The partial separation of sedative-hypnotic-anesthetic properties from anticonvulsant properties characteristic of phenobarbital led to searches for agents with more selective effects on CNS functions. As a result, relatively nonsedating anticonvulsants, notably phenytoin and trimethadione, were developed in the late 1930s and early 1940s (Chapter 17). The advent of chlorpromazine and meprobamate in the early 1950s, with their taming effects in animals, and the development of increasingly sophisticated methods for evaluating the behavioral effects of drugs, set the stage in the 1950s for the synthesis of chlordiazepoxide, the introduction of which into clinical medicine in 1961 ushered in the era of benzodiazepines. Most of the benzodiazepines in the marketplace were selected for high anxiolytic potency in relation to their depression of CNS function. However, all benzodiazepines possess sedative-hypnotic properties to varying degrees; these properties are exploited extensively clinically, especially to facilitate sleep. Mainly because of their remarkably low capacity to produce fatal CNS depression, the benzodiazepines displaced the barbiturates as sedative-hypnotic agents.

ACh: acetylcholine
ALA: δ -aminolevulinic acid
AMPA: α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
COPD: chronic obstructive pulmonary disease
CNS: central nervous system
CYP: cytochrome P450
EEG: electroencephalogram
FDA: Food and Drug Administration
GABA: γ -aminobutyric acid
GI: gastrointestinal
GPCR: G protein–coupled receptor
IM: intramuscular
IV: intravenous
MT: melatonin
OL: off-label use
OSA: obstructive sleep apnea
OTC: over the counter
REM: rapid eye movement
SSRI: selective serotonin reuptake inhibitor

Benzodiazepines

All benzodiazepines in clinical use promote the binding of the major inhibitory neurotransmitter GABA to the GABA_A receptor, a pentameric ligand-gated, anion-conducting channel. Considerable heterogeneity exists among human GABA_A receptors; this heterogeneity is thought to contribute to the myriad effects of these agents in vivo. Because receptor subunit composition appears to govern the interaction of various allosteric modulators with these channels, there has been a surge in efforts to find agents displaying different combinations of benzodiazepine-like properties that may reflect selective actions on one or more subtypes of GABA_A receptors. A number of distinct mechanisms of action, reflecting involvement of specific subunits of the GABA_A receptor, likely contribute to distinct effects of various benzodiazepines—the sedative-hypnotic, muscle-relaxant, anxiolytic, amnesic, and anticonvulsant effects.

Although the benzodiazepines exert qualitatively similar clinical effects, quantitative differences in their pharmacodynamic spectra and pharmacokinetic properties have led to varying patterns of therapeutic application. While only the benzodiazepines used primarily for hypnosis are discussed in detail, this chapter describes the general properties of the group and important differences amongst individual agents (Figure 19–1) (see also Chapters 15 and 17).

The Molecular Target for Benzodiazepines

Benzodiazepines act at GABA_A receptors by binding directly to a specific site that is distinct from the GABA binding site.

The GABA_A Receptor

The GABA_A receptor is the major inhibitory receptor in the CNS. It is a transmembrane protein composed of five subunits that co-assemble around a central anion-conducting channel. Each subunit is composed of a large extracellular amino terminus, four transmembrane segments (M1–M4) and a short carboxy terminus. The M2 segment of each subunit contributes to the formation of the central anion-conducting pore. GABA binds at the interfaces of α and β classes of subunits, while benzodiazepines bind at α/γ interfaces. The five subunits come from 19 isoforms, so the number of possible pentameric combinations is large. The number of pentamers actually expressed in nature is uncertain, but likely numbers in the dozens. The GABA_A receptor shares subunit organization with a number of other cys-loop ligand-gated ion channels and with the ACh binding protein (Figure 11–1).

Figure 19–1 Basic structure of benzodiazepines. Benzodiazepine refers to the portion of this structure comprising the benzene ring (A) fused to a seven-member diazepine ring (B). Because all the important benzodiazepines contain a 5-aryl substituent (ring C) and a 1,4-diazepine ring, the term has come to mean the 5-aryl-1,4-benzodiazepines. Numerous modifications in the structure of the ring systems and substituents have yielded compounds with similar activities, including the benzodiazepine receptor antagonist flumazenil, in which ring C is replaced with a keto function at position 5 and a methyl substituent is added at position 4. A number of nonbenzodiazepine compounds (e.g., β -carboline, zolpidem, eszopiclone) plus classic benzodiazepines and flumazenil bind to the benzodiazepine receptor, an allosteric site on the ionotropic GABA_A receptor, a pentameric structure that forms a GABA-stimulated Cl[−] channel.

The GABA_A receptor pentamer contains a single benzodiazepine binding site, as well as other allosteric sites at which a variety of sedative-hypnotic-anesthetic agents exert modulatory effects on GABA_A receptor function (Figure 14–11). The exact functional properties of the pentameric receptor depend on the subunit composition and arrangement of the individual subunits, and this heterogeneity likely contributes to the pharmacological diversity of benzodiazepine effects observed in behavioral, biochemical, and functional studies and to the selective effects of the Z compounds.

Effects of Benzodiazepines on GABA_A Receptor–Mediated Events

Benzodiazepines are allosteric modulators of GABA_A receptor function (Sieghart, 2015). They increase the affinity of the GABA_A receptor for GABA and thereby enhance GABA-induced Cl[−] currents. Thus, in terms of channel kinetics, benzodiazepines increase the frequency of opening of the GABA_A receptor Cl[−] channel in the presence of GABA (Nestler et al., 2015; Sigel and Steinmann, 2012). Inverse agonists do just the opposite, reducing GABA binding and the frequency of channel opening. Benzodiazepine antagonists (e.g., flumazenil) competitively block benzodiazepine binding and effect but do not independently alter channel function (Nestler et al., 2015; Sigel and Steinmann, 2012).

In pharmacodynamic terms, agonists at the benzodiazepine binding site shift the GABA concentration–response curve to the left, whereas inverse agonists shift the curve to the right. Both these effects are blocked by antagonists (e.g., flumazenil) that bind at the benzodiazepine binding site. Application of a benzodiazepine site antagonist, in the absence of either an agonist or antagonist at this same site, results in no change in GABA_A receptor function. The behavioral and electrophysiological effects of benzodiazepines can also be reduced or prevented by prior treatment with antagonists of GABA binding (e.g., bicuculline).

The remarkable safety profile of the benzodiazepines likely relates to the fact that their effects in vivo depend on the presynaptic release of GABA; in the absence of GABA, benzodiazepines have no effects on GABA_A receptor function.

The behavioral and sedative effects of benzodiazepines can be ascribed in part to potentiation of GABAergic pathways that serve to regulate the firing of monoamine-containing neurons known to promote behavioral arousal and to be important mediators of the inhibitory effects of fear and punishment on behavior. Inhibitory effects on muscular hypertonia or the spread of seizure activity can be attributed to potentiation of inhibitory GABAergic circuits at various levels of the neuraxis. The magnitude of the effects produced by benzodiazepines varies widely depending on such

factors as the types of inhibitory circuits that are operating, the sources and intensity of excitatory input, and the manner in which experimental manipulations are performed and assessed. Accordingly, benzodiazepines markedly prolong the period after brief activation of recurrent GABAergic pathways during which neither spontaneous nor applied excitatory stimuli can evoke neuronal discharge; this effect is reversed by the GABA_A receptor antagonist *bicuculline* (see Figure 14–10).

Benzodiazepines Versus Barbiturates at the GABA_A Receptor

The two classes of agents, barbiturates and benzodiazepines, differ in their potencies: Barbiturates act to enhance GABA_A receptor function at low micromolar concentrations; benzodiazepines bind with nanomolar affinity. Both benzodiazepines and barbiturates bind to allosteric sites on the GABA_A receptor pentamer and thereby enhance GABA-stimulated Cl[−] channel function. However, barbiturates also have an additional effect: Higher concentrations of barbiturates directly activate GABA_A receptors. Furthermore, when tested using equieffective concentrations of GABA, maximally effective concentrations of barbiturates produce greater enhancement of GABA_A receptor function than do benzodiazepines. This direct effect possibly contributes to the profound CNS depression that barbiturates can cause. The lack of direct channel activation by benzodiazepines and their dependence on the presynaptic release of GABA at the GABA_A receptor likely contribute to the safety of these agents as compared to barbiturates.

Pharmacological Properties of Benzodiazepines

The therapeutic effects of the benzodiazepines result from their actions on the CNS. The most prominent of these effects are sedation, hypnosis, decreased anxiety, muscle relaxation, anterograde amnesia, and anticonvulsant activity. Only two effects of these drugs result from peripheral actions: coronary vasodilation, seen after intravenous administration of therapeutic doses of certain benzodiazepines, and neuromuscular blockade, seen only with very high doses.

CNS Effects

While benzodiazepines depress activity at all levels of the neuraxis, some structures are affected preferentially. The benzodiazepines do not produce the same magnitudes of neuronal depression produced by barbiturates and volatile anesthetics, likely because they have weaker enhancing effects at GABA_A receptors than those compounds, even at saturating concentrations. All the benzodiazepines have similar pharmacological profiles. Nevertheless, the drugs differ in selectivity, and the clinical usefulness of individual benzodiazepines thus varies considerably. The vast majority of effects of benzodiazepine site agonists and inverse agonists can be reversed or prevented by flumazenil, which competes with agonists and inverse agonists at a common binding site at the GABA_A receptor. As the dose of a benzodiazepine is increased, sedation progresses to hypnosis and then to stupor. Although the clinical literature often refers to the “anesthetic” effects and uses of certain benzodiazepines, these drugs do not cause a true general anesthesia; awareness usually persists, and a failure to respond to a noxious stimulus sufficient to allow surgery cannot be achieved. Nonetheless, at “preanesthetic” doses, there is amnesia for events occurring subsequent to administration of the drug. Although many attempts have been made to separate the anxiolytic actions of benzodiazepines from their sedative-hypnotic effects, distinguishing between these behaviors is problematic. Accurate measurements of anxiety and sedation are difficult in humans, and the validity of animal models for measuring anxiety and sedation is uncertain.

Although analgesic effects of benzodiazepines have been observed in experimental animals, only transient analgesia is apparent in humans after intravenous administration. Such effects actually may involve the production of amnesia. Unlike barbiturates, benzodiazepines do not cause hyperalgesia.

Tolerance. Although most patients who chronically ingest benzodiazepines report that drowsiness wanes over a few days, tolerance to the impairment seen in some measures of psychomotor performance (e.g.,

visual tracking) is not usually observed. Whether tolerance develops to the anxiolytic effects of benzodiazepines remains debatable. Many patients use a fairly constant maintenance dose; increases or decreases in dosage appear to correspond with changes in their perceived problems or stresses. Conversely, other patients either do not reduce their dosages when stress is relieved or steadily escalate dosing. Such behavior may be associated with the development of drug dependence (see Chapter 24).

Some benzodiazepines induce muscle hypotonia without interfering with normal locomotion and can decrease rigidity in patients with cerebral palsy. *Clonazepam* in nonsedating doses causes muscle relaxation, but *diazepam* and most other benzodiazepines do not. Tolerance occurs to the muscle relaxant and ataxic effects of these drugs.

Experimentally, benzodiazepines inhibit seizure activity induced by either pentylenetetrazol or picrotoxin, but suppress strychnine- and maximal electroshock-induced seizures only at doses that also severely impair locomotor activity. *Clonazepam*, *nitrazepam*, and *nordazepam* have greater selective anticonvulsant activity than do most other benzodiazepines. Benzodiazepines also suppress photic seizures in baboons and ethanol withdrawal seizures in humans. However, the development of tolerance to the anticonvulsant effects has limited the usefulness of benzodiazepines in the treatment of recurrent seizure disorders in humans (see Chapter 17).

Effects on the Electroencephalogram and Sleep Stages. The effects of benzodiazepines on the waking EEG resemble those of other sedative-hypnotic drugs. Alpha rhythm activity is decreased, but there is an increase in low-voltage fast activity. Tolerance also occurs to these effects. With respect to sleep, some differences in the patterns of effects exerted by the various benzodiazepines have been noted, but benzodiazepine users usually report a sense of deep or refreshing sleep. Benzodiazepines decrease sleep latency, especially when first used, and diminish the number of awakenings and the time spent in stage 0 (a stage of wakefulness). They also produce an increased arousal threshold from sleep. Time in stage 1 (descending drowsiness) usually is decreased, and there is a prominent decrease in the time spent in slow-wave sleep (stages 3 and 4). Most benzodiazepines increase the latency from onset of spindle sleep to the first burst of REM sleep. The time spent in REM sleep is usually shortened, but the number of cycles of REM sleep is typically increased, mostly late in the sleep time. *Zolpidem* and *zaleplon* suppress REM sleep less extensively than benzodiazepines and thus may be superior to benzodiazepines for use as hypnotics (Dujardin et al., 1998).

Despite the shortening of durations of stage 4 and REM sleep, benzodiazepine administration typically increases total sleep time, largely by increasing the time spent in stage 2, which is the major fraction of non-REM sleep. This effect is greatest in subjects with the shortest baseline total sleep time. In addition, despite the increased number of REM cycles, the number of shifts to lighter sleep stages (1 and 0) and the amount of body movement are diminished with benzodiazepine use. Nocturnal peaks in the secretion of growth hormone, prolactin, and luteinizing hormone are not affected. During chronic nocturnal use of benzodiazepines, the effects on the various stages of sleep usually decline within a few nights. When such use is discontinued, the pattern of drug-induced changes in sleep parameters may “rebound,” and an increase in the amount and density of REM sleep may be especially prominent. If the dosage has not been excessive, patients usually will note only a shortening of sleep time rather than an exacerbation of insomnia.

Systemic Effects

Respiration. Hypnotic doses of benzodiazepines are without effect on respiration in normal subjects, but special care must be taken in the treatment of children and individuals with impaired hepatic or pulmonary function. At higher doses, such as those used for preanesthetic medication or for endoscopy, benzodiazepines slightly depress alveolar ventilation and cause respiratory acidosis as the result of a decrease in hypoxic rather than hypercapnic drive; these effects are exaggerated in patients with COPD, and alveolar hypoxia and CO₂ narcosis may result. These drugs can cause apnea during anesthesia or when given

with opioids. Patients severely intoxicated with benzodiazepines only require respiratory assistance when they also have ingested another CNS depressant drug, most commonly ethanol.

Hypnotic doses of benzodiazepines may worsen sleep-related breathing disorders by adversely affecting control of the upper airway muscles or by decreasing the ventilatory response to CO_2 . The latter effect may cause hypoventilation and hypoxemia in some patients with severe COPD. In patients with OSA, hypnotic doses of benzodiazepines may decrease muscle tone in the upper airway and exaggerate the impact of apneic episodes on alveolar hypoxia, pulmonary hypertension, and cardiac ventricular load. Benzodiazepines may promote the appearance of episodes of apnea during REM sleep (associated with decreases in O_2 saturation) in patients recovering from a myocardial infarction; however, no impact of these drugs on survival of patients with cardiac disease has been reported.

Cardiovascular System. The cardiovascular effects of benzodiazepines are minor in normal subjects except in cases of severe intoxication (see previous discussion for adverse effects in patients with obstructive sleep disorders or cardiac disease). At preanesthetic doses, all benzodiazepines decrease blood pressure and increase heart rate. With *midazolam*, the effects appear to be secondary to a decrease in peripheral resistance; however, with *diazepam*, the effects are secondary to a decrease in left ventricular work and cardiac output. *Diazepam* increases coronary flow, possibly by an action to increase interstitial concentrations of adenosine, and the accumulation of this cardiodepressant metabolite also may explain the negative inotropic effects of the drug. In large doses, *midazolam* considerably decreases cerebral blood flow and O_2 assimilation.

GI Tract. Benzodiazepines are thought by some gastroenterologists to improve a variety of “anxiety-related” GI disorders. There is a paucity of evidence for direct actions. Although *diazepam* markedly decreases nocturnal gastric secretion in humans, other drug classes are considerably more effective in acid-peptic disorders (see Chapter 49).

ADME

All benzodiazepines are absorbed completely except *clorazepate*. *Clorazepate* is decarboxylated rapidly in gastric juice to *N*-desmethyldiazepam (nordazepam), which subsequently is absorbed completely. Drugs active at the benzodiazepine receptor may be divided into four categories based on their elimination $t_{1/2}$:

- Ultrashort-acting benzodiazepines
- Short-acting agents ($t_{1/2} < 6$ h), including *midazolam*, *triazolam*, the nonbenzodiazepine *zolpidem* ($t_{1/2} \sim 2$ h), and *eszopiclone* ($t_{1/2}$, 5–6 h)
- Intermediate-acting agents ($t_{1/2}$, 6–24 h), including *estazolam* and *temazepam*
- Long-acting agents ($t_{1/2} > 24$ h), including *flurazepam*, *diazepam*, and *quazepam*

Flurazepam itself has a short $t_{1/2}$ (~ 2.3 h), but a major active metabolite, *N*-des-alkyl-flurazepam, is long lived ($t_{1/2}$, 47–100 h); such features complicate the classification of certain benzodiazepines.

The benzodiazepines and their active metabolites bind to plasma proteins. The extent of binding correlates strongly with the oil:water partition coefficient and ranges from about 70% for *alprazolam* to nearly 99% for *diazepam*. The concentration in the cerebrospinal fluid is approximately equal to the concentration of free drug in plasma. Uptake of benzodiazepines occurs rapidly into the brain and other highly perfused organs after intravenous administration (or oral administration of a rapidly absorbed compound); rapid uptake is followed by a phase of redistribution into tissues that are less well perfused but capacious, especially muscle and fat (see Table 2–2 and Figure 2–4). Redistribution is most rapid for benzodiazepines with the highest oil:water partition coefficients. The kinetics of redistribution of *diazepam* and other lipophilic benzodiazepines are complicated by enterohepatic circulation. These drugs cross the placental barrier and are also secreted into breast milk.

Most benzodiazepines are metabolized extensively by hepatic CYPs, particularly CYP 3A4 and 2C19. Some benzodiazepines, such as *oxazepam*, are not metabolized by CYPs but are conjugated directly by phase 2 enzymes. Erythromycin, clarithromycin, ritonavir, itraconazole, ketoconazole, nefazodone, and grapefruit juice are examples of CYP3A4 inhibitors (see Chapter 6) that can affect the rate of metabolism of benzodiazepines. Benzodiazepines do not significantly induce hepatic CYPs, so their chronic administration does not usually affect metabolism of benzodiazepines or other drugs. *Cimetidine* and oral contraceptives inhibit *N*-dealkylation and 3-hydroxylation of benzodiazepines. Ethanol, *isoniazid*, and *phenytoin* are less effective in this regard. These phase 1 reactions usually are reduced to a greater extent in elderly patients and in patients with chronic liver disease than are those reactions involving conjugation.

The active metabolites of some benzodiazepines are biotransformed more slowly than are the parent compounds; thus, the durations of action of many benzodiazepines bear little relationship to the $t_{1/2}$ of elimination of the parent drug. Conversely, the rate of biotransformation of drugs that are inactivated by the initial metabolic reaction is an important determinant of their durations of action; examples include *oxazepam*, *lorazepam*, *temazepam*, *triazolam*, and *midazolam*.

Benzodiazepine metabolism can seem daunting but can be organized around a few basic principles. Metabolism of the benzodiazepines occurs in three major stages. These stages and the relationships between the drugs and their metabolites are shown in Table 19–1.

For benzodiazepines that bear a substituent at position 1 (or 2) of the diazepine ring, the *first phase* of metabolism involves modification or removal of the substituent. The eventual products are *N*-desalkylated compounds that are biologically active. Exceptions are *triazolam*, *alprazolam*, *estazolam*, and *midazolam*, which contain either a fused triazolo or an imidazolo ring and are α -hydroxylated.

The *second phase* of metabolism involves hydroxylation at position 3 and also usually yields an active derivative (e.g., *oxazepam* from *nordazepam*). The rates of these reactions are usually much slower than the first stage ($t_{1/2} > 40$ –50 h), such that appreciable accumulation of hydroxylated products with intact substituents at position 1 does not occur. (There are two significant exceptions to this rule: First, small amounts of *temazepam* accumulate during the chronic administration of *diazepam*; and second, following the replacement of S with O in *quazepam*, most of the resulting 2-oxoquazepam is hydroxylated slowly at position 3 without removal of the *N*-alkyl group. However, only small amounts of the 3-hydroxyl derivative accumulate during chronic administration of *quazepam* because this compound is conjugated at an unusually rapid rate. In contrast, the *N*-desalkylflurazepam that is formed by the “minor” metabolic pathway does accumulate during *quazepam* administration, and it contributes significantly to the overall clinical effect.)

The *third major phase* of metabolism is the conjugation of the 3-hydroxyl compounds, principally with glucuronic acid; the $t_{1/2}$ values of these reactions usually are about 6–12 h, and the products invariably are inactive. Conjugation is the only major route of metabolism for *oxazepam* and *lorazepam* and is the preferred pathway for *temazepam* because of the slower conversion of this compound to *oxazepam*. *Triazolam* and *alprazolam* are metabolized principally by initial hydroxylation of the methyl group on the fused triazolo ring; the absence of a chlorine residue in ring C of *alprazolam* slows this reaction significantly. The products, sometimes referred to as α -hydroxylated compounds, are quite active but are metabolized rapidly, primarily by conjugation with glucuronic acid, such that there is no appreciable accumulation of active metabolites. The fused triazolo ring in *estazolam* lacks a methyl group and is hydroxylated to only a limited extent; the major route of metabolism involves the formation of the 3-hydroxyl derivative. The corresponding hydroxyl derivatives of *triazolam* and *alprazolam* also are formed to a significant extent. Compared with compounds without the triazolo ring, the rate of this reaction for all three drugs is unusually swift, and the 3-hydroxyl compounds are rapidly conjugated or oxidized further to benzophenone derivatives before excretion.

Midazolam is metabolized rapidly, primarily by hydroxylation of the methyl group on the fused imidazo ring; only small amounts of 3-hydroxyl

TABLE 19-1 ■ STAGES AND RELATIONSHIPS AMONG SOME OF THE DIAZEPINES^a

^a Compounds enclosed in boxes are marketed in the U.S. The approximate half-lives of the various compounds are denoted in parentheses; S (short-acting), $t_{1/2} < 6$ h; I (intermediate-acting), $t_{1/2} = 6-24$ h; L (long-acting), $t_{1/2} > 24$ h. All compounds except clorazepate are biologically active; the activity of 3-hydroxydesalkylflurazepam has not been determined. Clonazepam (not shown) is an N-desalkyl compound, and it is metabolized primarily by reduction of the 7-NO₂ group to the corresponding amine (inactive), followed by acetylation; its $t_{1/2}$ is 20-40 h. ^b See text for discussion of other pathways of metabolism.

compounds are formed. The α-hydroxylated compound, which has appreciable biological activity, is eliminated with a $t_{1/2}$ of 1 h after conjugation with glucuronic acid. Variable and sometimes substantial accumulation of this metabolite has been noted during intravenous infusion (Oldenhof et al., 1988).

The aromatic rings (A and C) of the benzodiazepines are hydroxylated only to a small extent. The only important metabolism at these sites is reduction of the 7-nitro substituents of clonazepam, nitrazepam, and flunitrazepam; the $t_{1/2}$ of these reactions are usually 20-40 h. The resulting amines are inactive and are acetylated to varying degrees before excretion.

Therapeutic Uses

Table 19-2 summarizes the therapeutic uses and routes of administration of benzodiazepines that are marketed in the U.S. Most benzodiazepines can be used interchangeably. For example, diazepam can be used to treat alcohol withdrawal symptoms, and most benzodiazepines work as hypnotics. Benzodiazepines that are useful as anticonvulsants have a long $t_{1/2}$, and rapid entry into the brain is required for efficacy in treatment of status epilepticus. Antianxiety agents, in contrast, should have a long $t_{1/2}$ despite the drawback of the risk of neuropsychological deficits caused by drug accumulation. For a hypnotic sleep medication, one would want to have a rapid onset of action when taken at bedtime, a sufficiently sustained action to maintain sleep throughout the night, and no residual action by the following morning. In practice, there are some disadvantages to the use of agents that have a relatively rapid rate of disappearance, such as triazolam, including the early morning insomnia experienced by some patients and a greater likelihood of rebound insomnia on drug discontinuation. With

careful selection of dosage, flurazepam and other benzodiazepines with slower rates of elimination than triazolam's can be used effectively.

Untoward Effects

At peak concentrations in plasma, hypnotic doses of benzodiazepines cause varying degrees of light-headedness, lassitude, increased reaction time, motor incoordination, impairment of mental and motor functions, confusion, and anterograde amnesia. Cognition appears to be affected less than motor performance. *All of these effects can greatly impair driving and other psychomotor skills, especially if combined with ethanol.* When the drug is given at the intended time of sleep, persistence of these effects into the following waking hours is adverse. These dose-related residual effects can be insidious because most subjects underestimate the degree of their impairment. Residual daytime sleepiness also may occur, even though successful drug therapy can reduce the daytime sleepiness resulting from chronic insomnia. The intensity and incidence of CNS toxicity generally increase with age (Monane, 1992). Other common side effects of benzodiazepines are weakness, headache, blurred vision, vertigo, nausea and vomiting, epigastric distress, and diarrhea; joint pains, chest pains, and incontinence are much rarer. Anticonvulsant benzodiazepines sometimes increase the frequency of seizures in patients with epilepsy.

A wide variety of serious allergic, hepatotoxic, and hematologic reactions to the benzodiazepines may occur, but the incidence is low; these reactions have been associated with the use of *flurazepam*, *triazolam*, and *temazepam*. Large doses taken just before or during labor may cause hypothermia, hypotonia, and mild respiratory depression in the neonate. Abuse by the pregnant mother can result in a withdrawal syndrome in the newborn.

TABLE 19-2 ■ THERAPEUTIC USES OF BENZODIAZEPINES

COMPOUND	ROUTES OF ADMINISTRATION	THERAPEUTIC USES ^a	COMMENTS	$t_{1/2}$ (h) ^b	USUAL SEDATIVE-HYPNOTIC DOSE, mg ^c
Alprazolam	Oral	Anxiety disorders, agoraphobia (OL)	Withdrawal symptoms may be especially severe	12 ± 2	—
Chlordiazepoxide	Oral, IM, IV	Anxiety disorders, management of alcohol withdrawal, preanesthetic medication (OL)	Long-acting and self-tapering because of active metabolites	10 ± 3.4	50–100, 1–41× daily ^d (1 daily for sleep)
Clobazam	Oral	Adjunctive treatment of seizures associated with Lennox-Gastaut syndrome (U.S. approved use), other types of epilepsies, anxiety disorders	Active metabolite $t_{1/2}$ 71–82 h; tolerance develops to anticonvulsant effects; not recommended in patients with severe hepatic impairment; decrease dose and titrate in CYP2C19 poor metabolizers	36–42	—
Clonazepam	Oral	Seizure disorders, panic disorder, adjunctive treatment in acute mania and certain movement disorders (OL)	Tolerance develops to anticonvulsant effects	23 ± 5	0.25–0.5 (hypnotic)
Clorazepate	Oral	Anxiety disorders, seizure disorders, management of alcohol withdrawal	Prodrug; activity due to formation of nordazepam during absorption	2.0 ± 0.9	3.75–20, 2–4× daily ^d
Diazepam	Oral, IM, IV, rectal	Anxiety disorders, alcohol withdrawal, status epilepticus, skeletal muscle relaxation, preanesthetic medication, Meniere disease (OL)	Prototypical benzodiazepine	43 ± 13	5–10, every 4 h
Estazolam	Oral	Insomnia	Contains triazolo ring; adverse effects may be similar to those of triazolam	10–24	1–2
Flurazepam	Oral	Insomnia	Active metabolites accumulate with chronic use	74 ± 24	15–30
Lorazepam	Oral, IM, IV	Anxiety disorders, alcohol withdrawal, preanesthetic medication, seizure disorders	Metabolized solely by conjugation	14 ± 5	1–4
Midazolam	Oral, IV, IM	Preanesthetic and intraoperative medication, anxiety disorders (agitation, alcohol withdrawal, seizure disorders, OL)	Rapidly inactivated	1.9 ± 0.6	1–5 ^e
Oxazepam	Oral	Anxiety disorders, alcohol withdrawal	Metabolized solely by conjugation	8.0 ± 2.4	15–30, 3–4× daily ^d
Quazepam	Oral	Insomnia	Active metabolites accumulate with chronic use	39	7.5–15
Temazepam	Oral	Insomnia	Metabolized mainly by conjugation	11 ± 6	7.5–30
Triazolam	Oral	Insomnia	Rapidly inactivated; may cause disturbing daytime side effects	2.9 ± 1.0	0.125–0.5

^aThe therapeutic uses are examples to emphasize that most benzodiazepines can be used interchangeably. In general, the therapeutic uses of a given benzodiazepine are related to its $t_{1/2}$ and may not match the marketed indications. The issue is addressed more extensively in the text.

^bHalf-life of active metabolite may differ. See Appendix II for additional information.

^cFor additional dosage information, see Chapter 21 (anesthesia), Chapter 15 (anxiety), and Chapter 17 (seizure disorders).

^dApproved as a sedative-hypnotic only for management of alcohol withdrawal; doses in a nontolerant individual would be smaller.

^eRecommended doses vary considerably depending on specific use, condition of patient, and concomitant administration of other drugs.

Adverse Psychological Effects

Benzodiazepines may at times cause paradoxical effects. *Flurazepam* occasionally increases the incidence of nightmares—especially during the first week of use—and sometimes causes garrulousness, anxiety, irritability, tachycardia, and sweating. Amnesia, euphoria, restlessness, hallucinations, sleep-walking, sleep-talking, other complex behaviors,

and hypomanic behavior have been reported to occur during use of various benzodiazepines. Bizarre uninhibited behavior may occur in some users, hostility and rage in others; collectively, these are sometimes referred to as *disinhibition* or *dyscontrol reactions*. Paranoia, depression, and suicidal ideation also occasionally may accompany the use of these agents. Such paradoxical or disinhibition reactions are rare and

appear to be dose related. Because of reports of an increased incidence of confusion and abnormal behaviors, triazolam has been banned in the U.K. The FDA declared triazolam to be safe and effective in low doses of 0.125–0.25 mg.

Chronic benzodiazepine use poses a risk for development of dependence and abuse (Woods et al., 1992). Mild dependence may develop in many patients who have taken therapeutic doses of benzodiazepines on a regular basis for prolonged periods, but not to the same extent as seen with older sedatives and other recognized drugs of abuse (Chapter 24; Uhlenhuth et al., 1999). Withdrawal symptoms may include temporary intensification of the problems that originally prompted their use (e.g., insomnia or anxiety). Dysphoria, irritability, sweating, unpleasant dreams, tremors, anorexia, and faintness or dizziness also may occur, especially when withdrawal of the benzodiazepine occurs abruptly. Hence, it is prudent to taper the dosage gradually when therapy is to be discontinued. Despite their adverse effects, benzodiazepines are relatively safe drugs, and fatalities are rare unless other drugs are taken concomitantly. Ethanol is a common contributor to deaths involving benzodiazepines, but true coma is uncommon in the absence of another CNS depressant. Although overdosage with a benzodiazepine rarely causes severe cardiovascular or respiratory depression, therapeutic doses of benzodiazepines can further compromise respiration in patients with COPD or OSA. Benzodiazepine abuse of a different sort includes the use of *flunitrazepam* (Rohypnol; not licensed for use in the U.S.) as a “date rape drug.”

Drug Interactions

Except for additive effects with other sedative or hypnotic drugs, reports of clinically important pharmacodynamic interactions between benzodiazepines and other drugs have been infrequent. Ethanol increases both the rate of absorption of benzodiazepines and the associated CNS depression. Valproate and benzodiazepines used in combination may cause psychotic episodes.

Novel Benzodiazepine Receptor Agonists

Hypnotics in this class are commonly referred to as “Z compounds.” They include zolpidem, zaleplon, zopiclone (not marketed in the U.S.), and eszopiclone, which is the S(+) enantiomer of zopiclone (Huedo-Medina et al., 2012). Although the Z compounds are structurally unrelated to each other and to benzodiazepines, their therapeutic efficacy as hypnotics is due to agonist effects at the benzodiazepine site of the GABA_A receptor (Hanson et al., 2008). Compared to benzodiazepines, Z compounds are less effective as anticonvulsants or muscle relaxants, which may be related to their relative selectivity for GABA_A receptors containing the α_1 subunit. Over the last decade, Z compounds have largely replaced benzodiazepines in the treatment of insomnia. Z compounds were initially promoted as having less potential for dependence and abuse than traditional benzodiazepines. However, based on postmarketing clinical experience with zopiclone and zolpidem, tolerance and physical dependence can be expected during long-term use of Z compounds, especially with higher doses. The Z drugs are classified as schedule IV drugs in the U.S. The clinical presentation of overdose with Z compounds is similar to that of benzodiazepine overdose and can be treated with the benzodiazepine antagonist flumazenil.

Zaleplon

Zaleplon is a member of the pyrazolopyrimidine class. Zaleplon preferentially binds to the benzodiazepine binding site on GABA_A receptors containing the α_1 receptor subunit. It is absorbed rapidly and reaches peak plasma concentrations in about 1 h. Its bioavailability is about 30% because of presystemic metabolism. Zaleplon is metabolized largely by aldehyde oxidase and to a lesser extent by CYP3A4. Its $t_{1/2}$ is short, about 1 h. Zaleplon's oxidative metabolites are converted to glucuronides and eliminated in urine. Less than 1% of zaleplon is excreted unchanged; none of zaleplon's metabolites is pharmacologically active. Zaleplon is usually administered in 5-, 10-, or 20-mg doses (Dooley and Plosker, 2000). Zaleplon-treated subjects with either chronic or transient insomnia experience shorter periods of sleep onset latency.

Zolpidem

Zolpidem is an imidazopyridine sedative-hypnotic. The actions of zolpidem are due to agonist effects at the benzodiazepine receptor site on GABA_A receptors and generally resemble those of benzodiazepines. The drug has little effect on the stages of sleep in normal human subjects. It is effective in shortening sleep latency and prolonging total sleep time in patients with insomnia. After discontinuation of zolpidem, the beneficial effects on sleep reportedly persist for up to 1 week, but mild rebound insomnia on the first night of withdrawal may occur. Zolpidem is approved only for the short-term treatment of insomnia; however, tolerance and physical dependence are rare (Morselli, 1993). At therapeutic doses (5–10 mg), zolpidem infrequently produces residual daytime sedation or amnesia; the incidence of other adverse effects also is low. As with the benzodiazepines, large overdoses of zolpidem do not produce severe respiratory depression unless other agents (e.g., ethanol) also are ingested. Hypnotic doses increase the hypoxia and hypercarbia of patients with OSA.

Zolpidem is absorbed readily from the GI tract; first-pass hepatic metabolism results in an oral bioavailability of about 70% (lower when the drug is ingested with food). Zolpidem is eliminated almost entirely by conversion to inactive products in the liver, largely through oxidation of the methyl groups on the phenyl and imidazopyridine rings to the corresponding carboxylic acids. Its plasma $t_{1/2}$ is about 2 h in normal individuals, but this value may increase 2-fold or more in those with cirrhosis and also tends to be greater in older patients, requiring adjustment of dosage. Although little or no unchanged zolpidem is found in the urine, elimination of the drug is slower in patients with chronic renal insufficiency; the increased elimination time largely is due to an increase in its apparent volume of distribution.

Zaleplon and Zolpidem Compared

Zaleplon and zolpidem are effective in relieving sleep-onset insomnia. Both drugs are FDA-approved for use up to 7–10 days at a time. Zaleplon and zolpidem have sustained hypnotic efficacy without occurrence of rebound insomnia on abrupt discontinuation. Zolpidem has a $t_{1/2}$ of about 2 h, which is sufficient to cover most of a typical 8-h sleep period, and is presently approved for bedtime use only. Zaleplon has a shorter $t_{1/2}$ of about 1 h, which offers the possibility for safe dosing later in the night, within 4 h of the anticipated rising time. Zaleplon and zolpidem differ in residual side effects; late-night administration of zolpidem has been associated with morning sedation, delayed reaction time, and anterograde amnesia, whereas zaleplon does not differ from placebo.

Eszopiclone

Eszopiclone is the active S(+) enantiomer of zopiclone. It exerts its sleep-promoting effects by enhancing GABA_A receptor function via the benzodiazepine binding site. Eszopiclone is used for the long-term (~12 months) treatment of insomnia, for sleep maintenance, and to decrease the latency to onset of sleep (Melton et al., 2005; Rosenberg et al., 2005). It is available in 1-, 2-, or 3-mg tablets. In clinical studies, no tolerance was observed, and no signs of serious withdrawal, such as seizures or rebound insomnia, were seen on discontinuation of the drug; however, there are such reports for *zopiclone*, the racemate used outside the U.S. Mild withdrawal consisting of abnormal dreams, anxiety, nausea, and upset stomach can occur ($\leq 2\%$). A minor reported adverse effect of eszopiclone is a bitter taste. Eszopiclone is absorbed rapidly after oral administration, with a bioavailability of about 80%, and shows wide distribution throughout the body. It is 50%–60% bound to plasma proteins, is metabolized by CYPs 3A4 and 2E1, and has a $t_{1/2}$ of about 6 h.

Management of Patients After Long-Term Benzodiazepine Therapy

If a benzodiazepine has been used regularly for more than 2 weeks, its use should be tapered rather than discontinued abruptly. In some patients taking hypnotics with a short $t_{1/2}$, it is easier to switch first to a hypnotic with a long $t_{1/2}$ and then to taper. The onset of withdrawal symptoms

Flumazenil: A Benzodiazepine Receptor Antagonist

Flumazenil is an imidazobenzodiazepine that binds with high affinity to the benzodiazepine binding site on the GABA_A receptor, where it competitively antagonizes the binding and allosteric effects of benzodiazepines and other ligands (Hoffman and Warren, 1993). Flumazenil antagonizes both the electrophysiological and behavioral effects of agonist and inverse-agonist benzodiazepines and β -carbolines.

