-type Ca^{2+} channels.
- The D_2 receptor can signal through recruitment of the scaffolding protein, β -arrestin, thereby coupling to downstream signaling through the protein kinases PKB and GSK-3 (Beaulieu and Gainetdinov, 2011; Beaulieu et al., 2015).

Figure 13-10 The two subfamilies of DA receptors and their major signaling pathways.

The D_3 Receptor

- The D_3 receptor is less abundant than the D_2 receptor and is mainly expressed in the limbic regions of the brain. The highest levels of the D_3 receptor are found in the islands of Calleja, nucleus accumbens, substantia nigra pars compacta, and ventral tegmental area.
- The D_3 receptor signals through pertussis toxin-sensitive $G_{i/o}$ proteins, although not as effectively as the D_2 receptor.
- The D_3 receptor's tertiary structure has been determined by X-ray crystallography (Chien et al., 2010).

The D_4 Receptor

- The D_4 receptor is expressed in the retina, hypothalamus, PFC, amygdala, and hippocampus.
- The D_4 receptor is highly polymorphic, containing a VNTR encoding sequences within the third intracellular loop. In humans, the four-repeat variant is the most common. Association between a seven-repeat VNTR variant of the D_4 receptor and ADHD has been suggested.
- The D_4 receptor couples to $G_{i/o}$ to inhibit AC activity and depress intracellular cAMP levels.

The D_5 Receptor

- The D_5 receptor is most highly expressed in the hippocampus, but also is found in the substantia nigra, hypothalamus, striatum, cerebral cortex, nucleus accumbens, and olfactory tubercle.
- The D_5 receptor gene, like the D_1 receptor gene, is intronless.
- The D_5 receptor activates G_s and G_{olf} to increase cAMP production and can also modulate Na^+ currents and N -, P -, and L -type Ca^{2+} currents via PKA-dependent pathways. The D_5 receptor can also directly interact with $GABA_A$ receptors to decrease Cl^- flux.

The Dopamine Transporter

- DAT (SLC6A3) clears extracellular DA released during neurotransmission and is a major target for both therapeutic and addictive psychostimulant drugs.
- Like SERT, the DAT is a member of the Neurotransmitter Sodium Symporter (NSS) family (see *Transporters and Pharmacodynamics: Drug Action in the Brain*, in Chapter 5), which couples neurotransmitter transport across the plasma membrane to the movement of Na^+ ions into the cell.
- The DAT has 12 membrane-spanning domains; a recent high-resolution X-ray structure of a *Drosophila* DAT has been determined (Penmatsa et al., 2015).
- The DAT protein is abundantly expressed in mesostriatal, mesolimbic, and mesocortical DA pathways, where it can be found on cell bodies, dendrites, and axons of DA neurons (Ciliax et al., 1999).

However, the DAT is not readily detected within synapses, suggesting that rather than regulating synaptic neurotransmitter concentrations, it is poised to regulate spillover and diffusion of DA away from sites of release.

- The DAT is the therapeutic target of methylphenidate and amphetamine, the two major drugs used to treat attention-deficit disorders. The DAT inhibitor bupropion is used to treat depression and to support smoking cessation.

Actions of Dopamine in Physiological Systems

Heart and Vasculature

At low concentrations, circulating DA primarily stimulates vascular D_1 receptors (see discussion that follows), causing vasodilation and reducing cardiac load. The net result is a decrease in blood pressure and an increase in cardiac contractility. As circulating DA concentrations rise, DA is able to activate β adrenergic receptors to further increase cardiac contractility. At very high concentrations, circulating DA activates α adrenergic receptors in the vasculature, thereby causing vasoconstriction; thus, high concentrations of DA increase blood pressure. Clinically, DA administration is used to treat severe congestive heart failure, sepsis, or cardiogenic shock. It is only administered intravenously and is not considered a long-term treatment.

Kidney

Dopamine is a paracrine/autocrine transmitter in the kidney and binds to receptors of both the D_1 and D_2 subfamilies. Renal DA primarily serves to increase natriuresis, although it can also increase renal blood flow and glomerular filtration. Under basal sodium conditions, DA regulates Na^+ excretion by inhibiting the activity of various Na^+ transporters, including the apical Na^+-H^+ exchanger and the basolateral $Na^+,K^+-ATPase$. Activation of D_1 receptors increases renin secretion, whereas DA, acting on D_3 receptors, reduces renin secretion. Abnormalities in the DA system and its receptors have been implicated in human hypertension.

Pituitary Gland

Dopamine is the primary regulator of prolactin secretion from the pituitary gland. DA released from the hypothalamus into the hypophyseal portal blood supply acts on lactotroph D_2 receptors to decrease prolactin secretion (see Chapter 42). The ergot-based DA agonists bromocriptine and cabergoline are used in the treatment of hyperprolactinemia. Both have high affinity for D_2 receptors, with lower affinity for D_1 , 5HT, and adrenergic receptors; both activate D_2 receptors in the pituitary to reduce prolactin secretion. The risk of valvular heart disease in ergot therapy is not associated with the lower doses used in treating hyperprolactinemia. The use of bromocriptine and cabergoline in the management of hyperprolactinemia is described in Chapter 42.

Both D_1 and D_2 receptors modulate the release of NE and EPI. The D_2 receptor provides tonic inhibition of EPI release from chromaffin cells of the adrenal medulla and of NE release from sympathetic nerve terminals. In contrast, activation of the D_1 receptor promotes the release of catecholamines from the adrenal medulla.

CNS

There are three major groups of DA projections in the brain (Figure 13–11): mesocortico-mesolimbic (originating in the ventral tegmental area), nigrostriatal (originating in the substantia nigra pars compacta), and tuberoinfundibular (originating in the hypothalamus). The physiological processes under dopaminergic control include reward, emotion, cognition, memory, and motor activity. Dysregulation of the dopaminergic system is critical in a number of disease states, including PD, Tourette syndrome, bipolar depression, schizophrenia, ADHD, and addiction/substance abuse.

The mesolimbic pathway is associated with reward and, less so, with learned behaviors. Dysfunction in this pathway is associated with addiction, schizophrenia, and psychoses (including bipolar depression) and learning deficits. The mesocortical projections are important for “higher-order” cognitive functions, including motivation, reward, emotion, and impulse control; they are also implicated in psychoses, including schizophrenia, and in ADHD. The nigrostriatal pathway is a key regulator of movement (see Chapter 18). Impairments in this pathway are involved in PD and underlie detrimental motor side effects associated with dopaminergic therapy, including tardive dyskinesia. As noted previously, DA released in the tuberoinfundibular pathway is carried by the hypophyseal blood supply to the pituitary, where it regulates prolactin secretion.

Dopaminergic neurons are strongly influenced by excitatory glutamate and inhibitory GABA input. In general, glutamate inputs enable burst-like firing of dopaminergic neurons, resulting in high concentrations of synaptic DA. GABA inhibition of DA neurons causes a tonic, basal level of DA release into the synapse. DA release also modulates GABA and glutamate neurons, thus providing an additional level of interaction between DA and other neurotransmitters.

Figure 13–11 Major dopaminergic projections in the CNS.

- The nigrostriatal (or mesostriatal) pathway. Neurons in the substantia nigra compacta project to the dorsal striatum (*upward dashed blue arrows*); this is the pathway that degenerates in Parkinson disease.
- The mesocortico-mesolimbic pathway. Neurons in the ventral tegmental area project to the ventral striatum (nucleus accumbens), olfactory bulb, amygdala, hippocampus, orbital and medial prefrontal cortex, and cingulate gyrus (*solid blue arrows*).
- The tuberoinfundibular pathway. Neurons in the arcuate nucleus of the hypothalamus project by the tuberoinfundibular pathway in the hypothalamus, from which DA is delivered to the anterior pituitary (*red arrows*).

Motor Control and Parkinson Disease

In the early 1980s, several young people in California developed rapid-onset Parkinsonism. All of the affected individuals had injected a synthetic analogue of meperidine that was contaminated with MPTP. MPTP is metabolized by MAO-B to the neurotoxin MPP⁺. Because of the high specificity of MPP⁺ for the DA transporter, neuronal death is largely restricted to the substantia nigra and ventral tegmental area, resulting in a phenotype remarkably similar to PD. 6-OHDA is similar to MPTP in both mechanism of action and utility in animal models. Administration of MPTP or 6-OHDA to animals results in tremor, grossly diminished locomotor activity, and rigidity. As with PD, these motor deficits are alleviated with L-dopa therapy or dopaminergic agonists.

Other pharmacological agents that act on the DAT are known to potentiate locomotor activity via dopaminergic actions, including cocaine and amphetamine. The accumulation of extracellular DA increases stimulation of DA receptors and results in heightened locomotor activity. Mice lacking DAT are hyperactive and do not display increased locomotion in response to cocaine or amphetamine treatment.

Reward: Implications for Addiction

In general, drugs of abuse increase DA levels in the nucleus accumbens, an area critical for rewarded behaviors. This role for mesolimbic DA in addiction has led to numerous studies of abused drugs in DA receptor “knockout” mice in which the genes expressing specific receptors have been disrupted. Studies of D_1 receptor knockout mice showed a reduction in the rewarding properties of ethanol, suggesting that the rewarding and reinforcing properties of ethanol are dependent, at least in part, on the D_1 receptor. D_2 receptor knockout mice also display reduced preference for ethanol consumption. Morphine lacks rewarding properties in D_2 knockout mice when measured by conditioned place-preference or self-administration paradigms. However, mice lacking the D_2 receptor exhibit enhanced self-administration of high doses of cocaine. These data suggest a complex and drug-specific role for the D_2 receptor in rewarding and reinforcing behaviors. The D_3 receptor, highly expressed in the limbic system, has also been implicated in the rewarding properties of several drugs of abuse. However, D_3 knockout mice display drug-associated place preference similar to wild-type mice following amphetamine or morphine administration. Recently developed D_3 receptor-preferring ligands implicate a role for the D_3 receptor in motivation for drug seeking and in drug relapse, rather than in the direct reinforcing effects of the drugs (Heidbreder and Newman, 2010).

Cognition and Memory

Seminal work by Goldman-Rakic, Arnsten, and their colleagues (Vijayraghavan et al., 2007) showed that an optimum level of D_1 receptor activity in the PFC is required for optimum performance in learning and memory tasks. Either too little or too much D_1 receptor stimulation impairs PFC function in rats, monkeys, and humans. Thus, low doses of D_1 agonists improve working memory and attention, whereas high levels of DA release, such as during stress, impair PFC function. These observations have led to the “inverted U” hypothesis of the relationship between D_1 receptor stimulation and normal physiological functioning of the PFC (see Figure 4–2A). Interestingly, suboptimal levels of D_1 receptor stimulation have been suggested to underlie age-associated learning deficits and to contribute to the decreased cognition observed in various pathophysiological states, especially schizophrenia. Unsurprisingly, the D_1 receptor provides an attractive drug target for the treatment of a number of neuropsychiatric disorders.

Drugs Affecting Dopamine Signaling

Dopamine Receptor Agonists

Dopamine receptor agonists are mainly used in the treatment of PD, RLS, and hyperprolactinemia. One of the primary limitations to the therapeutic use of dopaminergic agonists is the lack of receptor subtype selectivity.

TABLE 13-5 ■ EXPERIMENTAL TOOLS AT DA RECEPTORS

RECEPTOR	AGONIST	ANTAGONIST
D ₁ -like ^a	SKF-81297 SKF-83959	SCH-23390 SCH-39166
D ₂ -like ^b	Quinpirole	Sulpiride
D ₂	Sumanirole	L-741626 ML321
D ₃	PD128907	SB-277011 SB-269652
D ₄	PD168077	L-745870

^aThese compounds are selective for D₁-like versus D₂-like receptors. There are no useful tool compounds that can differentiate D₁ from D₅ receptors.

^bThese compounds are selective for D₂-like versus D₁-like receptors.

Recent advances in receptor-ligand structure-function relationships have enabled the development of drugs that can distinguish between D₁-like and D₂-like receptor subfamilies and, in some cases, show a preference for individual receptor subtypes. Many of these compounds have already proven to be useful experimental tools (Table 13-5), and this remains an active area of research.

Parkinson Disease

Dopamine does not cross the BBB; thus, the principal pharmacotherapy for PD is to administer the precursor to DA, L-dopa, which crosses the BBB and is converted to DA in the brain. Commonly, L-dopa is formulated with a decarboxylase inhibitor to prevent the peripheral conversion of L-dopa to DA, which can result in adverse side effects. While the response to L-dopa by patients with PD is usually quite favorable, longer-term treatment can result in a loss of effectiveness and the emergence of dyskinetic syndromes referred to as L-dopa-induced dyskinesias. These limitations to the therapeutic effects of L-dopa have generated interest in developing alternative therapies for PD, with the intent of either delaying the use of L-dopa or alleviating its side effects. DA receptor agonists can be used in conjunction with lower doses of L-dopa in a combined therapy approach or as monotherapy. Two general classes of dopaminergic agonists have been used in the treatment of PD: ergots and nonergots. The detailed use of these drugs in the management of PD is described in Chapter 18.

Ergot derivatives (see Table 13-4) act on several different neurotransmitter systems, including DA, 5HT, and adrenergic receptors. Bromocriptine and pergolide have been used for the treatment of PD; however, their use is associated with risk for serious cardiac complications, specifically, the promotion of valvular heart disease due to 5HT_{2B} serotonin receptor stimulation (Hutcheson et al., 2011). Bromocriptine is a potent D₂ receptor agonist and a weak D₁ antagonist. Pergolide is a partial agonist of D₁ receptors and a strong D₂ family agonist with high affinity for both D₂ and D₃ receptor subtypes. Ergot derivatives are commonly reported to cause unpleasant side effects, including nausea, dizziness, and hallucinations. Pergolide was removed from the U.S. market as therapy for PD after it was associated with an increased risk for valvular heart disease. Bromocriptine remains on the market primarily for the treatment of hyperprolactinemia or prolactin-secreting adenomas, where lower (D₂-selective) doses can be employed to avoid cardiac complications.

Several nonergot alkaloids are also employed in the management of PD. Apomorphine is a pan-DA receptor agonist most commonly used in the acute treatment of sudden “off” periods (bradykinesia, freezing) that can occur after long-term L-dopa treatment. Pramipexole and ropinirole are widely used in the treatment of PD, are agonists at all D₂-like receptors, but have the highest affinities for the D₃ receptor subtype. However, these agents are less effective than L-dopa in the early stages of PD treatment, and both are associated with the development of impulse control disorders, such as compulsive gambling or hypersexuality; notably, fewer drug-induced dyskinesias are observed.

The mechanisms underlying the impulse control disorders are currently unknown. Rotigotine is a DA agonist with preference for the D₂-like subfamily and is offered in a transdermal patch that is approved for the treatment of PD.

Hyperprolactinemia

Despite the contraindications for PD, ergot-based DA agonists are still used in the treatment of hyperprolactinemia. Like bromocriptine, cabergoline is a strong agonist at D₂ receptors and has lower affinity for D₁, 5HT, and α adrenergic receptors. The therapeutic utility of bromocriptine and cabergoline in hyperprolactinemia is derived from their properties as DA receptor agonists: They activate D₂ receptors in the pituitary to reduce prolactin secretion. The risk of valvular heart disease from ergot therapy is associated with higher doses of drug (necessary for PD treatment) but not with the lower doses used in treating hyperprolactinemia. The use of bromocriptine and cabergoline in the management of hyperprolactinemia is described in Chapter 42.

Restless Leg Syndrome

Restless leg syndrome is a neurological deficit characterized by abnormal sensations in the legs that are alleviated by movement. Decreased DA receptor expression and mild dopaminergic hypofunction are noted in patients with RLS. Rotigotine, ropinirole, and pramipexole are FDA-approved as pharmacotherapies for both PD and RLS.

Dopamine Receptor Antagonists

Just as enhancing DA neurotransmission can be clinically important, so can inhibiting dopaminergic signaling be useful in certain disease states. As with the DA receptor agonists, a lack of subtype-specific antagonists has limited the therapeutic utility of this group of ligands. Recent advances in elucidating GPCR structures and modeling ligand binding have advanced drug design, and subtype-selective antagonists are beginning to emerge as experimental tools (Table 13-5). Some receptor subtype-selective antagonists are in early stages of preclinical testing for therapeutic utility.

Schizophrenia

Dopamine receptor antagonists of the D₂-like subfamily are a mainstay in the pharmacotherapy of schizophrenia. While many neurotransmitter systems likely contribute to the complex pathology of schizophrenia (Chapter 16), modulating DA signaling is considered the basis of treatment. The DA hypothesis of schizophrenia has its origins in the characteristics of the drugs used to treat this disorder: All antipsychotic compounds used clinically have high affinity for DA receptors, especially with the D₂ receptor subtype. Moreover, psychostimulants that increase extracellular DA levels can induce or worsen psychotic symptoms in schizophrenic patients. The advent of neuroimaging techniques for visualization of DA in human brain regions has led to new insights in the role of specific DA systems. DA hyperfunction in subcortical regions, most notably the striatum, has been associated with the positive symptoms of schizophrenia, which respond well to antipsychotic treatment. In contrast, the PFC of schizophrenic patients exhibits dopaminergic hypofunction, which has been associated with the more treatment-refractory negative/cognitive symptoms. The drugs currently used to treat schizophrenia are classified as either typical (also referred to as first-generation) or atypical (second-generation) antipsychotics. This nomenclature stems from the fewer EPSs, or parkinsonian-like side effects, observed with atypical antipsychotics.

Typical Antipsychotics. The first antipsychotic drug used to treat schizophrenia was chlorpromazine. Its antipsychotic properties were attributed to its antagonism of DA receptors, especially the D₂ receptor. More D₂-selective ligands (e.g., haloperidol) were developed to improve the antipsychotic properties (see Chapter 16). Notably, drugs that are completely selective for the D₂ receptor subtype, without overlapping with affinity for the D₃ or D₄ receptor subtypes, are currently unavailable.

While all typical antipsychotics markedly improve positive symptoms (hallucinations, etc.), they are not very beneficial in the treatment of negative or cognitive symptoms of this disease.

CHLORPROMAZINE

ARIPIPAZOLE

HALOPERIDOL

Atypical Antipsychotics. This class of antipsychotic drugs originated with clozapine and is distinguished by lower EPSs than typical antipsychotics. Atypical agents are also less likely to stimulate prolactin production. The lack of extrapyramidal side effects has been partly attributed to a much lower affinity for the D_2 receptor compared to typical antipsychotics. Most atypical antipsychotics are also high-affinity antagonists or inverse agonists at the $5HT_{2A}$ receptor. While the precise role of $5HT_{2A}$ receptor blockade in the atypical effects of antipsychotics remains unclear, dual DA–5HT receptor blockade has contributed to the development of antipsychotics for several decades (see Chapter 16).

Partial D_2 -Like Receptor Agonists. Aripiprazole has even fewer side effects than earlier atypical antipsychotics. Aripiprazole diverges from the traditional atypical profile in several ways: First, it has higher affinity for D_2 receptors than for $5HT_{2A}$ receptors; second, it is a partial agonist at D_2 receptors. As a partial agonist, aripiprazole may diminish subcortical (striatal) DA hyperfunction by competing with DA for receptor binding, while simultaneously enhancing dopaminergic neurotransmission in the PFC by acting as an agonist. The dual mechanism afforded by a partial agonist may thus treat both the positive and negative symptoms associated with schizophrenia. Aripiprazole also exhibits functional selectivity at the D_2 receptor in that it exhibits higher efficacy for β -arrestin-mediated signaling than for G protein-mediated signaling. How this property may contribute to the unique effects of aripiprazole is not yet clear.

Recently, a derivative of aripiprazole, brexpiprazole, has been approved for the treatment of schizophrenia and as an adjunctive treatment of depression. The pharmacological properties of brexpiprazole are similar to those of aripiprazole except that brexpiprazole has lower D_2 receptor agonist efficacy and high partial agonist effects at the $5HT_{1A}$ receptor; perhaps this latter property underlies its effectiveness in treating depression.

Another partial agonist of the D_2 receptor, cariprazine, has recently been approved for treating schizophrenia and bipolar disorder. Interestingly, cariprazine is also a partial agonist at the D_3 receptor and actually exhibits higher affinity for the D_3 versus the D_2 receptor. In some studies, cariprazine has been shown to exhibit procognitive effects, suggesting that it may be useful for treating negative as well as positive symptoms of schizophrenia.

D_3 Receptor Antagonists and Drug Addiction

Although much work remains to determine their clinical utility, D_3 -selective antagonists show promise in the treatment of addiction (Heidbreder and Newman, 2010; Newman et al., 2012). This interest stems from the high expression of the D_3 receptor in the limbic system, the reward center of the brain, and from animal studies of highly D_3 -selective antagonists that suggest a role for the D_3 receptor in the motivation to abuse drugs and in the potential for drug-abuse relapse.

Acknowledgment: Elaine Sanders-Bush and Steven E. Mayer contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: Serotonergic Ligands

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
$5HT_3$ Receptor Antagonists • Antiemetic agents • Additional detail in Chapters 50 and 51		
Ondansetron Dolasetron Granisetron Palonosetron	<ul style="list-style-type: none"> • Antiemetics • Treatment of nausea 	<ul style="list-style-type: none"> • Associated with asymptomatic electrocardiogram changes, including prolongation of PT and QTc intervals
Cilansetron Alosetron	<ul style="list-style-type: none"> • Antiemetics • Treatment of nausea • Irritable bowel syndrome 	<ul style="list-style-type: none"> • Most useful in irritable bowel syndrome when diarrhea is the principal symptom
$5HT_{2C}$ Receptor Agonists • Weight loss		
Lorcaserin	<ul style="list-style-type: none"> • Promotes weight loss through decreased food consumption and increased satiety 	<ul style="list-style-type: none"> • Hallucinogenic at supraclinical doses, likely caused by $5HT_{2A}$ agonist activity that can occur with higher doses • Hallucinogenic properties resulted in a class IV schedule designation
The Triptans: $5HT_{1B/1D}$ Receptor Agonists • Migraine		
Almotriptan ^a Eletriptan Frovatriptan Naratriptan Rizatriptan Sumatriptan ^b Zolmitriptan	<ul style="list-style-type: none"> • Acute treatment of migraine 	<ul style="list-style-type: none"> • Most effective in acute settings; should be used as soon as possible after onset of attack • Usually dosed orally; onset, 1–3 h • Use with caution in patients with cardiovascular issues; contraindicated in patients with ischemic heart disease and coronary artery vasospasm • Drug interactions: CYP3A4 inhibitors ↑ C_p and $t_{1/2}$ of eletriptan, naratriptan; MAO inhibitors ↑ levels of almo-, riza-, suma-, and zolmitriptan. • Side effects: dizziness, somnolence, neck and chest pain • May cause fetal harm; not recommended during pregnancy and nursing; reduce dose in renal and hepatic impairment; do not administer within 24 h of other triptans, ergots, SSRIs/SNRIs • Beware serotonin syndrome, especially in combination with SSRIs and SNRIs

The Ergot Alkaloids • Interact with multiple 5HT receptor isoforms • Broad therapeutic utility		
LSD	<ul style="list-style-type: none"> No longer employed clinically Potent hallucinogen 	<ul style="list-style-type: none"> Positron emission tomographic imaging reveals similar activation patterns between schizophrenic patients experiencing hallucinations and LSD-induced hallucinations 5HT_{2A} receptor activation is believed to mediate the hallucinogenic effect of LSD
Methysergide	<ul style="list-style-type: none"> Acute treatment of migraine Treatment of vascular headaches 	<ul style="list-style-type: none"> Restricted to use in patients with frequent, moderate, or infrequent, severe migraine attacks Erratic drug absorption Potential for inflammatory fibrosis with prolonged use, including pleuropulmonary and endocardial fibrosis
Ergonovine Methylergonovine	<ul style="list-style-type: none"> Prevention of postpartum hemorrhage 	<ul style="list-style-type: none"> Increasing dose results in prolonged duration and increased force of uterine contraction Sustained contracture can result at high doses
5HT _{1A} Receptor Partial Agonists and SSRIs • Anxiolytics and antidepressants • Additional detail in Chapter 15		
Buspirone	Treatment of anxiety	<ul style="list-style-type: none"> Mimics anxiolytic effects of benzodiazepines but does not interact with GABA_A receptors Partial agonist of the 5HT_{1A} receptor
Fluoxetine Fluvoxamine Paroxetine Citalopram Escitalopram Sertraline Vilazodone	<ul style="list-style-type: none"> Antidepressants Also used to treat anxiety, panic disorder, obsessive-compulsive disorder, fibromyalgia, and neuropathic pain 	<ul style="list-style-type: none"> Selectively inhibit the serotonin transporter (SSRIs) Most widely used treatments for major depressive disorder Sexual dysfunction is a common side effect with SSRIs Precaution: serotonin syndrome
MSAAs • Treatment of sexual dysfunction • Activity at multiple receptor isoforms		
Flibanserin	<ul style="list-style-type: none"> Treatment of HSDD/FSIAD in premenopausal women 	<ul style="list-style-type: none"> Potent 5HT_{1A} receptor agonist and 5HT₂ receptor family antagonist Exerts both agonist and antagonist activity at 5HT receptors ⇒ MSAA designation (multifunctional serotonin agonist and antagonist)
Dopamine Receptor Agonists • Little to no subtype specificity		
Dopamine	<ul style="list-style-type: none"> Congestive heart failure Sepsis Cardiogenic shock 	<ul style="list-style-type: none"> Only used acutely via intravenous administration
Bromocriptine Cabergoline	<ul style="list-style-type: none"> PD (see Chapter 22) Hyperprolactinemia 	<ul style="list-style-type: none"> Ergot derivatives with D₂ agonist activity and D₁ antagonist activity Limited utility due to high potential for cardiac valvulopathies via 5HT_{2B} stimulation Bromocriptine and cabergoline can be used at low doses to treat hyperprolactinemia
Apomorphine Pramipexole Ropinirole Rotigotine	<ul style="list-style-type: none"> PD (see Chapter 22 for more details) RLS 	<ul style="list-style-type: none"> Nonergot alkaloids with broader DA receptor agonist activity Less efficacious than L-dopa in PD; often used as adjunct therapy in advanced PD Use in early PD can lead to poor impulse control Pramipexole, ropinirole, and rotigotine are used to treat RLS
Dopamine Receptor Antagonists • Antipsychotics • Emerging subtype specificity of ligands (Additional detail in Chapter 16)		
Chlorpromazine Haloperidol	<ul style="list-style-type: none"> Schizophrenia (see Chapter 16) 	<ul style="list-style-type: none"> Classified as typical antipsychotics Agents block D₂ receptors but are not completely selective Improvements are most notable in positive symptoms of schizophrenia
Clozapine	<ul style="list-style-type: none"> Schizophrenia (see Chapter 16) 	<ul style="list-style-type: none"> Classified as atypical antipsychotics Mixed 5HT_{2A}-D₂ receptor blockade Fewer extrapyramidal side effects than typical antipsychotics

- Purines
- Neuromodulatory Lipids
- Gases

REGULATORY SUBSTANCES

- Neurotrophins
- Neurosteroids
- Cytokines

The brain is a complex assembly of interacting cells that regulate many of life's activities in a dynamic fashion, generally through the communication process of chemical neurotransmission. Because the CNS drives so many physiological responses, it stands to reason that centrally-acting drugs are invaluable for a plethora of conditions. CNS-acting drugs are used not only to treat anxiety, depression, mania, and schizophrenia, but also to target diverse pathophysiological conditions, such as pain, fever, movement disorders, insomnia, eating disorders, nausea, vomiting, and migraine. However, as the CNS dictates such diverse physiology, the recreational use of some CNS-acting drugs can lead to physical dependence (Chapter 24) with enormous societal impacts. The sheer breadth of physiological and pathological activities mediated by drug molecules acting in the CNS makes this class of therapeutics both wide-ranging and immeasurably important.

The identification of CNS targets, as well as the development of drug molecules for those targets, presents extraordinary scientific challenges. While years of investigation have begun to dissect the cellular and molecular bases for many aspects of neuronal signaling, complete understanding of the functions of the human brain remains in its infancy. Complicating the effort is the fact that a CNS-active drug may act at multiple sites with disparate and even opposing effects. Furthermore, many CNS disorders likely involve multiple brain regions and pathways, which can frustrate efforts focusing on a single therapeutic agent.

The pharmacology of CNS-acting drugs is primarily driven by two broad and overlapping goals:

- to develop/use drugs as probe compounds to both elucidate and manipulate the normal CNS; and
- to develop drugs to correct pathophysiological changes in the abnormal CNS.

Modern advances in molecular biology, neurophysiology, structural biology, epigenetics, biomarkers, immunity, and an array of other fields have facilitated both our understanding of the brain and the development of an ever-expanding repertoire of drugs that can selectively treat diseases of the CNS.

This chapter introduces fundamental principles and guidelines for the comprehensive study of drugs that affect the CNS. Specific therapeutic approaches to neurological and psychiatric disorders are discussed in subsequent chapters. For further detail, see specialized texts (Brady et al., 2012;

Kandel et al., 2013; Nestler et al., 2015; Sibley, 2007). Detailed information on nearly all specific receptors and ion channels can be found at the official databases of the IUPHAR/BPS Guide to Pharmacology (<http://www.guidetopharmacology.org>).

Cellular Organization of the Brain

The CNS is made up of several types of specialized cells that are physiologically integrated to form complex functional brain tissue. The primary communicating cell is the neuron, which is strongly influenced and sustained by a variety of important supporting cells. Specific connections between neurons, both within and across the macrodivisions of the brain, are essential for neurological function. Through patterns of neuronal circuitry, individual neurons form functional ensembles to regulate the flow of information within and between the regions of the brain. Under these guidelines, present understanding of the cellular organization of the CNS can be viewed from the perspective of the size, shape, location, and interconnections between neurons (Shepherd, 2004; Squire, 2013).

Neurons

Neurons are the highly polarized signaling cells of the brain and are subclassified into types based on a large number of factors, including function (sensory, motor, or interneuron); location; morphology; neurotransmitter phenotype; or the class(es) of receptor expressed. Neurons are electrically active cells that express a variety of ion channels and ion transport proteins that allow them to conduct nerve impulses or action potentials that ultimately trigger release of neurotransmitters during chemical neurotransmission. Neurons also exhibit the cytological characteristics of highly active secretory cells: large nuclei, large amounts of smooth and rough endoplasmic reticulum, and frequent clusters of specialized smooth endoplasmic reticulum (Golgi complex), in which secretory products of the cell are packaged into membrane-bound organelles for transport from the perikaryon to the axon or dendrites (Figure 14-1). The sites of inter-neuronal communication in the CNS are termed *synapses*. Although synapses are functionally analogous to “junctions” in the somatic motor and autonomic nervous systems, central synapses contain an array of specific proteins that comprise the active zone for transmitter release and response.

Abbreviations

AC: adenylyl cyclase
ACh: acetylcholine
ACTH: corticotropin (formerly adrenocorticotrophic hormone)
ADHD: attention-deficit/hyperactivity disorder
AMPA: α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
AP: action potential
BBB: blood-brain barrier
BDNF: brain-derived neurotrophic factor
cAMP: cyclic adenosine monophosphate
CFTR channel: cystic fibrosis transmembrane conductance regulated channel
CGRP: calcitonin gene-related peptide
CLC: chloride channel
CLIP: corticotropin-like intermediate lobe peptide
CNG channel: cyclic nucleotide-gated channel
CNS: central nervous system
CO: carbon monoxide
COX: cyclooxygenase
CSF: cerebrospinal fluid
CYP: cytochrome P450
DA: dopamine
DAG: diacylglycerol
DAT: dopamine transporter
DHEAS: dehydroepiandrosterone sulfate
EAAT: excitatory amino acid transporter
EPAC: exchange protein activated by cyclic AMP
EPI: epinephrine
ERK: extracellular signal-regulated kinase
GABA: γ -aminobutyric acid
GABA-T: GABA transaminase
GAD: glutamic acid decarboxylase
GAT: GABA transporter
GHB: γ -hydroxybutyric acid
GluR: AMPA/kainate type of glutamate receptor
GLYT: glycine transporter
GPCR: G protein-coupled receptor
GRK: G protein-coupled receptor kinase
HCN channel: hyperpolarization-activated, cyclic nucleotide-gated channel
HP loops: hairpin loop
5HT: serotonin
IL: interleukin
IFN: interferon
IP₃: inositol 1,4,5-trisphosphate
IPSP: inhibitory postsynaptic potential

IUPHAR/BPS: International Union of Basic and Clinical Pharmacology/British Pharmacological Society
KA: kainic acid
LOX: lipoxygenase
 γ -LPH: γ -lipotrophic hormone
LTD: long-term depression
LTP: long-term potentiation
MAO: monoamine oxidase
MAPK: mitogen-activated protein kinase
mGluR: metabotropic glutamate receptor
MSH: melanocyte-stimulating hormone
mtPTP: mitochondrial permeability transition pore
NCX: $\text{Na}^+/\text{Ca}^{2+}$ exchanger
NE: norepinephrine
NET: norepinephrine transporter
NGF: nerve growth factor
NMDA: N-methyl-D-aspartate
NMDA-R: NMDA receptor
NO: nitric oxide
NOS: nitric oxide synthase
NT: neurotrophin
 O_2^- : superoxide radical
OCT: organic cation transporter
PC: phosphatidylcholine
PCP: phencyclidine
PDE: phosphodiesterase
PE: phosphatidylethanolamine
PEA: phenethylamine
PI3K: phosphoinositide 3-kinase
PIP₂: phosphatidylinositol 4,5-bisphosphate
PK_α: protein kinase α , as in PKA, PKC
PL_α: phospholipase α , as in PLA, PLD
POMC: pro-opiomelanocortin
SERT: serotonin transporter
SLC: solute carrier
TAAR: trace amine-associated receptor
TARPs: transmembrane AMPA receptor regulatory proteins
TAS2: taste receptor 2
THC: delta-9-tetrahydrocannabinol
TNF- α : tumor necrosis factor alpha
TRP channel: transient receptor potential channel
VACHT: vesicular acetylcholine transporter
VGAT: vesicular GABA and glycine transporter
VGLUT: vesicular glutamate transporter
VMAT: vesicular monoamine transporter
VSCC: voltage-sensitive Ca^{2+} channel

Like peripheral junctions, central synapses are denoted by accumulations of tiny (50- to 150-nm) *synaptic vesicles*. The proteins of these vesicles have specific roles in neurotransmitter storage, vesicle docking, and secretion and reaccumulation of neurotransmitter (see Figures 8–3 through Figures 8–6). The release of these neurotransmitters and their action on the neighboring cells via specific receptors, through mechanisms discussed in the material that follows, underlie the ability of these specialized cells to communicate with each other to dictate complex physiological actions.

Support Cells

A diverse cast of support cells outnumbers neurons in the CNS. These include neuroglia, vascular elements, the CSF-forming cells found within the intracerebral ventricular system, and the meninges that cover the

surface of the brain and comprise the CSF-containing envelope. *Neuroglia* (sometimes referred to simply as *glia*) are the most abundant support cells. They are nonneuronal cells that maintain important brain functions, such as holding neurons in place, supplying oxygen and nutrients to neurons, insulating signaling between neurons, and destroying potential pathogens. Traditionally, it was thought that neuroglia acted only in a supporting role; however, newer studies have demonstrated that they may also be involved in some signaling processes.

Neuroglia are classified as either *micro-* or *macroglia*. In the CNS, the macroglia consist of astrocytes, oligodendroglia, ependymal cells, and radial glia. Astrocytes (cells interposed between the vasculature and the neurons) are the most abundant of these and often surround individual compartments of synaptic complexes. They play a variety of metabolic

Figure 14-1 Principal features of a neuron. Dendrites, including apical dendrites, receive synapses from presynaptic terminals. The cell body (~50 μm in diameter) contains the nucleus and is the site of transcription and translation. The axon (0.2 to 20 μm wide, 100 μm to 2 m in length) carries information from the perikaryon to the presynaptic terminals, which form synapses (up to 1000) with the dendrites of other neurons. Axosomatic synapses also occur. Many CNS-active pharmacological agents act at the presynaptic and postsynaptic membranes of the synaptic clefts and at areas of transmitter storage near the synapses. (Adapted with permission from Kandel ER, et al., eds. *Principles of Neural Science*. 4th ed. McGraw-Hill, New York, 2000, p. 22.)

support roles, including furnishing energy intermediates, anchoring neurons to their blood supply, and regulating the external environment of the neuron by active removal of neurotransmitters and excess ions following release. The oligodendroglia produce myelin, the multilayer, compacted membranes that electrically insulate segments of axons and permit nondecremental propagation of action potentials. Ependymal cells line the spinal cord and ventricular system and are involved in the creation of CSF, while radial cells act as neuroprogenitors and scaffolds. Microglia consist of specialized immune cells found within the CNS. Although the brain is immunologically protected by the BBB (see discussion that follows), these microglia act as macrophages to protect the neurons and are therefore mediators of immune response in the CNS. Microglia respond to neuronal damage and inflammation, and many diseases are associated with deficient microglia. In some instances, such as in chronic neuroinflammation, the balance between the numbers of

microglia and astrocytes can determine whether there will be resulting cell damage or protection. Thus, in addition to neurons, support cells such as glia are key players in facilitating most aspects of neuronal function and CNS signaling.

Blood-Brain Barrier

The BBB is an important boundary separating the periphery (capillaries carrying blood) from the CNS. This barrier consists of endothelial cells, astrocytes, and pericytes on a noncellular basement membrane. The BBB prevents or diminishes unencumbered access to the brain by circulating blood components. In terms of CNS therapeutics, the BBB represents a substantial obstacle to overcome for drug delivery to the site of action. An exception exists for lipophilic molecules, which diffuse fairly freely across the BBB and accumulate in the brain. In addition to its relative impermeability to small charged molecules such as neurotransmitters, the BBB can be viewed as a combination of the partitioning of solute across the vasculature (which governs passage by definable properties such as molecular weight, charge, and lipophilicity) and the presence or absence of energy-dependent transport systems (see Chapter 5). However, the cells within the barrier also have the capacity to actively transport molecules such as glucose and amino acids that are critical for brain function (see Chapter 5). One of these transport systems that is selective for large amino acids catalyzes the movement of L-dopa across the BBB and thus contributes to the therapeutic utility of L-dopa in the treatment of Parkinson disease. Furthermore, for some compounds, including neurotransmitter metabolites such as homovanillic acid and 5-hydroxyindoleacetic acid, the acid transport system of the choroid plexus provides an important route for clearance from the brain.

Substances that rarely gain access to the brain from the bloodstream can often reach the brain when injected directly into the CSF, and, under certain therapeutic conditions, bypassing the barrier may be beneficial to permit the entry of chemotherapeutic agents. Other clinical manifestations, such as cerebral ischemia and inflammation, can also modify the BBB, thereby increasing access to substances that ordinarily would not enter the brain. The barrier is nonexistent in the peripheral nervous system and is much less prominent in the hypothalamus and several small, specialized organs (the circumventricular organs) lining the third and fourth ventricles of the brain: the median eminence, area postrema, pineal gland, subfornical organ, and subcommissural organ. Although their structure and anatomical positioning may make these areas more accessible for physiological and pharmacological modulation, overall the BBB remains a constant consideration for pharmacological access to the CNS. For a pharmacologist's view of the BBB, see *The Blood-Brain Barrier: A Pharmacological View* in Chapter 5.

Neuronal Excitability and Ion Channels

As noted, neurons, the primary signaling cells of the brain, release neurotransmitters in response to a rapid rise and fall in membrane potential known as an action potential. Voltage-dependent ion channels within the plasma membrane open when the membrane potential increases to a threshold value, thus regulating the electrical excitability of neurons. Action potentials are the signals by which the brain and neurons receive and transmit information to one another through pathways determined by their connectivity.

We now understand in considerable detail how three major cations, Na^+ , K^+ , and Ca^{2+} , as well as Cl^- anion, are regulated via their flow through highly discriminative ion channels (Figures 14-2 and 14-3). The relatively high extracellular concentration of Na^+ (~140 mM) compared to its intracellular concentration (~14 mM) means that increases in permeability to Na^+ cause cellular depolarization, ultimately leading to the generation of an action potential. In contrast, the intracellular

Figure 14–2 Voltage-sensitive Na^{+} , Ca^{2+} , and K^{+} channels. Voltage-dependent channels provide for rapid changes in ion permeability along axons and within dendrites and for excitation-secretion coupling that releases neurotransmitters from presynaptic sites. The transmembrane Na^{+} gradient (~ 140 mM outside vs. ~ 14 mM inside the cell) means that increases in permeability to Na^{+} causes *depolarization*. In contrast, the K^{+} gradient (~ 4 mM outside the cell vs. ~ 120 mM inside) is such that increased permeability to K^{+} results in *hyperpolarization*. Changes in the concentration of intracellular Ca^{2+} (extracellular free Ca^{2+} : 1.25 mM; intracellular Ca^{2+} : resting ~ 100 nM, rising to ~ 1 μM when Ca^{2+} entry is stimulated) affects multiple processes in the cell and are critical in the release of neurotransmitters. **A.** Structure of Ca^{2+} and Na^{+} channels. The α subunit in both Ca^{2+} and Na^{+} channels consists of four sub-subunits or segments (labeled I through IV), each with six TM hydrophobic domains (blue cylinders). The hydrophobic regions that connect TM5 and TM6 in each segment associate to form the pore of the channel. Segment 4 in each domain includes the voltage sensor. (Adapted with permission from Catterall W. *Neuron* **2000**, 26:13–25. © Elsevier.) **B.** Structural diversity of K^{+} channels. Inward rectifier, K_{ir} . The basic subunit of the inwardly rectifying K^{+} channel protein K_{ir} has the general configuration of TM5 and TM6 of a segment of the α subunit shown in panel A. Four of these subunits assemble to create the pore. Voltage-sensitive K^{+} channel, K_{v} . The α subunits of the voltage-sensitive K^{+} channel K_{v} and the rapidly activating K^{+} channel K_{A} share a putative hexaspanning structure resembling in overall configuration a single segment of the Na^{+} and Ca^{2+} channel structure, with six TM domains. Four of these assemble to form the pore. Regulatory β subunits (cytosolic) can alter K_{v} channel functions. **C.** Multisubunit assembly of Ca^{2+} channels. Ca^{2+} channels variably require several auxiliary small proteins (α_2 , β , γ , and δ); α_2 and δ subunits are linked by a disulfide bond. Likewise, regulatory subunits also exist for Na^{+} channels.

Figure 14-3 Three families of Cl^- channels. Due to the Cl^- gradient across the plasma membrane (~ 116 mM outside vs. 20 mM inside the cell), activation of Cl^- channels causes an IPSP that dampens neuronal excitability; inactivation of these channels can lead to hyperexcitability. There are three distinct types of Cl^- channel: *Ligand-gated channels* are linked to inhibitory transmitters, including GABA and glycine. *CLC Cl^- channels*, of which nine subtypes have been cloned, affect Cl^- flux, membrane potential, and the pH of intracellular vesicles. *CFTR channels* bind ATP and are regulated by phosphorylation of serine residues. M, transmembrane domains; NBF, nucleotide-binding fold; R, regulatory (phosphorylation) domain. (Reproduced with permission from Jentsch J. Chloride channels: a molecular perspective. *Curr Opin Neurobiol*, 1996, 6:303–310. Copyright Elsevier.)

concentration of K^+ is relatively high (~ 120 mM, vs. 4 mM outside the cell), and increased permeability to K^+ results in hyperpolarization. Changes in the concentration of intracellular Ca^{2+} (100 nM to 1 μM) affects multiple processes in the cell and are critical in the release of neurotransmitters. Under basal conditions, cellular homeostatic mechanisms (Na^+/K^+ -ATPase; $\text{Na}^+/\text{Ca}^{2+}$ exchanger; Ca^{2+} -ATPases; etc.) and the sequestration of releasable Ca^{2+} in storage vesicles maintain the concentrations of these ions. Electrical excitability thus generates the action potential through changes in the distribution of charged ions across the neuronal cell membrane.

The Cl^- channels are a superfamily of ion channels that are important for maintaining resting potential and are also responsible for the IPSPs that dampen neuronal excitability. In most neurons, the Cl^- gradient across the plasma membrane is inwardly driven (~ 116 mM outside vs. 20 mM inside the cell), and, as a result, inactivation of these channels leads to hyperexcitability. There are several families of both voltage-gated and ligand-gated Cl^- channels (Figure 14-3). Ligand-gated Cl^- channels are linked to inhibitory transmitters, including GABA and glycine (discussed in detail in material that follows). A class of secondary active transporters, the cation-chloride cotransporters, plays an essential role in establishing the electrochemical Cl^- gradient that is required for the hyperpolarizing postsynaptic inhibition mediated by both GABA receptors and glycine receptors. In addition, during brain development, changes in the expression of neuronal cation-chloride cotransporter isoforms can result in shifts in the direction of the chloride gradient such that activation of a ligand-gated chloride channel becomes excitatory.

The CLC family of chloride channels comprises plasma membrane channels that affect Cl^- flux and membrane potential as well as channels that function as Cl^-/H^+ antiporters. CLC members can also influence the pH of intracellular vesicles. CFTR channels are gated by ATP and increase the conductance of certain anions. Overall, these channels are responsible for a variety of important neurophysiological roles, including regulation of membrane potential, volume homeostasis, and regulation of pH on internal extracellular compartments.

The CNG channels are nonselective cation channels that regulate ion flux in neurons. CNG channels are activated as a result of cyclic nucleotide binding, and their primary function involves sensory transduction, especially in the retina and olfactory neurons. Because CNG channels are nonselective and also allow alkali ions to flow, they can result in either depolarization or hyperpolarization. These channels consist of four subunits assembled around a central pore and are subclassified into α (four genes) and β (two genes) subunits. HCN channels are another type of cyclic nucleotide-gated channel; they are nonselective, ligand-gated, cation channels that are encoded by four genes and are widely expressed in the heart and throughout the CNS. These channels open with hyperpolarization and close with depolarization; the binding of cyclic AMP or cyclic GMP to the channels shifts their activation curves to more hyperpolarized potentials. These channels play essential roles in cardiac pacemaker cells and in rhythmic and oscillatory activity in the CNS.

The TRP channels are a large family of about 28 ion channels that are nonselectively permeable to cations, including Na^+ , Ca^{2+} , and Mg^{2+} . They are broadly grouped into six receptor subfamilies possessing six transmembrane domains containing the cation-permeable pore. These channels can have diverse modes of activation and permeation. TRP channels respond to multiple stimuli and function in sensory physiology, including thermosensation, osmosensation, and taste. Importantly, some TRP channels are also mediators of pain as they function as detectors of thermal and chemical stimuli that activate sensory neurons. Spices such as garlic, chili powder, and wasabi activate certain subtypes. Others respond to such diverse chemicals as menthol, peppermint, and camphor. Mutations in TRP channels have been associated with neurodegenerative diseases as well as cancer. The diversity of their physiology has led to their investigation as important drug targets, particularly for the treatment of chronic pain, for which they play a central role in nociception associated with inflammation and neuropathy. In recent years, TRP channels have become novel and important targets for drug development (Nilius and Szallasi, 2014).

Chemical Communication in the CNS

A central concept of neuropsychopharmacology is that drugs that improve the functional status of patients with neurological or psychiatric diseases typically act by enhancing or blunting neurotransmission in the CNS. Therapeutic targets include *ion channels* (discussed previously), which mediate changes in excitability induced by neurotransmitters; *neurotransmitter receptors*, which physiologically respond to activation by neurotransmitters; and *transport proteins*, which reaccumulate released transmitter.

Identification of Central Neurotransmitters

Neurotransmitters are endogenous chemicals in the brain that act to enable signaling across a chemical synapse. They carry, boost, and modulate signals between neurons or other cell types and act on a variety of targets to elicit a host of biological functions. An essential step in understanding the functional properties of neurotransmitters within the context of the circuitry of the brain is to identify substances that are transmitters at specific interneuronal connections. The precise number of transmitters is unknown, but more than 100 chemical messengers have been identified to date. The criteria for identification of central transmitters is similar to that used to establish the transmitters of the autonomic nervous system (see Chapter 8):

- The transmitter must be present in the presynaptic terminals of the synapse and in the neurons from which those presynaptic terminals arise.
- The transmitter must be released from the presynaptic nerve concomitantly with nerve activity, and in high enough quantity to have an effect.
- The effects of experimental application of the putative transmitter should mimic the effects of stimulating the presynaptic pathway.

- If available, specific pharmacological agonists and antagonists should stimulate and block, respectively, the measured functions of the putative transmitter.
- There should be a mechanism present (either reuptake or enzymatic degradation) that terminates the actions of the transmitter.

Many nerve terminals contain multiple transmitter substances and coexisting substances (presumed to be released together) that either act jointly on the postsynaptic membrane or act presynaptically to affect release of transmitter from the presynaptic terminal. In these cases, the milieu of concurrently released signaling molecules makes mimicking or fully antagonizing the action of a given transmitter substance with a single drug compound difficult. This has emphasized complexity in identifying signaling molecules that has been partially overcome using defined *in vitro* cell culture systems, which can then be extrapolated back to the CNS.

Cell Signaling and Synaptic Transmission

Cellular signaling links neurotransmitter receptor activation to downstream biological effects. A number of mechanisms have been identified that can be broadly classified into two main types of signaling, fast and slow neurotransmission. The most commonly seen postreceptor events are fast transmission resulting from rapid changes in ion flux through ion channels. Slow neurotransmission is primarily the role of a second major group of receptors, the GPCRs, which interact with heterotrimeric GTP-binding proteins (Figure 3–10). There are additional and distinct mechanisms of signaling for growth factor receptors (Table 3–1; Figure 3–12) and for the nuclear receptors that transduce steroid hormone signaling (Figures 3–14 and 6–13). Because the majority of cell-to-cell communication in the CNS involves chemical transmission, neurons require specialized cellular functions to mediate these actions (Figure 14–4):

- **Neurotransmitter synthesis.** Small-molecule neurotransmitters are synthesized in nerve terminals, whereas others, such as peptides, are synthesized in cell bodies and transported to nerve terminals.
- **Neurotransmitter storage.** Synaptic vesicles store transmitters, often in association with various proteins and frequently with ATP.
- **Neurotransmitter release.** Release of stored transmitter from the storage vesicle into the synaptic cleft occurs by exocytosis. Depolarization of the presynaptic neuron results in a complex initiation of stimulus-secretion coupling, which involves vesicle docking at the plasma membrane, the formation of membrane fusion/release complexes, and the Ca^{2+} -dependent release of vesicular contents. Recycling of the transmitter storage vesicle generally follows. For details, see Figures 8–4 through 8–6.
- **Neurotransmitter recognition.** Neurotransmitters diffuse from sites of release and bind selectively to receptor proteins to initiate intracellular signal transduction events within the postsynaptic cell.
- **Termination of action.** A variety of mechanisms terminate the action of synaptically released transmitters, including diffusion from the synapse, enzymatic inactivation (for ACh and peptides), and uptake into neurons or glial cells by specific transporters.

Fast Neurotransmission

Responses to activation of receptors consisting of an ion channel as part of its structure tend to be rapid (milliseconds) because the effects are direct and generally do not require multiple steps leading to second-messenger generation and activation of a signaling pathway. In fast neurotransmission (also called directly gated transmission), neurotransmitters bind directly to ligand-gated ion channels on the postsynaptic membrane to rapidly open the channel and change the permeability of the postsynaptic site, leading to depolarization or hyperpolarization. Depolarization results in continuation of the nerve impulse, while hyperpolarization leads to diminished signaling (see Figure 11–5). Ligand-gated ion channels mediating fast transmission (also called ionotropic receptors) consist of multiple subunits, each usually having four transmembrane domains that associate to form pentameric receptors (Figure 14–5). Receptors with this structure include the receptors for the amino acids GABA, glycine, glutamate, and aspartate; the serotonin 5HT₃ receptor; and the nicotinic ACh

Figure 14–4 *Transmitter release, action, and inactivation.* Depolarization opens voltage-dependent Ca^{2+} channels in the presynaptic nerve terminal (1). The influx of Ca^{2+} during an action potential (AP) triggers (2) the exocytosis of small synaptic vesicles that store neurotransmitter (T). Released neurotransmitter interacts with receptors in the postsynaptic membranes that either couple directly with ion channels (3) or act through second messengers, such as GPCRs (4). Neurotransmitter receptors in the presynaptic nerve terminal membrane (5) can inhibit or enhance subsequent exocytosis. Released neurotransmitter is inactivated by reuptake into the nerve terminal by (6) a transport protein coupled to the Na^+ gradient (e.g., for DA, NE, or GABA); by (7) degradation (ACh, peptides); or by (8) uptake and metabolism by glial cells (glutamate). The synaptic vesicle membrane is recycled by (9) clathrin-mediated endocytosis. Neuropeptides and proteins are sometimes stored in (10) larger, dense core granules within the nerve terminal. These dense core granules can be released from sites (11) distinct from active zones after repetitive stimulation.

receptor. The nicotinic ACh receptor provides a good example of receptor structure and how subunit composition varies with anatomic location and affects function (Figure 14–6).

Slow Neurotransmission

Slower transmission (although still relatively fast, often on a time scale of seconds) is mediated by neurotransmitters that do not bind to ion channels but to receptors with a very different architecture called metabotropic receptors. Upon activation, these receptors generate second messengers. This major group of receptors consists of the membrane heptaspanning GPCRs (Figure 3–9). There are more than 825 human GPCRs, which can be classified into five major families: rhodopsin (class A); secretin (class B); adhesion; glutamate (class C); and frizzled. The GPCRs in the CNS are largely in the rhodopsin family. These receptors have sites for N-linked glycosylation on the extracellular amino tail and sometimes on the second extracellular loop. There are also multiple potential sites for phosphorylation on the third intracellular loop and the carboxyl tail, and some members of this class are palmitoylated on the carboxyl tail. Phosphorylation can regulate GPCR-G protein-effector coupling and provide docking sites for arrestins and other scaffolding proteins (see Chapter 3).

The GPCRs are associated with a broad spectrum of physiological effects, including activation of K^+ channels, activation of PLC-IP₃- Ca^{2+} pathways and regulation of adenylyl cyclase activity and downstream systems affected by cyclic AMP (multiple isoforms of PKA, EPAC, HCN,

Figure 14-5 Pentameric ligand-gated ion channels. The subunits of these channels, which mediate fast synaptic transmission, are embedded in the plasma membrane to form a roughly cylindrical structure with a central pore. In response to binding of transmitter, the receptor proteins change conformation; the channel gate opens, and ions diffuse along their concentration gradient across the membrane through a hydrophilic opening in the otherwise-hydrophobic membrane. **A. Subunit organization.** For each subunit of these pentameric receptors, the amino terminal region of ~ 210 amino acids is extracellular. It is followed by four hydrophobic regions that span the membrane (TM1–TM4); a small carboxyl terminus is on the extracellular surface. The TM2 region is α helical, and TM2 regions from each subunit line the internal pore of the pentameric receptor. Two disulfide loops at positions 128–142 and 192–193 are found in the α subunit of the nicotinic receptor. The 128–142 motif is conserved in the family of pentameric receptors; the vicinal cysteines at 192–193 occur only in a subunit of the nicotinic receptor. **B. Schematic rendering of a nicotinic ACh non- α subunit.** Five such subunits form a pentameric receptor. See Figure 14-6 for an example.

Figure 14-6 Subunit arrangement: the nicotinic ACh receptor. **A. Longitudinal view of receptor schematic with the γ subunit removed.** The remaining subunits, two copies of α , one of β , and one of δ , are shown to surround an internal channel with an outer vestibule and its constriction located deep in the membrane bilayer region. Spans of α helices with slightly bowed structures form the perimeter of the channel and come from the TM2 region of the linear sequence (Figure 14-5). ACh-binding sites, indicated by red arrows, occur at the $\alpha\gamma$ and $\alpha\delta$ (not visible) interfaces. **B. Nicotinic receptor subunit arrangements.** Agonist-binding sites (red circles) occur at α subunit-containing interfaces. At least 17 functional receptor isoforms have been observed *in vivo*, with different ligand specificity, relative $\text{Ca}^{2+}/\text{Na}^{+}$ permeability, and physiological function determined by their subunit composition. The only isoform found at the neuromuscular junction is shown for comparison. The neuronal receptor isoforms found at autonomic ganglia and in the CNS are homomeric or heteromeric pentamers of α ($\alpha 2$ – $\alpha 10$) and β ($\beta 2$ – $\beta 4$) subunits.

CNG, and PDE). These effects are typically mediated through the activation of specific G proteins, each a heterotrimer of α , β , and γ subunits where the β and γ units are constitutively associated. The GTP-binding α subunits can modulate the activities of numerous effectors (e.g., adenylyl cyclase, PLC). The $\beta\gamma$ subunits are also active in mediating signaling, especially in the regulation of ion channels. Table 14–1 shows examples of the variety of physiological functions mediated by G proteins. G protein activation-inactivation signaling dynamics are described in Chapter 3. Notably, GPCRs can also signal to downstream pathways through other intermediary proteins, such as the β arrestins (Shukla et al., 2011). Drugs targeting GPCRs represent a core of modern medicine and make up as much as 40% of all pharmaceuticals.