Flumazenil is available only for intravenous administration. Administration of a series of small injections is preferred to a single bolus injection. A total of 1 mg flumazenil given over 1–3 min usually is sufficient to abolish the effects of therapeutic doses of benzodiazepines. Additional courses of treatment with flumazenil may be needed within 20–30 min should sedation reappear. The duration of clinical effects usually is only 30–60 min. Although absorbed rapidly after oral administration, less than 25% of the drug reaches the systemic circulation owing to extensive first-pass hepatic metabolism. Flumazenil is eliminated almost entirely by hepatic metabolism to inactive products with a $t_{1/2}$ of about 1 h. Oral doses are apt to cause headache and dizziness.

The primary indications for the use of flumazenil are the management of suspected benzodiazepine overdose and the reversal of sedative effects produced by benzodiazepines administered during general anesthesia and diagnostic or therapeutic procedures. Flumazenil is not effective in single-drug overdoses with either barbiturates or tricyclic antidepressants. The administration of flumazenil in these settings may be associated with the onset of seizures, especially in patients poisoned with tricyclic antidepressants. Seizures or other withdrawal signs may be precipitated in patients taking benzodiazepines for protracted periods and in whom tolerance or dependence may have developed.

Melatonin Congeners

Melatonin is a circadian signaling molecule. In some fish and amphibians, melatonin modulates skin coloration through an action on melanin-containing pigment granules in melanophores. In humans, melatonin, not to be confused with the pigment melanin, is the principal indoleamine in the pineal gland, where it may be said to constitute a pigment of the imagination. The synthesis of melatonin in the pineal gland (by *N*-acetylation and *O*-methylation of serotonin; see Figure 13–2) is influenced by external factors, including environmental light. In mammals, melatonin induces pigment lightening in skin cells and suppresses ovarian functions; it also serves a role in regulating biological rhythms and has been studied as a treatment of jet lag and other sleep disturbances. Melatonin analogues have recently been approved for the treatment of insomnia.

Ramelteon

Ramelteon is a synthetic tricyclic analogue of melatonin, approved in the U.S. for the treatment of insomnia, specifically difficulties of sleep onset (Spadoni et al., 2011).

Mechanism of Action

Melatonin levels in the suprachiasmatic nucleus rise and fall in a circadian fashion, with concentrations increasing in the evening as an individual prepares for sleep and then reaching a plateau and ultimately decreasing as the night progresses. Two GPCRs for melatonin, MT₁ and MT₂, in the suprachiasmatic nucleus, each play a different role in sleep. Binding of agonists such as melatonin to MT₁ receptors promotes the onset of sleep; melatonin binding to MT₂ receptors shifts the timing of the circadian system. Ramelteon binds to both MT₁ and MT₂ receptors with high affinity, but, unlike melatonin, it does not bind appreciably to quinone reductase 2, the structurally unrelated MT₃ receptor. Ramelteon is not known to bind to any other classes of receptors, such as nicotinic ACh, neuropeptide, dopamine, and opiate receptors, or the benzodiazepine binding site on GABA_A receptors.

Clinical Pharmacology

Prescribing guidelines suggest that an 8-mg tablet be taken about 30 min before bedtime. Ramelteon is rapidly absorbed from the GI tract. Because of the significant first-pass metabolism that occurs after oral administration, ramelteon bioavailability is less than 2%. The drug is largely metabolized by hepatic CYPs 1A2, 2C, and 3A4, with a $t_{1/2}$ of about 2 h in humans. Of the four metabolites, M-II, acts as an agonist at MT₁ and MT₂ receptors and may contribute to the sleep-promoting effects of ramelteon.

Ramelteon is efficacious in combating both transient and chronic insomnia, with no tolerance occurring in its reduction of sleep onset latency even after 6 months of drug administration (Mayer et al., 2009). It is generally well tolerated by patients and does not impair next-day cognitive function. Sleep latency was consistently found to be shorter in patients given ramelteon compared to placebo controls. No evidence of rebound insomnia or withdrawal effects were noted on ramelteon withdrawal. Unlike most agents mentioned in this chapter, ramelteon is not a controlled substance.

Tasimelteon

Tasimelteon is a selective agonist for MT₁ and MT₂ receptors. It has been approved in the U.S. for treatment of non–24-h sleep-wake syndrome in totally blind patients experiencing circadian rhythm disorder (Johnsa and Neville, 2014).

Barbiturates

The barbiturates were once used extensively as sedative-hypnotic drugs. Except for a few specialized uses, they have been largely replaced by the much safer benzodiazepines and Z compounds. Table 19–3 lists the common barbiturates and their pharmacological properties.

Barbiturates are derivatives of this parent structure:

*O except in thiopental, where it is replaced by S.

Barbituric acid is 2,4,6-trioxohexahydropyrimidine. This compound lacks central depressant activity, but the presence of alkyl or aryl groups at position 5 confers sedative-hypnotic and sometimes other activities. Barbiturates in which the oxygen at C2 is replaced by sulfur are called *thiobarbiturates*. These compounds are more lipid soluble than the corresponding *oxybarbiturates*. In general, structural changes that increase lipid solubility decrease duration of action, decrease latency to onset of activity, accelerate metabolic degradation, and increase hypnotic potency.

Pharmacological Properties

The barbiturates reversibly depress the activity of all excitable tissues. The CNS is particularly sensitive, and even when barbiturates are given

TABLE 19-3 ■ THERAPEUTIC USES OF BARBITURATES

COMPOUND	ROUTES OF ADMINISTRATION	THERAPEUTIC USES	COMMENTS	$t_{1/2}$ (h)
Amobarbital	IM, IV	Insomnia, preoperative sedation, emergency management of seizures	Only Na ⁺ salt for injection is sold in the U.S.	10–40
Butobarbital	Oral	Insomnia, preoperative sedation, daytime sedation	Redistribution shortens duration of action of single dose to 8 h	35–50
Mephobarbital (not licensed for use in the U.S.)	Oral	Seizure disorders, daytime sedation	Second-line anticonvulsant	10–70
Methohexital	IV	Induction and maintenance of anesthesia	Only Na ⁺ salt available; single dose provides 5–7 min of anesthesia	3–5
Pentobarbital	Oral, IM, IV, rectal (only injectable form is marketed in the U.S.)	Insomnia, preoperative and procedural sedation, emergency management of seizures	Administer only Na ⁺ salt parenterally	15–50
Phenobarbital	Oral, IM, IV	Seizure disorders, status epilepticus, daytime sedation (hyperbilirubinemia, OL use)	First-line anticonvulsant; only Na ⁺ salt administered parenterally	80–120
Secobarbital	Oral	Insomnia, preoperative sedation	Only Na ⁺ salt available	15–40
Thiopental (not currently produced or marketed in the U.S.)	IV	Induction/maintenance of anesthesia, preoperative sedation, emergency management of seizures, intracranial pressure	Only Na ⁺ salt available; single dose provides brief period of anesthesia	8–10 ($t_{1/2}$ of anesthetic effects is short due to redistribution; see Figures 2–4 and 21–2)

in anesthetic concentrations, direct effects on peripheral excitable tissues are weak. However, serious deficits in cardiovascular and other peripheral functions occur in acute barbiturate intoxication.

ADME

For sedative-hypnotic use, the barbiturates usually are administered orally (see Table 19–2). Na⁺ salts are absorbed more rapidly than the corresponding free acids, especially from liquid formulations. The onset of action varies from 10 to 60 min and is delayed by the presence of food. Intramuscular injections of solutions of the Na⁺ salts should be placed deeply into large muscles to avoid the pain and possible necrosis that can result at more superficial sites. The intravenous route usually is reserved for the management of status epilepticus (phenobarbital sodium) or for the induction or maintenance of general anesthesia (e.g., thiopental or methohexital).

Barbiturates distribute widely in the body and readily cross the placenta. The highly lipid-soluble barbiturates such as *thiopental* and *methohexital*, used to induce anesthesia, undergo rapid redistribution after intravenous injection. Redistribution into less-vascular tissues, especially muscle and fat, leads to a decline in the concentration of barbiturate in the plasma and brain. With thiopental and methohexital, this results in the awakening of patients within 5–15 min of the injection of the usual anesthetic doses (see Figures 2–4 and 21–2).

Except for the less lipid-soluble *aprobarbital* and *phenobarbital*, nearly complete metabolism or conjugation of barbiturates in the liver precedes their renal excretion. The oxidation of radicals at C5 is the most important biotransformation that terminates biological activity. In some instances (e.g., phenobarbital), *N*-glycosylation is an important metabolic pathway. Other biotransformations include *N*-hydroxylation, desulfuration of thiobarbiturates to oxybarbiturates, opening of the barbituric acid ring, and *N*-dealkylation of *N*-alkyl barbiturates to active metabolites (e.g., mephobarbital to phenobarbital). About 25% of phenobarbital and nearly all of aprobarbital are excreted unchanged in the urine. Their renal excretion can be increased greatly by osmotic diuresis or alkalinization of the urine.

The metabolic elimination of barbiturates is more rapid in young people than in the elderly and infants, and half-lives are increased during

pregnancy partly because of the expanded volume of distribution. Chronic liver disease, especially cirrhosis, often increases the $t_{1/2}$ of the biotransformable barbiturates. Repeated administration, especially of phenobarbital, shortens the $t_{1/2}$ of barbiturates that are metabolized as a result of the induction of microsomal enzymes.

The barbiturates commonly used as hypnotics in the U.S. have $t_{1/2}$ values such that the drugs are not fully eliminated in 24 h (see Table 19–3). Thus, these barbiturates will accumulate during repeated administration unless appropriate adjustments in dosage are made. Furthermore, the persistence of the drug in plasma during the day favors the development of tolerance and abuse.

CNS Effects

Actions on the GABA_A Receptor

Enhancement of inhibition occurs primarily at synapses where neurotransmission is mediated by GABA acting at GABA_A receptors. Barbiturates bind to a distinct allosteric site on the GABA_A receptor (Figure 14–11); binding leads to an increase in the mean open time of the GABA-activated Cl[−] channel, with no effect on frequency. At higher concentrations, barbiturates directly activate channel opening, even in the absence of GABA (Nestler et al., 2015). Barbiturates also reportedly inhibit excitatory AMPA/kainate receptors (Marszalec and Narahashi, 1993) and inhibit glutamate release via an effect on voltage-activated Ca²⁺ channels. These multiple actions, especially the direct gating effect on the GABA_A channel, may explain the potent CNS depressant effects of barbiturates as compared to benzodiazepines.

Effects in the CNS

Barbiturates enhance GABA-mediated inhibitory transmission throughout the CNS; nonanesthetic doses preferentially suppress polysynaptic responses. Facilitation is diminished, and inhibition usually is enhanced. The site of inhibition is either postsynaptic, as at *cortical and cerebellar pyramidal cells* and in the *cuneate nucleus, substantia nigra*, and *thalamic relay neurons*, or presynaptic, as in the *spinal cord*.

Barbiturates can produce all degrees of depression of the CNS, ranging from mild sedation to general anesthesia (see Chapter 21).

Certain barbiturates, particularly those containing a 5-phenyl substituent (e.g., phenobarbital and mephobarbital), have selective anticonvulsant activity (see Chapter 17). The antianxiety properties of the barbiturates are inferior to those exerted by the benzodiazepines.

Except for the anticonvulsant activities of phenobarbital and its congeners, the barbiturates possess a low degree of selectivity and a low therapeutic index. Pain perception and reaction are relatively unimpaired until the moment of unconsciousness, and in small doses, barbiturates increase reactions to painful stimuli. Hence, they cannot be relied on to produce sedation or sleep in the presence of even moderate pain.

Effects on Stages of Sleep

Hypnotic doses of barbiturates increase the total sleep time and alter the stages of sleep in a dose-dependent manner. Like the benzodiazepines, barbiturates decrease sleep latency, the number of awakenings, and the durations of REM and slow-wave sleep. During repetitive nightly administration, some tolerance to the effects on sleep occurs within a few days, and the effect on total sleep time may be reduced by as much as 50% after 2 weeks of use. Discontinuation leads to rebound increases in all the sleep parameters initially decreased by barbiturates.

Tolerance, Abuse, and Dependence

With chronic administration of gradually increasing doses, pharmacodynamic tolerance continues to develop over a period of weeks to months, depending on the dosage schedule, whereas pharmacokinetic tolerance reaches its peak in a few days to a week. Tolerance to the euphoric, sedative, and hypnotic effects occurs more readily and is greater than that to the anticonvulsant and lethal effects; thus, as tolerance increases, the therapeutic index decreases. Pharmacodynamic tolerance to barbiturates confers cross-tolerance to all general CNS depressant drugs, including ethanol. Like other CNS depressant drugs, barbiturates are abused, and some individuals develop physical dependence (see Chapter 24).

Effects on Peripheral Nerve Structures

Barbiturates selectively depress transmission in autonomic ganglia and reduce nicotinic excitation by choline esters. This effect may account, at least in part, for the fall in blood pressure produced by intravenous oxybarbiturates and by severe barbiturate intoxication. At skeletal neuromuscular junctions, the blocking effects of both *tubocurarine* and *decamethonium* are enhanced during barbiturate anesthesia. These actions probably result from the capacity of barbiturates at hypnotic or anesthetic concentrations to inhibit current flow through nicotinic ACh receptors. Several distinct mechanisms appear to be involved, and little stereoselectivity is evident.

Systemic Effects

Respiration

Barbiturates depress both the respiratory drive and the mechanisms responsible for the rhythmic character of respiration. The neurogenic drive is essentially eliminated by a dose three times greater than that used normally to induce sleep. Such doses also suppress the hypoxic drive and, to a lesser extent, the chemoreceptor drive. However, the margin between the lighter planes of surgical anesthesia and dangerous respiratory depression is sufficient to permit the ultrashort-acting barbiturates to be used, with suitable precautions, as anesthetic agents.

The barbiturates only slightly depress protective reflexes until the degree of intoxication is sufficient to produce severe respiratory depression. Coughing, sneezing, hiccoughing, and laryngospasm may occur when barbiturates are employed as intravenous anesthetic agents.

Cardiovascular System

When given orally in sedative or hypnotic doses, barbiturates do not produce significant overt cardiovascular effects. In general, the effects of thiopental anesthesia on the cardiovascular system are benign in comparison with those of the volatile anesthetic agents; there usually is either no change or a fall in mean arterial pressure (see Chapter 21). Barbiturates can blunt cardiovascular reflexes by partial inhibition of ganglionic transmission, most evident in patients with congestive heart failure

or hypovolemic shock. Because barbiturates also impair reflex cardiovascular adjustments to inflation of the lung, positive-pressure respiration should be used cautiously and only when necessary to maintain adequate pulmonary ventilation in patients who are anesthetized or intoxicated with a barbiturate.

Other cardiovascular changes often noted when thiopental and other intravenous thiobarbiturates are administered after conventional preanesthetic medication include decreased renal and cerebral blood flow with a marked fall in CSF pressure. Although cardiac arrhythmias are observed only infrequently, intravenous anesthesia with barbiturates can increase the incidence of ventricular arrhythmias, especially when epinephrine and halothane also are present. Anesthetic concentrations of barbiturates depress the function of Na⁺ channels and at least two types of K⁺ channels. However, direct depression of cardiac contractility occurs only when doses several times those required to cause anesthesia are administered.

GI Tract

The oxybarbiturates tend to decrease the tone of the GI musculature and the amplitude of rhythmic contractions; the locus of action is partly peripheral and partly central. A hypnotic dose does not significantly delay gastric emptying in humans. The relief of various GI symptoms by sedative doses is probably largely due to the central depressant action.

Liver

The effects vary with the duration of exposure to the barbiturate. *Acutely*, the barbiturates interact with several CYPs and inhibit the biotransformation of a number of other drugs and endogenous substrates, such as steroids; other substrates may reciprocally inhibit barbiturate biotransformations (see Chapter 6).

Chronic administration of barbiturates markedly increases the protein and lipid content of the hepatic smooth endoplasmic reticulum, as well as the activities of glucuronyl transferase and CYPs 1A2, 2C9, 2C19, and 3A4. The induction of these enzymes increases the metabolism of a number of drugs (including barbiturates) and endogenous substances, including steroid hormones, cholesterol, bile salts, and vitamins K and D. The self-induced increase in barbiturate metabolism partly accounts for tolerance to barbiturates. The inducing effect is not limited to the microsomal enzymes; for example, there are increases in ALA synthetase, a mitochondrial enzyme, and aldehyde dehydrogenase, a cytosolic enzyme. The effect of barbiturates on ALA synthetase can cause dangerous disease exacerbations in persons with intermittent porphyria.

Kidney

Severe oliguria or anuria may occur in acute barbiturate poisoning largely as a result of the marked hypotension.

Therapeutic Uses

The major uses of individual barbiturates are listed in Table 19–3. As with the benzodiazepines, the selection of a particular barbiturate for a given therapeutic indication is based primarily on pharmacokinetic considerations. Benzodiazepines and other compounds have largely replaced barbiturates as sedatives.

Untoward Effects

Aftereffects

Drowsiness may last for only a few hours after a hypnotic dose of barbiturate, but residual CNS depression sometimes is evident the following day, and subtle distortions of mood and impairment of judgment and fine motor skills may be demonstrable. Residual effects also may take the form of vertigo, nausea, vomiting, or diarrhea or sometimes may be manifested as overt excitement.

Paradoxical Excitement

In some persons, barbiturates produce excitement rather than depression, and the patient may appear to be inebriated. This type of idiosyncrasy is relatively common among geriatric and debilitated patients and occurs most frequently with phenobarbital and *N*-methylbarbiturates.

Barbiturates may cause restlessness, excitement, and even delirium when given in the presence of pain and may worsen a patient's perception of pain.

Hypersensitivity

Allergic reactions occur, especially in persons with asthma, urticaria, angioedema, or similar conditions. Hypersensitivity reactions include localized swellings, particularly of the eyelids, cheeks, or lips, and erythematous dermatitis. Rarely, exfoliative dermatitis may be caused by phenobarbital and can prove fatal; the skin eruption may be associated with fever, delirium, and marked degenerative changes in the liver and other parenchymatous organs.

Other

Because barbiturates enhance porphyrin synthesis, they are absolutely contraindicated in patients with acute intermittent porphyria or porphyria variegata. Hypnotic doses in the presence of pulmonary insufficiency are contraindicated. Rapid intravenous injection of a barbiturate may cause cardiovascular collapse before anesthesia ensues. Blood pressure can fall to shock levels; even slow intravenous injection of barbiturates often produces apnea and occasionally laryngospasm, coughing, and other respiratory difficulties.

Drug Interactions

Barbiturates combine with other CNS depressants to cause severe depression; interactions with ethanol and with first-generation antihistamines are common. Isoniazid, methylphenidate, and monoamine oxidase inhibitors also increase the CNS depressant effects of barbiturates.

Barbiturates competitively inhibit the metabolism of certain other drugs; however, the greatest number of drug interactions results from induction of hepatic CYPs (as described previously) and the accelerated disappearance of many drugs and endogenous substances from the body. Hepatic enzyme induction enhances metabolism of endogenous steroid hormones, which may cause endocrine disturbances, and enhances metabolism of oral contraceptives, which may increase the likelihood of unwanted pregnancy. Barbiturates also induce the hepatic generation of toxic metabolites of chlorocarbons (chloroform, trichloroethylene, carbon tetrachloride) and consequently promote lipid peroxidation, which facilitates periportal necrosis of the liver caused by these agents.

Barbiturate Poisoning

The incidence of barbiturate poisoning has declined markedly, largely as a result of their decreased use as sedative-hypnotic agents. Most of the cases are the result of attempts at suicide, but some are from accidental poisonings in children or drug abusers. The lethal dose of barbiturate varies, but severe poisoning is likely to occur when more than 10 times the full hypnotic dose has been ingested at once. The lethal dose becomes lower if alcohol or other depressant drugs are present. In severe intoxication, the patient is comatose; respiration is affected early. Breathing may be either slow or rapid and shallow. Eventually, blood pressure falls because the effect of the drug and of hypoxia on medullary vasomotor centers; depression of cardiac contractility and sympathetic ganglia also contributes. Pulmonary complications (e.g., atelectasis, edema, and bronchopneumonia) and renal failure are likely to be the fatal complications of severe barbiturate poisoning.

The treatment of acute barbiturate intoxication is based on general supportive measures, which are applicable in most respects to poisoning by any CNS depressant. The use of CNS stimulants is contraindicated. If renal and cardiac functions are satisfactory and the patient is hydrated, forced diuresis and alkalinization of the urine will hasten the excretion of phenobarbital. See Chapter 4, Drug Toxicity and Poisoning.

Miscellaneous Sedative-Hypnotic Drugs

Many drugs with diverse structures have been used for their sedative-hypnotic properties, including *ramelteon*, *chloral hydrate*, *meprobamate*, and *paraldehyde* (no longer licensed in the U.S.). With the exception of

ramelteon and *meprobamate*, the pharmacological actions of these drugs generally resemble those of the barbiturates:

- They all are general CNS depressants that can produce profound hypnosis with little or no analgesia.
- Their effects on the stages of sleep are similar to those of the barbiturates.
- Their therapeutic indices are low, and acute intoxication, which produces respiratory depression and hypotension, is managed similarly to barbiturate poisoning.
- Their chronic use can result in tolerance and physical dependence.
- The syndrome after chronic use can be severe and life threatening.

Chloral Hydrate

Chloral hydrate may be used to treat patients with paradoxical reactions to benzodiazepines. Chloral hydrate is reduced rapidly to the active compound trichloroethanol ($\text{CCl}_3\text{CH}_2\text{OH}$), largely by hepatic alcohol dehydrogenase. Its pharmacological effects probably are caused by trichloroethanol, which can exert barbiturate-like effects on GABA_A receptor channels in vitro. Chloral hydrate is regulated as a schedule IV controlled substance.

In the U.S., chloral hydrate is best known as a literary poison, the “knockout drops” added to a strong alcoholic beverage to produce a “Mickey Finn” or “Mickey,” a cocktail given to an unwitting imbibitor to render the person malleable or unconscious, most famously Sam Spade in Dashiell Hammett's 1930 novel, *The Maltese Falcon*. Now that detectives drink wine rather than whiskey, this off-label use of chloral hydrate has waned.

Meprobamate

Meprobamate, a *bis*-carbamate ester, was introduced as an antianxiety agent, and this remains its only approved use in the U.S. However, it also became popular as a sedative-hypnotic agent. The pharmacological properties of meprobamate resemble those of the benzodiazepines in a number of ways. Meprobamate can release suppressed behaviors in experimental animals at doses that cause little impairment of locomotor activity, and although it can cause CNS depression, it cannot produce anesthesia. Large doses of meprobamate cause severe respiratory depression, hypotension, shock, and heart failure. Meprobamate appears to have a mild analgesic effect in patients with musculoskeletal pain, and it enhances the analgesic effects of other drugs.

Meprobamate is well absorbed when administered orally. Nevertheless, an important aspect of intoxication with meprobamate is the formation of gastric bezoars consisting of undissolved meprobamate tablets; treatment may require endoscopy, with mechanical removal of the bezoar. Most of the drug is metabolized in the liver by side-chain hydroxylation and glucuronidation; the kinetics of elimination may depend on dose. The $t_{1/2}$ of meprobamate may be prolonged during its chronic administration. The major unwanted effects of the usual sedative doses of meprobamate are drowsiness and ataxia; larger doses impair learning and motor coordination and prolong reaction time. Meprobamate enhances the CNS depression produced by other drugs. After long-term medication, abrupt discontinuation evokes a withdrawal syndrome usually characterized by anxiety, insomnia, tremors, and, frequently, hallucinations; generalized seizures occur in about 10% of cases.

Carisoprodol, a skeletal muscle relaxant whose active metabolite is meprobamate, also has abuse potential and has become a popular “street drug.” Meprobamate and *carisoprodol* are designated as schedule IV controlled substances.

Other Agents

Etomidate is used in the U.S. and other countries as an intravenous anesthetic, often in combination with fentanyl. It is advantageous because it lacks pulmonary and vascular depressant activity, although it has a negative inotropic effect on the heart. Its pharmacology and anesthetic uses are described in Chapter 21.

Clomethiazole has sedative, muscle relaxant, and anticonvulsant properties. Given alone, its effects on respiration are slight, and the therapeutic

index is high. However, deaths from adverse interactions with ethanol are relatively frequent.

Propofol is a rapidly acting and highly lipophilic diisopropylphenol used in the induction and maintenance of general anesthesia (see Chapter 21), as well as in the maintenance of long-term sedation. Propofol has found use in intensive care sedation in adults (McKeage and Perry, 2003), for sedation during GI endoscopy procedures, and during transvaginal oocyte retrieval.

Nonprescription Hypnotic Drugs

The antihistamines *diphenhydramine* and *doxylamine* are FDA-approved as ingredients in OTC nonprescription sleep aids. With elimination $t_{1/2}$ of about 9–10 h, these antihistamines can be associated with prominent residual sleepiness the morning after when taken as a sleep aid the night before.

New and Emerging Agents

Suvorexant

Suvorexant, an inhibitor of orexin 1 and 2 receptors, was approved by the FDA in late 2014 for the treatment of insomnia (Winrow and Renger, 2014). Orexins, produced by neurons in the lateral hypothalamus and projecting broadly throughout the CNS, play a major role in regulation of the sleep cycle. These neurons are quiescent during sleep but are active during wakefulness; thus, orexins promote wakefulness, while antagonists at orexin receptors enhance REM and non-REM sleep. Suvorexant decreases sleep onset latency and is superior to placebo in sleep maintenance. One 10-mg dose should be taken within 30 min of going to bed if at least 7 h remain until the projected time of awakening. The most common adverse reaction is daytime somnolence, and there is a possibility of the worsening of depression or suicidal ideation. Suvorexant is a schedule IV controlled substance. A number of other orexin receptor antagonists are currently in clinical trials.

Doxepin

Doxepin, a tricyclic antidepressant, enhances subjective measures of sleep quality and is indicated for the treatment of difficulties with sleep maintenance (Yeung et al., 2015). It acts presumably via antagonism of H_1 receptor function when administered in low doses. Doxepin should be taken in initial doses of 6 mg (3 mg in the elderly) within 30 min of bedtime. Abnormal thinking and behavior have been observed following its use, and it can worsen suicidal ideation and depression. Doxepin was approved by the FDA in 2010 for the treatment of sleep maintenance insomnia.

Pregabalin

Pregabalin, an anxiolytic agent that binds to Ca^{2+} channel $\alpha_2\delta$ subunits, has proved useful in clinical trials (Holsboer-Trachsler and Prieto, 2013); pregabalin slightly decreased sleep onset latency and increased the proportion of time spent in slow-wave sleep. Pregabalin appears to be an effective treatment of the insomnia seen in patients suffering from a generalized anxiety disorder. Pregabalin is designated as a schedule V controlled substance.

Ritanserin

Ritanserin and other $5HT_{2A/2C}$ receptor antagonists show an ability to promote slow-wave sleep in patients with chronic primary insomnia or generalized anxiety disorder (Monti, 2010). Ritanserin is not licensed for use in the U.S.

Agomelatine

Agomelatine, a melatonin receptor agonist and a $5HT_{2C}$ receptor antagonist, is prescribed for the treatment of depression and may aid in ameliorating sleep disturbances often associated with depression. Agomelatine is not licensed for use in the U.S.

Management of Insomnia

Insomnia is one of the most common complaints in general medical practice. A number of pharmacological agents are available for the treatment of insomnia. The “perfect” hypnotic would allow sleep to occur with normal sleep architecture. It would not cause next-day effects, either of rebound anxiety or of continued sedation. It would not interact with other medications. It could be used chronically without causing dependence or rebound insomnia on discontinuation. Controversy in the management of insomnia revolves around two issues:

- Pharmacological versus nonpharmacological treatment
- Use of short-acting versus long-acting hypnotics

The side effects of hypnotic medications must be weighed against the sequelae of chronic insomnia, which include a 4-fold increase in serious accidents (Balter and Uhlenhuth, 1992). Regular moderate exercise or even small amounts of exercise often are effective in promoting sleep. In addition to appropriate pharmacological treatment, the management of insomnia should correct identifiable causes, address inadequate sleep hygiene, eliminate performance anxiety related to falling asleep, provide entrainment of the biological clock so that maximum sleepiness occurs at the hour of attempted sleep, and suppress the use of alcohol and OTC sleep medications.

Categories of Insomnia

- *Transient insomnia* lasts less than 3 days and usually is caused by a brief environmental or situational stressor. If hypnotics are prescribed, they should be used at the lowest dose and for only 2–3 nights. Note that benzodiazepines given acutely before important life events, such as examinations, may result in impaired performance.
- *Short-term insomnia* lasts from 3 days to 3 weeks and usually is caused by a personal stressor such as illness, grief, or job problems. Hypnotics may be used adjunctively for 7–10 nights and are best used intermittently during this time, with the patient skipping a dose after 1–2 nights of good sleep.
- *Long-term insomnia* lasts for more than 3 weeks; a specific stressor may not be identifiable.

Insomnia Accompanying Major Psychiatric Illnesses

The insomnia caused by major psychiatric illnesses often responds to specific pharmacological treatment of that illness. For example, in major depressive episodes with insomnia, SSRIs, which may cause insomnia as a side effect, usually will result in improved sleep because they treat the depressive syndrome. In a patient whose depression is responding to an SSRI but has persistent insomnia as a side effect of the medication, judicious use of evening trazodone may improve sleep, as well as augment the antidepressant effect of the reuptake inhibitor. However, the patient should be monitored for priapism, orthostatic hypotension, and arrhythmias.

Adequate control of anxiety disorders often produces adequate resolution of the accompanying insomnia. Sedative use in patients with anxiety disorders is decreasing because of a growing appreciation of the effectiveness of other agents, such as β adrenergic receptor antagonists (Chapter 12) for performance anxiety and SSRIs for obsessive-compulsive disorder and perhaps generalized anxiety disorder. The profound insomnia in patients with acute psychosis owing to schizophrenia or mania usually responds to dopamine receptor antagonists (see Chapters 13 and 16). Benzodiazepines often are used adjunctively in this situation to reduce agitation and improve sleep.

Insomnia Accompanying Other Medical Illnesses

For long-term insomnia owing to other medical illnesses, adequate treatment of the underlying disorder, such as congestive heart failure, asthma, or COPD, may resolve the insomnia. Adequate pain management in conditions of chronic pain will treat both the pain and the insomnia and may make hypnotics unnecessary. *Adequate attention to sleep hygiene, including*

reduced caffeine intake, avoidance of alcohol, adequate exercise, and regular sleep and wake times, often will reduce the insomnia.

Conditioned (Learned) Insomnia

In those who have no major psychiatric or other medical illness and in whom attention to sleep hygiene is ineffective, attention should be directed to conditioned (learned) insomnia. These patients have associated the bedroom with activities consistent with wakefulness rather than sleep. In such patients, all other activities associated with waking, even such quiescent activities as reading and watching television, should be done outside the bedroom.

Sleep-State Misperception

Some patients complain of poor sleep but have been shown to have no objective polysomnographic evidence of insomnia. They are difficult to treat.

Long-Term Insomnia

Nonpharmacological treatments are important for all patients with long-term insomnia. These include education about sleep hygiene, relaxation training, and behavioral modification approaches, such as sleep restriction and stimulus-control therapies.

Long-term hypnotic use leads to a decrease in effectiveness and may produce rebound insomnia on discontinuance. Almost all hypnotics change sleep architecture. The barbiturates reduce REM sleep; the benzodiazepines reduce slow-wave non-REM sleep and, to a lesser extent, REM sleep. While the significance of these findings is not clear, there is an emerging consensus that slow-wave sleep is particularly important for physical restorative processes. REM sleep may aid in the consolidation of learning. The blockade of slow-wave sleep by benzodiazepines may partly account for their diminishing effectiveness over the long term, and it also may explain their effectiveness in blocking sleep terrors, a disorder of arousal from slow-wave sleep.

Long-acting benzodiazepines can cause next-day confusion, whereas shorter-acting agents can produce rebound next-day anxiety. Paradoxically, the acute amnestic effects of benzodiazepines may be responsible for the patient's subsequent report of restful sleep. Anterograde amnesia may be more common with triazolam. Hypnotics should not be given to patients with sleep apnea, especially the obstructive type, because these agents decrease upper airway muscle tone while also decreasing the arousal response to hypoxia.

Insomnia in Older Patients

The elderly, like the very young, tend to sleep in a *polyphasic* (multiple sleep episodes per day) pattern rather than the *monophasic* pattern

characteristic of younger adults. This pattern makes assessment of adequate sleep time difficult.

Changes in the pharmacokinetic profiles of hypnotic agents occur in the elderly because of reduced body water, reduced renal function, and increased body fat, leading to a longer $t_{1/2}$ for benzodiazepines. A dose that produces pleasant sleep and adequate daytime wakefulness during week 1 may produce daytime confusion and amnesia by week 3 as the drug level continues to rise, particularly with long-acting hypnotics. For example, the benzodiazepine diazepam is highly lipid soluble and is excreted by the kidney. Because of the increase in body fat and the decrease in renal excretion that typically occur from age 20 to 80, the $t_{1/2}$ of the drug may increase 4-fold over this span.

Injudicious use of hypnotics in the elderly can produce daytime cognitive impairment and thereby impair overall quality of life. Once an older patient has been taking benzodiazepines for an extended period, whether for daytime anxiety or for nighttime sedation, terminating the drug can be a long, involved process. Attempts at drug withdrawal may not be successful, and it may be necessary to leave the patient on the medication, with adequate attention to daytime side effects.

Prescribing Guidelines for Managing Insomnia

Hypnotics that act at GABA_A receptors—benzodiazepine hypnotics and the newer agents zolpidem, zopiclone, and zaleplon—are preferred to barbiturates; the GABA_A receptor agents have a higher therapeutic index, smaller effects on sleep architecture, and less abuse potential. Compounds with a shorter $t_{1/2}$ are favored in patients with sleep-onset insomnia but without significant daytime anxiety who need to function at full effectiveness during the day. These compounds also are appropriate for the elderly because of a decreased risk of falls and respiratory depression. However, the patient and physician should be aware that early morning awakening, rebound daytime anxiety, and amnestic episodes also may occur. These undesirable side effects are more common at higher doses of the benzodiazepines.

Benzodiazepines with longer $t_{1/2}$ values are favored for patients who have significant daytime anxiety. These benzodiazepines also are appropriate for patients receiving treatment of major depressive episodes because the short-acting agents can worsen early morning awakening. However, longer-acting benzodiazepines can be associated with next-day cognitive impairment or delayed daytime cognitive impairment (after 2–4 weeks of treatment) as a result of drug accumulation with repeated administration.

Older agents—barbiturates, chloral hydrate, and meprobamate—should be avoided for the management of insomnia. They have high abuse potential and are dangerous in overdose.