Termination of Neurotransmitter Action

Mechanisms to terminate the actions of released neurotransmitters are essential for maintaining the balance of neuronal signaling. There are two primary mechanisms for terminating the signaling of released transmitters. One is the conversion of the transmitter into an inactive compound via an enzymatic reaction. The best example of enzymatic inactivation is for the transmitter ACh, which, after activating the receptor, is hydrolyzed by acetylcholinesterase to choline and acetate. A second mechanism

involves the clearance of the neurotransmitter by transport proteins present on presynaptic neurons, neighboring glial cells, and other neurons so that it can no longer act on the target receptors. In addition to these, slow diffusion of the transmitter away from the synapse and subsequent degradation also play a role for both conventional neurotransmitters and neuropeptides.

Neurons and glial cells express specific transporter proteins, such as those for the monoamines NE (NET), serotonin (SERT) and DA (DAT), which remove NE, 5HT, and DA, respectively, from the extracellular space by transporting it back into the presynaptic neuron (see Chapters 5, 8, and 13). These plasma membrane carriers serve as a major mechanism for limiting the extent and duration of neurotransmitter signaling. To accomplish this task, they couple the movement of neurotransmitters to the influx of Na^+ , which provides a strong thermodynamic driving force for inward transport. The carriers for NE, 5HT, DA, GABA, and glycine have 12 hydrophobic membrane-spanning domains with their amino and carboxy termini located within the cytoplasm (Figure 14–8). These transporters are generally glycosylated along the large (second) extracellular loop and possess sites of phosphorylation and binding to intracellular regulatory proteins, primarily on their amino and carboxy tails.

Figure 14–7 The β adrenergic receptor as a model for GPCRs. This two-dimensional model illustrates features common to most GPCRs. Red lines mark segments with 10 amino acids. The amino terminus (N) is extracellular, and the carboxyl terminus (C) is intracellular; in between are seven hydrophobic TM domains and alternating intracellular and extracellular loops (e_{1-3} and i_{1-3}). Glycosylation sites are found near the N terminus; consensus sites for phosphorylation by PKA (arrows) are found in the i_3 loop and the carboxyl terminal tail. An aspartate residue in TM3 (asp¹¹³) interacts with the nitrogen of catecholamine agonists while two serines (ser²⁰⁴, ser²⁰⁷) in TM5 interact with the hydroxyl groups on the phenyl ring of catecholamine agonists. A cysteine residue (cys³⁴¹) is a substrate for palmitoylation. Interaction of the palmitoyl group with membrane lipids reduces the flexibility of the carboxyl tail. ^aKhan and colleagues (2013) have reviewed the expanding roles of the $\beta\gamma$ subunits.

A second family of plasma membrane neurotransmitter transporters mediates the clearance of glutamate and aspartate released during synaptic transmission. In humans, five subtypes of glutamate transporters (referred to as EAATs 1–5) clear glutamate into neurons and glial cells. The two glial carriers, EAATs 1 and 2, are responsible for the bulk of glutamate transport activity in the CNS and are critical for limiting the excitotoxic actions of glutamate described further in this chapter. These transporters have eight transmembrane domains (TM1–8) and two reentrant hairpin loops (HP1 and HP2) that appear to serve as intracellular and extracellular gates during the transport process (Figure 14–9). EAATs are members of the solute carrier family (SLC1A 1–3, 6, and 7) and are powered by Na⁺ and other cations running down their electrochemical gradients.

There are also at least three distinct gene families of vesicular neurotransmitter transporters that sequester the neurotransmitters within synaptic vesicles for storage and, ultimately, for release during neuronal signaling. These include VMAT1, VMAT2, and VACHT (see Chapter 8), a vesicular carrier for both GABA and glycine (VGAT), and three vesicular glutamate carriers, VGLUT1, VGLUT2, and VGLUT3. These transporters ensure that vesicles fill rapidly during neurotransmission and provide a means for reducing cytoplasmic concentrations of neurotransmitter in areas where rates of reuptake are high. The driving force for vesicular uptake of neurotransmitter by these transporters is a proton electrochemical gradient across the membrane of the storage vesicle (vesicle interior more acidic than the cytosol).

The monoamine transporters DAT, NET, and SERT are well-established targets for therapeutic antidepressants and for addictive drugs, including cocaine and amphetamines. Selective inhibitors of these carriers can increase the duration and spatial extent of the actions of neurotransmitters. Inhibitors of the uptake of NE or 5HT are used to treat depression and other behavioral disorders, as described in Chapters 15 and 16. The psychostimulants methylphenidate and amphetamine are the major drugs used to treat ADHD in children and in adults. Although the two drugs have stimulant actions in healthy individuals, in patients with ADHD they

reduce hyperactivity and increase attention by inhibiting DAT and NET and enhancing DA and NE neurotransmission. Transporters are discussed in further detail in Chapters 5, 8, and 13.

Central Neurotransmitters

Neurotransmitters can be classified by chemical structure into various categories, including *amino acids*, *ACh*, *monoamines*, *neuropeptides*, *purines*, *lipids*, and even *gases*. This section describes each category and examines some prominent members.

Amino Acids

The CNS contains high concentrations of certain amino acids, notably glutamate and GABA, that potently alter neuronal firing. They are ubiquitously distributed within the brain and produce rapid and readily reversible effects on neurons. The dicarboxylic amino acids glutamate and aspartate produce excitation, while the monocarboxylic amino acids GABA, glycine, β -alanine, and taurine cause inhibition. Following the emergence of selective agonists and antagonists, the identification of pharmacologically distinct amino acid receptor subtypes became possible (see discussion that follows). Figure 14–10 shows these amino acid transmitters and their drug congeners.

Gamma-Aminobutyric Acid

GABA is the main inhibitory neurotransmitter in the CNS. GABA is synthesized in the brain from the Krebs cycle intermediate α -ketoglutarate, which is transaminated to glutamate by GABA-T. GABA is subsequently formed from glutamate by the enzyme GAD; the presence of GAD in a neuron therefore delineates a neuron that uses GABA as a transmitter. Interestingly, intraneuronal GABA is also inactivated by GABA-T which converts it to succinic semialdehyde, but only in the presence of adequate α -ketoglutarate. This GABA shunt or cycle serves to maintain levels of GABA; thus, GABA-T is both a synthetic and a degradative enzyme (Brady et al., 2012). There is a vesicular GABA transporter (VGAT, SLC32A1, a member of the amino acid/polyamine transporter family) that is involved in storing GABA in vesicles for subsequent release into the synaptic cleft. The action of GABA is primarily terminated by reuptake by one of four different GATs present on both neurons and glia. GABA acts by binding to and activating specific ionotropic or metabotropic receptors on both pre- and postsynaptic membranes. *GABA_A receptors* (the most prominent GABA receptor subtype) are ionotropic, ligand-gated Cl[−] channels. The *GABA_B receptors* are metabotropic GPCRs. One subtype formerly known as the *GABA_C receptor* is now classified as a type of *GABA_A receptor*.

The *GABA_A receptors* have been extensively characterized as important drug targets and are the site of action of many neuroactive drugs, notably benzodiazepines (such as valium), barbiturates, ethanol, anesthetic steroids, and volatile anesthetics, among others. These drugs are used to treat various neuropsychiatric disorders, including epilepsy, Huntington disease, addictions, sleep disorders, and more. As ligand-gated ion channels, *GABA_A receptors* are pentamers of subunits that each contain four transmembrane domains and assemble around a central anion-specific pore (Figures 14–5 and 14–6). The major forms of the *GABA_A receptor* contain at least three different types of subunits: α , β , and γ , with a likely stoichiometry of 2 α , 2 β , and 1 γ . The IUPHAR/BPS recognizes 19 unique subunits that are known to form at least 11 native *GABA_A receptors* that can be pharmacologically differentiated. The particular combination of α and γ subunits can affect the efficacy of benzodiazepine binding and channel modulation. Many drugs, such as those noted, act as positive allosteric modulators of the *GABA_A receptor*, that is, act at sites distinct from the GABA-binding site to positively modulate the function of the receptor (Figure 14–11). The interaction of these drugs with the *GABA_A receptor* and their therapeutic use are discussed further in Chapter 17.

The *GABA_B receptors* are metabotropic GPCRs that function as obligate heterodimers of two subunits named *GABA_{B1}* and *GABA_{B2}*. *GABA_B receptors* are widespread in the CNS and regulate both pre- and postsynaptic activity. These receptors interact with G_i to inhibit adenylyl cyclase,

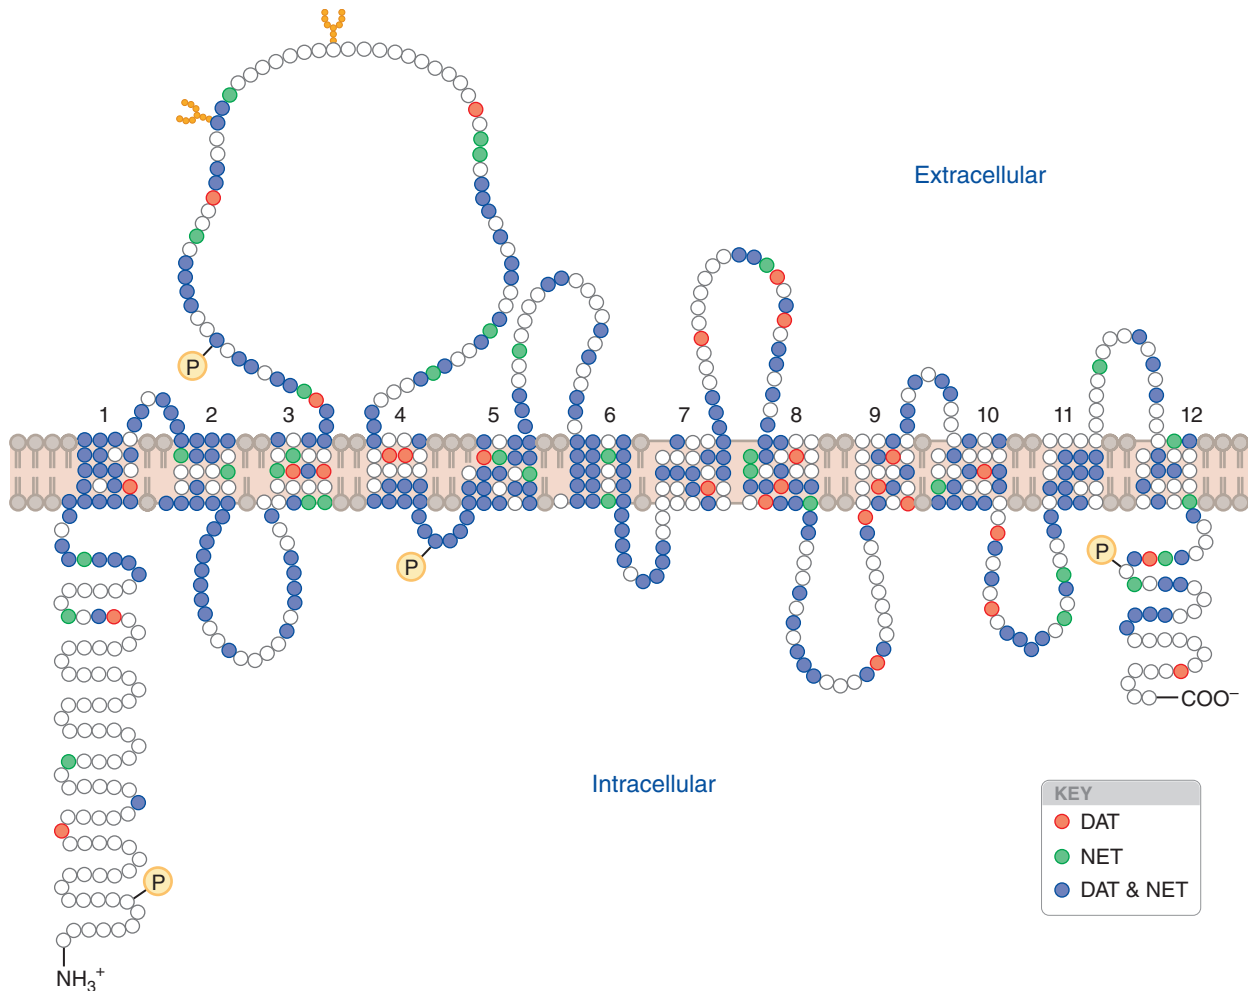

Figure 14-8 Structure of the rat 5HT transport protein. Both the N terminus (NH_3^+) and C terminus (COO^-) are intracellular. These proteins typically have 12 hydrophobic, membrane-spanning domains with intervening extracellular and intracellular loops. The second extracellular loop is the largest and contains several potential glycosylation sites (indicated with tree-like symbols). Amino acid residues that are homologous to those in the DAT and the NET are colored, as noted. The most highly conserved regions of these transporters are located in the transmembrane domains; the most divergent areas occur in the N and C termini. (Used with permission from Dr. Beth J. Hoffman, Vertex Pharmaceuticals, San Diego, CA.)

activate K^+ channels, and reduce Ca^{2+} conductance and interact with G_i to enhance PLC activity. Presynaptic GABA_B receptors function as autoreceptors, inhibiting GABA release, and may play the same role on neurons releasing other transmitters. A number of GABA_B agonists have been

identified, including baclofen (Figure 14-10), which is a skeletal muscle relaxant, and the psychoactive drug GHB, which is sometimes used to treat narcolepsy but is also used recreationally as an intoxicant.

Glycine

Glycine is an amino acid normally incorporated into proteins that can also act as an inhibitory neurotransmitter, particularly in the spinal cord and brainstem. Glycine is synthesized primarily from serine by serine hydroxymethyltransferase (SHMT). Glycine is imported into synaptic vesicles by a vesicular transport system identical to that used by GABA (VGAT). The action of glycine in the synaptic cleft is terminated by reuptake through specific transporters (GLYT1 and GLYT2) located on presynaptic nerve terminals and glia cells. These transporters can be distinguished pharmacologically and present attractive therapeutic targets for the modulation of glycine levels.

Actions of glycine are an active area of research, especially considering that there are glycine-binding sites on NMDA receptors. Glycine acts as a coagonist at NMDA receptors, such that both glutamate and glycine must be present for activation to occur (see discussion that follows). In addition to the NMDA receptor site, there are specific ionotropic glycine receptors that contain many of the structural features described for other ligand-gated ion channels (pentamers of subunits containing four transmembrane domains). These function as hyperpolarizing Cl^- channels and are prominent in the brainstem and spinal cord. Multiple subunits (currently four known

Figure 14-9 General model of the mammalian EAATs. The EAAT family includes the plasma membrane transporters EAAT1 to EAAT5. In this schematic model, transmembrane domains (colored oblongs) are labeled 1–8. Approximate binding sites occupied by Na^+ (blue dots) and substrate (green triangle) are formed by the nonhelical segments at the tips of two hairpin loops, HP1 and HP2.

Figure 14-10 Amino acid transmitters (red) and congeners (black).

α subunits and a single β subunit) can assemble into a variety of glycine receptor subtypes. Taurine and β -alanine are agonists of glycine receptors; strychnine, a potent convulsant, is a selective antagonist (Figure 14-10).

Glutamate

Glutamate and aspartate are dicarboxylate amino acid neurotransmitters with excitatory actions in the CNS. Both amino acids are found in high concentrations in the brain and have powerful excitatory effects on neurons in virtually every region of the CNS. Glutamate is the most abundant

excitatory neurotransmitter and the principal fast excitatory neurotransmitter. Glutamate acts through receptors that are classified as either *ligand-gated ion channels (ionotropic)* or *metabotropic GPCRs* (Table 14-2). A well-characterized phenomenon involving glutamate transmission is the induction of LTP and its converse, LTD. These phenomena are known for strengthening and changing synapses and have long been hypothesized to be an important mechanism in learning and memory.

Ionotropic glutamate receptors are ligand-gated ion channels that were historically divided into three classes, each named for its preferred

Figure 14-11 Pharmacologic binding sites on the GABA_A receptor. GABA binds at the orthosteric site on the GABA_A receptor. Other sites noted are allosteric sites at which agonists and antagonists may promote (green) or inhibit (red) receptor function. The GABA_A receptor is a member of the Cys-loop family (Figure 11-1) but has a larger number of cavities in the transmembrane region and is susceptible to fewer natural toxins than several other family members. Miller and Smart (2010) have reviewed the features of this receptor and other Cys-loop receptors that contribute to orthosteric and allosteric modulation of receptor function. Hibbs and colleagues (Hibbs and Gouaux, 2011; Morales-Perez et al, 2016) have recently provided structural data that suggest the mechanisms of activation, desensitization, and ion permeation in a Cys-loop receptor. Yamaura and colleagues (2016) have described a rapid screening procedure for putative allosteric modulators of the GABA_A receptor.(Modified with permission from Nestler EJ et al., eds. *Molecular Neuropharmacology*. 3rd ed. McGraw-Hill, New York, 2015.)

synthetic ligand (Figure 14-10): NMDA receptors, AMPA receptors, and KA receptors. With the discovery of an increasing number of subunits comprising these receptor categories, this classification has recently been refined (see Table 14-2).

The *NMDA receptors* consist of heteromers that are made up of multiple subunit combinations (termed GluN_x) with the minimal receptor

being a dimer of the GluN1 subunit and a GluN2 subunit. However, more complex heteromeric complexes are generated incorporating multiple subunits. The NMDA receptors have relatively high permeability to Ca²⁺ and are blocked by Mg²⁺ in a voltage-dependent manner. These receptors are unique in that their activation requires the simultaneous binding of two different agonists: In addition to glutamate, glycine binding appears necessary for activation (Figure 14-12). While NMDA receptors are involved in normal synaptic transmission, their activation is more closely associated with the induction of various forms of synaptic plasticity rather than fast point-to-point signaling in the brain. Aspartate is also a selective NMDA receptor agonist. Other NMDA receptor ligands include open-channel blockers such as PCP (“angel dust”); antagonists include 5,7-dichlorokynurenic acid, which acts at an allosteric glycine-binding site, and ifenprodil, which selectively inhibits NMDA receptors containing GluN2B subunits. The activity of NMDA receptors is sensitive to pH and to modulation by a variety of endogenous agents, including Zn²⁺, some neurosteroids, arachidonic acid, redox reagents, and polyamines such as spermine.

The *AMPA receptors* exist predominantly as heterotetramers and contain multiple subunits (termed GluA_x) as indicated in Table 14-2. In addition, there are TARPs that, together with a variety of scaffolding and regulatory proteins, modulate channel properties and alter the trafficking of receptors to and from perisynaptic and postsynaptic regions. AMPA receptors open and close rapidly, making them well suited to mediate the vast majority of excitatory synaptic transmission in the brain. Like NMDA receptors, AMPA receptors are involved in synaptic plasticity. They can be selectively antagonized by NBQX and CNQX, and similar antagonists are being explored as neuroprotective drugs for the treatment of stroke.

The *KA receptors* are composed of a distinct array of subunits (termed GluK_x) that assemble as homo- or heterotetramers to form functional receptors. An important difference between KA and AMPA receptors is that KA receptors require extracellular Na⁺ and Cl⁻ for activation. KA receptors differ functionally from AMPA and NMDA receptors in other important ways. KA receptors do not reside predominantly within postsynaptic signaling complexes and are positioned to modulate neuronal excitability and synaptic transmission by altering the likelihood that the postsynaptic cell will fire in

TABLE 14-2 ■ CLASSIFICATION OF GLUTAMATE RECEPTORS				
FAMILY	SUBTYPE	AGONISTS	ANTAGONISTS

AIDA, 1-aminoinidan-1,5-dicarboxylic acid; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; L-AP4, L-2-amino-4-phosphonobutiric acid; ATPA, 2-amino-3-(3-hydroxy-5-tert-butylisoxa-zol-4-yl)propanoic acid; CBPG, (S)-(+)-2-(3-carboxybicyclo(1.1.1)pentyl)-glycine; CNQX, 6-cyano-7-nitroquinoxaline-2,3-dione; D-AP5, D-2-amino-5-phosphonovaleric acid; DCG-IV, (2S,2'R,3'R)-2-(2';3'-Dicarboxycyclopropyl)glycine; (S)-3,4-DCPG, (S)-3,4-dicarboxyphenylglycine; 3,5-DHPG, 3,5-dihydroxyphenylglycine; EGLU, (2S)-α-ethylglutamic acid; MPPG, (RS)-α-methyl-4-phosphonophenylglycine; MSOP, (RS)-α-methylserine-O-phosphate; NBQX, 1,2,3,4-tetrahydro-6-nitro-2,3-dioxo-benzo[f]quinoxaline-7-sulfonamide; NMDA, N-methyl-D-aspartate; PCCG-4, phenylcarboxycyclopropylglycine; (RS)-PPG, (RS)-4-phosphonophenylglycine. Glutamate is the principal agonist at both ionotropic and metabotropic receptors for glutamate and aspartate.

Figure 14-12 Pharmacologic binding sites on the NMDA receptor. Agents that promote receptor function are shown in ●. Those that inhibit receptor function appear in ●. Binding of both glutamate and glycine is necessary for activation.

response to subsequent stimulation. Presynaptic KA receptors have also been implicated in modulating GABA release through presynaptic mechanisms.

Glutamate-mediated excitotoxicity may underlie the damage that occurs when ischemia or hypoglycemia in the brain leads to a massive release and impaired reuptake of glutamate, resulting in excess stimulation of glutamate receptors and subsequent cell death. The cascade of events leading to neuronal death is thought to be triggered by excessive activation of NMDA or AMPA/KA receptors, allowing significant influx of Ca^{2+} into neurons (Figure 14-13). NMDA receptor antagonists can attenuate neuronal cell death induced by activation of these receptors. Glutamate receptors have become targets for diverse therapeutic interventions. For example, disordered glutamatergic transmission may play a role in the etiology of chronic neurodegenerative diseases (Chapter 18).

The *mGluRs* are GPCRs structurally defined by the presence of a large glutamate-binding N-terminal (extracellular) domain of about 560 amino acids. There are eight unique *mGluRs* organized into three subgroups (Table 14-2). *mGluRs* bind glutamate and function to “fine-tune” excitatory and inhibitory transmission by presynaptic, postsynaptic, and glial mechanisms, including the modulation of release and signaling of other neurotransmitters, among which are GABA, purines, DA, 5HT, and neuropeptides. Group I *mGluRs* couple to G_q , while groups II and III couple to G_i/G_o . *mGluRs* are located in a variety of brain regions and sometimes are linked to opposing functional responses. In general, group I receptors increase neuronal excitability, whereas both group II and group III suppress excitability. *mGluRs* play roles in the modulation of other receptors, function in synaptic plasticity, and are linked to several neurological diseases. They have recently become important drug targets, as subtype-selective agents are being discovered and investigated as potential therapies for various neuropsychiatric disorders.

Acetylcholine

Acetylcholine is present throughout the nervous system and functions as a neurotransmitter. It was the first neurotransmitter discovered and plays a primary role in the autonomic nervous system in ganglionic transmission as well as the peripheral nervous system, where it is the main neurotransmitter at the neuromuscular junction in vertebrates. ACh is synthesized by choline acetyltransferase and stored in the nerve endings. Following release and receptor activation, it is degraded by acetylcholinesterase (see Chapters 8–11). The effects of ACh result from interaction with two broad classes of receptors: ionotropic ligand-gated ion channels termed nicotinic receptors and metabotropic GPCRs called muscarinic receptors. In the CNS, ACh is found primarily in interneurons. The degeneration of particular cholinergic pathways is a hallmark of Alzheimer disease.

Nicotinic ACh receptors are found in skeletal muscle (see Figures 11-1 and 11-2) as well as in autonomic ganglia, the adrenal gland, and the CNS. Their activation by ACh results in a rapid increase in the influx of Na^+ , depolarization, and the influx of Ca^{2+} . Nicotinic receptors are pentamers consisting of various combinations of 17 known subunits that can form the ion channel (Figure 14-6). In the CNS, nicotinic receptors are assembled as combinations of $\alpha(2-7)$ and $\beta(2-4)$ subunits. While pairwise combinations of α and β (e.g., $\alpha 3\beta 4$ and $\alpha 4\beta 2$), and in at least one case a homomeric $\alpha 7$ are sufficient to form a functional receptor in vitro, far more complex isoforms have been identified in vivo. The subunit composition strongly influences the biophysical and pharmacological properties of the receptor. Comprehensive listings of nicotinic receptor subunit combinations identified from recombinant expression systems, or in vivo, can be found in the work of Millar and Gotti (2009). Nicotinic cholinergic receptors have high therapeutic value, not only in the treatment of smoking cessation (they are the primary receptors for nicotine; see Chapter 11) but also for other neurological pathologies.

Muscarinic ACh receptors are GPCRs consisting of five subtypes, all of which are expressed in the brain. M_1 , M_3 , and M_5 couple to G_q , while the M_2 and M_4 receptors couple to G_i (Table 14-3). Chapter 9 presents detailed information on the physiology and pharmacology of muscarinic receptors.

Monoamines

Monoamines are neurotransmitters whose structure contains an amino group connected to an aromatic ring by a two-carbon chain. All are derived from aromatic amino acids and regulate neurotransmission that underlies cognitive processes, including emotion. Drugs that affect monoamine receptors and signaling are used to treat a variety of conditions, such as depression, schizophrenia, and anxiety, as well as movement disorders like Parkinson disease. Monoamines include DA, NE, EPI, histamine, 5HT, and the trace amines. Each system is anatomically distinct and serves separate, functional roles within its field of innervation.

Dopamine

Dopamine, NE, and EPI are catecholamine neurotransmitters (see Chapters 8 and 13). Notably, in contrast to the periphery, DA is the predominant catecholamine in the CNS. Its synthesis, degradation, and pharmacology are discussed in Chapter 13. There are several distinct pathways mediating DA signaling, including ones that play a role in motivation and reward (most drugs of abuse increase DA signaling), motor control, and the release of various hormones. These effects are mediated by five distinct GPCRs grouped into two subfamilies: D1-like receptors (D_1 and D_5) that stimulate adenylyl cyclase activity via coupling to G_s or G_{olp} and D2-like receptors (D_2 , D_3 , and D_4) that couple to G_i/G_o to inhibit adenylyl

the pharmacotherapy of these disorders (see Chapters 16 and 18). There are three major DA-containing pathways in the CNS: the nigrostriatal, the mesocortical/mesolimbic, and the tuberoinfundibular, depicted in Figure 13–11.

SUBTYPE	TRANSDUCER EFFECTOR	AGONISTS (EXAMPLES)	ANTAGONISTS (EXAMPLES)
M ₁	G _q Activation of PLC	Acetylcholine, carbachol, oxotremorine, pilocarpine, McN-A-343	Pirenzepine, telenzepine, 4-DAMP, xanomeline
M ₂	G _i /G _o Inhibition of AC	Acetylcholine, carbachol, oxotremorine	AF-DX 116, AF-DX 384, AQ-RA 741, tolterodine, (S)-(+)-dimethindene maleate, methoctramine
M ₃	G _q Activation of PLC	Acetylcholine, carbachol, oxotremorine, pilocarpine, cevimeline	Darifenacin, 4-DAMP, DAU 5884, J-104129, tropicamide, tolterodine
M ₄	G _i /G _o Inhibition of AC	Acetylcholine, carbachol oxotremorine	AF-DX384, 4-DAMP, PD 102807, xanomeline
M ₅	G _q Activation of PLC	Acetylcholine, carbachol, oxotremorine, pilocarpine	4-DAMP, xanomeline, VU-0488130 (ML381)

Acetylcholine is the endogenous transmitter for all muscarinic receptors. Nonselective antagonists include atropine, scopolamine, and ipratropium. 4-DAMP, 1,1-dimethyl-4-diphenylacetoxypiperidinium iodide.

TABLE 14-4 ■ ADRENERGIC RECEPTORS IN THE CNS

FAMILY	SUBTYPES	TRANSDUCER	AGONIST	ANTAGONIST
α_1 Adrenergic	α_{1A} α_{1B} α_{1D}	$G_{q/11}$	Epinephrine, phenylephrine, oxymetazoline, dabuzalgron (α_{1A}) A61603 (α_{1B})	Prazosin, doxazosin, terazosin, tamsulosin, alfuzosin, S(+)-niguldipine (α_{1A}), L-765314 (α_{1B}), BMY-7378 (α_{1D})
α_2 Adrenergic	α_{2A} α_{2B} α_{2C}	G_i/G_o	Epinephrine, norepinephrine, dexmedetomidine, clonidine, guanfacine	Yohimbine, rauwolscine
β Adrenergic	β_1 β_2 β_3	G_s	Epinephrine, norepinephrine, prenalterol (β_1), fenoterol (β_2), salbutamol (β_2), mirabegron (β_3), BRL37344 (β_3)	Carvedilol, bupranolol, levobunolol, metoprolol, propranolol, betaxolol (β_1), ICI118554 (β_2), SR 59230A (β_3)

Norepinephrine

NE is an endogenous neurotransmitter for the α and β adrenergic receptor subtypes that are present in the CNS; all are GPCRs (Table 14-4; see also Chapter 8). β adrenergic receptors couple to G_s to activate adenylyl cyclase. The α_1 adrenergic receptors couple to G_q , resulting in stimulation of the PLC-IP₃/DAG-Ca²⁺-PKC pathway, and are associated predominantly with neurons. The interaction of NE with α_1 adrenergic receptors on noradrenergic target neurons causes a decrease in K⁺ conductance, resulting in *depolarizing responses*. The α_2 adrenergic receptors are found on glial and vascular elements, as well as on neurons. They are prominent on noradrenergic neurons, where they couple to G_i , inhibit adenylyl cyclase, and mediate a *hyperpolarizing response* due to enhancement of an inwardly rectifying K⁺ channel (via the $\beta\gamma$ heterodimer). The α_2 adrenergic receptors are also located presynaptically, where they function as inhibitory autoreceptors to diminish the release of NE. The antihypertensive effects of clonidine may result from stimulation of such autoreceptors.

There are relatively large amounts of NE within the hypothalamus and in certain parts of the limbic system, such as the central nucleus of the amygdala and the dentate gyrus of the hippocampus. NE also is present in significant amounts in most brain regions. Mapping studies indicated that noradrenergic neurons of the locus ceruleus innervate specific target cells in a large number of cortical, subcortical, and spinomedullary fields.

Epinephrine

Most EPI in the brain is contained in vascular elements. Neurons in the CNS that contain EPI were recognized only after the development of sensitive enzymatic assays and immunocytochemical staining techniques for phenylethanolamine-N-methyltransferase, the enzyme that converts NE into EPI. EPI-containing neurons are found in the medullary reticular formation and make restricted connections to pontine and diencephalic nuclei, eventually coursing as far rostrally as the paraventricular nucleus of the thalamus. Their physiological properties have not been unequivocally identified.

Histamine

Histamine is a monoamine neurotransmitter in the CNS in addition to its well-known physiological function in immune and digestive responses in the periphery. Histaminergic neurons are located in the ventral posterior hypothalamus, where they give rise to long ascending and descending tracts that are typical of patterns characteristic of other monoaminergic systems. The histaminergic system is thought to affect arousal, body temperature, and vascular dynamics. The biosynthesis of histamine is described in Chapter 39. Histamine signals through four GPCR subtypes (H_1 – H_4) that regulate either adenylyl cyclase or PLC (Figure 14-14). Interestingly, unlike other monoamine and amino acid transmitters, histamine does not appear to be a substrate for a unique reuptake transporter following its release, however, there are reports of its transport by NET and OCT3. Termination of its action likely involves its degradation by histamine-N-methyltransferase, a widely expressed cytosolic enzyme; diamine oxidase, which can oxidatively deaminate histamine, is lacking in the CNS. The histamine receptors, structure, signaling, functioning, and current understandings are reviewed in Chapter 39 and by Panula and colleagues (2015).

The H_1 receptors are widely distributed in the brain, where high densities are found in regions linked to neuroendocrine, behavioral, and nutritional state control. H_1 receptor activation excites neurons in most brain regions, and genetic knockout of the H_1 receptor results in behavioral abnormalities, consistent with the receptor's being a major player in cortical control of the sleep/wake cycle. This is evident in the well-known sedative actions of first-generation H_1 receptor blockers that are used in the treatment of allergies. The development of H_1 antagonists with low CNS penetration has reduced the incidence of sedation in the treatment of allergy-related disorders (see the table, Drug Facts for Your Personal Formulary: *H₁ Antagonists*, in Chapter 39), although, in some conditions the sedative effect of first-generation antihistamines can be beneficial in inducing sleep.

The H_2 receptors activate adenylyl cyclase and are primarily involved in gastric acid secretion and smooth muscle relaxation. H_2 receptor antagonists are a mainstay of treatment of dyspepsia and GI ulcers (see Chapter 49). H_2 receptors are also highly expressed in the brain, where they regulate neuronal physiology and plasticity. Mice lacking H_2 receptors show cognitive defects and impaired hippocampal LTP along with abnormalities in nociception. Difficulties in studying H_2 receptor signaling in the CNS are attributed to the fact that H_2 receptor ligands generally exhibit poor BBB penetration. However, there have been several clinical trials investigating H_2 receptor antagonists for treating supraspinal nociception; these trials have met with mixed results.

The H_3 receptors are also present in the CNS and can act as autoreceptors on histaminergic neurons to inhibit histamine synthesis and release. These receptors act to inhibit adenylyl cyclase and to modulate N-type voltage-gated Ca²⁺ channels. While it is known that H_3 receptors function as autoreceptors, they are not confined to histaminergic neurons and have been found to regulate serotonergic, cholinergic, noradrenergic, and dopaminergic neurotransmitter release. Exploiting the ability to modulate other neurotransmitters, the H_3 receptor has become a therapeutic target for treating conditions such as obesity, movement disorders, schizophrenia, ADHD, and wakefulness. A wide array of compounds have been developed that interact with the H_3 receptor, which have proved to be useful pharmacological tools both in vitro and in vivo. One compound, pitolisant, an inverse agonist at the H_3 receptor, has been granted orphan drug status for the treatment of narcolepsy and is currently in clinical trials for schizophrenia and Parkinson disease.

The H_4 receptors are expressed on cells of hematopoietic origin (eosinophils, T cells, mast cells, basophils, and dendritic cells) and are involved in eosinophil shape and mast cell chemotaxis. While some evidence has suggested that H_4 receptors are expressed in the CNS, this remains controversial and in need of further research. H_4 receptors have recently been demonstrated on microglia where they may indirectly affect neurons. Regardless, the vast majority of information about this subtype is related to allergy, asthma, and the antipruritic properties of H_4 antagonists.

Serotonin

The synthesis and degradation of 5HT are discussed in Chapter 13. There are diverse pathways mediating serotonin signaling that play a role in modulating mood, depression, anxiety, phobia, and GI effects. All but one

Figure 14-14 Signal transduction pathways for histamine receptors. Histamine can couple to a variety of G protein–linked signal transduction pathways via four different receptors. H₁ receptors activate phosphatidylinositol turnover via G_{q/11}. The other receptors couple either positively (H₂ receptor) or negatively (H₃ and H₄ receptor) to adenylyl cyclase activity via G_s and G_{i/o}, respectively. Signaling pathways affected by histamine provide both immediate and long-term regulation of cell function.

of the serotonin receptors are GPCRs and are targets for both therapeutic and recreational (hallucinogenic) drugs. These effects are mediated by 13 distinct GPCRs and 1 ligand-gated ion channel, which exhibit characteristic ligand-binding profiles, couple to different intracellular signaling systems, and exhibit subtype-specific distribution within the CNS. The 5HT receptors and their pharmacology are discussed in detail in Chapter 13.

Trace Amines

Trace amines, while discovered long ago, have only recently been appreciated as neurotransmitters. As the name implies, they are detected at trace levels (they have very short half-lives due to rapid metabolism by MAO). However, at least some trace amines act as neuromodulators/neurotransmitters at specific trace amine receptors. Trace amines are structurally related to catecholamines and consist of the PEAs (*N*-methylphenethylamine [an endogenous amphetamine isomer], phenylethanolamine, tyramine, tryptamine, *N*-methyltyramine, octopamine, synephrine, and 3-methoxytyramine). These trace amines are thought to act through GPCRs that were originally termed “trace amine receptors” but are now called TAARs because not all members have very high affinity for trace amines. The first receptor was identified in 2001 (Borowsky et al., 2001), and to date six TAAR genes (*TAAR1*, *TAAR2*, *TAAR5*, *TAAR6*, *TAAR8*, and *TAAR9*) have been identified in humans along with several potential pseudogenes. Multiple TAAR-related receptor genes have been identified in other species; several display prominent expression in the olfactory epithelium and are regarded as putative olfactory receptors for volatile amines. Only one TAAR (*TAAR1*) has been recognized

by IUPHAR as a trace amine receptor; it has been given the abbreviation TA₁. TA₁ has the highest affinity for the trace amines tyramine, β-phenylephrine, and octopamine. Emerging evidence suggests that TA₁ may modulate monoaminergic activity in the CNS. In addition to trace amines, TAARs can be activated by amphetamine-like psychostimulants and endogenous thyronamines such as thyronamine and 3-iodothyronamine.

Peptides

Neuropeptides typically behave as modulators in the CNS rather than causing direct excitation or inhibition. A growing number of neuropeptides have been described (Table 14-5) and are involved in a wide array of brain functions, ranging from analgesia to social behaviors, learning, and memory. In contrast to the biogenic amines or amino acids, peptide synthesis requires transcription of DNA to mRNA and translation of mRNA into protein. This takes place primarily in perikarya, and the resulting peptide is then transported to nerve terminals. Single genes can therefore, through transcriptional and posttranslational modifications, give rise to multiple neuropeptides. For example, proteolytic processing of POMC gives rise to, among other peptides, ACTH; α-, γ-, and β-MSHs; and β-endorphin (Figure 14-15). In addition, alternative splicing of RNA transcripts in different tissues may result in distinct mRNA species (e.g., calcitonin and CGRP). Furthermore, while some CNS peptides function independently, most are thought to act in concert with coexisting neurotransmitters. They are often packaged into vesicles and released along with other neurotransmitters to modulate their actions. While classical neurotransmitters generally signal to neurons by depolarizing or hyperpolarizing, neuropeptides

TABLE 14-5 ■ EXAMPLES OF NEUROPEPTIDES

Calcitonin Family Calcitonin Calcitonin gene-related peptide (CGRP)	Pituitary Hormones Corticotropin (formerly adrenocorticotrophic hormone; ACTH) α -Melanocyte-stimulating hormone (α -MSH) Growth hormone (GH) Follicle-stimulating hormone (FSH) β -Lipotropin (β -LPH), luteinizing hormone (LH)
Hypothalamic Hormones Oxytocin, vasopressin	Tachykinins Neurokinins A and B Neuropeptide K, substance P

have more diverse mechanisms of action and can also affect gene expression. Their action is not terminated by rapid reuptake into the presynaptic cell; rather, they are enzymatically inactivated by extracellular peptidases. As a result, their effects on neuronal signaling can be prolonged.

Neuropeptide Receptors

Most neuropeptide receptors are GPCRs, with the extracellular domains of the receptors playing primary roles in peptide-receptor interaction. As with other transmitter systems, there are often multiple receptor subtypes for the same peptide transmitter (Table 14-6). Neuropeptide receptors can exhibit different affinities for nascent neuropeptides and peptide analogues. Because peptides are typically inefficient as drugs, particularly at CNS targets due to difficulties permeating the BBB, major efforts have been made to develop small-molecule drugs that are effective as either agonists or antagonists at peptide receptors. Through a combination of structural biology, chemistry, high-throughput screening, and drug development, there are now small-molecule ligands for many neuropeptide receptors. Some of these compounds are listed in Table 14-6. Notably, natural products have not typically been good sources of drugs that affect peptidergic transmission. One exception is the plant alkaloid morphine, which acts selectively at opioid receptor subtypes (see Chapter 20).

Purines

Adenosine, ATP, UDP, and UTP have roles as extracellular signaling molecules. ATP is also a component of many neurotransmitter storage vesicles and is released along with transmitters. Intracellular nucleotides may reach the exterior cell surface by other means; for example, for example, extracellular adenosine can result from cellular release and metabolism of ATP. Released nucleotides can be hydrolyzed extracellularly by ectonucleotidases. Extracellular nucleotides and adenosine can act on a family of diverse purinergic receptors, which have been implicated in a variety of functions, including memory and learning, locomotor behavior, and feeding.

Purinergic Receptors

Purinergic receptors are divided into three classes: adenosine receptors (also called P1), P2Y, and P2X (Table 14-7). *Adenosine receptors* are GPCRs that consist of four subtypes (A_1 , A_{2A} , A_{2B} , and A_3) activated

endogenously by adenosine. A_1 and A_3 couple to G_i ; A_2 receptors couple to G_s . Activation of A_1 receptors is associated with inhibition of adenylyl cyclase, activation of K^+ currents, and in some instances, activation of PLC; stimulation of A_2 receptors activates adenylyl cyclase. In the CNS, both A_1 and A_{2A} receptors are involved in regulating the release of other neurotransmitters, such as glutamate and DA, making the A_{2A} receptor a potential therapeutic target for disorders, including Parkinson disease.

The *P2Y receptors* are also GPCRs and are activated by ATP, ADP, UTP, UDP, and UDP-glucose. There are eight known subtypes of P2Y receptors that couple to a variety of G proteins (Table 14-7). The $P2Y_{14}$ receptor is expressed in the CNS, where it is stimulated by UDP-glucose and may play a role in neuroimmune functions. The $P2Y_{12}$ receptor is important clinically: Inhibition of this receptor in platelets inhibits platelet aggregation.

In contrast to the other two families, ATP-sensitive *P2X receptors* are ligand-gated cation channels that are expressed throughout the CNS on both presynaptic and postsynaptic nerve terminals and on glial cells. P2X receptors are found on nociceptive sensory neurons, where they primarily gate Na^+ , K^+ , and Ca^{2+} and are implicated in mediating sensory transduction. There are seven subtypes of P2X receptors with varying sensitivities to their endogenous agonist ATP (Table 14-7). Functional P2X receptors have a trimeric topology, existing as either homopolymers or heteropolymers with other P2X receptors, as confirmed by X-ray crystallography of a $P2X_4$ receptor (Kawate et al., 2009). The study of compounds that are selective for some P2X subtypes suggests that targeting these receptors may be useful in the therapy of neuropathic and inflammatory pain, thrombosis, arthritis, and depression.

Neuromodulatory Lipids

Cannabinoids

In the 1960s, THC (Figure 14-16) was identified as a psychoactive substance in marijuana. This led to the discovery and cloning of the two cannabinoid receptors and the identification of endogenous compounds that modulate them. The two receptor subtypes (CB₁ and CB₂) are GPCRs that couple to G_i/G_o to inhibit adenylyl cyclase and, in some

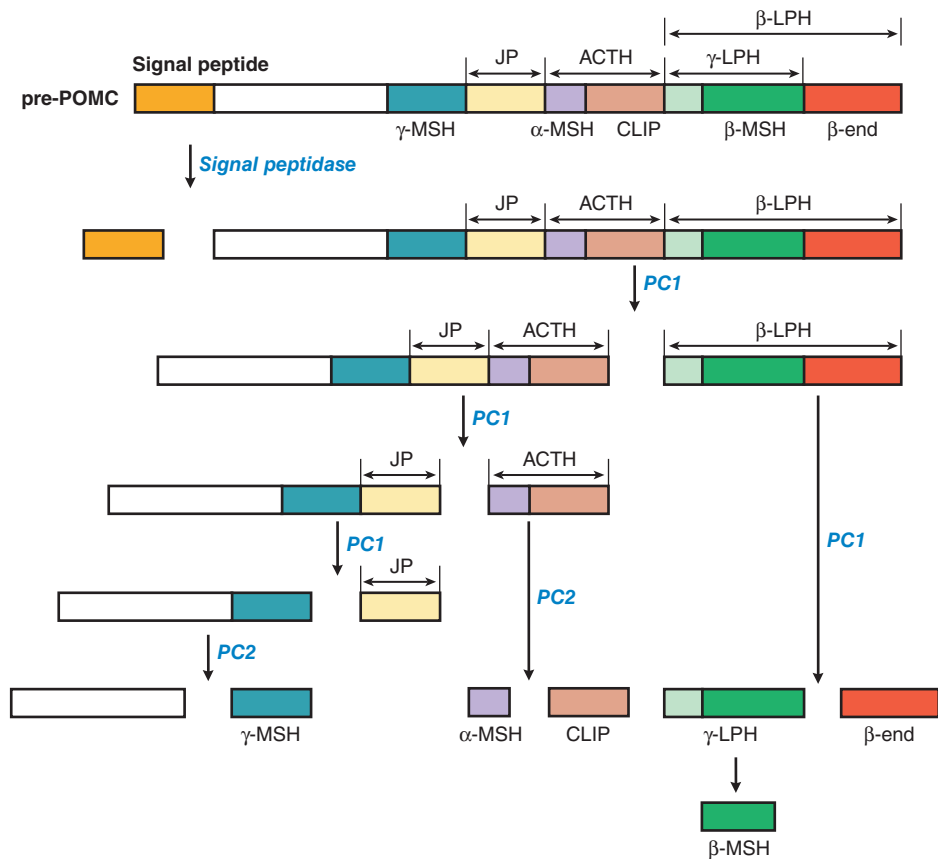

Figure 14-15 *Proteolytic processing of POMC.* After removal of the signal peptide from pre-POMC, the remaining propeptide undergoes endoproteolysis by prohormone convertases 1 and 2 (PC1 and PC2) at dibasic residues. PC1 liberates the bioactive peptides ACTH, β -endorphin (β -end), and γ -LPH. PC2 cleaves ACTH into CLIP and α -MSH and also releases γ -MSH from the N-terminal portion of the propeptide. The JP (joining peptide) is the region between ACTH and γ -MSH. β -MSH is formed by cleavage of γ -LPH. Some of the resulting peptides are amidated or acetylated before they become fully active.

For further details, consult information about the three classes of purinergic receptors at <http://www.guidetopharmacology.org>.

^aNECA is a nonselective agonist of P1 receptors.

^bP2Y₁₄ binds UDP-glucose, UDP-galactose, or UDP-acetylglucosamine.

Figure 14–16 Cannabinoid receptor ligands. Anandamide and 2-arachidonylglycerol are endogenous agonists. Rimonabant is a synthetic CB receptor antagonist. Δ⁹-tetrahydrocannabinol is a CB agonist derived from marijuana.

cell types, inhibit voltage-gated Ca⁺ channels or stimulate K⁺ channels. The receptors share relatively low overall homology and are found in differing locations, although both are found in the CNS. CB₁ receptors are found in high levels throughout the brain, whereas CB₂ receptors are prominent in immune cells. Within the CNS, CB₂ receptors are expressed less than CB₁ receptors and are thought to occur primarily on microglia. Several orphan GPCRs (GPCRs with no known endogenous agonist) have been implicated as being cannabinoid-like, and as such, more cannabinoid receptor subtypes may exist. The finding of endogenous cannabinoids responsible for signaling to these receptors, along with a host of clinical data from marijuana use, has fueled interest in this signaling system and has greatly expanded our understanding of its physiology.

The ECS (endogenous cannabinoid system) consists of the cannabinoid receptors, endogenous cannabinoids, and the enzymes that synthesize and degrade endocannabinoids. The endocannabinoids are lipid molecules and include anandamide (*N*-arachidonylethanolamine) and 2-arachidonylglycerol (2-AG), as well as other compounds that have been putatively identified to serve as endogenous endocannabinoids, including *O*-arachidonylethanolamine (virodhamine), *N*-dihomo-γ-linolenylethanolamine, *N*-docosatetraenoic-ethanolamine, oleamide, 2-arachidonyl-glyceryl-ether (2-AGE), *N*-arachidonoyl-dopamine (NADA), and *N*-oleoyl-dopamine. The actions of endocannabinoids are terminated by their uptake into cells, followed by hydrolysis. Two enzymes known to break down anandamide and 2-AG are fatty acid amide hydrolase (FAAH) and monoacylglycerol lipase (MGL), respectively. Although a few studies suggested the existence of a specific transport system for endocannabinoids, no molecular entity that mediates such a carrier-mediated process has been identified. Obviously, drugs that inhibit the transport or degradation of endocannabinoids would prolong their physiological actions.

There is now strong evidence that the ECS functions as a retrograde signaling messenger system, generally serving to inhibit the presynaptic release of neurotransmitters (Figure 14–17). Depending on the cell type, this action can last from seconds to hours, resulting in a large influence on neuronal circuit function. Endocannabinoids thus function as neuromodulators and have been linked to a variety of neuronal processes, including pain sensation, stress response, anxiety, appetite, and motor learning. The ECS has been targeted pharmacologically in a variety of ways, including compounds that act on the enzymes responsible for breaking down (FAAH inhibitors) or synthesizing endocannabinoids, compounds that target the transport mechanism (AM404, *N*-arachidonoylaminophenol), or drugs that directly stimulate or inhibit the CB receptors.

Marijuana is known to stimulate appetite via activation of the CB₁ receptor; thus, efforts have been undertaken to develop CB₁ antagonists for the treatment of obesity. Rimonabant, an inverse agonist of the CB₁

receptor, was initially approved in Europe as an anorectic, but subsequently was withdrawn due to adverse effects, including increased suicidality and depression. It currently remains unclear whether CB₁ receptor antagonism will prove useful for the treatment of appetitive or addictive disorders. However, CB₁ receptor agonists have a wide variety of effects that make them attractive candidates for drug discovery efforts. They stimulate appetite in patients with AIDS, reduce seizure frequency in epilepsy, decrease intraocular pressure in patients with glaucoma, treat nausea caused by cancer chemotherapy (dronabinol; see Table 50–4 and Figure 50–5), and reduce pain (nabilone). This wide range of potential therapeutic benefits has driven the medical marijuana movement such that, in some states, marijuana can be legally used as a therapeutic under a doctor's prescription.

Other Lipid Mediators

Arachidonic acid, normally stored within the cell membrane as a glycerol ester, can be liberated during phospholipid hydrolysis (by pathways involving phospholipases A₂, C, and D). Arachidonic acid can be converted to highly reactive modulators by three major enzymatic pathways (see Chapter 37: *cyclooxygenases* (leading to prostaglandins and thromboxane), *lipoxygenases* (leading to the leukotrienes and other transient catabolites of eicosatetraenoic acid), and *CYPs* (which are inducible and also expressed at low levels in brain)). Arachidonic acid metabolites have been implicated as diffusible modulators in the CNS, possibly involved with the formation of LTP and other forms of neuronal plasticity.

Gases

Nitric Oxide and Carbon Monoxide

Both constitutive and inducible forms of NOS are expressed in the brain. The application of inhibitors of NOS (e.g., methylarginine) and of NO donors (such as nitroprusside) suggests the involvement of NO in a host of CNS phenomena, including LTP, activation of soluble guanylyl cyclase, neurotransmitter release, and enhancement of glutamate (NMDA)-mediated neurotoxicity. CO, generated in neurons or glia, is another diffusible gas that may act as an intracellular messenger stimulating soluble guanylyl cyclase through nonsynaptic actions. NO synthesis and signaling are presented in Chapter 3.

Regulatory Substances

Neurotrophins

The NTs constitute a family of proteins that include NGF, BDNF, NT-3, and NT-4/5, which regulate neuronal proliferation, differentiation, survival, migration, dendritic arborization, synaptogenesis, and activity-dependent

Figure 14-17 Anandamide synthesis and signaling in the CNS. Endocannabinoids, synthesized on demand in stimulated postsynaptic cells, appear to function as a negative feedback system to limit further presynaptic transmitter release.

forms of synaptic plasticity in the developing and mature CNS. NTs are synthesized as pro-NT precursors and processed to smaller, active NTs of about 13–26 kDa. Biological effects of NTs and pro-NTs are mediated by the Trk family of tyrosine kinase receptors and the p75 NT receptor through activation of complex signaling mechanisms summarized by Figure 14-18.

The function of BDNF has been most prominently studied; it modulates the establishment of neuronal circuits that regulate complex behaviors. Transcription and translation of the *Bdnf* gene are exquisitely regulated in the CNS with at least eight distinct promoters that initiate transcription of multiple distinct mRNA transcripts, each containing a full-length BDNF transcript after alternative splicing (Aid et al., 2007). In addition, *Bdnf* transcripts populate two different pools of mRNAs that are localized to distinct subcellular compartments in neurons (Timmusk et al., 1993). Finally, BDNF is initially synthesized as a precursor protein (proBDNF) and, on cleavage of the signal peptide, is sorted into constitutive or regulated secretory vesicles. Conversion of the proBDNF to mature BDNF (mBDNF) occurs prior to release, and mBDNF is thought to be the main biologically active form, although proBDNF has biological activity at the sortilin-p75^{NTR} complex (Bothwell, 2016). There is strong evidence that BDNF plays a role in synaptic plasticity and cognitive function (Greenberg et al., 2009; Lu et al., 2008). As a consequence, dysregulation of BDNF function or expression is implicated in the pathophysiology of age-related neurodegenerative diseases (Pang and Lu, 2004) and susceptibility to

neuropsychiatric disorders such as anxiety and depression. Efforts to deliver NTs or modulate regulation of NT expression are being pursued as treatments for these CNS disorders. Despite these efforts, NTs are not yet used routinely in the clinic.

Neurosteroids

Neuroactive steroids that are synthesized in neuronal tissue are known as neurosteroids. Synthesis of neurosteroids occurs de novo from cholesterol or from circulating hormones (Reddy and Estes, 2016) by several key steroidogenic enzymes that are expressed throughout the vertebrate brain (Do Rego et al., 2009). Based on structural features, the neurosteroids can be categorized into three subtypes:

- pregnane neurosteroids such as allopregnanolone;
- androstane neurosteroids such as androstanediol; and
- sulfated neurosteroids such as DHEAS (Rahmani et al., 2015).

Neurosteroids can mediate an array of biological activities in the CNS through modulation of nuclear hormone receptors or through modulation of membrane receptor activity. More specifically, neurosteroids can allosterically modulate GABA_A receptor complexes; glutamate receptors, including NMDA, AMPA, and KA; nicotinic and muscarinic ACh receptors; as well as sigma and glycine receptors (Do Rego et al., 2009). While little is known regarding the regulation of neurosteroid synthesis in the brain, in vivo studies indicate that these molecules can regulate a variety of

Figure 14–18 *Neurotrophic factor signaling in the CNS.* This schematic is a simplification of NT signaling pathways, which are complex and incompletely understood, with differential expression of NT receptors and NTs in different areas of the nervous system and a host of interacting systems that can affect signaling (Skaper, 2012; Bothwell, 2016). Pro-NTs and NTs interact with membrane receptor dimers of TRK receptors A, B, and C and of p75^{NTR} (a “death receptor” and member of the TNF receptor superfamily) with the specificities indicated by the table at the upper right. Ligand-receptor interactions stimulate signaling pathways that regulate transcription. Formation of an NT-TRK receptor dimer activates intracellular TRK receptor tyrosine kinase activities on the cytosolic tail of the receptor. Tyrosine phosphorylation (Y-P) provides binding sites for the adaptor proteins that lead to activation of the PI3K, MAPK, and PLC_γ-PKC pathways (green boxes), which promote transcriptional regulation in support of neurite extension, cell growth, antiapoptosis, and cell survival. Unliganded p75^{NTR} may also modulate the activity of TRK receptor signaling. Unliganded p75^{NTR} dimers have a basal activity that results in activation of the RhoA pathway, leading to pro-apoptotic signaling (red boxes). NT binding to p75^{NTR} does not initiate intracellular signaling via activation of a receptor tyrosine kinase. Rather, NT binding to p75^{NTR} alters binding of various modulatory factors and causes proteolytic cleavages in the death domain region (DD); these perturbations of p75^{NTR} result in activation of the IRAK/NF-κB and PI3K pathways and inhibition of the RhoA pathway. The net result is neurite extension, cell growth, antiapoptosis, and cell survival. Pro-NT binding to p75^{NTR} in the presence of an accessory protein, sortilin, activates cellular events that permit binding/dimerization of death domain proteins (D), facilitating the activation of the NADE and JNK pathways, leading to inhibition of cell growth and an acceleration of pro-apoptotic events. A host of other signaling proteins can interact along the pathways sketched here. In addition, Trk receptors use signaling endosomes. Following activation near innervated tissues that produce NTs, Trk-NT complexes are endocytosed, and some receptors are recycled to the membrane, while others are destroyed in lysosomes. But, some other receptor-NT complexes (e.g., TrkA-NGF) are stable within the endosome and travel retrogradely along the neuron to the cell body as a signaling endosome. The cytoplasmic tail of an NT-p75^{NTR} complex may be cleaved and release into the cytosol, promoting signaling. IRAK, interleukin-associated kinase; JNK, c-Jun N-terminal kinase; NADE, p75^{NTR}-associated death executor; NF-κB, nuclear factor kappa B; NT, neurotrophin; NTR, neurotrophin receptor; Trk, tropomyosin receptor kinase (tyrosine receptor kinase).

neurophysiological and behavioral processes, including cognition, stress, sleep, and arousal (Engel and Grant, 2001; Reddy and Estes, 2016). Neurosteroids are not currently used in the clinic, but there is evidence to suggest their utility for the treatment of psychiatric disorders, including cognitive deficits and negative symptoms in schizophrenia, anxiety and mood disorders, as well as mood-stabilizing agents in bipolar disorder (Vallee, 2016).

Cytokines

Cytokines are low-molecular-weight proteins that are secreted by many different cell types to modulate key cellular functions. The primary immune effector cells in the CNS are glia, microglia, and astrocytes. These cells can express and release a variety of cytokines, including the IL-1 β and IL-6, TNF- α , and IFN- γ . Constitutive expression of cytokines is required for normal physiological functioning in the brain, particularly regarding the molecular and cellular mechanisms involved in neurite outgrowth, neurogenesis, neuronal survival, synaptic pruning during brain development, the strength of synaptic transmission, and synaptic plasticity. While glial cells are typically thought of as neuroprotective, overexpression or sustained stimulation can cause an elevation of pro-inflammatory cytokines in the brain, resulting in neuroinflammation, an innate immune response mediated by protein complexes known as inflammasomes (Singhal et al., 2014). Acute neuroinflammation involves the release of cytokines and chemokines, is the first line of defense against pathogens in the CNS, and is not likely to cause neuronal damage. Sustained chronic neuroinflammation accompanied by sustained brain exposure to pro-inflammatory cytokines is, however, a factor in the pathogenesis of neurodegenerative and psychiatric illnesses leading to cognitive and memory deficits and behavioral abnormalities (Furtado and Katzman, 2015; Heneka et al., 2015).

ANXIOLYTIC DRUGS

- Clinical Considerations With Anxiolytic Drugs

Depression and anxiety disorders are the most common mental illnesses, each affecting in excess of 15% of the population at some point in the life span. With the advent of more selective and safer drugs, the use of antidepressants and anxiolytics has moved from the exclusive domain of psychiatry to other medical specialties, including primary care. *The relative safety of the majority of commonly used antidepressants and anxiolytics notwithstanding, their optimal use requires a clear understanding of their mechanisms of action, pharmacokinetics, adverse effects, potential drug interactions, and the differential diagnosis of psychiatric illnesses* (Thronson and Pagalilauan, 2014).

Both depression and anxiety can affect an individual patient simultaneously; some of the drugs discussed here are effective in treating both types of disorders, suggesting common underlying mechanisms of pathophysiology and response to pharmacotherapy. In large measure, our current understanding of pathophysiological mechanisms underlying depression and anxiety has been inferred from the mechanisms of action of psychopharmacological compounds, notably their actions on neurotransmission involving serotonin (5HT), NE, and GABA (see Chapter 14). While depression and anxiety disorders comprise a wide range of symptoms, including changes in mood, behavior, somatic function, and cognition, some progress has been made in developing animal models that respond with some sensitivity and selectivity to antidepressant or anxiolytic drugs (Cryan and Holmes, 2005; Xu et al., 2012). The last half-century has seen notable advances in the discovery and development of drugs for treating depression and anxiety (Hillhouse and Porter, 2015).

Characterization of Depressive and Anxiety Disorders

Symptoms of Depression

Depression is classified as major depression (i.e., unipolar depression), persistent depressive disorder (dysthymia), or bipolar I and II disorders (i.e., manic-depressive illness). Bipolar depression and its treatment are discussed in Chapter 16. Lifetime risk of unipolar major depression is approximately 15%. Females are affected with major depression twice as frequently as males (Kessler et al., 1994). Depressive episodes are characterized by sad mood, pessimistic worry, diminished interest in normal activities, mental slowing and poor concentration, insomnia or increased sleep, significant weight loss or gain due to altered eating and activity patterns, psychomotor agitation or retardation, feelings of guilt and worthlessness, decreased energy and libido, and suicidal ideation. In depressive episodes, these symptoms occur most days for a period of at least 2 weeks. In some cases, the primary complaint of patients involves somatic pain or other physical symptoms and can present a diagnostic challenge for primary care physicians. Depressive symptoms also can occur secondary to

other illnesses, such as hypothyroidism, Parkinson disease, and inflammatory conditions. Further, depression often complicates the management of other medical conditions (e.g., severe trauma, cancer, diabetes, and cardiovascular disease, especially myocardial infarction) (Andrews and Nemeroff, 1994).

Depression is underdiagnosed and undertreated (Johansson et al., 2013; Suominen et al., 1998). Given that approximately 10%–15% of those with severe depression attempt suicide at some time (Chen and Dilsaver, 1996), it is important that symptoms of depression be recognized and treated in a timely manner. Furthermore, the response to treatment must be assessed and decisions made regarding continued treatment with the initial drug, dose adjustment, adjunctive therapy, or alternative medication.

Symptoms of Anxiety

Anxiety is a normal human emotion that serves an adaptive function from a psychobiological perspective. Anxiety disorders encompass a constellation of symptoms and include generalized anxiety disorder, obsessive-compulsive disorder, panic disorder, acute stress disorder, PTSD, separation anxiety disorder, social phobia, and specific phobias (Atack, 2003). In general, symptoms of anxiety that lead to pharmacological treatment are those that interfere significantly with normal function. In the psychiatric setting, feelings of fear or dread that are unfocused (e.g., generalized anxiety disorder) or out of scale with the perceived threat (e.g., specific phobias) often require treatment. All of these conditions, with the exception of specific phobias, can be treated with antidepressant medications, particularly SSRIs. Drug treatment includes acute drug administration to manage episodes of anxiety and chronic treatment to manage unrelieved and continuing anxiety disorders. Symptoms of anxiety also are often associated with depression and other medical conditions.

Pharmacotherapy for Depression and Anxiety

In general, antidepressants enhance serotonergic or noradrenergic transmission. Sites of interaction of antidepressant drugs with noradrenergic and serotonergic neurons are depicted in Figure 15–1. Table 15–1 summarizes the actions of the most widely used antidepressants. The most commonly used medications, often referred to as second-generation antidepressants, are the SSRIs and the SNRIs, which have less toxicity and improved safety compared to the first-generation drugs, which include MAOIs and TCAs (Millan, 2006; Rush et al., 2006).

In monoamine systems, neurotransmitter reuptake occurs via presynaptic high-affinity transporter proteins; inhibition of these transporters enhances neurotransmission, presumably by slowing clearance of the transmitter and prolonging its dwell time in the synapse (Shelton and Lester, 2006). Reuptake inhibitors block the neuronal SERT, the neuronal

Abbreviations

ACh: acetylcholine
ADHD: attention-deficit/hyperactivity disorder
 α_2 AR: α_2 adrenergic receptor
BDNF: brain-derived neurotrophic factor
CNS: central nervous system
 C_p : plasma concentration
CREB: cyclic AMP response element binding protein
CYP: cytochrome P450
DA: dopamine
DAT: dopamine transporter
EEG: electroencephalogram
FDA: Food and Drug Administration
GABA: γ -aminobutyric acid
GI: gastrointestinal
GPCR: G protein-coupled receptor
5HT: serotonin (5-hydroxytryptamine)
IP₃: inositol 1,4,5-trisphosphate
MAO: monoamine oxidase
MAOI: monoamine oxidase inhibitor
MDMA: methylenedioxymethamphetamine (Ecstasy)
NE: norepinephrine
NET: NE transporter
NMDA: N-methyl-D-aspartate
PTSD: posttraumatic stress disorder
SERT: 5HT transporter
SNRI: serotonin-norepinephrine reuptake inhibitor
SSRI: selective serotonin reuptake inhibitor
TCA: tricyclic antidepressant
VMAT2: vesicular monoamine transporter

NET, or both. Similarly, TCAs and MAOIs enhance monoaminergic neurotransmission—the TCAs by inhibiting 5HT and NE reuptake via SERT or NET and the MAOIs by inhibiting monoamine metabolism and thereby increasing the levels of neurotransmitter in storage granules available for later release.

Long-term effects of antidepressant drugs evoke regulatory mechanisms that might contribute to the effectiveness of therapy (Shelton, 2000). These responses include altered adrenergic or serotonergic receptor density or sensitivity, altered receptor–G protein coupling and cyclic nucleotide signaling, induction of neurotrophic factors, and increased neurogenesis in the hippocampus (Schmidt and Duman, 2007). Persistent antidepressant effects depend on the continued inhibition of SERT or NET or enhanced serotonergic or noradrenergic neurotransmission achieved by an alternative pharmacological mechanism (Delgado et al., 1991; Heninger et al., 1996). Compelling evidence suggests that sustained signaling via NE or 5HT increases the expression of specific downstream gene products, particularly BDNF, which appears to influence dendritic spine formation, synaptogenesis, and neurogenesis (Duman and Duman, 2015).

Genome-wide association studies have suggested novel pathways that might be exploited for the discovery of antidepressants (Cannon and Keller, 2006; Lin and Lane, 2015). One promising avenue of investigation is the targeting of NMDA glutamatergic receptors with ketamine; this results in a rapid and somewhat persistent antidepressant effect in patients (Abdallah et al., 2015). Other approaches involve enhancing neurogenesis (Pascual-Brazo et al., 2014) or cyclic nucleotide signaling (O'Donnell and Zhang, 2004), which may be impaired in depressed patients (Fujita et al., 2012).

Clinical Considerations With Antidepressant Drugs

The response to antidepressant drug treatment generally has a “therapeutic lag” lasting 3–4 weeks before a measurable therapeutic effect becomes

evident; however, symptoms respond differentially, with sleep disturbances improving sooner and mood and cognitive deficits later (Katz et al., 2004). While some of the lag is pharmacokinetic in nature, it is likely that a component is related to delayed postsynaptic changes. After the successful initial treatment phase, a 6- to 12-month maintenance treatment phase is typical, after which the drug is gradually withdrawn. If a patient is chronically depressed (i.e., has been depressed for more than 2 years), lifelong treatment with an antidepressant is advisable. Approximately two-thirds of patients show a marked decrease in depressive symptoms with an initial course of treatment, with one-third showing complete remission (Rush et al., 2006).

Antidepressants are not recommended as monotherapy for bipolar disorder. These drugs, notably TCAs, SNRIs, and, to a lesser extent, SSRIs, can induce a switch from a depressed episode to a manic or hypomanic episode in some patients (Gijsman et al., 2004; Goldberg and Truman, 2003).

A controversial issue regarding the use of all antidepressants is their relationship to suicide (Mann et al., 2006). Data establishing a clear link between antidepressant treatment and suicide are lacking. However, the FDA has issued a “black-box” warning regarding the use of SSRIs and a number of other antidepressants in children and adolescents due to the possibility of an association between antidepressant treatment and suicide (Isacson and Rich, 2014). For seriously depressed patients, the risk of not being on an effective antidepressant drug outweighs the risk of being treated with one (Gibbons et al., 2007). However, it is important to monitor patients closely, particularly during initial treatment.

Classes of Antidepressant and Antianxiety Agents Selective Serotonin Reuptake Inhibitors

The SSRIs are effective in treating major depression. SSRIs also are anxiolytics with demonstrated efficacy in the treatment of generalized anxiety, panic, social anxiety, and obsessive-compulsive disorders (Rush et al., 2006). Sertraline and paroxetine are approved for the treatment of PTSD. SSRIs also are used for treatment of premenstrual dysphoric syndrome and for preventing vasovagal symptoms in postmenopausal women.

The reuptake of 5HT into presynaptic terminals is mediated by SERT; neuronal uptake is the primary process by which neurotransmission via 5HT is terminated (see Figure 15–1). SSRIs block reuptake and enhance and prolong serotonergic neurotransmission. SSRIs used clinically are relatively selective for inhibition of SERT over NET (Table 15–2).

Treatment with an SSRI causes stimulation of 5HT_{1A} and 5HT₇ autoreceptors on cell bodies in the raphe nucleus and of 5HT_{1D} autoreceptors on serotonergic terminals; this reduces 5HT synthesis and release. With repeated treatment with SSRIs, there is a gradual downregulation and desensitization of these autoreceptor mechanisms. In addition, downregulation of postsynaptic 5HT_{2A} receptors may contribute to antidepressant efficacy directly or by influencing the function of noradrenergic and other neurons via serotonergic heteroreceptors. Other postsynaptic 5HT receptors likely remain responsive to increased synaptic concentrations of 5HT and contribute to the therapeutic effects of the SSRIs.

Later-developing effects of SSRI treatment also may be important in mediating ultimate therapeutic responses. These include sustained increases in cyclic AMP signaling and phosphorylation of the nuclear transcription factor CREB, as well as increases in the expression of trophic factors such as BDNF and increases of neurogenesis from progenitor cells in the hippocampus and subventricular zone (Licznarski and Duman, 2013; Santarelli et al., 2003). Repeated treatment with SSRIs reduces the expression of SERT, resulting in reduced clearance of released 5HT and increased serotonergic neurotransmission (Benmansour et al., 1999).

Serotonin-Norepinephrine Reuptake Inhibitors

Five medications with a nontricyclic structure that inhibit the reuptake of both 5HT and NE have been approved for use in the U.S. for treatment of depression, anxiety disorders, pain, or other specific conditions: venlafaxine and its demethylated metabolite desvenlafaxine; duloxetine; milnacipran, and levomilnacipran.

The SNRIs inhibit both SERT and NET (see Table 15–2) and cause enhanced serotonergic or noradrenergic neurotransmission. Similar

Figure 15-1 Sites of action of antidepressants at noradrenergic (top) and serotonergic (bottom) nerve terminals. SSRIs, SNRIs, and TCAs increase noradrenergic or serotonergic neurotransmission by blocking the NE or 5HT transporter (NET or SERT) at presynaptic terminals. MAOIs inhibit the catabolism of NE and 5HT. Trazodone and related drugs have direct effects on 5HT receptors (5HTRs) that contribute to their clinical effects. Chronic treatment with a number of antidepressants desensitizes presynaptic autoreceptors and heteroreceptors, producing long-lasting changes in monoaminergic neurotransmission. Postreceptor effects of antidepressant treatment, including modulation of GPCR signaling and activation of protein kinases and ion channels, are involved in the mediation of the long-term effects of antidepressant drugs. Li^+ inhibits IP breakdown and thereby enhances its accumulation and sequelae (Ca^{++} mobilization, PKC activation, depletion of cellular I). Li^+ may also alter release of neurotransmitters by a variety of putative mechanisms (see Chapter 16: Hypotheses for the Mechanism of Action of Lithium and Relationship to Anticonvulsants). Note that NE and 5HT may also affect each other's neurons by activating presynaptic receptors that couple to signaling pathways that reduce transmitter release. I, inositol; IP, inositol monophosphate; IP₃, inositol 1,4,5-trisphosphate; PIP₂, phosphatidylinositol 4,5-bisphosphate.

to the action of SSRIs, the initial inhibition of SERT induces activation of 5HT_{1A} and 5HT_{1D} autoreceptors, resulting in a decrease in serotonergic neurotransmission by a negative-feedback mechanism until these serotonergic autoreceptors are desensitized. Then, the enhanced 5HT concentration in the synapse can interact with postsynaptic 5HT receptors. The noradrenergic action of these drugs may contribute to downstream gene expression changes affecting BDNF, Trk-B (tyrosine receptor kinase B), and other neurotrophic factors and their signaling pathways (Shelton, 2000). Repeated treatment with SNRIs reduces the expression of SERT or NET, resulting in reduced neurotransmitter clearance and increased serotonergic or noradrenergic neurotransmission (Zhao et al., 2009).

The SNRIs were developed with the rationale that they might improve overall treatment response compared to SSRIs (Entsuah et al., 2001). The remission rate for venlafaxine appears slightly better than for SSRIs in head-to-head trials. Duloxetine, in addition to being approved for use in the treatment of depression and anxiety, is used for treatment of fibromyalgia and neuropathic pain associated with peripheral neuropathy (Finnerup et al., 2015). Off-label uses include stress urinary incontinence (duloxetine), autism, binge-eating disorders, hot flashes, pain syndromes, premenstrual dysphoric disorders, and PTSD (venlafaxine).

Serotonin Receptor Antagonists

Several antagonists of the 5HT₂ family of receptors are effective antidepressants. These include two close structural analogues, trazodone and nefazodone, as well as mirtazapine and mianserin (not marketed in the U.S.).

The efficacy of trazodone may be somewhat more limited than that of the SSRIs; however, low doses of trazodone (50–200 mg) have been used widely, both alone and concurrently with SSRIs or SNRIs, to treat insomnia. Both mianserin and mirtazapine are quite sedating and are treatments of choice for some depressed patients with insomnia. Trazodone blocks 5HT₂ and α_1 adrenergic receptors. Trazodone also inhibits SERT but is markedly less potent for this action relative to its blockade of 5HT_{2A} receptors. Similarly, the most potent pharmacological action of nefazodone also is the blockade of the 5HT₂ receptors. Both mirtazapine and mianserin potently block histamine H₁ receptors. They also have some affinity for α_2 adrenergic receptors. Their affinities for 5HT_{2A}, 5HT_{2C}, and 5HT₃ receptors are high, although less so than for histamine H₁ receptors. Both of these drugs increase the antidepressant response when combined with SSRIs compared to the action of the SSRIs alone. Vortioxetine is a potent SERT inhibitor and binds to a number of serotonergic receptors, resulting in complex mechanisms of action

0, negligible; 0/+, minimal; +, mild; 2+, moderate; 3+, moderately severe; 4+, severe. Other significant side effects for individual drugs are described in the text. Selegiline transdermal patch approved for depression.

^aHigher and lower doses are sometimes used, depending on patient's needs and response to the drug; see the literature and FDA recommendations.

^bChildren, 0.5–1 mg/kg, up to 70 kg; see black-box warning.

(Bang-Andersen et al., 2011). Vortioxetine is a partial agonist at 5HT_{1A} and 5HT_{1B} receptors and an antagonist at 5HT_{1D}, 5HT₃, and 5HT₇ receptors.

Bupropion

Bupropion has the backbone of β -phenethylamine; it is discussed separately because it appears to act via multiple mechanisms that differ somewhat from the mechanisms of SSRIs and SNRIs (Foley et al., 2006; Gobbi et al., 2003). It enhances both noradrenergic and dopaminergic neurotransmission via inhibition of reuptake by NET and DAT (although its effects on DAT are not potent in animal studies) (see Table 15–2). Bupropion's mechanism of action also may involve the presynaptic release of NE and DA and effects on VMAT2 (see Figure 8–6). The hydroxybupropion metabolite may contribute to the therapeutic effects of the parent compound: This metabolite appears to have a similar pharmacology and is present at substantial levels. Bupropion is indicated for the treatment of depression, prevention of seasonal depressive disorder, and as a smoking cessation treatment (Carroll et al., 2014). Bupropion has effects on sleep EEGs that are opposite those of most antidepressant drugs. Bupropion may improve symptoms of ADHD and has been used off label for neuropathic pain and weight loss. Clinically, bupropion is widely used in combination with SSRIs with the intent of obtaining a greater antidepressant response; however, there are limited clinical data providing strong support for this practice.

Atypical Antipsychotics

In addition to their use in schizophrenia, bipolar depression, and major depression with psychotic disorders, atypical antipsychotics have gained further, off-label use for major depression without psychotic features (Jarema, 2007). The combination of aripiprazole or quetiapine with SSRIs and SNRIs and a combination of olanzapine and the SSRI fluoxetine have been FDA-approved for treatment-resistant major depression (i.e., following an inadequate response to at least two different antidepressants).

The olanzapine-fluoxetine combination is available in fixed-dose combinations of 3, 6, or 12 mg of olanzapine and 25 or 50 mg of fluoxetine. Quetiapine may have either primary antidepressant actions on its own or adjunctive benefit for treatment-resistant depression; it is used off label

for insomnia. The mechanism of action and adverse effects of the atypical antipsychotics are described in Chapter 16. The major risks of these agents are weight gain and metabolic syndrome, a greater problem for quetiapine and olanzapine than for aripiprazole.

Tricyclic Antidepressants

While TCAs have long-established efficacy, they exhibit serious side effects and generally are not used as first-line drugs for the treatment of depression (Hollister, 1981). TCAs and first-generation antipsychotics are synergistic for the treatment of psychotic depression. Tertiary amine TCAs (e.g., doxepin, amitriptyline) have been used for many years in relatively low doses for treating insomnia. In addition, because of the roles of NE and 5HT in nociception, these drugs are commonly used to treat a variety of pain conditions (Finnerup et al., 2015).

The pharmacological action of TCAs is antagonism of SERT and NET (see Table 15–2). In addition to inhibiting NET somewhat selectively (desipramine, nortriptyline, protriptyline, amoxapine) or both SERT and NET (imipramine, amitriptyline), these drugs block other receptors (H₁ histamine, 5HT₂, α_1 adrenergic, and muscarinic cholinergic receptors). Given the comparable activities of clomipramine and SSRIs (see Tables 15–2 and 15–4; see also Decloedt and Stein, 2010), it is tempting to suggest that some combination of these additional pharmacological actions contributes to the therapeutic effects of TCAs and possibly SNRIs. One TCA, amoxapine, also is a DA receptor antagonist; its use, unlike that of other TCAs, poses some risk for the development of extrapyramidal side effects such as tardive dyskinesia.

Monoamine Oxidase Inhibitors

Monoamine oxidases A and B are widely distributed mitochondrial enzymes. MAO activities in the GI tract and liver, mainly MAO_A, protect the body from biogenic amines in the diet. In presynaptic nerve terminals, MAO metabolizes monoamine neurotransmitters via oxidative deamination. MAO_A preferentially metabolizes 5HT and NE and can metabolize DA; MAO_B is effective against 5HT and DA (see Chapters 8 and 13; see also Nestler et al., 2015). MAOIs have efficacy equivalent to that of the TCAs but are rarely used because of their toxicity and major interactions with some drugs (e.g., sympathomimetics and some opioids) and foods (those containing high amounts of tyramine) (Hollister, 1981). The MAOIs approved in the U.S. for treatment of depression include tranylcypromine, phenelzine, and isocarboxazid. These agents irreversibly inhibit both MAO_A and MAO_B, thereby inhibiting the body's capacity to metabolize not only endogenous monoamines such as NE and 5HT but also exogenous biogenic amines such as tyramine. Global inhibition of MAOs increases the bioavailability of dietary tyramine; tyramine-induced NE release can cause marked increases in blood pressure (hypertensive crisis) (see Chapter 8).

This potential to exacerbate the effects of indirectly acting sympathomimetic amines seems to relate mainly to inhibition of MAO_A. Selegiline is an irreversible MAO inhibitor but with specificity for MAO_B at low doses, thereby sparing MAO_A activity in the GI tract and elsewhere, and is less likely to cause this interaction (although at higher doses, selegiline will also inhibit MAO_A). Selegiline is available as a transdermal patch for the treatment of depression; transdermal delivery may reduce the risk for diet-associated hypertensive reactions. Some MAOIs are reversible competitive inhibitors of MAO_A. These agents such as moclobemide and eprobemide, permit tyramine to compete for MAO_A and thus exhibit reduced capacity to potentiate the effects of dietary tyramine; these agents are used elsewhere but are not approved for use in the U.S. (Finberg, 2014).

Pharmacokinetics

The metabolism of most antidepressants is mediated by hepatic CYPs (Table 15–3) (Probst-Schendzielorz et al., 2015). Some antidepressants inhibit the clearance of other drugs by the CYP system, and this possibility of drug interactions should be a significant factor in considering the choice of agents. Likewise, dose considerations have to include awareness of hepatic function (Mauri et al., 2014). While there are genetic polymorphisms that influence antidepressant metabolism, CYP genotyping

TABLE 15–2 ■ SELECTIVITY OF ANTIDEPRESSANTS AT THE HUMAN BIOGENIC AMINE TRANSPORTERS

DRUG	SELECTIVITY	DRUG	SELECTIVITY
NE SELECTIVE	NET vs. SERT	5HT SELECTIVE	SERT vs. NET
Oxaprotiline	800	S-Citalopram	7127
Maprotiline	532	R,S-Citalopram	3643
Viloxazine	109	Sertraline	1390
Nomifensine	64	Fluvoxamine	591
Desipramine	22	Paroxetine	400
Protriptyline	14	Fluoxetine	305
Atomoxetine	12	Clomipramine	123
Reboxetine	8.3	Venlafaxine	116
Nortriptyline	4.2	Zimelidine	60
Amoxapine	3.6	Trazodone	52
Doxepin	2.3	Imipramine	26
DA SELECTIVE	DAT vs. NET	Amitriptyline	8.0
Bupropion	1000	Duloxetine	7.0
		Dothiepin	5.5
		Milnacipran	1.6

Selectivity is defined as ratio of the relevant K_i values (SERT/NET, NET/SERT, NET/DAT). Bupropion is selective for the DAT relative to the NET and SERT.

Data from Frazer, 1997; Owens et al., 1997; and Leonard and Richelson, 2000.

TABLE 15-3 ■ DISPOSITION OF ANTIDEPRESSANTS

DRUG	ELIMINATION $t_{1/2}$ (h) OF PARENT DRUG ($t_{1/2}$ of active metabolite)	TYPICAL C_p (ng/mL)	PREDOMINANT CYP INVOLVED IN METABOLISM
Tricyclic antidepressants

Nefazodone	2–4	—	3A3/4
Reboxetine	12	—	—
Trazodone	6	800–1600	2D6

Values shown are elimination $t_{1/2}$ values for a number of clinically used antidepressant drugs; numbers in parentheses are $t_{1/2}$ values of active metabolites. Fluoxetine (2D6), fluvoxamine (1A2, 2C8, 3A3/4), paroxetine (2D6), and nefazodone (3A3/4) are potent inhibitors of CYPs; sertraline (2D6), citalopram (2C19), and venlafaxine are less-potent inhibitors. Plasma concentrations are those observed at typical clinical doses.

Information sources: FDA-approved package inserts and Appendix II of this book.

has not yet been shown to have a practical influence on choice of drug treatment in clinical settings (Dubovsky, 2015).

Selective Serotonin Reuptake Inhibitors

All of the SSRIs are orally active and possess elimination half-lives consistent with once-daily dosing (Hiemke and Hartter, 2000). In the case of fluoxetine, the combined action of the parent and the demethylated metabolite norfluoxetine allows for a once-weekly formulation. CYP2D6 is involved in the metabolism of most SSRIs, and the SSRIs are at least moderately potent inhibitors of this isoenzyme. This creates a significant potential for drug interaction for postmenopausal women taking the

breast cancer drug and estrogen antagonist tamoxifen (see Chapter 68). Because venlafaxine and desvenlafaxine are weak inhibitors of CYP2D6, these antidepressants are not contraindicated in this clinical situation. However, care should be used in combining SSRIs with drugs that are metabolized by CYPs. SSRIs such as escitalopram and citalopram that exhibit an age-dependent decrease in CYP2C19 metabolism should be dosed with care in elderly patients.

Serotonin-Norepinephrine Reuptake Inhibitors

Both immediate-release and extended-release (tablet or capsule) preparations of venlafaxine result in steady-state levels of drug in plasma within 3 days. The elimination half-lives for the parent venlafaxine and its active and major metabolite desmethylvenlafaxine are 5 and 11 h, respectively. Desmethylvenlafaxine is eliminated by hepatic metabolism and by renal excretion. Venlafaxine dose reductions are suggested for patients with renal or hepatic impairment. Duloxetine has a $t_{1/2}$ of 12 h. Duloxetine is not recommended for those with end-stage renal disease or hepatic insufficiency.

Serotonin Receptor Antagonists

Mirtazapine has an elimination $t_{1/2}$ of 16–30 h. Thus, dose changes are suggested no more often than 1–2 weeks. The recommended initial dosing of mirtazapine is 15 mg/d, with a maximal recommended dose of 45 mg/d. Clearance of mirtazapine is decreased in the elderly and in patients with moderate-to-severe renal or hepatic impairment. Pharmacokinetics and adverse effects of mirtazapine may have an enantiomer-selective component (Brockmüller et al., 2007). Steady-state trazodone is observed within 3 days following a dosing regimen. Trazodone typically is started at 150 mg/d in divided doses, with 50-mg increments every 3–4 days. The maximally recommended dose is 400 mg/d for outpatients and 600 mg/d for inpatients. Nefazodone has a $t_{1/2}$ of only 2–4 h; its major metabolite hydroxynefazodone has a $t_{1/2}$ of 1.5–4 h.

Bupropion

Bupropion elimination has a $t_{1/2}$ of 21 h and involves both hepatic and renal routes. Patients with severe hepatic cirrhosis should receive a maximum dose of 150 mg every other day; consideration for a decreased dose should also be made in cases of renal impairment.

Tricyclic Antidepressants

The TCAs, or their active metabolites, have plasma half-lives of 8–80 h; this makes once-daily dosing possible for most of the compounds (Rudorfer and Potter, 1999). Steady-state concentrations occur within several days to several weeks of beginning treatment, as a function of the $t_{1/2}$. TCAs are largely eliminated by hepatic CYPs (see Table 15-3). Dosage adjustments of TCAs are typically made according to a patient's clinical response, not based on plasma levels. Nonetheless, monitoring the plasma exposure has an important relationship to treatment response: There is a relatively narrow therapeutic window. About 7% of patients metabolize TCAs slowly due to a variant CYP2D6 isoenzyme, causing a 30-fold difference in plasma concentrations among different patients given the same TCA dose. To avoid toxicity in “slow metabolizers,” plasma levels should be monitored and doses adjusted downward.

Monoamine Oxidase Inhibitors

The MAOIs are metabolized by acetylation. A significant portion of the population (50% of the Caucasian population and an even higher percentage among Asians) are “slow acetylators” (see Table 7-2 and Figure 60-4) and will exhibit elevated plasma levels. The nonselective MAOIs used in the treatment of depression are irreversible inhibitors; thus, it takes up to 2 weeks for MAO activity to recover, even though the parent drug is excreted within 24 h (Livingston and Livingston, 1996). Recovery of normal enzyme function is dependent on synthesis and transport of new MAO to monoaminergic nerve terminals.

Adverse Effects

Selective Serotonin Reuptake Inhibitors

The SSRIs have no major cardiovascular side effects. The SSRIs are generally free of antimuscarinic side effects (dry mouth, urinary retention,

confusion) and do not block α adrenergic receptors; most SSRIs, with the exception of paroxetine, do not block histamine receptors and usually are not sedating (Table 15–4).

Adverse side effects of SSRIs from excessive stimulation of brain 5HT₂ receptors may result in insomnia, increased anxiety, irritability, and decreased libido, effectively worsening prominent depressive symptoms. Excess activity at spinal 5HT₂ receptors causes sexual side effects, including erectile dysfunction, anorgasmia, and ejaculatory delay (Clayton et al., 2014). These effects may be more prominent with paroxetine (Vaswani et al., 2003). Aspects of sexual dysfunction can be treated in both men and women with the phosphodiesterase 5 inhibitor sildenafil (Nurnberg, 2001; Nurnberg et al., 2008; see also Chapter 45). Stimulation of 5HT₃ receptors in the CNS and periphery contributes to GI effects, which are usually limited to nausea but may include diarrhea and emesis. Some patients experience an increase in anxiety, especially with the initial dosing of SSRIs. With continued treatment, some patients also report a dullness of intellectual abilities and concentration. In general, there is not a strong relationship between SSRI serum concentrations and therapeutic efficacy. Thus, dosage adjustments are based more on evaluation of clinical response and management of side effects.

TABLE 15–4 ■ POTENCIES OF SELECTED ANTIDEPRESSANTS AT MUSCARINIC, HISTAMINE H₁, AND α_1 ADRENERGIC RECEPTORS

DRUG	RECEPTOR TYPE		
	MUSCARINIC CHOLINERGIC	HISTAMINE H ₁	α_1 ADRENERGIC
Amitriptyline	18	1.1	27
Amoxapine	1000	25	50
Atomoxetine	≥1000	≥1000	≥1000
Bupropion	40,000	6700	4550
R,S-Citalopram	1800	380	1550
S-Citalopram	1240	1970	3870
Clomipramine	37	31.2	39
Desipramine	196	110	130
Doxepin	83.3	0.24	24
Duloxetine	3000	2300	8300
Fluoxetine	2000	6250	5900
Fluvoxamine	24,000	>100,000	7700
Imipramine	91	11.0	91
Maprotiline	560	2.0	91
Mirtazapine	670	0.1	500
Nefazodone	11,000	21	25.6
Nortriptyline	149	10	58.8
Paroxetine	108	22,000	>100,000
Protriptyline	25	25	130
Reboxetine	6700	312	11,900
Sertraline	625	24,000	370
Trazodone	>100,000	345	35.7
Trimipramine	59	0.3	23.8
Venlafaxine	>100,000	>100,000	>100,000

Values are experimentally determined potencies (K_i values, nM) for binding to receptors that contribute to common side effects of clinically used antidepressant drugs: muscarinic cholinergic receptors (e.g., dry mouth, urinary retention, confusion); histamine H₁ receptors (sedation); and α_1 adrenergic receptors (orthostatic hypotension, sedation).

Data from Leonard and Richelson, 2000.

Sudden withdrawal of antidepressants can precipitate a discontinuation syndrome (Harvey and Slabbert, 2014). For SSRIs or SNRIs, the symptoms of withdrawal may include dizziness, headache, nervousness, nausea, and insomnia. This withdrawal syndrome appears most intense for paroxetine and venlafaxine due to their relatively short half-lives and, in the case of paroxetine, lack of active metabolites. Conversely, the active metabolite of fluoxetine, norfluoxetine, has such a long $t_{1/2}$ (1–2 weeks) that few patients experience any withdrawal symptoms with discontinuation of fluoxetine.

Unlike the other SSRIs, paroxetine is associated with an increased risk of congenital cardiac malformations when administered in the first trimester of pregnancy (Gadot and Koren, 2015). Venlafaxine also is associated with an increased risk of perinatal complications.

Serotonin-Norepinephrine Reuptake Inhibitors

The SNRIs have a side-effect profile similar to that of the SSRIs, including nausea, constipation, insomnia, headaches, and sexual dysfunction. The immediate-release formulation of venlafaxine can induce sustained diastolic hypertension (diastolic blood pressure > 90 mm Hg at consecutive weekly visits) in 10%–15% of patients at higher doses; this risk is reduced with the extended-release form. This effect of venlafaxine may not be associated simply with inhibition of NET because duloxetine does not share this side effect.

Serotonin Receptor Antagonists

Regarding the serotonin receptor antagonists, the main side effects of mirtazapine, seen in more than 10% of the patients, are somnolence, increased appetite, and weight gain. A rare side effect of mirtazapine is agranulocytosis. Trazodone use is associated with priapism in rare instances. Nefazodone was voluntarily withdrawn from the market in several countries after rare cases of liver failure were associated with its use. In the U.S., nefazodone is marketed with a black-box warning regarding hepatotoxicity.

Bupropion

Typical side effects associated with bupropion include anxiety, mild tachycardia and hypertension, irritability, and tremor. Other side effects include headache, nausea, dry mouth, constipation, appetite suppression, insomnia, and, rarely, aggression, impulsivity, and agitation. Seizures are dependent on dose and C_p , with seizures occurring rarely within the recommended dose range. Bupropion should be avoided in patients with seizure disorders as well as those with bulimia due to an increased risk of seizures (Horne et al., 1988; Noe et al., 2011). At doses higher than that recommended for depression (450 mg/d), the risk of seizures increases significantly. The use of extended-release formulations often blunts the maximum concentration observed after dosing and minimizes the chance of reaching drug levels associated with an increased risk of seizures.

Tricyclic Antidepressants

The TCAs are potent antagonists at histamine H₁ receptors, and this antagonism contributes to the sedative effects of TCAs (see Table 15–4). Antagonism of muscarinic ACh receptors contributes to cognitive dulling as well as a range of adverse effects mediated by the parasympathetic nervous system (blurred vision, dry mouth, tachycardia, constipation, difficulty urinating). Some tolerance does occur for these anticholinergic effects. Antagonism of α_1 adrenergic receptors contributes to orthostatic hypotension and sedation. Weight gain is another side effect of this class of antidepressants.

The TCAs have quinidine-like effects on cardiac conduction that can be life threatening with overdose and limit the use of TCAs in patients with heart disease. This is the primary reason that only a limited supply should be available to the patient at any given time. Like other antidepressant drugs, TCAs also lower the seizure threshold.

Monoamine Oxidase Inhibitors

Hypertensive crisis resulting from food or drug interactions is one of the life-threatening toxicities associated with use of the MAOIs (Rapaport, 2007). Foods containing tyramine are a contributing factor. MAO_A within

the intestinal wall and MAO_A and MAO_B in the liver normally degrade dietary tyramine. When MAO_A is inhibited, tyramine can enter the systemic circulation and be taken up into adrenergic nerve endings, where it causes release of catecholamines from storage vesicles. The released catecholamines stimulate postsynaptic receptors in the periphery, increasing blood pressure to dangerous levels. The concurrent use of MAOIs and medications that contain sympathomimetic compounds also results in a potentially life-threatening elevation of blood pressure. In comparison to tranylcypromine and isocarboxazid, the selegiline (selective for MAO_B) transdermal patch is better tolerated and safer, as are the reversible, competitive inhibitors moclobemide and eprobemide. Another serious, life-threatening issue with chronic administration of MAOIs is hepatotoxicity.

Drug Interactions

Many of these drugs are metabolized by hepatic CYPs, especially CYP2D6. Thus, other agents that are substrates or inhibitors of CYP2D6 can increase plasma concentrations of the primary drug. The combination of other classes of antidepressant agents with MAOIs is inadvisable and can lead to *serotonin syndrome*, a serious triad of abnormalities consisting of cognitive, autonomic, and somatic effects due to excess serotonin. Symptoms of the serotonin syndrome include hyperthermia, muscle rigidity, myoclonus, tremors, autonomic instability, confusion, irritability, and agitation; this can progress toward coma and death.

Selective Serotonin Reuptake Inhibitors

Paroxetine and, to a lesser degree, fluoxetine are potent inhibitors of CYP2D6 (Hiemke and Hartter, 2000). The other SSRIs, outside of fluvoxamine, are at least moderate inhibitors of CYP2D6. This inhibition can result in disproportionate increases in plasma concentrations of drugs metabolized by CYP2D6 when doses of these drugs are increased. Fluvoxamine directly inhibits CYP1A2 and CYP2C19; fluoxetine and fluvoxamine also inhibit CYP3A4. A prominent interaction is the increase in TCA exposure that may be observed during coadministration of TCAs and SSRIs.

The MAOIs enhance the effects of SSRIs due to inhibition of 5HT metabolism. Administration of these drugs together can produce synergistic increases in extracellular brain 5HT, leading to the serotonin syndrome (see previous discussion). Other drugs that may induce the serotonin syndrome include substituted amphetamines such as MDMA (Ecstasy), which directly releases 5HT from nerve terminals.

The SSRIs should not be started until at least 14 days following discontinuation of treatment with an MAOI; this allows for synthesis of the new MAO. For all SSRIs but fluoxetine, at least 14 days should pass prior to beginning treatment with an MAOI following the end of treatment with an SSRI. Because the active metabolite norfluoxetine has a $t_{1/2}$ of 1–2 weeks, at least 5 weeks should pass between stopping fluoxetine and beginning an MAOI.

Serotonin-Norepinephrine Reuptake Inhibitors

While a 14-day period is recommended between ending MAOI therapy and starting venlafaxine treatment, an interval of 7 days is considered safe. Duloxetine has a similar interval for initiation following MAOI therapy; conversely, only a 5-day waiting period is needed before beginning MAOI treatment after ending duloxetine. Failure to observe these required waiting periods can result in the serotonin syndrome.

Serotonin Receptor Antagonists

Trazodone dosing may need to be lowered when given together with drugs that inhibit CYP3A4. Mirtazapine is metabolized by CYPs 2D6, 1A2, and 3A4 and may interact with drugs that share these CYP pathways, requiring mutual dose reductions. Trazodone and nefazodone are weak inhibitors of 5HT uptake and should not be administered with MAOIs due to concerns about serotonin syndrome.

Bupropion

The major route of metabolism for bupropion is CYP2B6. Bupropion and its metabolite hydroxybupropion can inhibit CYP2D6, the CYP responsible for metabolism of several SSRIs (Table 15–3) as well as some β blockers

and haloperidol, among others. Thus, the potential for interactions of bupropion with SSRIs and other drugs metabolized by CYP2D6 should be kept in mind until the safety of the combination is firmly established.

Tricyclic Antidepressants

Drugs that inhibit CYP2D6, such as bupropion and SSRIs, may increase plasma exposures of TCAs. TCAs can potentiate the actions of sympathomimetic amines and should not be used concurrently with MAOIs or within 14 days of stopping MAOIs. *A number of other drugs have similar side-effect profiles as TCAs, and concurrent use risks enhanced side effects* (see previous discussion in Adverse Effects); this includes phenothiazine antipsychotic agents, type 1C antiarrhythmic agents, and other drugs with antimuscarinic, antihistaminic, and α adrenergic antagonistic effects.

Monoamine Oxidase Inhibitors

Serotonin syndrome is the most serious drug interaction for the MAOIs (see Adverse Effects). The most common cause of serotonin syndrome in patients taking MAOIs is the accidental coadministration of a 5HT reuptake-inhibiting antidepressant or tryptophan. Other serious drug interactions include those with meperidine and tramadol. MAOIs also interact with sympathomimetics such as pseudoephedrine, phenylephrine, oxymetazoline, phenylpropanolamine, and amphetamine; these are commonly found in cold and allergy medication and diet aids and should be avoided by patients taking MAOIs. Likewise, patients on MAOIs must avoid foods containing high levels of tyramine: soy products, dried meats and sausages, dried fruits, home-brewed and tap beers, red wine, pickled or fermented foods, and aged cheeses (FDA, 2010).

ANXIOLYTIC DRUGS

Primary treatments for anxiety-related disorders include the SSRIs, SNRIs, benzodiazepines, buspirone, and β adrenergic antagonists (Atack, 2003). The SSRIs and the SNRI venlafaxine are well tolerated with a reasonable side-effect profile; in addition to their documented antidepressant activity, they have anxiolytic activity with chronic treatment. The benzodiazepines are effective anxiolytics as both acute and chronic treatment. There is concern regarding their use because of their potential for dependence and abuse as well as negative effects on cognition and memory. Buspirone, like the SSRIs, is effective following chronic treatment. It acts, at least in part, via the serotonergic system, where it is a partial agonist at 5HT_{1A} receptors. Buspirone also has antagonistic effects at DA D₂ receptors, but the relationship between this effect and its clinical actions is uncertain. β Adrenergic antagonists, particularly those with higher lipophilicity (e.g., propranolol and nadolol), are occasionally used for performance anxiety such as fear of public speaking; their use is limited due to significant side effects, such as hypotension.

Antihistamines and sedative-hypnotic agents have been tried as anxiolytics but are generally not recommended because of their side-effect profiles and the availability of superior drugs. Hydroxyzine, which produces short-term sedation, is used in patients who cannot use other types of anxiolytics (e.g., those with a history of drug or alcohol abuse where benzodiazepines would be avoided). Chloral hydrate has been used for situational anxiety, but there is a narrow dose range where anxiolytic effects are observed in the absence of significant sedation; therefore, the use of chloral hydrate is not recommended.

Clinical Considerations With Anxiolytic Drugs

The choice of pharmacological treatment of anxiety is dictated by the specific anxiety-related disorders and the clinical need for acute anxiolytic effects (Millan, 2003). Among the commonly used anxiolytics, only the benzodiazepines and β adrenergic antagonists are effective acutely; the use of β adrenergic antagonists is generally limited to treatment of situational anxiety. Chronic treatment with SSRIs, SNRIs, and buspirone is required to produce and sustain anxiolytic effects. When an immediate anxiolytic effect is desired, benzodiazepines are typically selected.

Benzodiazepines, such as alprazolam, chlordiazepoxide, clonazepam, clorazepate, diazepam, lorazepam, and oxazepam, are effective in the

treatment of generalized anxiety disorder, panic disorder, and situational anxiety. In addition to their anxiolytic effects, benzodiazepines produce sedative, hypnotic, anesthetic, anticonvulsant, and muscle relaxant effects. The benzodiazepines also impair cognitive performance and memory, adversely affect motor control, and potentiate the effects of other sedatives, including alcohol. The anxiolytic effects of this class of drugs are mediated by allosteric interactions with the pentameric benzodiazepine-GABA_A receptor complex, in particular GABA_A receptors comprising $\alpha 2$, $\alpha 3$, and $\alpha 5$ subunits (Chapters 14 and 19). The primary effect of the anxiolytic benzodiazepines is to enhance the inhibitory effects of the neurotransmitter GABA.

One area of concern regarding the use of benzodiazepines in the treatment of anxiety is the potential for habituation, dependence, and abuse. Patients with certain personality disorders or a history of drug or alcohol abuse are particularly susceptible. However, the risk of dependence must be balanced with the need for treatment because benzodiazepines are effective in both short- and long-term treatment of patients with sustained or recurring bouts of anxiety. Further, premature discontinuation of benzodiazepines, in the absence of other pharmacological treatment, results in a high rate of relapse. Withdrawal of benzodiazepines after chronic treatment, particularly with benzodiazepines with short durations of action, can include increased anxiety and seizures. For this reason, it is important that discontinuation be carried out in a gradual manner.

Benzodiazepines cause many adverse effects, including sedation, mild memory impairments, decreased alertness, and slowed reaction time (which may lead to accidents). Memory problems can include visual-spatial deficits but will manifest clinically in a variety of ways, including difficulty in word finding. Occasionally, paradoxical reactions can occur with benzodiazepines, such as increases in anxiety, sometimes reaching panic attack proportions. Other pathological reactions can include irritability, aggression, or behavioral disinhibition. Amnesic reactions (i.e., loss of memory for particular periods) can also occur. Benzodiazepines should not be used in pregnant women; there have been rare reports of craniofacial defects. In addition, benzodiazepines taken prior to delivery may result in sedated, underresponsive newborns and prolonged withdrawal reactions. In the elderly, benzodiazepines increase the risk for falls and must be used cautiously. These drugs are safer than classical sedative-hypnotics in overdose and typically are fatal only if combined with other CNS depressants.

Benzodiazepines have some abuse potential, although their capacity for abuse is considerably below that of other classical sedative-hypnotic agents. When these agents are abused, it is generally in a multidrug abuse pattern, frequently connected with failed attempts to control anxiety.

Tolerance to the anxiolytic effects develops with chronic administration, with the result that some patients escalate the dose of benzodiazepines over time. Ideally, benzodiazepines should be used for short periods of time and in conjunction with other medications (e.g., SSRIs) or evidence-based psychotherapies (e.g., cognitive behavioral therapy for anxiety disorders).

The SSRIs and the SNRI venlafaxine are first-line treatments for most types of anxiety disorders, except when an acute drug effect is desired; fluvoxamine is approved only for obsessive-compulsive disorder. As for their antidepressant actions, the anxiolytic effects of these drugs become manifest following chronic treatment. Other drugs with actions on serotonergic neurotransmission, including trazodone, nefazodone, and mirtazapine, also are used in the treatment of anxiety disorders. Details regarding the pharmacology of these classes were presented previously in this chapter.

Both SSRIs and SNRIs are beneficial in specific anxiety conditions, such as generalized anxiety disorder, social phobias, obsessive-compulsive disorder, and panic disorder. These effects appear to be related to the capacity of serotonin to regulate the activity of brain structures, such as the amygdala and locus coeruleus, that are thought to be involved in the genesis of anxiety. Interestingly, the SSRIs and SNRIs often will produce some increases in anxiety in the short term that dissipate with time. Therefore, the maxim “start low and go slow” is indicated with anxious patients; however, many patients with anxiety disorders ultimately will require doses that are about the same as those required for the treatment of depression. Anxious patients appear to be particularly prone to severe discontinuation reactions with certain medications such as venlafaxine and paroxetine; therefore, slow off-tapering is required.

Buspirone is used in the treatment of generalized anxiety disorder (Goodman, 2004). Like the SSRIs, buspirone requires chronic treatment for effectiveness. Also, like the SSRIs, buspirone lacks many of the other pharmacological effects of the benzodiazepines: It is not an anticonvulsant, muscle relaxant, or sedative, and it does not impair psychomotor performance or result in dependence. Buspirone is primarily effective in the treatment of generalized anxiety disorder, but not for other anxiety disorders. In fact, patients with panic disorder often note an increase in anxiety acutely following initiation of buspirone treatment; this may be the result of the fact that buspirone causes increased firing rates of the locus coeruleus, which is thought to underlie part of the pathophysiology of panic disorder.

CLINICAL SUMMARY: TREATMENT OF MANIA

Treatment of Psychosis

Psychosis is a symptom of mental illnesses characterized by a distorted or nonexistent sense of reality. Psychotic disorders have different etiologies, each of which demands a unique treatment approach. Common psychotic disorders include mood disorders (major depression or mania) with psychotic features, substance-induced psychosis, dementia with psychotic features, delirium with psychotic features, brief psychotic disorder, delusional disorder, schizoaffective disorder, and schizophrenia.

Schizophrenia has a worldwide prevalence of 1% and is considered the prototypic disorder for understanding the phenomenology of psychosis and the impact of antipsychotic treatment, but patients with schizophrenia exhibit features that extend beyond those seen in other psychotic illnesses. Hallucinations, delusions, disorganized speech, and disorganized or agitated behavior are psychotic symptoms found individually, and occasionally together, in all psychotic disorders and are typically responsive to pharmacotherapy. In addition to *positive symptoms*, schizophrenia patients also suffer from *negative symptoms* (apathy, avolition, alogia) and *cognitive deficits*, with the latter the most disabling aspect of the disorder (Young and Geyer, 2015).

The Dopamine Hypothesis

The syntheses of chlorpromazine (1950) and haloperidol (1958) allowed Carlsson to deduce that postsynaptic DA receptor antagonism was their common mechanism. Carlsson's discovery informed the development of numerous *typical* or first-generation antipsychotic drugs that were found to act specifically at D_2 receptors (Seeman, 2013). The discovery of clozapine's unique clinical features and binding profile stimulated development of second-generation antipsychotics that potently antagonize the $5HT_{2A}$ receptor while possessing less affinity for D_2 receptors than typical antipsychotic agents, resulting in antipsychotic efficacy with lower potential for extrapyramidal side effects. Subsequent research led to the development of agents with D_2 partial agonist properties that act as modulators of dopaminergic neurotransmission (Meyer and Leckband, 2013).

The DA model of antipsychotic action has limitations: It does not explain the psychotomimetic effects of LSD (e.g., a potent $5HT_{2A}$ receptor agonist) or the effects of phencyclidine and ketamine, antagonists of the NMDA glutamate receptor. However, phencyclidine and ketamine indirectly act to stimulate DA availability by decreasing the glutamate-mediated tonic inhibition of DA release in the mesolimbic DA pathway (Howes et al., 2015). Exploration of nondopaminergic antipsychotic mechanisms led to approval of pimavanserin, a potent $5HT_{2A}$ inverse agonist for treatment

of Parkinson disease psychosis (PDP). Phase 3 trials of glutamate modulators have not been successful. Except for pimavanserin, all approved antipsychotic agents share a common mechanism of action: direct modulation of D_2 receptor activity (Figure 16–1).

Mechanism of Action of D_2 Receptors

Dopamine D_2 receptors share common properties with D_3 and D_4 receptors in that each is linked to inhibitory G protein G_i , and receptor stimulation results in decreased cyclic AMP production and thus a reduction in intracellular cyclic AMP (Figure 16–1), whereas agonists at D_1 and D_5 receptors stimulate the G_s -adenylyl cyclase-cyclic AMP pathway (Seeman, 2013). Antipsychotic actions at D_2 receptors are also mediated through non-G protein, particularly via modulation of the activity of GSK-3 β through a β -arrestin-2/PKB/PP2A signaling complex (see Chapter 3). Atypical antipsychotics antagonize D_2 receptor/ β -arrestin-2 interactions more than G protein-dependent signaling, but typical antipsychotics inhibit both pathways with similar efficacy (Urs et al., 2012).

Review of Relevant Pathophysiology

Not all psychosis is schizophrenia, and the pathophysiology relevant to effective schizophrenia treatment may not apply to other psychotic disorders. The effectiveness of dopamine D_2 antagonists for the positive symptoms of psychosis seen in most psychotic disorders suggests a common etiology related to excessive dopaminergic neurotransmission in mesolimbic DA pathways (i.e., the associative striatum) (Kuepper et al., 2012).

Delirium, Dementia, and Parkinson Disease Psychosis

The psychoses related to delirium and dementia, particularly dementia of the Alzheimer type, may share a common etiology: deficiency in muscarinic cholinergic neurotransmission due to medications, age- or disease-related neuronal loss (Koppel and Greenwald, 2014; Salahudeen et al., 2014). Delirium may have precipitants besides medication, such as infection, electrolyte imbalance, metabolic derangement, all of which require specific treatment, in addition to removal of anticholinergic medications (Khan et al., 2012). The development of PDP is due to Lewy body associated loss of serotonin raphe neurons and subsequent upregulation of cortical $5HT_{2A}$ receptors. The specific treatment for PDP is pimavanserin, a selective $5HT_{2A}$ inverse agonist devoid of DA receptor activity (Cummings et al., 2014).

Schizophrenia

Schizophrenia is a neurodevelopmental disorder with complex genetics and incompletely understood pathophysiology. In addition to environmental exposures such as fetal second-trimester infectious or nutritional

Abbreviations

ACEI:	angiotensin-converting enzyme inhibitor
AUC:	area under the curve
CBC:	complete blood cell count

TH:	tyrosine hydroxylase
TSH:	thyrotropin (previously thyroid-stimulating hormone)
VMAT2:	vesicular monoamine transporter 2

insults, birth complications, and substance abuse in the late teen or early adult years, over 150 genes appear to contribute to schizophrenia risk. Implicated are genes that regulate neuronal migration, synaptogenesis, cellular adhesion, and neurite outgrowth (*neuregulin 1*, *disrupted-in-schizophrenia-1*); synaptic DA availability (*Val [108/158]Met polymorphism of catechol-O-methyltransferase*, which increases DA catabolism); glutamate and DA neurotransmission (*dystrobrevin binding protein 1* or *dysbindin*); and nicotinic activity (*$\alpha 7$ -receptor polymorphisms*) (Escudero and Johnstone, 2014). Patients with schizophrenia also have increased rates of genome-wide DNA microduplications, termed *copy number variants*, and *epigenetic* changes, including disruptions in DNA methylation patterns in various brain regions (Gavin and Floreani, 2014). This genetic variability is consistent with the heterogeneity of the clinical disease and suggests that any one specific mechanism is unlikely to account for large amounts of disease risk.

Review of Psychosis Pathology and the General Goals of Pharmacotherapy

Common to all psychotic disorders are positive symptoms, which may include hallucinatory behavior, disturbed thinking, and behavioral dyscontrol. Common to effective schizophrenia treatments is an impact on dopaminergic neurotransmission (Figure 16–1).

Short-Term Antipsychotic Treatment

For many psychotic disorders, the symptoms are transient, and antipsychotic drugs are only administered during and shortly after periods of symptom exacerbation. Patients with delirium, dementia, major depressive disorder or mania with psychotic features, substance-induced psychoses, and brief psychotic disorder will typically receive short-term antipsychotic treatment that is discontinued after resolution of psychotic symptoms, although the duration may vary considerably based on the etiology. Bipolar patients in particular may have antipsychotic treatment extended for several months after resolution of mania and psychosis because antipsychotic medications are effective in reducing mania relapse. Chronic psychotic symptoms in patients with dementia may also be amenable to drug therapy, but potential benefits must be balanced with the documented risk of mortality and cerebrovascular events associated with the use of antipsychotic medications in this patient population (Maust et al., 2015).

Long-Term Antipsychotic Treatment

Delusional disorder, schizophrenia, schizoaffective disorder, and PDP are chronic diseases that require long-term antipsychotic treatment. For schizophrenia and schizoaffective disorder in particular, the goal of antipsychotic treatment is to maximize functional recovery by decreasing the severity of positive symptoms and their behavioral influence and possibly improving negative symptoms and remediating cognitive dysfunction, although the impact on the last two symptom domains is modest at best. Continuous antipsychotic treatment reduces 1-year relapse rates from 80% among unmedicated patients to about 15% (Zipursky et al., 2014). Poor adherence to antipsychotic treatment increases relapse risk and is often related to adverse drug events, cognitive dysfunction, substance use, and limited illness insight (Remington et al., 2014).

Regardless of the underlying pathology, the immediate goal of antipsychotic treatment is a decrease in acute symptoms that induce patient distress, particularly behavioral symptoms (e.g., hostility, agitation) that may present a danger to the patient or others. The dosing, route of administration, and choice of antipsychotic depend on the underlying disease state, clinical acuity, drug-drug interactions with concomitant medications, and patient sensitivity to short- or long-term adverse effects. With the exception of pimavanserin for PDP, and clozapine's superior efficacy in treatment-refractory schizophrenia, neither the clinical presentation nor biomarkers predicts the likelihood of response to a specific antipsychotic class or agent. As a result, avoidance of adverse effects based on patient and drug characteristics and exploitation of certain medication properties (e.g., sedation related to histamine H_1 or muscarinic antagonism) are the principal determinants for choosing initial antipsychotic therapy (Leucht et al., 2013).

Short-Term Treatment

Delirium, Dementia, and Parkinson Disease Psychosis

Psychotic symptoms of delirium or dementia are generally treated with low medication doses, although doses may have to be repeated at frequent intervals initially to achieve adequate behavioral control. Despite widespread clinical use, no antipsychotic has received approval for dementia-related psychosis. Moreover, all antipsychotic drugs carry warnings that they may increase mortality in this setting (Maust et al., 2015). Because anticholinergic drug effects may worsen delirium and dementia, high-potency typical antipsychotic drugs (e.g., haloperidol) or atypical antipsychotic agents with limited antimuscarinic properties (e.g., risperidone) are often the drugs of choice (Khan et al., 2012).