Drug Facts for Your Personal Formulary: Sedative-Hypnotic Agents

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Benzodiazepines—synergistic with other CNS depressants, esp. ethanol; see Table 19–2.		
Alprazolam	Anxiety disorders, agoraphobia	Withdrawal symptoms may be especially severe
Chlordiazepoxide	Anxiety disorders, alcohol withdrawal, preanesthetic medication	Long-acting and self-tapering because of active metabolites
Clobazam	Adjunctive treatment of seizures associated with Lennox-Gastaut syndrome, other epilepsy and anxiety disorders	Active metabolite has long half-life Decrease dose and titrate in CYP2C19 poor metabolizers Tolerance develops to anticonvulsant effects
Clonazepam	Seizure disorders, adjunctive treatment in acute mania and certain movement disorders	Tolerance develops to anticonvulsant effects
Clorazepate	Anxiety disorders, seizure disorders	Prodrug; activity due to formation of nordazepam during absorption
Diazepam	Anxiety disorders, alcohol withdrawal, status epilepticus, skeletal muscle relaxation, preanesthetic medication	Prototypical benzodiazepine
Estazolam	Insomnia	Contains triazolo ring; adverse effects may be similar to those of triazolam

Drug Facts for Your Personal Formulary: *Sedative-Hypnotic Agents (continued)*

Drug	Therapeutic Uses	Clinical Pharmacology and Tips
Flurazepam	Insomnia	Active metabolites accumulate with chronic use
Lorazepam	Anxiety disorders, alcohol withdrawal, preanesthetic medication	Metabolized solely by conjugation
Midazolam	Preanesthetic and intraoperative medication	Rapidly inactivated
Oxazepam	Anxiety disorders, alcohol withdrawal	Metabolized solely by conjugation
Quazepam	Insomnia	Active metabolites accumulate with chronic use
Temazepam	Insomnia	Metabolized mainly by conjugation
Triazolam	Insomnia	Rapidly inactivated; may cause disturbing daytime side effects
"Z" Compounds-nonbenzodiazepines with agonist effects at the benzodiazepine site of GABA_A receptors; have largely replaced benzodiazepines for treating insomnia.		
Zaleplon	Insomnia	Very short elimination half-life
Zolpidem	Insomnia	Short-term (2–6 week) treatment of insomnia
Eszopiclone	Insomnia	S(+) enantiomer of zopiclone
Benzodiazepine Antagonist		
Flumazenil	Benzodiazepine overdose (benzodiazepine and β -carboline antagonist)	Headache, dizziness; do not use in tricyclic antidepressant poisoning (seizures!)
Miscellaneous and Emerging Agents		
Ramelteon	Insomnia	Melatonin receptor agonist; significant first-pass effect
Tasimelteon	Circadian rhythm disorder in blind patients	Melatonin receptor agonist
Suvorexant	Insomnia	Orexin receptor antagonist; needs at least 7 h after 10-mg dose before awakening
Doxepin	Depression, insomnia	Tricyclic antidepressant; sedating effects likely occur through H ₁ receptor antagonism; beware of abnormal behavior, suicide ideation, depression; use half dose in the elderly
Propofol	Induction/maintenance of anesthesia, procedural sedation	Rapid recovery
Pregabalin (β-isobutyl-GABA)	Nerve/muscle pain, fibromyalgia, seizures	Schedule V substance, abuse potential; some concern for suicide ideation and angioedema
Barbiturates-synergistic with other CNS depressants, esp. ethanol; induce CYPs; respiratory depressants; see Table 19–3.		
Amobarbital	Insomnia, preoperative sedation, emergency management of seizures	<ul style="list-style-type: none"> • IM and IV • Short-acting (3–8 h)
Butobarbital	Insomnia, preoperative sedation, daytime sedation	<ul style="list-style-type: none"> • Oral • Fast onset of action • Short-acting (3–8 h)
Mephobarbital (not licensed for use in U.S.)	Seizure disorders, daytime sedation	<ul style="list-style-type: none"> • Oral • Short-acting (3–8 h)
Methohexital	Induction and maintenance of anesthesia	<ul style="list-style-type: none"> • IV • Ultra short-acting (5–15 min)
Pentobarbital	Insomnia, preoperative and procedural sedation, emergency management of seizures	<ul style="list-style-type: none"> • Oral, IM, IV, or rectal • Administer Na⁺ salt parenterally • Short-acting (3–8 h)
Phenobarbital	Seizure disorders, status epilepticus, daytime sedation	<ul style="list-style-type: none"> • Oral, IM, IV • First-line anticonvulsant (see chapter 17); administer Na⁺ salt parenterally • Long-acting (days)
Secobarbital	Insomnia, preoperative sedation	<ul style="list-style-type: none"> • Oral • Short-acting (3–8 h)
Thiopental	Induction and maintenance of anesthesia, preoperative sedation, emergency management of seizures, intracranial hypertension	<ul style="list-style-type: none"> • IV single dose provides brief period of anesthesia • Ultra short-acting (5–15 min)

Chapter 20

Opioids, Analgesia, and Pain Management

Tony Yaksh and Mark Wallace

PAIN

ENDOGENOUS OPIOID PEPTIDES

- Pro-opiomelanocortin
- Proenkephalin
- Prodynorphin
- Endomorphins

OPIOID RECEPTORS

- Classes of Receptors
- Opioid Receptor Distribution
- Opioid Receptor Ligands
- Opioid Receptor Structure
- Opioid Receptor Signaling
- Regulation of Postactivation Opiate Receptor Trafficking; Biased Opioid Agonism

EFFECTS OF ACUTE AND CHRONIC OPIATE RECEPTOR ACTIVATION

- Desensitization
- Tolerance
- Dependence
- Addiction

MECHANISMS OF TOLERANCE/DEPENDENCE/WITHDRAWAL

- Receptor Disposition
- Adaptation of Intracellular Signaling Mechanisms
- System-Level Counteradaptation
- Differential Tolerance Development and Fractional Occupancy Requirements

EFFECTS OF CLINICALLY USED OPIOIDS

- Analgesia
- Mood Alterations and Rewarding Properties
- Respiratory Effects
- Opioid-Induced Hyperalgesia
- Sedation
- Neuroendocrine Effects

CLINICALLY EMPLOYED OPIOID DRUGS

- Morphine and Structurally Related Agonists
- Other Morphinans
- Piperidine and Phenylpiperidine Analgesics

- Fentanyl and Congeners
- Methadone
- Other Opioid Agonists
- Opioid Partial Agonists
- Opioid Antagonists

CENTRALLY ACTIVE ANTITUSSIVES

- Dextromethorphan
- Other Antitussives

ROUTES OF ANALGESIC DRUG ADMINISTRATION

- Patient-Controlled Analgesia
- Spinal Delivery
- Rectal Administration
- Oral Transmucosal Administration
- Transnasal Administration
- Transdermal Administration

THERAPEUTIC CONSIDERATIONS IN PAIN CONTROL

- Acute Pain States
- Chronic Pain States
- Guidelines for Opiate Dosing

VARIABLES MODIFYING THE THERAPEUTIC USE OF OPIATES

- Patient Variability
- Pain
- Opioid Tolerance
- Patient Physical State and Genetic Variables
- Routes of Administration
- Dose Selection and Titration
- Opioid Rotation
- Combination Therapy

NONANALGESIC THERAPEUTIC USES OF OPIOIDS

- Dyspnea
- Anesthetic Adjuvants

ACUTE OPIOID TOXICITY

- Symptoms and Diagnosis
- Treatment

NOVEL NONOPIOID TREATMENTS FOR PAIN

- Ziconotide

Pain

Pain is a component of virtually all clinical pathologies, and management of pain is a primary clinical imperative. Opioids are a mainstay of acute pain treatment, but in recent years, the efficacy and safety of long-term use of opioids to treat chronic pain has been questioned as instances of addiction and death from their misuse have mounted. Opioids are certainly no longer first-line treatment of chronic pain, and a more conservative approach may involve other drug classes, such as NSAIDs, anticonvulsants, and antidepressants.

The term *opiate* refers to compounds structurally related to products found in opium, a word derived from *opos*, the Greek word for “juice,” natural opiates being derived from the resin of the opium poppy, *Papaver somniferum*. Opiates include the natural plant alkaloids, such as morphine, codeine, thebaine, and many semisynthetic derivatives. An *opioid* is any agent that has the functional and pharmacological properties of an opiate. Endogenous opioids are naturally occurring ligands for opioid receptors found in animals. The term *endorphin* not only is used synonymously with *endogenous opioid peptides* but also refers to a specific endogenous opioid, β -*endorphin*. The term *narcotic* was derived from the

AAG: α_1 -acid glycoprotein
AC: adenylyl cyclase
ACE: angiotensin-converting enzyme
ACh: acetylcholine
ACTH: corticotropin; formerly adrenocorticotrophic hormone
ADH: antidiuretic hormone
ADME: absorption, distribution, metabolism, excretion
AT₁: angiotensin II receptor, type 1
ATC: around the clock
BBB: blood-brain barrier
CaMK: Ca²⁺/calmodulin-dependent protein kinase
CDC: Centers for Disease Control and Prevention
CLIP: corticotropin-like intermediate lobe peptide
CNS: central nervous system
COPD: chronic obstructive pulmonary disease
COX: cyclooxygenase
CRH: corticotropin-releasing hormone
CSF: cerebrospinal fluid
CYP: cytochrome P450
DA: dopamine
DAMGO: [D-Ala², MePhe⁴, Gly(ol)⁵]enkephalin
DHEA: dehydroepiandrosterone
DOR: δ opioid receptor
DYN: dynorphin
EEG: electroencephalogram
 β -END: β -endorphin
L-ENK: Leu-enkephalin
ER/LA: extended-release/long-acting (a)
FDA: Food and Drug Administration
FSH: follicle-stimulating hormone
GABA: γ -aminobutyric acid
GI: gastrointestinal
GIRK: G protein-activated inwardly rectifying K⁺ channel
GnRH: gonadotropin-releasing hormone
GPCR: G protein-coupled receptor
GRK: GPCR kinase
HPA: hypothalamic-pituitary-adrenal
5HT: serotonin
IM: intramuscular
IP₃: inositol triphosphate
IV: intravenous
JNK: c-Jun N-terminal kinase
KOR: κ opioid receptor
LH: luteinizing hormone
LPH: lipotropin
6-MAM: 6-monoacetylmorphine
MAO: monoamine oxidase
MAP: mitogen-activated protein
M-ENK: Met-enkephalin
MME: morphine milligram equivalent
MOR: μ opioid receptor
MSH: melanocyte-stimulating hormone
NAC: nucleus accumbens
NE: norepinephrine
 α -NEO: α neoendorphin
NF- κ B: nuclear factor kappa B
NMDA: N-methyl-D-aspartate
NOP: nociceptin/orphanin FQ (N/OFQ) receptor
NSAID: nonsteroidal anti-inflammatory drug
PAG: periaqueductal gray
PCA: patient-controlled anesthesia

PDMP: prescription drug monitoring program
PFC: prefrontal cortex
PI3K: phosphoinositide 3 kinase
PK: protein kinase
PLC: phospholipase C
POMC: pro-opiomelanocortin
pre-proDYN: pre-prodynorphin
pre-ProENK: pre-proenkephalin
SNRI: serotonin-norepinephrine reuptake inhibitor
SSRI: selective serotonin reuptake inhibitor
TM: transmembrane
VP: ventral pallidum
VTA: ventral tegmental area

Greek word *narkotikos*, for “benumbing” or “stupor.” Although the term *narcotic* originally referred to any drug that induced narcosis or sleep, the word has become associated with opioids and is often used in a legal context to refer to substances with abuse or addictive potential.

Endogenous Opioid Peptides

A biological molecule found within the brain that acts through an opioid receptor is an endogenous opioid. The opioid peptide precursors are a protean family defined by the prohormone from which they are derived (Figure 20-1). Several distinct families of endogenous opioid peptides have been identified: principally the *enkephalins*, *endorphins*, and *dynorphins* (Table 20-1) (Höllt, 1986). These families have several common properties:

- Each derives from a distinct precursor protein, pre-POMC, *pre-proenkephalin*, and *preprodynorphin*, respectively, each encoded by a corresponding gene.
- Each precursor is subject to complex cleavages by distinct trypsin-like enzymes and to a variety of posttranslational modifications resulting in the synthesis of multiple peptides, some of which are active as opioids.
- Most opioid peptides with activity at a receptor share the common amino-terminal sequence of *Tyr-Gly-Gly-Phe-(Met or Leu)*, followed by various C-terminal extensions yielding peptides of 5–31 residues; the endomorphins, with different terminal sequences, are exceptions.
- Not all cells that make a given opioid prohormone precursor store and release the same mixture of opioid peptides; this results from differential post-translational processing secondary to variations in the cellular complement of peptidases that produce and degrade the active opioid fragments.
- Processing of these peptides is altered by physiological demands, leading to the release of a different mix of post-translationally derived peptides by a given cell under different conditions.
- Opioid peptides are found in plasma and reflect release from secretory systems such as the pituitary and the adrenals and thus do not reflect neuraxial release. Conversely, levels of these peptides in brain/spinal cord and in CSF arise from neuraxial systems and not from peripheral systems.

Pro-opiomelanocortin

The major opioid peptide derived from POMC is the *potent opioid agonist β -endorphin*. The POMC sequence also is processed into a variety of nonopioid peptides, including ACTH, α -MSH, and β -LPH. Although β -endorphin contains the sequence for met-enkephalin at its amino terminus, it is not typically converted to this peptide.

Proenkephalin

The *prohormone* contains multiple copies of *met-enkephalin*, as well as a single copy of *leu-enkephalin*. *Proenkephalin peptides* are present in areas of the CNS believed to be related to the processing of pain information (e.g., spinal cord dorsal horn, the spinal trigeminal nucleus, and the PAG); to the modulation of affective behavior (e.g., amygdala, hippocampus,

HISTORICAL PERSPECTIVE

The first undisputed reference to opium is found in the writings of Theophrastus in the 3rd century BC. Arab physicians were well versed in the uses of opium. Arab traders introduced the opium concoction to the Orient, where it was employed mainly for the control of dysentery. Paracelsus named the product laudanum. By 1680, the utility of laudanum was so well appreciated that Thomas Sydenham, a 17th-century pioneer in English medicine noted that, "Among the remedies which it has pleased Almighty God to give to man to relieve his sufferings, none is so universal and so efficacious as opium," thereby, in his own way, connecting religion and opiates almost 200 years ahead of Marx.

Opium contains more than 20 distinct alkaloids. In 1806, Frederick Sertürner, a pharmacist's assistant, reported the isolation by crystallization of a pure substance in opium that he named morphine, after Morpheus, the Greek god of dreams (Booth, 1999). By the middle of the 19th century, the use of pure alkaloids in place of crude opium preparations began to spread throughout the medical world, an event that coincided with the development of the hypodermic syringe and hollow needle, permitting direct delivery of water-soluble formulations "under the skin" into the body.

In addition to the remarkable salutary benefits of opioids, the side effects and addictive potential of these drugs have been known for centuries. In the U.S. Civil War, the administration of "soldier's joy" often led to "soldier's disease," the opiate addiction brought about by medication of chronic pain states arising from war wounds. These problems stimulated a search for potent synthetic opioid analgesics free of addictive potential and other side effects. The early discovery of the synthetic product heroin by C.R. Alder Wright in 1874 was followed by its widespread utilization as a purportedly nonaddictive cough suppressant and sedative. Unfortunately, heroin and all subsequent synthetic opioids that have been introduced into clinical use share the liabilities of classical opioids, including their addictive properties. However, this search for new opioid agonists led to the synthesis of opioid antagonists and compounds with mixed agonist-antagonist properties, which expanded therapeutic options and provided important tools for exploring mechanisms of opioid actions.

Until the early 1970s, the effects of morphine, heroin, and other opioids as antinociceptive and addictive agents were well described, but mechanisms mediating the interaction of the opioid alkaloids with biological systems were unknown. Goldstein began a search for stereoselective binding sites in the CNS using radioligands (Goldstein et al., 1971), and Pert convincingly employed radioligands to demonstrate opiate-binding sites and an effect of Na^+ that distinguished agonist from antagonist binding (Pert et al., 1973). In vivo and in vitro physiological studies of the pharmacology of opiate agonists, their antagonists, and cross-tolerance led to the hypothesis of three separate receptors: mu (μ), kappa (κ), and sigma (σ) (Martin et al., 1976). Efforts to isolate endogenous opioids led to the discovery of the molecules (see discussion that follows) that acted on a distinct receptor, the delta (δ) receptor. The μ , κ , and δ receptors, but not the σ receptor, shared the common property of being sensitive to blockade from agonist by agents such as naloxone. In concert with identification of these opioid receptors, Kostelitz and associates (Hughes et al., 1975) identified an endogenous opiate-like factor that they called *enkephalin* ("from the head"). Soon afterward, two more classes of endogenous opioid peptides were isolated, the endorphins and dynorphins (Akil et al., 1984).

In the early work by Martin, the σ receptor was thought to represent a site that accounted for paradoxical excitatory effects of opiates; this site is now thought to be the phencyclidine-binding site and is not, strictly speaking, an opiate receptor or an opiate site. Thus, three distinct receptors are now the basis of opioid pharmacology. The three-receptor hypothesis has been confirmed by cloning (Waldhoer et al., 2004). In 2000, the Committee on Receptor Nomenclature and Drug Classification of the International Union of Pharmacology adopted the terms MOP, DOP, and KOP receptors (**mu** opioid peptide receptor, etc.). This text uses MOR, DOR, and KOR to refer to both peptide and nonpeptide MORs, DORs, and KORs.

Attempts over at least half a century to dissociate the powerful analgesic effects of opioids from their undesirable effects have failed (Corbett et al., 2006). However, with our advancing understanding of biased agonism, prospects are looking up.

Figure 20-1 Opioid peptide precursors. Opioid peptides derive from precursor proteins that may also contain nonopioid peptides. *Pre-POMC* is a good example. Proteolytic processing of a pre-pro form by a signal peptidase removes the signal peptide; then, various prohormone convertases (endoproteases) attack at dibasic sequences, yielding α -, β -, and γ -MSH, ACTH, CLIP, β - and γ -LPH, and β -END. In similar manners, *Pre-ProENK* yields L-ENK and M-ENK and two relatives of M-ENK, M-ENK-RGL (Arg-Gly-Leu), and M-ENK-RF (Arg-Phe); and *Pre-ProDYN* yields a neoendorphin (α -NEO) and DYN A and DYN B, each of which contains an L-ENK sequence (Tyr-Gly-Gly-Phe-Leu) at its amino terminus. Figure 14–15 shows the processing of pre-POMC in greater detail. JP, joining peptide.

locus ceruleus, and frontal cerebral cortex); to the modulation of motor control (e.g., caudate nucleus and globus pallidus); to the regulation of the autonomic nervous system (e.g., medulla oblongata); and to neuroendocrinological functions (e.g., median eminence). Peptides from proenkephalin also are found in chromaffin cells of the adrenal medulla and in nerve plexuses and exocrine glands of the stomach and intestine. Circulating proenkephalin products are considered to be largely derived from these sites.

Prodynorphin

Prodynorphin contains three peptides of differing lengths that all begin with the leu-enkephalin sequence: *dynorphin A*, *rimorphin* (*dynorphin B*), and *neendorphin*. *Nociceptin peptide* or *orphanin FQ* (now termed *N/OFQ*) shares structural similarity with dynorphin A. The peptides derived from prodynorphin are distributed widely in neurons and to a lesser extent in astrocytes throughout the brain and spinal cord and are frequently found coexpressed with other opioid peptide precursors.

Endomorphins

The endomorphin peptides belong to a novel family of peptides that include *endomorphin 1* (Tyr-Pro-Trp-Phe-NH₂) and *endomorphin 2* (Tyr-Pro-Phe-Phe-NH₂). Endomorphins have an atypical structure and display selectivity toward the MOR.

Opioid Receptors

Classes of Receptors

The three classes of opiate receptors—MOR, DOR, and KOR—share extensive sequence homologies (55%–58%) and belong to the rhodopsin family

of GPCRs (see Figure 3–9). Opioid receptors appear early in vertebrate evolution (Stevens, 2009). Human opiate receptors have been mapped to chromosome 1p355–33 (DOR), chromosome 8q11.23–21 (KOR), and chromosome 6q25–26 (MOR) (Dreborg et al., 2008). Low-stringency hybridization procedures have identified no opioid receptor types other than these three cloned opioid receptors.

An opiate receptor-like protein (ORL₁ or NOP; chromosome 20q13.33) was cloned based on its structural homology (48%–49% identity) to other members of the opioid receptor family; it is G protein coupled, has an endogenous ligand (nociceptin [orphanin FQ]) but does not display an opioid pharmacology. As noted, a sigma (σ) receptor was early identified and was thought to represent a site that accounted for the paradoxical excitatory effects of opiates; agonist binding to the σ receptor is not antagonized by naloxone, and the receptor is not classified as an opiate receptor (Waldhoer et al., 2004).

Opioid Receptor Distribution

As defined by the distribution of receptor protein, message, ligand binding, and the pharmacological effects initiated by opiate molecules, all of the opioid receptors are widely distributed in the periphery and neuraxis on neuronal cell soma and terminals. Less well appreciated is the presence of opioid-binding sites on a variety of nonneuronal cells, including macrophage cell types (peripheral and central microglia) and astrocytes (Dannals, 2013; Yaksh, 1987), and in the enteric nervous system of the GI tract (Galligan and Akbarali, 2014).

Opioid Receptor Ligands

Opioid receptor ligands may be broadly defined by their functional properties as agonists and antagonists at the particular receptor.

Agonists

Highly selective agonists have been developed for the three binding sites (e.g., DAMGO for MOR; DPDPE for DOR; and U-50,488 for KOR) (Table 20–2). Virtually all of the clinically useful agonists are targeted at the μ receptor. Ligands that bind specifically but have limited intrinsic activity are referred to as partial agonists; for MOR, one such ligand is *buprenorphine*.

Antagonists

Commonly used opiate antagonists, such as *naloxone* or *naltrexone*, are pan antagonists with affinity for all known opioid receptors. Antagonists for specific opiate receptors have been developed for research (Table 20-3) and include cyclic analogues of somatostatin, such as CTOP (D-Phe-Cys-Tyr-D-Trp-Orn-Thr-Pen-Thr-NH₂) as an MOR antagonist, a derivative of naloxone called *naltrindole* as a DOR antagonist, and a bivalent derivative of naltrexone called nor-BNI as a KOR antagonist.

Opioid Receptor Structure

Each of the opiate receptors consists of an extracellular N-terminus, seven TM helices, three extra- and intracellular loops, and an intracellular

C-terminus characteristic of the GPCRs (Figure 20-2). The opioid receptors also possess two conserved cysteine residues in the first and second extracellular loops, which form a disulfide bridge. Though there is significant complexity in opiate-receptor interactions (Kane et al., 2006), several general principles define binding and selectivity.

- All opioid receptors display a binding pocket formed by TM₃-TM₇.
- The pocket in the respective receptor is partially covered by the extracellular loops, which, together with the extracellular termini of the TM segments, provide a gate-conferring selectivity, allowing ligands, particularly peptides, to be differentially accessible to the different receptor types. Thus, alkaloids (e.g., morphine) bind in the core of the TM portion of the receptor, whereas large peptidyl ligands bind at the extracellular loops. As noted, it is the extracellular loops that show the greatest structural diversity across receptors.
- Selectivity has been attributed to extracellular loops: first and third for the MOR, second for the KOR, and third for the DOR. Alkaloid antagonists are thought to bind more deeply in the pocket, sterically hindering conformational changes and leading to a functional antagonism.
- In the membrane, opiate receptors can form both homo- and heterodimers, thereby altering the pharmacological properties of the receptors. Thus, the diversity of responses is increased beyond those of the basic MOR, DOR, and KOR monomers.
- Hetero- and homodimerization of opiate receptors and their postactivation trafficking are important in understanding the selectivity of several ligands and the physiological responses to them. The development of tolerance to opioids may involve mechanisms of receptor trafficking.
- Splice variants exist for the opioid receptors. For example, the gene for the human MOR has at least two promoters, multiple exons, with many exons generating at least 11 splice variants that encode multiple morphine-binding isoforms, varying largely at their carboxy termini. This alternative splicing is likely crucial to receptor and response diversity (Pan, 2005; Xu et al., 2017).

Opioid Receptor Signaling

The MOR, DOR, and KOR couple to pertussis toxin-sensitive, G_i/G_o proteins. On receptor activation, the G_i/G_o coupling results in a number

Figure 20-2 General structure of an opioid receptor. This schematic is based on the DOR (Gendron et al., 2016). The receptor has the characteristics of a GPCR: long external amino terminus with glycosylation sites, seven TM regions, a long intracellular carboxy tail, and phosphorylation sites in the areas where arrestins interact (portions of intracellular loop III and the carboxy tail, noted in green). The differential interaction of arrestins 1 and 2 with the phosphorylated sites may be a factor in the differential responses to different agonists (see Figure 20-4). An unusual feature is the extracellular disulfide linkage between Cys¹²¹ and Cys¹⁹⁸. Na⁺ affects receptor constitutive activity and ligand specificity of DOR, effects that have been localized to an allosteric site for Na⁺ in the core of the seven-TM bundle of DOR; changing Asn¹³¹ in the Na⁺ site to Ala or Val alters the effect of naltrindole from DOR antagonist to a β -arrestin-biased agonist. The Na⁺-interacting residues seem to function as an “efficacy switch” (Fenalti et al., 2014).

Figure 20-3 Receptor specificity of endogenous opioids and effects of receptor activation on neurons.

of intracellular events that are mediated by α and $\beta\gamma$ subunits of these G proteins (see Figure 20-3), including the following:

- Inhibition of AC activity
- Reduced opening of voltage-gated Ca^{2+} channels (reduces neurotransmitter release from presynaptic terminals)
- Stimulation of K^+ current through several channels, including GIRKs (hyperpolarizes and inhibits postsynaptic neurons)
- Activation of PKC and PLC β (Shang and Filizola, 2015)

Regulation of Postactivation Opiate Receptor Trafficking; Biased Opioid Agonism

The MORs and DORs undergo rapid agonist-mediated internalization. MORs recycle to the membrane after internalization; DORs are degraded on internalization (Zhang et al., 2015). KORs do not internalize after prolonged agonist exposure (Williams et al., 2013).

Internalization of the MORs and DORs apparently occurs via partially distinct endocytic pathways, suggesting receptor-specific interactions with different mediators of intracellular trafficking. These processes may be induced differentially as a function of the structure of the ligand. For example, certain agonists, such as etorphine and enkephalins, cause rapid internalization of the receptor, whereas morphine does not cause MOR internalization, even though it decreases AC activity equally well. In addition, a truncated receptor with normal G protein coupling recycles constitutively from the membrane to the cytosol, suggesting that activation of signal transduction and internalization are controlled by distinct molecular mechanisms (von Zastrow et al., 2003). These studies support the assertion that different ligands induce different conformational changes in the receptor that result in divergent intracellular signaling, and they

may provide an explanation for differences in the spectrum of effects of various opioids and point to novel therapeutics (Violin et al., 2014). Figure 20-4 shows some of the receptor-effector-signaling pathways that may contribute to biased opioid agonism and the complexity of immediate and long-term responses (desensitization, tolerance, dependence, withdrawal).

As noted, more than a single type of opioid receptor may be expressed on a cell. Functional data suggest opioid receptors may interact, forming homo- and heterodimers, and that such complexes may alter receptor signaling and trafficking and contribute to tolerance to morphine and possibly to disease states (Massotte, 2015; Zhang et al., 2015). The intracellular loops and amino tail of opioid receptors have numerous known and potential sites of phosphorylation by several cellular protein kinases that can alter the receptor's signaling and interaction with intracellular scaffolds and signaling pathways (Figures 20-2 and 20-4).

Effects of Acute and Chronic Opiate Receptor Activation

In addition to the intended relief from pain, agonist occupancy of opiate receptors over both short- and long-term intervals leads to the loss of effect, with distinguishable properties relating to the development of tolerance and dependence.

Desensitization

In the face of a transient activation (minutes to hours), acute tolerance or desensitization occurs that is specific for that receptor and disappears with a time course parallel to the clearance of the agonist. Short-term desensitization probably involves phosphorylation of the receptors resulting in

A. Cell signaling pathways that may be differentially regulated opioid agonists. Responses to opioid agonists may be biased toward β -arrestin signaling or toward G-protein signaling. ERK1/2 may be activated by either pathway, but possibly in distinct subcellular compartments with different sequelae. Activation of PI3K and PLC β may lead to activation of additional protein kinases with numerous downstream effects. In addition to initiating signaling (e.g., ERK1/2), β -arrestins interact with phosphorylated receptors with consequences for desensitization and receptor trafficking. The differentiated state of the responding cell can affect what responses are possible, as can the properties of the agonist. Panel B shows some of the variables that can contribute to biased signaling in response to mu opioid agonists.

B. Putative factors affecting the variable consequences of MOR activation. The panoply of interactions that result from ligand binding to MOR is complex. As a consequence, biased activation of MOR may differentially affect multiple downstream pathways. A few possibilities are shown here, noted by number on the figure:

1. *Mu* agonists bind to MOR, a membrane GPCR. Biased responses could result from agonist preference for one of several forms of MOR that may result from alternative splicing. Biased responses could also result from interactions of *mu* agonists with MOR that stabilize conformations of the receptor that are agonist-specific and differ in their capacity to produce sequelae. In response to agonist, MOR interacts with a G-protein and is subject to phosphorylation, events that may also reflect a receptor isoform and the particular conformation stabilized by the agonist.
2. MOR has over a dozen phosphorylation sites accessible to various protein kinases. The pattern of phosphorylation may be determined by the receptor conformation that the agonist induces, mobilizing distinct protein kinases (e.g., GRKs, PKC, ERK1/2, CaMKII), or the receptor may fail to be phosphorylated. These protein kinases exist in multiple isoforms, lending additional variability/selectivity to the process. There are seven GRK isoforms (not uniformly expressed in all cells), and GRK-mediated phosphorylation may also be specific to agonist and receptor form (i.e., dependent on agonist-induced receptor conformation and heterogeneities [splice variants] in receptor structure).
3. MOR phosphorylation, largely by GRKs, facilitates β -arrestin binding, promotes uncoupling of MOR from G-proteins, and affects desensitization, receptor trafficking, and possibly tolerance. Two isoforms of β -arrestin can interact with phospho-MOR. These interactions appear to be agonist-specific (see **Panel C**). Interaction of phospho-MOR with β -arrestins initiates processes of receptor desensitization, internalization, and recycling. There is a strong correlation between MOR phosphorylation, recruitment of β -arrestin 2, and MOR internalization. The β -arrestin/phospho-MOR complex is recognized by clathrin. Phospho-MOR can be internalized to different fates depending on its participation in a clathrin-dependent or a clathrin-independent process.
4. The phospho-MOR/ β -arrestin complexes can initiate cell signaling independently of G-proteins.
5. Agonist-liganded MOR interacts with the $G_{i/o}$ family to alter cell signaling pathways. The components of $G_{i/o}$ provide large possibilities for diversity of signaling (four α subunits; five β and twelve γ isoforms) and regulate proteins in the membrane and in various subcellular compartments (Khan et al, 2013).
6. Agonist-specific homo- and hetero-dimerization of receptor and its interaction with other proteins may also play roles in biased agonism.

Thus, a variety of ultimate responses are possible following the binding of a mu agonist to MOR. **Panel C** gives two examples.

Figure 20–4 (Continued).

an uncoupling of the receptor from its G protein or internalization of the receptor (Williams et al., 2013).

Tolerance

Tolerance to opioids refers to a decrease in the apparent effectiveness of the opioid agonist with continuous or repeated agonist administration (over days to weeks), that, following removal of the agonist, disappears over several weeks. This tolerance is reflected by a reduction in the maximum achievable effect or a right shift in the dose-response curve. This phenomenon can be manifested at the level of the intracellular cascade (e.g., reduced inhibition of AC) and at the organ system level (e.g., loss of sedative and analgesic effects) (Christie, 2008).

This loss of effect with persistent exposure to an opiate agonist has several key properties:

- Different physiological responses can develop tolerance at markedly different rates. Thus, at the organ system level, some end points show little or no tolerance development (pupillary miosis); some show moderate tolerance (constipation, emesis, analgesia, sedation); and some show rapid tolerance (euphoria). Accordingly, the chronic heroin abuser will continue to show pinpoint pupils and will require a rapid increase in dosing to achieve the drug-related euphoria.
- In general, opiate agonists of a given class will typically show a reduced response in a system rendered tolerant to another agent of that class (e.g., cross-tolerance between the MOR agonists, such as morphine and fentanyl). For reasons that are not clear, this cross-tolerance is neither absolute nor complete. This lack of complete cross-tolerance between agonists forms the basis for the clinical strategy of “opioid rotation” in pain therapy (Smith and Peppin, 2014).

Dependence

Dependence represents a state of adaptation manifested by a withdrawal syndrome produced by cessation of drug exposure (e.g., by drug abstinence) or administration of an antagonist (e.g., naloxone). Dependence is specific to the drug class and receptor involved. At the organ system level, opiate withdrawal is manifested by significant somatomotor and autonomic outflow (reflected by agitation, hyperalgesia, hyperthermia, hypertension, diarrhea, pupillary dilation, and release of virtually all pituitary and adrenomedullary hormones) and by affective symptoms (dysphoria, anxiety, and depression). The state of withdrawal is highly aversive and motivates the drug recipient to make robust efforts to avoid withdrawal, that is, to consume more of the drug. Consistent with the phenomenon of cross-tolerance, drugs interacting with the same opiate receptor will

suppress the withdrawal observed in organisms tolerant to another drug acting on the same receptor (e.g., morphine and methadone).

Addiction

Addiction is a behavioral pattern characterized by compulsive use of a drug. The positive, rewarding effects of opiates are considered to be the driving component for initiating the recreational use of opiates. This positive reward property is subject to the development of tolerance. Given the aversive nature of withdrawal symptoms, avoidance and alleviation of withdrawal symptoms may become a primary motivation for compulsive drug taking (Kreek and Koob, 1998). When the drive to acquire the drug leads to drug-seeking behaviors that occur in spite of the physical, emotional, or societal damage suffered by the drug seeker, then the obsession or compulsion to acquire and use the drug is considered to reflect an addicted state. In animals, this may be manifest by willingness to tolerate stressful conditions to acquire drug delivery. Importantly, *drug dependence is not synonymous with drug addiction*. Tolerance and dependence are physiological responses seen in all patients but are not predictors of addiction (see Chapter 24). For example, cancer pain often requires prolonged treatment with high doses of opioids, leading to tolerance and dependence. Yet, such patients are not considered to be either addicts or abusers of the drug.

Mechanisms of Tolerance/Dependence/Withdrawal

The mechanisms underlying chronic tolerance and dependence/withdrawal are controversial. Several types of events may contribute.

Receptor Disposition

Acute desensitization or receptor internalization may play a role in the initiation of chronic tolerance but is not sufficient to explain the persistent changes observed. For instance, morphine, unlike other μ agonists, does not promote significant MOR internalization, receptor phosphorylation, or desensitization. Receptor desensitization and downregulation are agonist specific. Endocytosis and sequestration of receptors do not invariably lead to receptor degradation but can also result in receptor dephosphorylation and recycling to the surface of the cell. Accordingly, opioid tolerance may not be related to receptor desensitization but rather to a lack of desensitization. Agonists that cause rapid internalization of opioid receptors also rapidly desensitize signaling, but sensitivity can be at least partially restored by recycling of “reactivated” opioid receptors.

Adaptation of Intracellular Signaling Mechanisms

Assessment of the coupling of MOR to cellular effects, such as inhibition of AC, activation of inwardly rectifying K^+ channels, inhibition of Ca^{2+} currents, and inhibition of neurotransmitter release demonstrates functional uncoupling of receptor occupancy from effector function. Importantly, chronic application of opioids initiates adaptive counterregulatory change. A common example of such cellular counterregulatory processes is the rebound increase in cellular cyclic AMP levels produced by “super-activation” of AC and upregulation of the amount of enzyme as a result of long-term exposure to an opiate followed by its abrupt withdrawal (Williams et al., 2013).

System-Level Counteradaptation

The loss of antinociceptive effect with chronic opiate exposure may reflect an enhanced excitability of the regulated link. Thus, tolerance to the analgesic action of chronically administered μ opiates may result from an activation of *bulbosplinal* pathways that increases the excitability of spinal dorsal horn pain transmission linkages. With chronic opiate exposure, opiate receptor occupancy will lead to the activation of PKC, which can phosphorylate and enhance the activation of local NMDA glutamate receptors. These receptors are considered to play an important role as an excitatory link in enhanced pain processing (see Chapter 14). Blockade of these receptors can at least partially attenuate the loss of analgesic efficacy with continued opiate exposure. Such system-level counteradaptation mechanisms may apply to specific systems (e.g., pain modulation) but not necessarily to others (e.g., sedation or miosis) (Christie, 2008). These changes may be mechanistically important in the phenomenon called opioid-induced hyperalgesia, by which higher doses of opiates may lead to a paradoxical increase in pain processing (Fletcher and Martinez, 2014).

Differential Tolerance Development and Fractional Occupancy Requirements

An interesting problem in explaining tolerance relates to the differential rates of the development of tolerance. It is unclear why responses such as miosis show no tolerance over extended exposure (indeed, miosis is considered symptomatic in drug overdose of highly tolerant patients), whereas analgesia and sedation are likely to show a reduction. One possibility is that tolerance represents a functional uncoupling of some fraction of the receptor population and that different physiological end points may require activation of different fractions of their coupled receptors to produce a given physiological effect.

Effects of Clinically Used Opioids

Opiates, depending on their receptor specificities, produce a variety of effects consistent with the roles played by the organ systems with which the receptors are associated. Although the primary clinical use of opioids is for their pain-relieving properties, opioids produce a host of other effects. This is not surprising in view of the wide distribution of opioid receptors in brain, spinal cord, and the periphery. Within the nervous system, these effects range from analgesia to effects on motivation and higher-order affect (euphoria), arousal, and a number of autonomic, hormonal, and motor processes. In the periphery, opiates can influence a variety of visceromotor systems, including those related to GI motility and smooth muscle tone.

Analgesia

Morphine-like drugs produce *analgesia*, *drowsiness*, and *euphoria* (changes in mood and mental clouding). When therapeutic doses of morphine are given to patients with pain, patients report the pain to be less intense or entirely gone. In addition to relief of distress, some patients may experience euphoria. Analgesia often occurs without loss of consciousness, although drowsiness commonly occurs. Morphine at these doses does not

have anticonvulsant activity and usually does not cause slurred speech, emotional lability, or significant impairment of motor coordination. When an analgesic dose of morphine is administered to normal, pain-free individuals, the patients may report the drug experience to be frankly unpleasant. They may experience drowsiness, difficulty in mentation, apathy, and lessened physical activity. As the dose is increased, the subjective, analgesic, and toxic effects, including respiratory depression, become more pronounced. The relief of pain by morphine-like opioids is selective in that other sensory modalities, such as light touch, proprioception, and the sense of moderate temperatures, are unaffected. Low doses of morphine can produce reductions in the affective response but not the perceived intensity of the pain experience; higher, clinically effective doses reduce both perceived intensity and affective responses to the pain (Price et al., 1985). Continuous dull pain (as generated by tissue injury and inflammation) is relieved more effectively than sharp intermittent (incident) pain, such as that associated with the movement of an inflamed joint. With sufficient amounts of opioid, it is possible to relieve even the severe piercing pain associated with, for example, acute renal or biliary colic.

Pain States and Mechanisms

Any meaningful discussion of the action of analgesic agents must include the appreciation that all pain is not the same, and that a number of variables contribute to the patient's pain report and therefore to the effect of the analgesic. Heuristically, one may think mechanistically of pain as several distinct sets of events, described in the next sections (Yaksh et al., 2015).

Acute Nociception. Acute activation of small, high-threshold sensory afferents ($A\delta$ and C fibers) generates transient, stimulus-dependent input into the spinal cord, which in turn leads to activation of dorsal horn neurons that project contralaterally to the thalamus and thence to the somatosensory cortex. A parallel spinofugal projection runs through the medial thalamus and thence to portions of the limbic cortex, such as the anterior cingulate. The output produced by acutely activating these ascending systems is sufficient to evoke pain reports. Examples of such stimuli include a hot coffee cup, a needlestick, or an incision.

Tissue Injury. Following tissue injury or local inflammation (e.g., local skin burn, toothache, rheumatoid joint), an ongoing pain state arises that is characterized by burning, throbbing, or aching, and an abnormal pain response termed *hyperalgesia*, which can be evoked by otherwise innocuous or mildly aversive stimuli (tepid bathwater on a sunburn; moderate extension of an injured joint). This pain typically reflects the effects of active factors such as prostaglandins, bradykinin, cytokines, serine proteases, and H^+ ions, among many mediators. Such mediators are released locally into the injury site and have the capacity, through eponymous receptors on the terminals of small, high-threshold afferents ($A\delta$ and C fibers), to activate these sensory afferents and to reduce the stimulus intensity required for their activation (e.g., peripheral sensitization). In addition, the ongoing afferent traffic initiated by the tissue injury and inflammation leads to activation of spinal facilitatory cascades, yielding a greater output to the brain for any given afferent input. This facilitation is thought to underlie hyperalgesic states (e.g., central sensitization). Such tissue injury/inflammation-evoked pain is often referred to as *nociceptive* pain (Figure 20–5) (Sorkin and Wallace, 1999). Examples of such states would be burn, postincision, abrasion of the skin, musculoskeletal injury, or inflammation of the joint.

Nerve Injury. Injury to a peripheral nerve yields complex anatomical and biochemical changes in the nerve and spinal cord that induce *spontaneous dysesthesias* (shooting, burning pain) and *allodynia* (hurt from a light touch). This nerve injury pain state may not depend on the activation of small afferents but may be initiated by low-threshold sensory afferents (e.g., $A\beta$ fibers). Such nerve injuries result in the development of ectopic activity arising from neuromas formed by nerve injury and the dorsal root ganglia of the injured axons as well as changes in dorsal horn sensory processing. Such changes include activation of nonneuronal (glial) cells and loss of constitutive inhibitory circuits, such that low-threshold afferent input carried by $A\beta$ fibers evokes a pain

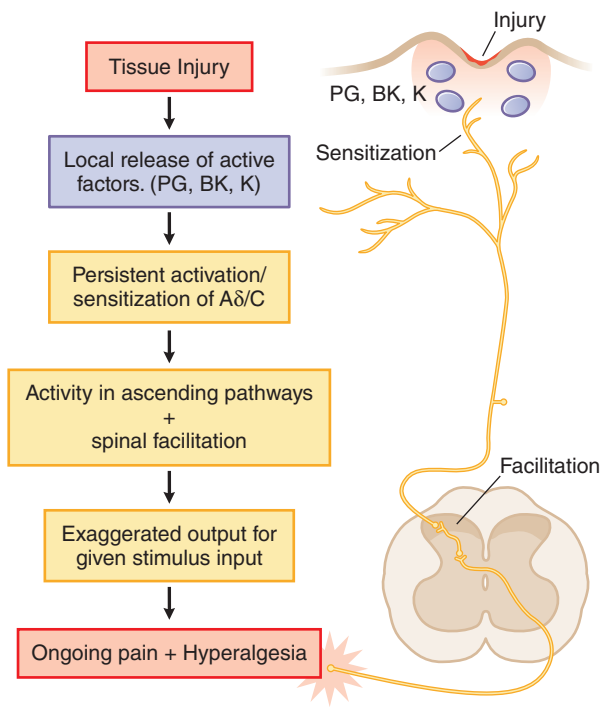

Figure 20-5 Mechanisms of tissue injury-evoked nociception. BK, bradykinin; K, potassium; PG, prostaglandins.

state (West et al., 2015). Examples of such nerve injury-inducing events include mononeuropathies secondary to nerve trauma or compression (carpal tunnel syndrome) and the postherpetic state (shingles). Polyneuropathies such as those occurring in diabetes or after chemotherapy (as for cancer) can also lead to ongoing dysesthesias and evoked hyperpathias. These pain states are said to be neuropathic (Figure 20-6). Many clinical pain syndromes, such as found in cancer, typically represent a combination of these inflammatory and neuropathic mechanisms. Although nociceptive pain usually is responsive to opioid analgesics, neuropathic pain is typically considered to respond less well to opioid analgesics. There is a growing perception that, in the face of chronic tissue injury or inflammation (e.g., arthritis), there can be a transition from an inflammatory to a neuropathic pain phenotype. Such a transition has important implications for analgesic drug efficacy.

Sensory Versus Affective Dimensions. Information generated by a high-intensity peripheral stimulus initiates activity in pathways activating higher-order systems that reflect the aversive magnitude of the stimulus.

Figure 20-6 Mechanisms of nerve injury-evoked nociception.

Painful stimuli have the certain ability to generate strong emotional components that reflect a distinction between pain as a specific sensation subserved by distinct neurophysiological structures (the *sensory discriminative* dimension) and pain such as suffering (the original sensation plus the reactions evoked by the sensation: the *affective motivational* dimension of the pain experience) (Melzack and Casey, 1968). Opiates have potent effects on both components of the pain experience.

Mechanisms of Opioid-Induced Analgesia

The analgesic actions of opiates after systemic delivery represent actions in the brain, spinal cord, and in some instances the periphery.

Supraspinal Actions. Microinjections of morphine into a number of highly circumscribed brain regions will produce a potent analgesia that is reversible by naloxone, an MOR antagonist. The best characterized of these sites is the mesencephalic PAG region. Several mechanisms exist whereby opiates with an action limited to the PAG may act to alter nociceptive transmission. These are summarized in Figure 20-7. MOR agonists block release of the inhibitory transmitter GABA from tonically active PAG systems that regulate activity in projections to the medulla. PAG projections to the medulla activate medullospinal release of NE and 5HT at the level of the spinal dorsal horn. This release can attenuate dorsal horn excitability (Yaksh, 1997). Interestingly, this PAG organization can also serve to increase excitability of dorsal raphe and locus coeruleus, from which ascending serotonergic and noradrenergic projections to the limbic

Figure 20-7 Mechanisms of opiate action in producing analgesia. **Top left:** Schematic of organization of opiate action in the PAG. **Top right:** Opiate-sensitive pathways in the PAG. Opiate actions via MOR block the release of GABA from tonically active systems that otherwise regulate the projections to the medulla (1), leading to an activation of PAG outflow that results in activation of forebrain (2) and spinal (3) monoamine receptors that regulate spinal cord projections (4), which provide sensory input to higher centers and mood. **Bottom left:** Schematic of primary afferent synapse with second-order dorsal horn spinal neuron, showing pre- and postsynaptic opiate receptors coupled to Ca^{2+} and K^{+} channels, respectively. Opiate receptor binding is highly expressed in the superficial spinal dorsal horn (substantia gelatinosa). These receptors are located presynaptically on the terminals of small primary afferents (C fibers) and postsynaptically on second-order neurons. Presynaptically, activation of MOR blocks the opening of the voltage-sensitive Ca^{2+} channel, which otherwise initiates transmitter release. Postsynaptically, MOR activation enhances opening of K^{+} channels, leading to hyperpolarization. Thus, an opiate agonist acting at these sites jointly serves to attenuate the afferent-evoked excitation of the second-order neuron.

forebrain, respectively, originate. Aside from direct supraspinal effects on forebrain structures, these limbic projections provide a mechanism for the effects of opiates on emotional tone (the role of forebrain 5HT and NE in mediating emotional tone is discussed in Chapter 15).

Spinal Opiate Action. A local action of opiates in the spinal cord will selectively depress the discharge of spinal dorsal horn neurons evoked by small (high-threshold) but not large (low-threshold) afferent nerve fibers. Intrathecal administration of opioids in animals ranging from mice to humans will reliably attenuate the response of the organism to a variety of somatic and visceral stimuli that otherwise evoke pain states. Specific opiate receptors are largely limited to the *substantia gelatinosa* of the superficial dorsal horn, the region in which small, high-threshold sensory afferents show their principal termination. A significant proportion of these opiate receptors are associated with small peptidergic primary afferent C fibers; the remainder are on local dorsal horn neurons.

Spinal opiates act on opiate receptors located presynaptically on small, high-threshold primary afferents to *prevent the opening of voltage-sensitive Ca^{2+} channels*, thereby preventing transmitter release from those afferents. A postsynaptic action is demonstrated by the ability of opiates to block excitation of dorsal horn neurons directly evoked by glutamate, reflecting a direct activation of dorsal horn projection neurons partly by *hyperpolarizing the neurons through the activation of K^+ channels*, such that the membrane potential more closely approximates the equilibrium potential for K^+ . The joint capacity of spinal opiates to reduce the release of excitatory neurotransmitters from C fibers and to decrease the excitability of dorsal horn neurons is believed to account for the powerful and selective effect of opiates on spinal nociceptive processing. A variety of opiates delivered spinally (intrathecally or epidurally) can induce powerful analgesia that is reversed by low doses of systemic naloxone (Yaksh, 1997).

Peripheral Action. Direct application of high concentrations of opiates to a peripheral nerve can, in fact, produce a local anesthetic-like action, but this effect is not reversed by naloxone and is believed to reflect a “nonspecific” action. Conversely, at peripheral sites under conditions of inflammation where there is an increased terminal sensitivity leading to an exaggerated pain response (e.g., hyperalgesia), direct injection of opiates produces a local action that can exert a normalizing effect on the exaggerated thresholds. Whether the effects are uniquely on the peripheral afferent terminal or whether the opiate acts on inflammatory cells that release products that sensitize the nerve terminal, or both, is not known (Stein and Machelska, 2011).

Mood Alterations and Rewarding Properties

The mechanisms by which opioids produce euphoria, tranquility, and other alterations of mood (including rewarding properties) are complex and not entirely understood. Neural systems that mediate opioid reinforcement overlap with, but are distinct from, those involved in physical dependence and analgesia (Koob and Le Moal, 2008). Behavioral and pharmacological data point to a pivotal role of the mesocorticolimbic dopamine system that projects to the *NAc* in drug-induced reward and motivation (Figure 20–8). Increased dopamine release in this region is considered to underlie a positive reward state. In the *NAc*, MORs are present postsynaptically on GABAergic neurons. The reinforcing effects of opiates are thought to be mediated partly via inhibition of local GABAergic neuronal activity, which otherwise acts to inhibit DA outflow.

Respiratory Effects

Although effects of opiates on respiration are readily demonstrated, clinically significant respiratory depression rarely occurs with standard analgesic doses in the absence of other contributing variables (discussed in the next sections). It should be stressed, however, that *respiratory depression represents the primary cause of morbidity secondary to opiate therapy*. In humans, death from opiate poisoning is nearly always due to respiratory arrest or obstruction. Opiates depress all phases of respiratory activity (rate, minute volume, and tidal exchange) and produce irregular and aperiodic breathing. The diminished respiratory volume

Figure 20–8 Pathways underlying rewarding properties of opiates. **Upper panel:** This sagittal section of rat brain shows DA and GABA inputs from the VTA and PFC, respectively, into the *NAc*. **Lower panel:** Neurons are labeled with their primary neurotransmitters. At a cellular level, MOR agonists reduce excitability and transmitter release at the sites indicated by inhibiting Ca^{2+} influx and enhancing K^+ current (see Figure 20–7). Thus, opiate-induced inhibition in the VTA on GABAergic interneurons or in the *NAc* reduce GABA-mediated inhibition and increase outflow from the ventral pallidum (VP), which appears to correlate with a positive reinforcing state (enhanced reward).

is due primarily to a slower rate of breathing; with toxic amounts of opioids, the rate may fall to 3–4 breaths/min. Thus, to avoid apnea due to a decrease in respiratory drive coinciding with an increased airway resistance, opioids must be used with caution in patients with asthma, COPD, cor pulmonale, decreased respiratory reserve, preexisting respiratory depression, hypoxia, or hypercapnia. Although respiratory depression is not considered to be a favorable therapeutic effect of opiates, their ability to suppress respiratory drive is used as therapeutic advantage to treat dyspnea resulting, for example, in patients with COPD, where air hunger leads to extreme agitation, discomfort, and gasping; opiates will suppress the gasping and decrease the panic of the patient. Similarly, opiates find use in patients who require artificial ventilation (Clemens and Klaschik, 2007).

Mechanisms Underlying Respiratory Depression

Morphine-like opioids depress respiration through MOR by several mechanisms:

- direct depressant effect on rhythm generation;
- depression of the ventilatory response to increased CO_2 ; and
- an effect on carotid and aortic body chemosensors that reduces ventilatory responses that are normally driven by hypoxia.

Respiratory rate and tidal volume depend on intrinsic rhythm generators located in the ventrolateral medulla. These systems generate a “respiratory” rhythm that is driven by afferent input reflecting the partial pressure of arterial O_2 as measured by chemosensors in the carotid and aortic bodies and CO_2 as measured by chemosensors in the brainstem. Morphine-like opioids depress respiration through MORs in part by a direct depressant effect on rhythm generation, with changes in respiratory pattern and rate observed at lower doses than changes in tidal volume. A key property of opiate effects on respiration is the depression of the ventilatory response to increased CO_2 . This effect is mediated by opiate depression of the excitability of brainstem chemosensory neurons. In addition to the effects on the CO_2 response, opiates will depress ventilation otherwise driven by hypoxia though an effect on carotid and aortic body chemosensors. Importantly, with opiates, hypoxic stimulation of chemoreceptors still may be effective when opioids have decreased the responsiveness to CO_2 , and inhalation of O_2 may remove the residual drive resulting from the elevated PO_2 and produce apnea (Pattinson, 2008). In addition to the effect on respiratory rhythm and chemosensitivity, opiates can have mechanical effects on airway function by increasing chest wall rigidity and diminishing upper airway patency (Lalley, 2008).

Factors Exacerbating Opiate-Induced Respiratory Depression

A number of factors can increase the risk of opiate-related respiratory depression even at therapeutic doses:

- *Other medications.* The combination of opiates with other depressant medications, such as general anesthetics, tranquilizers, alcohol, or sedative-hypnotics, produces additive depression of respiratory activity.
- *Sleep.* Natural sleep produces a decrease in the sensitivity of the medullary center to CO_2 , and the depressant effects of morphine and sleep are at least additive. Obstructive sleep apnea is considered to be an important risk factor for increasing the likelihood of fatal respiratory depression.
- *Age.* Newborns can show significant respiratory depression and desaturation; this may be evident in lower Apgar scores if opioids are administered parenterally to women within 2–4 h of delivery because of transplacental passage of opioids. Elderly patients are at greater risk of depression because of reduced lung elasticity, chest wall stiffening, and decreased vital capacity.
- *Disease.* Opiates may cause a greater depressant action in patients with chronic cardiopulmonary or renal diseases because they can manifest a desensitization of their response to increased CO_2 .
- *COPD.* Enhanced depression can also be noted in patients with COPD and sleep apnea secondary to diminished hypoxic drive.
- *Relief of pain.* Because pain stimulates respiration, removal of the painful condition (as with the analgesia resulting from the therapeutic use of the opiate) will reduce the ventilatory drive and lead to apparent respiratory depression.

Comparative Respiratory Effects of Different Opiates

Numerous studies have compared morphine and morphine-like opioids with respect to their ratios of analgesic to respiratory-depressant activities, and most have found that when equianalgesic doses are used, there is no significant difference. Maximal respiratory depression occurs within 5–10 min of intravenous administration of morphine or within 30–90 min of intramuscular or subcutaneous administration. Maximal respiratory depressant effects occur more rapidly with more lipid-soluble agents. After therapeutic doses, respiratory minute volume may be reduced for as long as 4–5 h. Agents that have persistent kinetics, such as methadone, must be carefully monitored, particularly after dose incrementation. Respiratory depression produced by any opiate agonist can be readily reversed by delivery of an opiate antagonist. Opiate antagonist reversal in the somnolent patient is considered to be indicative of an opiate-mediated depression. It is important to remember that most opiate antagonists have a relatively short duration of action compared to an agonist such as morphine or methadone, and fatal “renarcotization” can occur if vigilance is not exercised.

Opioid-Induced Hyperalgesia

A paradoxical increase in pain states has been observed in response to acute (hours to days) and chronic opiate exposure. This increase may be reflected by unexplained increases in pain reports, increased levels of pain with increasing opiate dosages, or a diffuse sensitivity unassociated with the original pain (Lee et al., 2011). The mechanisms of this increased pain profile is not understood, although an enhanced excitability of central systems with chronic opiate exposure is considered relevant. Other avenues have pointed to the stimulatory effects of opioids on innate immune signaling through Toll-like receptor 4 activation, leading to central sensitization (Grace et al., 2014).

Sedation

Opiates can produce drowsiness and cognitive impairment. Such depression can augment respiratory impairment. These effects are most typically noted following initiation of opiate therapy or after dose incrementation. Importantly, these effects on arousal resolve over a few days. As with respiratory depression, the degree of drug effect can be enhanced by a variety of predisposing patient factors, including dementia, encephalopathies, brain tumors, and other depressant medications, including sleep aids, antihistamines, antidepressants, and anxiolytics (Cherny, 1996).

Neuroendocrine Effects

The regulation of the release of hormones and factors from the pituitary is under complex regulation by opiate receptors in the HPA axis. Broadly considered, morphine-like opioids reduce the release of a large number of HPA hormones (Armario, 2010).

Sex Hormones

In males, acute opiate therapy reduces plasma cortisol, testosterone, and gonadotrophins. Inhibition of adrenal function is reflected by reduced cortisol production and reduced adrenal androgens (DHEA). In females, morphine will also result in lower LH and FSH release. In both males and females, chronic therapy can result in endocrinopathies, including hypogonadotrophic hypogonadism. In men, this may result in decreased libido and, with extended exposure, reduced secondary sex characteristics. In women, these exposures are associated with menstrual cycle irregularities. These changes are reversible with removal of the opiate.

Prolactin. Prolactin release from the anterior pituitary is under inhibitory control by DA released from neurons of the arcuate nucleus. MOR agonists act presynaptically on these DA-releasing terminals to inhibit DA release and thereby increase plasma prolactin.

Antidiuretic Hormone and Oxytocin. The effects of opiates on ADH and oxytocin release are complex. These hormones are synthesized in the perikarya of the magnocellular neurons in the paraventricular and supraoptic nuclei of the hypothalamus and released from the posterior pituitary (Chapter 42). KOR agonists inhibit the release of oxytocin and ADH and cause prominent diuresis. Note, however, that agents such as morphine may yield a hypotension secondary to histamine release; this would, by itself, promote ADH release.

Miosis

The MOR agonists induce pupillary constriction (miosis) in the awake state and block pupillary reflex dilation during anesthesia. The parasympathetic outflow from the *Edinger Westphal nucleus* activates parasympathetic outflow through the ciliary ganglion to the pupil, producing constriction. This outflow is locally regulated by GABAergic interneurons. Opiates block this GABAergic interneuron-mediated inhibition, leading to increased parasympathetic outflow (Larson, 2008). At high doses of agonists, the miosis is marked, and pinpoint pupils are pathognomonic; however, marked mydriasis will occur with the onset of asphyxia. While some tolerance to the miotic effect develops, addicts with high circulating concentrations of opioids continue to have constricted pupils. Therapeutic doses of morphine increase accommodative power and lower intraocular tension in normal and glaucomatous eyes (Larson, 2008).

Seizures and Convulsions

In older children and adults, moderately higher doses of opiates produce EEG slowing. In the newborn, morphine can produce epileptiform activity and occasionally seizure activity (Young and da Silva, 2000). Several mechanisms are likely involved in these excitatory actions:

- *Inhibition of inhibitory interneurons.* Morphine-like drugs indirectly excite certain groups of neurons, such as hippocampal pyramidal cells, by inhibiting the inhibition otherwise exerted by GABAergic interneurons (McGinty, 1988).
- *Direct stimulatory effects.* Opiates may interact with receptors coupled through both inhibitory and stimulatory G proteins, with the inhibitory coupling but not the excitatory coupling showing tolerance with continued exposures (King et al., 2005).
- *Actions mediated by nonopioid receptors.* The metabolites of several opiates (morphine-3-glucuronide, normeperidine) have been implicated in seizure activity (Seifert and Kennedy, 2004; Smith, 2000).

A special case is the withdrawal syndrome from an opiate-dependent state in the adult and in the infant born to an opiate-dependent mother. Withdrawal in these circumstances, either by antagonists or abstinence, can lead to prominent EEG activation, tremor, and rigidity. Approaches to the management of such activation are controversial. Anticonvulsant agents may not always be effective in suppressing opioid-induced seizures (see Chapter 17).

Cough

Cough is a protective reflex evoked by airway stimulation. It involves rapid expression of air against a transiently closed glottis. The reflex is complex, involving the central and peripheral nervous systems as well as the smooth muscle of the bronchial tree. Morphine and related opioids depress the cough reflex at least in part by a direct effect on a cough center in the medulla; this cough suppression can be achieved without altering the protective glottal function (Chung and Pavord, 2008). There is no obligatory relationship between depression of respiration and depression of coughing, and effective antitussive agents are available that do not depress respiration (antitussives are discussed further in the chapter).

Nauseant and Emetic Effects

Nausea and vomiting produced by morphine-like drugs are side effects caused by direct stimulation of the chemoreceptor trigger zone for emesis in the *area postrema* of the medulla (see Figure 50–5). All clinically useful agonists produce some degree of nausea and vomiting. Nausea and vomiting are relatively uncommon in recumbent patients given therapeutic doses of morphine, but nausea occurs in about 40% and vomiting in 15% of ambulatory patients given analgesic doses. Morphine and related synthetic analgesics produce an increase in vestibular sensitivity. A component of nausea is likely also due to the gastric stasis that occurs postoperatively and that is exacerbated by analgesic doses of morphine. (Greenwood-Van Meerveld, 2007).

Cardiovascular System

In the supine patient, therapeutic doses of morphine-like opioids have no major effect on blood pressure or cardiac rate and rhythm. Such doses can, however, produce peripheral vasodilation, reduced peripheral resistance, and an inhibition of baroreceptor reflexes. Thus, when supine patients assume the head-up position, orthostatic hypotension and fainting may occur. The peripheral arteriolar and venous dilation produced by morphine involves several mechanisms:

- Morphine induces *release of histamine* from mast cells, leading to vasodilation; this effect is reversed by naloxone but only partially blocked by H_1 antagonists.
- Morphine *blunts reflex vasoconstriction* caused by increased PCO_2 .

High doses of MOR agonists, such as fentanyl and sufentanil, used as anesthetic induction agents, have only modest effects on hemodynamic stability, in part because they do not cause release of histamine (Monk et al., 1988). Morphine may exert its therapeutic effect in the treatment

of angina pectoris and acute myocardial infarction by decreasing preload, inotropy, and chronotropy, thus favorably altering determinants of myocardial O_2 consumption. Morphine also produces cardioprotective effects. Morphine can mimic the phenomenon of ischemic preconditioning, whereby a short ischemic episode paradoxically protects the heart against further ischemia. This effect appears to be mediated through receptors signaling through a mitochondrial ATP-sensitive K^+ channel in cardiac myocytes; the effect also is produced by other GPCRs signaling through G_i . Morphine-like opioids should be used with caution in patients who have decreased blood volume because these agents can aggravate hypovolemic shock. Morphine should be used with great care in patients with cor pulmonale; deaths after ordinary therapeutic doses have been reported. Concurrent use of certain CNS depressants (phenothiazines, ethanol, benzodiazepines) may increase the risk of morphine-induced hypotension. Cerebral circulation is not affected directly by therapeutic doses of opiates. However, opioid-induced respiratory depression and CO_2 retention can result in cerebral vasodilation and an increase in CSF pressure. This pressure increase does not occur when PCO_2 is maintained at normal levels by artificial ventilation.

Skeletal Muscle Tone

At therapeutic doses required for analgesia, opiates have little effect on motor tone or function. However, high doses of opioids, as used for anesthetic induction, produce muscular rigidity. Myoclonus, ranging from mild twitching to generalized spasm, is an occasional side effect that has been reported with all clinically used opiate agonists and is particularly prevalent in patients receiving high doses. The increased muscle tone is mediated by a central effect, although the mechanisms of its effects are not clear. High doses of spinal opiates can increase motor tone, possibly through an inhibition of inhibitory interneurons in the ventral horn of the spinal cord. Alternately, intracranial delivery can initiate rigidity in animal models, possibly reflecting increased extrapyramidal activity. Increased motor tone and rigidity are reversed by opiate antagonists.

GI Tract

Opiates have important effects on all aspects of GI function. Between 40% and 95% of patients treated with opioids develop constipation and changes in bowel function (Benyamin et al., 2008). Opioid receptors are densely distributed in enteric neurons between the myenteric and submucosal plexuses and on a variety of secretory cells. The importance of these peripheral systems in altering GI motility is emphasized by the therapeutic efficacy of peripherally limited opiate agonists such as loperamide as antidiarrheals and the utility of peripherally limited opiate antagonists such as methylaltrexone to reverse the constipatory actions of systemic opiate agonists.

Esophagus. The esophageal sphincter is under control by brainstem reflexes that activate cholinergic motor neurons originating in the esophageal myenteric plexus. This system regulates passage of material from the esophagus to the stomach and prevents regurgitation; conversely, it allows relaxation in the act of emesis. Morphine inhibits lower esophageal sphincter relaxation induced by swallowing and by esophageal distension; the effect is believed to be centrally mediated because peripherally restricted opiates such as loperamide do not alter esophageal sphincter tone (Sidhu and Triadafilopoulos, 2008).

Stomach. Morphine increases tonic contracture of the antral musculature and upper duodenum and reduces resting tone in the musculature of the gastric reservoir, thereby prolonging gastric emptying time and increasing the likelihood of esophageal reflux. Passage of the gastric contents through the duodenum may be delayed by as much as 12 h, and the absorption of orally administered drugs is retarded. Morphine and other opioid agonists usually decrease secretion of hydrochloric acid. Activation of opioid receptors on parietal cells enhances secretion, but indirect effects, including increased secretion of somatostatin from the pancreas and reduced release of ACh appear to be dominant in most circumstances (Kromer, 1988).

Intestine. Morphine reduces propulsive activity in the small and large intestines and diminishes intestinal secretions. Opiate agonists suppress

rhythmic inhibition of muscle tone, leading to concurrent increases in basal tone in the circular muscle of the small and large intestines. This results in enhanced high-amplitude phasic contractions, which are *non-propulsive* (Wood and Galligan, 2004). The upper part of the small intestine, particularly the duodenum, is affected more than the ileum. A period of relative atony may follow the period of elevated basal tone. The reduced rate of passage of the intestinal contents, along with reduced intestinal secretion, leads to increased water absorption, increasing viscosity of the bowel contents, and constipation. The tone of the anal sphincter is augmented greatly, and reflex relaxation in response to rectal distension is reduced. Patients who take opioids chronically remain constipated. Intestinal secretion arises from activation of enterocytes by local cholinergic submucosal plexus secretomotor neurons. Opioids act through μ/δ receptors on these secretomotor neurons to inhibit their excitatory output to the enterocytes and thereby reduce intestinal secretion (Kromer, 1988).

Biliary Tract. Morphine constricts the sphincter of Oddi, and the pressure in the common bile duct may rise more than 10-fold within 15 min. Fluid pressure also may increase in the gallbladder and produce symptoms that may vary from epigastric distress to typical biliary colic. All opioids can cause biliary spasm. Some patients with biliary colic experience exacerbation rather than relief of pain when given opioids. Spasm of the sphincter of Oddi probably is responsible for elevations of plasma amylase and lipase that sometimes occur after morphine administration. Atropine only partially prevents morphine-induced biliary spasm, but opioid antagonists prevent or relieve it.

Ureter and Urinary Bladder

Morphine inhibits the urinary voiding reflex and increases the tone of the external sphincter with a resultant increase in the volume of the bladder. Tolerance develops to these effects of opioids on the bladder. Clinically, opiate-mediated inhibition of micturition can be of such clinical severity that catheterization sometimes is required after therapeutic doses of morphine, particularly with spinal drug administration. Importantly, the inhibition of systemic opiate effects on micturition is reversed by peripherally restricted antagonists (Rosow et al., 2007).

Uterus

Morphine may prolong labor. If the uterus has been made hyperactive by oxytocics, morphine tends to restore the contractions to normal.

Skin

Therapeutic doses of morphine cause dilation of cutaneous blood vessels. The skin of the face, neck, and upper thorax frequently becomes flushed. Pruritus commonly follows systemic administration of morphine. Itching is readily seen with morphine and meperidine but to a much lesser extent with fentanyl or sufentanil. The systemic action is sensitive to antihistamines (diphenhydramine) and correlates with the mast cell degranulating properties of the opiate. Neither the pruritus nor the degranulation is reversed by opiate antagonists (Barke and Hough, 1993). This pruritus also can be caused by epidural or intrathecal opiate administration through a centrally mediated, naloxone-reversible mechanism (Kumar and Singh, 2013).

Immune System

Opioids modulate immune function by direct effects on cells of the immune system and indirectly through centrally mediated neuronal mechanisms (Vallejo et al., 2004). The acute central immunomodulatory effects of opioids may be mediated by activation of the sympathetic nervous system; the chronic effects of opioids may involve modulation of the HPA axis. Direct effects on immune cells may involve unique variants of the classical neuronal opioid receptors, with MOR variants being most prominent. A proposed mechanism for the immune-suppressive effects of morphine on neutrophils is through NO-dependent inhibition of NF- κ B activation, or via activation of MAP kinases. Convincing data suggest that several opiates, including morphine, may interact with Toll-like receptor 4 to activate a variety of immunocytes independent of an opiate receptor (Hutchinson et al., 2007). Overall, however, opioids are modestly immunosuppressive, and increased susceptibility to infection and tumor spread have been observed. In some situations, immune effects appear more

prominent with acute administration than with chronic administration, which could have important implications for the care of the critically ill.

In addition to the effects of opiates on immune function, many opiate agonists evoke mast cell degranulation and histamine release. This action can cause bronchoconstriction and vasodilation. As a consequence, morphine has the potential to precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. The effect on mast cells is not prevented by opiate antagonists and appears to be independent of MORs. After potent opioids such as fentanyl, the incidence of mast cell degranulation is reduced compared to the effect of morphine. Through such mechanisms, opioid analgesics may evoke allergic phenomena that usually are manifested as urticaria, other types of skin rashes, and pruritus. The pruritus is often managed with antihistamines.

Temperature Regulation

Opioids alter the equilibrium point of the hypothalamic heat-regulatory mechanisms such that body temperature usually falls slightly. Agonists at the MOR (e.g., alfentanil and meperidine), acting in the CNS, result in slightly increased thresholds for sweating and significantly lower the threshold temperatures for evoking vasoconstriction and shivering.

Clinically Employed Opioid Drugs

Most of the clinically used opioid agonists presented in Table 20–4 are relatively selective for MORs. They produce analgesia, affect mood and rewarding behavior, and alter respiratory, cardiovascular, GI, and neuroendocrine function. KOR agonists, with few exceptions (e.g., butorphanol), are not typically employed for long-term therapy because they may produce dysphoric and psychotomimetic effects. DOR agonists, while analgesically active, have not found clinical utility, and NOP agonists lack analgesic effects. Opiates that are relatively receptor selective at lower doses may interact with additional receptor types when given at high doses, especially as doses are escalated to overcome tolerance.

The mixed agonist-antagonist agents frequently interact with more than one receptor type at usual clinical doses. A “ceiling effect” limiting the amount of analgesia attainable often is seen with these drugs, as is the case with buprenorphine, which is approved for the treatment of opioid dependence. Some mixed agonist-antagonist drugs, such as pentazocine and nalorphine (not available in the U.S.), can precipitate withdrawal in opioid-tolerant patients. For these reasons, except for the sanctioned use of buprenorphine to manage opioid addiction, the clinical use of mixed agonist-antagonist drugs is generally limited.

The dosing guidelines and duration of action for the numerous drugs that are part of opioid therapy are summarized in Table 20–4.

Morphine and Structurally Related Agonists

Sources of Opium

Two groups have recently reported the scalable biosynthesis of opiates in the laboratory using yeast (Galanie et al., 2015) or *Escherichia coli* (Nakagawa et al., 2016); thus, nonagricultural systems of opiate production may be at hand. Typically, however, morphine is obtained from opium or extracted from poppy straw. Opium is obtained from the unripe seed capsules of the poppy plant, *Papaver somniferum*. The milky juice is dried and powdered to make powdered opium. Powdered opium contains a number of alkaloids, only a few of which (morphine, codeine, and papaverine) have clinical utility. These opium alkaloids are divided into two distinct chemical classes, phenanthrenes and benzylisoquinolines. The principal phenanthrenes are morphine (10% of opium), codeine (0.5%), and thebaine (0.2%). The principal benzylisoquinolines are papaverine (1%) (a smooth muscle relaxant) and noscapine (6%).

Morphine and Its Congeners

Morphine remains the standard against which new analgesics are measured.

Chemistry. The structures of morphine and some of its surrogates and antagonists are shown in Figure 20–9. Many semisynthetic derivatives

TABLE 20-4 ■ DOSING DATA FOR CLINICALLY EMPLOYED OPIOID ANALGESICS

DRUG	APPROXIMATE EQUIANALGESIC ORAL DOSE	APPROXIMATE EQUIANALGESIC PARENTERAL DOSE	RECOMMENDED STARTING DOSE (Adults > 50 kg)		RECOMMENDED STARTING DOSE (Children and Adults < 50 kg)	
			ORAL	PARENTERAL	ORAL	PARENTERAL
Opioid Agonists						
Morphine	30 mg/3–4 h	10 mg/3–4 h	15 mg/3–4 h	5 mg/3–4 h	0.3 mg/kg/3–4 h	0.1 mg/kg/3–4 h
Codeine	130 mg/3–4 h	75 mg/3–4 h	30 mg/3–4 h	30 mg/2 h (IM/ SC)	0.5 mg/kg/3–4 h	Not recommended
Hydromorphone	6 mg/3–4 h	1.5 mg/3–4 h	2 mg/3–4 h	0.5 mg/3–4 h	0.03 mg/kg/3–4 h	0.005 mg/kg/3–4 h
Hydrocodone (typically with acetaminophen)	30 mg/3–4 h	Not available	5 mg/3–4 h	Not available	0.1 mg/kg/3–4 h	Not available
Levorphanol	4 mg/6–8 h	2 mg/6–8 h	4 mg/6–8 h	2 mg/6–8 h	0.04 mg/kg/6–8 h	0.02 mg/kg/6–8 h
Meperidine	300 mg/2–3 h	100 mg/3 h	Not recommended	50 mg/3 h	Not recommended	0.75 mg/kg/2–3 h
Methadone	10 mg/6–8 h	10 mg/6–8 h	5 mg/12 h	Not recommended	0.1 mg/kg/12 h	Not recommended
Oxycodone	20 mg/3–4 h	Not available	5 mg/3–4 h	Not available	0.1 mg/kg/3–4 h	Not available
Oxymorphone	10 mg/3–4 h	1 mg/3–4 h	5 mg/3–4 h	1 mg/3–4 h	0.1 mg/kg/3–4 h	Not recommended
Tramadol	100 mg	100 mg	50–100 mg/6 h	50–100 mg/6 h	Not recommended	Not recommended
Fentanyl	Transdermal 72-h patch (25 µg/h) = morphine 50 mg/24 h					
Opioid Agonist-Antagonists or Partial Agonists						
Buprenorphine	Not available	0.3–0.4 mg/6–8 h	Not available	0.4 mg/6–8 h	Not available	0.004 mg/kg/6–8 h
Butorphanol	Not available	2 mg/3–4 h	Not available	2 mg/3–4 h	Not available	Not recommended
Nalbuphine	Not available	10 mg/3–4 h	Not available	10 mg/3–4 h	Not available	0.1 mg/kg/3–4 h

These data are merely guidelines. Clinical response must be the guide for each patient, with consideration to hepatic and renal function, disease, age, concurrent medications (their effects and dose limitations [acetaminophen, 3 g/d for adults]), and other factors that could modify pharmacokinetics and drug response. Recommended start doses are approximately but not precisely equianalgesic and are driven by doses available from manufacturers. Transdermal fentanyl is contraindicated for acute pain and in patients receiving < 60 mg oral morphine equivalent per day. Use Table 20-8 for converting morphine to methadone dosing.

For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences.

Doses listed for patients with body weight less than 50 kg cannot be used as initial starting doses in babies less than 6 months of age; consult the *Clinical Practice Guideline #1, Acute Pain Management: Operative or Medical Procedures and Trauma* (cited below), section on neonates, for recommendations.

Source: Modified and updated from Agency for Healthcare Policy and Research, 1992. Acute Pain Management Guideline Panel. AHCPR Clinical Practice Guidelines, No. 1: Acute Pain Management: Operative or Medical Procedures and Trauma [Rockville (MD): Agency for Health Care Policy and Research (AHCPR); 1992].

are made by relatively simple modifications of morphine or thebaine. Codeine is methylmorphine, the methyl substitution being on the phenolic hydroxyl group. Thebaine differs from morphine only in that both hydroxyl groups are methylated and that the ring has two double bonds (6,7; 8,14). Thebaine has little analgesic action but is a precursor of several important 14-OH compounds, such as oxycodone and naloxone. Certain derivatives of thebaine are more than 1000 times as potent as morphine (e.g., etorphine). Diacetylmorphine, or heroin, is made from morphine by acetylation at the 3 and 6 positions. Apomorphine, which also can be prepared from morphine, is a potent emetic and dopaminergic agonist at D₂- and D₁-type receptors, does not interact with opiate receptors, and displays no analgesic actions (see Chapters 13, 18, and 50). Hydromorphone, oxymorphone, hydrocodone, and oxycodone also are made by modifying the morphine molecule.

Structure-Activity Relationship of the Morphine-Like Opioids. In addition to morphine, codeine, and the semisynthetic derivatives of the natural opium alkaloids, a number of other structurally distinct chemical classes of drugs have pharmacological actions similar to those of morphine. Clinically useful compounds include the morphinans, benzomorphans, methadones, phenylpiperidines, and propionanilides. Although the two-dimensional representations of these chemically diverse compounds appear to be quite different, molecular models show common

characteristics. Among the important properties of the opioids that can be altered by structural modification are their affinities for various types of opioid receptors, their activities as agonists versus antagonists, their lipid solubilities, and their resistance to metabolic breakdown. For example, blockade of the phenolic hydroxyl at position 3, as in codeine and heroin, drastically reduces binding to receptors; these compounds are converted in vivo to the potent analgesics morphine and 6-acetyl morphine, respectively.

ADME. Absorption. In general, the opioids are modestly well absorbed from the GI tract; absorption through the rectal mucosa is adequate, and a few agents (e.g., morphine, hydromorphone) are available in suppositories. The more lipophilic opioids are absorbed readily through the nasal or buccal mucosa. Those with the greatest lipid solubility also can be absorbed transdermally. Opioids, particularly morphine, have been widely used for spinal delivery to produce analgesia through a spinal action. These agents display useful transdural movement adequate to permit their use epidurally.

With most opioids, including morphine, the effect of a given dose is less after oral than after parenteral administration because of variable but significant first-pass metabolism in the liver. For example, the bioavailability of oral preparations of morphine is only about 25%. The shape of the time-effect curve also varies with the route of administration, so the duration of action often is somewhat longer with the oral route.

Figure 20–9 Structures of morphine-related opiate agonists and antagonists.

If adjustment is made for variability of first-pass metabolism and clearance, adequate relief of pain can be achieved with oral administration of morphine. Satisfactory analgesia in patients with cancer is associated with a broad range of steady-state concentrations of morphine in plasma (16–364 ng/mL) (Neumann et al., 1982).

When morphine and most opioids are given intravenously, they act promptly. However, the more lipid-soluble compounds (e.g., fentanyl) act more rapidly than morphine after subcutaneous administration because of differences in the rates of absorption and entry into the CNS. Compared with more lipid-soluble opioids such as codeine, heroin, and methadone, morphine crosses the blood-brain barrier at a considerably lower rate.