Figure 16-1 Sites of action of antipsychotic agents and Li^+ . Following exocytotic release, DA interacts with postsynaptic receptors (R) of D_1 and D_2 types and presynaptic D_2 and D_3 autoreceptors. Termination of DA action occurs primarily by active transport of DA into presynaptic terminals via the DAT, with secondary deamination by mitochondrial MAO. Stimulation of postsynaptic D_1 receptors activates the G_s -adenylyl cyclase-cAMP pathway. D_2 receptors couple through G_i to inhibit adenylyl cyclase and through G_q to activate the PLC- IP_3 - Ca^{2+} pathway. Activation of the G_i pathway can also activate K^+ channels, leading to hyperpolarization. Li^+ inhibits IP breakdown and thereby enhances its accumulation and sequelae (Ca^{2+} mobilization, PKC activation, depletion of cellular I). Li^+ may also alter release of neurotransmitter by a variety of putative mechanisms (see text). D_2 -like autoreceptors suppress synthesis of DA by diminishing phosphorylation of rate-limiting TH, and by limiting DA release. In contrast, presynaptic A_2Rs activate the adenylyl cyclase-cAMP-PKA pathway and thence TH activity. All antipsychotic agents act at D_2 receptors and autoreceptors; some also block D_1 receptors (Table 16-2). Stimulant agents inhibit DA reuptake by DAT, thereby prolonging the dwell time of synaptic DA. Initially in antipsychotic treatment, DA neurons release more DA, but following repeated treatment, they enter a state of physiological depolarization inactivation, with diminished production and release of DA, in addition to continued receptor blockade. —, inhibition or blockade; +, elevation of activity; —, reduction of activity; cAMP, cyclic AMP; IP_3 , inositol phosphate; IP_3 , inositol 1,4,5-trisphosphate; PIP₂, phosphatidylinositol 4,5-bisphosphate.

The doses for patients with dementia are one-fourth of adult schizophrenia doses (e.g., risperidone 0.5–1.5 mg/d), as EPSs, orthostasis, and sedation are particularly problematic in this patient population (Chapter 18). In acute psychosis, significant antipsychotic benefits are usually seen within 60–120 min after drug administration. Delirious or demented patients may be reluctant or unable to swallow tablets, but ODT preparations or liquid concentrate forms are available. Intramuscular administration of ziprasidone or olanzapine represents an option for treating agitated and minimally cooperative patients and presents less risk for drug-induced parkinsonism than haloperidol. An inhaled form of loxapine 10 mg is available in the U.S., with a median T_{max} of less than 2 min. Following rapid distribution, levels drop 75% over the next 10 min and then follow typical kinetics with a $t_{1/2}$ of 7.6 h. Inhaled loxapine can be administered only in healthcare facilities that can provide advanced airway management in the rare event of acute bronchospasm. Pimavanserin for PDP has a $t_{1/2}$ of 57 h, and clinical effects are seen over 2–6 weeks. (See Use in Pediatric Populations and Use in Geriatric Populations later in the chapter.)

Mania

All atypical antipsychotics medications with the exception of clozapine, iloperidone, brexpiprazole, and lurasidone, have indications for acute mania, and doses are titrated rapidly close to or at the maximum FDA-approved dose over the first 24–72 h of treatment. Typical antipsychotic drugs are also effective in acute mania, but often are eschewed due to the risk for EPSs. Clinical response (decreased psychomotor agitation and irritability, increased sleep, and reduced or absent delusions and hallucinations) usually occurs within 7 days but may be apparent as early as day 2. Patients with mania may need to continue on antipsychotic treatment for many months after the resolution of psychotic and manic symptoms, typically in combination with a mood stabilizer such as lithium or valproic acid preparations (e.g., divalproex) (Malhi et al., 2012). Oral aripiprazole and olanzapine have indications as monotherapy for bipolar disorder maintenance treatment, but the use of olanzapine has decreased dramatically due to concerns over adverse metabolic effects (e.g., weight gain, hyperlipidemia, hyperglycemia). LAI risperidone also has indications for maintenance monotherapy (and adjunctively with lithium or valproate) in patients with bipolar I disorder.

Combining an antipsychotic agent with a mood stabilizer often improves control of manic symptoms and further reduces the risk of relapse. Weight gain from the additive effects of antipsychotic agents and mood stabilizers presents a significant clinical problem. Antipsychotic agents with greater weight-gain liabilities (e.g., olanzapine, clozapine) should be avoided unless patients are refractory to preferred treatments.

The recommended duration of treatment after resolution of bipolar mania varies considerably, but as symptoms permit, a gradual drug taper should be attempted after 6 months of treatment, to lessen weight gain when combined with a mood stabilizer (Yatham et al., 2016).

Major Depression

Patients with major depressive disorder with psychotic features require lower-than-average doses of antipsychotic drugs, given in combination with an antidepressant. Extended antipsychotic treatment is not usually required, but certain atypical antipsychotic agents provide adjunctive antidepressant benefit (Farahani and Correll, 2012). Most antipsychotic drugs show limited antidepressant benefit when used as monotherapy, with the exception of amisulpride, loxapine, lurasidone, and quetiapine. Some atypical antipsychotic agents are effective as adjunct therapy in treatment-resistant unipolar depression. The primary mechanisms of action include 5HT_{2C} antagonism (olanzapine and quetiapine's metabolite, norquetiapine), which facilitates DA and NE release, and DA D_3 partial agonism (aripiprazole, brexpiprazole, ciraiprazine), which may result in stimulation of reward centers. Quetiapine at doses of 300 mg/d is effective for bipolar depression, as is lurasidone in the dosage range of 20–120 mg/d administered with an evening meal of at least 350 kcal. One of lurasidone's postulated antidepressant mechanisms is potent 5HT_7 antagonism (Turner et al., 2014; Wright et al., 2013).

Schizophrenia

The immediate goals of acute antipsychotic treatment are the reduction of agitated, disorganized, or hostile behavior, decreasing the impact of hallucinations, improvement in the organization of thought, and the reduction of social withdrawal. Doses used acutely may be higher than those required for maintenance treatment of stable patients. Aside from

clozapine, which is uniquely efficacious in refractory schizophrenia, atypical antipsychotics are not more effective than typical agents but offer a better neurological side-effect profile than typical antipsychotic drugs. Excessive D_2 blockade, as is often the case with the use of high-potency typical agents (e.g., haloperidol), not only increases risk for neurological effects (e.g., muscular rigidity, bradykinesia, tremor, akathisia) but also slows mentation (bradyphrenia) and interferes with central reward pathways, resulting in patient complaints of anhedonia (loss of capacity to experience pleasure). Low-potency typical agents such as chlorpromazine are not commonly used due to the high affinities for H_1 , M_1 , and α_1 receptors that result in undesirable effects (sedation, anticholinergic properties, orthostasis). Concerns regarding QT_c prolongation further limit their clinical usefulness. In acute psychosis, sedation may be desirable, but the use of a sedating antipsychotic drug may interfere with cognitive function and assessment.

Because schizophrenia requires long-term treatment, antipsychotic agents with greater metabolic liabilities, especially weight gain (discussed further in this chapter), should be avoided as first-line therapies. Ziprasidone, aripiprazole, iloperidone, brexpiprazole, cariprazine, and lurasidone are the most weight and metabolically benign atypical agents (De Hert et al., 2012; Rummel-Kluge et al., 2010). Ziprasidone is available in acute intramuscular form, thus permitting continuation of the same drug treatment initiated parenterally in the emergency room. Patients with schizophrenia have a 2-fold higher prevalence of metabolic syndrome and type 2 DM and 2-fold greater CV-related mortality rates than the general population (Tornaiainen et al., 2015). For this reason, consensus guidelines recommend baseline determination of serum glucose, lipids, weight, blood pressure, and personal and family histories of metabolic and CV disease.

With the low EPS risk among atypical antipsychotic agents, prophylactic use of antiparkinsonian medications (e.g., benztropine, trihexyphenidyl) is not necessary. Drug-induced parkinsonism can occur at higher dosages or among elderly patients exposed to antipsychotic agents that have higher D_2 affinity; recommended doses are about 50% of those used in younger patients with schizophrenia. (See also Use in Pediatric Populations and Use in Geriatric Populations further in the chapter.)

Long-Term Treatment

The need for long-term treatment poses issues almost exclusively to the chronic psychotic illnesses, schizophrenia and schizoaffective disorder. However, long-term antipsychotic treatment is sometimes used for manic patients, for ongoing psychosis in patients with dementia, for PDP, and for adjunctive use in treatment-resistant depression. Safety concerns combined with limited long-term efficacy data have dampened enthusiasm for extended antipsychotic drug use in patients with dementia (Maust et al., 2015). Justification for ongoing use, based on documentation of patient response to tapering of antipsychotic medication, is often mandated in long-term care settings.

Antipsychotic Agents

The choice of antipsychotic agents for long-term schizophrenia treatment is based primarily on avoidance of adverse effects, prior history of patient response, and the need for a long-acting injectable formulation due to adherence issues. While concerns over EPSs and TD have abated with the introduction of the atypical antipsychotic agents, there has been increased concern over metabolic effects of antipsychotic treatment: weight gain, dyslipidemia (particularly hypertriglyceridemia), and an adverse impact on glucose-insulin homeostasis (Rummel-Kluge et al., 2010). Clozapine and olanzapine have the highest metabolic risk and are only used as last resort. Olanzapine is often used prior to clozapine after failure of more metabolically benign agents such as aripiprazole, ziprasidone, asenapine, iloperidone, and lurasidone.

Acutely psychotic patients usually respond within hours after drug administration, but weeks may be required to achieve maximal drug response, especially for negative symptoms. Analyses of symptom response in clinical trials indicate that the majority of response to any antipsychotic treatment in acute schizophrenia is seen by week 4 (Jager et al., 2010). Failure of response after 2 weeks should prompt clinical reassessment, including determination of medication adherence, before a decision is

made to increase the dose or consider switching to another agent (Kinon et al., 2010). Patients with first-episode schizophrenia often respond to lower doses, and chronic patients may require doses that exceed recommended ranges. While the acute behavioral impact of treatment is seen within hours to days, long-term studies indicate improvement may not plateau for 6 months, underscoring the importance of ongoing antipsychotic treatment in functional recovery for patients with schizophrenia.

Usual dosages for acute and maintenance treatment are noted in Table 16-1. Dosing should be adjusted based on clinically observable signs of antipsychotic benefit and adverse effects. For example, higher EPS risk is noted for risperidone doses that exceed 6 mg/d in nonelderly adult patients with schizophrenia. However, in the absence of EPSs, increasing the dose from 6 to 8 mg would be a reasonable approach in a patient with ongoing positive symptoms. Certain antipsychotic adverse effects, including weight gain, sedation, orthostasis, and EPSs, can be predicted based on potencies at neurotransmitter receptors (Table 16-2). The detection of dyslipidemia or hyperglycemia is based on laboratory monitoring (Table 16-1). Dose reduction often resolves hyperprolactinemia, EPSs, orthostasis, and sedation, but metabolic abnormalities improve only with discontinuation of the offending agent and a switch to a more metabolically benign medication. The decision to switch patients with stable schizophrenia and metabolic dysfunction solely for metabolic benefit must be individualized based on patient preferences, severity of the metabolic disturbance, likelihood of metabolic improvement with antipsychotic switching, and history of response to prior agents. Patients with refractory schizophrenia on clozapine are not good candidates for switching because they are resistant to other medications (see the definition of refractory schizophrenia further in this section).

Psychotic Relapse

There are many reasons for psychotic relapse or inadequate response to antipsychotic treatment in patients with schizophrenia; reasons include substance use, psychosocial stressors, inherent refractory illness, and poor medication adherence. The common problem of medication nonadherence among patients with schizophrenia has led to the development of LAI antipsychotic medications, often referred to as depot antipsychotics (Meyer, 2013). There are currently eight LAI forms available in the U.S.: decanoate esters of fluphenazine and haloperidol, risperidone-impregnated microspheres, 1-month and 3-month formulations of paliperidone palmitate, aripiprazole monohydrate, aripiprazole lauroxil, and olanzapine pamoate (Table 16-3). Patients receiving LAI antipsychotic medications show consistently lower relapse rates compared to patients receiving comparable oral forms and may have fewer adverse effects due to lower peak plasma levels.

Refractory Illness

Lack of response to adequate antipsychotic drug doses for adequate periods of time may indicate treatment-refractory illness. Use of antipsychotic plasma levels can help separate those who are nonadherent or are kinetic failures from those who are not responding to adequate medication exposure (Meyer, 2014). In treatment-refractory schizophrenia, response rates are 0% for typical antipsychotic agents, less than 10% for newer agents, but consistently about 60% for clozapine. Various studies have found correlations between trough plasma clozapine levels greater than 327–504 ng/mL and likelihood of clinical response (Rostami-Hodjegan et al., 2004). When therapeutic serum concentrations are reached, response to clozapine occurs within 8 weeks. Clozapine can have numerous adverse effects: risk of agranulocytosis (requires hematological monitoring), high metabolic burden, dose-dependent lowering of the seizure threshold, orthostasis, sedation, anticholinergic effects (especially constipation), and sialorrhea.

Electroconvulsive therapy also has proven efficacy for refractory schizophrenia.

Pharmacology of Antipsychotic Agents

Chemistry

Most early agents were derived from phenothiazine or butyrophenone structures. Presently, antipsychotic agents include many different chemical structures with a range of activities at different neurotransmitter receptors

Dosage Forms: IM, acute intramuscular; ODT, orally dissolving tablet; O, tablet; S, solution.

^aAripiprazole monohydrate dose: 300–400 mg IM/4 wks, with 14 days oral overlap. Aripiprazole lauroxil dose: 662–882 mg/4 wks or 882 mg/6 wks (equiv. to 662 mg/4 wks) with 21 days oral overlap. Dosages need to be adjusted for patients who are CYP2D6 poor metabolizers or those who are exposed to CYP2D6 or CYP3A4 inhibitors.

^bNot available in the U.S.

^cDue to orthostasis risk, dose titration of iloperidone is 1 mg twice daily on day 1, increasing to 2, 4, 6, 8, 10, and 12 mg twice daily on days 2–7 (as needed).

^dDose must be given with 350 kcal food to facilitate absorption. Administration with evening meal improves tolerability.

^eDue to cases of postinjection delirium/sedation syndrome, patients must be observed after the injection for at least 3 h in a registered facility with ready access to emergency response services.

^fExists in two forms: 1-month and 3-month doses. In acute schizophrenia, deltoid intramuscular loading of 1-month form using doses of 234 mg at day 1 and 156 mg at day 8 to provide paliperidone levels equivalent to 6 mg oral paliperidone during the first week and peaking on day 15 at a level comparable to 12 mg oral paliperidone. No oral antipsychotic needed in first week. Maintenance intramuscular doses can be given every 4 weeks after day 8. Maintenance dose options for 1-month form: 39 to 234 mg every 4 weeks. Failure to give initiation doses (except for those switching from depot) will result in subtherapeutic levels for months. The 3-month form is only for those on 1-month dosing for at least 4 months. The 3-month dose is 3.5 times the stable monthly dose, administered every 12 weeks.

^gOral dose must be given with 500 kcal food to facilitate absorption.

^bDosages need to be adjusted for patients who are CYP2D6 poor metabolizers or those who are exposed to CYP2D6 or CYP3A4 inhibitors.

^cDue to cases of postinjection delirium/sedation syndrome, patients must be observed after the injection for at least 3 h in a registered facility with ready access to emergency response services.

^dOnly indicated for patients who have been on paliperidone palmitate monthly injectable for at least 4 months.

(e.g., 5HT_{2A} antagonism, 5HT_{1A} partial agonism). As a result, structure-function relationships that were relied on in the past have become less important, while receptor binding and functional assays are more clinically relevant. Aripiprazole represents a good example of how an examination of the structure provides little insight into its mechanism, which is based on partial agonism at D₂ DA receptors (discussed further in this chapter). Detailed knowledge of receptor affinities (Table 16–2) and the functional effect at specific receptors (e.g., full, partial, or inverse agonism or antagonism) can provide important insight into the therapeutic and adverse effects of antipsychotic agents. Nevertheless, there are limits. For example, it is not known which properties are responsible for clozapine's unique effectiveness in refractory schizophrenia, although many hypotheses exist. Other notable antipsychotic properties not fully explained by receptor parameters include the reduced seizure threshold, the effects of antipsychotic agents on glucose and lipid metabolism, and the increased risk for cerebrovascular events and mortality among patients with dementia (see Adverse Effects and Drug Interactions further in the chapter).

Mechanism of Action

With the exception of pimavanserin for PDP, no clinically available effective antipsychotic is devoid of D₂-modulating activity (Howes et al., 2015). This reduction in dopaminergic neurotransmission is presently achieved through one of two mechanisms: D₂ antagonism or partial D₂ agonism (aripiprazole, brexpiprazole, and cariprazine). The mechanism of action for partial agonist antipsychotics relies on intrinsic activity at D₂ receptors that is a fraction of the efficacy of DA (i.e., 20%–25% of DA's activity), as depicted in Figure 16–2 for aripiprazole. (Recall that a partial agonist will also occupy the receptor and antagonize the binding of full agonists; see Chapter 3). Unlike other antipsychotic agents, in which striatal D₂ occupancy (i.e., reduction in postsynaptic D₂ signal) greater than 78% increases risk for EPSs, partial agonist antipsychotics require significantly higher D₂ occupancy levels (80%–95%) (Sparshatt et al., 2010). However, the intrinsic dopaminergic agonism generates a sufficient postsynaptic signal to remain below the EPS threshold, although reports do exist, primarily in antipsychotic-naïve, younger patients.

Clozapine was not suspected to possess antipsychotic activity until experimental human use in the mid-1960s revealed it to be an effective treatment of schizophrenia, particularly in patients who had failed other antipsychotic medications, and with virtually absent EPS risk. Clozapine possesses weaker D₂ antagonism than existing antipsychotic agents, combined with potent 5HT_{2A} antagonism that facilitates DA release in mesocortical and nigrostriatal pathways. Clozapine, and its active metabolite *N*-desmethylclozapine, also possesses activity at numerous other receptors, including antagonism and agonism at various muscarinic receptor subtypes and antagonism at DA D₄ receptors (other D₄ antagonists that do not also have D₂ antagonism lack antipsychotic activity; Meyer and Leckband, 2013).

A search for the basis of clozapine's unique efficacy in refractory schizophrenia has recently pointed toward activity at glutamatergic sites, especially the NMDA receptor. The evolving NMDA hypofunction hypothesis

Figure 16–2 Partial agonist activity of aripiprazole at D₂ receptors. Aripiprazole is a partial D₂ agonist and thus also an antagonist. In this stylized representation, aripiprazole inhibits the effects of DA and reduces stimulation at the D₂ receptor only to the extent of its own capacity as an agonist (orange tracing); in the absence of DA, its partial agonist effects are apparent (green line), becoming maximal at about 25% of the maximal effect of DA alone (purple line). Haloperidol, an antagonist without agonist activity, completely antagonizes D₂ receptor activation by 100 nM DA (red tracing). Here, receptor activation is measured as inhibition of forskolin-induced cAMP accumulation in cultured cells transfected with human D_{2L} DNA. (Data from Burris KD, et al. Aripiprazole, a novel antipsychotic, is a high-affinity partial agonist at human dopamine D₂ receptors. *J Pharmacol Exp Ther*, 2002, 302: 381–389.)

of schizophrenia led to clinical development of metabotropic glutamate mGlu₂ and mGlu₃ agonists and inhibitors of the type 1 glycine transporter. At present, however, it is unclear whether glutamate agonists that lack direct D₂ antagonist properties will be effective for schizophrenia treatment; agents with the mechanisms indicated have failed phase III studies (Howes et al., 2015).

Patients with schizophrenia also exhibit specific neurophysiological and cognitive abnormalities, including deficiencies in sensorimotor gating as assessed by prepulse inhibition (PPI) of the acoustic startle reflex. PPI is the automatic suppression of startle magnitude that occurs when the louder acoustic stimulus is preceded 30–500 milliseconds by a weaker prepulse (Javitt and Freedman 2015; Powell et al., 2012). In patients with schizophrenia, PPI is increased more robustly with atypical than typical antipsychotic agents, and in animal models, atypical antipsychotic agents are also more effective at opposing PPI disruption by NMDA antagonists.

Increased understanding of the pharmacological basis for neurophysiological deficits provides another means for developing antipsychotic treatments that are specifically effective for schizophrenia and may not necessarily apply to other forms of psychosis. Numerous agents have also been examined for remediating the cognitive deficits of schizophrenia, typically utilizing nicotinic and muscarinic agonism, but none has been approved (Prickaerts et al., 2012).

Dopamine Receptor Occupancy and Behavioral Effects

Dopaminergic projections from the midbrain terminate on septal nuclei, the olfactory tubercle and basal forebrain, the amygdala, and other structures within the temporal and prefrontal cerebral lobes and the hippocampus. Excessive dopaminergic neurotransmission in the associative striatum is central to the positive symptoms of psychosis. The behavioral effects and the time course of antipsychotic response parallel the decrease in postsynaptic D₂ activity in this region (Kuepper et al., 2012). Receptor occupancy predicts clinical efficacy, EPSs, and plasma level–clinical response relationships. Occupancy of greater than 78% of D₂ receptors in

Figure 16-3 Receptor occupancy and clinical response for antipsychotic agents. Typically, in D_2 receptor occupancy by the drug more than 60% provides antipsychotic effects, receptor occupancy greater than 80% causes EPSs. Atypical agents combine weak D_2 receptor blockade with more potent $5HT_{2A}$ antagonism/inverse agonism. Inverse agonism at $5HT_2$ receptor subtypes may contribute to the reduced EPS risk of olanzapine (A) and risperidone (B) and efficacy at lower D_2 receptor occupancy (olanzapine, A). Aripiprazole is a partial D_2 agonist that can achieve only 75% functional blockade (see Figure 16-2).

the basal ganglia is associated with a risk of EPSs across all DA antagonist antipsychotic agents, while occupancies in the range of 60%–75% are associated with antipsychotic efficacy (Figure 16-3). With the exception of the D_2 partial agonists, all atypical antipsychotic drugs at low doses have much greater occupancy of $5HT_{2A}$ receptors (e.g., 75%–99%) than typical agents (Table 16-3). Given the large variations in drug metabolism, plasma levels of antipsychotic agents (rather than doses) are the best predictors of D_2 occupancy.

The Role of Nondopamine Receptors for Atypical Antipsychotic Agents. The concept of atypicality was initially based on clozapine's absence of EPSs combined with potent $5HT_2$ receptor antagonism. $5HT_{2A}$ antagonism exerts its greatest effect on prefrontal and basal ganglia DA release, decreasing EPS risk in the context of nigrostriatal D_2 antagonism. The $5HT_{2C}$ antagonists stimulate midbrain noradrenergic outflow (Dremencov et al., 2006). Thus, $5HT_{2C}$ antagonist atypical agents exhibit a spectrum of antidepressant properties, although pure $5HT_{2C}$ agents are not, by themselves, effective antidepressants (Dremencov et al., 2006). Most atypical antipsychotics are partial agonists at $5HT_{1A}$ receptors, resulting in hyperpolarization of cortical pyramidal cells and clinically relevant anxiolytic effects. Pimavanserin is an inverse agonist at $5HT_{2A}$ receptors; its effectiveness in PDP may reflect on the unique pathology of PDP.

PIMAVANSERIN

Tolerance and Physical Dependence

As defined in Chapter 24, antipsychotic drugs are not addicting; however, tolerance to the α adrenergic, antihistaminic, and anticholinergic effects of antipsychotic agents usually develops over days or weeks. Loss of efficacy with prolonged treatment is not known to occur with antipsychotic agents; however, tolerance to antipsychotic drugs and cross-tolerance among the agents are demonstrable in behavioral and biochemical experiments in animals. One correlate of tolerance in striatal dopaminergic systems is the development of receptor supersensitivity (mediated by upregulation of supersensitive DA receptors), referred to as D_2^{High} receptors (Seeman, 2013). These changes may underlie the clinical phenomenon of

withdrawal-emergent dyskinesias and may contribute to the pathophysiology of TD. These effects may also partly explain the ability of certain patients with chronic schizophrenia to tolerate high doses of potent DA antagonists with limited EPSs.

ADME

Absorption for most of these agents following oral administration is quite high, and concurrent administration of anticholinergic antiparkinsonian agents does not appreciably diminish intestinal absorption. Most ODTs and liquid preparations provide similar pharmacokinetics because there is little mucosal absorption and effects depend on swallowed drug. Asenapine is the only exception: it is available only as an ODT preparation administered sublingually; and absorption occurs via the oral mucosa with bioavailability of 35%. If asenapine is swallowed, the first-pass effect is greater than 98% and the drug is essentially not bioavailable. Intramuscular administration avoids much of the first-pass enteric metabolism and provides measurable concentrations in plasma within 15–30 min.

The pharmacokinetic constants and metabolic pathways for many atypical and typical antipsychotic drugs are listed in Table 16-4. Most antipsychotic drugs are highly lipophilic and accumulate in the brain, lung, and other tissues with a rich blood supply. Most antipsychotic agents are highly protein bound, primarily to acid glycoprotein, and do not significantly displace other medications bound to prealbumin or albumin. Antipsychotic agents also enter the fetal circulation and breast milk. Despite half-lives that may be short, the biological effects of single doses of most antipsychotic medications usually persist for at least 24 h, permitting once-daily dosing after the patient has adjusted to initial side effects. Due to accumulation in tissue stores, both parent compound and metabolites of LAI medications can be detected several months after discontinuation, a useful property for those who may miss injections (see Table 16-3).

Other Therapeutic Uses

Antipsychotic agents are also utilized in several nonpsychotic neurological disorders and as antiemetics.

Anxiety Disorders

Double-blind, placebo-controlled trials have shown the benefit of adjunctive treatment with antipsychotic drugs for obsessive-compulsive disorder, with a recent meta-analysis showing significant efficacy for risperidone but not for quetiapine and olanzapine (Dold et al., 2013). For generalized anxiety disorder, clinical trials demonstrated efficacy for quetiapine as monotherapy and for adjunctive low-dose risperidone. Recent data do not support routine use of risperidone for posttraumatic stress disorder (Krystal et al., 2011).

TABLE 16-4 ■ DRUG DISPOSITION AND EFFECTS OF CYP INHIBITION AND INDUCTION ON ORAL ANTIPSYCHOTIC LEVELS

	T_{\max} ; Oral Tablet Bioavailability	METABOLISM	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Commonly used atypical antipsychotics				
Aripiprazole	Bioavailability: 87% T_{\max} 3–5 h	CYPs 2D6 and 3A4 produce active metabolite, dehydroaripiprazole. $t_{1/2}$: aripiprazole, 75h; dehydroaripiprazole, 94 h, Metabolite = 40% of AUC at steady state	In 2D6 PM: \uparrow AUC of aripiprazole up to 80%, 30% \downarrow AUC of metabolite. $t_{1/2}$: 146 h in PMs. Strong CYP2D6 inhibitors (e.g., ketoconazole) can double AUC of parent drug. Ketoconazole (a strong 3A4 inhibitor) increased the AUCs of aripiprazole and its active metabolite by 63% and 77%, respectively.	3A4 induction \downarrow max concentration and AUC of aripiprazole and metabolite by 70%.
Asenapine	Bioavailability: Sublingual: 35% Oral: <2% T_{\max} 1 h	Primarily glucuronidation (UGT 1A4); limited oxidation via CYP 1A2 and to lesser extent 2D6 and 3A4. No active metabolites. $t_{1/2}$: 24 h	Fluvoxamine, (25 mg twice daily for 8 days) $\uparrow C_{\max}$ by 13% and AUC 29%. Paroxetine \downarrow AUC and C_{\max} (13%) Asenapine can double paroxetine exposure.	Smoking: no effect on clearance or other kinetic parameters. Carbamazepine, can $\downarrow C_{\max}$ and AUC (16%).
Brexipiprazole	Bioavailability: 95% T_{\max} 4 h	CYPs 2D6 and 3A4 convert brexipiprazole to inactive metabolite (DM-3411). $t_{1/2}$: 91 h	Strong 2D6 or 3A4 inhibitor: \uparrow AUC _{0-24h} by 2-fold. Strong 3A4 inhibitor with 2D6 inhibitor (or with 2D6 PM): \uparrow AUC _{0-24h} by ~5 fold. \downarrow dose by 50% with strong 2D6 or 3A4 inhibitor. \downarrow dose by 75% with combined 2D6/3A4 inhibitors.	Inducers of CYP3A4 \downarrow exposure AUC by ~70%. Do not use brexipiprazole with inducers.
Cariprazine	Bioavailability: 65% T_{\max} 3–6 h	CYP3A4 converts cariprazine to active metabolites DCAR and DDCAR. At steady state on 6 mg/d: cariprazine 28%, DCAR 9%, and DDCAR 63%. CYP2D6 is a minor pathway. Parent drug and DDCAR show good brain penetration; after oral cariprazine, brain-to-plasma ratios for both are ~9.8 $t_{1/2}$: 31.6–68.4 h; DCAR, 29.7–39.5 h; DDCAR, 314–446 h $\geq 50\%$ of DDCAR present 1 week after discontinuation.	Ketoconazole 400 mg/d + cariprazine 0.5 mg/kg: \uparrow AUCs of cariprazine (4 \times) and DDCAR (1.5), and \uparrow DCAR AUC (~33%). Reduce dose by 50% with strong 3A4 inhibitors. No impact from 2D6 inhibitors.	Not studied. Impact unknown. Not recommended with 3A4 inducers.
Clozapine	Bioavailability: 60%–70% T_{\max} 2.5 h	Multiple CYPs (mainly 1A2, 2C19, 3A4) produce active desmethyl metabolite $t_{1/2}$: 12 h (up to 66 h with chronic dosing)	Fluvoxamine \uparrow serum levels 5- to 10-fold. 2D6 inhibition may double Cp.	Loss of smoking-related 1A2 induction \Rightarrow 50% \uparrow in clozapine serum levels. Carbamazepine decreases clozapine levels on average by 50%.

(Continued)

TABLE 16-4 ■ DRUG DISPOSITION AND EFFECTS OF CYP INHIBITION AND INDUCTION ON ORAL ANTIPSYCHOTIC LEVELS (CONTINUED)

	T_{\max} ; Oral Tablet Bioavailability	METABOLISM	EFFECT OF CYP INHIBITION	EFFECT OF CYP INDUCTION
Iloperidone	Bioavailability: well absorbed, no food effect on AUC T_{\max} 2–4 h	2D6/3A4 produce active metabolites P88 & P95 Exposure to P88 and P95 can be significant P88 $t_{1/2}$: EM, 26 h; PM, 37 h P95 $t_{1/2}$: EM, 23h; PM, 31 h $t_{1/2}$: 18 h (CYP 2D6 EMs), 33 h (CYP 2D6 PMs)	Ketoconazole, fluoxetine, and paroxetine can ↑ AUC of iloperidone and metabolites by 50% to 300%, with similar effects on C_{\max} at steady-state.	Impact of 3A4 inducers not documented.
Lurasidone	Bioavailability: 9%–19% Mean C_{\max} and AUC increased 3-fold and 2-fold, respectively, when administered with food T_{\max} 1–3 h	CYP 3A4 $t_{1/2}$: 18–36 h	DO NOT USE with strong 3A4 inhibitors (e.g., ketoconazole), which increase C_{\max} 6.9-fold and AUC 9-fold. Moderate 3A4 inhibitors (diltiazem) increase C_{\max} 2.1-fold and AUC 2.2-fold.	DO NOT USE with strong 3A4 inducers. Concurrent rifampin can decrease C_{\max} to a seventh of prior levels and AUC by 80%.
Olanzapine	Bioavailability: 60% T_{\max} 6 h	Direct glucuronidation or 1A2-mediated oxidation to <i>N</i> -desmethylolanzapine (inactive) $t_{1/2}$: 30 (21–54) h	Increase in olanzapine C_{\max} following fluvoxamine is 54% in female nonsmokers and 77% in male smokers. Mean increases in olanzapine AUC are 52% and 108%, respectively.	Carbamazepine use increases clearance by 50%. Smokers have lower C_p and increased clearance.
Paliperidone	Bioavailability: 28% T_{\max} 24 h	59% excreted unchanged in urine, 32% excreted as metabolites. Phase 2 metabolism accounts for no more than 10%.	Unlikely to have much of an effect	Carbamazepine use decreased steady-state C_{\max} and AUC by 37%.
Quetiapine	Bioavailability: 9% T_{\max} 1.5 h	3A4 mediated sulfoxidation to inactive metabolite $t_{1/2}$: 6 h (CNS half-life longer by neuroimaging)	Ketoconazole (200 mg once daily for 4 days) reduced oral clearance of quetiapine by 84%, ⇒ 335% increase in C_{\max} .	Phenytoin increases clearance 5-fold.
Risperidone	Bioavailability: 66% in 2D6 EMs T_{\max} : 1 h for risperidone, 3 h for 9-OH risperidone (paliperidone)	2D6 converts risperidone to, 9-OH risperidone (active). $t_{1/2}$: 3–4 h; 20–24 h (9-OH risperidone) In 2D6 PMs, half-lives are: risperidone, 20 h; 9-OH risperidone, 30 h.	SSRIs can increase plasma levels. Fluoxetine: ↑ [risperidone] ~2.6 fold Paroxetine: ↑ [risperidone] ~3–9 fold	Risperidone (6 mg/day for 3 weeks), followed by Carbamazepine (3 weeks), ⇒ 50% decrease in concentration (risperidone + 9-OH risperidone).

Ziprasidone	Bioavailability: 60% when given with food A 500-kcal meal (of any composition) ↑ AUC of a 20-mg, 40-mg, and 80-mg capsule by 48%, 87% and 101%, respectively. T_{\max} 6–8 h	Aldehyde oxidase (66%), CYP3A4 (34%) $t_{1/2}$: 7.5 h	35%–40% increase in ziprasidone AUC by concomitantly administered ketoconazole.	35% decrease in ziprasidone AUC by carbamazepine.
Typical antipsychotics				
Haloperidol	Bioavailability: 60% T_{\max} 2–6 h	Multiple CYP pathways, particularly 2D6, 3A4. Most metabolites inactive, except reduced haloperidol formed by ketone reductase and transformed to haloperidol via CYP2D6. Therapeutic serum levels not well defined; 5–20 ng/mL used as a target for dosing. $t_{1/2}$: 24 h (12–36 h) ^a	In CYP2D6 PM: $t_{1/2}$ prolonged, [reduced haloperidol] increased significantly. Individuals with only one functional 2D6 gene experience 2-fold greater trough serum levels; those with no functioning alleles 3- to 4-fold higher.	Carbamazepine or phenytoin ↑ haloperidol clearance ~32%, with variable decrease in plasma levels (mean 47%). Discontinuation of carbamazepine results in 2.2- to 3.0-fold ↑ in serum levels.
Chlorpromazine	Bioavailability: 20–32% T_{\max} 1–4 h	CYP2D6, over 10 identified human metabolites, most inactive. Chlorpromazine is a 2D6 inhibitor and induces its own metabolism. Levels drop ~30% during weeks 1–3 of treatment. $t_{1/2}$: 24 h (8–35 h with chronic dosing)	Case report of fluoxetine-chlorpromazine interaction, but no serum level data on extent of effect.	3A4/PGP inducers (e.g., phenobarbital, carbamazepine) ↓ chlorpromazine levels by ~35%. Carbamazepine discontinuation increases serum levels (~50%).

^aMay have multiphasic elimination with much longer terminal half-life.

The ability of antipsychotic drugs to suppress tics in patients with Tourette disorder relates to reduced D_2 neurotransmission in basal ganglia sites. Aripiprazole is the only antipsychotic that is FDA-approved for the treatment of Tourette disorder; this agent is considered a first-line agent for this purpose, starting at doses of 2 mg/d and increasing if needed to a maximum of 10 mg/d for those weighing less than 50 kg or 20 mg/d if weighing 50 kg or more (Mogwitz et al., 2013).

In prior decades, low-dose, high-potency typical antipsychotic agents (e.g., haloperidol, pimozide) were treatments of choice, but these non-psychotic patients are extremely sensitive to the impact of DA blockade on cognitive processing speed and on reward centers. Moreover, safety concerns regarding pimozide's QT_c prolongation and increased risk for ventricular arrhythmias have largely ended its clinical use.

Huntington Disease

Huntington disease is another neuropsychiatric condition that, like tic disorders, is associated with basal ganglia pathology. DA blockade can suppress the severity of choreoathetotic movements but is not strongly endorsed due to the risks associated with excessive DA antagonism that outweigh the marginal benefit. Inhibition of the vesicular monoamine transporter 2 (VMAT2) with tetrabenazine compounds has replaced DA receptor blockade in the management of chorea (Chapter 18).

Autism

Autism is a disease whose neuropathology is incompletely understood, but in some patients is associated with explosive behavioral outbursts and aggressive or self-injurious behaviors that may be stereotypical. Risperidone and aripiprazole have FDA approval for irritability associated with autism in child and adolescent patients ages 5–16, with common use for disruptive behavior problems in autism and forms of mental retardation. Initial risperidone daily doses are 0.25 mg for patients weighing less than 20 kg and 0.5 mg for others, with a target dose of 0.5 mg/d in those weighing less than 20 kg and 1.0 mg/d for other patients, with a range of

0.5–3.0 mg/d. For aripiprazole, the starting dose is 2 mg/d, with a target range of 5–10 mg/d and maximum daily dose of 15 mg.

Antiemetic Use

Most antipsychotic drugs protect against the nausea- and emesis-inducing effects of DA agonists such as apomorphine that act at central DA receptors in the chemoreceptor trigger zone of the medulla. Drugs or other stimuli that cause emesis by an action on the nodose ganglion, or locally on the GI tract, are not antagonized by antipsychotic drugs, but potent piperazines and butyrophenones are sometimes effective against nausea caused by vestibular stimulation. The commonly used antiemetic phenothiazines are weak DA antagonists (e.g., prochlorperazine) without antipsychotic activity but can occasionally be associated with EPSs or akathisia. Emesis and antiemetic agents are discussed at length in Chapter 50.

Adverse Effects and Drug Interactions

Adverse Effects Predicted by Monoamine Receptor Affinities

Dopamine D_2 Receptors. With the exception of pimavanserin and the D_2 partial agonists (aripiprazole, brexpiprazole, cariprazine), all other antipsychotic agents possess D_2 antagonist properties, the strength of which determines the likelihood for EPSs, long-term TD risk, akathisia, NMS, and hyperprolactinemia.

Extrapyramidal Symptoms. The manifestations of EPSs are described in Table 16–5, along with the usual treatment approach. Acute dystonic reactions occur in the early hours and days of treatment, with highest risk among younger patients (peak incidence ages 10–19), especially antipsychotic, naïve individuals, in response to abrupt decreases in nigrostriatal D_2 neurotransmission. The dystonia typically involves head and neck muscles and the tongue and, in its severest form, the oculogyric crisis, extraocular muscles, and is frightening to the patient.

Parkinsonism resembling its idiopathic form may occur; it will respond to dose reduction or switching to an antipsychotic with weaker

TABLE 16–5 ■ NEUROLOGICAL SIDE EFFECTS OF ANTIPSYCHOTIC DRUGS

REACTION	FEATURES	TIME OF ONSET AND RISK INFO	PROPOSED MECHANISM	TREATMENT
Acute dystonia	Spasm of muscles of tongue, face, neck, back	Time: 1–5 days. Young, antipsychotic, naïve patients at highest risk	Acute DA antagonism	Antiparkinsonian agents are diagnostic and curative ^a
Akathisia	Subjective and objective restlessness; <i>not</i> anxiety or “agitation”	Time: 5–60 days	Unknown	Reduce dose or change drug; clonazepam, propranolol more effective than antiparkinsonian agents ^b
Parkinsonism	Bradykinesia, rigidity, variable tremor, mask facies, shuffling gait	Time: 5–30 days. Elderly at greatest risk	DA antagonism	Dose reduction; change medication; antiparkinsonian agents ^c
Neuroleptic malignant syndrome	Extreme rigidity, fever, unstable blood pressure, myoglobinemia; can be fatal	Time: weeks–months. Can persist for days after stopping antipsychotic	DA antagonism	Stop antipsychotic immediately; supportive care; dantrolene and bromocriptine ^d
Perioral tremor (“rabbit syndrome”)	Perioral tremor (may be a late variant of parkinsonism)	Time: months or years of treatment	Unknown	Antiparkinsonian agents often help ^c
Tardive dyskinesia	Orofacial dyskinesia; rarely widespread choreoathetosis or dystonia	Time: months or years of treatment. Elderly at 5-fold greater risk. Risk proportional to potency of D_2 blockade	Postsynaptic DA receptor supersensitivity, upregulation	May be reversible with early recognition and drug discontinuation. VMAT2 inhibitors valbenazine and deutetrabenazine are FDA-approved for TD

^aTreatment: diphenhydramine 25–50 mg IM or benztropine 1–2 mg IM. Due to long antipsychotic $t_{1/2}$, may need to repeat or follow with oral medication.

^bPropranolol often effective in relatively low doses (20–80 mg/d in divided doses). β_1 -selective adrenergic receptor antagonists are less effective. Nonlipophilic β adrenergic antagonists have limited CNS penetration and are of no benefit (e.g., atenolol).

^cUse of amantadine avoids anticholinergic effects of benztropine or diphenhydramine.

^dDespite the response to dantrolene, there is no evidence of abnormal Ca^{2+} transport in skeletal muscle; with persistent antipsychotic effects (e.g., long-acting injectable agents) prolonged bromocriptine may be necessary in large doses (10–40 mg/d). Antiparkinsonian agents are not effective.

D₂ antagonism. If this is neither possible nor desirable, antiparkinsonian medication may be employed. Elderly patients are at greatest risk.

Muscarinic cholinergic receptors modulate nigrostriatal DA release, with blockade increasing synaptic DA availability. Important issues in the use of anticholinergics include the negative impact on cognition and memory; peripheral antimuscarinic adverse effects (e.g., urinary retention, dry mouth, cycloplegia, etc.); exacerbation of TD; and risk of cholinergic rebound following abrupt anticholinergic withdrawal. For parenteral administration, diphenhydramine (25–50 mg IM) and benztropine (1–2 mg IM) are the agents most commonly used. The antihistamine diphenhydramine also possesses anticholinergic properties. Benztropine combines a benzhydryl group with a tropane group to create a compound that is more anticholinergic than trihexyphenidyl but less antihistaminic than diphenhydramine. The clinical effect of a single dose lasts 5 h, thereby requiring two or three daily doses. Dosing usually starts at 0.5–1 mg twice daily, with a daily maximum of 6 mg, although slightly higher doses are used in rare circumstances. The piperidine compound trihexyphenidyl was one of the first synthetic anticholinergic agents available; it also inhibits the presynaptic DA reuptake transporter, which creates a higher risk of abuse than for the antihistamines or benztropine. Trihexyphenidyl has good GI absorption, achieving peak plasma levels in 1–2 h, with a serum $t_{1/2}$ of about 10–12 h generally necessitating multiple-daily dosing to achieve satisfactory clinical results. The total daily dosage range is 5–15 mg, given two or three times a day as divided doses. Biperiden is another drug in this class.

Amantadine, originally marketed as an antiviral agent for influenza A, is an alternative medication for antipsychotic-induced parkinsonism and avoids the adverse CNS and peripheral effects of anticholinergic medications (Ogino et al., 2014). Its mechanism of action is unclear but appears to involve presynaptic DA reuptake blockade, facilitation of DA release, postsynaptic DA agonism, and receptor modulation. Amantadine is well absorbed after oral administration, with peak levels achieved 1–4 h after ingestion; clearance is renal, with more than 90% recovered unmetabolized in the urine. The plasma $t_{1/2}$ is 12–18 h in healthy young adults but is longer in those with renal impairment, necessitating a 50% dose reduction. Starting dosage is 100 mg orally once daily in healthy adults, which may be increased to 100 mg twice daily. A dose of 100 mg twice daily yields peak plasma levels of 0.5–0.8 µg/mL and trough levels of 0.3 µg/mL. Toxicity is seen at serum levels between 1 and 5 µg/mL.

Tardive Dyskinesia. Tardive dyskinesia results from increased nigrostriatal dopaminergic activity as a consequence of postsynaptic receptor supersensitivity and upregulation from chronically high levels of postsynaptic D₂ blockade (and possible direct toxic effects of high-potency DA antagonists). TD occurs more frequently in older patients, and the risk may be somewhat greater in patients with mood disorders than in those with schizophrenia. Its prevalence averages 15%–25% in young adults treated with typical antipsychotic agents for more than a year; the risk is a third to a fifth of that with atypical agents.

Tardive dyskinesia is characterized by stereotyped, repetitive, painless, involuntary, quick choreiform (tic-like) movements of the face, eyelids (blinks or spasm), mouth (grimaces), tongue, extremities, or trunk, with varying degrees of slower athetosis (twisting movements); tardive dystonia and tardive akathisia are rare now that the use of high-dose, high-potency typical antipsychotic medications has abated. The movements disappear during sleep (as do many other extrapyramidal syndromes), vary in intensity over time, and are dependent on the level of arousal or emotional distress, sometimes reappearing during acute psychiatric illnesses following prolonged disappearance. The dyskinetic movements can be suppressed partially by use of a potent DA antagonist, but such interventions over time may worsen the severity, as this was part of the initial pharmacological insult. Switching patients from potent D₂ antagonists to weaker agents, especially clozapine, can be effective. When possible, drug discontinuation may be beneficial but is effective in less than 33% of cases.

The VMAT2 inhibitors valbenazine and deuterated-tetrabenazine (deutetabenazine) were FDA-approved for TD in 2017. Both are derivatives of tetrabenazine and share mechanism and many of the adverse effects of tetrabenazine. Valbenazine is active and is metabolized to an

active metabolite, dihydrotetrabenazine. The clearance of valbenazine and its active metabolite involve CYPs 2D6 and 3A4. Thus, exposure to the parent drug and its active metabolite will be increased in CYP2D6 poor metabolizers, in the presence of strong inhibitors of 2D6 (e.g., paroxetine) or 3A4 (e.g., ketoconazole), or in patients with moderate-to-severe hepatic impairment. Use of valbenazine in the presence of strong inducers of 3A4 (e.g., rifampin) is not recommended; concomitant use of MAOIs should be avoided. Valbenazine inhibits P-glycoprotein and will increase digoxin exposure. Deutetabenazine is also approved for treating the chorea of Huntington disease and is described in Chapter 18, as is tetrabenazine.

Akathisia. Unlike antipsychotic-induced parkinsonism and acute dystonia, the phenomenology and treatment of akathisia suggest involvement of structures outside the nigrostriatal pathway. Despite the association with D₂ blockade, akathisia does not have as robust a response to antiparkinsonian drugs, so other treatment strategies are often employed acutely, including high-potency benzodiazepines (e.g., clonazepam) and nonselective β blockers with good CNS penetration (e.g., propranolol). Over time, one should consider dose reduction or switching to another antipsychotic agent. That clonazepam and propranolol have significant cortical activity and are ineffective for other forms of EPSs points to an extrastriatal origin for akathisia symptoms.

Neuroleptic Malignant Syndrome. The rare NMS resembles a severe form of parkinsonism, with signs of autonomic instability (hyperthermia and labile pulse, blood pressure, and respiration rate), stupor, elevation of creatine kinase in serum, and sometimes myoglobinemia with potential nephrotoxicity. At its most severe, this syndrome may persist for more than a week after the offending agent is discontinued and is associated with mortality. This reaction has been associated with myriad antipsychotic agents, but its prevalence may be greater with relatively high doses of potent agents. Aside from cessation of antipsychotic treatment and provision of supportive care, including aggressive cooling measures, specific pharmacological treatment is unsatisfactory, although administration of dantrolene and the dopaminergic agonist bromocriptine may be helpful. While dantrolene also is used to manage the syndrome of malignant hyperthermia induced by general anesthetics, the neuroleptic-induced form of hyperthermia probably is not associated with a defect in Ca²⁺ metabolism in skeletal muscle. There are anecdotal reports of NMS with atypical antipsychotic agents, but this syndrome is now rarely seen in its full presentation (Gurrera et al., 2011).

Hyperprolactinemia. Hyperprolactinemia results from blockade of the pituitary actions of the tuberoinfundibular dopaminergic neurons; these neurons project from the arcuate nucleus of the hypothalamus to the median eminence, where they deliver DA to the anterior pituitary via the hypophyseal portal vessels. D₂ receptors on lactotrophs in the anterior pituitary mediate the tonic prolactin-inhibiting action of DA. Correlations between the D₂ potency of antipsychotic drugs and prolactin elevations are excellent. With the exception of risperidone and paliperidone, atypical antipsychotic agents show limited effects (asenapine, iloperidone, olanzapine, quetiapine, ziprasidone) to almost no effects (clozapine, aripiprazole, brexpiprazole, cariprazine) on prolactin secretion.

Hyperprolactinemia can directly induce breast engorgement and galactorrhea and can cause amenorrhea in women and sexual dysfunction or infertility in women and men. Dose reduction can be tried to decrease serum prolactin levels, but caution must be exercised to keep treatment within the antipsychotic therapeutic range. When switching from offending antipsychotic agents is not feasible, bromocriptine can be employed. The hyperprolactinemia from antipsychotic drugs is rapidly reversed when the drugs are discontinued.

Histamine H₁ Receptors. Central antagonism of H₁ receptors is associated with two major adverse effects: sedation and weight gain via appetite stimulation (Kim et al., 2007), and certain antipsychotic agents cause these adverse effects.

Sedation. Examples of sedating antipsychotic drugs include low-potency typical agents such as chlorpromazine and the atypical agents clozapine and quetiapine. The sedating effect is predicted by their high H₁ receptor affinities (Table 16–2). Some tolerance to the sedative properties will

develop, a helpful fact to remember when considering switching a patient to a nonsedating agent. Rapid discontinuation of sedating antihistaminic antipsychotic drugs is inevitably followed by significant complaints of rebound insomnia and sleep disturbance. If discontinuation of sedating antipsychotic treatment is deemed necessary, except for emergency cessation of clozapine for agranulocytosis, the medication should be tapered slowly over 4–12 weeks, and the clinician should be prepared to utilize a sedative at the end of the taper. Generous dosing of another antihistamine (hydroxyzine) or the anticholinergic antihistamine diphenhydramine are reasonable replacements. Sedation may be useful during acute psychosis, but excessive sedation can interfere with patient evaluation, may prolong emergency room and psychiatric hospital stays unnecessarily, and is poorly tolerated among elderly patients with dementia and delirium; thus, appropriate caution must be exercised with the choice of agent and the dose.

Weight Gain. Weight gain is a significant problem during long-term use of antipsychotic drugs and represents a major barrier to medication adherence, as well as a significant threat to the physical and emotional health of the patient. Weight gain has effectively replaced concerns over EPS as the adverse effect causing the most consternation among patients and clinicians alike. Appetite stimulation is the primary mechanism involved, with little evidence to suggest that decreased activity (due to sedation) is a main contributor to antipsychotic-related weight gain. Laboratory studies indicated that medications with significant H_1 antagonism induce appetite stimulation through effects at hypothalamic sites (Kim et al., 2007). The low-potency phenothiazine chlorpromazine and the atypical antipsychotic drugs olanzapine and clozapine are the agents of highest risk, but some weight gain occurs with nearly all antipsychotic drugs.

Acutely psychotic patients may lose weight; in placebo-controlled acute schizophrenia trials, the placebo cohort inevitably loses weight. Younger and antipsychotic drug-naïve patients are much more sensitive to the weight gain from all antipsychotic agents, including those that appear roughly weight neutral in adult studies, leading some to conjecture that DA blockade may also play a small additive role in weight gain (Correll et al., 2014). Antagonism at $5HT_{2C}$ receptors may play an additive role in promoting weight gain for medications that possess high H_1 affinities (e.g., clozapine, olanzapine) but appears to have no effect in the absence of significant H_1 blockade, as seen with ziprasidone, an antipsychotic with low weight gain risk but an extremely high $5HT_{2C}$ affinity.

Switching to more weight-neutral medications can achieve significant results; however, when changing medications is not feasible or unsuccessful, behavioral strategies must be employed, and should be considered for all chronically mentally ill patients given the prevalence of obesity in this patient population. There is also compelling data for the use of metformin to moderate the antipsychotic-induced weight gain from olanzapine and clozapine, particularly when commencing the antipsychotic (Prahara et al., 2011).

Muscarinic M_1 Receptors. Muscarinic antagonism is responsible for the central and peripheral anticholinergic effects of medications. The muscarinic receptor affinity and clinically relevant anticholinergic effects of the atypical antipsychotics are limited, whereas clozapine and low-potency phenothiazines have significant anticholinergic adverse effects (Table 16–2). Quetiapine has modest muscarinic affinity; its active metabolite norquetiapine is likely responsible for anticholinergic effects. Clozapine is particularly associated with significant constipation, perhaps due to anticholinergic properties, and possibly effects at sigma receptors. Routine use of stool softeners and repeated inquiry into bowel habits are necessary to prevent serious intestinal obstruction from undetected constipation. Medications with significant anticholinergic properties should be particularly avoided in elderly patients, especially those with dementia or delirium.

Adrenergic α_1 Receptors. α_1 Adrenergic antagonism is associated with risk of orthostatic hypotension and can be particularly problematic for elderly patients who have poor vasomotor tone. The extent to which antipsychotic agents cause this effect in clinical practice is dependent on the doses employed and the rapidity of titration. Compared to high-potency typical agents, low-potency typical agents generally have greater affinities

for α_1 receptors and pose greater risk for orthostasis. Among newer medications, iloperidone carries a warning regarding minimization of orthostasis risk through slower titration. Clozapine can be associated with significant orthostasis, even when titrated slowly. Because clozapine-treated patients have few other antipsychotic options, the potent mineralocorticoid fludrocortisone is sometimes tried (0.1–0.3 mg/d) as a volume expander.

Adverse Effects Not Predicted by Monoamine Receptor Affinities

Adverse Metabolic Effects. Metabolic effects are the area of greatest concern during long-term antipsychotic treatment, paralleling the overall concern for the high prevalence of prediabetic conditions, type 2 DM, and 2-fold greater CV mortality among patients with schizophrenia (Correll et al., 2014). Aside from weight gain, the two predominant metabolic adverse side effects seen with antipsychotic drugs are dyslipidemia, primarily elevated serum triglycerides, and impairments in glycemic control.

Low-potency phenothiazines elevate serum triglyceride values, an effect that is not seen with high-potency phenothiazines. Among atypical antipsychotic drugs, significant increases in fasting triglyceride levels are noted during clozapine and olanzapine exposure and, to a lesser extent, with quetiapine. Effects on total cholesterol and cholesterol fractions are significantly less but show expected associations related to agents of highest risk: clozapine, olanzapine, and quetiapine (Rummel-Kluge et al., 2010). Weight gain in general may induce deleterious lipid changes; the evidence indicates that antipsychotic-induced hypertriglyceridemia is a weight-independent adverse event that occurs within weeks of starting an offending medication and resolves within 6 weeks after medication discontinuation. In individuals not exposed to antipsychotic drugs, elevated fasting triglycerides are a direct consequence of insulin resistance because insulin-dependent lipases in fat cells are normally inhibited by insulin. As insulin resistance worsens, inappropriately high levels of lipolysis lead to the release of excess amounts of free fatty acids, which are transformed into triglyceride particles (Meyer and Stahl, 2009). Elevated fasting triglyceride levels thus become a sensitive marker of insulin resistance, leading to the hypothesis that the triglyceride increases seen during antipsychotic treatment are the result of derangements in glucose-insulin homeostasis.

The ability of antipsychotic drugs to induce hyperglycemia was first noted during low-potency phenothiazine treatment; indeed, chlorpromazine was occasionally exploited for this specific property as adjunctive presurgical treatment of insulinoma. As atypical antipsychotic drugs found widespread use, numerous case series documented the association of new-onset diabetes and diabetic ketoacidosis associated with treatment with atypical antipsychotic drugs, with most of cases observed during clozapine and olanzapine therapy (Meyer and Stahl, 2009). The mechanism by which antipsychotic drugs disrupt glucose-insulin homeostasis is not known, but in vivo animal experiments document immediate dose-dependent effects of clozapine and olanzapine on whole-body and hepatic insulin sensitivity (Meyer and Stahl, 2009).

There may also be inherent disease-related mechanisms that increase risk for metabolic disorders among patients with schizophrenia (Meyer and Stahl, 2009), but the medication itself is the primary risk factor, and all atypical antipsychotic drugs in the U.S. include a hyperglycemia warning on the drug label, although there is limited evidence that the newer medications asenapine, iloperidone, aripiprazole, brexpiprazole, cariprazine, and ziprasidone cause hyperglycemia. Use of metabolically more benign agents is recommended for the initial treatment of all patients for whom long-term treatment is expected. Clinicians should obtain baseline metabolic data, including a fasting glucose or hemoglobin A_{1c} , a fasting lipid panel, and weight and establish a plan for ongoing monitoring of these metabolic parameters. As with weight gain, the changes in fasting glucose and lipids should prompt reevaluation of ongoing treatment, institution of measures to improve metabolic health (diet, exercise, nutritional counseling), and consideration of switching antipsychotic agents.