Distribution and Metabolism. About one-third of morphine in the plasma is protein bound after a therapeutic dose. Morphine itself does

not persist in tissues, and 24 h after the last dose, tissue concentrations are low.

The major pathway for the metabolism of morphine is conjugation with glucuronic acid. The two major metabolites formed are morphine-6-glucuronide and morphine-3-glucuronide. Small amounts of morphine-3,6-diglucuronide also may be formed. Although the 3- and 6-glucuronides are polar, both still can cross the blood-brain barrier to exert significant clinical effects (Christrup, 1997).

Morphine-6-glucuronide has pharmacological actions indistinguishable from those of morphine. Morphine-6-glucuronide given systemically is approximately twice as potent as morphine in animal models and in humans (Osborne et al., 1992). With chronic administration, the 6-glucuronide accounts for a significant portion of morphine's

analgesic actions. Indeed, with chronic oral dosing, the blood levels of morphine-6-glucuronide typically exceed those of morphine. Given its greater MOR potency and its higher concentration, morphine-6-glucuronide may be responsible for most of morphine's analgesic activity in patients receiving chronic oral morphine. Morphine-6-glucuronide is excreted by the kidney. In renal failure, the levels of morphine-6-glucuronide can accumulate, perhaps explaining morphine's potency and long duration in patients with compromised renal function. In adults, the $t_{1/2}$ of morphine is about 2 h; the $t_{1/2}$ of morphine-6-glucuronide is somewhat longer. Children achieve adult renal function values by 6 months of age. In elderly patients, lower doses of morphine are recommended based on a smaller volume of distribution and the general decline in renal function in the elderly (Owens, et al, 1983).

Morphine-3-glucuronide, another important metabolite, has little affinity for opioid receptors but may contribute to excitatory effects of morphine (Smith, 2000). *N*-Demethylation of morphine to normorphine is a minor metabolic pathway in humans. *N*-Dealkylation also is important in the metabolism of some congeners of morphine.

Excretion. Morphine is eliminated by glomerular filtration, primarily as morphine-3-glucuronide; 90% of the total excretion takes place during the first day. Very little morphine is excreted unchanged. Enterohepatic circulation of morphine and its glucuronides occurs, which accounts for the presence of small amounts of morphine in feces and urine for several days after the last dose.

Morphine Congeners. Codeine. Codeine is an important natural product found in the poppy resin. It displays a modest affinity for the μ receptor, but its analgesic actions are considered by many to arise at least in part by its hepatic metabolism to morphine (see further discussion). Thus, in contrast to morphine, codeine is about 60% as effective orally as parenterally as an analgesic and as a respiratory depressant. Codeine is commonly employed for the management of cough, frequently in combination dose forms with acetaminophen or aspirin. The drug has an exceptionally low affinity for opioid receptors, and while the analgesic effect of codeine is likely due to its conversion to morphine, codeine's antitussive actions may involve distinct receptors that bind codeine itself.

Once absorbed, codeine is metabolized by the liver. Codeine analogues such as levorphanol, oxycodone, and methadone have a high ratio of oral-to-parenteral potency. The greater oral efficacy of these drugs reflects lower first-pass metabolism in the liver. Codeine's metabolites are excreted chiefly as inactive forms in the urine. A small fraction (~10%) of administered codeine is *O*-demethylated to morphine, and free and conjugated morphine can be found in the urine after therapeutic doses of codeine. The $t_{1/2}$ of codeine in plasma is 2–4 h. CYP2D6 catalyzes the conversion of codeine to morphine. Genetic polymorphisms in CYP2D6 lead to the inability to convert codeine to morphine, thus making codeine ineffective as an analgesic for about 10% of the Caucasian population (Eichelbaum and Evert, 1996). Other polymorphisms (e.g., the CYP2D6*2x2 genotype) can lead to ultrarapid metabolism and thus increased sensitivity to codeine's effects due to higher than expected serum morphine levels. Other variations in metabolic efficiency among ethnic groups are apparent. For example, Chinese produce less morphine from codeine than do Caucasians and also are less sensitive to morphine's effects. The reduced sensitivity to morphine may be due to decreased production of morphine-6-glucuronide (Caraco et al., 1999). Thus, it is important to consider the possibility of metabolic enzyme polymorphism in any patient who experiences toxicity or does not receive adequate analgesia from codeine or other opioid prodrugs (e.g., hydrocodone and oxycodone) (Johansson and Ingelman-Sundberg, 2011).

Heroin. Heroin (diacetylmorphine) is rapidly hydrolyzed to 6-MAM, which in turn is hydrolyzed to morphine. Heroin and 6-MAM are more lipid soluble than morphine and enter the brain more readily. Evidence suggests that morphine and 6-MAM are responsible for the pharmacological actions of heroin. Heroin is excreted mainly in the urine, largely as free and conjugated morphine (Rook et al., 2006).

Hydromorphone. Hydromorphone is a semisynthetic hydrogenated ketone derivative of morphine. It displays all of the opioid actions of

morphine. It is commonly used as an intravenous medication. The drug is formulated in parenteral, rectal, subcutaneous, and oral preparations and as a nebulized formulation and is given off label by epidural or intrathecal routes. Hydromorphone has a higher lipid solubility than morphine, resulting in more rapid onset than morphine, and is considered to be several times more potent than morphine. Hydromorphone is metabolized in the liver to hydromorphone-3-glucuronide.

Oxycodone. Oxycodone is a semisynthetic opioid synthesized from the alkaloid thebaine. The molecule undergoes hepatic metabolism to the more potent μ opioid oxymorphone. Oxycodone is available as single-ingredient medication in immediate-release and controlled-release formulations. Parenteral formulations of 10 mg/mL and 50 mg/mL are available in the U.K. for intravenous or intramuscular administration. Combination products are also available as immediate-release formulations with non-narcotic ingredients such as NSAIDs. At present, oxycodone is one of the most commonly abused pharmaceutical drugs in the U.S.

Hydrocodone. Hydrocodone is synthesized from codeine. It is used orally for relief of moderate-to-severe pain and is employed in a liquid formulation as a cough suppressant. It is approximately equipotent to oxycodone, with an onset of action of 10–30 min and duration of 4–6 h. Hepatic CYPs 2D6 and 3A4 convert hydrocodone to hydromorphone and norhydrocodone, respectively. Hydrocodone shows a serum half-life of about 4 h.

Oxymorphone. Oxymorphone, a semisynthetic alkaloid, is produced from thebaine. Oxymorphone is a potent MOR agonist with an onset of analgesia after parenteral dosing of about 5–10 min and a duration of action of 3–4 h. Oxymorphone is extensively metabolized in liver and excreted as the 3- and 6-glucuronides.

Adverse Effects and Precautions

Morphine and related opioids, aside from their effects as analgesics, produce a wide spectrum of effects reflecting the distribution of opiate receptors across organ systems. These effects include respiratory depression, nausea, vomiting, dizziness, mental clouding, dysphoria, pruritus, constipation, increased pressure in the biliary tract, urinary retention, hypotension, and, rarely, delirium. Increased sensitivity to pain may occur after analgesia has worn off, and removal of opiate receptor occupancy (abstinence, antagonism) may lead to a highly aversive state of withdrawal.

Factors Affecting Patient Response to Morphine and Congeners

Beyond those mentioned, a number of other factors may alter a patient's response to opioid analgesics.

- **Blood-Brain Barrier.** Morphine is hydrophilic, so proportionately less morphine normally crosses into the CNS than with more lipophilic opioids. In neonates or when the blood-brain barrier is compromised, lipophilic opioids may give more predictable clinical results than morphine.
- **Age.** In adults, the duration of the analgesia produced by morphine increases progressively with age; however, the degree of analgesia that is obtained with a given dose changes little.
- **Pain State.** The patient with severe pain may tolerate larger doses of morphine. However, as the pain subsides, the patient may exhibit sedation and even respiratory depression as the stimulatory effects of pain are diminished.
- **Opioid Metabolism.** All opioid analgesics are metabolized by the liver and should be used with caution in patients with hepatic disease. Renal disease also significantly alters the pharmacokinetics of morphine, codeine, dihydrocodeine, and meperidine. Although single doses of morphine are well tolerated, the active metabolite, morphine-6-glucuronide, may accumulate with continued dosing, and symptoms of opioid overdose may result. This metabolite also may accumulate during repeated administration of codeine to patients with impaired renal function. When repeated doses of meperidine are given to such patients, the accumulation of normeperidine may cause tremor and seizures. Similarly, the repeated administration of propoxyphene

may lead to naloxone-insensitive cardiac toxicity caused by accumulation of the metabolite norpropoxyphene.

- **Sex.** There is a growing body of data that examines gender differences in the responses to pain and analgesics (Mogil, 2012). Females have the majority of chronic pain syndromes, and surveys examining sex differences in acute pain models report either no sex difference or greater sensitivity in females. Data on sex differences in opiate analgesia have thus far been inconsistent (Lloyd and Murphy, 2014).
- **Respiratory Function.** Morphine and related opioids must be used cautiously in patients with compromised respiratory function (e.g., emphysema, kyphoscoliosis, severe obesity, or cor pulmonale). Although many patients with such conditions seem to be functioning within normal limits, they are already using compensatory mechanisms, such as increased respiratory rate. Many have chronically elevated levels of plasma CO_2 and may be less sensitive to the stimulating actions of CO_2 . The further imposition of the depressant effects of opioids can be disastrous.
- **Head Injury.** The respiratory-depressant effects of opioids and the related capacity to elevate intracranial pressure must be considered in the presence of head injury or an already-elevated intracranial pressure. While head injury per se does not constitute an absolute contraindication to the use of opioids, the possibility of exaggerated depression of respiration and the potential need to control ventilation of the patient must be considered. Finally, because opioids may produce mental clouding and side effects such as miosis and vomiting, which are important signs in following the clinical course of patients with head injuries, the advisability of their use must be weighed carefully against these risks.
- **Hypovolemia; Hypotension.** Reduced blood volume causes patients to be considerably more susceptible to the vasodilating effects of morphine and related drugs, and these agents must be used cautiously in patients with hypotension from any cause.
- **Asthma; Allergic Responses; Histamine Release.** Morphine causes histamine release, which can cause bronchoconstriction and vasodilation. Morphine can precipitate or exacerbate asthmatic attacks and should be avoided in patients with a history of asthma. Other receptor agonists associated with a lower incidence of histamine release, such as the fentanyl derivatives, may be better choices for such patients.

Aside from their capacity to release histamine, opioid analgesics may evoke allergic phenomena, but a true allergic response is uncommon. The effects usually are manifested as urticaria and fixed eruptions; contact dermatitis in nurses and pharmaceutical workers also occurs. Wheals at the site of injection of morphine, codeine, and related drugs are likely secondary to histamine release. Anaphylactoid reactions have been reported after intravenous administration of codeine and morphine, but such reactions are rare. In addicts who use intravenous heroin, such reactions may contribute to sudden death, episodes of pulmonary edema, and other complications.

Other Morphinans

Levorphanol

Levorphanol is an opioid agonist of the morphinan series (Figure 20–9). Levorphanol has affinity at the MORs, KORs, and DORs and is available for intravenous, intramuscular, and oral administration. The pharmacological effects of levorphanol closely parallel those of morphine. Compared to morphine, this agent is about seven times more potent and may produce less nausea and vomiting. Levorphanol is metabolized less rapidly than morphine and has a $t_{1/2}$ of 12–16 h; repeated administration at short intervals may thus lead to accumulation of the drug in plasma (Prommer, 2014). The D-isomer (dextrorphan) is devoid of analgesic action but has inhibitory effects at NMDA receptors.

Piperidine and Phenylpiperidine Analgesics

Meperidine, Diphenoxylate, Loperamide

The agents meperidine, diphenoxylate, and loperamide are MOR agonists with principal pharmacological effects on the CNS and neural elements in the bowel.

Meperidine. Meperidine is predominantly an MOR agonist that produces a pattern of effects similar but not identical to those already described for morphine (Latta et al., 2002).

CNS Actions. Meperidine is a potent agonist at MORs in the CNS, yielding strong analgesic actions. Meperidine causes pupillary constriction, increases the sensitivity of the labyrinthine apparatus, and has effects on the secretion of pituitary hormones similar to those of morphine. Meperidine sometimes causes CNS excitation, characterized by tremors, muscle twitches, and seizures. These effects are due largely to accumulation of a metabolite, normeperidine. Meperidine has well-known local anesthetic properties, particularly noted after epidural administration. As with morphine, respiratory depression is responsible for an accumulation of CO_2 , which in turn leads to cerebrovascular dilation, increased cerebral blood flow, and elevation of CSF pressure.

Cardiovascular Effects. The effects of meperidine on the cardiovascular system generally resemble those of morphine, including the release of histamine following parenteral administration. Intramuscular administration of therapeutic doses of meperidine does not affect heart rate significantly, but intravenous administration frequently produces a marked increase in heart rate.

Actions on Smooth Muscle, GI Tract, and Uterus. Meperidine does not cause as much constipation as morphine, even when given over prolonged periods; this may be related to its greater ability to enter the CNS, thereby producing analgesia at lower systemic concentrations. As with other opioids, clinical doses of meperidine slow gastric emptying sufficiently to delay absorption of other drugs significantly. The uterus of a nonpregnant woman usually is mildly stimulated by meperidine. Administered before an oxytocic, meperidine does not exert any antagonistic effect. Therapeutic doses given during active labor do not delay the birth process; in fact, frequency, duration, and amplitude of uterine contraction may be increased.

ADME. Meperidine is absorbed by all routes of administration. The peak plasma concentration usually occurs at about 45 min, but the range is wide. After oral administration, only about 50% of the drug escapes first-pass metabolism to enter the circulation, and peak concentrations in plasma occur in 1–2 h. Meperidine is metabolized chiefly in the liver, with a $t_{1/2}$ of about 3 h. Metabolites are the N-demethyl product, normeperidine, and the hydrolysis product, meperidate, both of which may be conjugated. In patients with cirrhosis, the bioavailability of meperidine is increased to as much as 80%, and the $t_{1/2}$ of both meperidine and the metabolite normeperidine ($t_{1/2} \sim 15\text{--}20\text{ h}$) are prolonged. Only a small amount of meperidine is excreted unchanged.

Therapeutic Use. The major use of meperidine is for analgesia. The analgesic effects of meperidine are detectable about 15 min after oral administration, peak in 1–2 h, and subside gradually. The onset of analgesic effect is faster (within 10 min) after subcutaneous or intramuscular administration, and the effect reaches a peak in about 1 h, corresponding closely to peak concentrations in plasma. In clinical use, the duration of effective analgesia is about 1.5–3 h. Peak respiratory depression is observed within 1 h of intramuscular administration, and there is a return toward normal starting at about 2 h. In general, 75–100 mg meperidine hydrochloride given parenterally is approximately equivalent to 10 mg morphine. In terms of total analgesic effect, meperidine is about one-third as effective when given orally as when administered parenterally.

Single doses of meperidine can be effective in the treatment of postanesthetic shivering. Meperidine, 25–50 mg, is used frequently with antihistamines, corticosteroids, acetaminophen, or NSAIDs to prevent or ameliorate infusion-related rigors and shaking chills that accompany the intravenous administration of agents such as amphotericin B, aldesleukin (interleukin 2), trastuzumab, and alemtuzumab. Meperidine crosses the placental barrier, and even in reasonable analgesic doses causes a significant increase in the percentage of babies who show delayed respiration, decreased respiratory minute volume, or decreased O_2 saturation or who require resuscitation. Fetal and maternal respiratory depression induced by meperidine can be treated with naloxone. Meperidine produces less

respiratory depression in the newborn than does an equianalgesic dose of morphine or methadone (Fishburne, 1982).

Untoward Effects, Precautions, and Contraindications. The overall incidence of untoward effects is similar to those observed after equianalgesic doses of morphine, except that constipation and urinary retention and nausea may be less common. Patients who experience nausea and vomiting with morphine may not do so with meperidine; the converse also may be true. In patients or addicts who are tolerant to the depressant effects of meperidine, large doses repeated at short intervals may produce an excitatory syndrome that includes hallucinations, tremors, muscle twitches, dilated pupils, hyperactive reflexes, and convulsions. These excitatory symptoms are due to the accumulation of the long-lived metabolite normeperidine, which has a $t_{1/2}$ of 15–20 h, compared to 3 h for meperidine. Decreased renal or hepatic function increases the likelihood of toxicity. As a result of these properties, meperidine is not recommended for the treatment of chronic pain because of concerns over metabolite toxicity. It should not be used for longer than 48 h or in doses greater than 600 mg/d.

Interactions With Other Drugs. Severe reactions may follow the administration of meperidine to patients being treated with MAO inhibitors. There are two basic types of interaction. The more prominent is an excitatory reaction (“serotonin syndrome”) with delirium, hyperthermia, headache, hyper- or hypotension, rigidity, convulsions, coma, and death. This reaction may be due to the capacity of meperidine to block neuronal reuptake of 5HT, resulting in serotonergic overactivity. Dextromethorphan (an analogue of levorphanol used as a nonnarcotic cough suppressant) also inhibits neuronal 5HT uptake and must be avoided in these patients. In the second type of interaction, several MAO inhibitors are substrates or inhibitors of hepatic CYPs and reduce meperidine metabolism, creating a condition resembling acute narcotic overdose. Therefore, meperidine and its congeners are contraindicated in patients taking MAO inhibitors or within 14 days after discontinuation of an MAO inhibitor.

Chlorpromazine increases the respiratory-depressant effects of meperidine, as do tricyclic antidepressants (but not diazepam). Concurrent administration of drugs such as promethazine or chlorpromazine also may greatly enhance meperidine-induced sedation without slowing clearance of the drug. Treatment with phenobarbital or phenytoin increases systemic clearance and decreases oral bioavailability of meperidine. As with morphine, concomitant administration of amphetamine has been reported to enhance the analgesic effects of meperidine and its congeners while counteracting sedation.

Diphenoxylate. Diphenoxylate is a meperidine congener that has a definite constipating effect in humans. Its only approved use is in the treatment of diarrhea. Diphenoxylate is unusual in that even its salts are virtually insoluble in aqueous solution, thus reducing the probability of abuse by the parenteral route. Diphenoxylate hydrochloride is available only in combination with atropine sulfate. The recommended daily dosage of diphenoxylate for the treatment of diarrhea in adults is 20 mg in divided doses. Difenoxin a metabolite of diphenoxylate and is marketed in a fixed dose with atropine for the management of diarrhea.

Loperamide. Loperamide, like diphenoxylate, is a piperidine derivative. It slows GI motility by effects on the circular and longitudinal muscles of the intestine (Kromer, 1988). Part of its antidiarrheal effect may be due to a reduction of GI secretory processes (see Chapter 50). In controlling chronic diarrhea, loperamide is as effective as diphenoxylate and little tolerance develops to its constipating effect. Concentrations of drug in plasma peak about 4 h after ingestion. The apparent elimination $t_{1/2}$ is 7–14 h. Loperamide is poorly absorbed after oral administration and, in addition, apparently does not penetrate well into the brain due to the exporting activity of P-glycoprotein, which is widely expressed in the brain endothelium. The usual dosage is 4–8 mg/d; the daily dose should not exceed 16 mg (Regnard et al., 2011). The most common side effect is abdominal cramps. Loperamide is unlikely to be abused parenterally because of its low solubility; large doses of loperamide given to human volunteers do not elicit pleasurable effects typical of opioids.

Fentanyl and Congeners

Fentanyl

Fentanyl is a synthetic opioid related to the phenylpiperidines. The actions of fentanyl and its congeners sufentanil, remifentanil, and alfentanil are similar to those of other MOR agonists. Fentanyl and sufentanil are important drugs in anesthetic practice because of their relatively short time to peak analgesic effect, rapid termination of effect after small bolus doses, cardiovascular safety, and capacity to significantly reduce the dosing requirement for the volatile agents (see Chapter 21). In addition to a role in anesthesia, fentanyl is used in the management of severe pain states delivered by several routes of administration (Willens and Myslinski, 1993).

ADME. These agents are highly lipid soluble and rapidly cross the blood-brain barrier. This is reflected in the $t_{1/2}$ for equilibration between the plasma and CSF of about 5 min for fentanyl and sufentanil. The levels in plasma and CSF decline rapidly owing to redistribution of fentanyl from highly perfused tissue groups to other tissues, such as muscle and fat. As saturation of less well-perfused tissue occurs, the duration of effect of fentanyl and sufentanil approaches the length of their elimination $t_{1/2}$, 3–4 h. Fentanyl and sufentanil undergo hepatic metabolism and renal excretion. With the use of higher doses or prolonged infusions, the drugs accumulate, these clearance mechanisms become progressively saturated, and fentanyl and sufentanil become longer acting.

Pharmacological Effects. **CNS.** Fentanyl and its congeners are all extremely potent analgesics and typically exhibit a very short duration of action when given parenterally. As with other opioids, nausea, vomiting, and itching can be observed. Muscle rigidity, while possible after all narcotics, appears to be more common after the high doses used in anesthetic induction. Rigidity can be treated with depolarizing or nondepolarizing neuromuscular-blocking agents, while controlling the patient's ventilation, but care must be taken to make sure that the patient is not simply immobilized and aware. Respiratory depression is similar to that observed with other MOR agonists, but onset is more rapid. As with analgesia, respiratory depression after small doses is of shorter duration than with morphine but of similar duration after large doses or long infusions. Delayed respiratory depression also can be seen after the use of fentanyl or sufentanil, possibly owing to enterohepatic circulation.

Cardiovascular System. Fentanyl and its derivatives decrease heart rate through vagal activation and may modestly decrease blood pressure. However, these drugs do not release histamine, and direct depressant effects on the myocardium are minimal. For this reason, high doses of fentanyl or sufentanil are commonly used as the primary anesthetic for patients undergoing cardiovascular surgery or for patients with poor cardiac function.

Therapeutic Uses. Fentanyl citrate and sufentanil citrate have widespread popularity as anesthetic adjuvants (see Chapter 21), administered intravenously and epidurally. After systemic delivery, fentanyl is about 100 times more potent than morphine; sufentanil is about 1000 times more potent than morphine. The time to peak analgesic effect after intravenous administration of fentanyl and sufentanil (~5 min) is notably less than that for morphine and meperidine (~15 min). Recovery from analgesic effects also occurs more quickly. However, with larger doses or prolonged infusions, the effects of these drugs become more lasting, with durations of action becoming similar to those of longer-acting opioids.

The use of fentanyl in chronic pain treatment has become more widespread. Transdermal patches that provide sustained release of fentanyl for 48–72 h are available. However, factors promoting increased absorption (e.g., fever) can lead to relative overdosage and increased side effects. Transbuccal absorption by the use of buccal tablets and lollipop-like lozenges permits rapid absorption and has found use in the management of acute incident pain and for the relief of breakthrough cancer pain. As fentanyl is poorly absorbed in the GI tract, the optimal absorption is through buccal administration. Fentanyl should only be used in opioid-tolerant patients, defined as consuming more than 60 mg of oral morphine equivalent. Epidural use of fentanyl and sufentanil for postoperative or labor analgesia is popular. A combination of epidural opioids with local anesthetics permits

reduction in the dosage of both components. Illicit use (self-administration by chewing) of fentanyl patches can be deadly, and practitioners must be aware of this potential and keep careful control of fentanyl stocks.

Remifentanyl

The pharmacological properties of remifentanyl are similar to those of fentanyl and sufentanyl. Remifentanyl produces similar incidences of nausea, vomiting, and dose-dependent muscle rigidity.

ADME. Remifentanyl has a more rapid onset of analgesic action than fentanyl or sufentanyl. Analgesic effects occur within 1–1.5 min following intravenous administration. Peak respiratory depression after bolus doses of remifentanyl occurs after 5 min. Remifentanyl is metabolized by plasma esterases, with a $t_{1/2}$ of 8–20 min; thus, elimination is independent of hepatic metabolism or renal excretion. Age and weight can affect clearance of remifentanyl. After 3- to 5-h infusions of remifentanyl, recovery of respiratory function can be seen within 3–5 min; full recovery from all effects of remifentanyl occurs within 15 min. The primary metabolite, remifentanyl acid, has 0.05%–0.025% of the potency of the parent compound and is excreted renally.

Therapeutic Uses. Remifentanyl hydrochloride is useful for short, painful procedures that require intense analgesia and blunting of stress responses; the drug is routinely given by continuous intravenous infusion because of its short duration of action. When postprocedural analgesia is required, remifentanyl alone is a poor choice. In this situation, either a longer-acting opioid or another analgesic modality should be combined with remifentanyl for prolonged analgesia, or another opioid should be used. Remifentanyl is not used intraspinally (epidural or intrathecal administration) because of its formulation with glycine, an inhibitory neurotransmitter in the dorsal horn of the spinal cord (Stroumpou et al., 2010).

Methadone

Methadone is a long-acting MOR agonist with pharmacological properties qualitatively similar to those of morphine. The analgesic activity of methadone, a racemate, is almost entirely the result of its content of L-methadone, which is 8–50 times more potent than the D-isomer. D-Methadone also lacks significant respiratory depressant action and addiction liability but possesses antitussive activity (Fredheim et al., 2008).

Propoxyphene is a methadone analogue that was used to treat mild-to-moderate pain. The FDA removed the drug (trade name: DARVON) from the U.S. market in 2010 due to reports of cardiac toxicity.

Pharmacological Effects

The outstanding properties of methadone are its analgesic activity, its efficacy by the oral route, its extended duration of action in suppressing withdrawal symptoms in physically dependent individuals, and its tendency to show persistent effects with repeated administration. Miotic and respiratory-depressant effects can be detected for more than 24 h after a single dose; on repeated administration, marked sedation is seen in some patients. Effects on cough, bowel motility, biliary tone, and the secretion of pituitary hormones are qualitatively similar to those of morphine.

ADME

Methadone is absorbed well from the GI tract and can be detected in plasma within 30 min of oral ingestion; it reaches peak concentrations at about 4 h. Peak concentrations occur in brain within 1–2 h of subcutaneous or intramuscular administration, and this correlates well with the intensity and duration of analgesia. Methadone also can be absorbed from the buccal mucosa. Methadone undergoes extensive biotransformation in the liver. The major metabolites, pyrrolidine and pyrroline, result from N-demethylation and cyclization and are excreted in the urine and the bile along with small amounts of unchanged drug. The amount of methadone excreted in the urine is increased when the urine is acidified. The $t_{1/2}$ of methadone is long, 15–40 h. Methadone appears to be firmly bound to protein in various tissues, including brain. After repeated administration, there is gradual accumulation in tissues. When administration is discontinued, low concentrations are maintained in plasma by slow release from

extravascular binding sites; this process probably accounts for the relatively mild but protracted withdrawal syndrome.

Therapeutic Uses

The primary use of methadone hydrochloride is detoxification and maintenance treatment of opioid addiction within certified treatment programs. Outside treatment programs, methadone is used for the management of chronic pain. The onset of analgesia occurs 10–20 min after parenteral administration and 30–60 min after oral medication. The typical oral dose is 2.5–10 mg repeated every 8–12 h as needed depending on the severity of the pain and the response of the patient. Care must be taken when increasing the dosage because of the prolonged $t_{1/2}$ of the drug and its tendency to accumulate over a period of several days with repeated dosing. The peak respiratory depressant effects of methadone typically occur later and persist longer than peak analgesia, so it is necessary to exercise vigilance and strongly caution patients against self-medicating with CNS depressants, particularly during treatment initiation and dose titration. Methadone should not be used in labor. Despite its longer plasma $t_{1/2}$, the duration of the analgesic action of single doses is essentially the same as that of morphine. With repeated use, cumulative effects are seen, so either lower dosages or longer intervals between doses become possible.

Because of its oral bioavailability and long $t_{1/2}$, methadone has been widely implemented as a replacement modality to treat heroin addiction. Figure 24-3 compares the time courses of response to heroin and methadone, emphasizing the favorable pharmacokinetics of oral methadone in treating addiction. Methadone, like other opiates, will produce tolerance and dependence. Thus, addicts who receive daily subcutaneous or oral therapy develop partial tolerance to the nauseant, anorectic, miotic, sedative, respiratory-depressant, and cardiovascular effects of methadone. Many former heroin users treated with oral methadone show virtually no overt behavioral effects. Development of physical dependence during the long-term administration of methadone can be demonstrated following abrupt drug withdrawal or by administration of an opioid antagonist. Likewise, subcutaneous administration of methadone to former opioid addicts produces euphoria equal in duration to that caused by morphine, and its overall abuse potential is comparable with that of morphine.

Adverse Effects

Side effects are similar to those described for morphine. Rifampin and phenytoin accelerate the metabolism of methadone and can precipitate withdrawal symptoms. Unlike other opioids, methadone is associated with the prolonged QT syndrome and is additive with agents known to prolong the QT interval.

Other Opioid Agonists

Tramadol

Tramadol is a synthetic codeine analogue that is a weak MOR agonist. Part of its analgesic effect is produced by inhibition of uptake of NE and 5HT. In the treatment of mild-to-moderate pain, tramadol is as effective as morphine or meperidine. However, for the treatment of severe or chronic pain, tramadol is less effective. Tramadol is as effective as meperidine in the treatment of labor pain and may cause less neonatal respiratory depression (Grond and Sablotzki, 2004). Tramadol is also available as a fixed-dose combination with acetaminophen.

ADME. Tramadol is 68% bioavailable after a single oral dose. Its affinity for the MOR is only 1/6000 that of morphine. The primary O-demethylated metabolite of tramadol is two to four times more potent than the parent drug and may account for part of the analgesic effect. Tramadol is supplied as a racemate that is more effective than either enantiomer alone. The (+)-enantiomer binds to the receptor and inhibits 5HT uptake. The (–)-enantiomer inhibits NE uptake and stimulates α_2 adrenergic receptors. Tramadol undergoes extensive hepatic metabolism by a number of pathways, including CYPs 2D6 and 3A4, and by conjugation with subsequent renal excretion. The elimination $t_{1/2}$ is 6 h for tramadol and 7.5 h for its active metabolite. Analgesia begins within an hour of oral dosing and

peaks within 2–3 h. The duration of analgesia is about 6 h. The maximum recommended daily dose is 400 mg (300 mg in patients > 75 years old and for extended-release formulations; 200 mg is given for patients with low creatinine clearance).

Adverse Effects. Side effects of tramadol include nausea, vomiting, dizziness, dry mouth, sedation, and headache. Respiratory depression appears to be less than with equianalgesic doses of morphine, and the degree of constipation is less than that seen after equivalent doses of codeine. Tramadol can cause seizures and possibly exacerbate seizures in patients with predisposing factors. Tramadol-induced respiratory depression is reversed by naloxone. Precipitation of withdrawal necessitates that tramadol be tapered prior to discontinuation. Tramadol should not be used in patients taking MAO inhibitors, SSRIs, or other drugs that lower the seizure threshold.

Tapentadol

Tapentadol is structurally and mechanistically similar to tramadol. It is a weak inhibitor of monoamine reuptake but has a significantly more potent activity at MORs, similar to oxycodone. Serotonin syndrome is a risk, especially when tapentadol is used concomitantly with SSRIs, SNRIs, tricyclic antidepressants, or MAO inhibitors that impair 5HT metabolism. Tapentadol is metabolized largely by glucuronidation. The drug is in pregnancy category C.

Opioid Partial Agonists

The drugs described in this section differ from clinically used MOR agonists. Drugs such as *nalbuphine* and *butorphanol* are competitive MOR antagonists but exert their analgesic actions by acting as agonists at KOR receptors. *Pentazocine* qualitatively resembles these drugs, but it may be a weaker MOR receptor antagonist or partial agonist while retaining its KOR agonist activity. *Buprenorphine* is a partial MOR agonist. The stimulus for the development of mixed agonist-antagonist drugs was a desire for analgesics with less respiratory depression and addictive potential. However, the clinical use of these compounds is often limited by undesirable side effects and limited analgesic effects.

Pentazocine

Pentazocine was synthesized as part of a deliberate effort to develop an effective analgesic with little or no abuse potential. It has agonistic actions and weak opioid antagonistic activity (Goldstein, 1985).

Pharmacological Actions and Side Effects. The pattern of CNS effects produced by pentazocine generally is similar to that of the morphine-like opioids, including analgesia, sedation, and respiratory depression. The analgesic effects of pentazocine are due to agonistic actions at KORs. Higher doses of pentazocine (60–90 mg) elicit dysphoric and psychotomimetic effects; these effects may be reversible by naloxone. The cardiovascular responses to pentazocine differ from those seen with typical receptor agonists in that high doses cause an increase in blood pressure and heart rate. Pentazocine acts as a weak antagonist or partial agonist at MORs. Pentazocine does not antagonize the respiratory depression produced by morphine. However, when given to patients who are dependent on morphine or other MOR agonists, pentazocine may precipitate withdrawal. Ceiling effects for analgesia and respiratory depression are observed at doses above 50–100 mg of pentazocine.

Pentazocine lactate injection is indicated for the relief of mild-to-moderate pain and is also used as a preoperative medication and as a supplement to anesthesia. Pentazocine tablets for oral use are only available in fixed-dose combinations with acetaminophen or naloxone. Combination of pentazocine with naloxone reduces the potential misuse of tablets as a source of injectable pentazocine by producing undesirable effects in subjects dependent on opioids. An oral dose of about 50 mg pentazocine results in analgesia equivalent to that produced by a 60-mg oral dose of codeine.

Nalbuphine

Nalbuphine is a KOR agonist–MOR antagonist opioid with effects that qualitatively resemble those of pentazocine; however, nalbuphine produces fewer dysphoric side effects than pentazocine (Schmidt et al., 1985).

Pharmacological Actions and Side Effects. An intramuscular dose of 10 mg nalbuphine is equianalgesic to 10 mg morphine, with similar onset and duration of analgesic and subjective effects. Nalbuphine depresses respiration as much as equianalgesic doses of morphine; however, nalbuphine exhibits a ceiling effect such that increases in dosage beyond 30 mg produce no further respiratory depression or analgesia. In contrast to pentazocine and butorphanol, 10 mg nalbuphine given to patients with stable coronary artery disease does not produce an increase in cardiac index, pulmonary arterial pressure, or cardiac work, and systemic blood pressure is not significantly altered; these indices also are relatively stable when nalbuphine is given to patients with acute myocardial infarction. Nalbuphine produces few side effects at doses of 10 mg or less; sedation, sweating, and headache are the most common. At much higher doses (70 mg), psychotomimetic side effects (e.g., dysphoria, racing thoughts, and distortions of body image) can occur. Nalbuphine is metabolized in the liver and has a plasma $t_{1/2}$ of 2–3 h. Nalbuphine is 20%–25% as potent when administered orally as when given intramuscularly. Prolonged administration of nalbuphine can produce physical dependence. The withdrawal syndrome is similar in intensity to that seen with pentazocine.

Therapeutic Use. Nalbuphine is used to produce analgesia. Because it is an agonist-antagonist, administration to patients who have been receiving morphine-like opioids may create difficulties unless a brief drug-free interval is interposed. The usual adult dose is 10 mg parenterally every 3–6 h; this may be increased to 20 mg in nontolerant individuals. A caveat: Agents that act through the KORs are reportedly more effective in women than in men (Fillingim and Gear, 2004).

Butorphanol

Butorphanol is a morphinan congener with a profile of actions similar to those of pentazocine and nalbuphine: KOR agonist and MOR antagonist.

Pharmacological Actions and Side Effects. In postoperative patients, a parenteral dose of 2–3 mg butorphanol produces analgesia and respiratory depression approximately equal to that produced by 10 mg morphine or 80–100 mg meperidine. The plasma $t_{1/2}$ of butorphanol is about 3 h. Like pentazocine, analgesic doses of butorphanol produce an increase in pulmonary arterial pressure and in the work of the heart; systemic arterial pressure is slightly decreased. The major side effects of butorphanol are drowsiness, weakness, sweating, feelings of floating, and nausea. While the incidence of psychotomimetic side effects is lower than that with equianalgesic doses of pentazocine, they are qualitatively similar. Nasal administration is associated with drowsiness and dizziness. Physical dependence can occur.

Therapeutic Use. Butorphanol is used for the relief of acute pain (e.g., postoperative) and, because of its potential for antagonizing MOR agonists, should not be used in combination. Because of its side effects on the heart, it is less useful than morphine or meperidine in patients with congestive heart failure or myocardial infarction. The usual dose is 1–4 mg of the tartrate given intramuscularly, or 0.5–2 mg given intravenously, every 3–4 h. A nasal formulation is available and has proven to be effective in pain relief, including migraine pain (Gillis et al., 1995).

Buprenorphine

Buprenorphine is a highly lipophilic MOR partial agonist that is derived from thebaine and is 25–50 times more potent than morphine. As a partial MOR agonist, buprenorphine has limited intrinsic activity and accordingly can display antagonism when used in conjunction with a full agonist such as morphine. These properties have led it to have utility in managing opiate abuse and withdrawal (Elkader and Sproule, 2005).

ADME. Buprenorphine is well absorbed by most routes and produces analgesia and other CNS effects that are qualitatively similar to those of morphine. The $t_{1/2}$ for dissociation from the receptor is 166 min for buprenorphine, as opposed to 7 min for fentanyl. Therefore, plasma levels of buprenorphine may not parallel clinical effects. Cardiovascular and other side effects (e.g., sedation, nausea, vomiting, dizziness, sweating, and headache) appear to be similar to those of morphine-like opioids. Administered sublingually, buprenorphine (0.4–0.8 mg) produces satisfactory analgesia in postoperative patients. Concentrations in blood peak within

5 min of intramuscular injection and within 1–2 h of oral or sublingual administration. While the plasma $t_{1/2}$ in plasma is about 3 h, this value bears little relationship to the rate of disappearance of effects. Buprenorphine is metabolized to norbuprenorphine by CYP3A4 and should not be taken with known inhibitors of CYP3A4 (e.g., azole antifungals, macrolide antibiotics, and HIV protease inhibitors) or drugs that induce CYP3A4 activity (e.g., certain anticonvulsants and rifampin). Both *N*-dealkylated and conjugated metabolites are detected in the urine, but most of the drug is excreted unchanged in the feces. When buprenorphine is discontinued, a withdrawal syndrome develops that is delayed in onset for 2–14 days and persists for 1–2 weeks.