Adverse Cardiac Effects. Multiple ion channels are involved in the depolarization and repolarization of cardiac ventricular cells (Chapters 29 and 30). Some antipsychotic agents can interfere with the functioning

of these channels, making the risk of ventricular arrhythmias and SCD a concern with the use of these drugs. While most of the older antipsychotic agents (e.g., thioridazine) significantly inhibited inwardly rectifying K^+ channels (I_{kr}) in cardiac myocytes, this effect is much less pronounced for newer agents (Leucht et al., 2013). Chapters 29 and 30. Antagonism of voltage-gated Na^+ channels causes QRS widening and an increase in the PR interval, with increased risk for ventricular arrhythmia. Thioridazine can inhibit Na^+ channels at high dosages, but other antipsychotic medications do not (Nielsen et al., 2011). Myocyte repolarization is mediated in part by K^+ current through two channels: the rapid I_{kr} and the slow I_{ks} channels. The α subunit of the I_{kr} channel, $K_v11.1$, is encoded by *hERG*, the human-ether-à-go-go related gene that codes for $Kv11.1$, the α subunit of the K^+ channel that mediates the repolarizing I_{kr} current of the cardiac action potential. Polymorphisms of *hERG* are involved in the congenital long QT syndrome associated with syncope and SCD. Antagonism of I_{kr} channels is responsible for most cases of drug-induced QT prolongation and is the suspected mechanism for the majority of antipsychotic-induced SCDs (Nielsen et al., 2011).

Aside from individual agents, for which anecdotal and pharmacosurveillance data indicate risk for torsade de pointes (e.g., thioridazine, pimozide), most of the commonly used newer antipsychotic agents are not associated with a known increased risk for ventricular arrhythmias, including ziprasidone in overdose up to 12,000 mg. One exception is sertindole, an agent not available in the U.S. that was withdrawn in 1998 based on anecdotal reports of torsade de pointes, but reintroduced in Europe in 2006 with strict ECG monitoring guidelines (Nielsen et al., 2011). Although in vitro data revealed sertindole's affinity for I_{kr} , several epidemiological studies published over the past decade were unable to confirm an increased risk of sudden death due to sertindole exposure, thereby providing justification for its reintroduction.

Currently, no data suggest a benefit of routine ECG monitoring for prevention of SCD among patients using antipsychotic drugs. Nonetheless, all antipsychotic medications marketed in the U.S. (with the exception of lurasidone) carry a class label warning regarding QT_c prolongation. A specific black-box warning exists for thioridazine, pimozide, intramuscular droperidol, and haloperidol (intravenous formulation but not oral or intramuscular) concerning torsade de pointes and subsequent fatal ventricular arrhythmias (discussed next and in Chapter 30).

Other Adverse Effects. In the U.S., there is a class label warning for seizure risk on all antipsychotic agents (except pimavanserin), with reported incidences well below 1%. Among commonly used newer antipsychotic drugs, only clozapine has a dose-dependent seizure risk, with a prevalence of 3%–5%. The structurally related olanzapine had an incidence of 0.9% in premarketing studies. Patients with seizure disorder who commence antipsychotic treatment must receive adequate prophylaxis, with consideration given to avoiding carbamazepine and phenytoin due to their capacity to induce CYPs and P-glycoprotein. Carbamazepine is also contraindicated during clozapine treatment due to its bone marrow effects. Valproate derivatives (e.g., divalproex sodium) are used for clozapine-associated seizures as they best cover the spectrum of generalized and myoclonic seizures (Meltzer, 2012).

Clozapine causes a host of other adverse effects, the most concerning of which is agranulocytosis, with an incidence of slightly under 1%; the highest risk occurs during the initial 6 months of treatment, peaking at months 2–3 and diminishing rapidly thereafter (Meltzer, 2012). The mechanism is immune mediated, and patients who have verifiable clozapine-related agranulocytosis are usually not rechallenged. An extensive algorithm guiding clinical response to agranulocytosis and lesser forms of neutropenia is available from manufacturer websites and must be followed, along with mandated CBC monitoring.

Other adverse effects include pigmentary retinopathy (thioridazine at daily doses ≥ 800 mg/d), photosensitivity (low-potency phenothiazines), and elevations of alkaline phosphatase and, rarely, hepatic transaminases (phenothiazines).

Increased Mortality in Patients With Dementia. Perhaps the least-understood adverse effect is the increased risk for cerebrovascular

events and all-cause mortality among elderly patients with dementia exposed to antipsychotic medications (~1.7-fold increased mortality risk for drug vs. placebo) (Maust et al., 2015). Mortality is due to heart failure, sudden death, or pneumonia. The underlying etiology for antipsychotic-related cerebrovascular and mortality risk is unknown, but the finding of virtually equivalent mortality risk for typical agents compared to atypical antipsychotic drugs (including aripiprazole) suggests an impact of reduced D_2 signaling regardless of individual antipsychotic mechanisms.

Overdose with typical antipsychotic agents is of particular concern with low-potency agents (e.g., chlorpromazine) due to the risk of torsades de pointes, sedation, anticholinergic effects, and orthostasis. Patients who overdose on high-potency typical antipsychotic drugs (e.g., haloperidol) and the substituted benzamides are at greater risk for EPSs (due to the high D_2 affinity) and for ECG changes. Overdose experience with newer agents indicates a much lower risk for torsade de pointes ventricular arrhythmias compared to older antipsychotic medications; however, combinations of antipsychotic agents with other medications can lead to fatality, primarily through respiratory depression.

Drug-Drug Interactions

Antipsychotic agents are not significant inhibitors of CYPs, with a few notable exceptions: chlorpromazine, perphenazine, and thioridazine inhibit CYP2D6. The plasma half-lives of a number of these agents are altered by induction or inhibition of hepatic CYPs and by genetic polymorphisms that alter specific CYP activities (Table 16–4). While antipsychotic drugs are highly protein bound, there is no evidence of significant displacement of other protein-bound medications, so dosage adjustment is not required for anticonvulsants, warfarin, or other agents with narrow therapeutic indices.

With respect to drug-drug interactions, it is important to consider the effects of environmental exposures (smoking, nutraceuticals, grapefruit juice) and changes in these behaviors. Changes in smoking status can be especially problematic for clozapine-treated patients and will alter serum levels by 50% or more (Rostami-Hodjegan et al., 2004) due to the capacity of aromatic hydrocarbons in tobacco smoke to induce CYP1A2, the major metabolizer of clozapine. Thus, hospitalization of a smoker in a smoke-free environment results in decreased CYP1A2 activity and an elevation of clozapine plasma levels, with potentially toxic results. Conversely, a patient discharged from a nonsmoking ward who resumes smoking will experience an increase in CYP1A2 activity and a 50% decrease in plasma clozapine levels. Monitoring of plasma clozapine concentrations, anticipation of changes in smoking habits, and dosage adjustment can minimize development of subtherapeutic or supratherapeutic levels.

Use in Pediatric Populations

Aripiprazole, olanzapine, quetiapine, risperidone, lurasidone, and paliperidone have indications for adolescent schizophrenia (ages 13–17). Aripiprazole, quetiapine, and risperidone are approved in child and adolescent bipolar disorder (acute mania) for ages 10–17; risperidone and aripiprazole are also FDA-approved for irritability associated with autism in child and adolescent patients ages 5–16. As discussed in the sections on adverse effects, antipsychotic drug-naïve patients and younger patients are more susceptible than other patients to EPSs and weight gain (Correll et al., 2014; Peruzzolo et al., 2013). Use of the minimum effective dose can minimize EPS risk, and use of agents with lower weight gain liability is critical. The greater impact of risperidone and paliperidone on serum prolactin must be monitored by clinical inquiry. Delayed sexual maturation was not seen in adolescents in clinical trials with risperidone; nonetheless, the physician must be alert for such changes and for issues such as amenorrhea in girls and gynecomastia in boys and girls.

Use in Geriatric Populations

The increased sensitivity to EPSs, orthostasis, sedation, and anticholinergic effects are important for the geriatric population and often dictate the choice of antipsychotic medication. Avoidance of drug-drug interactions is also important, as older patients on numerous concomitant medications have multiple opportunities for interactions. Dose adjustment can offset known drug-drug interactions, but clinicians must be attentive to

changes in concurrent medications and the potential pharmacokinetic consequences. Vigilance must also be maintained for the additive pharmacodynamic effects of α_1 adrenergic, antihistaminic, and anticholinergic properties of other agents.

Elderly patients have an increased risk for TD and parkinsonism, with TD rates about 5-fold higher than those seen with younger patients. With typical antipsychotics, the reported annual TD incidence among elderly patients is 20%–25% compared to 4%–5% for younger patients. With atypical antipsychotics, the annual TD rate in elderly patients is much lower (2%–3%). Increased risk for cerebrovascular events and all-cause mortality is also seen in elderly patients with dementia (see Increased Mortality in Patients With Dementia). Compared to younger patients, antipsychotic-induced weight gain is lower in elderly patients.

Use During Pregnancy and Lactation

Human data from large database studies do not show increased rates of major congenital malformations after first trimester exposure (Huybrechts et al., 2016). Nonetheless, the use of any medication during pregnancy must be balanced by concerns over fetal impact, especially first-trimester exposure, and the mental health of the mother. As antipsychotic drugs are designed to cross the blood-brain barrier, all have high rates of placental passage. Placental passage ratios are estimated to be highest for olanzapine (72%), followed by haloperidol (42%), risperidone (49%), and quetiapine (24%). Neonates exposed to olanzapine, the atypical agent with highest placental passage ratio, exhibit a trend toward greater neonatal intensive care unit admission. Use in nursing mothers raises a separate set of concerns due to the reduced capacity of the newborn to metabolize xenobiotics, thus presenting a significant risk for antipsychotic drug toxicity. Available data do not provide adequate guidance on choice of agent.

Major Drugs Available in the Class

Atypical antipsychotic drugs have largely replaced older agents, primarily due to their more favorable EPS profile. The older, typical agents are widely used when a higher level of D_2 antagonism is required. Table 16–1 describes the acute and maintenance doses for adult schizophrenia treatment based on consensus recommendations. There are numerous LAI formulations of typical antipsychotics (Table 16–3), but in the U.S., the only available LAI typical agents are fluphenazine and haloperidol (as decanoate esters) (Meyer, 2013), suitable for weekly injections. There are now six LAI atypical antipsychotics approved, including a 3-month form of LAI paliperidone. Pimavanserin is the only medication indicated for PDP, and does not worsen motor symptoms due to the lack of DA antagonism (Cummings et al., 2014).

Treatment of Mania

Mania is a period of elevated, expansive, or irritable mood with coexisting symptoms of increased energy and goal-directed activity and decreased need for sleep. Mania represents one pole of bipolar disorder (American

Psychiatric Association, 2013). As with psychosis, mania may be induced by medications (e.g., DA agonists, antidepressants, stimulants) or substances of abuse, primarily cocaine and amphetamines, although periods of substance-induced mania should not be relied on solely to make a diagnosis of bipolar disorder. Nonetheless, there is recognition that patients who develop antidepressant-induced mania do have a bipolar diathesis even with no prior independent history of mania and should be followed carefully, especially if antidepressant treatment is again considered during periods of major depression.

Mania is distinguished from its less-severe form, hypomania, by the fact that hypomania, by definition, does not result in functional impairment or hospitalization and is not associated with psychotic symptoms. Patients who experience periods of hypomania and major depression have bipolar II disorder; those with mania at any time, bipolar I; and those with hypomania but less-severe forms of depression, cyclothymia (American Psychiatric Association, 2013). The prevalence of bipolar I disorder is roughly 1% of the population, and the prevalence of all forms of bipolar disorder is 3%–5%.

Genetics studies of bipolar disorder have yielded several loci of interest associated with disease risk and predictors of treatment response, but the data are not yet at the phase of clinical application. Unlike schizophrenia, for which the biological understanding of monoamine neurotransmission has permitted synthesis of numerous effective compounds, no medication has yet been designed to treat the full spectrum of bipolar disorder based on biological hypotheses of the illness. Lithium carbonate was introduced fortuitously in 1949 for the treatment of mania and approved for this purpose in the U.S. in 1970. While many classes of agents demonstrate efficacy in acute mania, including Li^+ , antipsychotic drugs, and certain anticonvulsants, no medication has surpassed lithium's efficacy for prophylaxis of future manic and depressive phases of bipolar disorder, and no other medication has demonstrated lithium's reduction in suicidality among bipolar patients (Geddes and Miklowitz, 2013).

Pharmacological Properties of Agents for Mania

Antipsychotic Agents

The chemistry and pharmacology of antipsychotic medications are addressed earlier in this chapter. When used for acute mania, the dosages are often at the high end of approved maximum dosing. Clozapine can be beneficial in patients with refractory mania as adjunctive therapy and as monotherapy (Geddes and Miklowitz, 2013). Certain antipsychotics have efficacy for adjunctive use (olanzapine) or as monotherapy (quetiapine, lurasidone) for bipolar depression, typically at much lower dosages than for acute mania.

Anticonvulsants

The pharmacology and chemistry of the anticonvulsants with significant use in treating acute mania (valproic acid compounds, carbamazepine) and for bipolar maintenance (lamotrigine) are covered extensively in Chapter 17. The therapeutic serum levels for the commonly used mood-stabilizing anticonvulsants and for Li^+ are listed in Table 16–6.

TABLE 16–6 ■ COMPARATIVE EFFICACY AND TARGET SERUM LEVELS FOR MOOD STABILIZERS

	ACUTE MANIA	PROPHYLAXIS	BIPOLAR DEPRESSION
Lithium	+++ 1.0–1.5 mEq/L ^a	+++ 0.6–1.0 mEq/L	++ 0.6–1.0 mEq/L
Valproate	++++ 100–120 µg/mL ^b	+++ 60–100 µg/mL	—
Carbamazepine	+ 6–12 µg/mL	++ 6–12 µg/mL	+/– 6–12 µg/mL
Lamotrigine	–	++	++

^aLithium can be loaded with individual 10-mg/kg doses of an extended-release preparation administered at 4 PM, 6 PM, and 8 PM (Kook et al., 1985). Treatment should continue on day 2 with lithium carbonate given once nightly to minimize the risk of polyuria and renal insufficiency.

^bDivalproex can be loaded at 30 mg/kg over 24 h, administered as a single dose or separated into two doses.

Lithium

Lithium is the lightest of the alkali metals (group Ia). Salts of Li^+ share some characteristics with those of Na^+ and K^+ . Li^+ is readily assayed in biological fluids and can be detected in brain tissue by magnetic resonance spectroscopy. Traces of the ion occur normally in animal tissues, but it has no known physiological role. Lithium carbonate and lithium citrate are used therapeutically in the U.S.

Therapeutic concentrations of Li^+ have almost no discernible psychotropic effects in individuals without psychiatric symptoms. There are numerous molecular and cellular actions of Li^+ , some of which overlap with identified properties of other mood-stabilizing agents (particularly valproate) and are discussed next. An important characteristic of Li^+ is that, unlike Na^+ and K^+ , Li^+ develops a relatively small gradient across biological membranes. Although it can replace Na^+ in supporting a single action potential in a nerve cell, it is not a substrate for the Na^+ pump and therefore cannot maintain membrane potentials. It is uncertain whether therapeutic concentrations of Li^+ (0.5–1.0 mEq/L) affect the transport of other monovalent or divalent cations by nerve cells.

Hypotheses for the Mechanism of Action of Lithium and Relationship to Anticonvulsants

Plausible hypotheses for the mechanism of action focus on lithium's impact on monoamines implicated in the pathophysiology of mood disorders and on second-messenger and other intracellular molecular mechanisms involved in signal transduction, gene regulation, and cell survival. Li^+ has limited effects on catecholamine-sensitive adenylyl cyclase activity or on the binding of ligands to monoamine receptors in brain tissue, although it can influence response of 5HT autoreceptors to agonists (Grandjean and Aubry, 2009b). 5HT release from presynaptic terminals is regulated by 5HT_{1A} autoreceptors located on the cell body and 5HT_{1B} receptors on the nerve terminal. In vitro electrophysiological studies suggest that Li^+ facilitates 5HT release. Li^+ augments effects of antidepressants, and in animal models of depression, lithium's activity appears to be mediated through desensitizing actions at 5HT_{1B} sites; Li^+ also antagonizes mouse behaviors induced by administration of selective 5HT_{1B} agonists (Grandjean and Aubry, 2009b).

Li^+ inhibits inositol monophosphatase and interferes with the cycling of the PI pathway (Figure 16–1) (Grandjean and Aubry, 2009b). One result is an enhancement of IP_3 accumulation when the G_q -PLC- IP_3 - Ca^{2+} pathway is activated. As a result, IP_3 signaling and consequent mobilization of Ca^{2+} from intracellular stores may also be enhanced acutely, along with the sequelae of those effects; Ca^{2+} mobilization, PKC activation, depletion of cellular inositol; another result is a decrease in available inositol for resynthesis/reincorporation into membrane PI phosphates. The uncompetitive inhibition of IP phosphatase by Li^+ occurs within the range of therapeutic Li^+ concentrations. A genome-wide association study implicated diacylglycerol kinase in the etiology of bipolar disorder, strengthening the association between Li^+ actions and PI metabolism. Further support for the role of inositol signaling in mania rests on the finding that valproate and its derivatives decrease intracellular inositol concentrations. Unlike Li^+ , valproate decreases inositol through inhibition of *myo*-inositol-1-phosphate synthase. In cultured cell systems, carbamazepine appears to act via inositol depletion. Perhaps such a mechanism contributes to carbamazepine's mood-stabilizing properties (Rapoport et al., 2009).

Treatment with Li^+ ultimately leads to decreased activity of several protein kinases in brain tissue, including PKC, particularly isoforms α and β (Einat, 2014). Among other proposed antimanic or mood-stabilizing agents, this effect is also shared with valproate (particularly for PKC) but not with carbamazepine. Long-term treatment of rats with lithium carbonate or valproate decreases cytoplasm-to-membrane translocation of PKC and reduces PKC stimulation-induced release of 5HT from cerebral cortical and hippocampal tissue. Excessive PKC activation can disrupt prefrontal cortical regulation of behavior, but pretreatment of monkeys and rats with lithium carbonate or valproate blocks the impairment in working memory induced by activation of PKC in a manner also seen with the PKC inhibitor chelerythrine (Einat, 2014). A major substrate for cerebral PKC is the MARCKS protein, which is implicated in synaptic

and neuronal plasticity. The expression of MARCKS protein is reduced by treatment with both Li^+ and valproate but not by carbamazepine, antipsychotic medications, or antidepressants (Wang et al., 2001). This proposed mechanism of PKC inhibition has been the basis for therapeutic trials of tamoxifen, a selective estrogen receptor modulator that is also a potent centrally active PKC inhibitor. In acutely manic patients with bipolar I, tamoxifen has shown evidence of efficacy as adjunctive treatment (Einat, 2014). The impact of Li^+ or valproate on PKC activity may secondarily alter the activity of tyrosine hydroxylase. Li^+ may alter the release of neurotransmitters and hormones by a variety of putative mechanisms, and its acute effects may differ from its longterm effects (Sharp et al., 1991; Millienne-Petiot et al., 2017; Can et al., 2016; Fortin et al., 2016).

Both Li^+ and valproate treatment also inhibit the activity of GSK-3 β (Williams et al., 2002). GSK-3 inhibition increases hippocampal levels of β -catenin, a function implicated in mood stabilization. In animal models, Li^+ induces molecular and behavioral effects comparable to that seen when one GSK-3 β gene locus is inactivated (Urs et al., 2012). These lithium-sensitive behaviors are related to the impact of GSK-3 β inhibition on the β -arrestin-2/PKB/PP2A signaling complex. Li^+ disrupts β -arrestin-2/PKB/PP2A complex formation by directly inhibiting GSK-3 β .

Another proposed common mechanism for the actions of Li^+ and valproate relates to reduction in arachidonic acid turnover in brain membrane phospholipids. Rats fed Li^+ in amounts that achieve therapeutic CNS drug levels have reduced turnover of PI (\downarrow 83%) and phosphatidylcholine (\downarrow 73%); chronic intraperitoneal valproate achieves reductions of 34% and 36%, respectively. Li^+ also decreases gene expression of phospholipase A₂ and levels of COX-2 and its products (Rapoport et al., 2009).

ADME

Li^+ is almost completely absorbed from the GI tract. Peak plasma concentrations occur 2–4 h after an oral dose. Slow-release preparations of lithium carbonate minimize peak-to-trough ratios and permit once-daily dosing. Li^+ initially distributes to the extracellular fluid, does not bind appreciably to plasma proteins, and gradually accumulates in tissues, with a volume of distribution of 0.7–0.9 L/kg. The concentration gradient across plasma membranes is much smaller than those for Na^+ and K^+ . Passage through the blood-brain barrier is slow, and when a steady state is achieved, the concentration of Li^+ in the cerebrospinal fluid and in brain tissue is about 40%–50% of the concentration in plasma. The kinetics of Li^+ can be monitored in human brain with magnetic resonance spectroscopy (Grandjean and Aubry, 2009b).

Approximately 95% of a single dose of Li^+ is eliminated in the urine, with a $t_{1/2}$ of about 24 h (varies with age and can be \sim 12 h in the young and \sim 36 h in the elderly [secondary to reduced GFR]). The $t_{1/2}$ generally supports once-daily dosing, which improves adherence and decreases risk for renal insufficiency by at least 20% (Castro et al., 2016). With repeated administration, Li^+ levels and excretion increase until a steady state is achieved (after four to five half-lives). When Li^+ is stopped, there is a rapid phase of renal excretion followed by a slow 10- to 14-day phase. Although the pharmacokinetics of Li^+ vary considerably among subjects, the volume of distribution and clearance are relatively stable in an individual patient.

Less than 1% of ingested Li^+ leaves the human body in the feces; 4%–5% is secreted in sweat (Grandjean and Aubry, 2009c). Li^+ is secreted in saliva in concentrations about twice those in plasma, while its concentration in tears is about equal to that in plasma. Li^+ is secreted in human milk, but serum levels in breast-fed infants are about 20% that of maternal levels and are not associated with notable behavioral effects (Diav-Citrin et al., 2014).

Li^+ competes with Na^+ for tubular reabsorption, and Li^+ retention can be increased by Na^+ loss related to diuretic use or diarrhea and other GI illness. Heavy sweating leads to a preferential secretion of Li^+ over Na^+ ; the repletion of excessive sweating using free water without electrolytes can cause hyponatremia and promote Li^+ retention (Grandjean and Aubry, 2009b).

Serum-Level Monitoring and Dose

Because of the low therapeutic index for Li^+ , regular determination of serum concentrations is crucial. Concentrations considered to be

effective and acceptably safe are between 0.6 and 1.5 mEq/L. The range of 1.0–1.5 mEq/L is favored for treatment of acutely manic patients. Somewhat lower values (0.6–1.0 mEq/L) are considered adequate and are safer for long-term prophylaxis. Serum concentrations of Li^+ have been found to follow a clear dose-effect relationship between 0.4 and 1.0 mEq/L, but with a corresponding dose-dependent rise in polyuria and tremor as indices of adverse effects (Grandjean and Aubry, 2009b, 2009c). Nonetheless, patients who maintain trough levels of 0.8–1.0 mEq/L experience decreased relapse risk compared to those maintained at lower serum concentrations. There are patients who may do well with serum levels of 0.5–0.8 mEq/L, but there are no current clinical or biological predictors to permit a priori identification of these individuals. Individualization of serum levels is often necessary to obtain a favorable risk-benefit relationship.

By convention, the serum Li^+ concentration is measured from samples obtained 10–12 h after the last oral dose of the day. When the peaks are reached, intoxication may result, even when concentrations in morning samples of plasma at the daily nadir are in the acceptable range of 0.6–1 mEq/L. Single daily doses generate relatively large oscillations of plasma Li^+ concentration but lower mean trough levels than with multiple-daily dosing; moreover, single-nightly dosing means that peak serum levels occur during sleep, so complaints of CNS adverse effects are minimized (Grandjean and Aubry, 2009c). While relatively uncommon, GI complaints are a compelling reason for using delayed-release Li^+ preparations, also given once daily.

Therapeutic Uses

Drug Treatment of Bipolar Disorder. Treatment with Li^+ ideally is conducted in patients with normal cardiac and renal function. Occasionally, patients with severe systemic illnesses are treated with Li^+ , provided that the indications are compelling, but the need for diuretics, nonsteroidal anti-inflammatory agents, or other medications that pose potential kinetic problems often precludes Li^+ use in those with multiple medical problems. Treatment of acute mania and the prevention of recurrences of bipolar illness in adults or adolescents are uses approved by the FDA. Li^+ is the mood stabilizer with the most robust data on suicide reduction in bipolar patients; Li^+ is also efficacious for augmentation in unipolar depressive patients who respond inadequately to antidepressant therapy (Grandjean and Aubry, 2009a).

Pharmacotherapy of Mania. The modern treatment of the manic, depressive, and mixed-mood phases of bipolar disorder was revolutionized by the introduction of Li^+ in 1949, initially for acute mania only and later for prevention of recurrences of mania. While Li^+ , valproate, and carbamazepine have efficacy in acute mania, in clinical practice these are usually combined with atypical antipsychotic drugs, even in manic patients without psychotic features, due to their complementary modes of action. Li^+ , carbamazepine, and valproic acid preparations are effective only with daily dosing that maintains adequate serum levels (requires monitoring of serum levels). Patients with mania are often irritable and poorly cooperative with medication administration and phlebotomy; thus, atypical antipsychotic drugs may be the sole initial therapy, and they have proven efficacy as monotherapy. Moreover, acute intramuscular forms of olanzapine and ziprasidone can be used to achieve rapid control of psychosis and agitation. Benzodiazepines are often used adjunctively for agitation and sleep induction.

Li^+ is effective in acute mania and can be loaded in those with normal renal function using three individual 10-mg/kg doses of a sustained-release preparation administered at 2-h intervals. The sustained-release form is used to minimize GI adverse effects (e.g., nausea, diarrhea); treatment may then be continued with Li^+ carbonate. Acutely manic patients may require higher dosages to achieve therapeutic serum levels, and downward adjustment may be necessary once the patient is euthymic. Efficacy following loading can be achieved within 5 days. When adherence with oral capsules or tablets is an issue, the liquid Li^+ citrate can be used.

The anticonvulsant sodium valproate also provides antimanic effects, with therapeutic benefit seen within 3–5 days (Cipriani et al., 2013). The most common form of valproate in use is divalproex sodium due to lower

incidence of GI and other adverse effects. Divalproex is initiated at 30 mg/kg given as single or divided doses and titrated to effect based on the desired serum level. Serum concentrations of 90–120 $\mu\text{g/mL}$ show the best response in clinical studies (Cipriani et al., 2013). With immediate-release forms of valproic acid and divalproex sodium, 12-h troughs are used to guide treatment. With the extended-release divalproex preparation, the true trough occurs 24 h after dosing. Obtaining serum levels at night may be difficult in outpatient settings, so 12-h troughs are commonly used, bearing in mind that 12-h trough levels are 18%–25% higher than the 24-h trough (Reed and Dutta, 2006).

Carbamazepine is effective for acute mania, but immediate-release forms of carbamazepine cannot be loaded or rapidly titrated over 24 h due to the development of adverse effects such as dizziness or ataxia, even within the therapeutic range (6–12 $\mu\text{g/mL}$) (Geddes and Miklowitz, 2013). An extended-release form of carbamazepine is effective as monotherapy with once-daily dosing. Carbamazepine response rates are lower than those for valproate compounds or for Li^+ , with mean rates of 45%–60% cited in the literature (Geddes and Miklowitz, 2013). Nevertheless, certain individuals respond to carbamazepine after failing Li^+ and valproate. Initial doses are 400 mg/d in two divided doses. Titration proceeds by 200-mg increments every 24–48 h based on clinical response and serum trough levels, not to exceed 1600 mg/d.

The FDA has warned that serious and potentially fatal skin reactions (e.g., Stevens-Johnson syndrome and toxic epidermal necrolysis) may occur with the administration of carbamazepine in patients positive for the *HLA-B*1502* allele. Thus, the FDA recommends genetic screening for patients of Asian ancestry (among whom the prevalence of this allele exceeds 15%) before initiation of carbamazepine therapy and using alternative therapies in patients positive for the allele. See Chapter 17 for more information on carbamazepine.

Lamotrigine has no role in acute mania due to the slow, extended titration necessary to minimize risk of Stevens-Johnson syndrome and is used for bipolar maintenance (Rapoport et al., 2009; Selle et al., 2014).

Prophylactic Treatment of Bipolar Disorder. The choice of ongoing prophylaxis is determined by the need for continued antipsychotic drug use and for use of a mood-stabilizing agent. Both aripiprazole and olanzapine are effective as monotherapy for mania prophylaxis, but olanzapine use is eschewed out of concern for metabolic effects, and aripiprazole shows no benefit for prevention of depressive relapse. LAI risperidone is approved for bipolar maintenance treatment as monotherapy or adjunctively with Li^+ or valproate. If LAI risperidone is used as monotherapy, coverage with an oral antipsychotic is necessary for the first 4 weeks after the initial injection. When antipsychotic drugs have been employed as adjunctive agents, the optimal duration of treatment is unclear; recent data indicate no greater benefit beyond 6 months after remission from an acute manic episode (Yatham et al., 2016).

Overriding concerns guiding bipolar treatment are the high recurrence rate and the high risk of suicide. Individuals who experience mania have an 80%–90% lifetime risk of subsequent manic episodes. As with schizophrenia, lack of insight, poor psychosocial support, and substance abuse all interfere with treatment adherence. While the anticonvulsants lamotrigine, carbamazepine, and divalproex have data supporting their use in bipolar prophylaxis, only lithium has consistently been shown to reduce the risk of suicide compared to other treatments, specifically when compared to valproate acid derivatives (Goodwin et al., 2003).

A recent large trial comparing Li^+ and valproate found no significant differences in time to relapse between the two agents (Cipriani et al., 2013). Lamotrigine has proven effective for bipolar patients whose most recent mood episode was manic or depressed, with greater effect on depressive relapse (Selle et al., 2014). The ability to provide prophylaxis for future depressive episodes combined with data in acute bipolar depression has made lamotrigine a useful choice for bipolar treatment, given that patients with bipolar I and II spend large amounts of time in depressive phases (Selle et al., 2014).

Bipolar disorder is a lifetime illness with high recurrence rates. Individuals who experience an episode of mania should be educated about the

probable need for ongoing treatment. Stopping mood stabilizer therapy can be considered in patients who have experienced only one lifetime manic episode, particularly when there may have been a pharmacological precipitant (e.g., substance or antidepressant use), and who have been euthymic for extended periods. For patients with bipolar II, the impact of hypomania is relatively limited, so the decision to recommend prolonged maintenance treatment with a mood stabilizer is based on clinical response and risk:benefit ratio. Discontinuation of maintenance Li^+ treatment in patients with bipolar I carries a high risk of early recurrence and of suicidal behavior over a period of several months, even if the treatment had been successful for several years. Recurrence is much more rapid than is predicted by the natural history of untreated bipolar disorder, in which cycle lengths average about 1 year. This risk may be moderated by slow, gradual removal of Li^+ ; rapid discontinuation should be avoided unless dictated by medical emergencies.

Other Uses of Lithium. Li^+ is effective as adjunct therapy in treatment-resistant major depression (Grandjean and Aubry, 2009a). Clinical data also support Li^+ use as monotherapy for unipolar depression. Meta-analyses indicated that lithium's benefit on suicide reduction extends to patients with unipolar mood disorder (Baldessarini and Tondo, 2000). While maintenance Li^+ levels of 0.6–1.0 mEq/L are used for bipolar prophylaxis, a lower range (0.4–0.8 mEq/L) is recommended for antidepressant augmentation.

Based on its neuroprotective properties, Li^+ treatment has been suggested for conditions associated with excitotoxic and apoptotic cell death, such as stroke and spinal cord injury, and in neurodegenerative disorders, including dementia of the Alzheimer type, Parkinson disease, Huntington disease, amyotrophic lateral sclerosis, progressive supranuclear palsy, and spinocerebellar ataxia type I (Chiu et al., 2013).

Drug Interactions. Thiazide diuretics cause significant reductions in Li^+ clearance that result in toxic levels. The K^+ -sparing diuretics have more modest effects on the excretion of Li^+ , with concomitantly smaller increases in serum levels. Loop diuretics such as furosemide seem to have limited impact on Li^+ levels (Grandjean and Aubry, 2009b). Administration of osmotic diuretics or acetazolamide increases renal excretion of Li^+ but not sufficiently for the management of acute Li^+ intoxication. Through alteration of renal perfusion, some nonsteroidal anti-inflammatory agents can facilitate renal proximal tubular resorption of Li^+ and thereby increase serum concentrations (Grandjean and Aubry, 2009b). This interaction appears to be particularly prominent with indomethacin, but also may occur with ibuprofen, naproxen, and COX-2 inhibitors and possibly less so with sulindac and aspirin. ACEIs, particularly lisinopril, also cause Li^+ retention, with isolated reports of toxicity among stable Li^+ -treated patients switched from fosinopril to lisinopril (Meyer et al., 2005).

Amiloride blocks entry of Li^+ into renal distal tubule ENaCs and has been used to safely manage NDI associated with Li^+ therapy (Bedford et al., 2008). The development of NDI is related to accumulation of Li^+ in distal tubular cells and subsequent inhibition of GSK-3 β , leading to vasopressin insensitivity and downregulation of aquaporin-2 channels. The use of amiloride for this purpose requires electrolyte monitoring and Li^+ dosage adjustments to prevent toxicity (Bedford et al., 2008).

Adverse Effects of Lithium

CNS Effects. The most common effect of Li^+ in the therapeutic dose range is fine postural hand tremor, indistinguishable from essential tremor. Severity and risk for tremor are dose dependent, with incidence ranging from 15% to 70%. In addition to the avoidance of caffeine and other agents that increase tremor amplitude, therapeutic options include dose reduction (bearing in mind the increased relapse risk with lower serum Li^+ levels) and β adrenergic blockade (Grandjean and Aubry, 2009c); the approach to valproate-induced tremor is identical. At peak serum (and CNS) levels of Li^+ , patients may complain of incoordination, ataxia, or slurred speech, all of which can be avoided by dosing Li^+ at bedtime. Patients may also complain of mental fatigue or cognitive dulling at higher serum Li^+ levels, but this should be carefully assessed to determine whether this reflects a true side effect or a desire to regain the mental high from hypomania.

Seizures have been reported in nonepileptic patients with therapeutic plasma concentrations of Li^+ . Li^+ treatment has also been associated with increased risk of post-ECT confusion and is generally tapered off prior to a course of ECT (Grandjean and Aubry, 2009c). In some instances, addition of Li^+ to existing antipsychotics may increase the sensitivity to D_2 blockade, resulting in EPSs.

Li^+ treatment results in significant weight gain, a problem that is magnified by concurrent use of antipsychotic drugs. Mean weight change at 1 year in prospective Li^+ trials ranges from –1 kg to +4 kg, but the proportion of individuals who gain more than 5% of baseline weight is 13%–62%. Although the mechanism is unclear, central appetite stimulation at hypothalamic sites is the most plausible explanation (Grandjean and Aubry, 2009c).

Renal Effects. The kidney's ability to concentrate urine decreases during Li^+ therapy, and about 60% of individuals exposed to Li^+ experience some form of polyuria and compensatory polydipsia. The mechanism of polyuria is related to the fact that Li^+ has 1.5- to 2.0-fold greater affinity than Na^+ for ENaC present on the apical (i.e., luminal) surfaces of distal tubular cells. Once in the cell, Li^+ is a poor substrate for the Na^+ - K^+ -ATPase present on the basal membrane, leading to accumulation of Li^+ in these distal tubular cells (Grunfeld and Rossier, 2009). High intracellular Li^+ concentrations inhibit GSK-3 β , leading to vasopressin insensitivity, downregulation of aquaporin-2 channels, and NDI. Mean 24-h urinary volumes of 3 L/d are common among long-term Li^+ users. Li^+ discontinuation or a switch to single-daily dosing may reverse the impact on renal concentrating ability in patients with less than 5 years of Li^+ exposure. Patients exposed to multiple-daily dosing are at greater risk for renal effects. Renal function should be monitored with semiannual serum blood urea nitrogen and creatinine levels and calculation of eGFR using standard formulas (Morris and Benjamin, 2008). Spot urine osmolality measurements are used to determine the extent and development of problems with NDI and polyuria. Reassessment of Li^+ treatment should be considered when the eGFR is less than 60 mL/min on several periodic measurements, daily urinary volume exceeds 4 L, or serum creatinine continues to rise on three separate occasions (Morris and Benjamin, 2008). With modern monitoring principles, no patient should develop chronic kidney disease to the extent of requiring renal dialysis (Aiff et al., 2014).

Thyroid and Endocrine Effects. A small number of patients on Li^+ develop a benign, diffuse, nontender thyroid enlargement suggestive of compromised thyroid function; many of these patients will have normal thyroid function. Measurable effects of Li^+ on thyroid indices are seen in a fraction of patients: 7%–10% develop overt hypothyroidism, and 23% have subclinical disease, with women at three to nine times greater risk (Grandjean and Aubry, 2009c). Ongoing monitoring of TSH and free T_4 is recommended throughout the course of Li^+ treatment. The development of hypothyroidism is easily treated through exogenous replacement and is not a reason to discontinue Li^+ therapy. Rare reports of hyperthyroidism during Li^+ treatment also exist (Persad et al., 1993). Hypercalcemia related to hyperparathyroidism has been reported in about ~10% of Li^+ -treated patients. Routine monitoring of serum Ca^{2+} should be included with measurements of electrolytes, thyroid indices, renal function, and serum Li^+ levels (Shapiro and Davis, 2015).

ECG Effects. The prolonged use of Li^+ causes benign and reversible T-wave flattening in about 20% of patients. At therapeutic concentrations, there are rare reports of Li^+ -induced effects on cardiac conduction and pacemaker automaticity, effects that become pronounced during overdose and lead to sinus bradycardia, A-V block, and possible CV compromise (Grandjean and Aubry, 2009c). Routine ECG monitoring may be considered in older patients, particularly those with a history of arrhythmia or coronary heart disease.

Skin Effects. Allergic reactions such as dermatitis, folliculitis, and vasculitis can occur with Li^+ administration. Worsening of acne vulgaris, psoriasis, and other dermatological conditions is a common problem that is usually treatable by topical measures but in a small number may

improve only on discontinuation of Li^+ (Grandjean and Aubry, 2009c). Some patients on Li^+ (and valproate) may experience alopecia.

Pregnancy and Lactation. The use of Li^+ in early pregnancy may be associated with an increase in the incidence of CV anomalies of the newborn, especially Ebstein malformation. The risk of Ebstein anomaly (about 1 per 20,000 live births in controls) may rise several-fold with first-trimester Li^+ exposure; recent estimates indicate a risk of up to 1 per 2500 (Diav-Citrin et al., 2014). In balancing the risk versus benefit of using Li^+ in pregnancy, it is important to evaluate the risk of inadequate prophylaxis for the patient with bipolar disorder and subsequent risk that mania poses for the patient and fetus. If there is a compelling need for Li^+ , screening ultrasonography for CV anomalies is recommended. In patients who choose to forgo medication exposure during the first trimester, potentially safer treatments for acute mania include antipsychotic drugs or ECT.

In pregnancy, maternal polyuria may be exacerbated by Li^+ . Concomitant use of Li^+ with medications that waste Na^+ or a low- Na^+ diet during pregnancy can contribute to maternal and neonatal Li^+ intoxication. Li^+ freely crosses the placenta, and fetal or neonatal Li^+ toxicity may develop when maternal blood levels are within the therapeutic range (Grandjean and Aubry, 2009c). Fetal Li^+ exposure is associated with neonatal goiter, CNS depression, hypotonia (“floppy baby” syndrome), and cardiac murmur. Most experts recommend withholding Li^+ therapy for 24–48 h before delivery, and this is considered standard practice to avoid the potentially toxic increases in maternal and fetal serum Li^+ levels associated with postpartum diuresis. The physical and CNS sequelae of late-term neonatal Li^+ exposure are reversible once Li^+ exposure has ceased, and no long-term neurobehavioral consequences are observed (Diav-Citrin et al., 2014).

Other Effects. A benign, sustained increase in circulating polymorphonuclear leukocytes (12,000–15,000 cells/mm³) commonly occurs, related to Li^+ -induced increases in urinary levels of G-CSF and augmented production of G-CSF by peripheral blood mononuclear cells (Focosi et al., 2009). Li^+ also directly stimulates the proliferation of pluripotent stem cells. Some patients may complain of a metallic taste, making food less palatable.

Acute Toxicity and Overdose. The occurrence of toxicity is related to the serum concentration of Li^+ and its rate of rise following administration. Acute intoxication is characterized by vomiting, profuse diarrhea, coarse tremor, ataxia, coma, and convulsions. Symptoms of milder toxicity are most likely to occur at the absorptive peak of Li^+ and include nausea, vomiting, abdominal pain, diarrhea, sedation, and fine tremor. The more serious effects involve the nervous system and include mental confusion, hyperreflexia, gross tremor, dysarthria, seizures, and cranial nerve and focal neurological signs, progressing to coma and death. Sometimes both cognitive and motor neurological damage may be irreversible, with persistent cerebellar tremor the most common (El-Mallakh, 1986). Other toxic effects are cardiac arrhythmias, hypotension, and albuminuria.

Treatment of Lithium Intoxication. There is no specific antidote for Li^+ intoxication, and treatment is supportive, including intubation if indicated and continuous cardiac monitoring. Levels greater than 1.5 mEq/L are considered toxic, but inpatient medical admission is usually not indicated (in the absence of symptoms) until levels exceed 2 mEq/L. Care must be taken to ensure that the patient is not Na^+ and water depleted (Grandjean and Aubry, 2009c). Dialysis is the most effective means of removing Li^+ and is necessary in severe poisonings, that is, in patients exhibiting symptoms of toxicity or patients with serum Li^+ concentrations of 3 mEq/L or greater in acute overdoses. Complete recovery occurs with an average maximal level of 2.5 mEq/L; permanent neurological symptoms result from mean levels of 3.2 mEq/L; death occurs with mean maximal levels of 4.2 mEq/L (El-Mallakh, 1986).

Use in Pediatric Populations. Li^+ is FDA-approved for child/adolescent bipolar disorder for ages 12 years or older (Peruzzolo et al., 2013).

Aripiprazole, quetiapine, and risperidone are FDA approved for acute mania in children and adolescents aged 10–17 years. Children and adolescents have higher volumes of body water and higher eGFR than adults. The resulting shorter $t_{1/2}$ of Li^+ demands dosing increases on a milligram/kilogram basis, and multiple-daily dosing is often required. In children ages 6–12 years, a dose of 30 mg/kg/d given in three divided doses will produce a Li^+ concentration of 0.6–1.2 mEq/L in 5 days, although dosing is always guided by serum levels and clinical response (Peruzzolo et al., 2013). Use in children under 12 represents an off-label use for Li^+ , and caregivers should be alert to signs of toxicity. As with adults, ongoing monitoring of renal and thyroid function is important, along with clinical inquiry into extent of polyuria.

A limited number of controlled studies suggested that valproate has efficacy comparable to that of Li^+ for mania in children or adolescents (Peruzzolo et al., 2013). As with Li^+ , weight gain and tremor can be problematic; moreover, there are reports of hyperammonemia in children with urea cycle disorders. Ongoing monitoring of platelets and liver function tests, in addition to serum drug levels, is recommended.

Use in Geriatric Populations. The majority of older patients on Li^+ therapy are those maintained for years on the medication. Elderly patients frequently take numerous medications for other illnesses, and the potential for drug-drug interactions is substantial. Age-related reductions in total body water and creatinine clearance reduce the safety margin for Li^+ treatment in older patients. Targeting lower maintenance serum levels (0.6–0.8 mEq/L) may reduce the risk of toxicity. As eGFR drops below 50 mL/min, strong consideration must be given to use of alternative agents, despite lithium's therapeutic advantages (Morris and Benjamin, 2008). Li^+ toxicity occurs more frequently in elderly patients, in part as the result of concurrent use of loop diuretics and ACEIs (Grandjean and Aubry, 2009c). Anticonvulsants, especially extended-release divalproex, are a reasonable alternative to Li^+ . Elderly patients who are drug naïve may be more sensitive to the CNS adverse effects of all types of medications used for acute mania, especially parkinsonism and TD from D_2 antagonism, confusion from antipsychotic medications with antimuscarinic properties, and ataxia or sedation from Li^+ or anticonvulsants.

Clinical Summary: Treatment of Mania

Despite decades of data substantiating the superior efficacy of Li^+ in patients with bipolar disorder, including suicide reduction, Li^+ remains underutilized. Long-term studies spanning 10 or more years demonstrated that while polyuria may be relatively common, significant declines in renal function to the point of stage 4 chronic kidney disease are rare during Li^+ treatment. Many agents are effective for acute mania, but long-term treatment requires careful consideration of extent and severity of prior depressive episodes, past history of treatment response, concurrent medical illness and medication use, patient preference, and concerns over particular adverse effects (e.g., weight gain). Combining mood stabilizers and antipsychotic agents shows greater benefit for acute mania than monotherapy of either agent class but may be associated with increased long-term weight gain. A realistic discussion with patients regarding long-term side effects for various treatments and clinical outcomes is paramount to improve adherence.

Serum-level monitoring is necessary for Li^+ , valproate acid compounds, and carbamazepine. Lamotrigine may be particularly useful in patients with type II bipolar disorder, for which mania prophylaxis is not a concern. The clinical data make a compelling argument for Li^+ as the treatment of choice in bipolar I disorder. Ongoing research into lithium's mechanism of action may yield new agents without lithium's adverse effect profile, as well as genetic predictors of Li^+ response.

Chapter 17

Pharmacotherapy of the Epilepsies

Misty D. Smith, Cameron S. Metcalf, and Karen S. Wilcox

EPILEPSY AND ANTISEIZURE THERAPY

TERMINOLOGY AND SEIZURE CLASSIFICATION

NATURE AND MECHANISMS OF SEIZURES AND ANTISEIZURE DRUGS

- Focal Epilepsies
- Generalized-Onset Epilepsies: Absence Seizures
- Genetics of the Epilepsies

ANTISEIZURE DRUGS: GENERAL CONSIDERATIONS

- History of ASD Development
- Therapeutic Aspects

HYDANTOINS

- Phenytoin

BENZODIAZEPINES

ANTISEIZURE BARBITURATES

- Phenobarbital
- Primidone

IMINOSTILBENES

- Carbamazepine
- Oxcarbazepine
- Eslicarbazepine Acetate

SUCCINIMIDES

- Ethosuximide

OTHER ANTISEIZURE DRUGS

- Acetazolamide
- Ezogabine
- Felbamate
- Gabapentin and Pregabalin
- Lacosamide
- Lamotrigine
- Levetiracetam and Brivaracetam
- Perampanel
- Rufinamide
- Stiripentol
- Tiagabine
- Topiramate
- Valproate
- Vigabatrin
- Zonisamide

GENERAL PRINCIPLES AND CHOICE OF DRUGS FOR THERAPY OF THE EPILEPSIES

- Duration of Therapy
- Focal and Focal-to-Bilateral Tonic-Clonic Seizures
- Generalized Absence Seizures
- Myoclonic Seizures
- Febrile Convulsions
- Seizures in Infants and Young Children
- Status Epilepticus and Other Convulsive Emergencies
- Antiseizure Therapy and Pregnancy

Epilepsy and Antiseizure Therapy

The epilepsies are common and frequently devastating disorders, affecting about 2.5 million people in the U.S. alone. More than 40 distinct forms of epilepsy have been identified. Seizures often cause transient impairment of awareness, leaving the individual at risk of bodily harm and often interfering with education and employment. Current therapy is symptomatic: available ASDs inhibit seizures; neither effective prophylaxis nor cure is available. Adherence to prescribed treatment regimens is a major problem because of the need for long-term therapy together with unwanted effects of many drugs.

The mechanisms of action of ASDs fall into these major categories (see also Porter et al., 2012):

1. Modulation of cation channels (Na^+ , K^+ , Ca^{2+}). This can include prolongation of the inactivated state of voltage-gated Na^+ channels, positive modulation of K^+ channels, and inhibition of Ca^{2+} channels.
2. Enhancement of GABA neurotransmission through actions on GABA_A receptors, modulation of GABA metabolism, and inhibition of GABA reuptake into the synaptic terminal.

3. Modulation of synaptic release through actions on the synaptic vesicle protein SV2A or Ca^{2+} channels containing the $\alpha 2\delta$ subunit.
4. Diminishing synaptic excitation mediated by ionotropic glutamate receptors (e.g., AMPA receptors).

Beyond these broad classifications, many ASDs act through mechanisms distinct from the primary known mode of action. Furthermore, ASDs with similar mechanistic categories may have disparate clinical uses.

Much effort is devoted to elucidating the genetic causes and the cellular and molecular mechanisms by which a neural circuit becomes prone to seizure activity, with the goal of providing molecular targets for both symptomatic and preventive therapies.

Terminology and Seizure Classification

The term *seizure* refers to a transient alteration of behavior due to the disordered, synchronous, and rhythmic firing of populations of brain neurons. The term *epilepsy* refers to a disorder of brain function characterized by the periodic and unpredictable occurrence of seizures. Seizures can be provoked (i.e., by chemical agents or electrical stimulation) or unprovoked; the condition of

Abbreviations

AMPA: α -amino-3-hydroxy 5-methyl-4-isoxazolepropionic acid
ASD: antiseizure drug
CSF: cerebrospinal fluid
DS: depolarization shift
EEG: electroencephalogram
ETSP: Epilepsy Therapy Screening Project
GABA: γ -aminobutyric acid
JME: juvenile myoclonic epilepsy
NMDA: N-methyl-D-aspartate receptor
PEMA: phenylethylmalonamide
SV2A: synaptic vesicle glycoprotein 2A

epilepsy denotes the occurrence of spontaneous, unprovoked seizures. While agents in current clinical use inhibit seizures, whether any of these prevent the development of epilepsy (epileptogenesis) is uncertain.

This chapter employs the revised classification for seizures. Thus, seizures previously classified as *partial* seizures are referred to as *focal* seizures, whereas *generalized* seizures, those that involve both hemispheres widely from the outset, will still be referred to as generalized seizures (Fisher et al., 2017). In addition, the International League Against Epilepsy (ILAE) has added a classification for seizures with *unknown onset*, which includes such seizure types as tonic-clonic, atonic, and epileptic spasms.

From a network perspective, seizures arise from cortical, thalamocortical, limbic, or even brainstem circuits. The behavioral manifestations of a seizure are determined by the functions normally served by the brain

region at which the seizure arises. For example, a seizure involving motor cortex is associated with clonic jerking of the body part controlled by this region of cortex. Thus, this type of focal seizure is associated with preservation of awareness. Focal seizures may also be associated with impairments of awareness. The majority of such focal seizures originate from the temporal lobe. Generalized seizures are now distinguished by the involvement of the motor system or those that lack motor involvement, for example, typical and atypical absence, eyelid myoclonic. The type of seizure is one determinant of the drug selected for therapy. Detailed information pertaining to seizure classifications is presented in Table 17–1.

Apart from this seizure classification, an additional classification specifies epilepsy syndromes, which refer to a cluster of symptoms frequently occurring together and include seizure types, etiology, age of onset, and other factors (Fisher RJ et al., 2017). More than 50 distinct epilepsy syndromes have been identified and categorized into focal versus generalized epilepsies. The focal epilepsies may consist of any of the focal seizure types (Table 17–1) and account for roughly 60% of all epilepsies. The etiology commonly consists of a cortical lesion, such as a tumor, developmental malformation, or damage due to trauma or stroke. Such lesions often are evident on brain MRI. Alternatively, the etiology may be genetic. The generalized epilepsies are characterized most commonly by one or more of the generalized seizure types listed in Table 17–1 and account for about 40% of all epilepsies; the etiology is usually genetic. The most common generalized epilepsy is referred to as juvenile myoclonic epilepsy (JME), accounting for about 10% of all epilepsy syndromes. The age of onset is in the early teens, and the condition is characterized by myoclonic, tonic-clonic, and often absence seizures. Like most of the generalized-onset epilepsies, JME is a complex genetic disorder that is probably due to inheritance of multiple susceptibility genes; there is a familial clustering of cases, but the pattern of inheritance is not Mendelian. The classification of epileptic syndromes guides clinical assessment and management and, in some instances, selection of ASDs.

TABLE 17–1 ■ CLASSIFICATION OF EPILEPTIC SEIZURES

SEIZURE TYPE	FEATURES	CONVENTIONAL ANTISEIZURE DRUGS	RECENTLY DEVELOPED ANTISEIZURE DRUGS
Focal seizures			
Focal Aware	Diverse manifestations determined by the region of cortex activated by the seizure (e.g., if motor cortex representing left thumb, clonic jerking of left thumb results; if somatosensory cortex representing left thumb, paresthesia of left thumb results), lasting approximating 20–60 sec. <i>Key feature is preservation of awareness.</i>	Carbamazepine, phenytoin, valproate	Brivaracetam, eslicarbazepine, ezogabine, gabapentin, lacosamide, lamotrigine, levetiracetam, perampanel, rufinamide, tiagabine, topiramate, zonisamide
Focal with Impaired Awareness	Impaired consciousness lasting 30 sec to 2 min, often associated with purposeless movements such as lip smacking or hand wringing.		
Focal to Bilateral Tonic-Clonic	Simple or complex focal seizure evolves into a tonic-clonic seizure with loss of awareness and sustained contractions (tonic) of muscles throughout the body, followed by periods of muscle contraction alternating with periods of relaxation (clonic), typically lasting 1–2 min.		
Generalized seizures			
Generalized Absence	Abrupt onset of impaired consciousness associated with staring and cessation of ongoing activities, typically lasting less than 30 sec.	Ethosuximide, valproate, clonazepam	Lamotrigine
Generalized Myoclonic	A brief (perhaps a second), shock-like contraction of muscles that may be restricted to part of one extremity or may be generalized.	Valproate, clonazepam	Levetiracetam
Generalized Tonic-Clonic	As described above for partial with secondarily generalized tonic-clonic seizure except that it is not preceded by a partial seizure.	Carbamazepine, phenobarbital, phenytoin, primidone, valproate	Lamotrigine, levetiracetam, topiramate

Figure 17-1 Cortical EEG, extracellular, and intracellular recordings in a seizure focus induced by local application of a convulsant agent to mammalian cortex. The extracellular recording was made through a high-pass filter. High-frequency firing of the neuron is evident in both extracellular and intracellular recording during the paroxysmal depolarization shift (PDS). (Modified with permission from Ayala GF *et al.* Genesis of epileptic interictal spikes. New knowledge of cortical feedback systems suggests a neurophysiological explanation of brief paroxysms. *Brain Res*, 1973, 52:1–17. © Elsevier.)

Nature and Mechanisms of Seizures and Antiseizure Drugs

Focal Epilepsies

More than a century ago, John Hughlings Jackson, the father of modern concepts of epilepsy, proposed that seizures were caused by “occasional, sudden, excessive, rapid and local discharges of gray matter,” and that a generalized seizure resulted when normal brain tissue was invaded by the seizure activity initiated in the abnormal focus. This insightful proposal provided a framework for thinking about mechanisms of focal epilepsy. The advent of the EEG in the 1930s permitted the recording of electrical activity from the scalp of humans with epilepsy and demonstrated that the epilepsies are disorders of neuronal excitability.

The pivotal role of synapses in mediating communication amongst neurons in the mammalian brain suggested that defective synaptic function might lead to a seizure. That is, a reduction of inhibitory synaptic activity or enhancement of excitatory synaptic activity might be expected to trigger a seizure. Pharmacological studies of seizures support this notion. The neurotransmitters mediating the bulk of synaptic transmission in the mammalian brain are amino acids, with GABA and glutamate the principal inhibitory and excitatory neurotransmitters, respectively (Chapter 14). Pharmacological studies disclosed that *antagonists* of the GABA_A receptor or *agonists* of different glutamate-receptor subtypes (NMDA, AMPA, or kainic acid) trigger seizures in experimental animals *in vivo*. Conversely, pharmacological agents that enhance GABA-mediated synaptic inhibition suppress seizures in diverse models. Glutamate-receptor antagonists also inhibit seizures in diverse models, including seizures evoked by electroshock and chemical convulsants (e.g., pentylenetetrazol).