Therapeutic Use. Buprenorphine injection and transdermal film are indicated for use as an analgesic. Sublingual/buccal formulations of buprenorphine alone and in fixed-dose combinations with naloxone are used for treatment of opioid dependence; the partial agonist properties of buprenorphine limit its utility in the treatment of addicts who require high maintenance doses of opioids; in the U.S., this use is limited by the Drug Addiction Treatment Act. The usual intramuscular or intravenous dose for analgesia is 0.3 mg given every 6 h.

About 0.3 mg IM buprenorphine is equianalgesic with 10 mg IM morphine. Some of the subjective and respiratory-depressant effects are unequivocally slower in onset and last longer than those of morphine. Buprenorphine is a partial MOR agonist; thus, it may cause symptoms of abstinence in patients who have been receiving MOR agonists for several weeks. It antagonizes the respiratory depression produced by anesthetic doses of fentanyl about as well as naloxone without completely reversing opioid pain relief. The respiratory depression and other effects of buprenorphine can be prevented by prior administration of naloxone, but they are not readily reversed by high doses of naloxone once the effects have been produced, probably due to slow dissociation of buprenorphine from opioid receptors.

Opioid Antagonists

A variety of agents bind competitively to one or more of the opioid receptors, display little or no intrinsic activity, and robustly antagonize the effects of receptor agonists. Relatively minor changes in the structure of an opioid can convert a drug that is primarily an agonist into one with antagonistic actions at one or more types of opioid receptors. Simple substitutions transform morphine to *nalorphine*, levorphanol to *levallorphan*, and oxymorphone to *naloxone* or *naltrexone*. In some cases, congeners are produced that are competitive antagonists at MOR but that also have agonistic actions at KORs; *nalorphine* and *levallorphan* have such properties. Other congeners, especially *naloxone* and *naltrexone*, appear to be devoid of agonistic actions and interact with all types of opioid receptors, albeit with somewhat different affinities. *Nalmefene* (not marketed in the U.S.) is a relatively pure MOR antagonist that is more potent than naloxone. The majority of these agents are relatively lipid soluble and have excellent CNS penetration after systemic delivery (Barnett et al., 2014). A recognition for antagonism limited to peripheral sites, as for example to manage opiate-induced constipation, led to the development of agents that have poor CNS bioavailability, such as *methylnaltrexone* (Becker et al., 2007).

Pharmacological Properties

Opioid antagonists have obvious therapeutic utility in the treatment of opioid overdose. Under ordinary circumstances, these opioid antagonists produce few effects in the absence of an exogenous agonist. However, under certain conditions (e.g., shock), when the endogenous opioid systems are activated, the administration of an opioid antagonist alone may have positive effects on hemodynamic changes.

Effects in the Absence of Opioid Agonist. Subcutaneous doses of naloxone up to 12 mg produce no discernible effects in humans, and 24 mg causes only slight drowsiness. Naltrexone also is a relatively pure antagonist but with higher oral efficacy and a longer duration of action. The effects of opiate receptor antagonists are usually both subtle and limited, likely reflecting the low levels of tonic activity and organizational

complexity of the opioid systems in various physiologic systems. Opiate antagonism in humans is associated with variable effects, ranging from no effect to mild hyperalgesia. A number of studies have suggested that agents such as naloxone may attenuate the analgesic effects of placebo medications and acupuncture.

Endogenous opioid peptides participate in the regulation of pituitary secretion apparently by exerting tonic inhibitory effects on the release of certain hypothalamic hormones (see Chapter 42). Thus, the administration of naloxone or naltrexone increases the secretion of GnRH and CRH and elevates the plasma concentrations of LH, FSH, and ACTH, as well as the steroid hormones produced by their target organs. Naloxone stimulates the release of prolactin in women. Endogenous opioid peptides probably have some role in the regulation of feeding or energy metabolism; however, naltrexone does not accelerate weight loss in very obese subjects, even though short-term administration of opioid antagonists reduces food intake in lean and obese individuals. Long-term administration of antagonists increases the density of opioid receptors in the brain and causes a temporary exaggeration of responses to the subsequent administration of opioid agonists.

Effects in the Presence of Opioid Agonists. Antagonistic Effects. Small doses (0.4–0.8 mg) of naloxone given intramuscularly or intravenously prevent or promptly reverse the effects of receptor agonists. In patients with respiratory depression, an increase in respiratory rate is seen within 1–2 min. Sedative effects are reversed, and blood pressure, if depressed, returns to normal. Higher doses of naloxone are required to antagonize the respiratory-depressant effects of buprenorphine; 1 mg naloxone intravenously completely blocks the effects of 25 mg heroin. Naloxone reverses the psychotomimetic and dysphoric effects of agonist-antagonist agents such as pentazocine, but much higher doses (10–15 mg) are required. The duration of antagonistic effects depends on the dose but usually is 1–4 h. Antagonism of opioid effects by naloxone often is accompanied by an “overshoot” phenomenon. For example, respiratory rates depressed by opioids transiently become higher than before the period of depression. Rebound release of catecholamines may cause hypertension, tachycardia, and ventricular arrhythmias. Pulmonary edema also has been reported after naloxone administration.

Effects in Opioid-Dependent Patients. In subjects who are dependent on morphine-like opioids, small subcutaneous doses of naloxone (0.5 mg) precipitate a moderate-to-severe withdrawal syndrome that is similar to that seen after abrupt withdrawal of opioids, except that the syndrome appears within minutes of administration and subsides in about 2 h. The severity and duration of the syndrome are related to the dose of the antagonist and to the degree and type of dependence. Higher doses of naloxone will precipitate a withdrawal syndrome in patients dependent on pentazocine, butorphanol, or nalbuphine. In dependent patients, peripheral side effects of opioids, notably reduced GI motility and constipation, can be reversed by methylnaltrexone, with subcutaneous doses (0.15 mg/kg) producing reliable bowel movements and no evidence of centrally mediated withdrawal signs (Thomas et al., 2008). Naloxone produces an *overshoot phenomenon* suggestive of early acute physical dependence 6–24 h after even a single dose of an MOR agonist.

ADME

Although absorbed readily from the GI tract, naloxone is almost completely metabolized by the liver (primarily by conjugation with glucuronic acid) before reaching the systemic circulation and thus must be administered parenterally. The $t_{1/2}$ of naloxone is about 1 h, but its clinically effective duration of action can be even less.

Compared with naloxone, naltrexone has more efficacy by the oral route, and its duration of action approaches 24 h after moderate oral doses. Peak concentrations in plasma are reached within 1–2 h and then decline with an apparent $t_{1/2}$ of about 3 h. Naltrexone is metabolized to 6-naltrexol, which is a weaker antagonist with longer $t_{1/2}$, about 13 h. Naltrexone is much more potent than naloxone, and 100-mg oral doses given to patients addicted to opioids produce concentrations in tissues sufficient to block the euphorogenic effects of 25-mg IV doses of heroin for 48 h. Methylnaltrexone is similar to naltrexone; it is converted

to methyl-6-naltrexol isomers and eliminated primarily via active renal secretion. The $t_{1/2}$ of methylnaltrexone is about 8 h.

Therapeutic Uses

Treatment of Opioid Overdoses. Opioid antagonists, particularly naloxone, have an established use in the treatment of opioid-induced toxicity, especially respiratory depression. Its specificity is such that reversal by naloxone is virtually diagnostic for the contribution of an opiate to the depression. Naloxone acts rapidly to reverse the respiratory depression associated with even high doses of opioids. It should be titrated cautiously as it will precipitate withdrawal in dependent subjects and cause undesirable cardiovascular side effects (hypertension/tachycardia). The duration of action of naloxone is relatively short, and it often must be given repeatedly or by continuous infusion to prevent renarcotization. In the home setting, 0.4 mg of naloxone can be administered via autoinjector every 2–3 min while awaiting emergency medical assistance. Opioid antagonists also have been employed effectively to decrease neonatal respiratory depression secondary to the intravenous or intramuscular administration of opioids to the mother. In the neonate, the initial dose is 10 $\mu\text{g}/\text{kg}$ given intravenously, intramuscularly, or subcutaneously.

Management of Constipation. The peripherally limited antagonists methylnaltrexone and naloxegol have important roles in the management of the constipation and the reduced GI motility present in the patient undergoing chronic opioid therapy (as for chronic pain or methadone maintenance). The use of the type 2 chloride channel activator lubiprostone and other strategies for the management of opioid-induced constipation are described in Chapter 50. An important application of the peripherally restricted opiate receptor antagonists is their use in managing ileus (disruption of normal propulsive activity in the GI tract) secondary to abdominal surgery. Treatment with such agents facilitates recovery of normal bowel function and leaves the analgesic (CNS) activity of the postoperative opiate intact (Vaughan-Shaw et al., 2012).

Alvimopan. Alvimopan is an MOR antagonist with quaternary amino group that restricts the distribution of the drug to the periphery. The drug has a high affinity for MOR of 0.4 nM. Following oral administration, a deamidated metabolite of alvimopan slowly and variably appears in the bloodstream and is attributed to activity of the intestinal microbiome. This metabolite is also an MOR antagonist ($K_i = 0.8$ nM). The parent drug appears to enter an enterohepatic cycle coupled to deamidation in the GI tract; both parent drug and metabolite have terminal half-lives of 10–18 h. The drug, as the deamidated metabolite, is excreted in the feces and urine. Alvimopan is FDA-approved for treatment of postoperative ileus in patients with less than 7 days of opioid exposure immediately prior to beginning alvimopan (usually 12 mg administered just prior to surgery and 12 mg twice daily for 7 days). This agent carries a black-box warning about increased incidence of myocardial infarction with prolonged use and thus is available only for short-term use (15 doses) through a restricted program.

Management of Abuse Syndromes. There has been interest in the use of opiate antagonists such as naltrexone and nalmefene (not available in the U.S.) as adjuvants in treating a variety of nonopioid dependency syndromes, such as alcoholism (see Chapters 23 and 24), where an opiate antagonist may decrease the rate of relapse (Anton, 2008). Interestingly, patients with a single-nucleotide polymorphism in the MOR gene have significantly lower relapse rates to alcoholism when treated with naltrexone (Haile et al., 2008). Naltrexone is FDA-approved for treatment of alcohol dependence, to block the effects of exogenously administered opioids, and for the prevention of relapse to opioid dependence following detoxification. Naltrexone in combination with bupropion is also FDA-approved as an adjunct for weight management in patients with obesity.

Centrally Active Antitussives

Cough is a useful physiological mechanism that serves to clear the respiratory passages of foreign material and excess secretions; it should not be suppressed indiscriminately. There are, however, situations in which cough

does not serve any useful purpose but may, instead, annoy the patient, prevent rest and sleep, or hinder adherence to otherwise-beneficial medication regimens (e.g., ACE inhibitor-induced cough). In such situations, the physician should try to substitute a drug with a different side-effect profile (e.g., an AT_1 antagonist in place of an ACE inhibitor) or add an antitussive agent that will reduce the frequency or intensity of the coughing. A number of drugs reduce cough as a result of their central actions, including opioid analgesics, of which codeine and hydrocodone are most commonly used. Cough suppression often occurs with lower doses of opioids than those needed for analgesia. A 10- or 20-mg oral dose of codeine, although ineffective for analgesia, produces a demonstrable antitussive effect, and higher doses produce even more suppression of chronic cough. A few other antitussive agents are noted next.

Dextromethorphan

Dextromethorphan (D-3-methoxy-N-methylmorphinan) is the D-isomer of the codeine analogue methorphan; however, unlike the L-isomer, it has no analgesic or addictive properties and does not act through opioid receptors. Rather, the drug acts centrally to elevate the threshold for coughing. Its effectiveness in patients with pathological cough has been demonstrated in controlled studies; its potency is nearly equal to that of codeine, but dextromethorphan produces fewer subjective and GI side effects. In therapeutic dosages, the drug does not inhibit ciliary activity, and its antitussive effects persist for 5–6 h. Its toxicity is low, but extremely high doses may produce CNS depression. The average adult dosage of dextromethorphan hydrobromide is 10–20 mg every 4 h or 30 mg every 6–8 h, not to exceed 120 mg daily. The drug is marketed for over-the-counter sale in liquids, syrups, capsules, soluble strips, lozenges, and freezer pops or in combinations with antihistamines, bronchodilators, expectorants, and decongestants. An extended-release dextromethorphan suspension is approved for twice-daily administration.

Although dextromethorphan is known to function as an NMDA receptor antagonist, the dextromethorphan binding sites are not limited to the known distribution of NMDA receptors. Naloxone antagonizes the antitussive effects of codeine but not those of dextromethorphan. Thus, the mechanisms by which dextromethorphan exerts its antitussive effects still are not clear. Pharmacological cough suppression can apparently be achieved by a variety of mechanisms.

Other Antitussives

Pholcodine [3-O-(2-morpholinoethyl) morphine] is used clinically in many countries outside the U.S. Although structurally related to the opioids, pholcodine has no opioid-like actions. Pholcodine is at least as effective as codeine as an antitussive; it has a long $t_{1/2}$ and can be given once or twice daily.

Benzonatate is a long-chain polyglycol derivative chemically related to procaine and believed to exert its antitussive action on stretch or cough receptors in the lung, as well as by a central mechanism. It is available in oral capsules. The dosage is 100 mg three times daily; doses as high as 600 mg daily have been used safely.

Routes of Analgesic Drug Administration

In addition to the traditional oral and parenteral formulations for opioids, many other methods of administration have been developed in an effort to improve therapeutic efficacy while minimizing side effects.

Patient-Controlled Analgesia

With PCA, the patient has limited control of the dosing of opioid from an infusion pump programmed within tightly mandated parameters. PCA can be used for intravenous, subcutaneous, epidural, or intrathecal administration of opioids. This technique avoids delays inherent in administration by a caregiver and generally permits better alignment between pain control and individual differences in pain perception and responsiveness to opioids. The PCA technique also gives the patient a greater sense of control over the pain. With shorter-acting opioids, serious

toxicity or excessive use rarely occurs; however, caution is warranted due to the potential for serious medication errors associated with this delivery method. PCA is suitable for adults and children capable of understanding the principles involved. It is generally conceded that PCA is preferred over intramuscular injections for postoperative pain control.

Spinal Delivery

Administration of opioids into the epidural or intrathecal spaces provides more direct access to the first pain-processing synapse in the dorsal horn of the spinal cord. This permits the use of doses substantially lower than those required for oral or parenteral administration (Table 20–5). In postoperative pain management, sustained-release epidural injections are accomplished through the incorporation of morphine into a liposomal formulation, providing up to 48 h of pain relief (Hartrick and Hartrick, 2008). The management of chronic pain with spinal opiates has been addressed by the use of chronically implanted intrathecal catheters connected to subcutaneously implanted refillable pumps (Yaksh et al., 2017).

Epidural and intrathecal opioids have their own dose-dependent side effects, such as pruritus, nausea, vomiting, respiratory depression, and urinary retention. *Hydrophilic opioids* such as morphine have longer residence times in the CSF. As a consequence, after intrathecal or epidural morphine, respiratory depression can be delayed for as long as 24 h after a bolus dose. Given their more rapid clearance, the risk of *delayed* respiratory depression is reduced, *but not eliminated*, with *opioids that are more lipophilic*.

Extreme vigilance and appropriate monitoring are required for all opioid-naïve patients receiving intraspinal narcotics. Use of intraspinal opioids in the opioid-naïve patient is reserved for postoperative pain control in an inpatient monitored setting. Epidural administration of opioids has become popular in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic opioid levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn. Many opioids and other adjuvants are commonly used for neuraxial administration in adults and children; however, the majority of agents employed have not undergone appropriate preclinical safety evaluation and approval for these clinical indications; thus, such uses are “off label.” Thus, at this time, those agents approved for spinal delivery are certain preservative-free formulations of morphine sulfate and sufentanil. It is important to remember that the spinal route of delivery represents a novel environment wherein the neuraxis may be exposed to exceedingly high concentrations of an

agent for an extended period of time and safety by another route (e.g., oral, intravenous) may not translate to safety after spinal delivery (Yaksh and Allen, 2004).

Patients on chronic spinal opioid therapy are less likely to experience respiratory depression. Selected patients who fail conservative therapies for chronic pain may receive intraspinal opioids chronically through an implanted programmable pump. Analogous to the relationship between systemic opioids and NSAIDs, intraspinal narcotics often are combined with other agents that include local anesthetics, N-type Ca^{2+} channel blockers (e.g., ziconotide), α_2 adrenergic agonists, and GABA_B agonists. This permits synergy between drugs with different mechanisms, allowing the use of lower concentrations of both agents, minimizing side effects and the opioid-induced complications (Yaksh et al., 2017).

Use of intraspinal opioids in the opioid-naïve patient is reserved for postoperative pain control in an inpatient monitored setting. Epidural administration of opioids has become popular in the management of postoperative pain and for providing analgesia during labor and delivery. Lower systemic opioid levels are achieved with epidural opioids, leading to less placental transfer and less potential for respiratory depression of the newborn. Agents approved for spinal delivery are *specific preservative-free formulations* of morphine sulfate. A hydromorphone formulation is currently in clinical trials. The spinal route of delivery represents a novel environment wherein the neuraxis may be exposed to exceedingly high concentrations of an agent for an extended period of time. Safety as defined by another route of administration (e.g., oral, intravenous) may not translate temporally or dose-wise to safety after spinal delivery.

An important side effect associated with continued infusion of high concentrations of several opiates is formation of a space-occupying mass (a granuloma) at the catheter tip in the intrathecal space. These granulomas arise from meningeal mast cell degranulation and are the result of meningeal-derived fibroblast proliferation though an effect independent of an opioid receptor (Eddinger et al., 2016). The consequence of the spinal cord compression and neurologic sequelae may require discontinuation of spinal delivery and, in the extreme case, surgical removal of the mass (Deer, 2017).

Rectal Administration

The rectal route is an alternative for patients with difficulty swallowing or other oral pathology and who prefer a less invasive route than parenteral

TABLE 20–5 ■ EPIDURAL OR INTRATHECAL OPIOIDS FOR THE TREATMENT OF ACUTE (BOLUS) OR CHRONIC (INFUSION) PAIN

DRUG	SINGLE DOSE (mg) ^a	INFUSION RATE (mg/h) ^b	ONSET (min)	DURATION OF EFFECT OF SINGLE DOSE (h) ^c
Epidural				
Morphine	1–6	0.1–1.0	30	6–24
Meperidine	20–150	5–20	5	4–8
Methadone	1–10	0.3–0.5	10	6–10
Hydromorphone	1–2	0.1–0.2	15	10–16
Fentanyl	0.025–0.1	0.025–0.10	5	2–4
Sufentanil	0.01–0.06	0.01–0.05	5	2–4
Alfentanil	0.5–1	0.2	15	1–3
Subarachnoid (Intrathecal)				
Morphine	0.1–0.3		15	8–24+
Fentanyl	0.005–0.025		5	3–6

^aLow doses may be effective when administered to the elderly or when injected in the thoracic region.

^bIf combining with a local anesthetic, consider using 0.0625% bupivacaine.

^cDuration of analgesia varies widely; higher doses produce longer duration. With the exception of epidural/intrathecal morphine or epidural sufentanil, all other spinal opioid use is considered to be off label.

Source: Adapted and updated from Ready LB, Edwards WT, eds. *Management of Acute Pain: A Practical Guide*. International Association for Study of Pain, Seattle, 1992.

administration. This route is not well tolerated by most children. Onset of action is within 10 min. In the U.S., only morphine, hydromorphone, and opium (in combination with belladonna) are available in rectal suppository formulations.

Oral Transmucosal Administration

Opioids can be absorbed through the oral mucosa more rapidly than through the stomach. Bioavailability is greater owing to avoidance of first-pass metabolism, and lipophilic opioids are absorbed better by this route than are hydrophilic compounds such as morphine. A variety of formulations of fentanyl are available for oral transmucosal use: Suspensions of fentanyl in a dissolvable sugar-based lollipop or rapidly dissolving buccal tablet, a buccal fentanyl “film,” and a sublingual fentanyl tablet are approved for the treatment of cancer pain. In this setting, transmucosal fentanyl relieves pain within 15 min, and patients easily can titrate the appropriate dose.

Transnasal Administration

Butorphanol, a KOR agonist/MOR antagonist, has been employed intranasally. A transnasal, pectin-based, metered fentanyl spray is FDA-approved for the treatment of breakthrough cancer pain. Administration is well tolerated, and pain relief occurs within 10 min of delivery.

Transdermal Administration

Transdermal fentanyl patches are approved for use in sustained pain. The opioid permeates the skin, and a “depot” is established in the *stratum corneum* layer (see Figure 70–1). However, fever and external heat sources (heating pads, hot baths) can increase absorption of fentanyl and potentially lead to an overdose.

This modality is well suited for cancer pain treatment because of its ease of use, prolonged duration of action, and stable blood levels. It may take up to 12 h to develop analgesia and up to 16 h to observe full clinical effect. Plasma levels stabilize after two sequential patch applications, and the kinetics do not appear to change with repeated applications (Portenoy et al., 1993). However, there may be substantial variability in plasma levels after a given dose. The plasma $t_{1/2}$ after patch removal is about 17 h. If excessive sedation or respiratory depression occurs, antagonist infusions may need to be maintained for an extended period. Dermatological side effects from the patches, such as rash and itching, usually are mild. Opiate-addicted patients have been known to chew the patches and receive an overdose, sometimes with fatal outcomes, following rapid and efficient buccal and sublingual absorption.

Therapeutic Considerations in Pain Control

Given its profound impact on patient physiology and quality of life, the management of pain must be an important element in any therapeutic intervention. Failure to adequately manage pain can have important negative consequences on physiological function, such as autonomic hyperactivity (increased blood pressure, heart rate, suppression of GI motility, reduced secretions); and reduced mobility, leading to deconditioning, muscle wasting, joint stiffening, and decalcification; and can contribute to deleterious changes in the psychological state (depression, helplessness syndromes, anxiety). By many hospital-accrediting organizations, and by law in many states, appropriate pain assessment and adequate pain management are considered to be standard of care, with pain considered the “fifth vital sign.”

Acute Pain States

In acute pain states, opioids will reduce the intensity of pain. However, physical signs (such as abdominal rigidity with an acute abdomen) generally will remain. Relief of pain can facilitate history taking and examination in the emergency room and the patient's ability to tolerate diagnostic procedures. In most cases, analgesics should not be withheld for fear of obscuring the progression of underlying disease.

Chronic Pain States

The problems that arise in the relief of pain associated with chronic conditions are more complex. Repeated daily administration of opioid analgesics eventually will produce tolerance and some degree of physical dependence. The degree will depend on the particular drug, the frequency of administration, the quantity administered, the genetic predisposition, and the psychosocial status of the patient. The decision to control any chronic symptom, especially pain, by the repeated administration of an opioid must be made carefully. When pain is due to chronic nonmalignant disease, conservative measures using nonopioid drugs should be tried before resorting to the opioids. Such measures include the use of NSAIDs, local nerve blocks, antidepressant drugs, electrical stimulation, acupuncture, hypnosis, and behavioral modification. In end-of-life care, the analgesia, tranquility, and even euphoria afforded by the use of opioids can make the final days of life far less distressing for patient and family. Although physical dependence and tolerance may develop, this possibility should not prevent physicians from fulfilling their primary obligation to ease the patient's discomfort. The physician should not wait until the pain becomes agonizing; no patient should ever wish for death because of a physician's reluctance to use adequate amounts of effective opioids. This sometimes may entail the regular use of opioid analgesics in substantial doses. Such patients, while they may be physically dependent, are not “addicts” even though they may need large doses on a regular basis. As noted, physical dependence is not equivalent to addiction.

Guidelines for Opiate Dosing

The World Health Organization provides a three-step ladder as a guide to treat both cancer pain and chronic noncancer pain (Table 20–6). The three-step ladder encourages the use of more conservative therapies before initiating opioid therapy. Weaker opioids can be supplanted by stronger opioids in cases of moderate and severe pain. Antidepressants such as duloxetine and amitriptyline that are used in the treatment of chronic neuropathic pain have limited intrinsic analgesic actions in acute pain; however, antidepressants may enhance morphine-induced analgesia. In the presence of severe pain, the opioids should be considered sooner rather than later.

There has been a growing concern over the appropriate use of opiates in pain management. Since the last edition of this textbook, there has been increasing scrutiny of the use of opioids to treat chronic pain due to the high correlation between prescription opioids and opioid abuse. Drug overdose has become the leading cause of accidental death in the

TABLE 20–6 ■ WORLD HEALTH ORGANIZATION ANALGESIC LADDER

Step 1 Mild-to-Moderate Pain

Nonopioid ± adjuvant agent

- Acetaminophen or an NSAID should be used, unless contraindicated. Adjuvant agents are those that enhance analgesic efficacy, treat concurrent symptoms that exacerbate pain, or provide independent analgesic activity for specific types of pain.

Step 2 Mild-to-Moderate Pain or Pain Uncontrolled After Step 1

Short-acting opioid as required ± nonopioid ATC ± adjuvant agent

- Morphine, oxycodone, or hydromorphone should be added to acetaminophen or an NSAID for maximum flexibility of opioid dose.

Step 3 Moderate-to-Severe Pain or Pain Uncontrolled After Step 2

Sustained-release/long-acting opioid ATC or continuous infusion + short-acting opioid as required ± nonopioid ± adjuvant agent

- Sustained-release oxycodone, morphine, oxymorphone, or transdermal fentanyl is indicated.

U.S., driven by opioid addiction (NIDA, 2017; Rudd et al., 2016). These circumstances have led to several changes in the use of opioids in the U.S.:

- the rescheduling of hydrocodone to schedule II
- an FDA mandate that all ER/LA opioids fall under the Risk Evaluation and Mitigation Strategy, a classification reserved for “high-risk pharmaceuticals”
- the FDA’s relabeling of all ER/LA opioids with a black-box warning that highlights the risks of addiction, abuse, misuse, overdose, and death; the risk of fatal respiratory depression on initiation or increase of dose; the necessity of swallowing, not chewing, an oral opioid formulation; the danger of accidental consumption, especially by children; for pregnant women who require opioids, possible requirement for treatment of neonatal opioid withdrawal syndrome and danger of life-threatening fetal opioid withdrawal syndrome with prolonged maternal use; and any adverse interactions with ethanol
- an updating by the FDA of postmarketing surveillance requirements for opioid analgesics, especially for ER/LA opioid analgesics
- the release by the CDC of new chronic opioid treatment guidelines (Dowell et al., 2016), as summarized by Table 20–7

The CDC guidelines were in response to an increasing number of deaths related to opioid overdose (of both prescription and illicit opioids), which exceeded 33,000 in 2015. The new guidelines are intended for primary care physicians who prescribe opioids to treat chronic pain. The guidelines

stress the primary use of nonopioid pharmacotherapy, avoidance of ER/LA opioids in favor of immediate-release agents, and frequent and persistent follow-up by the prescribing physician. Methadone dosing is considered separately in Table 20–8. Suggestions for the oral and parenteral dosing of commonly used opioids (see Table 20–2) must be appreciated as representing only guidelines. Such guidelines are typically based on the use of these agents in the management of acute (e.g., postoperative) pain in opioid-naïve patients. A number of factors contribute to the dosing requirement (see the discussion that follows).

Variables Modifying the Therapeutic Use of Opiates

Patient Variability

There is substantial individual variability in the response to opioids. Thus, a standard intramuscular dose of 10 mg morphine sulfate will relieve severe pain adequately in two of three patients but will not suffice in one of three patients. Similarly, the minimal effective analgesic concentration for opioids, such as morphine, meperidine (pethidine), alfentanil, and sufentanil, varies among patients by factors of 5–10. Adjustments must be made based on clinical response. Appropriate therapeutics typically involve undertaking a treatment strategy that most efficiently addresses the pain state, minimizes the potential for undesired drug effects, and

TABLE 20–7 ■ SUMMARY OF CDC RECOMMENDATIONS FOR PRESCRIBING OPIOIDS FOR CHRONIC PAIN

Determining When to Initiate or Continue Opioids for Chronic Pain

- Nonpharmacological therapy and nonopioid pharmacologic therapy are preferred for chronic pain. Consider opioid therapy only if expected benefits for both pain and function are anticipated to outweigh risks to the patient. If opioids are used, combine them with nonpharmacological therapy and nonopioid pharmacotherapy, as appropriate.
- Before starting opioid therapy for chronic pain, establish treatment goals with the patient, including realistic goals for pain and function. Consider how therapy will be discontinued if benefits do not outweigh risks. Continue opioid therapy only if there is clinically meaningful improvement in pain and function that outweighs risks to patient safety.
- Before starting and periodically during opioid therapy, discuss with patient the known risks and realistic benefits of opioid therapy and patient and clinician responsibilities for managing therapy.

Opioid Selection, Dosage, Duration, Follow-Up, and Discontinuation

- When starting opioid therapy for chronic pain, prescribe immediate-release opioids instead of ER/LA opioids.
- When opioids are started, prescribe the lowest effective dosage. Use caution when prescribing opioids at any dosage. Reassess evidence of individual benefits and risks when increasing dosage to ≥ 50 MME/d. Avoid increasing dosage to ≥ 90 MME/d or carefully justify a decision to exceed this limit.
- Long-term opioid use often begins with treatment of acute pain. When opioids are used for acute pain, prescribe the lowest effective dose of immediate-release opioids and in no greater quantity than needed for the expected duration of pain severe enough to require opioids. Three days or less will often be sufficient; more than 7 days will rarely be needed.
- Reevaluate benefits and harms of opioids with the patient within 1 to 4 weeks of starting opioid therapy for chronic pain or of dose escalation and thereafter every 3 months or more frequently. If benefits do not outweigh harms of continued opioid therapy, optimize other therapies and work with the patient to taper opioids to lower dosages or to taper and discontinue opioids.

Assessing Risk and Addressing Harms of Opioid Use

- Incorporate into the management plan strategies to mitigate risk, including considering offering naloxone when factors that increase risk for opioid overdose, such as history of overdose, history of substance use disorder, higher opioid dosages (≥ 50 MME/d), or concurrent benzodiazepine use are present.
- Review the patient’s history of controlled substance prescriptions using state PDMP data to determine whether the patient is receiving opioid dosages or dangerous combinations that carry high risk for overdose. Review PDMP data when starting opioid therapy for chronic pain and periodically during opioid therapy for chronic pain, ranging from every prescription to every 3 months.
- When prescribing opioids for chronic pain, use urine drug testing before starting opioid therapy and consider urine drug testing at least annually to assess for prescribed medications and other controlled prescription drugs and illicit drugs.
- Avoid prescribing opioid pain medication and benzodiazepines concurrently whenever possible.
- Offer or arrange evidence-based treatment (usually medication-assisted treatment with buprenorphine or methadone in combination with behavioral therapies) for a patient with opioid use disorder.

Note: Excluding active cancer, palliative, and end-of-life care.

Source: Adapted from Dowell D, et al. CDC guideline for prescribing opioids for chronic pain—United States, 2016. *MMWR Recomm Rep* 2016, 65(RR-1):1–49. doi: <http://dx.doi.org/10.15585/mmwr.rr6501e1>. Accessed May 4, 2017.

TABLE 20-8 ■ MORPHINE MILLIGRAM EQUIVALENT (MME) DOSES FOR COMMONLY PRESCRIBED OPIOIDS

OPIOID	CONVERSION FACTOR ^a
Codeine	0.15
Fentanyl transdermal (in µg/h)	2.4
Hydrocodone	1
Hydromorphone	4
Methadone	
1–20 mg/d	4
21–40 mg/d	8
41–60 mg/d	10
≥61–80 mg/d	12
Morphine	1
Oxycodone	1.5
Oxymorphone	3

^aMultiply the dose for each opioid by the conversion factor to determine the dose in MMEs. For example, tablets containing hydrocodone 5 mg and acetaminophen 300 mg taken four times a day would contain a total of 20 mg of hydrocodone daily, equivalent to 20 MME daily; extended-release tablets containing oxycodone 10 mg taken twice a day would contain a total of 20 mg of oxycodone daily, equivalent to 30 MME daily. Note the following precautions: (1) All doses are in milligrams/day except for fentanyl, which is micrograms/hour. (2) Equianalgesic dose conversions are only estimates and cannot account for individual variability in genetics and pharmacokinetics. (3) Do not use the calculated dose in MMEs to determine the doses to use when converting one opioid to another; when converting opioids, the new opioid is typically dosed at substantially lower than the calculated MME dose to avoid accidental overdose due to incomplete cross-tolerance and individual variability in opioid pharmacokinetics. (4) Use particular caution with methadone dose conversions because the conversion factor increases at higher doses. (5) Use particular caution with fentanyl because it is dosed in micrograms/hour instead of milligrams/day, and its absorption is affected by heat and other factors.

Adapted by the CDC from Von Korff M, et al. *Clin J Pain*, 2008; 24:521–527 and Washington State Interagency Guideline on Prescribing Opioids for Pain (<http://www.agencymeddirectors.wa.gov/Files/2015AMDGOpioidGuideline.pdf>).

accounts for the variables described next that can influence an individual patient's response to opiate analgesia.

Pain

Pain Intensity

Increased pain intensity may require titrating doses to produce acceptable analgesia with tolerable side effects.

Type of Pain State

Systems underlying a pain state may be broadly categorized as being mediated by events secondary to injury and inflammation and by injury to the sensory afferent or nervous system. Neuropathic conditions may be less efficaciously managed by opiates than pain secondary to tissue injury and inflammation. Such pain states are more efficiently managed by combination treatment modalities.

Acuity and Chronicity of Pain

In chronic pain states, the daily course of the pain may fluctuate, for example, being greater in the morning hours or on awakening. Arthritic states display flares that are associated with an exacerbated pain condition. Changes in the magnitude of pain occur during the daily routine, resulting in “breakthrough pain” during episodic events such as dressing changes (incident pain). These examples emphasize the need for individualized management of increased or decreased pain levels with baseline analgesic dosing supplemented with the use of short-acting “rescue” medications as required. In the face of ongoing severe pain, analgesics should be dosed

in continuous or “around-the-clock” fashion rather than on an as-needed basis. This provides more consistent analgesic levels and avoids unnecessary suffering.

Opioid Tolerance

Chronic exposure to one opiate agonist typically leads to a reduction in the efficacy of other opiate agonists. The degree of tolerance can be remarkable. For example, 10 mg of an oral opioid (such as morphine) is considered a high dose for a treatment-naïve individual, whereas 100 mg IV may produce only minor sedation in a severely tolerant individual.

Patient Physical State and Genetic Variables

Codeine, hydrocodone, and oxycodone are weak analgesic prodrugs that are metabolized into the much more effective analgesic drugs morphine, hydromorphone, and oxymorphone, respectively, by CYP2D6 (Supernaw, 2001). CYP2D6 activity is genetically diminished in 7% of whites, 3% of blacks, and 1% of Asians (Eichelbaum and Evert, 1996), rendering oxycodone, hydrocodone, and codeine relatively ineffective analgesics in these “poor metabolizers” and potentially toxic for “ultra-rapid” metabolizers.

The activity of CYP2D6 is inhibited by SSRIs, which may render opioids less effective as analgesics in some patients. Whereas diminished activity of the CYP2D6 isoenzyme will lead to less efficacy of prodrug opioids, the opposite occurs with methadone. Although methadone is primarily metabolized by CYP3A4, other CYPs participate, and genetic polymorphisms involving deficiencies in the CYPs 2B6 and 2D6 may lead to high methadone C_p values (Zhou et al., 2009).

Opioids are highly protein bound, and factors such as plasma pH may dramatically change binding. In addition, AAG is an acute-phase reactant protein that is elevated in cancer patients and has a high affinity for basic drugs such as methadone and meperidine. Morphine and meperidine should be avoided in patients with renal impairment because morphine-6-glucuronide (a metabolite of morphine) and normeperidine (a metabolite of meperidine) are excreted by the kidney and will accumulate and lead to toxicity. Other states that may increase the risk of adverse effects of the opioids include COPD, sleep apnea, dementia, benign prostatic hypertrophy, unstable gait, and pretreatment constipation.

Routes of Administration

Typically, one chooses the least invasive routes, such as oral, buccal, or transdermal delivery, to facilitate patient compliance. Intravenous routes are more useful in pre- and post-operative in-hospital pain management and during end-of-life care. Patients with chronic pain states where side effects from systemic drug exposure are intolerable may be candidates for chronic spinal drug delivery, requiring surgery for indwelling catheterization and pump placement.

Dose Selection and Titration

The conservative approach to initiating chronic opioid therapy suggests starting with low doses that may be incremented on the basis of the pharmacokinetics of the drug. In chronic pain states, the aim would be to use long-acting medications to permit once- or twice-daily dosing (e.g., controlled-release formulations or methadone). Such agents reach steady state slowly. Rapid incrementation is to be avoided, and rescue medication should be made available for breakthrough pain during initial dosing titration.

Opioid Rotation

Changing to a different opioid, when the patient fails to achieve benefit or side effects become limiting before analgesia is sufficient, is widely employed. Failure or intolerance of one opioid cannot necessarily predict the patient's response or acceptance to another (Quang-Cantagrel et al., 2000). Practically, opioid rotation involves incrementing the dose of a given opioid (e.g., morphine) to a level limited by side effects and insufficient analgesia and then substituting an alternate opioid medication at an equieffective dose. Agents typically involved in such rotation sequences are various oral opioids (e.g., morphine, methadone, dilaudid, oxycodone)

TABLE 20-9 ■ SUMMARY OF DRUG TARGET AND SITE OF ACTION OF COMMON DRUG CLASSES AND RELATIVE EFFICACY BY PAIN STATE

DRUG CLASS (example)	DRUG ACTION	SITE OF ACTION ^a	RELATIVE EFFICACY IN PAIN STATES ^a
NSAIDs (ibuprofen, aspirin, acetaminophen)	Nonspecific COX inhibitors	Peripheral and spinal	Tissue injury >> acute stimuli = nerve injury = 0 (Chapter 38)
COX-2 inhibitor (celecoxib)	COX-2-selective inhibitor	Peripheral and spinal	Tissue injury >> acute stimuli = nerve injury = 0 (Chapter 38)
Opioids (morphine)	μ receptor agonist	Supraspinal and spinal	Tissue injury = acute stimuli ≥ nerve injury > 0 (see this chapter)
Anticonvulsants (gabapentin)	Na ⁺ channel block, α ₂ δ subunit of Ca ²⁺ channel	Supraspinal and spinal	Nerve injury > tissue injury = acute stimuli = 0 (Chapter 17)
Tricyclic antidepressants (amitriptyline)	Inhibit uptake of 5HT/NE	Supraspinal and spinal	Nerve injury ≥ tissue injury >> acute stimuli = 0 (Chapters 15 and 19)

^aAs defined by studies in preclinical models.

and the fentanyl patch systems. Care must be taken to titrate the doses and monitor the patient closely during such drug transitions.