These findings suggest pharmacological regulation of synaptic function can regulate the propensity for seizures and provide a framework for electrophysiological analyses aimed at elucidating the role of both synaptic and nonsynaptic mechanisms in seizures and epilepsy. Technical progress has fostered the progressive refinement of the analysis of seizure mechanisms from the EEG to populations of neurons (field potentials) to individual neurons to individual synapses and individual ion channels on individual neurons. Beginning in the mid-1960s, cellular electrophysiological studies of epilepsy focused on elucidating the mechanisms underlying the DS, the intracellular correlate of the “interictal spike” (Figure 17-1). The interictal (or between-seizures) spike is a sharp waveform recorded in the EEG of patients with epilepsy; it is asymptomatic, as it is not accompanied by overt change in the patient’s behavior. However, the location of the interictal spike helps localize the brain region from which seizure activity originates in a given patient. The DS consists of a large depolarization of the neuronal membrane associated with a burst of action potentials. In most cortical neurons, the DS is generated by a large excitatory synaptic current that can be enhanced by activation of voltage-gated intrinsic membrane currents. Although the mechanisms generating the DS and whether the interictal spike triggers a seizure, inhibits a seizure, or is an epiphenomenon remains unclear, the study of the mechanisms underlying DS generation set the stage for inquiry into the cellular mechanisms of a seizure.

During the 1980s, various *in vitro* models of seizures were developed in isolated brain slice preparations in which many synaptic connections are preserved. Electrophysiological events with features similar to those recorded during seizures *in vivo* have been produced in hippocampal slices by multiple methods, including altering ionic constituents of media bathing the brain slices (McNamara, 1994), such as low Ca^{2+} , zero Mg^{2+} , or elevated K^{+} . The accessibility and experimental control provided by these *in vitro*

preparations has permitted mechanistic investigations into the induction of seizures. Data from *in vitro* models confirmed the importance of synaptic function for initiating a seizure, demonstrating that subtle reductions (e.g., 20%) of inhibitory synaptic function could lead to epileptiform activity and that activation of excitatory synapses could be pivotal in seizure initiation. Other important factors include the volume of the extracellular space and intrinsic properties of a neuron, such as voltage-gated ion channels (e.g., K^+ , Na^+ , and Ca^{2+} channels) (Traynelis and Dingledine, 1988). Identification of these diverse synaptic and nonsynaptic factors controlling seizures *in vitro* provides potential pharmacological targets for regulating seizure susceptibility *in vivo*.

Some common forms of focal epilepsy arise months to years after cortical injury sustained as a consequence of stroke, trauma, infection, or other factors. Effective prophylaxis administered to patients at high risk would be highly desirable in the clinical setting. However, no effective antiepileptogenic agent has been identified. The drugs described in this chapter provide symptomatic therapy; that is, the drugs inhibit seizures in patients with epilepsy.

Understanding the mechanisms of epileptogenesis in cellular and molecular terms should provide a framework for development of novel therapeutic approaches. The availability of animal models provides an opportunity to investigate the underlying mechanisms and have also enabled the discovery of numerous ASDs that are proven safe and efficacious in humans.

One model, termed *kindling*, is induced by periodic administration of brief, low-intensity electrical stimulation of the amygdala or other limbic structures that evoke a brief electrical seizure recorded on the EEG without behavioral change. Repeated (e.g., 10–20) stimulations result in progressive intensification of seizures, culminating in tonic-clonic seizures that, once established, persist for the life of the animal. Additional models are produced by induction of continuous seizures that last for hours (“status epilepticus”). The inciting agent used in these models is typically either a chemoconvulsant, such as kainic acid or pilocarpine, or sustained electrical stimulation. The episode of status epilepticus is followed weeks later by the onset of spontaneous seizures, an intriguing parallel to the scenario of complicated febrile seizures in young children preceding the emergence of spontaneous seizures years later. In contrast to the limited or absent neuronal loss characteristic of the kindling model, overt destruction of hippocampal neurons occurs in models of status epilepticus, reflecting aspects of hippocampal sclerosis observed in humans with severe limbic seizures. Indeed, the discovery that complicated febrile seizures precede and presumably are the cause of hippocampal sclerosis in young children (VanLandingham et al., 1998) establishes yet another commonality between these preclinical models and the human condition.

Several questions arise with respect to these models. What transpires during the latent period between status epilepticus and emergence of spontaneous seizures that causes the epilepsy? Might an antiepileptogenic agent that was effective in one of these models demonstrate disease-modifying effects in other models and perhaps in patients?

Important insights into the mechanisms of action of drugs that are effective against focal seizures have emerged (Rogawski and Löscher, 2004), insights largely from electrophysiological studies of relatively simple *in vitro* models, such as neurons isolated from the mammalian CNS and maintained in primary culture. The experimental control and accessibility provided by these models—together with careful attention to clinically relevant concentrations of the drugs—led to clarification of their mechanisms. Although it is difficult to prove unequivocally that a given drug effect observed *in vitro* is both necessary and sufficient to inhibit a seizure in an animal or humans *in vivo*, there is an excellent likelihood that the putative mechanisms identified (Table 17–2) do in fact underlie the clinically relevant antiseizure effects. Electrophysiological analyses of individual neurons during a focal seizure demonstrate that the neurons undergo depolarization and fire action potentials at high frequencies (Figure 17–1). This pattern of neuronal firing is characteristic of a seizure and is uncommon during physiological neuronal activity. Thus, selective inhibition of this pattern of firing would be expected to reduce seizures with minimal adverse effects on neurons.

Carbamazepine, lamotrigine, phenytoin, lacosamide, and valproate inhibit high-frequency firing at concentrations known to be effective at limiting seizures in humans (Rogawski and Löscher, 2004). Inhibition of the high-frequency firing is thought to be mediated by reducing the ability of Na^+ channels to recover from inactivation (Figure 17–2). The rationale is as follows:

1. Depolarization-triggered opening of the Na^+ channels in the axonal membrane of a neuron is required for an action potential.
2. After opening, the channels spontaneously close, a process termed *inactivation*.
3. This inactivation period is thought to cause the refractory period, a short time after an action potential during which it is not possible to evoke another action potential.
4. On recovery from inactivation, the Na^+ channels are again poised to participate in another action potential.
5. Inactivation has little or no effect on low-frequency firing because firing at a slow rate permits sufficient time for Na^+ channels to recover from inactivation.
6. Reducing the rate of recovery of Na^+ channels from inactivation could limit the ability of a neuron to fire at high frequencies, an effect that likely underlies the effects of carbamazepine, lamotrigine, lacosamide, phenytoin, topiramate, valproate, and zonisamide against focal seizures.

Insights into mechanisms of seizures suggest that enhancing GABA-mediated synaptic inhibition would reduce neuronal excitability and raise the seizure threshold. Several drugs are thought to inhibit seizures by regulating GABA-mediated synaptic inhibition through an action at distinct sites of the synapse (Rogawski and Löscher, 2004). The principal postsynaptic receptor of synaptically released GABA is termed the $GABA_A$ receptor (Chapter 14). Activation of the $GABA_A$ receptor inhibits the postsynaptic cell by increasing the inflow of Cl^- ions into the cell, which tends to hyperpolarize the neuron. Clinically relevant concentrations of benzodiazepines and barbiturates enhance $GABA_A$ receptor-mediated inhibition through distinct actions on the $GABA_A$ receptor (Figure 17–3), and this enhanced inhibition probably underlies the effectiveness of these compounds against focal and tonic-clonic seizures in humans. At higher concentrations, such as might be used for status epilepticus, these drugs also can inhibit high-frequency firing of action potentials. A second mechanism of enhancing GABA-mediated synaptic inhibition is thought to underlie the antiseizure mechanism of tiagabine; tiagabine inhibits the GABA transporter GAT-1, reducing neuronal and glial uptake of GABA (Rogawski and Löscher, 2004), prolonging its dwell time in the synaptic cleft where it activates $GABA_A$ receptors. Finally, ASDs can decrease GABA metabolism GABA transaminase (i.e., valproate, vigabatrin) resulting in increased GABA concentrations (Ben-Menachem, 2011; Cai et al., 2012; Larsson et al., 1986) and increased signaling via the $GABA_A$ receptor.

Generalized-Onset Epilepsies: Absence Seizures

In contrast to focal seizures, which arise from localized regions of the brain, generalized-onset seizures arise from the reciprocal firing of the thalamus and cerebral cortex (Huguenard and McCormick, 2007). Amongst the diverse forms of generalized seizures, absence seizures have been studied most intensively. The striking synchrony in appearance of generalized seizure discharges in widespread areas of neocortex led to the idea that a structure in the thalamus or brainstem (the “centrencephalon”) synchronized these seizure discharges. Focus on the thalamus emerged from the demonstration that low-frequency stimulation of midline thalamic structures triggered EEG rhythms in the cortex similar to spike-and-wave discharges characteristic of absence seizures. Intracerebral electrode recordings from humans subsequently demonstrated the presence of thalamic and neocortical involvement in the spike-and-wave discharge of absence seizures. Many of the structural and functional properties of the thalamus and neocortex that led to the generalized spike-and-wave discharges have been elucidated (Huguenard and McCormick, 2007).

TABLE 17-2 ■ PROPOSED MECHANISMS OF ACTION OF ANTISEIZURE DRUGS

MOLECULAR TARGET AND ACTIVITY	DRUG	CONSEQUENCES OF ACTION
Na⁺ channel modulators that: <i>Enhance fast inactivation</i>	PHT, CBZ, LTG, FBM, OxCBZ, TPM, VPA, ESL, RUF	<ul style="list-style-type: none"> • Block action potential propagation • Stabilize neuronal membranes • ↓ Neurotransmitter release, focal firing, and seizure spread

The EEG hallmark of an absence seizure is generalized spike-and-wave discharges at a frequency of 3 Hz (3/s). These bilaterally synchronous spike-and-wave discharges, recorded locally from electrodes in both the thalamus and the neocortex, represent oscillations between the thalamus and neocortex. A comparison of EEG and intracellular recordings reveals that the EEG spikes are associated with the firing of action potentials and the following slow wave with prolonged inhibition. These reverberatory, low-frequency rhythms are made possible by a combination of factors, including reciprocal excitatory synaptic connections between the neocortex and thalamus as well as intrinsic properties of neurons in the thalamus (Huguenard and McCormick, 2007).

One intrinsic property of thalamic neurons that is involved in the generation of the 3-Hz spike-and-wave discharges is the low threshold (“T-type”) Ca²⁺ current. T-type Ca²⁺ channels are activated at a much

more negative membrane potential (hence, “low threshold”) than most other voltage-gated Ca²⁺ channels expressed in the brain. T-type currents are much larger in many thalamic neurons than in neurons outside the thalamus. Indeed, bursts of action potentials in thalamic neurons are mediated by activation of the T-type currents. T-type currents amplify thalamic membrane potential oscillations, with one oscillation being the 3-Hz spike-and-wave discharge of the absence seizure. Importantly, the principal mechanism by which anti-absence seizure drugs (ethosuximide, valproate) are thought to act is by inhibition of the T-type Ca²⁺ channels (Figure 17-4) (Rogawski and Löscher, 2004). Thus, inhibiting voltage-gated ion channels is a common mechanism of action among ASDs, with anti-focal seizure drugs inhibiting voltage-activated Na⁺ channels and anti-absence seizure drugs inhibiting voltage-activated Ca²⁺ channels.

Figure 17-2 Antiseizure drug-enhanced Na^+ channel inactivation. Some anti-seizure drugs (noted in blue text) prolong the inactivation of the Na^+ channels, thereby reducing the ability of neurons to fire at high frequencies. The inactivated channel itself appears to remain open but is blocked by the inactivation gate, I. Activation gate, A.

Genetics of the Epilepsies

Genetic causes contribute to a wide diversity of human epilepsies. Genetic causes are solely responsible for rare forms inherited in an autosomal dominant or autosomal recessive manner. Genetic causes also are mainly responsible for more common forms such as Dravet syndrome, JME, or childhood absence epilepsy, the majority of which are likely due to inheritance of two or more susceptibility genes. Genetic determinants also may contribute some degree of risk to epilepsies caused by injury of the cerebral cortex.

Mutations in more than 70 genes are known to contribute to epilepsy. Not surprisingly, many of the identified epilepsy-conferring mutations

Figure 17-3 Some antiseizure drugs enhance GABA synaptic transmission. In the presence of GABA, the GABA_A receptor (structure on bottom left) is opened, allowing an influx of Cl^- , which in turn increases membrane polarization. Some ASDs (shown in blue text) act by reducing the metabolism of GABA. Others act at the GABA_A receptor, enhancing Cl^- influx in response to GABA or by prolonging its synaptic dwell time by inhibiting its reuptake by GAT-1. Gabapentin acts presynaptically to promote GABA release; its molecular target is currently under investigation. \blacktriangleright , GABA molecules. GABA-T, GABA transaminase; GAT-1, neuronal GABA transporter (SLC6A1).

Figure 17-4 Antiseizure drug-induced reduction of current through T-type Ca^{2+} channels. Some antiseizure drugs (e.g., valproate and ethosuximide) reduce the flow of Ca^{2+} through T-type Ca^{2+} channels, thereby reducing the pacemaker current that underlies the thalamic rhythm in spikes and waves seen in generalized absence seizures.

are in genes that encode voltage- or ligand-gated ion channels (Reid et al., 2009). However, mutations have also been identified in signaling pathways, transporters, and even synaptic vesicle proteins (EpiPM Consortium, 2015). Furthermore, many of the mutations arise de novo, thus complicating efforts in diagnoses. The genotype-phenotype correlations of these genetic syndromes are complex; the same mutation in one channel can be associated with divergent clinical syndromes, ranging from simple febrile seizures to intractable seizures with intellectual decline. Conversely, clinically indistinguishable epilepsy syndromes have been associated with mutation of distinct genes. The implication of genes encoding ion channels in familial epilepsy is particularly interesting because episodic disorders involving other organs also result from mutations of these genes. For example, episodic disorders of the heart (cardiac arrhythmias), skeletal muscle (periodic paralyses), cerebellum (episodic ataxia), vasculature (familial hemiplegic migraine), and other organs all have been linked to mutations in genes encoding components of voltage-gated ion channels (Ptacek and Fu, 2001).

The cellular electrophysiological consequences of these mutations can inform our understanding of the mechanisms of seizures and the actions of ASDs and allow for the determination of precise therapies for patients with specific mutations. For example, generalized epilepsy with febrile seizures is caused, in some cases, by a point mutation in the β subunit of a voltage-gated Na^+ channel (*SCN1B*). Several ASDs act on Na^+ channels to promote their inactivation; the phenotype of the mutated Na^+ channel appears to involve defective inactivation (Wallace et al., 1998).

Spontaneous mutations in *SCN1A* (encoding the α subunit of the major voltage-gated Na^+ channel in neurons) that result in truncations and presumed loss of Na^+ channel function have been identified in a subset of infants with a catastrophic severe myoclonic epilepsy of infancy or Dravet syndrome. That these loss-of-function mutations in Na^+ channels result in seizures is somewhat surprising. However, seizures may arise as a consequence of the cell types that express these channels within neural circuits that underlie seizure initiation. Interestingly, patients with these mutations are generally found to be refractory to ASDs that block Na^+ channels.

Antiseizure Drugs: General Considerations

History of ASD Development

The first ASD was bromide, which was used in the late 19th century. Phenobarbital was the first synthetic organic agent recognized as having antiseizure activity. Its usefulness, however, was limited to generalized tonic-clonic seizures and, to a lesser degree, focal seizures. It had no effect on absence seizures. Merritt and Putnam developed the electroshock seizure test in experimental animals to screen chemical agents for antiseizure

effectiveness; in the course of screening a variety of drugs, they discovered that diphenylhydantoin (later renamed phenytoin) suppressed seizures in the absence of sedative effects. The maximal electroshock seizure test is extremely valuable because drugs that are effective against the tonic hind limb extension induced by corneal electroshock generally have proven to be effective against focal and generalized tonic-clonic seizures in humans. In contrast, seizures induced by the chemoconvulsant pentylenetetrazol are most useful in the identification of ASDs that are effective against myoclonic seizures in humans. These screening tests and other phenotypically or etiologically relevant acute and chronic animal models are used in developing new ASDs.

The chemical structures of most of the drugs introduced before 1965 were closely related to phenobarbital. These included the hydantoins and the succinimides. Between 1965 and 1990, the chemically distinct structures of the benzodiazepines, an iminostilbene (carbamazepine), and a branched-chain carboxylic acid (valproate) were introduced, followed in the 1990s by a phenyltriazine (lamotrigine), a cyclic analogue of GABA (gabapentin), a sulfamate-substituted monosaccharide (topiramate), a nipecotic acid derivative (tiagabine), and a pyrrolidine derivative (levetiracetam). Since the 1970s, the National Institutes of Health has spurred development of ASDs via sponsorship of the Epilepsy Therapy Screening Program (ETSP), an ongoing partnership between government, private industry, and the University of Utah.

Therapeutic Aspects

The ideal ASD would suppress all seizures without causing any unwanted effects. Unfortunately, the drugs used currently not only fail to control seizure activity in approximately one-third of patients, but frequently cause unwanted adverse effects that range in severity from minimal impairment of the CNS to death from aplastic anemia or hepatic failure. In 2009, all manufacturers of ASDs were required by the FDA to update their product labeling to include a warning about an increased risk of suicidal thoughts or actions and to develop information targeted at helping patients understand this risk. The risk applies to all ASDs used for any indication. Details are available online at the FDA website.

The clinician who treats patients with epilepsy is faced with the task of selecting the appropriate drug or combination of drugs that best controls seizures in an individual patient at an acceptable level of untoward effects. As a general rule, complete control of seizures can be achieved in up to 50% of patients, while another 25% can be improved significantly. The degree of success varies as a function of seizure type, cause, and other factors.

To minimize toxicity, treatment with a single drug is preferred. If seizures are not controlled with the initial agent at adequate plasma concentrations, substitution of a second drug is preferred to the concurrent administration of another agent. However, multiple-drug therapy may be required, especially when two or more types of seizure occur in the same patient. With each concurrent add-on ASD, the likelihood of seizure freedom decreases (Kwan and Brodie, 2000).

Measurement of drug concentrations in plasma facilitates optimizing antiseizure medication, especially when therapy is initiated, after dosage adjustments, in the event of therapeutic failure, when toxic effects appear, or when multiple-drug therapy is instituted. However, clinical effects of some drugs do not correlate well with their concentrations in plasma, and recommended concentrations are only guidelines for therapy. *The ultimate therapeutic regimen must be determined by clinical assessment of effect and toxicity.*

The individual agents are introduced in the next sections, followed by a discussion of some general principles of the drug therapy of the epilepsies.

Hydantoins

Phenytoin

Phenytoin is effective against all types of focal and tonic-clonic seizures but not absence seizures. Oral phenytoin is indicated for the control of focal-to-bilateral tonic-clonic seizures and the prevention and treatment

of seizures occurring during or following neurosurgery. Parenteral phenytoin is indicated for the control of generalized tonic-clonic status epilepticus and the treatment of seizures occurring during neurosurgery. Parenteral phenytoin should only be used when oral phenytoin administration is not possible.

Pharmacological Effects in the CNS

Phenytoin exerts antiseizure activity without causing general depression of the CNS. In toxic doses, it may produce excitatory signs and at lethal levels a type of decerebrate rigidity.

Mechanism of Action

Phenytoin limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord neurons maintained in vitro (McLean and Macdonald, 1986a). This effect is mediated by slowing of the rate of recovery of voltage-activated Na^+ channels from inactivation, an action that is both voltage (greater effect if membrane is depolarized) and use dependent. At therapeutic concentrations, the effects on Na^+ channels are selective, and no changes of spontaneous activity or responses to iontophoretically applied GABA or glutamate are detected. At concentrations 5- to 10-fold higher, multiple effects of phenytoin are evident, including reduction of spontaneous activity and enhancement of responses to GABA; these effects may underlie some of the unwanted toxicity associated with high levels of phenytoin.

ADME and Drug Interactions

Phenytoin is available in two types of oral formulations that differ in their pharmacokinetics: rapid-release and extended-release forms. Once-daily dosing is possible only with the extended-release formulations, and due to differences in dissolution and other formulation-dependent factors, the plasma phenytoin level may change when converting from one formulation to another. Confusion also can arise because different formulations can include either phenytoin or phenytoin sodium. Therefore, comparable doses can be approximated by considering “phenytoin equivalents,” but serum-level monitoring is also necessary to ensure therapeutic safety. When changing routes of administration from oral to intramuscular (or vice versa), appropriate dose adjustments and blood level monitoring are recommended.

The pharmacokinetic characteristics of phenytoin are influenced markedly by its binding to serum proteins, by the nonlinearity of its elimination kinetics, and by its metabolism by hepatic CYPs (Table 17-3). Phenytoin is extensively bound (~90%) to serum proteins, mainly albumin. Small variations in the percentage of phenytoin that is bound dramatically affect the absolute amount of free (active) drug. Some agents can compete with phenytoin for binding sites on plasma proteins and increase free phenytoin at the time the new drug is added to the regimen. However, the effect on free phenytoin is only short-lived and usually does not cause clinical complications unless inhibition of phenytoin metabolism also occurs. For example, valproate competes for protein-binding sites and inhibits phenytoin metabolism, resulting in marked and sustained increases in free phenytoin. Measurement of free rather than total phenytoin permits direct assessment of this potential problem in patient management.

The rate of elimination of phenytoin varies as a function of its concentration (i.e., the rate is nonlinear). The plasma $t_{1/2}$ of phenytoin ranges between 6 and 24 h at plasma concentrations below 10 $\mu\text{g/mL}$. At low blood levels, metabolism follows first-order kinetics; as blood levels rise, the maximal limit of the liver to metabolize phenytoin is approached, and C_p increases disproportionately as dosage is increased, even with small adjustments for levels near the therapeutic range.

The majority (95%) of phenytoin is metabolized by CYP2C9 and to a lesser extent by CYP2C19 (Table 17-3). The principal metabolite, a parahydroxyphenyl derivative, is inactive. Because its metabolism is saturable, other drugs that are metabolized by these CYP enzymes can inhibit the metabolism of phenytoin and increase its plasma concentration. Conversely, the degradation rate of other drugs that serve as substrates for these enzymes can be inhibited by phenytoin; one such drug is warfarin, and addition of phenytoin to a patient receiving warfarin can lead to bleeding disorders (Chapter 32).

TABLE 17-3 ■ INTERACTIONS OF ANTI-SEIZURE DRUGS WITH HEPATIC MICROSOMAL ENZYMES

CYP, cytochrome P450; UGT, uridine diphosphate-glucuronosyltransferase. (Data modified from Johannessen and Johannessen, 2010 and Wheles and Vasquez, 2010, *Epilepsy Currents*, 10:1–6 and Cawello, 2015, *Clin Pharmacokinetic*, 54: 904–914.)

An alternative mechanism of drug interactions arises from phenytoin's ability to induce various CYPs (see discussion that follows and Chapter 6). Of particular note in this regard are oral contraceptives, which are metabolized by CYP3A4; treatment with phenytoin can enhance the metabolism of oral contraceptives and lead to unplanned pregnancy. The potential teratogenic effects of phenytoin underscore the importance of attention to this interaction. Carbamazepine, oxcarbazepine, phenobarbital, and primidone also induce CYP3A4 and likewise might increase degradation of oral contraceptives.

Concurrent administration of any drug metabolized by CYP2C9 can increase the plasma concentration of phenytoin by decreasing its rate of metabolism (Table 17-3). Conversely, the degradation rate of other drugs that are substrates for these enzymes can be inhibited by phenytoin. Carbamazepine, which may enhance the metabolism of phenytoin, causes a well-documented *decrease* in phenytoin concentration. Phenytoin can also induce expression of a number of different CYPs, leading to increased degradation of coadministered drugs, such as oral contraceptives. Conversely, phenytoin reduces the concentration of carbamazepine.

The low water solubility of phenytoin hindered its intravenous use and led to production of fosphenytoin, a water-soluble prodrug. Fosphenytoin is converted into phenytoin by phosphatases in liver and red blood cells

with a $t_{1/2}$ of 8–15 min. Fosphenytoin is extensively bound (95%–99%) to human plasma proteins, primarily albumin. This binding is saturable and fosphenytoin displaces phenytoin from protein-binding sites. Fosphenytoin is useful for adults with focal or generalized seizures when either intravenous or intramuscular route of administration is indicated.

Adverse Effects and Toxicity

The toxic effects of phenytoin depend on the route of administration, the duration of exposure, and the dosage. When fosphenytoin, the water-soluble prodrug, is administered intravenously at an excessive rate in the emergency treatment of status epilepticus, the most notable toxic signs are cardiac arrhythmias with or without hypotension and CNS depression. Although cardiac toxicity occurs more frequently in older patients and in those with known cardiac disease, it also can develop in young, healthy patients. Because of the risk of adverse cardiovascular reactions with rapid administration, IV administration should not exceed 50 mg per minute in adults. In pediatric patients, the drug should be administered at a rate not exceeding 1–3 mg/kg/min or 50 mg/min, whichever is slower. Acute oral overdosage results primarily in signs referable to the cerebellum and vestibular system; high doses have been associated with marked cerebellar atrophy.

Toxic effects associated with chronic treatment also are primarily dose-related cerebellar-vestibular effects but also include other CNS effects, behavioral changes, increased frequency of seizures, GI symptoms, gingival hyperplasia, osteomalacia, and megaloblastic anemia. Hirsutism is an annoying untoward effect in young females. Usually, these phenomena can be diminished by proper adjustment of dosage. Serious adverse effects, including those on the skin, bone marrow, and liver, probably are manifestations of drug allergy. Although rare, they necessitate withdrawal of the drug. Moderate transient elevation of the plasma concentrations of hepatic transaminases sometimes can also occur.

Gingival hyperplasia occurs in about 20% of all patients during chronic administration and can be minimized by good oral hygiene. Related to this, phenytoin can also produce coarsening of facial features. Inhibition of release of ADH has been observed. Hyperglycemia and glycosuria appear to be due to inhibition of insulin secretion. Osteomalacia, with hypocalcemia and elevated alkaline phosphatase activity, has been attributed to both altered metabolism of vitamin D and the attendant inhibition of intestinal absorption of Ca^{2+} . Phenytoin also increases the metabolism of vitamin K and reduces the concentration of vitamin K-dependent proteins that are important for normal Ca^{2+} metabolism in bone. This may explain why the osteomalacia is not always ameliorated by the administration of vitamin D.

Hypersensitivity reactions include morbilliform rash in 2%–5% of patients and occasionally more serious skin reactions, including Stevens-Johnson syndrome and toxic epidermal necrolysis. Drug-induced systemic lupus erythematosus; potentially fatal hepatic necrosis; hematological reactions, including neutropenia and leukopenia; red cell aplasia; agranulocytosis; and mild thrombocytopenia also have been reported. Hypoprothrombinemia and hemorrhage have occurred in the newborns of mothers who received phenytoin during pregnancy; vitamin K is effective treatment or prophylaxis.

Plasma Drug Concentrations

A good correlation usually is observed between the total concentration of phenytoin in plasma and its clinical effect. Thus, control of seizures generally is obtained with total concentrations above 10 $\mu\text{g/mL}$, while toxic effects such as nystagmus develop at total concentrations around 20 $\mu\text{g/mL}$. Control of seizures generally is obtained with free phenytoin concentrations of 0.75–1.25 $\mu\text{g/mL}$.

Therapeutic Uses

Epilepsy. Phenytoin is one of the more widely used ASDs; it is effective against focal and generalized tonic-clonic, focal-to-bilateral tonic-clonic, tonic-clonic of unknown onset (tonic-clonic), but not generalized absence seizures. The use of phenytoin and other agents in the therapy of epilepsies is discussed further at the end of this chapter. Phenytoin preparations differ significantly in bioavailability and rate of absorption. In general, patients should consistently be treated with the same drug from a single manufacturer. However, if it becomes necessary to temporarily switch between products, care should be taken to select a therapeutically equivalent product, and patients should be monitored for loss of seizure control or onset of new toxicities.

Other Uses. Trigeminal and related neuralgias occasionally respond to phenytoin, but carbamazepine may be preferable. The use of phenytoin in the treatment of cardiac arrhythmias is discussed in Chapter 30.

Benzodiazepines

The benzodiazepines are used primarily as sedative-anxiety drugs; their pharmacology is described in Chapters 15 and 19. Discussion here is limited to their use in the therapy of the epilepsies. A large number of benzodiazepines have broad antiseizure properties. Clonazepam is FDA-approved alone or as an adjunctive treatment of Lennox-Gestaut syndrome, akinetic, and myoclonic seizures. It may also benefit patients with absence seizures which are inadequately responding to succinimides. Clorazepate is approved as an adjunct therapy for the management of focal seizures. Midazolam was designated an orphan drug in 2006 for intermittent treatment of bouts of increased seizure

activity in refractory patients with epilepsy who are on stable regimens of ASDs. More recently, midazolam was granted orphan drug designation in 2009 as a rescue treatment of seizures in patients who require control of intermittent bouts of increased seizure activity (i.e., acute repetitive seizure clusters), in 2012 for the treatment of nerve agent-induced seizures, and in 2016 for the treatment of status epilepticus and seizures induced by organophosphorous poisoning. Diazepam and lorazepam have well-defined roles in the management of status epilepticus. Unlike other marketed 1,4-benzodiazepines, clobazam is a 1,5-benzodiazepine that is less lipophilic and less acidic and may be better tolerated than traditional 1,4-benzodiazepines (see benzodiazepine structure in Chapter 19). Clobazam is used in a variety of seizure phenotypes and is approved in the U.S. for the treatment of Lennox-Gastaut syndrome in patients aged 2 years or older.

Antiseizure Properties

In animal models, inhibition of pentylenetetrazol-induced seizures by the benzodiazepines is much more prominent than is their modification of the maximal electroshock seizure pattern. Clonazepam is unusually potent in antagonizing the effects of pentylenetetrazol, but it is almost without action on seizures induced by maximal electroshock. Benzodiazepines, including clonazepam, suppress the spread of kindled seizures and generalized seizures produced by stimulation of the amygdala, but do not abolish the abnormal discharge at the site of stimulation.

Mechanism of Action

The antiseizure actions of the benzodiazepines result in large part from their capacity to enhance GABA-mediated synaptic inhibition. Molecular cloning and study of recombinant receptors have demonstrated that the benzodiazepine receptor is an integral part of the GABA_A receptor (see Figures 14–11 and 17–3). At therapeutically relevant concentrations, benzodiazepines act at subsets of GABA_A receptors and increase the frequency, but not duration, of openings at GABA-activated Cl^- channels (Twyman et al., 1989). At higher concentrations, diazepam and many other benzodiazepines can reduce sustained high-frequency firing of neurons, similar to the effects of phenytoin, carbamazepine, and valproate. Although these concentrations correspond to concentrations achieved in patients during treatment of status epilepticus with diazepam, they are considerably higher than those associated with antiseizure or anxiolytic effects in ambulatory patients. Clobazam potentiates GABA-mediated neurotransmission in the same fashion as other benzodiazepines at GABA_A receptors.

ADME

Benzodiazepines are well absorbed after oral administration, and concentrations in plasma are usually maximal within 1–4 h. After intravenous administration, they redistribute in a manner typical of that for highly lipid-soluble agents. Central effects develop promptly, but wane rapidly as the drugs move to other tissues. Diazepam is redistributed especially rapidly, with a $t_{1/2}$ of redistribution of about 1 h. The extent of binding of benzodiazepines to plasma proteins correlates with lipid solubility, ranging from about 99% for diazepam to about 85% for clonazepam.

Table 19–1 shows the scheme for metabolism of benzodiazepines, the major metabolite of diazepam, *N*-desmethyl-diazepam, is somewhat less active than the parent drug and may behave as a partial agonist. This metabolite also is produced by the rapid decarboxylation of clorazepate following its ingestion. Both diazepam and *N*-desmethyl-diazepam are slowly hydroxylated to other active metabolites, such as oxazepam. The $t_{1/2}$ of diazepam in plasma is ~43 h (see Table 19–2); that of *N*-desmethyl-diazepam is about 60 h. Clonazepam is metabolized principally by reduction of the nitro group to produce inactive 7-amino derivatives. Less than 1% of the drug is recovered unchanged in the urine. The $t_{1/2}$ of clonazepam in plasma is about 23 h. Lorazepam is metabolized chiefly by conjugation with glucuronic acid; its $t_{1/2}$ in plasma is about 14 h. Clobazam has a $t_{1/2}$ of 18 h and is effective at doses between 0.5 and 1 mg/kg daily, with limited development of tolerance. The active metabolite of clobazam is norclobazam.

Plasma Drug Concentrations

Because tolerance affects the relationship between drug concentration and drug antiseizure effect, plasma concentrations of benzodiazepines are of limited value.

Therapeutic Uses

Clonazepam is useful in the therapy of absence seizures as well as myoclonic seizures in children. However, tolerance to its antiseizure effects usually develops after 1–6 months of administration, after which some patients will no longer respond to clonazepam at any dosage. The initial dose of clonazepam for adults should not exceed 1.5 mg per day and for children 0.01–0.03 mg/kg per day. The dose-dependent side effects are reduced if two or three divided doses are given each day. The dose may be increased every 3 days in amounts of 0.25–0.5 mg per day in children and 0.5–1 mg per day in adults. The maximal recommended dose is 20 mg per day for adults and 0.2 mg/kg per day for children. Clonazepam intranasal spray is designated as an orphan drug for recurrent acute repetitive seizures.

While diazepam is an effective agent for treatment of status epilepticus, the effective duration of action of this lipid soluble agent is shortened by its rapid redistribution. Thus, lorazepam is more frequently used; it is less lipid soluble, is more effectively confined to the vascular compartment, and has a longer effective half-life after a single dose. Diazepam is not useful as an oral agent for the treatment of seizure disorders. Clorazepate is effective in combination with certain other drugs in the treatment of focal seizures. The maximal initial dose of clorazepate is 22.5 mg/d in three portions for adults and children older than 12 years and 15 mg/d in two divided doses in children 9–12 years of age. Clorazepate is not recommended for children under the age of 9. Clobazam is used in a variety of seizure phenotypes and is FDA-approved for the treatment of Lennox-Gastaut syndrome in patients aged 2 years or older. In patients weighing more than 30 kg, clobazam is initiated orally at 5 mg every 12 h and then titrated up to a maximum of 40 mg/d if tolerated. Dose escalation must be done gradually, not exceeding more than once per week.

Adverse Effects

The principal side effects of long-term oral therapy with clonazepam are drowsiness and lethargy. According to FDA-approved labeling, up to 30% of patients show a loss of anticonvulsant activity with continued administration of clonazepam, often within 3 months. In some cases, dose adjustment may reestablish efficacy. Muscular incoordination and ataxia are less frequent. Although these symptoms usually can be kept to tolerable levels by reducing the dosage or the rate at which it is increased, they sometimes force drug discontinuation.

Other side effects include hypotonia, dysarthria, and dizziness. Behavioral disturbances, especially in children, can be troublesome; these include aggression, hyperactivity, irritability, and difficulty in concentration. Both anorexia and hyperphagia have been reported. Increased salivary and bronchial secretions may cause difficulties in children. Seizures are sometimes exacerbated, and status epilepticus may be precipitated if the drug is discontinued abruptly. Other aspects of the toxicity of the benzodiazepines are discussed in Chapter 19. Cardiovascular and respiratory depression may occur after the intravenous administration of diazepam, clonazepam, or lorazepam, particularly if other ASDs or central depressants have been administered previously.

Antiseizure Barbiturates

While most barbiturates have antiseizure properties, only some barbiturates, such as phenobarbital, exert maximal antiseizure effects at doses below those that cause hypnosis. This therapeutic index determines a barbiturate's clinical utility as an antiseizure therapeutic drug. The pharmacology of the barbiturates as a class is described in Chapter 19; discussion in this chapter is limited to phenobarbital and primidone.

Phenobarbital

Phenobarbital was the first effective organic antiseizure agent. It has relatively low toxicity, is inexpensive, and is still one of the more effective and widely used antiseizure drugs.

Mechanism of Action

The mechanism by which phenobarbital inhibits seizures likely involves potentiation of synaptic inhibition through an action on the GABA_A receptor. Phenobarbital enhances responses to iontophoretically applied GABA in mouse cortical and spinal neurons, effects that are observed at therapeutically relevant concentrations of phenobarbital; in patch-clamp studies, phenobarbital increases the GABA_A receptor-mediated current by increasing the duration of bursts of GABA_A receptor-mediated currents without changing the frequency of bursts (Twyman et al., 1989). At levels exceeding therapeutic concentrations, phenobarbital also limits sustained repetitive firing; this may underlie some of the antiseizure effects of higher concentrations of phenobarbital achieved during therapy of status epilepticus.

ADME

Oral absorption of phenobarbital is complete but somewhat slow; peak concentrations in plasma occur several hours after a single dose. It is 40%–60% bound to plasma proteins and bound to a similar extent in tissues, including brain. Up to 25% of a dose is eliminated by pH-dependent renal excretion of the unchanged drug; the remainder is inactivated by hepatic microsomal enzymes, principally CYP2C9, with minor metabolism by CYP2C19 and CYP2E1. Phenobarbital induces UGT enzymes as well as the CYP2C and CYP3A subfamilies. Drugs metabolized by these enzymes can be more rapidly degraded when coadministered with phenobarbital; importantly, oral contraceptives are metabolized by CYP3A4. The terminal $t_{1/2}$ of phenobarbital varies widely, 50–140 h in adults and 40–70 h in children younger than 5 years of age, often longer in neonates. Phenobarbital's duration of effect usually exceeds 6–12 h in nontolerant patients.

Plasma Drug Concentrations

During long-term therapy in adults, the plasma concentration of phenobarbital averages 10 µg/mL per daily dose of 1 mg/kg; in children, the value is 5–7 µg/mL per 1 mg/kg. Although a precise relationship between therapeutic results and concentration of drug in plasma does not exist, plasma concentrations of 10–35 µg/mL are usually recommended for control of seizures. The relationship between plasma concentration of phenobarbital and adverse effects varies with the development of tolerance. Sedation, nystagmus, and ataxia usually are absent at concentrations below 30 µg/mL during long-term therapy, but adverse effects may be apparent for several days at lower concentrations when therapy is initiated or whenever the dosage is increased. Concentrations more than 60 µg/mL may be associated with marked intoxication in the nontolerant individual. Because significant behavioral toxicity may be present despite the absence of overt signs of toxicity, the tendency to maintain patients, particularly children, on excessively high doses of phenobarbital should be resisted. The plasma phenobarbital concentration should be increased above 30–40 µg/mL only if the increment is adequately tolerated and only if it contributes significantly to control of seizures.

Therapeutic Uses

Phenobarbital is an effective agent for generalized tonic-clonic, focal-to-bilateral tonic-clonic, tonic-clonic of unknown onset (generalized tonic-clonic), and focal seizures. Its efficacy, low toxicity, and low cost make it an important agent for these types of epilepsy. However, its sedative effects and its tendency to disturb behavior in children have reduced its use as a primary agent. It is not effective for absence seizures.

Adverse Effects, Drug Interactions, and Toxicity

Sedation, the most frequent undesired effect of phenobarbital, is apparent to some extent in all patients on initiation of therapy, but tolerance develops during chronic medication. Nystagmus and ataxia occur at excessive dosage. Phenobarbital can produce irritability and hyperactivity in

children and agitation and confusion in the elderly. Scarletiform or morbilliform rash, possibly with other manifestations of drug allergy, occurs in 1%–2% of patients. Exfoliative dermatitis is rare. Hypoprothrombinemia with hemorrhage has been observed in the newborns of mothers who have received phenobarbital during pregnancy; vitamin K is effective for treatment or prophylaxis. As with phenytoin, megaloblastic anemia that responds to folate and osteomalacia that responds to high doses of vitamin D occur during chronic phenobarbital therapy of epilepsy. Other adverse effects of phenobarbital are discussed in Chapter 19.

Interactions between phenobarbital and other drugs usually involve induction of the hepatic CYPs by phenobarbital. The interaction between phenytoin and phenobarbital is variable. Concentrations of phenobarbital in plasma may be elevated by as much as 40% during concurrent administration of valproate.

Primidone

Although primidone is indicated in the U.S. for patients with focal or generalized epilepsy, it has largely been replaced by carbamazepine and other newer ASDs that possess lower incidence of sedation.

Mechanism of Action

The exact mechanism of primidone's antiseizure effects is not fully understood. It is metabolized to two active metabolites: phenobarbital and phenylethylmalonamide (PEMA). Primidone and its two metabolites each have antiseizure effects on focal and generalized tonic-clonic seizures.

ADME

Primidone is completely absorbed and generally reaches peak plasma concentration within about 3 h of oral administration. Primidone is 30% protein bound in plasma and is rapidly metabolized to both phenobarbital and PEMA. Both primidone and phenobarbital undergo extensive conjugation prior to excretion. Primidone's $t_{1/2}$ is about 6–8 h. In contrast, the terminal $t_{1/2}$ of phenobarbital varies with age, with values ranging in adults from 50 to 140 h and in children less than 5 years of age from 40 to 70 h. Because of both slow accumulation and clearance, phenobarbital reaches therapeutic concentrations approximately two to three times higher than that of primidone. In fact, care should be taken and plasma closely monitored during titration of primidone doses because primidone may reach steady-state levels rapidly (1–2 days), whereas the metabolites phenobarbital and PEMA each attain steady state more slowly (20 days and 3–4 days, respectively).

Therapeutic Uses

Doses of 10–20 mg/kg/d reach clinically relevant steady-state plasma concentrations (8–12 $\mu\text{g/mL}$), although interpatient variability is common. In addition to its early use in patients with focal-onset or generalized epilepsy, primidone is still considered to be a first-line therapy for essential tremor with the β blocker propranolol.

Adverse Effects

The dose-dependent adverse effects of primidone are similar to those of phenobarbital, except that pronounced drowsiness is observed early after primidone administration. Common adverse effects include ataxia and vertigo, both of which diminish and may disappear with continued therapy. Primidone is contraindicated in patients with either porphyria or hypersensitivity to phenobarbital.

Iminostilbenes

Carbamazepine

Carbamazepine is considered to be a primary drug for the treatment of generalized tonic-clonic, focal-to-bilateral tonic-clonic, tonic-clonic of unknown onset (generalized tonic-clonic), and focal seizures. It is also used for the treatment of trigeminal neuralgia.

Carbamazepine is related chemically to the tricyclic antidepressants. It is a derivative of iminostilbene with a carbamyl group at the 5 position; this moiety is essential for potent antiseizure activity.

CARBAMAZEPINE

Mechanism of Action

Like phenytoin, carbamazepine limits the repetitive firing of action potentials evoked by a sustained depolarization of mouse spinal cord or cortical neurons maintained in vitro (McLean and Macdonald, 1986a). This appears to be mediated by slowing of the rate of recovery of voltage-activated Na^+ channels from inactivation. These effects of carbamazepine are evident at concentrations in the range of therapeutic drug levels in CSF in humans and are relatively selective, producing no effects on spontaneous activity or on responses to iontophoretically applied GABA or glutamate. The carbamazepine metabolite 10,11-epoxycarbamazepine also limits sustained repetitive firing at therapeutically relevant concentrations, suggesting that this metabolite may contribute to the anti-seizure efficacy of carbamazepine.

ADME

The pharmacokinetics of carbamazepine are complex. They are influenced by its limited aqueous solubility and by the capacity of many ASDs, including carbamazepine itself, to increase conversion to active metabolites by hepatic enzymes (Table 17–3). Carbamazepine is absorbed slowly and erratically after oral administration. Peak concentrations in plasma usually are observed 4–8 h after oral ingestion, but may be delayed by as much as 24 h, especially following the administration of a large dose. Once absorbed, the drug distributes rapidly into all tissues. Approximately 75% of carbamazepine binds to plasma proteins; concentrations in the CSF appear to correspond to the concentration of free drug in plasma. The predominant pathway of metabolism in humans involves conversion to the 10,11-epoxide, a metabolite as active as the parent compound; its concentrations in plasma and brain may reach 50% of those of carbamazepine, especially during the concurrent administration of phenytoin or phenobarbital. The 10,11-epoxide is metabolized further to inactive compounds that are excreted in the urine principally as glucuronides. Carbamazepine also is inactivated by conjugation and hydroxylation. Hepatic CYP3A4 is primarily responsible for the agent's biotransformation. Carbamazepine induces CYP2C, CYP3A, and UGT, thus enhancing the metabolism of drugs degraded by these enzymes. Of particular importance in this regard are oral contraceptives, which are also metabolized by CYP3A4.

Plasma Drug Concentrations

There is no simple relationship between the dose of carbamazepine and concentrations of the drug in plasma. Therapeutic concentrations are reported to be 6–12 $\mu\text{g/mL}$, although considerable variation occurs. Side effects referable to the CNS are frequent at concentrations above 9 $\mu\text{g/mL}$.

Therapeutic Uses

Carbamazepine is useful in patients with generalized tonic-clonic and both focal aware and focal with impaired awareness seizures (Table 17–1). When it is used, renal and hepatic function and hematological parameters should be monitored. The therapeutic use of carbamazepine is discussed further at the end of this chapter.

Carbamazepine can produce therapeutic responses in patients with bipolar disorder, including some for whom lithium carbonate is not effective. Further, carbamazepine has antidiuretic effects that are sometimes associated with increased concentrations of antidiuretic hormone (ADH) in plasma via mechanisms that are not clearly understood.

Carbamazepine is the primary agent for treatment of trigeminal and glossopharyngeal neuralgias. It is also effective for lightning-type ("tabetic") pain associated with bodily wasting. Carbamazepine is also used in the treatment of bipolar affective disorders, as discussed further in Chapter 16.

Adverse Effects, Drug Interactions, and Toxicity

Acute intoxication with carbamazepine can result in stupor or coma, hyperirritability, convulsions, and respiratory depression. During long-term therapy, the more frequent untoward effects of the drug include drowsiness, vertigo, ataxia, diplopia, and blurred vision. The frequency of seizures may increase, especially with overdose. Other adverse effects include nausea; vomiting; serious hematological toxicity (aplastic anemia, agranulocytosis); and hypersensitivity reactions (dangerous skin reactions, eosinophilia, lymphadenopathy, splenomegaly). A late complication of therapy with carbamazepine is retention of water, with decreased osmolality and concentration of Na^+ in plasma, especially in elderly patients with cardiac disease.

Some tolerance develops to the neurotoxic effects of carbamazepine, and they can be minimized by gradual increase in dosage or adjustment of maintenance dosage. Various hepatic or pancreatic abnormalities have been reported during therapy with carbamazepine, most commonly a transient elevation of hepatic transaminases in plasma in 5%–10% of patients. A transient, mild leukopenia occurs in about 10% of patients during initiation of therapy and usually resolves within the first 4 months of continued treatment; transient thrombocytopenia also has been noted. In about 2% of patients, a persistent leukopenia may develop that requires withdrawal of the drug. The initial concern that aplastic anemia might be a frequent complication of long-term therapy with carbamazepine has not materialized. In most cases, the administration of multiple drugs or the presence of another underlying disease has made it difficult to establish a causal relationship. The prevalence of aplastic anemia appears to be about 1 in 200,000 patients. It is not clear whether monitoring of hematological function can help to avert the development of irreversible aplastic anemia. Carbamazepine is not known to be carcinogenic in humans. Possible teratogenic effects are discussed later in the chapter.

Phenobarbital, phenytoin, and valproate may increase the metabolism of carbamazepine by inducing CYP3A4; carbamazepine may enhance the biotransformation of phenytoin. Concurrent administration of carbamazepine may lower concentrations of valproate, lamotrigine, tiagabine, and topiramate. Carbamazepine reduces both the plasma concentration and the therapeutic effect of haloperidol. The metabolism of carbamazepine may be inhibited by propoxyphene, erythromycin, cimetidine, fluoxetine, and isoniazid.

Oxcarbazepine

Oxcarbazepine is FDA-approved for monotherapy or adjunct therapy for focal seizures in adults, as monotherapy for focal seizures in children ages 4–16, and as adjunctive therapy in children aged 2–16 years. Oxcarbazepine (10,11-dihydro-10-oxocarbamazepine) is a keto analogue of carbamazepine and is a prodrug that is rapidly converted to its metabolite, eslicarbazepine. Eslicarbazepine is then extensively converted to its S(+) enantiomer, the active metabolite S-licarbazepine. Oxcarbazepine is inactivated by glucuronide conjugation, is eliminated by renal excretion, and has a short $t_{1/2}$ of only about 1–2 h.

Oxcarbazepine has a mechanism of action similar to that of carbamazepine but is a less-potent enzyme inducer than carbamazepine. Substitution of oxcarbazepine for carbamazepine is associated with increased levels of phenytoin and valproate, presumably because of reduced induction of hepatic enzymes. Oxcarbazepine does not induce the hepatic enzymes involved in its own degradation. Although oxcarbazepine does not appear to reduce the anticoagulant effect of warfarin, it does induce CYP3A and thus reduces plasma levels of steroid oral contraceptives. Fewer hypersensitivity reactions have been associated with oxcarbazepine, and cross-reactivity with carbamazepine does not always occur. Although most adverse effects are similar to that with carbamazepine, hyponatremia may occur more commonly with oxcarbazepine than with carbamazepine.

Eslicarbazepine Acetate

Eslicarbazepine acetate is a prodrug approved in the U.S. as a monotherapy and adjunctive treatment of focal-onset seizures. Eslicarbazepine is converted to its active metabolite S-licarbazepine faster than its prodrug,

oxcarbazepine; eslicarbazepine has a similar mechanism of action as oxcarbazepine because both are prodrugs that produce the same active metabolite, S-licarbazepine. Eslicarbazepine competitively inhibits fast voltage-gated sodium channels, stabilizing the inactivated state and the sodium-dependent release of neurotransmitters. Eslicarbazepine has a $t_{1/2}$ similar to that of carbamazepine, about 8–12 h, after which it is excreted as a glucuronide. Eslicarbazepine acetate in adults may be initiated at 400–1200 mg/d. Higher doses require careful titration based on patient response. Reduction in dosing is necessary in patients with renal impairment.

Succinimides

Ethosuximide

Ethosuximide is a primary agent for the treatment of generalized absence seizures.

Mechanism of Action

Ethosuximide reduces low threshold T-type Ca^{2+} currents in thalamic neurons (Coulter et al., 1989), and inhibition of T-type currents likely is the mechanism by which ethosuximide inhibits absence seizures. The thalamus plays an important role in generation of 3-Hz spike-and-wave rhythms typical of absence seizures (Huguenard and McCormick, 2007). Neurons in the thalamus exhibit large-amplitude T-type currents that underlie bursts of action potentials and likely play an important role in thalamic oscillatory activity, such as 3-Hz spike-and-wave activity. Ethosuximide reduces this current without modifying the voltage dependence of steady-state inactivation or the time course of recovery from inactivation. Ethosuximide does not inhibit sustained repetitive firing or enhance GABA responses at clinically relevant concentrations.

ADME

Absorption of ethosuximide appears to be complete, with peak C_p occurring within about 3 h after a single oral dose. Ethosuximide is not significantly bound to plasma proteins; during long-term therapy, its concentration in the CSF is similar to that in plasma. The apparent volume of distribution averages 0.7 L/kg.

Approximately 25% of the drug is excreted unchanged in the urine. The remainder is metabolized by hepatic microsomal enzymes, but whether CYPs are responsible is unknown. The major metabolite, the hydroxyethyl derivative, accounts for about 40% of ethosuximide metabolism, is inactive, and is excreted as such and as the glucuronide in the urine. The plasma $t_{1/2}$ of ethosuximide averages between 40 and 50 h in adults and about 30 h in children.

Plasma Drug Concentrations

During long-term therapy, the plasma concentration of ethosuximide averages about 2 $\mu\text{g/mL}$ per daily dose of 1 mg/kg. A plasma concentration of 40–100 $\mu\text{g/mL}$ usually is required for satisfactory control of absence seizures.

Therapeutic Uses

Ethosuximide is effective against absence seizures, but not tonic-clonic seizures. An initial daily dose of 250 mg in children (3–6 years old) and 500 mg in older children, and adult dosage is increased by 250-mg increments at weekly intervals until seizures are adequately controlled or toxicity intervenes. Divided dosage is required occasionally to prevent nausea or drowsiness associated with once-daily dosing. The usual maintenance dose is 20 mg/kg/d. Increased caution is required if the daily dose exceeds 1500 mg in adults or 750–1000 mg in children. The therapeutic use of ethosuximide is discussed further at the end of the chapter.

Adverse Effects and Toxicity

The most common dose-related side effects are GI complaints (nausea, vomiting, and anorexia) and CNS effects (drowsiness, lethargy, euphoria, dizziness, headache, and hiccough). Some tolerance to these effects develops. Parkinson-like symptoms and photophobia have been reported.

Restlessness, agitation, anxiety, aggressiveness, inability to concentrate, and other behavioral effects have occurred primarily in patients with a prior history of psychiatric disturbance.

Urticaria and other skin reactions, including Stevens-Johnson syndrome, systemic lupus erythematosus, eosinophilia, leukopenia, thrombocytopenia, pancytopenia, and aplastic anemia, also have been attributed to the drug. The leukopenia may be transient despite continuation of the drug, but several deaths have resulted from bone marrow depression. Renal and hepatic toxicity have not been reported.

Other Antiseizure Drugs

Acetazolamide

Acetazolamide, the prototype for the carbonic anhydrase inhibitors, is discussed in Chapter 25. Its antiseizure actions have been discussed in previous editions of this textbook. Although it is sometimes effective against absence seizures, its usefulness is limited by the rapid development of tolerance. Adverse effects are minimal when it is used in moderate dosage for limited periods.

Ezogabine

Mechanisms of Action

Ezogabine is a first-in-class K^+ channel opener, known as retigabine in the E.U. Ezogabine enhances transmembrane K^+ currents mediated by the KCNQ family of ion channels (i.e., Kv7.2–Kv7.5). Through its activation of the KCNQ channels, ezogabine may stabilize the resting membrane potential and reduce neuronal excitability. In vitro studies suggested that ezogabine may also enhance GABA-mediated currents.

ADME

Dosing in adults is typically initiated at 300 mg per day and gradually titrated to 600–1200 mg/d over several weeks. Ezogabine is rapidly absorbed after oral administration, and absorption is not affected by food. Ezogabine is approximately 80% protein bound in plasma. Ezogabine is metabolized by glucuronidation and acetylation and has a $t_{1/2}$ of 7–11 h; it and its metabolites are excreted in the urine. Thus, ezogabine generally requires dosing thrice daily. Concomitant administration of phenytoin or carbamazepine may reduce plasma concentrations of ezogabine; consequently, an increase in ezogabine dosage should be considered when adding phenytoin or carbamazepine.

Therapeutic Use

Ezogabine was approved in the U.S. as adjunctive treatment of focal-onset seizures in patients aged 18 years and older with inadequate response to alternative ASDs and for whom the benefits outweigh the risk of retinal abnormalities and potential visual acuity deficits. However, the FDA issued a warning for ezogabine citing safety concerns, including blue discoloration and retinal abnormalities. In response, the manufacturer announced that production of ezogabine would cease in June, 2017.

Adverse Effects and Toxicity

The most common adverse effects associated with ezogabine include dizziness, somnolence, fatigue, confusion, and blurred vision. Vertigo, diplopia, memory impairment, gait disturbance, aphasia, dysarthria, and balance problems also may occur. Serious side effects include skin discoloration, QT prolongation, and neuropsychiatric symptoms, including suicidal thoughts and behavior, psychosis, and hallucinations. Due to the presence of Kv7.2–Kv7.5 in the bladder uroepithelium, ezogabine is also associated with urinary retention. Blue pigmentation of skin and lips occurs in as many as one-third of patients maintained on long-term ezogabine therapy. Chronic treatment with ezogabine may cause retinal abnormalities, independent of changes in skin coloration. The FDA has changed the labeling of ezogabine to warn about the risks serious adverse effects, all of which may be permanent. Ezogabine should thus be discontinued if clinical benefit is not achieved after careful titration; however, the discontinuation of ezogabine should be done gradually, while under the care of a physician. In addition, the FDA recommends that all patients taking ezogabine should have baseline and periodic (every 6

months) systemic visual monitoring by an ophthalmic professional, which includes both visual acuity and dilated fundus photography.

Felbamate

Felbamate is not indicated as a first-line therapy for any type of seizure activity. Rather, felbamate is FDA-approved for focal seizures in patients who have inadequately responded to alternative ASDs and in patients for whom the severity of their epilepsy outweighs the substantial risk of drug-induced aplastic anemia or liver failure. The potential for such serious and life-threatening adverse effects has limited the clinical utility of felbamate.

Mechanisms of Action

Clinically relevant concentrations of felbamate inhibit NMDA-evoked responses and potentiate GABA-evoked responses in whole-cell, voltage-clamp recordings of cultured rat hippocampal neurons (Rho et al., 1994). This dual action on excitatory and inhibitory transmitter responses may contribute to the wide spectrum of action of the drug in seizure models; however, the mechanism(s) by which felbamate exerts its anticonvulsant activity remain unknown.

Therapeutic Use

Despite the potential serious adverse effects, felbamate is used at doses ranging from 1 to 4 g/d. Clinical studies demonstrate the efficacy of felbamate in patients with poorly controlled focal and secondarily generalized seizures (Sachdeo et al., 1992) and in patients with Lennox-Gastaut syndrome (Felbamate Study Group in Lennox-Gastaut Syndrome, 1993). The clinical efficacy of this unique compound, which inhibits responses to NMDA while potentiating GABAergic neurotransmission, underscores the potential therapeutic value of identifying additional ASDs with novel mechanisms of action.