Combination Therapy

In general, the use of combinations of drugs with the same pharmacological kinetic profile is not warranted (e.g., morphine plus methadone). The same holds if the drugs have overlapping targets and opposing effects (e.g., combining an MOR agonist with an agent having mixed agonist/antagonist properties). On the other hand, certain opiate combinations are useful. For example, in a chronic pain state with periodic incident or breakthrough pain, the patient might receive a slow-release formulation of morphine for baseline pain relief, and the acute incident (breakthrough) pain may be managed with a rapid-onset/short-lasting formulation such as buccal fentanyl. For inflammatory or nociceptive pain, opioids may be usefully combined with other analgesic agents, such as acetaminophen or other NSAIDs (Table 20-9). In some situations, NSAIDs can provide analgesia equal to that produced by 60 mg codeine. In the case of neuropathic pain, other drug classes may be useful alone or in combination with an opiate. For example, antidepressants that block amine reuptake, such as amitriptyline or duloxetine, and anticonvulsants such as gabapentin may enhance the analgesic effect and may be synergistic in some pain states.

Nonanalgesic Therapeutic Uses of Opioids

Dyspnea

Morphine is used to alleviate the dyspnea of acute left ventricular failure and pulmonary edema, and the patient's response to intravenous morphine may be dramatic. The mechanism underlying this pronounced relief is not clear. It may involve an alteration of the patient's reaction to impaired respiratory function and an indirect reduction of the work of the heart owing to reduced fear and apprehension. However, it is more probable that the major benefit is due to cardiovascular effects, such as decreased peripheral resistance secondary to histamine release and an increased capacity of the peripheral and splanchnic vascular compartments. Nitroglycerin, which also causes vasodilation, may be superior to morphine in this condition. In patients with normal blood gases but severe breathlessness owing to chronic obstruction of airflow ("pink puffers"), dihydrocodeine, 16 mg orally before exercise, reduces the feeling of breathlessness and increases exercise tolerance. Nonetheless, opioids generally are contraindicated in pulmonary edema unless severe pain is also present.

Anesthetic Adjuvants

High doses of opioids, notably fentanyl and sufentanil, are widely used as the primary anesthetic agents in many surgical procedures. They have

powerful "MAC-sparing" effects; for example, they reduce the concentrations of volatile anesthetic otherwise required to produce an adequate anesthetic depth (see Chapter 21). Although respiration is so depressed that physical assistance is required, patients can retain consciousness. Therefore, when using an opioid as the primary anesthetic agent, it is used in conjunction with an agent that results in unconsciousness and produces amnesia, such as the benzodiazepines or lower concentrations of volatile anesthetics. High doses of opiate as employed in the operating room setting also result in prominent rigidity of the chest wall and masseters, requiring concurrent treatment with muscle relaxants to permit intubations and ventilation.

Acute Opioid Toxicity

Acute opioid toxicity may result from clinical overdosage, accidental overdosage, or attempts at suicide. Occasionally, a delayed type of toxicity may occur from the injection of an opioid into chilled skin areas or in patients with low blood pressure and shock. The drug is not fully absorbed; therefore, a subsequent dose may be given. When normal circulation is restored, an excessive amount may be absorbed suddenly. In nontolerant individuals, serious toxicity with methadone may follow the oral ingestion of 40–60 mg. In the case of morphine, a normal, pain-free adult is not likely to die after oral doses less than 120 mg or to have serious toxicity with less than 30 mg parenterally.

Symptoms and Diagnosis

The triad of coma, pinpoint pupils, and depressed respiration strongly suggests opioid poisoning. The patient who has taken an overdose of an opioid usually is stuporous or, if a large overdose has been taken, may be in a profound coma. The respiratory rate will be very low, or the patient may be apneic, and possibly cyanotic. If adequate oxygenation is restored early, the blood pressure will improve; if hypoxia persists untreated, there may be capillary damage, and measures to combat shock may be required. The pupils will be symmetrical and pinpoint in size; however, if hypoxia is severe, they may be dilated. Urine formation is depressed. Body temperature falls, and the skin becomes cold and clammy. The skeletal muscles are flaccid, the jaw is relaxed, and the tongue may fall back and block the airway. Frank convulsions occasionally may be noted in infants and children. When death occurs, it is nearly always from respiratory failure. Even if respiration is restored, death still may occur as a result of complications that develop during the period of coma, such as pneumonia or shock. Noncardiogenic pulmonary edema is seen commonly with opioid poisoning.

Treatment

The first step is to establish a patent airway and ventilate the patient. Opioid antagonists can produce dramatic reversal of the severe respiratory

depression, and the antagonist naloxone is the treatment of choice. However, care should be taken to avoid precipitating withdrawal in dependent patients, who may be extremely sensitive to antagonists. The safest approach is to dilute the standard naloxone dose (0.4 mg) and slowly administer it intravenously, monitoring arousal and respiratory function. With care, it usually is possible to reverse the respiratory depression without precipitating a major withdrawal syndrome. If no response is seen with the first dose, additional doses can be given. Patients should be observed for rebound increases in sympathetic nervous system activity, which may result in cardiac arrhythmias and pulmonary edema. For reversing opioid poisoning in children, the initial dose of naloxone is 0.01 mg/kg. If no effect is seen after a total dose of 10 mg, one can reasonably question the role of an opiate in the diagnosis. Pulmonary edema sometimes associated with opioid overdosage may be countered by positive-pressure respiration. Tonic-clonic seizures, occasionally seen as part of the toxic syndrome with meperidine and tramadol, are ameliorated by treatment with naloxone.

The presence of general CNS depressants does not prevent the salutary effect of naloxone, and in cases of mixed intoxications, the situation will be improved largely owing to antagonism of the respiratory-depressant effects of the opioid (however, some evidence indicates that naloxone and naltrexone may also antagonize some of the depressant actions of sedative-hypnotics). One need not attempt to restore the patient to full consciousness. The duration of action of the available antagonists is shorter than that of many opioids; hence, patients can slip back into coma (e.g., renarcotization). This is particularly important when the overdosage is due to methadone. The depressant effects of these drugs may persist for 24–72 h, and fatalities have occurred as a result of premature discontinuation of naloxone. In cases of overdoses of these drugs, a continuous infusion of naloxone should be considered. Toxicity from overdose of pentazocine and other opioids with mixed actions may require higher doses of naloxone.

Novel Nonopioid Treatments for Pain

Myriad marine toxins target GPCRs, neurotransmitter transporters, and ion channels; a number (i.e., tetrodotoxin, saxitoxin, kainic acid, and various venoms from cone snails) have been useful to basic scientists (Sakai and Swanson 2014). One that has become an FDA-approved treatment of chronic pain is ziconotide.

Ziconotide

Ziconotide is a synthetic copy of a neuroactive cone snail toxin, a 25–amino acid basic polypeptide with three disulfide bridges. The molecule is hydrophilic and readily soluble in water and isotonic saline.

Mechanism of Action

Ziconotide binds to and blocks N-type Ca^{2+} channels on nociceptive afferents in the dorsal horn of the spinal cord. This leads to blockade of the release of excitatory neurotransmitter involved in nociception (Patel et al., 2017).

ADME

Ziconotide is administered intrathecally as a continuous infusion by a controlled microinfusion pump. The toxin's serum $t_{1/2}$ is 1.3 h; the $t_{1/2}$ in CSF is 4.6 h. The volume distribution in CSF approximates the total CSF volume, 140 mL. Ziconotide is stable in CSF but, following passage from the CSF into the systemic circulation, is metabolized by endo- and exopeptidases that are widely expressed in most tissues.

Therapeutic Use

Ziconotide is used to treat severe chronic pain in adults for whom intrathecal therapy is warranted and for whom other treatments have failed or are not suitable (allergy, etc.). The dosing should follow the FDA-approved schedule, titrating upward from 2.4 $\mu\text{g}/\text{d}$ in increments of 2.4 μg no more than two or three times weekly to the maximum recommended intrathecal dose of 19.2 $\mu\text{g}/\text{d}$.

Adverse Effects and Precautions

Side effects include dizziness, nausea, confusion, nystagmus, anxiety, confusion, and blurred vision. Hallucinations and paranoia can occur; thus, ziconotide is contraindicated in patients with a preexisting history of psychosis. Inadvertent intravenous or epidural administration of ziconotide will cause hypotension. The analgesic effects of ziconotide appear to add with those of morphine; in laboratory experiments, intrathecal ziconotide potentiated the GI effects of morphine but not the respiratory depressant effects. Ziconotide is not an opiate, and its effects cannot be reversed by naloxone. Treatment of overdose is withdrawal of the agent and supportive care in a hospital. The agent is classified in pregnancy category C. The difficulties of long-term intrathecal delivery, the production of state-independent blockade, and the side-effect profile have been barriers to use of ziconotide (Patel et al., 2017).

Drug Facts for Your Personal Formulary: Opioid Agonists and Antagonists

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Agonists: See Table 20-7 for CDC guidelines for prescribing opioids for chronic pain		
Morphine Hydromorphone Oxycodone Hydrocodone	<ul style="list-style-type: none"> Potent μ agonists Strong analgesic in moderate-to-severe pain states. Morphine is a useful adjunct in pulmonary edema and general anesthesia. 	<ul style="list-style-type: none"> \downarrow GI motility \Rightarrow constipation Hydrocodone, oxycodone formulated with NSAIDs Hydrocodone, oxycodone, and fentanyl are more potent than morphine Among licit agents, LA/ER agents often preferred by abusers
Fentanyl	<ul style="list-style-type: none"> Potent μ agonist Administered orally (buccal tablet, sublingual tablet/spray, oral lozenge), intravenous (push/infusion), intramuscular, topical, topical iontophoretic, neuraxial 	<ul style="list-style-type: none"> Rapid onset, short duration of action Slightly longer effective $t_{1/2}$ than sufentanil, alfentanil, and remifentanyl
Sufentanil Alfentanil Remifentanyl	<ul style="list-style-type: none"> Similar to fentanyl Rapid onset, short duration of action Administered intravenously 	<ul style="list-style-type: none"> Sufentanil and alfentanil also given epidurally Remifentanyl: ultrashort acting
Meperidine	<ul style="list-style-type: none"> Potent μ agonist Rapid onset, intermediate duration of action 	<ul style="list-style-type: none"> Not for extended use due to accumulation of seizure-inducing metabolite
Methadone	<ul style="list-style-type: none"> Potent MOR agonist Rapid onset, long duration of action Used in maintenance/rehab programs 	<ul style="list-style-type: none"> Long $t_{1/2}$ \sim 27 h \Rightarrow potential for accumulation with too frequent repeated delivery Anticholinergic effects

Drug Facts for Your Personal Formulary: *Opioid Agonists and Antagonists* (continued)

Drug	Therapeutic Use	Clinical Pharmacology and Tips
Codeine	<ul style="list-style-type: none"> Weak prodrug for morphine Useful for mild-to-moderate pain Less efficacious than morphine but will antagonize strong μ agonists Administered orally 	<ul style="list-style-type: none"> Useful antitussive effects Formulated with NSAIDs
Levorphanol	<ul style="list-style-type: none"> Affinity at the MOR, KOR, and DOR 5HT/NE reuptake inhibitor; NMDA receptor antagonist Rapid onset, modest duration of analgesia Administered orally 	<ul style="list-style-type: none"> Long elimination $t_{1/2} \sim 14\text{h} \Rightarrow$ potential for accumulation with too frequent repeated delivery Adverse effects: delirium, hallucinations
Peripherally Restricted Agonist		
Loperamide	<ul style="list-style-type: none"> Mu opioid agonist Effective antidiarrheal Administered orally 	<ul style="list-style-type: none"> Loperamide crosses BBB poorly, can be formulated with simethicone
Agonist Restricted by Coformulation		
Diphenoxylate	<ul style="list-style-type: none"> Mu opioid agonist Effective antidiarrheal Administered orally 	<ul style="list-style-type: none"> Diphenoxylate will cross the BBB, so it is formulated with atropine, the anticholinergic effects of which (weakness, nausea) discourage abuse.
Partial Agonists; Agonist/Antagonist Combinations		
Buprenorphine	<ul style="list-style-type: none"> Partial agonist at MOR; KOR antagonist Mild-to-moderate pain (ceiling effect) Administered by intramuscular, intravenous, sublingual, transdermal, buccal film Coformulated with naloxone for use in abuse management 	<ul style="list-style-type: none"> Delivery to a patient on a full opiate agonist may initiate withdrawal (may be done therapeutically in management of heroin addiction)
Butorphanol Nalbuphine Pentazocine	<ul style="list-style-type: none"> KOR agonist/MOR antagonist Analgesia to mild-to-moderate pain 	<ul style="list-style-type: none"> Delivery to patient on a full opiate agonist may initiate withdrawal Ceiling effect Pentazocine is also formulated with naloxone.
Other Agonists		
Tramadol	<ul style="list-style-type: none"> Weak μ agonist and a 5HT/NE uptake inhibitor Analgesia for moderate pain Available as a fixed-dose combination with acetaminophen 	<ul style="list-style-type: none"> Potential for seizures Serotonin syndrome risk As an adjunct to other opioids for chronic pain
Tapentadol	<ul style="list-style-type: none"> Weak μ agonist and a 5HT/NE uptake inhibitor Analgesia for moderate pain 	<ul style="list-style-type: none"> Serotonin syndrome risk
Central Antitussives		
Dextromethorphan	<ul style="list-style-type: none"> \downarrow Cough reflex; receptor mechanisms unclear Administered orally Available as an extended-release formulation 	<ul style="list-style-type: none"> Serotonin syndrome risk Has no analgesic or addictive properties
Codeine	<ul style="list-style-type: none"> See codeine listing, above 	<ul style="list-style-type: none"> See codeine listing, above
Antagonists		
Naloxone	<ul style="list-style-type: none"> Antagonist at MOR/DOR/KOR Rapid onset, moderately short acting Rapidly reverses central and peripheral opiate effects Used in treating opioid overdose Autoinjector available for emergency administration 	<ul style="list-style-type: none"> $t_{1/2} \sim 64\text{ min}$ Renarcotization may occur with long-lasting agonists as naloxone is metabolized May induce moderate hyperalgesia Known as NARCAN; used by emergency medical technicians to revive comatose opioid abusers
Naltrexone Nalmefene	<ul style="list-style-type: none"> Antagonist at MOR/DOR/KOR Rapid onset, longer acting than naloxone Reverses central and peripheral opiate effects Used in treating alcohol and opiate dependence 	<ul style="list-style-type: none"> Naltrexone: formulated with bupropion for managing obesity and with morphine for severe pain; contraindicated in hepatitis and liver failure (<i>Black-Box Warning</i>: excessive doses cause hepatocellular injury) Start naltrexone only after 7–10 days of abstinence from opioids Long-term use of naltrexone \Rightarrow hypersensitivity to opioids

Peripherally Restricted Antagonists

Methylnaltrexone	<ul style="list-style-type: none"> • Antagonist at MOR/DOR/KOR • Reverses peripheral opiate effects (e.g., opiate-induced constipation) but not analgesia 	<ul style="list-style-type: none"> • Does not cross BBB, thus not useful in treating addiction or reversing CNS effects of opioids
Alvimopan	<ul style="list-style-type: none"> • Antagonist at MOR/DOR/KOR • Penetrates poorly into CNS • FDA approved for ileus 	<ul style="list-style-type: none"> • Reverses peripheral opiate effects

Chapter 21

General Anesthetics and Therapeutic Gases

Hemal H. Patel, Matthew L. Pearn, Piyush M. Patel, and David M. Roth

GENERAL PRINCIPLES OF SURGICAL ANESTHESIA

- Hemodynamic Effects of General Anesthesia
- Respiratory Effects of General Anesthesia
- Hypothermia
- Nausea and Vomiting
- Other Emergent and Postoperative Phenomena

ACTIONS AND MECHANISMS OF GENERAL ANESTHETICS

- The Anesthetic State
- Mechanisms of Anesthesia
- Anatomic Sites of Anesthetic Action

PARENTERAL ANESTHETICS

- Pharmacokinetic Principles
- Specific Parenteral Agents

INHALATIONAL ANESTHETICS

- Pharmacokinetic Principles
- Specific Inhalational Agents

ANESTHETIC ADJUNCTS

- Benzodiazepines
- α_2 Adrenergic Agonists
- Analgesics
- Neuromuscular Blocking Agents

ANESTHETIC TOXICITY AND CYTOPROTECTION

THERAPEUTIC GASES

- Oxygen
- Carbon Dioxide
- Nitric Oxide
- Helium
- Hydrogen Sulfide

General anesthetics depress the CNS to a sufficient degree to permit the performance of surgery and unpleasant procedures. General anesthetics have low therapeutic indices and thus require great care in administration. The selection of specific drugs and routes of administration to produce general anesthesia is based on the pharmacokinetic properties and on the secondary effects of the various drugs. The practitioner should consider the context of the proposed diagnostic or surgical procedure and the individual patient's characteristics and associated medical conditions when choosing appropriate anesthetic agents.

General Principles of Surgical Anesthesia

The administration of general anesthesia is driven by three general objectives:

1. *Minimizing the potentially deleterious direct and indirect effects of anesthetic agents and techniques.*
2. *Sustaining physiologic homeostasis during surgical procedures* that may involve major blood loss, tissue ischemia, reperfusion of ischemic tissue, fluid shifts, exposure to a cold environment, and impaired coagulation.
3. *Improving postoperative outcomes* by choosing techniques that block or treat components of the surgical stress response that may lead to short- or long-term sequelae.

Hemodynamic Effects of General Anesthesia

The most prominent physiological effect of anesthesia induction is a decrease in systemic arterial blood pressure. The causes include direct vasodilation, myocardial depression, or both; a blunting of baroreceptor control; and a generalized decrease in central sympathetic tone. Agents vary in the magnitude of their specific effects, but in all cases the hypotensive response is enhanced by underlying volume depletion or preexisting myocardial dysfunction.

Respiratory Effects of General Anesthesia

Nearly all general anesthetics reduce or eliminate both ventilatory drive and the reflexes that maintain airway patency. Therefore, ventilation generally must be assisted or controlled for at least some period during surgery. The gag reflex is lost, and the stimulus to cough is blunted. Lower esophageal sphincter tone also is reduced, so both passive and active regurgitation may occur. Endotracheal intubation has been a major reason for a decline in the number of aspiration deaths during general anesthesia. Muscle relaxation is valuable during the induction of general anesthesia where it facilitates management of the airway, including endotracheal intubation. Neuromuscular blocking agents commonly are used to effect such relaxation (see Chapter 11). Alternatives to an endotracheal tube include a face mask and a laryngeal mask, an inflatable mask placed in the oropharynx forming a seal around the glottis. Airway management techniques are based on the anesthetic procedure, the need for neuromuscular relaxation, and the physical characteristics of the patient.

Hypothermia

Patients commonly develop hypothermia (body temperature $< 36^{\circ}\text{C}$) during surgery. The reasons include low ambient temperature, exposed body cavities, cold intravenous fluids, altered thermoregulatory control, and reduced metabolic rate. Metabolic rate and total body O_2 consumption decrease with general anesthesia by about 30%, reducing heat generation. Hypothermia may lead to an increase in perioperative morbidity. Prevention of hypothermia is a major goal of anesthetic care.

Nausea and Vomiting

Nausea and vomiting continue to be significant problems following general anesthesia and are caused by an action of anesthetics on the chemoreceptor trigger zone and the brainstem vomiting center, which are modulated by 5HT, histamine, ACh, DA, and NK1. The 5HT₃ receptor antagonists ondansetron, dolasetron, and palonosetron (see Chapters 13 and 50) are

Abbreviations

ACh: acetylcholine
AChE: acetylcholinesterase
ADME: absorption, distribution, metabolism, excretion
CBF: cerebral blood flow
CL: clearance
CMR: cerebral metabolic rate
CMRO₂: cerebral metabolic rate of O₂ consumption
CNS: central nervous system
CO: cardiac output
DA: dopamine
ED₅₀: median effective dose
EEG: electroencephalogram
FDA: Food and Drug Administration
Fio₂: inspired O₂ fraction
GABA: γ-aminobutyric acid
GFR: glomerular filtration rate
GPCR: G protein-coupled receptor
Hb: hemoglobin
HR: heart rate
5HT: 5-hydroxytryptamine: serotonin
ICP: intracranial pressure
IV: intravenous
LD₅₀: median lethal dose
MAC: minimum alveolar concentration
MAP: mean arterial pressure
MI: myocardial infarction
NE: norepinephrine
NK1: neurokinin 1
NMDA: N-methyl-D-aspartate
NSAID: nonsteroidal anti-inflammatory drug
Paco₂: arterial CO₂ tension
Po₂: partial pressure of O₂
PRIS: propofol infusion syndrome
RBF: renal blood flow
RR: respiratory rate
RT: room temperature
t_{1/2β}: β-phase (tissue elimination) half-life

effective in suppressing nausea and vomiting. Common preventive strategies include anesthetic induction with propofol; the combined use of droperidol, metoclopramide, and dexamethasone; and avoidance of nitrous oxide (N₂O). A new subclass of antiemetic drugs includes NK1 antagonists (e.g., aprepitant, rolapitant).

Other Emergent and Postoperative Phenomena

Hypertension and tachycardia are common during emergence from anesthesia as the sympathetic nervous system regains its tone and is enhanced by pain. Myocardial ischemia can appear or worsen during emergence in patients with coronary artery disease. Emergence excitement occurs in 5%–30% of patients and is characterized by tachycardia, restlessness, crying, moaning, and thrashing. Neurologic signs, including delirium, spasticity, hyperreflexia, and Babinski sign, are often manifest in the patient emerging from anesthesia. Postanesthesia shivering occurs frequently because of core hypothermia. A small dose of meperidine (12.5 mg) lowers the shivering trigger temperature and effectively stops the activity. The incidence of all of these emergence phenomena is greatly reduced with opioids and α₂ adrenergic agonists (dexmedetomidine).

Airway obstruction may occur during the postoperative period because of residual anesthetic effects. Pulmonary function is reduced following all types of anesthesia and surgery, and hypoxemia may occur. In the immediate postoperative period, pulmonary function reduction can be compounded by the respiratory suppression associated with opioids used for pain control. Regional anesthetic techniques are an important part of a perioperative approach that employs local anesthetic wound infiltration; epidural, spinal, and plexus blocks; and nonsteroidal anti-inflammatory drugs, opioids, α₂ adrenergic receptor agonists, and NMDA receptor antagonists.

Actions and Mechanisms of General Anesthetics

The Anesthetic State

The components of the anesthetic state include

- *Amnesia*
- *Analgesia*
- *Unconsciousness*
- *Immobility* in response to noxious stimulation
- *Attenuation of autonomic responses* to noxious stimulation

The potency of general anesthetic agents is measured by determining the concentration of general anesthetic that prevents movement in response to surgical stimulation. For inhalational anesthetics, anesthetic potency is measured in *MAC units*, with 1 MAC defined as the minimum alveolar concentration that prevents movement in response to surgical stimulation in 50% of subjects. The strengths of MAC as a measurement are the following:

- Alveolar concentrations can be monitored continuously by measuring end-tidal anesthetic concentration using infrared spectroscopy or mass spectrometry.
- MAC provides a direct correlate of the free concentration of the anesthetic at its site(s) of action in the CNS.
- MAC is a simple-to-measure end point that reflects an important clinical goal.

End points other than immobilization also can be used to measure anesthetic potency. For example, the ability to respond to verbal commands (MAC_{awake}) and the ability to form memories also have been correlated with alveolar anesthetic concentration. Verbal response and memory formation are suppressed at a fraction of MAC. The ratio of the anesthetic concentrations required to produce amnesia and immobility vary significantly among different inhalational anesthetic agents.

Generally, the potency of intravenous agents is defined as the free plasma concentration (at equilibrium) that produces loss of response to surgical incision (or other end points) in 50% of subjects.

Mechanisms of Anesthesia

The molecular and cellular mechanisms by which general anesthetics produce their effects have remained one of the great mysteries of pharmacology. The leading unitary theory was that anesthesia is produced by perturbation of the physical properties of cell membranes. This thinking was based largely on the observation that the anesthetic potency of a gas correlated with its solubility in olive oil. This correlation is referred to as the Meyer-Overton rule. Clear exceptions to the Meyer-Overton rule (Franks, 2006) suggest protein targets that may account for anesthetic effect. Increasing evidence supports the hypothesis that different anesthetic agents produce specific components of anesthesia by actions at different molecular targets. Given these insights, the unitary theory of anesthesia has been largely discarded.

Molecular Mechanisms of General Anesthetics

Most intravenous general anesthetics act predominantly through GABA_A receptors and perhaps through some interactions with other ligand-gated ion channels such as NMDA receptors and two-pore K⁺ channels.

Chloride channels gated by the inhibitory GABA_A receptors (see Figures 14–5 and 14–11) are sensitive to a wide variety of anesthetics, including the halogenated inhalational agents, many intravenous agents (propofol, barbiturates, and etomidate), and neurosteroids. At clinical concentrations, general anesthetics increase the sensitivity of the GABA_A receptor to GABA, thereby enhancing inhibitory neurotransmission and depressing nervous system activity. The action of anesthetics on the GABA_A receptor probably is mediated by binding of the anesthetics to specific sites on the GABA_A receptor protein (but they do not compete with GABA for its binding site). The capacity of propofol and etomidate to inhibit the response to noxious stimuli is mediated by a specific site on the β_3 subunit of the GABA_A receptor, whereas the sedative effects of these anesthetics are mediated by on the β_2 subunit.

Structurally related to the GABA_A receptors are other ligand-gated ion channels, including *glycine receptors* and neuronal *nicotinic ACh receptors* (see Figure 14–5). Glycine-gated Cl[−] channels (glycine receptors) may play a role in mediating inhibition by anesthetics of responses to noxious stimuli. Inhalational anesthetics enhance the capacity of glycine to activate glycine receptors, which play an important role in inhibitory neurotransmission in the spinal cord and brainstem. Propofol, neurosteroids, and barbiturates also potentiate glycine-activated currents, whereas etomidate and ketamine do not. Subanesthetic concentrations of the inhalational anesthetics inhibit some classes of neuronal nicotinic ACh receptors, which seem to mediate other components of anesthesia such as analgesia or amnesia.

Ketamine, nitrous oxide, cyclopropane, and xenon are the only general anesthetics that do not have significant effects on GABA_A or glycine receptors. These agents inhibit a different type of ligand-gated ion channel, the NMDA receptor (see Figure 14–12 and Table 14–2). NMDA receptors are glutamate-gated cation channels that are somewhat selective for Ca²⁺ and are involved in long-term modulation of synaptic responses (long-term potentiation) and glutamate-mediated neurotoxicity.

Halogenated inhalational anesthetics activate some members of a class of K⁺ channels known as *two-pore domain channels*; other two-pore domain channel family members are activated by xenon, N₂O, and cyclopropane. These channels are located in both presynaptic and postsynaptic sites. The postsynaptic channels may be the molecular locus through which these agents hyperpolarize neurons.

Cellular Mechanisms of Anesthesia

General anesthetics produce two important physiologic effects at the cellular level:

1. Inhalational anesthetics can hyperpolarize neurons. Neuronal hyperpolarization may affect pacemaker activity and pattern-generating circuits.
2. Both inhalational and intravenous anesthetics have substantial effects on synaptic transmission and much smaller effects on action potential generation or propagation.

Inhalational anesthetics inhibit excitatory synapses and enhance inhibitory synapses in various preparations. The inhalational anesthetics inhibit neurotransmitter release. Inhalational anesthetics also can act postsynaptically, altering the response to released neurotransmitter. These actions are thought to be due to specific interactions of anesthetic agents with neurotransmitter receptors.

Intravenous anesthetics produce a narrower range of physiological effects. Their predominant actions are at the synapse, where they have profound and relatively specific effects on the postsynaptic response to released neurotransmitter. Most of the intravenous agents act predominantly by enhancing inhibitory neurotransmission, whereas ketamine predominantly inhibits excitatory neurotransmission at glutamatergic synapses.

Anatomic Sites of Anesthetic Action

In principle, general anesthetics could interrupt nervous system function at myriad levels, including peripheral sensory neurons, the spinal cord, the brainstem, and the cerebral cortex. Most anesthetics cause, with some

exceptions, a global reduction in CMR and in CBF. A consistent feature of general anesthesia is a suppression of metabolism in the thalamus (Alkire et al., 2008), which serves as a major relay by which sensory input from the periphery ascends to the cortex. Suppression of thalamic activity may serve as a switch between the awake and anesthetized states (Franks, 2008). General anesthesia also suppresses activity in specific regions of the cortex, including the mesial parietal cortex, posterior cingulate cortex, precuneus, and inferior parietal cortex.

Similarities between natural sleep and the anesthetized state suggest that anesthetics might also modulate endogenous sleep-regulating pathways, which include VLPO and tuberomammillary nuclei. VLPO projects inhibitory GABAergic fibers to ascending arousal nuclei, which in turn project to the cortex, forebrain, and subcortical areas; release histamine, 5HT, orexin, NE, and ACh; and mediate wakefulness. Intravenous and inhalational agents with activity at GABA_A receptors can increase the inhibitory effects of VLPO, thereby suppressing consciousness. Dexmedetomidine, an α_2 adrenergic agonist, also increases VLPO-mediated inhibition by suppressing the inhibitory effect of locus ceruleus neurons on VLPO. Finally, both intravenous and inhalational anesthetics depress hippocampal neurotransmission, a probable locus for their amnesic effects.

Parenteral Anesthetics

Parenteral anesthetics are the most common drugs used for anesthetic induction of adults. Their lipophilicity, coupled with the relatively high perfusion of the brain and spinal cord, results in rapid onset and short duration after a single bolus dose. These drugs ultimately accumulate in fatty tissue. Each of these anesthetics has its own unique properties and side effects (Tables 21–1 and 21–2). Propofol is advantageous for procedures where rapid return to a preoperative mental status is desirable. Etomidate usually is reserved for patients at risk for hypotension or myocardial ischemia. Ketamine is best suited for patients with asthma or for children undergoing short, painful procedures. Thiopental has a long-established track record of safety; however, clinical use is limited currently by availability.

Pharmacokinetic Principles

Parenteral anesthetics are small, hydrophobic, substituted aromatic or heterocyclic compounds (Figure 21–1). Hydrophobicity is the key factor governing their pharmacokinetics. After a single intravenous bolus, these drugs preferentially partition into the highly perfused and lipophilic tissues of the brain and spinal cord, where they produce anesthesia within a single circulation time. Subsequently, blood levels fall rapidly, resulting in drug redistribution out of the CNS back into the blood. The anesthetic then diffuses into less-perfused tissues, such as muscle and viscera, and at a slower rate into the poorly perfused but very hydrophobic adipose tissue. Termination of anesthesia after single boluses of parenteral anesthetics primarily reflects redistribution out of the CNS rather than metabolism (see Figure 2–4).

After redistribution, anesthetic blood levels fall according to a complex interaction between the metabolic rate and the amount and lipophilicity of the drug stored in the peripheral compartments. Thus, parenteral anesthetic half-lives are “context sensitive,” and the degree to which a $t_{1/2}$ is contextual varies greatly from drug to drug, as might be predicted based on their differing hydrophobicities and metabolic clearances (Figure 21–2; Table 21–1). For example, after a single bolus of thiopental, patients usually emerge from anesthesia within 10 min; however, a patient may require more than a day to awaken from a prolonged thiopental infusion. Most individual variability in sensitivity to parenteral anesthetics can be accounted for by pharmacokinetic factors. For example, in patients with lower cardiac output, the relative perfusion of the brain and the fraction of anesthetic dose delivered to the brain are higher; thus, patients in septic shock or with cardiomyopathy usually require lower doses of parenteral anesthetics. The elderly also typically require a smaller parenteral anesthetic dose, primarily because of a smaller initial volume of distribution.

TABLE 21-1 ■ PHARMACOLOGICAL PROPERTIES OF PARENTERAL ANESTHETICS

DRUG	IV INDUCTION DOSE (mg/kg)	MINIMAL HYPNOTIC LEVEL (μg/mL)	INDUCTION DOSE DURATION (min)	$t_{1/2\beta}$ (h)	CL (mL/min/kg)	PROTEIN BINDING (%)	V_{ss} (L/kg)
Propofol	1.5–2.5	1.1	4–8	1.8	30	98	2.3
Etomidate	0.2–0.4	0.3	4–8	2.9	17.9	76	2.5
Ketamine	1.0–4.5	1	5–10	2.5	19.1	27	3.1
Thiopental	3–5	15.6	5–8	12.1	3.4	85	2.3
Methohexital	1.0–1.5	10	4–7	3.9	10.9	85	2.2

Specific Parenteral Agents

Propofol, Fospropofol

Propofol is the most commonly used parenteral anesthetic in the U.S. Fospropofol is a prodrug form that is converted to propofol in vivo. The clinical pharmacological properties of propofol are summarized in Table 21-1.

The active ingredient in propofol, 2,6-diisopropylphenol, is an oil at room temperature and insoluble in aqueous solutions. Propofol is formulated for intravenous administration as a 1% (10-mg/mL) emulsion in 10% soybean oil, 2.25% glycerol, and 1.2% purified egg phosphatide. In the U.S., disodium EDTA (0.05 mg/mL) or sodium metabisulfite (0.25 mg/mL) is added to inhibit bacterial growth. Propofol should be administered within 4 h of its removal from sterile packaging; unused drug should be discarded. The lipid emulsion formulation of propofol is associated with significant pain on injection and hyperlipidemia.

A new aqueous formulation of propofol, fospropofol, which is not associated with these adverse effects, is available for use for sedation in patients undergoing diagnostic procedures (Fechner et al., 2008). Fospropofol, which itself is inactive, is a phosphate ester prodrug of propofol that is hydrolyzed by endothelial alkaline phosphatases to yield propofol, phosphate, and formaldehyde. The formaldehyde is rapidly converted to formic acid, which then is metabolized by tetrahydrofolate dehydrogenase to CO_2 and water.

Clinical Use and ADME. The induction dose of propofol in a healthy adult is 2–2.5 mg/kg. Dosages should be reduced in the elderly and in the presence of other sedatives and increased in young children. Because of its reasonably short elimination $t_{1/2}$, propofol often is used for maintenance of anesthesia as well as for induction. For short procedures, small boluses (10%–50% of the induction dose) every 5 min or as needed are effective. An infusion of propofol produces a more stable drug level (100–300 μg/kg/min) and is better suited for longer-term anesthetic maintenance. Sedating doses of propofol are 20%–50% of those required for general anesthesia.

Propofol has a context-sensitive $t_{1/2}$ of about 10 min with an infusion lasting 3 h and about 30 min for infusions lasting up to 8 h (see Figure 21-2). Propofol's shorter duration of action after infusion can be explained by its very high clearance, coupled with the slow diffusion of drug from the peripheral to the central compartment. Propofol is metabolized in the liver by conjugation to sulfate and glucuronide to less-active metabolites that are renally excreted. Propofol is highly protein bound, and its

pharmacokinetics, like those of the barbiturates, may be affected by conditions that alter serum protein levels. Clearance of propofol is reduced in the elderly. In neonates, propofol clearance is also reduced. By contrast, in young children, a more rapid clearance in combination with a larger central volume may necessitate larger doses of propofol for induction and maintenance of anesthesia.

Fospropofol produces dose-dependent sedation and can be administered in otherwise-healthy individuals at 2–8 mg/kg intravenously (delivered either as a bolus or by a short infusion over 5–10 min). The optimum dose for sedation is about 6.5 mg/kg. This results in a loss of consciousness in about 10 min. The duration of the sedative effect is approximately 45 min.

Side Effects

Nervous System. The sedation and hypnotic actions of propofol are mediated by its action on GABA_A receptors; agonism at these receptors results in an increased Cl^- conduction and hyperpolarization of neurons. Propofol suppresses the EEG, and, in sufficient doses, can produce burst suppression of the EEG. Propofol decreases the CMRO_2 , CBF, and intracranial and intraocular pressures by about the same amount as thiopental. Propofol can be used in patients at risk for cerebral ischemia; however, no human outcome studies have been performed to determine its efficacy as a neuroprotectant.

Cardiovascular System. Propofol produces a dose-dependent decrease in blood pressure that is significantly greater than that produced by thiopental. The fall in blood pressure can be explained by both vasodilation and possibly mild depression of myocardial contractility. Propofol appears to blunt the baroreceptor reflex and reduce sympathetic nerve activity. Propofol should be used with caution in patients at risk for, or intolerant of, decreases in blood pressure.

Respiratory System. Propofol produces a slightly greater degree of respiratory depression than thiopental. Patients given propofol should be monitored to ensure adequate oxygenation and ventilation. Propofol appears to be less likely than barbiturates to provoke bronchospasm and may be the induction agent of choice in patients with asthma. The bronchodilator properties of propofol may be attenuated by the metabisulfite preservative in some propofol formulations.

Other Side Effects. Propofol has a significant antiemetic action. Propofol elicits pain on injection that can be reduced with lidocaine and the use of larger arm and antecubital veins. A rare but potentially fatal complication, *PRIS*, has been described primarily in prolonged, higher-dose

TABLE 21-2 ■ SOME PHARMACOLOGICAL EFFECTS OF PARENTERAL ANESTHETICS^a

DRUG	CBF	CMRO_2	ICP	MAP	HR	CO	RR	\dot{V}_E

Figure 21-1 Structures of some parenteral anesthetics.

infusions of propofol in young or head-injured patients (Kam and Cardone, 2007). PRIS is characterized by metabolic acidosis, hyperlipidemia, rhabdomyolysis, and liver enlargement.