Gabapentin and Pregabalin

Gabapentin and pregabalin are ASDs that consist of a GABA molecule covalently bound to a lipophilic cyclohexane ring or isobutane, respectively. Gabapentin was designed to be a centrally active GABA agonist, with its high lipid solubility aimed at facilitating its transfer across the blood-brain barrier; the actual mechanism of action is notably different (see below).

Mechanisms of Action

Gabapentin inhibits tonic hind limb extension in the electroshock seizure model. Interestingly, gabapentin also inhibits clonic seizures induced by pentylenetetrazol. Its efficacy in both of these tests parallels that of valproate and distinguishes it from phenytoin and carbamazepine. Despite their design as GABA agonists, neither gabapentin nor pregabalin mimics GABA when iontophoretically applied to neurons in primary culture. Rather, these compounds bind with high affinity to a protein in cortical membranes with an amino acid sequence identical to that of the Ca^{2+} channel subunit $\alpha 2\delta$ -1 (Gee et al., 1996). This interaction with the $\alpha 2\delta$ -1 protein may mediate the anticonvulsant effects of gabapentin, but whether and how the binding of gabapentin to the $\alpha 2\delta$ -1 subunit regulates neuronal excitability remains unclear. Pregabalin binding is reduced but not eliminated in mice carrying a mutation in the $\alpha 2\delta$ -1 protein (Field et al., 2006). Analgesic efficacy of pregabalin is eliminated in these mice; whether the anticonvulsant effects of pregabalin are also eliminated was not reported.

ADME

Gabapentin and pregabalin are absorbed after oral administration and are not metabolized in humans. These compounds are not bound to plasma proteins and are excreted unchanged, mainly in the urine. Their half-lives, when used as monotherapy, approximate 6 h. These compounds have no known interactions with other ASDs.

Therapeutic Uses

Gabapentin and pregabalin are effective for focal onset seizures, with and without progression to bilateral tonic-clonic seizures, when used in addition to other ASDs. Gabapentin is also indicated for the management of the neuropathic pain associated with postherpetic neuralgia in adults.

Pregabalin is FDA-approved as an adjunctive therapy for adults with focal onset seizures. It is also indicated for the management of fibromyalgia and the neuropathic pain associated diabetic peripheral neuropathy, postherpetic neuralgia, or spinal cord injury.

In double-blind, placebo-controlled trials of adults with refractory focal seizures, addition of gabapentin or pregabalin to other ASDs is superior to placebo (French et al., 2003; Sivenius et al., 1991). Gabapentin monotherapy (900 or 1800 mg/d) is equivalent to carbamazepine (600 mg/d) for newly diagnosed focal or generalized epilepsy (Chadwick et al., 1998).

Gabapentin usually is effective in doses of 900–1800 mg daily in three doses, although 3600 mg may be required in some patients to achieve reasonable seizure control. Therapy usually is begun with a low dose (300 mg once on the first day), which is increased in daily increments of 300 mg until an effective dose is reached. In comparison, pregabalin is generally initiated at 50 mg three times a day (150 mg/day) and increase within 1 week to 300 mg/day based on efficacy and tolerability. Since both gabapentin and pregabalin are eliminated by renal excretion, appropriate dose adjustments are necessary in patients with reduced renal function.

Adverse Effects

Overall, gabapentin is well tolerated, with the most common adverse effects of somnolence, dizziness, ataxia, and fatigue. These effects usually are mild to moderate in severity but resolve within 2 weeks of onset during continued treatment. Gabapentin and pregabalin are both listed in pregnancy category C.

Lacosamide

Lacosamide is a stereoselective enantiomer of the amino acid, L-serine. This functionalized amino acid is FDA approved as adjunctive therapy for focal-onset seizures in patients older than 17 years. The FDA assigned lacosamide a Controlled Substance Act (CSA) schedule V designation, meaning it has a low potential for abuse.

Mechanisms of Action

Lacosamide is the first ASD to enhance (prolong) the slow inactivation of voltage-gated Na^+ channels and to limit sustained repetitive firing, the neuronal firing pattern characteristic of focal seizures. Lacosamide also binds collapsin response mediator protein-2 (CRMP-2), a phosphoprotein involved in neuronal differentiation and axon outgrowth, but the contribution of CRMP-2 to lacosamide's antiseizure efficacy remains unclear. Lacosamide was extensively evaluated by the ETSP and found to be highly effective in numerous preclinical animal models of seizures and epilepsy, including maximal electroshock, hippocampal kindling, Frings and 6-Hz models, giving lacosamide a unique preclinical profile compared to other Na^+ channel blockers.

ADME

Peak lacosamide plasma concentrations occur about 1–4 h after oral administration, and food consumption does not affect the absorption. Lacosamide has a $t_{1/2}$ of 12–16 h; 95% is excreted in the urine, about half of which is the unchanged parent compound. The major metabolite, O-desmethyl-lacosamide, is inactive.

Therapeutic Uses

Lacosamide is approved for both monotherapy and add-on therapy for focal-onset seizures in patients 17 years and older. As a monotherapy for the treatment of focal seizures, the initial recommended dose is 50–100 mg twice daily and, depending on patient response, may be increased at weekly intervals by 50 mg twice daily to a recommended maintenance dose of 100 mg to 200 mg twice daily, or 200–400 mg/d. The pharmacological profile is advantageous for hospitalized patients because it is available in an intravenous formulation, has minimal hepatic metabolism, and has no adverse respiratory effects. In addition, double-blind, placebo-controlled studies of adults with refractory focal seizures suggest that addition of lacosamide to other ASDs is superior to the addition of placebo.

Adverse Effects

Lacosamide is generally well tolerated. Although it has been associated with a brief (6-ms) prolongation of the PR interval, well-controlled studies

in healthy patients suggested lacosamide does not prolong the QT interval. However, patients who are taking concomitant agents that prolong the PR interval should have a baseline electrocardiogram before starting lacosamide and be closely monitored due to a risk of AV block or bradycardia. Patients with renal impairment or hepatic impairment who are taking inhibitors of CYP3A4 or CYP2C9 may experience a significant increase in lacosamide exposure. No major adverse effects have been reported, although minor adverse effects include headache, dizziness, double vision, nausea, vomiting, fatigue, tremor, loss of balance, and somnolence. Like most currently available ASDs, lacosamide may contribute to suicidal ideations and suicide. As a consequence, the FDA has mandated a black-box warning for this agent.

Lamotrigine

Lamotrigine is a phenyltriazine derivative initially developed as an antifolate agent, based on the incorrect idea that reducing folate would effectively combat seizures. Structure-activity studies have since indicated that its effectiveness as an ASD is unrelated to its antifolate properties (Macdonald and Greenfield, 1997).

Mechanisms of Action

Lamotrigine suppresses tonic hind limb extension in the maximal electroshock model and focal and secondarily generalized seizures in the kindling model, but does not inhibit clonic motor seizures induced by pentylenetetrazol. Lamotrigine blocks sustained repetitive firing of mouse spinal cord neurons and delays the recovery from inactivation of recombinant Na^+ channels, mechanisms similar to those of phenytoin and carbamazepine (Xie et al., 1995). This may well explain lamotrigine's actions on focal and secondarily generalized seizures. However, as mentioned below, lamotrigine is effective against a broader spectrum of seizures than are phenytoin and carbamazepine, suggesting that lamotrigine may have actions in addition to regulating recovery from inactivation of Na^+ channels. One possibility, supported by basic research, is that lamotrigine inhibits synaptic release of glutamate by acting at Na^+ channels themselves.

ADME

Lamotrigine is completely absorbed from the GI tract. The drug is metabolized primarily by glucuronidation, yielding a plasma $t_{1/2}$ of a single dose of 24–30 h. Administration of phenytoin, carbamazepine, or phenobarbital reduces the $t_{1/2}$ and plasma concentrations of lamotrigine. Conversely, addition of valproate markedly increases plasma concentrations of lamotrigine, likely by inhibiting glucuronidation. Addition of lamotrigine to valproate produces a reduction of valproate concentrations by about 25% over a few weeks. Concurrent use of lamotrigine and carbamazepine is associated with increases of the 10,11-epoxide of carbamazepine and clinical toxicity in some patients.

Therapeutic Use

Lamotrigine is useful for monotherapy and add-on therapy of focal and secondarily generalized tonic-clonic seizures in adults and Lennox-Gastaut syndrome in both children and adults. Lennox-Gastaut syndrome is a disorder of childhood characterized by multiple seizure types, mental retardation, and refractoriness to antiseizure medication.

Lamotrigine monotherapy in newly diagnosed focal or generalized tonic-clonic seizures is equivalent to monotherapy with carbamazepine or phenytoin (Brodie et al., 1995; Steiner et al., 1999). Addition of lamotrigine to existing ASDs is effective against tonic-clonic seizures and drop attacks in children with the Lennox-Gastaut syndrome (Motte et al., 1997). Lamotrigine is also superior to placebo in children with newly diagnosed absence epilepsy (Frank et al., 1999).

Patients who are already taking a CYP-inducing ASD (e.g., carbamazepine, phenytoin, phenobarbital, or primidone, but not valproate) should be given lamotrigine initially at 50 mg/d for 2 weeks. The dose is increased to 50 mg twice per day for 2 weeks and then increased in increments of 100 mg/d each week up to a maintenance dose of 300–500 mg/d divided into two doses. For patients taking valproate in addition to an enzyme-inducing ASD, the initial dose should be 25 mg every other day for 2 weeks, followed by an increase to 25 mg/d for 2 weeks; the dose then

can be increased by 25–50 mg/d every 1–2 weeks up to a maintenance dose of 100–150 mg/d divided into two doses.

Adverse Effects

The most common adverse effects are dizziness, ataxia, blurred or double vision, nausea, vomiting, and rash when lamotrigine is added to another ASD. A few cases of Stevens-Johnson syndrome and disseminated intravascular coagulation have been reported. The incidence of serious rash in pediatric patients (~0.8%) is higher than in the adult population (0.3%).

Levetiracetam and Brivaracetam

Levetiracetam is a pyrrolidine, the racemically pure *S*-enantiomer of α -ethyl-2-oxo-1-pyrrolidineacetamide, and is FDA-approved for adjunctive therapy for myoclonic, focal-onset, and generalized onset tonic-clonic seizures in adults and children as young as 4 years old. Brivaracetam, an analogue of levetiracetam, was FDA-approved in 2016 as an adjunctive therapy for focal-onset seizures in patients aged 16 years and older with epilepsy.

Mechanism of Action

Levetiracetam exhibits a novel pharmacological profile: It inhibits focal and secondarily generalized tonic-clonic seizures in the kindling model, yet is ineffective against maximum electroshock- and pentylenetetrazol-induced seizures, findings consistent with clinical effectiveness against focal and secondarily generalized tonic-clonic seizures. The mechanism by which levetiracetam exerts these antiseizure effects is not fully understood. However, the correlation between binding affinity of levetiracetam and its analogues and their potency toward audiogenic seizures suggests that the synaptic vesicle protein SV2A mediates the anticonvulsant effects of levetiracetam (Rogawski and Bazil, 2008). SV2A is an integral transmembrane glycoprotein; expression of human SV2A in hexose transport-deficient yeast shows that SV2A can function as a galactose transporter (Madeo et al, 2014). The neuronal function of the SV2A protein is not fully understood, but binding of levetiracetam to SV2A might affect neuronal excitability by modifying the release of glutamate and GABA through an action on vesicular function. In mice, a missense mutation in SV2A is reportedly associated with disruption of action-potential invoked GABA release in limbic regions (Ohno and Tokudome, 2017). Other workers have suggested that SV2A may play a role in vesicle recycling following exocytosis of neurotransmitter (Bartolome, et al., 2017). In addition, levetiracetam inhibits N-type Ca^{2+} channels and Ca^{2+} release from intracellular stores.

Brivaracetam binds with high affinity to SV2A and inhibits neuronal voltage-gated Na^+ channels (Kenda et al., 2004; Zona et al., 2010); pre-clinical studies suggested a broad spectrum of anticonvulsant protection (Matagne et al., 2008).

ADME

Levetiracetam is rapidly and almost completely absorbed after oral administration and is not bound to plasma proteins. The plasma $t_{1/2}$ is 6–8 h, but may be longer in elderly patients. Ninety-five percent of the drug and its inactive metabolite are excreted in the urine, 65% of which is unchanged drug; 24% of the drug is metabolized by hydrolysis of the acetamide group. Because levetiracetam neither induces nor is a high-affinity substrate for CYPs or glucuronidation enzymes, it is devoid of known interactions with other ASDs, oral contraceptives, or anticoagulants.

Brivaracetam is rapidly absorbed and well tolerated, with an elimination $t_{1/2}$ of approximately 7–8 h.

Therapeutic Use

Levetiracetam is marketed for the adjunctive treatment of focal seizures in adults and children, for primary onset tonic-clonic seizures, and for myoclonic seizures of JME. It is available in tablet (10, 25, 50, 75, or 100 mg), oral solution (10 mg/mL), or injectable form (50 mg/5 mL). Adult dosing is initiated at 500–1000 mg/d and increased every 2–4 weeks by 1000 mg to a maximum dose of 3000 mg/d. The drug is administered twice daily. In adults with either refractory focal seizures or uncontrolled generalized tonic-clonic seizures associated with idiopathic generalized epilepsy, addition of levetiracetam to other antiseizure medications is superior to

placebo. Levetiracetam also has efficacy as adjunctive therapy for refractory generalized myoclonic seizures (Andermann et al., 2005). Insufficient evidence is available about its use as monotherapy for focal or generalized epilepsy.

The recommended starting dose for brivaracetam is 50 mg twice daily, which may be adjusted to either 25 mg twice daily or 100 mg twice daily, based on patient response and tolerability.

Adverse Effects

Both levetiracetam and brivaracetam are well tolerated. The most frequently reported adverse effects associated with levetiracetam are somnolence, asthenia, ataxia, and dizziness. Behavioral and mood changes are serious, but less common. For brivaracetam, the most common adverse effects are similarly mild and include somnolence, sedation, dizziness, and GI upset. In patients with hepatic insufficiency, dose adjustment may be required with brivaracetam to 25 mg twice daily and a maximal dosage of 75 mg twice daily. Hypersensitivity reactions may occur.

Perampanel

Mechanisms of Action

Perampanel is a first-in class selective, noncompetitive antagonist of the AMPA-type ionotropic glutamate receptor (Bialer and White, 2010; Stephen and Brodie, 2011). Unlike NMDA antagonists, which shorten the duration of repetitive discharges, AMPA receptor antagonists prevent repetitive neuronal firing. Preclinical studies demonstrated a broad spectrum of activity in both acute and chronic seizure models, indicating that perampanel reduces fast excitatory signaling critical to the seizure generation (Tortorella et al., 1997) and spread (Namba et al., 1994; Rogawski and Donevan, 1999). Perampanel seems to have a greater inhibitory effect on seizure propagation than on seizure initiation (Hanada et al., 2011).

ADME and Drug Interactions

Perampanel is absorbed well after oral administration with a plasma $t_{1/2}$ of about 105 h, permitting once-daily administration. The drug is 95% bound to plasma protein, mainly albumin, and is metabolized by hepatic oxidation and glucuronidation. A linear relationship between perampanel dose and plasma concentration has been reported over the dose range of 2–12 mg/d.

Primary metabolism is mediated by hepatic CYP3A; thus, specific drug interactions and dose adjustments need to be considered. For example, perampanel may decrease the effectiveness of progesterone-containing hormone contraceptives, carbamazepine, clobazam, lamotrigine, and valproate, but it may increase the level of oxcarbazepine. Furthermore, serum perampanel may be decreased when taken with carbamazepine, oxcarbazepine, and topiramate.

Therapeutic Use

Perampanel is FDA-approved as an adjunctive therapy for the treatment of focal-onset seizures in patients 12 years and older with or without secondarily generalized seizures. The recommended oral starting dose is 2 mg once daily, titrated to a maximal dose of 4–12 mg/d at bedtime.

Adverse Effects

Common adverse effects include somnolence, anxiety, confusion, imbalance, double vision, dizziness, GI distress or nausea, and weight gain. Rare, but serious, adverse behavioral reactions, including hostility, aggression, and suicidal thoughts and behaviors, independent of clinical history of psychiatric disorder, have also been reported.

Rufinamide

Rufinamide, a triazole derivative, is structurally unrelated to other marketed ASDs. It is FDA-approved for adjunctive treatment of seizures related to Lennox-Gastaut syndrome in children more than 4 years old and adults.

Mechanism of Action

Rufinamide prolongs slow inactivation of voltage-gated Na^+ channels and limits sustained repetitive firing, the firing pattern characteristic of focal seizures. The complete mechanism of action of rufinamide remains unclear.

Rufinamide is well absorbed orally, binds minimally to plasma proteins, and reaches peak plasma concentrations about 4–6 h after oral administration. The $t_{1/2}$ is 6–10 h. Rufinamide is metabolized independent of CYPs and then excreted in the urine.

Therapeutic Use

Rufinamide has been shown to be effective against all seizure phenotypes in Lennox-Gastaut syndrome. In adults, 400–800 mg/d rufinamide is initially administered in two equal doses. Doses are then titrated upward every other day by 10 mg/kg to a maximum of the lesser of 45 mg/kg/d or 3200 mg/d. Children are initiated at 10 mg/kg/d divided into two equal daily doses, increasing to a maximum of the lesser of 45 mg/kg/d or 3200 mg/d.

Adverse Effects

Common adverse effects include headache, dizziness, somnolence, fatigue, and nausea.

Stiripentol

Stiripentol is an aromatic alcohol, structurally unrelated to any other ASDs. Stiripentol was granted orphan drug status for the treatment of Dravet syndrome in 2008 but has not received FDA approval due its complex pharmacokinetic and pharmacodynamic interactions with other drugs.

Mechanisms of Action

Although the exact nature of its antiseizure mechanism is not clear, stiripentol may increase CNS levels of the inhibitory transmitter GABA by inhibition of synaptosomal uptake of GABA or by inhibition of GABA transaminase. In model systems, stiripentol also enhances GABA_A receptor-mediated neurotransmission and increases the mean open duration of GABA_A receptor chloride channels in a barbiturate-like fashion (Fisher, 2011; Quilichini et al., 2006).

ADME and Drug Interactions

Stiripentol is quickly absorbed, reaching a peak C_p in about 1.5 h; the drug is highly bound to plasma proteins. Stiripentol's elimination kinetics are nonlinear, with a $t_{1/2}$ ranging from 4 to 13 h. Plasma clearance decreases markedly at high doses and after repeated administration, probably due to inhibition or saturation of the CYPs responsible for stiripentol metabolism. Metabolites are excreted in the urine.

Stiripentol has diverse pharmacokinetic and pharmacodynamic interactions with concomitantly administered drugs. It is a potent inhibitor of CYPs 3A4, 1A2, and 2C19. Thus, adjunctively administered ASDs, such as carbamazepine, valproate, phenytoin, phenobarbital, and benzodiazepines, may require dose adjustments due to the potent inhibition of CYPs involved in their hepatic metabolism. Concomitant stiripentol can increase clobazam and valproate concentrations by 2- to 3-fold, and dose reduction of either or both ASDs may be necessary to avoid toxicity.

Therapeutic Use

Stiripentol is used clinically in conjunction with clobazam and valproate as an adjunctive therapy for refractory generalized tonic-clonic seizures in patients with severe myoclonic epilepsy in infancy (Dravet syndrome) whose seizures are not adequately controlled with clobazam and valproate (Aneja and Sharma, 2013; Plosker, 2012). Adjunctive stiripentol in children with Dravet syndrome who fail to respond to valproate and clobazam have a 71% response rate (Chiron et al., 2000; Nabout and Chiron, 2012). Stiripentol also reduces the frequency and severity of tonic-clonic seizures as well as status epilepticus in infants and children with a variety of epilepsy syndromes (Inoue et al., 2009; Perez et al., 1999; Rey et al., 1999).

Use of stiripentol is replete with potential drug interactions (see the section on ADME) that must be considered. Initiation of adjunctive therapy with stiripentol should be undertaken gradually, with frequent plasma monitoring for both the parent ASDs and their active metabolites. Plasma monitoring is important to inform reductions in concomitant ASDs as needed, based on patient response.

Adverse Effects

The most commonly reported adverse effects in patients on stiripentol include anorexia, weight loss, insomnia, drowsiness, ataxia, hypotonia, and dystonia.

Tiagabine

Tiagabine is a derivative of nipecotic acid and is FDA-approved as adjunct therapy for focal seizures in adults.

Mechanism of Action

Tiagabine inhibits the GABA transporter GAT-1 and thereby reduces GABA uptake into neurons and glia and prolongs the dwell time of GABA in the synaptic space. In CA1 neurons of the hippocampus, tiagabine increases the duration of inhibitory synaptic currents, findings consistent with prolonging the effect of GABA at inhibitory synapses through reducing its reuptake by GAT-1. Tiagabine inhibits maximum electroshock seizures and both limbic and secondarily generalized tonic-clonic seizures in the kindling model, results suggestive of clinical efficacy against focal and tonic-clonic seizures.

ADME

Tiagabine is rapidly absorbed after oral administration, extensively bound to serum proteins, and metabolized mainly in the liver, predominantly by CYP3A. Its $t_{1/2}$ of about 8 h is shortened by 2–3 h when coadministered with CYP-inducing drugs such as phenobarbital, phenytoin, or carbamazepine.

Therapeutic Use

Tiagabine is efficacious as add-on therapy for refractory focal seizures with or without secondary generalization. Its efficacy as monotherapy for newly diagnosed or refractory focal and generalized epilepsy has not been established.

Adverse Effects and Precautions

The principal adverse effects include dizziness, somnolence, and tremor; they are mild to moderate in severity and appear shortly after initiation of therapy. Tiagabine and other drugs that enhance effects of synaptically released GABA can facilitate spike-and-wave discharges in animal models of absence seizures. Case reports suggest that tiagabine treatment of patients with a history of spike-and-wave discharges causes exacerbations of their EEG abnormalities. Thus, tiagabine may be contraindicated in patients with generalized absence epilepsy. Paradoxically, tiagabine has been associated with the occurrence of seizures in patients without epilepsy; thus, off-label use of the drug is discouraged.

Topiramate

Topiramate is a sulfamate-substituted monosaccharide that is FDA-approved as initial monotherapy (in patients at least 10 years old) and as adjunctive therapy (for patients as young as 2 years) for focal-onset or primary generalized tonic-clonic seizures, for Lennox-Gastaut syndrome in patients 2 years of age and older, and for migraine headache prophylaxis in adults.

Mechanisms of Action

Topiramate reduces voltage-gated Na⁺ currents in cerebellar granule cells and may act on the inactivated state of the channel similarly to phenytoin. In addition, topiramate activates a hyperpolarizing K⁺ current, enhances postsynaptic GABA_A receptor currents, and limits activation of the AMPA-kainate subtype(s) of glutamate receptors.

The drug is a weak inhibitor of carbonic anhydrase. Topiramate inhibits its maximal electroshock and pentylenetetrazol-induced seizures as well as focal and secondarily generalized tonic-clonic seizures in the kindling model, findings predictive of a broad spectrum of antiseizure actions clinically.

ADME

Topiramate is rapidly absorbed after oral administration, exhibits little (10%–20%) binding to plasma proteins, and is excreted largely unchanged in the urine. A small fraction undergoes metabolism by hydroxylation, hydrolysis, and glucuronidation, with no single metabolite accounting for more than 5% of an oral dose. Its $t_{1/2}$ is about 1 day. Reduced estradiol plasma concentrations occur with concurrent topiramate, suggesting the need for higher doses of oral contraceptives when coadministered with topiramate.

Therapeutic Use

Topiramate is equivalent to valproate and carbamazepine in children and adults with newly diagnosed focal and primary generalized epilepsy (Privitera et al., 2003). The agent is effective as monotherapy for refractory focal epilepsy (Sachdeo et al., 1997) and refractory generalized tonic-clonic seizures (Biton et al., 1999). Topiramate is significantly more effective than placebo against both drop attacks and tonic-clonic seizures in patients with Lennox-Gastaut syndrome (Sachdeo et al., 1999).

Adverse Effects

Topiramate is well tolerated. The most common adverse effects are somnolence, fatigue, weight loss, and nervousness. It may precipitate renal calculi (kidney stones), probably due to inhibition of carbonic anhydrase. Topiramate has been associated with cognitive impairment, and patients may complain about a change in the taste of carbonated beverages.

Valproate

The antiseizure properties of valproic acid were discovered serendipitously when it was employed as a vehicle for other compounds that were being screened for antiseizure activity. Valproate (*n*-dipropylacetic acid) is a simple branched-chain carboxylic acid. Certain other branched-chain carboxylic acids have potencies similar to that of valproic acid in antagonizing pentylenetetrazol-induced seizures. However, increasing the number of carbon atoms to nine introduces marked sedative properties. Straight-chain carboxylic acids have little or no activity.

Pharmacological Effects

Valproate is strikingly different from phenytoin or ethosuximide in that it is effective in inhibiting seizures in a variety of models. Like phenytoin and carbamazepine, valproate inhibits tonic hind limb extension in maximal electroshock seizures and kindled seizures at nontoxic doses. Like ethosuximide, valproate at subtoxic doses inhibits clonic motor seizures induced by pentylenetetrazol. Its efficacy in diverse models parallels its efficacy against absence as well as focal and generalized tonic-clonic seizures in humans.

Mechanisms of Action

Valproate produces effects on isolated neurons similar to those of phenytoin and ethosuximide. At therapeutically relevant concentrations, valproate inhibits sustained repetitive firing induced by depolarization of mouse cortical or spinal cord neurons (McLean and Macdonald, 1986b). The action is similar to that of phenytoin and carbamazepine (Table 17–2) and appears to be mediated by a prolonged recovery of voltage-activated Na^+ channels from inactivation. Valproate does not modify neuronal responses to iontophoretically applied GABA. In neurons isolated from the nodose ganglion, valproate also produces small reductions of T-type

Ca^{2+} currents (Kelly et al., 1990) at clinically relevant concentrations that are slightly higher than those that limit sustained repetitive firing; this effect on T-type currents is similar to that of ethosuximide in thalamic neurons (Coulter et al., 1989). Together, these actions of limiting sustained repetitive firing and reducing T-type currents may contribute to the effectiveness of valproate against focal and tonic-clonic seizures and absence seizures, respectively.

In model systems, valproate can increase brain content of GABA, stimulate GABA synthesis (by glutamate decarboxylase), and inhibit GABA degradation (by GABA transaminase and succinic semialdehyde dehydrogenase). Such data notwithstanding, it has been difficult to relate the increased GABA levels to the antiseizure activity of valproate. Valproate is also a potent inhibitor of histone deacetylase. Thus, some of its antiseizure activity may be due to its ability to modulate gene expression through this mechanism.

ADME

Valproate is absorbed rapidly and completely after oral administration. Peak C_p occurs in 1 to 4 h, although this can be delayed for several hours if the drug is administered in enteric-coated tablets or is ingested with meals. Its extent of binding to plasma proteins is usually about 90%, but the fraction bound is reduced as the total concentration of valproate is increased through the therapeutic range. Although concentrations of valproate in CSF suggest equilibration with free drug in the blood, there is evidence for carrier-mediated transport of valproate both into and out of the CSF.

Valproate undergoes hepatic metabolism (95%), with less than 5% excreted unchanged in urine. Its hepatic metabolism occurs mainly by UGTs and β -oxidation. Valproate is a substrate for CYPs 2C9 and 2C19, but these enzymes account for a relatively minor portion of its elimination. Some of the drug's metabolites, notably 2-propyl-2-pentenoic acid and 2-propyl-4-pentenoic acid, are nearly as potent antiseizure agents as the parent compound; however, only the former accumulates in plasma and brain to a potentially significant extent. The $t_{1/2}$ of valproate is about 15 h but is reduced in patients taking other antiseizure drugs.

Plasma Drug Concentrations

Valproate plasma concentrations associated with therapeutic effects are about 30–100 $\mu\text{g/mL}$. However, there is a poor correlation between the plasma concentration and efficacy. There appears to be a threshold at about 30–50 $\mu\text{g/mL}$, the concentration at which binding sites on plasma albumin begin to become saturated.

Therapeutic Uses

Valproate is a broad-spectrum ASD effective in the treatment of absence, myoclonic, focal, and tonic-clonic seizures. The initial daily dose usually is 15 mg/kg, increased at weekly intervals by 5–10 mg/kg/d to a maximum daily dose of 60 mg/kg. Divided doses should be given when the total daily dose exceeds 250 mg. The therapeutic uses of valproate in epilepsy are discussed further at the end of this chapter.

Adverse Effects and Drug Interactions

The most frequent side effects are transient GI symptoms, including anorexia, nausea, and vomiting (~16%). Effects on the CNS include sedation, ataxia, and tremor; these symptoms occur infrequently and usually respond to a decrease in dosage. Rash, alopecia, and stimulation of appetite have been observed occasionally; weight gain has been seen with chronic valproate treatment in some patients. Elevation of hepatic transaminases in plasma is observed in up to 40% of patients and often occurs asymptotically during the first several months of therapy.

A rare but frequently fatal complication is fulminant hepatitis. Children below 2 years of age with other medical conditions who were given multiple ASDs were especially likely to suffer fatal hepatic injury; there were no deaths reported for patients over the age of 10 years who received only valproate (Dreifuss et al., 1989). Acute pancreatitis and hyperammonemia have been frequently associated with the use of valproate. This agent can also produce teratogenic effects, such as neural tube defects.

Valproate inhibits the metabolism of drugs that are substrates for CYP2C9, including phenytoin and phenobarbital. Valproate also inhibits UGTs and thus inhibits the metabolism of lamotrigine and lorazepam. The high molar concentrations of valproate used clinically result in valproate's displacing phenytoin and other drugs from albumin. With respect to phenytoin in particular, valproate's inhibition of that drug's metabolism is exacerbated by displacement of phenytoin from albumin. The concurrent administration of valproate and clonazepam is associated with the development of absence status epilepticus; however, this complication appears to be rare.

Vigabatrin

Vigabatrin is FDA-approved as adjunct therapy of refractory focal seizures with impaired awareness in adults. In addition, vigabatrin is designated as an orphan drug for treatment of infantile spasms (described in the Therapeutic Use section that follows).

Mechanism of Action

Vigabatrin, a structural analogue of GABA, irreversibly inhibits the major degradative enzyme for GABA, GABA transaminase, thereby leading to increased concentrations of GABA in the brain. This effect is hypothesized to result in increased extracellular GABA at its receptors and enhanced GABAergic transmission.

ADME

An oral dose is well absorbed, reaching a maximal C_p within 1 h; the presence of food prolongs absorption but does not reduce the area under the curve. Vigabatrin is excreted unmetabolized by the kidney, and the dose must be reduced for patients with renal impairment. Although vigabatrin has a $t_{1/2}$ of only 6–8 h, the pharmacodynamic effects are prolonged and do not correlate well with plasma $t_{1/2}$ or the C_p . Such kinetics would be expected due to the irreversible nature of the drug's inhibition of GABA transaminase and a recovery period that reflects the rate of enzyme resynthesis rather than the rate of drug elimination. Vigabatrin induces CYP2C9.

Therapeutic Use

Adult dosing is generally initiated orally at 500 mg twice daily and then increased in 500-mg increments weekly to 1.5 g twice daily.

A 2-week, randomized, single masked clinical trial of vigabatrin for infantile spasms in children younger than 2 years revealed time- and dose-dependent increases in responders, evident as freedom from spasms for 7 consecutive days. Children in whom infantile spasms were caused by tuberous sclerosis were particularly responsive to vigabatrin. As with other ASDs, vigabatrin should be withdrawn slowly, not stopped abruptly.

Toxicity, Adverse Effects, and Precautions

Due to progressive and permanent bilateral vision loss (FDA box warning), vigabatrin must be reserved for patients who have failed several alternative therapies. A patient's vision must be professionally monitored at the beginning of therapy and regularly throughout and after a therapeutic course. Due to this serious toxicity, vigabatrin is available only through SHARE (1-888-45-SHARE), a restricted distribution program.

The most common side effects (>10% patients) include weight gain, concentric visual field constriction, fatigue, somnolence, dizziness, hyperactivity, and seizures. Data in animal models suggest that vigabatrin may harm a developing fetus, and the drug is classified in pregnancy category C. Vigabatrin is excreted in the milk of nursing mothers.

Zonisamide

Zonisamide is FDA-approved as adjunctive therapy of focal seizures in adults 12 years or older.

Mechanism of Action

Zonisamide inhibits the sustained, repetitive firing of spinal cord neurons, presumably by prolonging the inactivated state of voltage-gated Na^+ channels in a manner similar to actions of phenytoin and carbamazepine and by preventing neurotransmitter release. In addition, zonisamide inhibits T-type Ca^{2+} currents and reduces the influx of calcium. Zonisamide can also inhibit carbonic anhydrase and scavenge free radicals; whether and how these actions may contribute to the drug's neuroprotective effects are unknown.

ADME

Zonisamide is almost completely absorbed after oral administration, has a long $t_{1/2}$ (~60 h), is about 40% bound to plasma protein, and has linear kinetics at doses ranging from 100 to 400 mg. Approximately 85% of an oral dose is excreted in the urine, principally as unmetabolized zonisamide and a glucuronide of sulfamoylacetophenol, the product of metabolism by CYP3A4. Thus, phenobarbital, phenytoin, and carbamazepine will decrease the plasma concentration/dose ratio of zonisamide, whereas lamotrigine will increase this ratio. Zonisamide has little effect on the plasma concentrations of other ASDs.

Therapeutic Use

The addition of zonisamide to other drugs is superior to placebo. There is insufficient evidence for zonisamide's efficacy as monotherapy for newly diagnosed or refractory epilepsy.

Toxicity

Overall, zonisamide is well tolerated. The most common adverse effects include somnolence, dizziness, cognitive impairment, ataxia, anorexia, nervousness, and fatigue. Potentially serious skin rashes are rare but may occur. Approximately 1% of individuals develop renal calculi during treatment, which may relate to inhibition of carbonic anhydrase by zonisamide. As a carbonic anhydrase inhibitor, zonisamide may also cause metabolic acidosis. Thus, patients with predisposing conditions (e.g., renal disease, severe respiratory disorders, diarrhea, surgery, ketogenic diet) may be at greater risk for metabolic acidosis while taking zonisamide, a risk that appears to be more frequent and severe in younger patients. Measurement of serum bicarbonate prior to initiating therapy and periodically thereafter, even in the absence of symptoms, is recommended. Last, spontaneous abortions and congenital abnormalities have been reported at twice the rate (7%) of the healthy, control population (2%–3%) in female patients of childbearing age receiving polytherapy including zonisamide.

General Principles and Choice of Drugs for Therapy of the Epilepsies

Early diagnosis and treatment of seizure disorders with a single appropriate agent offers the best prospect of achieving prolonged seizure-free periods with the lowest risk of toxicity. An attempt should be made to determine the cause of the epilepsy with the hope of discovering a correctable lesion, either structural or metabolic. The drugs commonly used for distinct seizure types are listed in Table 17–1. The cost/benefit ratio of the efficacy and the adverse effects of a given drug should be considered in determining which drug is optimal for a given patient.

The first decision to make is whether and when to initiate treatment (French and Pedley, 2008). For example, it may not be necessary to initiate therapy after an isolated tonic-clonic seizure in a healthy young adult who lacks a family history of epilepsy and who has a normal neurological exam, a normal EEG, and a normal brain MRI scan. The odds of seizure recurrence in the next year (15%) are similar to the risk of a drug reaction sufficiently severe to warrant discontinuation of

medication (Bazil and Pedley, 1998). On the other hand, a similar seizure occurring in an individual with a positive family history of epilepsy, an abnormal neurological exam, an abnormal EEG, and an abnormal MRI carries a risk of recurrence approximating 60%, odds that favor initiation of therapy.

Unless extenuating circumstances such as status epilepticus exist, only monotherapy should be initiated. Initial dosing should target a C_{pss} within the lower portion of the range associated with clinical efficacy to minimize dose-related adverse effects. Dosage is increased at appropriate intervals as required for control of seizures or as limited by toxicity, with monitoring of plasma drug concentrations. Compliance with a properly selected, single drug in maximal tolerated dosage results in complete control of seizures in about 50% of patients. If a seizure occurs despite optimal drug levels, the physician should assess the presence of potential precipitating factors such as sleep deprivation, a concurrent febrile illness, or drugs (e.g., large amounts of caffeine or over-the-counter medications that can lower the seizure threshold).

If compliance has been confirmed yet seizures persist, substitute another drug. Unless serious adverse effects of the drug dictate otherwise, always reduce dosage gradually to minimize risk of seizure recurrence. In the case of focal seizures in adults, the diversity of available drugs permits selection of a second drug that acts by a different mechanism (see Table 17-2). Among previously untreated patients, 47% became seizure free with the first drug and an additional 14% became seizure free with a second or third drug (Kwan and Brodie, 2000).

If therapy with a second single drug also is inadequate, combination therapy is warranted. This decision should not be taken lightly because most patients obtain optimal seizure control with the fewest adverse effects when taking a single drug. Nonetheless, some patients will not be controlled adequately without the simultaneous use of two or more ASDs. The chances of complete control with this approach are not high; according to Kwan and Brodie (2000), epilepsy is controlled by treatment with two drugs in only 3% of patients. It seems wise to select two drugs that act by distinct mechanisms (e.g., one that promotes Na^+ channel inactivation and another that enhances GABA-mediated synaptic inhibition). Side effects of each drug and the potential drug interactions also should be considered. As specified in Table 17-3, many of these drugs induce expression of CYPs and thereby affect the metabolism of themselves or other drugs.

Essential to optimal management of epilepsy is the filling out of a seizure chart by the patient or a relative. Frequent visits to the physician may be necessary early in the period of treatment because hematological and other possible side effects may require a change in medication. Long-term follow-up with neurological examinations and possibly EEG and neuroimaging studies is appropriate. *Most crucial for successful management is patient adherence to the drug regimen; noncompliance is the most frequent cause for failure of therapy with ASDs.*

Measurement of plasma drug concentration at appropriate intervals facilitates the initial adjustment of dosage to minimize dose-related adverse effects without sacrificing seizure control. Periodic monitoring during maintenance therapy can also detect noncompliance. Knowledge of plasma drug concentrations can be especially helpful during multidrug therapy. If toxicity occurs, monitoring helps to identify the particular drug(s) responsible and can guide adjustment of dosage.

Duration of Therapy

Once initiated, ASDs are typically continued for at least 2 years. Tapering and discontinuing therapy should be considered if the patient is seizure free after 2 years; tapering should be done slowly over several months.

Factors associated with high risk for recurrent seizures following discontinuation of therapy include EEG abnormalities, known structural lesions, abnormalities on neurological exam, and history of frequent seizures or medically refractory seizures prior to control. Conversely, factors associated with low risk for recurrent seizures include idiopathic epilepsy, normal EEG, onset in childhood, and seizures easily controlled with a single drug. The risk of recurrent seizures ranges from 12% to

66% (French and Pedley, 2008). Typically, 80% of recurrences will occur within 4 months of discontinuing therapy. The clinician and patient must weigh the risk of recurrent seizure and the associated potential deleterious consequences (e.g., loss of driving privileges) against the implications of continuing medication, including cost, unwanted effects, implications of diagnosis of epilepsy, and so on.

Focal and Focal-to-Bilateral Tonic-Clonic Seizures

The efficacy and toxicity of carbamazepine, phenobarbital, and phenytoin for treatment of focal and secondarily generalized tonic-clonic seizures in adults have been examined (Mattson et al., 1985). Carbamazepine and phenytoin were the most effective agents. The choice between carbamazepine and phenytoin required assessment of toxic effects of each drug. Decreased libido and impotence were associated with all three drugs (carbamazepine 13%, phenobarbital 16%, and phenytoin 11%). In direct comparison with valproate, carbamazepine provided superior control of complex focal seizures (Mattson et al., 1992). With respect to adverse effects, carbamazepine was more commonly associated with skin rash, but valproate was more commonly associated with tremor and weight gain. Overall, carbamazepine and phenytoin are preferable for treatment of focal seizures, but phenobarbital and valproate are also efficacious.

Control of secondarily generalized tonic-clonic seizures does not differ significantly with carbamazepine, phenobarbital, or phenytoin (Mattson et al., 1985). Valproate was as effective as carbamazepine for control of secondarily generalized tonic-clonic seizures (Mattson et al., 1992). Because secondarily generalized tonic-clonic seizures usually coexist with focal seizures, these data indicate that among drugs introduced before 1990, carbamazepine and phenytoin are the first-line drugs for these conditions.

One key issue confronting the treating physician is choosing the optimal drug for initiating treatment in new-onset epilepsy. At first glance, this issue may appear unimportant because about 50% of newly diagnosed patients become seizure free with the first drug, whether old or new drugs are used (Kwan and Brodie, 2000). However, responsive patients typically receive the initial drug for several years, underscoring the importance of proper drug selection. Phenytoin, carbamazepine, and phenobarbital induce hepatic CYPs, thereby complicating use of multiple ASDs as well as affecting metabolism of oral contraceptives, warfarin, and many other drugs. Phenytoin, carbamazepine, and phenobarbital also enhance metabolism of endogenous compounds, including gonadal steroids and vitamin D, potentially affecting reproductive function and bone density. By contrast, most of the newer drugs have little, if any effect, on the CYPs. Factors arguing against use of recently introduced drugs include higher costs and less clinical experience with the compounds.

Ideally, a prospective study would systematically compare newly introduced ASDs with drugs available before 1990 in a study design adjusting dose as needed and observing responses for extended periods of time (e.g., 2 years or more), in much the same manner as that used when comparing the older ASDs with one another as described previously (Mattson et al., 1985). Unfortunately, such a study has not been performed. Many studies have compared a new ASD with an older ASD, but study design did not permit declaring a clearly superior drug; moreover, differences in study design and patient populations preclude comparing a new drug with multiple older drugs or with other new drugs.

The use of recently introduced ASDs for newly diagnosed epilepsy was analyzed by subcommittees of the American Academy of Neurology and the American Epilepsy Society (French et al., 2004a, 2004b); the authors concluded that available evidence supported the use of gabapentin, lamotrigine, and topiramate for newly diagnosed focal or mixed seizure disorders. None of these drugs, however, has been approved by the FDA for either of these indications. Insufficient evidence is available on the remaining newly introduced drugs to permit meaningful assessment of their effectiveness for this indication.

Generalized Absence Seizures

Ethosuximide and valproate are considered equally effective in the treatment of generalized absence seizures (Mikati and Browne, 1988). Between 50% and 75% of newly diagnosed patients are free of seizures following therapy with either drug. If tonic-clonic seizures are present or emerge during therapy, valproate is the agent of first choice. Available evidence also indicates that lamotrigine is effective for newly diagnosed absence epilepsy, but lamotrigine is not approved for this indication by the FDA (Ben-Menachem, 2011).

Myoclonic Seizures

Valproate is the drug of choice for myoclonic seizures in the syndrome of JME, in which myoclonic seizures often coexist with tonic-clonic and absence seizures. Levetiracetam also has demonstrated efficacy as adjunctive therapy for refractory generalized myoclonic seizures.

Febrile Convulsions

Between 2% and 4% of children experience a convulsion associated with a febrile illness; 25%–33% of these children will have another febrile convulsion. Only 2%–3% become epileptic in later years, a 6-fold increase in risk compared with the general population. Several factors are associated with an increased risk of developing epilepsy: preexisting neurological disorder or developmental delay, a family history of epilepsy, or a complicated febrile seizure (i.e., the febrile seizure lasted > 15 min, was one sided, or was followed by a second seizure in the same day). If all of these risk factors are present, the risk of developing epilepsy is about 10%.

The increased risk of developing epilepsy or other neurological sequelae led many physicians to prescribe ASDs prophylactically after a febrile seizure. Uncertainties regarding the efficacy of prophylaxis for reducing epilepsy combined with substantial side effects of phenobarbital prophylaxis (Farwell et al., 1990) argue against the use of chronic therapy for prophylactic purposes (Freeman, 1992). For children at high risk of developing recurrent febrile seizures and epilepsy, rectally administered diazepam at the time of fever may prevent recurrent seizures and avoid side effects of chronic therapy.

Seizures in Infants and Young Children

Infantile spasms with *hypsarrhythmia* (abnormal interictal high-amplitude slow waves and multifocal asynchronous spikes on EEG) are refractory to the usual ASD. Corticotropin or glucocorticoids are commonly used; repository corticotropin is designated as an orphan drug for this purpose. Vigabatrin (γ -vinyl GABA) is efficacious in comparison to placebo (Appleton et al., 1999); however, constriction of visual fields has been reported in a high percentage of patients treated with vigabatrin (Miller et al., 1999). To emphasize the potential for progressive and permanent vision loss, the FDA has instituted a black-box warning for vigabatrin, which is marketed under a restrictive distribution program. Vigabatrin has orphan drug status for the treatment of infantile spasms in the U.S. and is FDA-approved as adjunctive therapy for adults with refractory focal seizures with impaired awareness. Ganaxolone also has been designated as an orphan drug for the treatment of infantile spasms and completed a phase II clinical trial for uncontrolled focal-onset seizures in adults in 2009.

The Lennox-Gastaut syndrome is a severe form of epilepsy that usually begins in childhood and is characterized by cognitive impairments and multiple types of seizures, including tonic-clonic, tonic, atonic, myoclonic, and atypical absence seizures. Addition of lamotrigine to other ASDs improves seizure control in comparison to placebo in this treatment-resistant form of epilepsy (Motte et al., 1997). Felbamate also is effective for seizures in this syndrome, but the occasional occurrence of aplastic anemia and hepatic failure have limited its use (French et al., 1999). Topiramate is effective for Lennox-Gastaut syndrome (Sachdeo et al., 1999), and clobazam is approved for the adjunctive treatment in Lennox-Gastaut.

Status Epilepticus and Other Convulsive Emergencies

Status epilepticus is a neurological emergency. Mortality for adults approximates 20% (Lowenstein and Alldredge, 1998). The goal of treatment is rapid termination of behavioral and electrical seizure activity; the longer the episode of status epilepticus goes untreated, the more difficult it is to control and the greater the risk of permanent brain damage. Critical to the management are a clear plan, prompt treatment with effective drugs in adequate doses, and attention to hypoventilation and hypotension. Because hypoventilation may result from high doses of drugs used for treatment, it may be necessary to assist respiration temporarily.

To assess the optimal initial drug regimen, four intravenous treatments have been compared: diazepam followed by phenytoin; lorazepam; phenobarbital; and phenytoin alone (Treiman et al., 1998). The treatments had similar efficacies, with success rates ranging from 44% to 65%. Lorazepam alone was significantly better than phenytoin alone. No significant differences were found with respect to recurrences or adverse reactions. The more recent RAMPART trial indicated that midazolam (intramuscular) is as effective as intravenous lorazepam and was not associated with respiratory distress or seizure recurrence. Thus, emergency treatment with midazolam (intramuscular) may prove to be the preferred treatment prior to arrival to the hospital.

Antiseizure Therapy and Pregnancy

Use of ASDs has diverse implications of great importance for the health of women. Issues include interactions with oral contraceptives, potential teratogenic effects, and effects on vitamin K metabolism in pregnant women (Pack, 2006). Guidelines for the care of women with epilepsy have been published by the American Academy of Neurology (Morrell, 1998).

The effectiveness of oral contraceptives appears to be reduced by concomitant use of ASDs. The failure rate of oral contraceptives is 3.1/100 years in women receiving ASDs compared to a rate of 0.7/100 years in nonepileptic controls. One attractive explanation of the increased failure rate is the increased rate of oral contraceptive metabolism caused by ASDs that induce hepatic enzymes (Table 17-2); particular caution is needed with ASDs that induce CYP3A4.

Teratogenicity

Epidemiological evidence suggests that ASDs have teratogenic effects (Pack, 2006). These teratogenic effects add to the deleterious consequences of oral contraceptive failure. Infants of epileptic mothers are at 2-fold greater risk of major congenital malformations than offspring of nonepileptic mothers (4%–8% compared to 2%–4%). These malformations include congenital heart defects, neural tube defects, cleft lip, cleft palate, and others. Inferring causality from the associations found in large epidemiological studies with many uncontrolled variables can be hazardous, but a causal role for ASDs is suggested by association of congenital defects with higher concentrations of a drug or with polytherapy compared to monotherapy. Phenytoin, carbamazepine, valproate, lamotrigine, and phenobarbital all have been associated with teratogenic effects. Newer ASDs have teratogenic effects in animals, but whether such effects occur in humans is yet uncertain.

One consideration for a woman with epilepsy who wishes to become pregnant is a trial free of ASDs; monotherapy with careful attention to drug levels is another alternative. Polytherapy with toxic levels should be avoided. Folate supplementation (0.4 mg/d) has been recommended by the U.S. Public Health Service for all women of childbearing age to reduce the likelihood of neural tube defects, and this is appropriate for epileptic women as well.

The ASDs that induce CYPs have been associated with vitamin K deficiency in the newborn, which can result in a coagulopathy and intracerebral hemorrhage. Treatment with vitamin K₁, 10 mg/d during the last month of gestation, has been recommended for prophylaxis.

Drug Facts for Your Personal Formulary: Antiseizure Agents

Drugs	Therapeutic Uses (Seizure Types)	Clinical Pharmacology and Tips
Sodium Channel Modulators • Enhance fast inactivation		
Phenytoin	<i>Focal</i> <ul style="list-style-type: none"> Aware With impaired awareness <i>Generalized</i> <ul style="list-style-type: none"> Tonic-clonic 	<ul style="list-style-type: none"> Once-daily dosing only available with extended-release formulation Intravenous use with fosphenytoin Nonlinear pharmacokinetics May interfere with drugs metabolized by CYP2C9/19 Induces CYPs (e.g., CYP3A4) <i>Side effects:</i> gingival hyperplasia, facial coarsening; hypersensitivity (rare)
Carbamazepine	<i>Focal</i> <ul style="list-style-type: none"> Aware With impaired awareness <i>Generalized</i> <ul style="list-style-type: none"> Focal to bilateral tonic-clonic Tonic-clonic 	<ul style="list-style-type: none"> Induces CYP enzymes (e.g., CYP2C, CYP3A) and UGT Active metabolite (10,11-epoxide) <i>Side effects:</i> drowsiness, vertigo, ataxia, blurred vision, increased seizure frequency
Eslicarbazepine	<i>Focal</i> <ul style="list-style-type: none"> Aware With impaired awareness

Introduction to Neurodegenerative Disorders

Neurodegenerative disorders are characterized by progressive and irreversible loss of neurons from specific regions of the brain. Prototypical neurodegenerative disorders include PD and HD, where loss of neurons from structures of the basal ganglia results in abnormalities in the control of movement; AD, where the loss of hippocampal and cortical neurons leads to impairment of memory and cognitive ability; and ALS, where muscular weakness results from the degeneration of spinal, bulbar, and cortical motor neurons. Currently available therapies for neurodegenerative disorders alleviate the disease symptoms but do not alter the underlying neurodegenerative process.

Common Features of Neurodegenerative Disorders

Proteinopathies

Each of the major neurodegenerative disorders is characterized by accumulation of particular proteins in cellular aggregates: α -synuclein in PD; A β and the microtubule-associated protein tau in AD; TDP-43 in most cases of ALS; and huntingtin in HD (Prusiner, 2013). The reason for accumulation of these proteins is unknown, and it is also unclear in most cases whether it is the large cellular aggregates or smaller soluble species of the proteins that most strongly drive pathogenesis.

Selective Vulnerability

A striking feature of neurodegenerative disorders is the exquisite specificity of the disease processes for particular types of neurons. For example, in PD there is extensive destruction of the dopaminergic neurons of the substantia nigra, whereas neurons in the cortex and many other areas of the brain are unaffected. In contrast, neural injury in AD is most severe in the hippocampus and neocortex, and even within the cortex, the loss of neurons is not uniform but varies dramatically in different brain networks. In HD, the mutant gene responsible for the disorder is expressed throughout the brain and in many other organs, yet the pathological changes are most prominent in the neostriatum. In ALS, there is loss of spinal motor

neurons and the cortical neurons that provide their descending input. The diversity of these patterns of neural degeneration suggests that the process of neural injury results from the interaction of intrinsic properties of different neural circuits, genetics, and environmental influences. The intrinsic factors may include susceptibility to excitotoxic injury, regional variation in capacity for oxidative metabolism, and the production of toxic free radicals as by-products of cellular metabolism.

Genetics and Environment

Each of the major neurodegenerative disorders may be familial in nature. HD is exclusively familial; it is transmitted by autosomal dominant inheritance of an expanded repeat in the huntingtin gene. Nevertheless, environmental factors importantly influence the age of onset and rate of progression of HD symptoms. PD, AD, and ALS are usually sporadic, but for each there are well-recognized genetic forms. For example, there are both dominant (α -synuclein, LRRK2) and recessive (parkin, DJ-1, PINK1) gene mutations that may give rise to PD (Kumar et al., 2012; Singleton et al., 2013). In AD, mutations in the genes coding for APP and the presenilins (involved in APP processing) lead to inherited forms of the disease. About 10% of ALS cases are familial, most commonly due to mutations in the C9ORF72 gene (Renton et al., 2014).

There are also genetic risk factors that influence the probability of disease onset and modify the phenotype. For example, the apoE genotype constitutes an important risk factor for AD. Three distinct isoforms of this protein exist, and individuals with even one copy of the high-risk allele, ϵ 4, having several-fold higher risk of developing AD than those with the most common allele, ϵ 3.

Environmental factors, including infectious agents, environmental toxins, and acquired brain injury, have been proposed in the etiology of neurodegenerative disorders. Traumatic brain injury has been suggested as a trigger for neurodegenerative disorders. At least one toxin, MPTP, can induce a condition closely resembling PD. More recently, evidence has linked pesticide exposure with PD. Exposure of soldiers to neurotoxic chemicals has been implicated in ALS (as part of "Gulf War syndrome").

Approaches to Therapy

Certain themes are apparent in the pharmacological approaches described in this chapter. Many of the existing therapies are *neurochemical*, aiming

AADC: aromatic L-amino acid decarboxylase
A β : amyloid β
ACh: acetylcholine
AChE: acetylcholinesterase
AD: Alzheimer disease
ALDH: aldehyde dehydrogenase
ALS: amyotrophic lateral sclerosis
apoE: apolipoprotein E
APP: amyloid precursor protein
BuChE: butyrylcholinesterase
CNS: central nervous system
COMT: catechol-O-methyltransferase
DA: dopamine
DAT: DA transporter
D β H: dopamine- β -hydroxylase
DOPAC: 3,4-dihydroxyphenylacetic acid
GABA: γ -aminobutyric acid
Glu: glutamatergic
GPe: globus pallidus extern
GPI: globus pallidus interna
HD: Huntington disease
5HT: serotonin
HVA: homovanillic acid
MAO: monamine oxidase
MCI: mild cognitive impairment
MPTP: N-methyl-4-phenyl-1,2,3,6-tetrahydropyridine
3MT: 3-methoxytyramine
NE: norepinephrine
NET: NE transporter
NMDA: N-methyl-D-aspartate
3-OMD: 3-O-methyl dopa
PD: Parkinson disease
PDD: Parkinson disease dementia
PET: positron emission tomography
PH: phenylalanine hydroxylase
REM: rapid eye movement
SNpc: substantia nigra pars compacta
SNpr: substantia nigra pars reticulata
SOD: superoxide dismutase
SSRI: selective serotonin reuptake inhibitor
STN: subthalamic nucleus
TAR: transactivation response element
TDP-43: TAR DNA-binding protein 43
TH: tyrosine hydrolase
VA/VL: ventroanterior and ventrolateral
VMAT2: vesicular monoamine transporter 2

to replace or compensate for damage to specific neurotransmitter systems that are selectively impaired. For example, dopaminergic therapy is a mainstay of PD therapy, and the primary agents used in AD aim to boost acetylcholinergic transmission. The goal of much current research is to identify therapies that are *neuroprotective* and can modify the underlying neurodegenerative process.

One target of neuroprotective therapies is *excitotoxicity*, *neural injury* that results from the presence of excess glutamate in the brain. *Glutamate* is used as a neurotransmitter to mediate most excitatory synaptic transmission in the mammalian brain. The presence of excessive amounts of glutamate can lead to excitotoxic cell death (see Figure 14–13). The destructive effects of glutamate are mediated by glutamate receptors, particularly those of the NMDA type (see Table 14–2). Excitotoxic injury

contributes to the neuronal death that occurs in acute processes such as stroke and head trauma. The role of excitotoxicity is less certain in the chronic neurodegenerative disorders; nevertheless, *glutamate antagonists* have been developed as neuroprotective therapies for neurodegeneration, with two such agents (*memantine* and *riluzole*, described later in the chapter) currently in clinical use.

Aging is the most important risk factor for all of the neurodegenerative diseases, and a likely contributor to the effect of age is the progressive impairment in the capacity of neurons for oxidative metabolism with consequent production of reactive compounds such as hydrogen peroxide and oxygen radicals. These reactive species can lead to DNA damage, peroxidation of membrane lipids, and neuronal death. This has led to pursuit of drugs that can enhance cellular metabolism (such as the mitochondrial cofactor coenzyme Q₁₀) and antioxidant strategies as treatments to prevent or retard degenerative diseases.

The discovery of specific proteins that accumulate and aggregate in each of the neurodegenerative disorders has opened the door to new therapeutic approaches. To date, there are no approved therapies that directly target the disease proteins (e.g., α -synuclein, A β , tau, TDP-43). However, there is intensive research to bring disease-modifying treatments that do directly target these proteins, such as passive immunotherapy with antibodies, into clinical care.

Parkinson Disease

Clinical Overview

Parkinsonism is a clinical syndrome with four cardinal features:

- Bradykinesia (slowness and poverty of movement)
- Muscular rigidity
- Resting tremor (which usually abates during voluntary movement)
- Impairment of postural balance, leading to disturbances of gait and to falling

The most common form of parkinsonism is idiopathic PD, first described by James Parkinson in 1817 as *paralysis agitans*, or the “shaking palsy.” *The pathological hallmark of PD is the loss of the pigmented, dopaminergic neurons of the substantia nigra pars compacta, with the appearance of intracellular inclusions known as Lewy bodies.* The principal component of the Lewy bodies is aggregated α -synuclein (Goedert et al., 2013). A loss of 70%–80% of the DA-containing neurons accompanies symptomatic PD.

Without treatment, PD progresses over 5–10 years to a rigid, akinetic state in which patients are incapable of caring for themselves (Suchowersky et al., 2006). Death frequently results from complications of immobility, including aspiration pneumonia or pulmonary embolism. The availability of effective pharmacological treatment has radically altered the prognosis of PD; in most cases, good functional mobility can be maintained for many years. Life expectancy of adequately treated patients is increased substantially, but overall mortality remains higher than that of the general population.

While DA neuron loss is the most well-recognized feature of the disease, the disorder affects a wide range of other brain structures, including the brainstem, hippocampus, and cerebral cortex (Langston, 2006). There is increasing awareness of the “nonmotor” features of PD, which likely arise from pathology outside the DA system (Zesiewicz et al., 2010). Some nonmotor features may present before the characteristic motor symptoms: anosmia, or loss of the sense of smell; REM behavior disorder, a disorder of sleep with marked agitation and motion during periods of REM sleep; and disturbances of autonomic nervous system function, particularly constipation. Other nonmotor features are seen later in the disease and include depression, anxiety, and dementia.

Several disorders other than idiopathic PD also may produce parkinsonism, including some relatively rare neurodegenerative disorders, stroke, and intoxication with DA receptor antagonists. Drugs that may cause parkinsonism include antipsychotics such as haloperidol and chlorpromazine (see Chapter 16) and antiemetics such as prochlorperazine and

metoclopramide (see Chapter 50). The distinction between idiopathic PD and other causes of parkinsonism is important because parkinsonism arising from other causes usually is refractory to all forms of treatment.

Pathophysiology

The dopaminergic deficit in PD arises from a loss of the neurons in the substantia nigra pars compacta that provide innervation to the striatum (caudate and putamen). The current understanding of the pathophysiology of PD is based on the finding that the striatal DA content is reduced in excess of 80%, with a parallel loss of neurons from the substantia nigra, suggesting that replacement of DA could restore function. We now have a model of the function of the basal ganglia that, while incomplete, is still useful.

Dopamine Synthesis, Metabolism, and Receptors

Dopamine, a catecholamine, is synthesized in the terminals of dopaminergic neurons from tyrosine and stored, released, reaccumulated, and metabolized by processes described in Chapter 13 and summarized in Figure 18–1. The actions of DA in the brain are mediated by the DA receptor, of which there are two broad classes, D1 and D2, with five distinct subtypes, D₁–D₅. All the DA receptors are GPCRs. Receptors of the **D1 group** (D₁ and D₅ subtypes) couple to G_s and thence to activation of the cyclic AMP pathway. The **D2 group** (D₂, D₃, and D₄ receptors) couple to

G_i to reduce the adenylyl cyclase activity and voltage-gated Ca²⁺ currents while activating K⁺ currents. Each of the five DA receptors has a distinct anatomical pattern of expression in the brain. D₁ and D₂ proteins are abundant in the striatum and are the most important receptor sites with regard to the causes and treatment of PD. The D₄ and D₅ proteins are largely extrastriatal, whereas D₃ expression is low in the caudate and putamen but more abundant in the nucleus accumbens and olfactory tubercle.

Neural Mechanism of Parkinsonism: A Model of Basal Ganglia Function

Considerable effort has been devoted to understanding how the loss of dopaminergic input to the neurons of the neostriatum gives rise to the clinical features of PD (Hornykiewicz, 1973). The basal ganglia can be viewed as a modulatory side loop that regulates the flow of information from the cerebral cortex to the motor neurons of the spinal cord (Albin et al., 1989) (Figure 18–2).

The neostriatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of the cortex. Most neurons within the striatum are projection neurons that innervate other basal ganglia structures. A small but important subgroup of striatal neurons consists of interneurons that connect neurons within the striatum but do not project beyond its borders. ACh and neuropeptides are used as transmitters by these striatal interneurons.

Figure 18–1 Dopaminergic nerve terminal. Dopamine is synthesized from tyrosine in the nerve terminal by the sequential actions of TH and AADC. DA is sequestered by VMAT2 in storage granules and released by exocytosis. Synaptic DA activates presynaptic autoreceptors and postsynaptic D1 and D2 receptors. Synaptic DA may be taken up into the neuron via the DA and NE transporters (DAT, NET) or removed by postsynaptic uptake via the organic cation transporter, OCT3 (see Chapter 5). Cytosolic DA is subject to degradation by MAO and ALDH in the neuron and by COMT and MAO/ALDH in nonneuronal cells; the final metabolic product is HVA. See structures in Figure 18–4.

Figure 18-2 Schematic wiring diagram of the basal ganglia. The striatum is the principal input structure of the basal ganglia and receives excitatory glutamatergic input from many areas of cerebral cortex. The striatum contains projection neurons expressing predominantly D_1 or D_2 DA receptors, as well as interneurons that use ACh as a neurotransmitter. Outflow from the striatum proceeds along two routes. The direct pathway, from the striatum to the SNpr and GPi, uses the inhibitory transmitter GABA. The indirect pathway, from the striatum through the GPe and the STN to the SNpr and GPi, consists of two inhibitory GABA-ergic links and one excitatory Glu projection. The SNpc provides dopaminergic innervation to the striatal neurons, giving rise to both the direct and the indirect pathways, and it regulates the relative activity of these two paths. The SNpr and GPi are the output structures of the basal ganglia and provide feedback to the cerebral cortex through the VA/VL nuclei of the thalamus.

The outflow of the striatum proceeds along two distinct routes, termed the *direct* and *indirect pathways* (Calabresi et al., 2014). The direct pathway is formed by neurons in the striatum that project directly to the output stages of the basal ganglia, the SNpr and the GPi; these, in turn, relay to the VA and VL thalamus, which provides excitatory input to the cortex. The neurotransmitter in both links of the direct pathway is GABA, which is inhibitory, so that *the net effect of stimulation of the direct pathway at the level of the striatum is to increase the excitatory outflow from the thalamus to the cortex.*

The indirect pathway is composed of striatal neurons that project to the GPe. This structure, in turn, innervates the STN, which provides outflow to the SNpr and GPi output stage. The first two links—the projections from striatum to GPe and GPe to STN—use the inhibitory transmitter GABA; however, the final link—the projection from STN to SNpr and GPi—is an excitatory glutamatergic pathway. Thus, *the net effect of stimulating the indirect pathway at the level of the striatum is to reduce the excitatory outflow from the thalamus to the cerebral cortex.* The key feature of this model of basal ganglia function, which accounts for the symptoms observed in PD as a result of loss of dopaminergic neurons, is the differential effect of DA on the direct and indirect pathways (Figure 18-3).

The dopaminergic neurons of the SNpc innervate all parts of the striatum; however, the target striatal neurons express distinct types of DA receptors. The striatal neurons giving rise to the direct pathway express primarily the *excitatory* D_1 DA receptor protein, whereas the striatal neurons forming the indirect pathway express primarily the *inhibitory* D_2 type. Thus, *DA released in the striatum tends to increase the activity of the direct pathway and reduce the activity of the indirect pathway, whereas the depletion that occurs in PD has the opposite effect. The net effect of the reduced dopaminergic input in PD is to increase markedly the inhibitory outflow from the SNpr and GPi to the thalamus and reduce excitation of the motor cortex.* There are several limitations of this model of basal ganglia function. The anatomical connections are considerably more complex, and many of the pathways involved use several neurotransmitters. Limitations notwithstanding, the model is useful and has important implications for the rational design and use of pharmacological agents in PD.

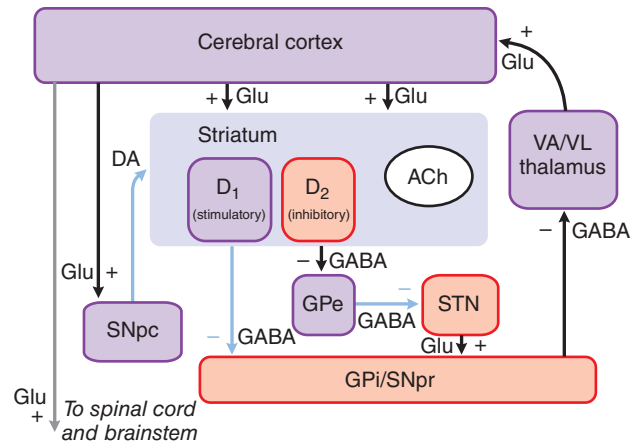

Figure 18-3 The basal ganglia in PD. The primary defect is destruction of the dopaminergic neurons of the SNpc. The striatal neurons that form the direct pathway from the striatum to the SNpr and GPi express primarily the *excitatory* D_1 DA receptor, whereas the striatal neurons that project to the GPe and form the indirect pathway express the *inhibitory* D_2 DA receptor. Thus, loss of the dopaminergic input to the striatum has a differential effect on the two outflow pathways; the direct pathway to the SNpr and GPi is less active (structures in purple), whereas the activity in the indirect pathway is increased (structures in red). The net effect is that neurons in the SNpr and GPi become more active. This leads to increased inhibition of the VA/VL thalamus and reduced excitatory input to the cortex. Light blue lines indicate primary pathways with reduced activity. (See Abbreviations list for definitions of anatomical abbreviations.)

Treatment of Parkinson Disease

Levodopa

Levodopa (also called L-DOPA or L-3,4-dihydroxyphenylalanine), the metabolic precursor of DA, is the single most effective agent in the treatment of PD (Cotzias et al., 1969; Fahn et al., 2004). The effects of levodopa result from its decarboxylation to DA. When administered orally, levodopa is absorbed rapidly from the small bowel by the transport system for aromatic amino acids. Concentrations of the drug in plasma usually peak between 0.5 and 2 h after an oral dose. The $t_{1/2}$ in plasma is short (1–3 h). The rate and extent of absorption of levodopa depend on the rate of gastric emptying, the pH of gastric juice, and the length of time the drug is exposed to the degradative enzymes of the gastric and intestinal mucosa. Administration of levodopa with high-protein meals delays absorption and reduces peak plasma concentrations. Entry of the drug into the CNS across the blood-brain barrier is mediated by a membrane transporter for aromatic amino acids. In the brain, levodopa is converted to DA by decarboxylation primarily within the presynaptic terminals of dopaminergic neurons in the striatum. The DA produced is responsible for the therapeutic effectiveness of the drug in PD; after release, it is either transported back into dopaminergic terminals by the presynaptic uptake mechanism or metabolized by the actions of MAO and COMT (Figure 18-4).

In clinical practice, levodopa is almost always administered in combination with a peripherally acting inhibitor of AADC, such as *carbidopa* (used in the U.S.) or *benserazide* (available outside the U.S.), drugs that do not penetrate well into the CNS. If levodopa is administered alone, the drug is largely decarboxylated by enzymes in the intestinal mucosa and other peripheral sites so that relatively little unchanged drug reaches the cerebral circulation, and probably less than 1% penetrates the CNS. In addition, DA release into the circulation by peripheral conversion of levodopa produces undesirable effects, particularly nausea. Inhibition of peripheral decarboxylase markedly increases the fraction of administered levodopa that remains unmetabolized and available to cross the blood-brain barrier (Figure 18-5), and reduces the incidence of GI side effects and drug-induced orthostatic hypotension.

Figure 18-4 Metabolism of levodopa (L-DOPA).

A daily dose of 75 mg carbidopa is generally sufficient to prevent the development of nausea. For this reason, the most commonly prescribed form of carbidopa/levodopa is the 25/100 form, containing 25 mg carbidopa and 100 mg levodopa. With this formulation, dosage schedules of three or more tablets daily provide acceptable inhibition of decarboxylase in most individuals.

Levodopa therapy can have a dramatic effect on all the signs and symptoms of PD. Early in the course of the disease, the degree of improvement in tremor, rigidity, and bradykinesia produced by carbidopa/levodopa may be nearly complete. With long-term levodopa therapy, the “buffering” capacity is lost, and the patient’s motor state may fluctuate dramatically with each dose of levodopa, producing the *motor complications* of levodopa (Pahwa et al., 2006).

A common problem is the development of the “wearing off” phenomenon: Each dose of levodopa effectively improves mobility for a period of time, perhaps 1–2 h, but rigidity and akinesia return rapidly at the end of the dosing interval. Increasing the dose and frequency of administration can improve this situation, but this often is limited by the development of dyskinesias, excessive and abnormal involuntary movements. In the later stages of PD, patients may fluctuate rapidly between being “off,” having no beneficial effects from their medications, and being “on” but with disabling

dyskinesias (the *on/off phenomenon*). A sustained-release formulation consisting of carbidopa/levodopa in an erodible wax matrix is helpful in some cases, but absorption of this older sustained-release formulation is not entirely predictable.

Recently, two new formulations of levodopa intended to address wearing off have been approved. RYTARY carbidopa-levodopa extended-release capsules contain both immediate- and extended-release beads that provide reduced off time in patients with motor fluctuations (Hauser et al., 2013). DUOPA carbidopa-levodopa intestinal gel is administered through a gastrostomy tube into the jejunum using a pump and can have a dramatic effect on reducing “off” time (Olanow et al., 2014).

Does levodopa alter the course of the underlying disease or merely modify the symptoms? While the answer to this question is not entirely certain, a randomized trial has provided evidence that levodopa does not have an adverse effect on the course of the underlying disease, but has also confirmed that high doses of levodopa are associated with early onset of dyskinesias. Most practitioners have adopted a pragmatic approach, using levodopa only when the symptoms of PD cause functional impairment and other treatments are inadequate or not well tolerated.

A frequent and troubling adverse effect is the induction of hallucinations and confusion, especially in elderly patients or in patients with preexisting cognitive dysfunction. Conventional antipsychotic agents, such as the phenothiazines, are effective against levodopa-induced psychosis but may cause marked worsening of parkinsonism, probably through actions at the D_2 DA receptor, and should not be used in PD. An alternative approach has been to use “atypical” antipsychotic agents (see Chapter 16). The two drugs that are most effective and best tolerated in patients with advanced PD are clozapine and quetiapine. Both of these drugs, and others in the class, are associated with an increased rate of death due to stroke and other causes when used in the elderly. This risk needs to be weighed carefully against the risks created by hallucinations and psychosis.

Levodopa (and the DA agonists, described in the next section) may also lead to the development of “impulse control disorders” (Weintraub et al., 2015). These include compulsive behaviors, gambling, and hypersexuality and can be destructive socially. PD also appears to be associated with an increased risk of suicidality, but whether this is associated with the disease or a specific treatment is uncertain. Vigilance for signs of depression and suicidality should be practiced in all patients with PD.

Administration of levodopa with nonspecific inhibitors of MAO accentuates the actions of levodopa and may precipitate life-threatening hypertensive crisis and hyperpyrexia; nonspecific MAO inhibitors always should be discontinued at least 14 days before levodopa is administered (note that this prohibition does not include the MAO-B subtype-specific inhibitors selegiline and rasagiline). Abrupt withdrawal of levodopa or other dopaminergic medications may precipitate the *neuroleptic malignant syndrome* of confusion, rigidity, and hyperthermia, a potentially lethal adverse effect.

Figure 18-5 Pharmacological preservation of levodopa (L-dopa) and striatal DA. The principal site of action of inhibitors of COMT (e.g., tolcapone and entacapone) is in the peripheral circulation. They block the O-methylation of L-dopa and increase the fraction of the drug available for delivery to the brain. Tolcapone also has effects in the CNS. Inhibitors of MAO-B, such as low-dose selegiline and rasagiline, will act within the CNS to reduce oxidative deamination of DA, thereby enhancing vesicular stores.

Dopamine Receptor Agonists

The DA receptor agonists in clinical use have durations of action substantially longer than that of levodopa; they are often used in the management of dose-related fluctuations in motor state and may be helpful in preventing motor complications (Parkinson Study Group, 2000). DA receptor agonists are proposed to have the potential to modify the course of PD by reducing endogenous release of DA as well as the need for exogenous levodopa, thereby reducing free-radical formation.

Two orally administered DA receptor agonists are commonly used for treatment of PD: *ropinirole* and *pramipexole*. Both are well absorbed orally and have similar therapeutic actions. There is also a transdermal formulation of the DA agonist *rotigotine* available. Ropinirole and pramipexole have selective activity at D_2 class sites (specifically at the D_2 and D_3 receptor). Rotigotine acts at D_2 sites and also has activity at D_1 class sites. Like levodopa, these DA agonists can relieve the clinical symptoms of PD. The duration of action of the DA agonists (8–24 h) often is longer than that of levodopa (6–8 h), and they are particularly effective in the treatment of patients who have developed on/off phenomena. Both ropinirole and

pramipexole are also available in once-daily sustained-release formulations, which are more convenient and may reduce adverse effects related to intermittent dosing. The transdermal delivery of rotigotine produces stable plasma drug levels over 24 h.

Pramipexole, ropinirole, and rotigotine may produce hallucinosis or confusion, similar to that observed with levodopa, and may cause nausea and orthostatic hypotension. They should be initiated at low dose and titrated slowly to minimize these effects. The DA agonists, as well as levodopa itself, are also associated with fatigue and somnolence. Patients should be warned about the potential for sleepiness, especially while driving. Many practitioners prefer a DA agonist as initial therapy in younger patients to reduce the occurrence of motor complications. In older patients or those with substantial comorbidity, levodopa/carbidopa is generally better tolerated.

Apomorphine. Apomorphine is a dopaminergic agonist that can be administered by subcutaneous injection. It has high affinity for D_1 receptors; moderate affinity for D_2 , D_3 , D_5 , and adrenergic α_{1D} , α_{2B} , and α_{2C} receptors; and low affinity for D_1 receptors. Apomorphine is FDA-approved as a “rescue therapy” for the acute intermittent treatment of “off” episodes in patients with a fluctuating response to dopaminergic therapy.

Apomorphine has the same side effects as the oral DA agonists. Apomorphine is highly emetogenic and requires pre- and posttreatment antiemetic therapy. Oral trimethobenzamide, at a dose of 300 mg, three times daily, should be started 3 days prior to the initial dose of apomorphine and continued at least during the first 2 months of therapy. Profound hypotension and loss of consciousness have occurred when apomorphine was administered with ondansetron; hence, the concomitant use of apomorphine with antiemetic drugs of the 5HT₃ antagonist class is contraindicated. Other potentially serious side effects of apomorphine include QT prolongation, injection site reactions, and the development of a pattern of abuse characterized by increasingly frequent dosing leading to hallucinations, dyskinesia, and abnormal behavior.

Because of these potential adverse effects, use of apomorphine is appropriate only when other measures, such as oral DA agonists or COMT inhibitors, have failed to control the off episodes. Apomorphine therapy should be initiated with a 2-mg test dose in a setting where the patient can be monitored carefully. If tolerated, it can be titrated slowly up to a maximum dosage of 6 mg. For effective control of symptoms, patients may require three or more injections daily.

Catechol-O-Methyltransferase Inhibitors

Orally administered levodopa is largely converted by AADC to DA (see Figure 18–5), which causes nausea and hypotension. Addition of an AADC inhibitor such as carbidopa reduces the formation of DA but increases the fraction of levodopa that is methylated by COMT. COMT inhibitors block this peripheral conversion of levodopa to 3-O-methyl DOPA, increasing both the plasma $t_{1/2}$ of levodopa and the fraction of each dose that reaches the CNS.

The COMT inhibitors *tolcapone* and *entacapone* reduce significantly the “wearing off” symptoms in patients treated with levodopa/carbidopa (Parkinson Study Group, 1997). The two drugs differ in their pharmacokinetic properties and adverse effects: Tolcapone has a relatively long duration of action and appears to act by inhibition of both central and peripheral COMT. Entacapone has a short duration of action (2 h) and principally inhibits peripheral COMT. Common adverse effects of both agents include nausea, orthostatic hypotension, vivid dreams, confusion, and hallucinations. An important adverse effect associated with tolcapone is hepatotoxicity. At least three fatal cases of fulminant hepatic failure in patients taking tolcapone have been observed, leading to addition of a black-box warning to the label. Tolcapone should be used only in patients who have not responded to other therapies and with appropriate monitoring for hepatic injury.

Entacapone has not been associated with hepatotoxicity. Entacapone is also available in fixed-dose combinations with levodopa/carbidopa.

Selective MAO-B Inhibitors

Two isoenzymes of MAO oxidize catecholamines: MAO-A and MAO-B. MAO-B is the predominant form in the striatum and is responsible for

most of the oxidative metabolism of DA in the brain. Selective MAO-B inhibitors are used for the treatment of PD: *selegiline* and *rasagiline*. These agents selectively and irreversibly inactivate MAO-B. Both agents exert modest beneficial effects on the symptoms of PD. The basis of this efficacy is, presumably, inhibition of breakdown of DA in the striatum.

Selective MAO-B inhibitors do not substantially inhibit the peripheral metabolism of catecholamines and can be taken safely with levodopa. These agents also do not exhibit the “cheese effect,” the potentially lethal potentiation of catecholamine action observed when patients on nonspecific MAO inhibitors ingest indirectly acting sympathomimetic amines such as the tyramine found in certain cheeses and wine.

Selegiline is generally well tolerated in younger patients for symptomatic treatment of early or mild PD. In patients with more advanced PD or underlying cognitive impairment, selegiline may accentuate the adverse motor and cognitive effects of levodopa therapy. Metabolites of selegiline include amphetamine and methamphetamine, which may cause anxiety, insomnia, and other adverse symptoms. Selegiline is available in an orally disintegrating tablet as well as a transdermal patch. Both of these delivery routes are intended to reduce hepatic first-pass metabolism and limit the formation of the amphetamine metabolites.

Unlike selegiline, rasagiline does not give rise to undesirable amphetamine metabolites. Rasagiline monotherapy is effective in early PD. Adjunctive therapy with rasagiline significantly reduces levodopa-related wearing off symptoms in advanced PD (Olanow et al., 2008). Although selective MAO-B inhibitors are generally well tolerated, drug interactions can be troublesome. Similar to the nonspecific MAO inhibitors, selegiline can lead to the development of stupor, rigidity, agitation, and hyperthermia when administered with the analgesic meperidine. Although the mechanics of this interaction are uncertain, selegiline or rasagiline should not be given in combination with meperidine. Tramadol, methadone, propoxyphene dextromethorphan, St. John's wort, and cyclobenzaprine are also contraindicated with MAO-B inhibitors. Although development of the *serotonin syndrome* has been reported with coadministration of MAO-B inhibitors and antidepressants (tricyclic or serotonin reuptake inhibitors), this appears to be rare, and many patients are treated with this combination without difficulty. If concurrent treatment with MAO-B inhibitors and antidepressants is undertaken, close monitoring and use of low doses of the antidepressant are advisable (Panisset et al., 2014).

Muscarinic Receptor Antagonists

Antimuscarinic drugs currently used in the treatment of PD include *trihexyphenidyl* and *benztropine mesylate*, as well as the antihistaminic *diphenhydramine hydrochloride*, which also interacts at central muscarinic receptors. The biological basis for the therapeutic actions of muscarinic antagonists is not completely understood. They may act within the neostriatum through the receptors that normally mediate the response to intrinsic cholinergic innervation of this structure, which arises primarily from cholinergic striatal interneurons.

These drugs have relatively modest antiparkinsonian activity and are used only in the treatment of early PD or as an adjunct to dopaminergic therapy. Adverse effects result from their anticholinergic properties. Most troublesome are sedation and mental confusion. All anticholinergic drugs must be used with caution in patients with narrow-angle glaucoma (see Chapter 69), and in general anticholinergics are not well tolerated in the elderly. The pharmacology and signaling mechanisms of muscarinic receptors are thoroughly covered in Chapter 9.

Amantadine

Amantadine, an antiviral agent used for the prophylaxis and treatment of influenza A (see Chapter 62), has antiparkinsonian activity. Amantadine appears to alter DA release in the striatum, has anticholinergic properties, and blocks NMDA glutamate receptors. It is used as initial therapy of mild PD. It also may be helpful as an adjunct in patients on levodopa with dose-related fluctuations and dyskinesias. Amantadine is usually administered at a dose of 100 mg, twice per day, and is well tolerated. Dizziness, lethargy, anticholinergic effects, and sleep disturbance, as well as nausea and vomiting, side effects are mild and reversible.

Clinical Summary

Pharmacological treatment of PD should be tailored to the individual patient (Connolly and Lang, 2014). Drug therapy is not obligatory in early PD; many patients can be managed for a time with exercise and lifestyle interventions. For patients with mild symptoms, MAO-B inhibitors, amantadine, or (in younger patients) anticholinergics are reasonable choices. In most patients, treatment with a dopaminergic drug, either levodopa or a DA agonist, is eventually required. Many practitioners prefer a DA agonist as initial therapy in younger patients in an effort to reduce the occurrence of motor complications, although the evidence supporting this practice is inconclusive. In older patients or those with substantial comorbidity, levodopa/carbidopa is generally better tolerated.

Alzheimer Disease

Clinical Overview

The brain region most vulnerable to neuronal dysfunction and cell loss in AD is the medial temporal lobe, including entorhinal cortex and hippocampus. The proteins that accumulate in AD are A β and tau (Giacobini and Gold, 2013). AD has three major stages:

1. A “preclinical” stage during which accumulation of A β and tau begins, before any symptoms appear.
2. An MCI stage with episodic memory loss (repeated questions, misplaced items, etc.) that is not severe enough to impair daily function.
3. A dementia stage with progressive loss of functional abilities.

Death usually ensues within 6–12 years of onset, most often from a complication of immobility such as pneumonia or pulmonary embolism.

Diagnosis

Alzheimer disease remains a clinical diagnosis, based on the presence of memory impairment and other cognitive impairments that are insidious, progressive, and not well explained by another disorder. In recent years, there has been steady progress toward inclusion of biomarkers in the diagnostic criteria. This includes both *fluid biomarkers*, such as changes in A β and tau in the cerebrospinal fluid, and *imaging biomarkers*, such as hippocampal atrophy on structural magnetic resonance imaging and cortical hypometabolism on fluorodeoxyglucose PET scans. One of the most exciting advances is the ability to detect, using amyloid PET scans, A β deposition in patients. Three agents, *florbetapir*, *flutemetamol*, and *florbetaben*, are FDA-approved for determining whether individuals with cognitive impairment have A β deposition, which would suggest AD as a possible etiology. Similar agents for PET imaging of tau deposition are currently in development.

Genetics

Mutations in three genes have been identified as causes of autosomal dominant, early onset AD: *APP*, which encodes A β precursor protein, and *PSEN1* and *PSEN2*, encoding presenilin 1 and 2, respectively. All three genes are involved in the production of A β peptides. A β is generated by sequential proteolytic cleavage of APP by two enzymes, β -secretase and γ -secretase; the presenilins form the catalytic core of γ -secretase. The genetic evidence, combined with the fact that A β accumulates in the brain in the form of soluble oligomers and amyloid plaques and is toxic when applied to neurons, forms the basis for the amyloid hypothesis of AD pathogenesis. Many genes have been identified as having alleles that increase AD risk. By far the most important of these is *APOE*, which encodes the lipid carrier protein apoE. Individuals inheriting the $\epsilon 4$ allele of *APOE* have a 3-fold or more higher risk of developing AD. While these individuals make up less than one-fourth of the population, they account for more than half of all AD cases.

Pathophysiology

The pathological hallmarks of AD are amyloid plaques, which are extracellular accumulations of A β , and intracellular neurofibrillary tangles

composed of the microtubule-associated protein tau. The development of amyloid plaques occurs earlier, and tangle burden accrues over time in a manner that correlates more closely with the development of cognitive impairment. In autosomal dominant AD, A β accumulates due to mutations that cause its overproduction. Aggregation of A β is an important event in AD pathogenesis. While plaques consist of highly ordered fibrils of A β , it appears that soluble A β oligomers, perhaps as small as dimers, are more highly pathogenic. Tau also aggregates to form the paired helical filaments that make up neurofibrillary tangles. Posttranslational modifications of tau, including phosphorylation, proteolysis, and other changes, increase tau's propensity to aggregate. Mechanisms by which A β and tau induce neuronal dysfunction and death may include direct impairment of synaptic transmission and plasticity, excitotoxicity, oxidative stress, and neuroinflammation.

Neurochemistry

The most striking neurochemical disturbance in AD is a *deficiency of ACh*. The anatomical basis of the cholinergic deficit is atrophy and degeneration of subcortical cholinergic neurons. The selective deficiency of ACh in AD and the observation that central cholinergic antagonists (e.g., atropine) can induce a confusional state resembling the dementia of AD have given rise to the “cholinergic hypothesis” that a deficiency of ACh is critical in the genesis of the symptoms of AD. AD, however, is complex and also involves multiple neurotransmitter systems, including glutamate, 5HT, and neuropeptides, and there is destruction of not only cholinergic neurons but also the cortical and hippocampal targets that receive cholinergic input.

Treatment

At present, no disease-modifying therapy for AD is available; current treatment is aimed at alleviating symptoms (Roberson and Mucke, 2006; Selkoe, 2013).

Treatment of Cognitive Symptoms

Augmentation of the cholinergic transmission is currently the mainstay of AD treatment. Three drugs, *donepezil*, *rivastigmine*, and *galantamine*, are widely used for this purpose (Table 18–1). All three are reversible antagonists of cholinesterases (see Chapter 10). Cholinesterase inhibitors are the usual first-line therapy for symptomatic treatment of cognitive impairments in mild or moderate AD. They are also widely used to treat other neurodegenerative diseases with cholinergic deficits, including dementia with Lewy bodies and vascular dementia. Their effect is generally modest, usually producing no dramatic improvement in symptoms but rather a 6- to 12-month delay in progression, after which clinical deterioration resumes. The drugs are usually well tolerated, with the most common side effects being GI distress, muscle cramping, and abnormal dreams. They should be used with caution in patients with bradycardia or syncope.

Memantine. Memantine is a noncompetitive antagonist of the NMDA-type glutamate receptor. It is used as either an adjunct or an alternative to cholinesterase inhibitors in AD, generally in later stages of dementia, as there is less evidence for its efficacy earlier. Memantine delays clinical deterioration in patients with moderate-to-severe AD dementia. Adverse effects of memantine include mild headache or dizziness. The drug is excreted by the kidneys, and dosage should be reduced in patients with severe renal impairment.

Treatment of Behavioral Symptoms

In addition to cognitive decline, behavioral and psychiatric symptoms in dementia (BPSD) are common, particularly in middle stages of the disease. These symptoms include irritability and agitation, paranoia and delusional thinking, wandering, anxiety, and depression. Treatment can be difficult, and nonpharmacological approaches should generally be first line.

A variety of pharmacological options are also available. Both cholinesterase inhibitors and memantine reduce some BPSD. However, their effects are modest, and they do not treat some of the most troublesome

TABLE 18-1 ■ CHOLINESTERASE INHIBITORS USED FOR THE TREATMENT OF ALZHEIMER DISEASE

	DONEPEZIL	RIVASTIGMINE	GALANTAMINE
Enzymes inhibited ^a	AChE	AChE, BuChE	AChE
Mechanism	Noncompetitive	Noncompetitive	Competitive
Typical maintenance dose ^b	10 mg once daily	9.5 mg/24 h (transdermal) 3–6 mg twice daily (oral)	8–12 mg twice daily (immediate release) 16–24 mg/d (extended release)
FDA-approved indications	Mild-severe AD	Mild-moderate AD Mild-moderate PDD	Mild-moderate AD
Metabolism ^c	CYP2D6, CYP3A4	Esterases	CYP2D6, CYP3A4

^aAChE is the major cholinesterase in the brain; BuChE is a serum and hepatic cholinesterase that is upregulated in AD brain.

^bTypical starting doses are one-half of the maintenance dose and are given for the first month of therapy.

^cDrugs metabolized by CYP2D6 and CYP3A4 are subject to increased serum levels when coadministered with drugs known to inhibit these enzymes, such as ketoconazole and paroxetine.

symptoms, such as agitation. *Citalopram*, an SSRI (see Chapter 15), showed efficacy for agitation in a randomized clinical trial. Atypical antipsychotics, such as risperidone, olanzapine, and quetiapine (see Chapter 16) are perhaps even more efficacious for agitation and psychosis in AD, but their use is often limited by adverse effects, including parkinsonism, sedation, and falls. In addition, the use of atypical antipsychotics in elderly patients with dementia-related psychosis has been associated with a higher risk of stroke and overall mortality, leading to an FDA black-box warning (Schneider et al., 2005). Benzodiazepines (see Chapter 15) can be used for occasional control of acute agitation but are not recommended for long-term management because of their adverse effects on cognition and other risks in the elderly population. The typical antipsychotic haloperidol (see Chapter 16) may be useful for aggression, but sedation and extrapyramidal symptoms limit its use to control of acute episodes.

Clinical Summary

The typical patient with AD presenting in early stages of disease should probably be treated with a cholinesterase inhibitor. Patients and families should be counseled that a realistic goal of therapy is to induce a temporary reprieve from progression, or at least a reduction in the rate of decline, rather than long-term recovery of cognition. As the disease progresses, memantine can be added to the regimen. Behavioral symptoms are often treated with a serotonergic antidepressant or, if they are severe enough to warrant the risk of higher mortality, an atypical antipsychotic. Eliminating drugs likely to aggravate cognitive impairments, particularly anticholinergics, benzodiazepines, and other sedative/hypnotics, from the patient's regimen is another important aspect of AD pharmacotherapy.

Huntington Disease

Huntington disease is a dominantly inherited disorder characterized by the gradual onset of motor incoordination and cognitive decline in mid-life (Bates et al., 2015). Symptoms develop insidiously, as a movement disorder manifest by brief, jerk-like movements of the extremities, trunk, face, and neck (chorea), as personality changes, or both. Fine-motor incoordination and impairment of rapid eye movements are early features. As the disorder progresses, the involuntary movements become more severe, dysarthria and dysphagia develop, and balance is impaired. The cognitive disorder manifests first as slowness of mental processing and difficulty in organizing complex tasks. Memory is impaired, but affected persons rarely lose their memory of family, friends, and the immediate situation. Such persons often become irritable, anxious, and depressed. The outcome of HD is invariably fatal; over a course of 15–30 years, the affected person becomes totally disabled and unable to communicate, requiring full-time care; death ensues from the complications of immobility.

Pathology and Pathophysiology

Huntington disease is characterized by prominent neuronal loss in the striatum (caudate/putamen) of the brain. Atrophy of these structures proceeds in an orderly fashion, first affecting the tail of the caudate nucleus and then proceeding anteriorly from mediodorsal to VL. Other areas of the brain also are affected. Interneurons and afferent terminals are largely spared, whereas the striatal projection neurons (the medium spiny neurons) are severely affected. This leads to large decreases in striatal GABA concentrations, whereas somatostatin and DA concentrations are relatively preserved.

Selective vulnerability also appears to underlie the development of chorea. In most adult-onset cases, the medium spiny neurons that project to the GPi and SNpr (the indirect pathway) appear to be affected earlier than those projecting to the GPe (the direct pathway; see Figure 18-2). *The disproportionate impairment of the indirect pathway increases excitatory drive to the neocortex, producing involuntary choreiform movements* (Figure 18-6). In some individuals, rigidity rather than chorea is the predominant clinical feature; this is especially common in juvenile-onset

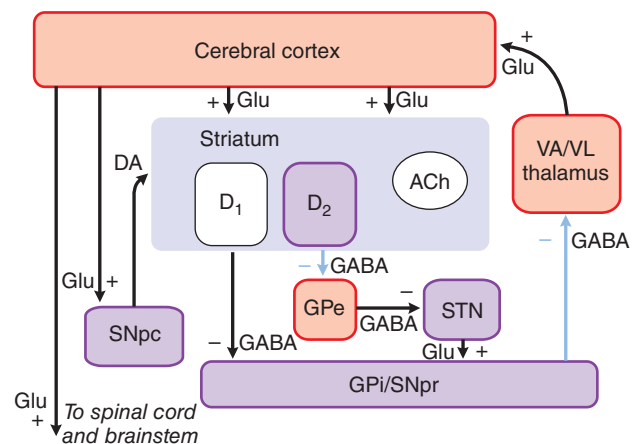

Figure 18-6 The basal ganglia in Huntington disease. HD is characterized by loss of neurons from the striatum. The neurons that project from the striatum to the GPe and form the indirect pathway are affected earlier in the course of the disease than those that project to the GPi. This leads to a loss of inhibition of the GPe. The increased activity in this structure, in turn, inhibits the STN, SNpr, and GPi, resulting in a loss of inhibition to the VA/VL thalamus and increased thalamocortical excitatory drive. Structures in purple have reduced activity in HD, whereas structures in red have increased activity. Light blue lines indicate primary pathways of reduced activity. (See Abbreviations list for definitions of anatomical abbreviations.)

cases. Here, the striatal neurons giving rise to both the direct and indirect pathways are impaired to a comparable degree.

Genetics

Huntington disease is an autosomal dominant disorder with nearly complete penetrance. The average age of onset is between 35 and 45 years, but the range varies from as early as age 2 to as late as the middle 80s. Although the disease is inherited equally from mother and father, more than 80% of those developing symptoms before age 20 inherit the defect from the father. Known homozygotes for HD show clinical characteristics identical to the typical HD heterozygote, indicating that the unaffected chromosome does not attenuate the disease symptomatology.

A region near the end of the short arm of chromosome 4 contains a polymorphic (CAG)_n trinucleotide repeat that is significantly expanded in all individuals with HD. The expansion of this trinucleotide repeat is the genetic alteration responsible for HD. The range of CAG repeat length in normal individuals is between 9 and 34 triplets, with a median repeat length on normal chromosomes of 19. The repeat length in HD varies from 40 to over 100. Repeat length is correlated inversely with age of onset of HD. The younger the age of onset, the higher the probability of a large repeat number. The mechanism by which the expanded trinucleotide repeat leads to the clinical and pathological features of HD is unknown. The HD mutation lies within a large gene (10 kb) designated *HTT* (previously *IT15*) that encodes *huntingtin*, a protein of about 348,000 Da. The trinucleotide repeat, which encodes the amino acid glutamine, occurs at the 5' end of *HTT*. Huntingtin does not resemble any other known protein.

Treatment

Symptomatic Treatment

None of the currently available medications slows the progression of the disease (Ross et al., 2014).

Tetrabenazine is used for the treatment of chorea associated with HD. Tetrabenazine and the related drug reserpine are inhibitors of VMAT2 and cause presynaptic depletion of catecholamines. Tetrabenazine is a reversible inhibitor; inhibition by reserpine is irreversible and may lead to long-lasting effects. Both drugs may cause hypotension and depression with suicidality; the shorter duration of effect of tetrabenazine simplifies clinical management. The recommended starting dose of tetrabenazine is 12.5 mg daily. Most patients can be managed with doses of 50 mg a day or less; however, tetrabenazine is extensively metabolized by CYP2D6. Genotyping for CYP2D6 may be needed to optimize therapy and is recommended for patients who require more than 50 mg daily. As might be expected with a drug that depletes DA stores, tetrabenazine can also cause parkinsonism. The recently approved deuterated tetrabenazine, *deutetrabenazine*, takes advantage of the stronger bonds that deuterium forms with carbon (the kinetic-isotope effect). The active deuterated dehydro-metabolites are VMAT2 inhibitors with longer half-lives than the corresponding products of tetrabenazine metabolism. Deutetrabenazine has therapeutic uses and an adverse effect profile similar to those of tetrabenazine.

Symptomatic treatment is needed for patients who are depressed, irritable, paranoid, excessively anxious, or psychotic. Depression can be treated effectively with standard antidepressant drugs with the caveat that drugs with substantial anticholinergic profiles can exacerbate chorea. Fluoxetine (see Chapter 15) is effective treatment of both the depression and the irritability manifest in symptomatic HD. Carbamazepine (see Chapter 17) also has been found to be effective for the depression. Paranoia, delusional states, and psychosis are treated with antipsychotic drugs, usually at lower doses than those used in primary psychiatric disorders (see Chapter 16). These agents also reduce cognitive function and impair mobility and thus should be used in the lowest doses possible and should be discontinued when the psychiatric symptoms resolve. In individuals with predominantly rigid HD, clozapine, quetiapine (see Chapter 16), or carbamazepine may be more effective for treatment of paranoia and psychosis.

Many patients with HD exhibit worsening of involuntary movements as a result of anxiety or stress. In these situations, judicious use of sedative or anxiolytic benzodiazepines can be helpful. In juvenile-onset cases where rigidity rather than chorea predominates, DA agonists have had variable

success in the improvement of rigidity. These individuals also occasionally develop myoclonus and seizures that can be responsive to clonazepam, valproate, and other anticonvulsants (see Chapter 17).

Amyotrophic Lateral Sclerosis

Amyotrophic lateral sclerosis (ALS or Lou Gehrig disease) is a disorder of the motor neurons of the ventral horn of the spinal cord (lower motor neurons) and the cortical neurons that provide their afferent input (upper motor neurons) (Gordon, 2013). The disorder is characterized by rapidly progressive weakness, muscle atrophy and fasciculations, spasticity, dysarthria, dysphagia, and respiratory compromise. Many patients with ALS exhibit behavioral changes and cognitive dysfunction, and there is clinical, genetic, and neuropathological overlap between ALS and frontotemporal dementia spectrum disorders. ALS usually is progressive and fatal. Most patients die of respiratory compromise and pneumonia after 2–3 years, although some survive for many years.

Etiology

About 10% of ALS cases are familial (FALS), usually with an autosomal dominant pattern of inheritance. The most common genetic cause is a hexanucleotide repeat expansion in *C9ORF72*, which is responsible for up to 40% of FALS and around 5% of sporadic cases (Rohrer et al., 2015). Another 10% of FALS cases are due to mutations in the Cu/Zn SOD1. Mutations in the *TARDBP* gene encoding TDP-43 and in the *FUS/TLS* gene have been identified as causes of FALS. Both TDP-43 and FUS/TLS bind DNA and RNA and regulate transcription and alternative splicing. About 90% of ALS cases are sporadic. Of these, a few are caused by de novo mutations in *C9ORF72* (up to 7%), *SOD1*, *TDP-43*, *FUS/TLS*, or other genes, but for the majority of sporadic cases, the etiology remains unclear. The underlying pathophysiology remains under investigation, including roles for abnormal RNA processing, glutamate excitotoxicity, oxidative stress, and mitochondrial dysfunction.

Treatments

Riluzole

Riluzole (2-amino-6-[trifluoromethoxy] benzothiazole) is an agent with complex actions in the nervous system. Riluzole is absorbed orally and is highly protein bound. It undergoes extensive metabolism in the liver by CYP-mediated hydroxylation and glucuronidation. Its *t*_{1/2} is about 12 h. In vitro studies showed that riluzole has both presynaptic and postsynaptic effects. It not only inhibits glutamate release, but also blocks postsynaptic NMDA- and kainate-type glutamate receptors and inhibits voltage-dependent Na⁺ channels. The recommended dose is 50 mg twice daily, taken 1 h before or 2 h after a meal. Riluzole usually is well tolerated, although nausea or diarrhea may occur. Rarely, riluzole may produce hepatic injury with elevations of serum transaminases, and periodic monitoring of these is recommended. Meta-analyses of the available clinical trials indicated that riluzole extends survival by 2–3 months. Although the magnitude of the effect of riluzole on ALS is small, it represents a significant therapeutic milestone in the treatment of a disease refractory to all previous treatments (Miller et al., 2007).

Edaravone

Edaravone

Edaravone was approved by the FDA in 2017 for treatment of ALS, the first new drug approved for this indication since 1995. It is a small molecule with free radical scavenging properties that may reduce oxidative stress, although the exact mechanism of action is unknown. Edaravone has been used in Japan for acute stroke since 2001 and was approved by

the FDA for ALS under an orphan drug designation. A phase 3 study showed no benefit, but after posthoc subgroup analyses suggested an effect in early ALS, a subsequent trial enrolling only early stage patients showed a smaller functional decline over 6 months in patients treated with edaravone. It is administered intravenously, with the first round daily for 14 days, followed by a 14-day holiday, then in subsequent cycles, 10 out of every 14 days followed by a 14-day holiday. The drug is metabolized to a glucuronide and a sulfate and excreted primarily in the urine as the glucuronide, yielding a terminal $t_{1/2}$ of 4.5–6 h. At clinical doses, edaravone is not expected to inhibit major CYPs, UGTs, or drug transporters, or to induce CYPs 1A2, 2B6, or 3A4; nor should inhibitors of these enzymes have substantial effects on the pharmacokinetics of edaravone. The infusion contains sodium bisulfite, which can cause hypersensitivity reactions. Other adverse effects include bruising, gait disorder, and headache.

Symptomatic Therapy of ALS: Spasticity

Spasticity is an important component of the clinical features of ALS and the feature most amenable to present forms of treatment. *Spasticity* is defined as an increase in muscle tone characterized by an initial resistance to passive movement of a joint, followed by a sudden relaxation (the so-called clasp-knife phenomenon). Spasticity results from loss of descending inputs to the spinal motor neurons, and the character of the spasticity depends on which nervous system pathways are affected.

Baclofen

The best agent for the symptomatic treatment of spasticity in ALS is baclofen, a GABA_B receptor agonist (see Figure 14–10). Initial doses of 5–10 mg/d are recommended, which can be increased to as much as 200 mg/d, if necessary. Alternatively, baclofen can be delivered directly

into the space around the spinal cord using a surgically implanted pump and an intrathecal catheter. This approach minimizes the adverse effects of the drug, especially sedation, but it carries the risk of potentially life-threatening CNS depression.

Tizanidine

Tizanidine is an agonist of α_2 adrenergic receptors in the CNS. It reduces muscle spasticity, probably by increasing presynaptic inhibition of motor neurons. Tizanidine is primarily used in the treatment of spasticity in multiple sclerosis or after stroke, but it also may be effective in patients with ALS. Treatment should be initiated at a low dose of 2–4 mg at bedtime and titrated upward gradually. Drowsiness, asthenia, and dizziness may limit the dose that can be administered.

Other Agents

Benzodiazepines (see Chapter 19) such as *clonazepam* are effective antispasticity agents, but they may contribute to respiratory depression in patients with advanced ALS.

Dantrolene, approved in the U.S. for the treatment of muscle spasm, is *not used* in ALS because it can exacerbate muscular weakness. Dantrolene acts directly on skeletal muscle fibers, impairing Ca^{2+} release from the sarcoplasmic reticulum. It is effective in treating spasticity associated with stroke or spinal cord injury and in treating malignant hyperthermia (see Chapter 11). Dantrolene may cause hepatotoxicity, so it is important to monitor liver-associated enzymes before and during therapy with the drug.

Acknowledgment: David G. Standaert contributed to this chapter in recent editions of this book. We have retained some of his text in the current edition.

Drug Facts for Your Personal Formulary: Drugs for Neurodegenerative Disease

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Anti-Parkinson: L-DOPA (DA precursor); Carbidopa (inhibits AADC, reduces peripheral conversion of L-DOPA to DA)		
Carbidopa/levodopa	• Most effective symptomatic therapy for PD	• Therapeutic window narrows after several years of treatment: wearing off, dyskinesias, on/off phenomenon • Available as immediate-release tablets and orally disintegrated tablets
Carbidopa/levodopa sustained release	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Bioavailability of immediate-release form, 75%
Carbidopa-levodopa extended-release capsules (RYTARY)	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Mixture of immediate- and extended-release beads
Carbidopa-levodopa intestinal gel (DUOPA)	• Patients with PD with motor fluctuations on regular carbidopa/levodopa	• Requires placement of gastrostomy tube with jejunal extension • Useful for wearing off issues
Anti-Parkinson: DA agonists (longer acting than L-DOPA; can produce psychosis, impulse control disorder, sleepiness)		
Ropinirole	• PD • Restless legs syndrome	• Selective D2 receptor class agonist • Available in immediate release (3 times daily) and sustained release (once daily)
Pramipexole	• PD • Restless legs syndrome	• Selective D2 receptor class agonist • Available in immediate release (3 times daily) and sustained release (once daily)
Rotigotine	• PD • Restless legs syndrome	• D2 and D1 receptor class agonist • Transdermal formulation
Apomorphine	• Rescue therapy for acute intermittent treatment of off episodes	• Subcutaneous formulation • Emetogenic, requires concurrent antiemetic • Contraindicated with 5HT ₃ antagonists
Anti-Parkinson: COMT Inhibitors (reduce peripheral conversion of levodopa, increasing $t_{1/2}$ and CNS dose)		
Entacapone	• Adjunctive PD therapy given with each dose of levodopa, for wearing off	• Short $t_{1/2}$, inhibits peripheral COMT
Tolcapone	• Adjunctive PD therapy given with each dose of levodopa, for wearing off	• Long $t_{1/2}$, inhibits central and peripheral COMT • May be hepatotoxic; use only in patients not responding satisfactorily to other treatments; monitor liver function
Carbidopa/levodopa/entacapone	• PD, especially for wearing off on levodopa alone	• Fixed-dose combination formulation

Anti-Parkinson: MAO-B Inhibitors (reduce oxidative metabolism of dopamine in the CNS)		
Rasagiline	<ul style="list-style-type: none"> • PD, either as initial monotherapy or adjunct to levodopa 	<ul style="list-style-type: none"> • Adjunct to reduce wearing off • Many drug interactions • Should not be given with meperidine • When administered with CYP1A2 inhibitors, C_p of rasagiline may double • Risk of serotonin syndrome
Selegiline	<ul style="list-style-type: none"> • PD, as adjunctive therapy in patients with deteriorating response to levodopa 	<ul style="list-style-type: none"> • Generates amphetamine metabolites, which can cause anxiety and insomnia • MAO-B selectivity lost at doses > 30–40 mg/d • Many drug interactions • Should not be given with meperidine • Risk of serotonin syndrome • Available in immediate release, orally disintegrating tablet, or transdermal patch
Anti-Parkinson: Other		
Amantadine	<ul style="list-style-type: none"> • Early, mild PD • Levodopa-induced dyskinesias • Influenza 	<ul style="list-style-type: none"> • Unclear mechanism of antiparkinsonian effects • Effective against dyskinesia
Trihexyphenidyl	<ul style="list-style-type: none"> • PD, as adjunctive therapy 	<ul style="list-style-type: none"> • Muscarinic receptor antagonist • Anticholinergic side effects
Benztropine	<ul style="list-style-type: none"> • PD, as adjunctive therapy 	<ul style="list-style-type: none"> • Muscarinic receptor antagonist
Anti-Alzheimer: Acetylcholinesterase Inhibitors (boost cholinergic neurotransmission; first line treatment)		
Donepezil	<ul style="list-style-type: none"> • Mild, moderate, severe AD dementia 	<ul style="list-style-type: none"> • GI symptoms: main dose-limiting side effect • Bradycardia/syncope less common
Rivastigmine	<ul style="list-style-type: none"> • Mild-moderate AD dementia • Mild-moderate PD dementia 	<ul style="list-style-type: none"> • Transdermal formulation available, with lower risk of GI side effects • Also inhibits BuChE
Galantamine	<ul style="list-style-type: none"> • Mild-moderate AD dementia 	<ul style="list-style-type: none"> • GI symptoms: main dose-limiting side effect • Bradycardia/syncope less common than GI side effects
Anti-Alzheimer: Low-Affinity Uncompetitive NMDA Antagonist		
Memantine	<ul style="list-style-type: none"> • Moderate, severe AD dementia 	<ul style="list-style-type: none"> • Reduces excitotoxicity through use-dependent blockade of NMDA receptors
Anti-Huntington		
Tetrabenazine Deutetrabenazine	<ul style="list-style-type: none"> • Chorea in HD 	<ul style="list-style-type: none"> • Reversible VMAT2 inhibitor: depletes presynaptic catecholamines • Adverse effects: hypotension, depression with suicidality • Adjust dose for CYP2D6 status; 2D6 inhibitors (e.g., paroxetine, fluoxetine, quinidine, bupropion) ↑ exposure ~3 fold • Contraindications: concurrent or recent MAO inhibitor or reserpine
Anti-ALS		
Riluzole	Extends survival in ALS up to 3 months	<ul style="list-style-type: none"> • Uncertain mechanism of action: inhibits glutamate release, blocks sodium channels and glutamate receptors
Edaravone	Reduces progression in early stages of ALS	<ul style="list-style-type: none"> • Intensive intravenous administration regimen
Anti-Spastic Agents		
Baclofen	<ul style="list-style-type: none"> • GABA_B receptor agonist 	<ul style="list-style-type: none"> • Sedation and CNS depression
Tizanidine	<ul style="list-style-type: none"> • α_2 adrenergic receptor agonist 	<ul style="list-style-type: none"> • Causes drowsiness; treatment is initiated with low dose and titrated upward
Benzodiazepines (e.g., clonazepam)	<ul style="list-style-type: none"> • See Chapter 19 	<ul style="list-style-type: none"> • May contribute to respiratory depression
Dantrolene	<ul style="list-style-type: none"> • <i>Not used in ALS</i>, but for treating muscle spasm in stroke or spinal injury and for treating malignant hyperthermia 	<ul style="list-style-type: none"> • May cause hepatotoxicity

Chapter 19

Hypnotics and Sedatives

S. John Mihic, Jody Mayfield, and R. Adron Harris

BENZODIAZEPINES

- The Molecular Target for Benzodiazepines
- Pharmacological Properties of Benzodiazepines

NOVEL BENZODIAZEPINE RECEPTOR AGONISTS

- Zaleplon
- Zolpidem
- Eszopiclone

MANAGEMENT OF PATIENTS AFTER LONG-TERM BENZODIAZEPINE THERAPY

FLUMAZENIL: A BENZODIAZEPINE RECEPTOR ANTAGONIST

MELATONIN CONGENERS

- Ramelteon
- Tasimelteon

BARBITURATES

MISCELLANEOUS SEDATIVE-HYPNOTIC DRUGS

- Chloral Hydrate
- Meprobamate
- Other Agents

NONPRESCRIPTION HYPNOTIC DRUGS

NEW AND EMERGING AGENTS

- Suvorexant
- Doxepin
- Pregabalin
- Ritanerlin
- Agomelatine

MANAGEMENT OF INSOMNIA

- Categories of Insomnia
- Prescribing Guidelines for Managing Insomnia

A *sedative* drug decreases activity, moderates excitement, and calms the recipient, whereas a *hypnotic* drug produces drowsiness and facilitates the onset and maintenance of a state of sleep that resembles natural sleep in its electroencephalographic characteristics and from which the recipient can be aroused easily. Sedation is a side effect of many drugs that are not considered general CNS depressants (e.g., antihistamines and antipsychotic agents). Although these and other agents can intensify the effects of CNS depressants, they usually produce their desired therapeutic effects at concentrations lower than those causing substantial CNS depression. For example, benzodiazepine sedative-hypnotics do not produce generalized CNS depression. Although coma may occur at very high doses, neither surgical anesthesia nor fatal intoxication is produced by benzodiazepines unless other drugs with CNS-depressant actions are concomitantly administered; an important exception is *midazolam*, which has been associated with decreased tidal volume and respiratory rate. Moreover, specific antagonists of benzodiazepines exist, such as *flumazenil*, which is used to treat cases of benzodiazepine overdose. This constellation of properties sets the benzodiazepine receptor agonists apart from other sedative-hypnotic drugs and imparts a measure of safety, such that benzodiazepines and the newer benzodiazepine receptor agonists (the “Z compounds”) have largely displaced older agents for the treatment of insomnia and anxiety.

The CNS depressants discussed in this chapter include benzodiazepines, the Z compounds, barbiturates, as well as several sedative-hypnotic agents of diverse chemical structure. The sedative-hypnotic drugs that do not specifically target the benzodiazepine receptor belong to a group of older, less-safe, sedative-hypnotic drugs that depress the CNS in a dose-dependent fashion, progressively producing a spectrum of responses from mild sedation to coma and death. These older sedative-hypnotic compounds share these properties with a large number of chemicals, including general anesthetics (see Chapter 21) and alcohols,

most notably ethanol (see Chapter 23). The newer sedative-hypnotic agents, such as benzodiazepines and Z drugs, are safer in this regard.

HISTORICAL PERSPECTIVE

Humans have long sought sleep unburdened by worry and, to this end, have consumed many potions. In the mid-19th century, bromide was introduced specifically as a sedative-hypnotic. Chloral hydrate, paraldehyde, urethane, and sulfonal were used before the introduction of barbiturates (barbital, 1903; phenobarbital, 1912), of which about 50 were distributed commercially. Barbiturates were so dominant that fewer than a dozen other sedative-hypnotics were marketed successfully before 1960.