Etomidate

Etomidate is a substituted imidazole that is supplied as the active d-isomer. Etomidate is poorly soluble in water and is formulated as a 2-mg/mL solution in 35% propylene glycol. Unlike thiopental, etomidate does not induce precipitation of neuromuscular blockers or other drugs frequently given during anesthetic induction.

Clinical Use and ADME. Etomidate is primarily used for anesthetic induction of patients at risk for hypotension. Induction doses of etomidate (see Table 21-1) are accompanied by a high incidence of pain on injection and myoclonic movements. Lidocaine effectively reduces the pain of injection, while myoclonic movements can be reduced by premedication with either benzodiazepines or opiates. Etomidate is pharmacokinetically suitable for off-label infusion for anesthetic maintenance (10 µg/kg/min) or sedation (5 µg/kg/min); however, long-term infusions are not recommended because of side effects.

An induction dose of etomidate has a rapid onset; redistribution limits the duration of action. Metabolism occurs in the liver, primarily to inactive compounds. Elimination is both renal (78%) and biliary (22%). Compared to thiopental, the duration of action of etomidate increases less with repeated doses (see Figure 21-2).

Figure 21-2 Context-sensitive half-time of general anesthetics. The duration of action of single intravenous doses of anesthetic/hypnotic drugs is similarly short for all and is determined by redistribution of the drugs away from their active sites (see Figure 2-4). However, after prolonged infusions, drug half-lives and durations of action are dependent on a complex interaction between the rate of redistribution of the drug, the amount of drug accumulated in fat, and the drug's metabolic rate. This phenomenon has been termed the *context-sensitive half-time*; that is, the $t_{1/2}$ of a drug can be estimated only if one knows the context—the total dose and over what time period it has been given. Note that the half-times of some drugs such as etomidate, propofol, and ketamine increase only modestly with prolonged infusions; others (e.g., diazepam and thiopental) increase dramatically. (Reproduced with permission from Reves JG, Glass PSA, Lubarsky DA, et al. Intravenous anesthetics. In: Miller RD, et al., eds. *Miller's Anesthesia*. 7th ed. Churchill Livingstone, Philadelphia, 2010, 718. Copyright © Elsevier.)

Side Effects

Nervous System. Etomidate produces hypnosis and has no analgesic effects. The effects of etomidate on CBF, metabolism, and intracranial and intraocular pressures are similar to those of thiopental (without dropping mean arterial blood pressure). Etomidate produces increased EEG activity in epileptogenic foci and has been associated with seizures.

Cardiovascular System. Cardiovascular stability after induction is a major advantage of etomidate over either propofol or barbiturates. Induction doses of etomidate typically produce a small increase in heart rate and little or no decrease in blood pressure or cardiac output. Etomidate has little effect on coronary perfusion pressure while reducing myocardial O_2 consumption.

Respiratory and Other Side Effects. The degree of respiratory depression due to etomidate appears to be less than that due to thiopental. Like methohexital, etomidate may induce hiccups; it does not significantly stimulate histamine release. Etomidate has been associated with nausea and vomiting. The drug also inhibits adrenal biosynthetic enzymes required for the production of cortisol and some other steroids. Although the hemodynamic profile of etomidate may be advantageous, potential negative effects on steroid synthesis raise concerns about its use in trauma and critically ill patients (van den Heuvel et al., 2013) and obviate etomidate use for long-term infusion. A rapidly metabolized and ultra-short-acting analogue, methoxycarbonyl-etomidate, retains the favorable pharmacological properties of etomidate but does not produce adrenocortical suppression after bolus dosing (Cotton and Claing, 2009).

Ketamine

Ketamine is an arylcyclohexylamine and congener of phencyclidine. Ketamine is supplied as a mixture of the R+ and S- isomers even though the S- isomers is more potent and has fewer side effects. Although more lipophilic than thiopental, ketamine is water soluble.

Clinical Use and ADME. Ketamine is useful for anesthetizing patients at risk for hypotension and bronchospasm and for certain pediatric procedures. However, significant side effects limit its routine use. Ketamine rapidly produces a hypnotic state quite distinct from that of other anesthetics. Patients have profound analgesia, unresponsiveness to commands, and amnesia but may have their eyes open, move their limbs involuntarily, and breathe spontaneously. This cataleptic state has been termed *dissociative anesthesia*. The administration of ketamine has been shown to reduce the development of tolerance to long-term opioid use. Ketamine typically is administered intravenously but also is effective by intramuscular, oral, and rectal routes. Ketamine does not elicit pain on injection or true excitatory behavior as described for methohexital, although involuntary movements produced by ketamine can be mistaken for anesthetic excitement. Low-dose ketamine has potential use in depression (Rasmussen et al., 2013).

The onset and duration of an induction dose of ketamine are determined by the same distribution/redistribution mechanisms operant for all the other parenteral anesthetics. Ketamine is metabolized to norketamine by hepatic CYPs (mainly by 3A4; less by 2B6 and 2D9). Norketamine, with ~20% of the activity of ketamine, is hydroxylated and excreted in urine and bile. Ketamine's large volume of distribution and rapid clearance make it suitable for continuous infusion (see Table 21-1 and Figure 21-2).

Side Effects

Nervous System. Ketamine has indirect sympathomimetic activity and produces distinct behavioral effects. The ketamine-induced cataleptic state is accompanied by nystagmus with pupillary dilation, salivation,

lacrimation, and spontaneous limb movements with increased overall muscle tone. Patients are amnesic and unresponsive to painful stimuli. Ketamine produces profound analgesia, a distinct advantage over other parenteral anesthetics. Unlike other parenteral anesthetics, ketamine increases CBF and ICP with minimal alteration of cerebral metabolism. The effects of ketamine on CBF can be readily attenuated by the simultaneous administration of sedative-hypnotic agents.

Emergence delirium, characterized by hallucinations, vivid dreams, and delusions, is a frequent complication of ketamine that can result in serious patient dissatisfaction and can complicate postoperative management. Benzodiazepines reduce the incidence of emergence delirium.

Cardiovascular System. Unlike other anesthetics, induction doses of ketamine typically increase blood pressure, heart rate, and cardiac output. The cardiovascular effects are indirect and are most likely mediated by inhibition of both central and peripheral catecholamine reuptake. Ketamine has direct negative inotropic and vasodilating activity, but these effects usually are overwhelmed by the indirect sympathomimetic action. Thus, ketamine is a useful drug, along with etomidate, for patients at risk for hypotension during anesthesia. While not arrhythmogenic, ketamine increases myocardial O_2 consumption and is not an ideal drug for patients at risk for myocardial ischemia.

Respiratory System. The respiratory effects of ketamine are perhaps the best indication for its use. Induction doses of ketamine produce small and transient decreases in minute ventilation, but respiratory depression is less severe than with other parenteral anesthetics. Ketamine is a potent bronchodilator and is particularly well suited for anesthetizing patients at high risk for bronchospasm.

Barbiturates

Barbiturates are derivatives of barbituric acid with either an oxygen or a sulfur at the 2-position (see Figure 21-1 and Chapters 17 and 19). The three barbiturates most commonly used in clinical anesthesia are sodium *thiopental* (not currently marketed in the U.S.), *thiamylal* (currently licensed in the U.S. only for veterinary use), and *methohexital*. Sodium thiopental was used most frequently for inducing anesthesia.

Barbiturates are supplied as racemic mixtures despite enantioselectivity in their anesthetic potency. Barbiturates are formulated as the sodium salts with 6% sodium carbonate and reconstituted in water or isotonic saline to alkaline solutions, $10 < \text{pH} < 11$. *Mixing barbiturates with drugs in acidic solutions during anesthetic induction can result in precipitation of the barbiturate as the free acid; thus, standard practice is to delay the administration of other drugs until the barbiturate has cleared the intravenous tubing.*

The pharmacological properties and other therapeutic uses of the barbiturates are presented in Chapter 19. Table 19-3 lists the common barbiturates with their clinical pharmacological properties.

Clinical Use and ADME. Recommended intravenous dosing for parenteral barbiturates in a healthy young adult is given in Table 21-1. The availability of thiopental is limited currently by the lack of an FDA-licensed product and the prohibition of its import due to controversy over its use in administration of the death penalty by lethal injection.

The principal mechanism limiting anesthetic duration after single doses is redistribution of these hydrophobic drugs from the brain to other tissues. However, after multiple doses or infusions, the duration of action of the barbiturates varies considerably depending on their clearances. See Table 21-1 for pharmacokinetic parameters.

Methohexital differs from the other two intravenous barbiturates in its much more rapid clearance; thus, it accumulates less during prolonged infusions. Because of their slow elimination and large volumes of distribution, prolonged infusions or very large doses of thiopental and thiamylal can produce unconsciousness lasting several days. All three barbiturates are primarily eliminated by hepatic metabolism and subsequent renal excretion of inactive metabolites; a small fraction of thiopental undergoes desulfuration to the longer-acting hypnotic pentobarbital. Hepatic disease or other conditions that reduce serum protein concentrations will increase the initial free concentration and hypnotic effect of an induction dose.

Side Effects

Nervous System. Barbiturates suppress the EEG and can produce EEG burst suppression. They reduce the CMR, as measured by CMRO_2 , in a dose-dependent manner. As a consequence of the decrease in CMRO_2 , CBF and ICP are similarly reduced. Presumably, their CNS depressant activity contributes to their anticonvulsant effects (see Chapter 17). Methohexital can increase ictal activity, and seizures have been described in patients who received doses sufficient to produce burst suppression of the EEG, properties that make methohexital a good choice for anesthesia in patients who undergo electroconvulsive therapy.

Cardiovascular System. The anesthetic barbiturates produce dose-dependent decreases in blood pressure. The effect is due primarily to vasodilation, particularly venodilation, and to a lesser degree to a direct decrease in cardiac contractility. Typically, heart rate increases as a compensatory response to a lower blood pressure, although barbiturates also blunt the baroreceptor reflex. Thiopental maintains the ratio of myocardial O_2 supply to demand in patients with coronary artery disease within a normal blood pressure range. Hypotension can be severe in patients with an impaired ability to compensate for venodilation, such as those with hypovolemia, cardiomyopathy, valvular heart disease, coronary artery disease, cardiac tamponade, or β adrenergic blockade. None of the barbiturates has been shown to be arrhythmogenic.

Respiratory System. Barbiturates are respiratory depressants. Induction doses of thiopental decrease minute ventilation and tidal volume, with a smaller and inconsistent decrease in respiratory rate. Reflex responses to hypercarbia and hypoxia are diminished by anesthetic barbiturates; at higher doses or in the presence of other respiratory depressants such as opiates, apnea can result. Compared to propofol, barbiturates produce a higher incidence of wheezing in asthmatics, attributed to histamine release from mast cells during induction of anesthesia.

Other Side Effects. Short-term administration of barbiturates has no clinically significant effect on the hepatic, renal, or endocrine systems. True allergies to barbiturates are rare; however, direct drug-induced histamine release is occasionally seen. Barbiturates can induce fatal attacks of porphyria in patients with acute intermittent or variegated porphyria and are contraindicated in such patients. Methohexital can produce pain on injection to a greater degree than thiopental. Inadvertent intra-arterial injection of thiobarbiturates can induce a severe inflammatory and potentially necrotic reaction that can threaten limb survival. Methohexital, and to a lesser degree other barbiturates, can produce excitatory symptoms on induction, such as cough, hiccup, muscle tremors, twitching, and hypertonus.

Inhalational Anesthetics

A wide variety of gases and volatile liquids can produce anesthesia. The structures of the currently used inhalational anesthetics are shown in Figure 21-3. The inhalational anesthetics have therapeutic indices ($\text{LD}_{50}/\text{ED}_{50}$) that range from 2 to 4, making these among the most dangerous drugs in clinical use. The toxicity of these drugs is largely a function of their side effects, and each of the inhalational anesthetics has a unique side-effect profile. Hence, the selection of an inhalational anesthetic often is based on balancing a patient's pathophysiology with drug side-effect profiles.

Table 21-3 lists the widely varying physical properties of the inhalational agents in clinical use. Ideally, an inhalational agent would produce rapid induction of anesthesia and rapid recovery following discontinuation.

Pharmacokinetic Principles

Inhalational agents behave as gases rather than as liquids and thus require different pharmacokinetic constructs to be used in analyzing their uptake and distribution. Inhalational anesthetics distribute between tissues (or between blood and gas) such that equilibrium is achieved when the partial pressure of anesthetic gas is equal in the two tissues. When a person has breathed an inhalational anesthetic for a sufficiently long time that all tissues are equilibrated with the anesthetic, the partial pressure of the anesthetic in all tissues will be equal to the partial pressure of the anesthetic in inspired gas. While the partial pressure of the anesthetic may be equal in all tissues, the concentration of anesthetic in each tissue will be different.

Figure 21-3 Structures of inhalational general anesthetics. Note that all inhalational general anesthetic agents except nitrous oxide and halothane are ethers, and that fluorine replaces chlorine in the development of the halogenated agents. All structural differences are associated with important differences in pharmacological properties.

Indeed, anesthetic partition coefficients are defined as the ratio of anesthetic concentration in two tissues when the partial pressures of anesthetic are equal in the two tissues. Blood:gas, brain:blood, and fat:blood partition coefficients for the various inhalational agents are listed in Table 21-3. These partition coefficients show that inhalational anesthetics are more soluble in some tissues (e.g., fat) than they are in others (e.g., blood). In clinical practice, equilibrium is achieved when the partial pressure in inspired gas is equal to the partial pressure in end-tidal (alveolar) gas. For inhalational agents that are not very soluble in blood or any other tissue, equilibrium is achieved quickly, as illustrated for nitrous oxide in Figure 21-4. If an agent is more soluble in a tissue such as fat, equilibrium may take many hours to reach. This occurs because fat represents a huge anesthetic reservoir that will be filled slowly because of the modest blood flow to fat. Anesthesia is produced when anesthetic partial pressure in brain is equal to or greater than MAC. Because the brain is well perfused, anesthetic partial pressure in brain becomes equal to the partial pressure in alveolar gas (and in blood) over the course of several minutes. Therefore, anesthesia is achieved shortly after alveolar partial pressure reaches MAC.

Elimination of inhalational anesthetics is largely a reversal of uptake. For inhalational agents with high blood and tissue solubility, recovery will be a function of the duration of anesthetic administration. This occurs because the accumulated amounts of anesthetic in the fat reservoir will prevent blood (and therefore alveolar) partial pressures from falling rapidly. Patients will be arousable when alveolar partial pressure reaches MAC_{awake}, a partial pressure somewhat lower than MAC (see Table 21-3).

Specific Inhalational Agents

Isoflurane

Isoflurane is a volatile liquid at room temperature and is neither flammable nor explosive in mixtures of air or O₂. Isoflurane is a commonly used inhalational anesthetic worldwide.

Clinical Use and ADME. Isoflurane is typically used for maintenance of anesthesia *after induction* with other agents because of its pungent odor. Induction of anesthesia can be achieved in less than 10 min with an inhaled concentration of 1.5%–3% isoflurane in O₂; this concentration is reduced to 1%–2% (~1–2 MAC) for maintenance of anesthesia. The use of adjunct agents such as opioids or nitrous oxide reduces the concentration of isoflurane required for surgical anesthesia.

Isoflurane has a blood:gas partition coefficient substantially lower than that of enflurane. Consequently, induction with isoflurane and recovery from isoflurane are relatively faster. More than 99% of inhaled isoflurane is excreted unchanged by the lungs. Isoflurane does not appear to be a mutagen, teratogen, or carcinogen.

Side Effects

Cardiovascular System. Isoflurane produces a concentration-dependent decrease in arterial blood pressure; cardiac output is well maintained; hypotension is the result of decreased systemic vascular resistance. Isoflurane produces vasodilation in most vascular beds, with pronounced effects in skin and muscle, and is a potent coronary vasodilator, simultaneously producing increased coronary blood flow and decreased myocardial O₂ consumption. Isoflurane significantly attenuates baroreceptor function. Patients anesthetized with isoflurane generally have mildly elevated heart rates as a compensatory response to reduced blood pressure; however, rapid changes in isoflurane concentration can produce both transient tachycardia and hypertension due to isoflurane-induced sympathetic stimulation.

Respiratory System. Isoflurane produces concentration-dependent depression of ventilation. This drug is particularly effective at depressing the ventilatory response to hypercapnia and hypoxia. Although isoflurane is a bronchodilator, it also is an airway irritant and can stimulate airway reflexes during induction of anesthesia, producing coughing and laryngospasm.

TABLE 21-3 ■ PROPERTIES OF INHALATIONAL ANESTHETIC AGENTS

AGENT	MAC ^a (vol%)	MAC _{AWAKE} ^b (vol%)	VAPOR PRESSURE (mm Hg, 20°C)	PARTITION COEFFICIENT AT 37°C			% RECOVERED AS METABOLITES
				BLOOD/GAS	BRAIN/BLOOD (Brain/Gas)	FAT/BLOOD (Fat/Gas)	
Isoflurane ^c	1.05–1.28	0.4	238	1.43	2.6	45 (91)	0.17
Enflurane	1.68	0.4	175	1.91	1.4	36 (98)	2.4
Sevoflurane	1.4–3.3	0.6	157	0.63–0.69	1.7 (1.2)	48 (50)	3.5
Desflurane	5.2–9.2	2.4	669	0.424	1.3 (0.54)	27 (19)	<0.02
N ₂ O ^c	105	60.0	Gas	0.47	1.1	2.3	0.004
Xe	55–71	32.6	Gas	0.115	—	(1.9)	0

^aMAC values are expressed as volume percent, the percentage of the atmosphere that is anesthetic. An MAC value greater than 100% means that hyperbaric conditions would be required.

^bMAC_{AWAKE} is the concentration at which appropriate responses to commands are lost.

^cEC₅₀ for memory suppression (vol%): isoflurane, 0.24; N₂O, 52.5; values not available for other agents.

Figure 21-4 Uptake of inhalational general anesthetics. The rise in end-tidal alveolar F_A anesthetic concentration toward the inspired F_I concentration is most rapid with the least-soluble anesthetics (nitrous oxide and desflurane) and slowest with the most soluble anesthetic, halothane. All data are from human studies. (Reproduced with permission from Eger EI II. *Inhaled anesthetics: uptake and distribution*. In: Miller RD et al., eds. *Miller's Anesthesia*. 7th ed. Churchill Livingstone, Philadelphia, 2010, 540. Copyright © Elsevier.)

Nervous System. Isoflurane dilates the cerebral vasculature, producing increased CBF (Drummond et al., 1983). There is a modest risk of an increase in ICP in patients with preexisting intracranial hypertension. Isoflurane reduces $CMRO_2$ in a dose-dependent manner.

Muscle. Isoflurane produces some relaxation of skeletal muscle by its central effects. It also enhances the effects of both depolarizing and nondepolarizing muscle relaxants. Like other halogenated inhalational anesthetics, isoflurane relaxes uterine smooth muscle and is not recommended for analgesia or anesthesia for labor and vaginal delivery.

Kidney. Isoflurane reduces renal blood flow and GFR, resulting in a small volume of concentrated urine.

Liver and GI Tract. Splanchnic and hepatic blood flows are reduced with increasing doses of isoflurane as systemic arterial pressure decreases. There are no reported incidences of hepatic toxicity.

Sevoflurane

Sevoflurane is a clear, colorless, volatile liquid at room temperature and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or O_2 . However, sevoflurane can undergo an exothermic reaction with desiccated CO_2 absorbent to produce airway burns or spontaneous ignition, explosion, and fire. *Sevoflurane must not be used with an anesthesia machine in which the CO_2 absorbent has been dried by prolonged gas flow through the absorbent. The reaction of sevoflurane with desiccated CO_2 absorbent also can produce CO , which can result in serious patient injury.*

Clinical Use and ADME. Sevoflurane is widely used for outpatient anesthesia because of its rapid recovery profile and because it is not irritating to the airway. Induction of anesthesia is rapidly achieved using inhaled concentrations of 2%–4% sevoflurane. Sevoflurane has properties that make it an ideal induction agent: pleasant smell, rapid onset, and lack of irritation to the airway. Thus, it has largely replaced halothane (not available in the U.S.) as the preferred agent for anesthetic induction in adult and pediatric patients.

The low solubility of sevoflurane in blood and other tissues provides for rapid induction of anesthesia and rapid changes in anesthetic depth following changes in delivered concentration. Approximately 5% of absorbed sevoflurane is metabolized by hepatic CYP2E1, with the predominant product being hexafluoroisopropanol. Hepatic metabolism of sevoflurane also produces inorganic fluoride. Interaction of sevoflurane with soda lime produces decomposition products that may be toxic, such

as compound A, pentafluoroisopropenyl fluoromethyl ether (see kidney discussion under Side Effects).

Side Effects

Cardiovascular System. Sevoflurane produces concentration-dependent decreases in arterial blood pressure (due to systemic vasodilation) and cardiac output. Sevoflurane does not produce tachycardia and thus may be a preferable agent in patients prone to myocardial ischemia.

Respiratory System. Sevoflurane produces a concentration-dependent reduction in tidal volume and increase in respiratory rate in spontaneously breathing patients. The increased respiratory frequency does not compensate for reduced tidal volume, with the net effect being a reduction in minute ventilation and an increase in $Paco_2$. Sevoflurane is not irritating to the airway and is a potent bronchodilator. As a result, sevoflurane is the most effective clinical bronchodilator of the inhalational anesthetics.

Nervous System. Sevoflurane produces effects on cerebral vascular resistance, $CMRO_2$, and CBF that are similar to those produced by isoflurane and desflurane. Sevoflurane can increase ICP in patients with poor intracranial compliance, the response to hypocapnia is preserved during sevoflurane anesthesia, and increases in ICP can be prevented by hyperventilation. In children, sevoflurane is associated with delirium on emergence from anesthesia. This delirium is short lived and without any reported adverse long-term sequelae.

Muscle. Sevoflurane produces skeletal muscle relaxation and enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents.

Kidney. Controversy has surrounded the potential nephrotoxicity of compound A, which is produced by interaction of sevoflurane with the CO_2 absorbent soda lime. Biochemical evidence of transient renal injury has been reported in human volunteers (Eger et al., 1997). Large clinical studies have shown no evidence of increased serum creatinine, blood urea nitrogen, or any other evidence of renal impairment following sevoflurane administration. *The FDA recommends that sevoflurane be administered with fresh gas flows of 1–2 L/min, with sevoflurane exposures not exceeding 2 MAC-hours to minimize exposure to compound A.*

Liver and GI Tract. Sevoflurane is not known to cause hepatotoxicity or alterations of hepatic function tests.

Desflurane

Desflurane is a highly volatile liquid at room temperature (vapor pressure = 669 mm Hg) and must be stored in tightly sealed bottles. Delivery of a precise concentration of desflurane requires the use of a specially heated vaporizer that delivers pure vapor that then is diluted appropriately with other gases (O_2 , air, or N_2O). Desflurane is nonflammable and nonexplosive in mixtures of air or O_2 .

Clinical Use and ADME. Desflurane is for outpatient surgery because of its rapid onset of action and rapid recovery time. The drug irritates the tracheobronchial tree and can provoke coughing, salivation, and bronchospasm. Anesthesia therefore usually is induced with an intravenous agent, with desflurane subsequently administered for maintenance of anesthesia. Maintenance of anesthesia usually requires inhaled concentrations of 6%–8% (~1 MAC). Lower concentrations of desflurane are required if it is coadministered with nitrous oxide or opioids.

Desflurane has a very low blood:gas partition coefficient (0.42) and also is not very soluble in fat or other peripheral tissues. Thus, the alveolar and blood concentrations rapidly rise to the level of inspired concentration, providing rapid induction of anesthesia and rapid changes in depth of anesthesia following changes in the inspired concentration. Emergence from desflurane anesthesia also is rapid. Desflurane is minimally metabolized; more than 99% of absorbed desflurane is eliminated unchanged through the lungs.

Side Effects

Cardiovascular System. Desflurane produces hypotension primarily by decreasing systemic vascular resistance. Cardiac output is well preserved, as is blood flow to the major organ beds (splanchnic, renal, cerebral, and coronary) (Eger, 1994). Transient tachycardia is often noted with abrupt increases in desflurane's delivered concentration, a result of this

desflurane-induced stimulation of the sympathetic nervous system. The hypotensive effects of desflurane do not wane with increasing duration of administration.

Respiratory System. Desflurane causes a concentration-dependent increase in respiratory rate and a decrease in tidal volume. At low concentrations (<1 MAC), the net effect is to preserve minute ventilation. Desflurane concentrations greater than 1 MAC depress minute ventilation, resulting in elevated arterial CO_2 tension (PaCO_2). Desflurane is a bronchodilator. However, it also is a strong airway irritant and can cause coughing, breath-holding, laryngospasm, and excessive respiratory secretions. *Because of its irritant properties, desflurane is not used as the primary anesthetic for induction of anesthesia.*

Nervous System. Desflurane decreases cerebral vascular resistance and CMRO_2 . Burst suppression of the EEG is achieved with ~2 MAC; at this level, CMRO_2 is reduced by ~50%. Under conditions of normocapnia and normotension, desflurane produces an increase in CBF and can increase ICP in patients with poor intracranial compliance. The vasoconstrictive response to hypocapnia is preserved during desflurane anesthesia, and increases in ICP thus can be prevented by hyperventilation.

Muscle, Kidney, Liver, and GI Tract. Desflurane produces direct skeletal muscle relaxation as well as enhances the effects of nondepolarizing and depolarizing neuromuscular blocking agents. Consistent with its minimal metabolic degradation, desflurane has no reported nephrotoxicity or hepatotoxicity.

Desflurane and Carbon Monoxide. Inhaled anesthetics are administered via a system that permits unidirectional flow of gas and rebreathing of exhaled gases. To prevent rebreathing of CO_2 (which can lead to hypercarbia), CO_2 absorbers are incorporated into the anesthesia delivery circuits. With almost complete desiccation of the CO_2 absorbents, substantial quantities of carbon monoxide can be produced. This effect is greatest with desflurane and can be prevented by the use of well-hydrated, fresh CO_2 absorbent.

Halothane

Halothane is a volatile liquid at room temperature and must be stored in a sealed container. Because halothane is a light-sensitive compound, it is marketed in amber bottles with thymol added as a preservative. Mixtures of halothane with O_2 or air are neither flammable nor explosive.

Clinical Use and ADME. Halothane has been used for maintenance of anesthesia. Concerns over hepatic toxicity have limited its use in developed countries. Halothane can produce fulminant hepatic necrosis (*halothane hepatitis*) in ~1 in 10,000 patients receiving halothane and “is referred to as halothane hepatitis” (“Summary,” 1966). This syndrome (with a 50% fatality rate) is characterized by fever, anorexia, nausea, and vomiting, developing several days after anesthesia, and can be accompanied by a rash and peripheral eosinophilia. Halothane hepatitis may be the result of an immune response to hepatic proteins that become trifluoroacetylated as a consequence of halothane metabolism. Halothane has a low cost and is still widely used in developing countries. Due to its side-effect profile and the availability of safer agents with more favorable pharmacokinetic profiles, halothane is no longer marketed in the U.S. Those interested in further information on halothane should consult previous recent editions of this book.

Enflurane

Enflurane is a clear, colorless liquid at room temperature and has a mild, sweet odor. Like other inhalational anesthetics, it is volatile and must be stored in a sealed bottle. It is nonflammable and nonexplosive in mixtures of air or oxygen.

Clinical Use and ADME. Enflurane is primarily utilized for maintenance rather than induction of anesthesia. Surgical anesthesia can be induced with enflurane in less than 10 min with an inhaled concentration of 2%–4.5% in oxygen and maintained with concentrations from 0.5% to 3%. Enflurane concentrations required to produce anesthesia are reduced when it is coadministered with nitrous oxide or opioids. Concerns over enflurane’s ability to decrease seizure threshold and potentially produce nephrotoxicity have limited its clinical utility in developed countries (Mazze et al., 1977).

Because of its relatively high blood:gas partition coefficient, induction of anesthesia and recovery from enflurane are relatively slow. Enflurane is metabolized to a modest extent, with 2%–8% of absorbed enflurane undergoing oxidative metabolism by hepatic CYP2E1. Fluoride ions are a by-product of enflurane metabolism, but plasma fluoride levels are low and nontoxic. Patients taking isoniazid exhibit enhanced metabolism of enflurane with consequent elevation of serum fluoride.

Side Effects. Enflurane causes a decrease in arterial blood pressure, the result of vasodilation and depression of myocardial contractility, with minimal effects on heart rate. The drug is an effective bronchodilator and produces a pattern of rapid shallow breathing. Due to its actions as a cerebral vasodilator, enflurane can increase ICP. It can produce seizure activity and should not be used in patients with seizure disorders. Enflurane relaxes skeletal and uterine muscle. As with other anesthetic gases, enflurane reduces renal blood flow, GFR, and urinary output.

Nitrous Oxide

Nitrous oxide is a colorless, odorless gas at room temperature. N_2O is sold in steel cylinders and must be delivered through calibrated flowmeters provided on all anesthesia machines. N_2O is neither flammable nor explosive, but it does support combustion as actively as oxygen does when it is present in proper concentration with a flammable anesthetic or material.

Clinical Use and ADME. N_2O is a weak anesthetic agent that has significant analgesic effects. Surgical anesthetic depth is only achieved under hyperbaric conditions. By contrast, analgesia is produced at concentrations as low as 20%. The analgesic property of N_2O is a function of the activation of opioidergic neurons in the periaqueductal gray matter and the adrenergic neurons in the locus ceruleus. N_2O is frequently used in concentrations of ~50% to provide analgesia and mild sedation in outpatient dentistry. N_2O cannot be used at concentrations above 80% because this limits the delivery of adequate O_2 . Because of this limitation, N_2O is used primarily as an adjunct to other inhalational or intravenous anesthetics.

Nitrous oxide is very insoluble in blood and other tissues. This results in rapid equilibration between delivered and alveolar anesthetic concentrations and provides for rapid induction of anesthesia and rapid emergence following discontinuation of administration. The rapid uptake of N_2O from alveolar gas serves to concentrate coadministered halogenated anesthetics; this effect (the “second gas effect”) speeds induction of anesthesia. On discontinuation of N_2O administration, N_2O gas can diffuse from blood to the alveoli, diluting O_2 in the lung. This can produce an effect called *diffusional hypoxia*. *To avoid hypoxia, 100% O_2 rather than air should be administered when N_2O is discontinued.* Almost all (99.9%) of the absorbed N_2O is eliminated unchanged by the lungs.

Side Effects

Cardiovascular System. Although N_2O produces a negative inotropic effect on heart muscle in vitro, depressant effects on cardiac function generally are not observed in patients because of the stimulatory effects of N_2O on the sympathetic nervous system. The cardiovascular effects of N_2O also are heavily influenced by the concomitant administration of other anesthetic agents. When N_2O is coadministered with halogenated inhalational anesthetics, one observes increases in heart rate, arterial blood pressure, and cardiac output. In contrast, when N_2O is coadministered with an opioid, one generally sees decreases in arterial blood pressure and cardiac output. N_2O also increases venous tone in both the peripheral and the pulmonary vasculature. The effects of N_2O on pulmonary vascular resistance can be exaggerated in patients with preexisting pulmonary hypertension; thus, the drug generally is not used in these patients.

Respiratory System. N_2O causes modest increases in respiratory rate and decreases in tidal volume in spontaneously breathing patients. Even modest concentrations of N_2O markedly depress the ventilatory response to hypoxia. Thus, it is prudent to monitor arterial O_2 saturation directly in patients receiving or recovering from N_2O .

Nervous System. N_2O can significantly increase CBF and ICP. This cerebral vasodilatory capacity of N_2O is significantly attenuated by the simultaneous administration of intravenous agents such as opiates and propofol. By contrast, the combination of N_2O and inhaled agents results

in greater vasodilation than the administration of the inhaled agent alone at equivalent anesthetic depth.

Muscle. N_2O does not relax skeletal muscle and does not enhance the effects of neuromuscular blocking drugs.

Kidney, Liver, and GI Tract. N_2O is not known to have nephrotoxic or hepatotoxic effects.

Other Adverse Effects. A major problem with N_2O is that it will exchange with N_2 in any air-containing cavity in the body. Moreover, because of their differential blood:gas partition coefficients, N_2O will enter the cavity faster than N_2 escapes, thereby increasing the volume or pressure in this cavity. Examples of air collections that can be expanded by N_2O include a pneumothorax, an obstructed middle ear, an air embolus, an obstructed loop of bowel, an intraocular air bubble, a pulmonary bulla, and intracranial air. N_2O should be avoided in these clinical settings.

Nitrous oxide interacts with the cobalt of vitamin B_{12} , thereby preventing vitamin B_{12} from acting as a cofactor for methionine synthase (Sanders and Maze, 2007). Inactivation of methionine synthase can produce signs of vitamin B_{12} deficiency, including megaloblastic anemia and peripheral neuropathy, a particular concern in patients with malnutrition, vitamin B_{12} deficiency, or alcoholism. The clinical use of N_2O is controversial due to its potential metabolic effects related to increased homocysteine and changes in DNA and protein synthesis (Ko et al., 2014). For this reason, N_2O is not used as a chronic analgesic or as a sedative in critical care settings.

Xenon

Xenon, an inert gaseous element, is not approved for use in the U.S. and is unlikely to enjoy widespread use because it is a rare gas that cannot be manufactured and must be extracted from air; thus, xenon is expensive and available in limited quantities. Xenon, unlike other anesthetic agents, has minimal cardiorespiratory and other side effects.

Xenon exerts its analgesic and anesthetic effects at a number of receptor systems in the CNS. Of these, noncompetitive antagonism of the NMDA receptor and agonism at the TREK channel (a member of the two-pore K^+ channel family) are thought to be the central mechanisms of xenon action (Franks and Honore, 2004).

Xenon is extremely insoluble in blood and other tissues, providing for rapid induction and emergence from anesthesia. It is sufficiently potent to produce surgical anesthesia when administered with 30% oxygen. However, supplementation with an intravenous agent such as propofol appears to be required for clinical anesthesia. Xenon is well tolerated in patients of advanced age. No long-term side effects from xenon anesthesia have been reported.

Anesthetic Adjuncts

A general anesthetic is usually given with adjuncts to augment specific components of anesthesia, permitting lower doses of general anesthetics with fewer side effects.

Benzodiazepines

Benzodiazepines (see Chapters 15 and 19) can produce anesthesia similar to that of barbiturates; they are more commonly used for sedation rather than general anesthesia because prolonged amnesia and sedation may result from anesthetizing doses. As adjuncts, benzodiazepines are used for anxiolysis, amnesia, and sedation prior to induction of anesthesia or for sedation during procedures not requiring general anesthesia. The benzodiazepine most frequently used in the perioperative period is midazolam, followed distantly by diazepam and lorazepam.

Midazolam is water soluble and typically is administered intravenously but also can be given orally, intramuscularly, or rectally; oral midazolam is particularly useful for sedation of young children. Midazolam produces minimal venous irritation (as opposed to diazepam and lorazepam, which are formulated in propylene glycol and are painful on injection, sometimes producing thrombophlebitis). Midazolam has the pharmacokinetic advantage, particularly over lorazepam, of being more rapid in onset and shorter in duration of effect. Sedative doses of midazolam (0.01–0.05 mg/kg IV) reach peak effect in about 2 min and provide sedation for approximately 30 min. Elderly patients tend to be more sensitive to and have a

slower recovery from benzodiazepines. Midazolam is metabolized principally by hepatic CYP3A4, and drug interactions with inducers, inhibitors, and substrates of that CYP are predictable. Either for prolonged sedation or for general anesthetic maintenance, midazolam is more suitable than other benzodiazepines for infusion, although midazolam's duration of action ($t_{1/2}$) does significantly increase with prolonged infusions (see Figure 21–2). Benzodiazepines reduce CBF and cerebral metabolism, but at equianesthetic doses are less effective than barbiturates in this respect. Benzodiazepines modestly decrease blood pressure and respiratory drive, occasionally resulting in apnea.

α_2 Adrenergic Agonists

Dexmedetomidine is a selective α_2 adrenergic receptor agonist (Kamibayashi and Maze, 2000) used for short-term (<24 h) sedation of critically ill adults and for sedation prior to and during surgical or other medical procedures in nonintubated patients. Activation of the α_{2A} adrenergic receptor by dexmedetomidine produces both sedation and analgesia.

The recommended loading dose is 1 μ g/kg given over 10 min, followed by infusion at a rate of 0.2–0.7 μ g/kg/h. Reduced doses should be considered in patients with risk factors for severe hypotension. Dexmedetomidine is highly protein bound and is metabolized primarily in the liver; the glucuronide and methyl conjugates are excreted in the urine. Common side effects of dexmedetomidine include hypotension and bradycardia, attributed to decreased catecholamine release by activation peripherally and in the CNS of the α_{2A} receptor. Nausea and dry mouth also are common untoward reactions. At higher drug concentrations, the α_{2B} subtype is activated, resulting in hypertension and a further decrease in heart rate and cardiac output. Dexmedetomidine provides sedation and analgesia with minimal respiratory depression. However, dexmedetomidine does not appear to provide reliable amnesia, and additional agents may be needed.

Analgesics

Analgesics typically are administered with general anesthetics to reduce anesthetic requirements and minimize hemodynamic changes produced by painful stimuli. Nonsteroidal anti-inflammatory drugs, cyclooxygenase 2 inhibitors, and acetaminophen (see Chapter 38) sometimes provide adequate analgesia for minor surgical procedures. However, opioids are the primary analgesics used during the perioperative period because of the rapid and profound analgesia they produce. Fentanyl, sufentanil, alfentanil, remifentanil, meperidine, and morphine are the major parenteral opioids used in the perioperative period. The primary analgesic activity of each of these drugs is produced by agonist activity at μ opioid receptors (see Chapter 20).

The choice of a perioperative opioid is based primarily on duration of action because, at appropriate doses, all produce similar analgesia and side effects. Remifentanil has an ultrashort duration of action (<10 min), accumulates minimally with repeated doses, and is particularly well suited for procedures that are briefly painful. Single doses of fentanyl, sufentanil, and alfentanil all have similar intermediate durations of action (30, 20, and 15 min, respectively), but recovery after prolonged administration varies considerably. Fentanyl's duration of action lengthens the most with infusion, sufentanil's much less so, and alfentanil's the least.

The frequency and severity of nausea, vomiting, and pruritus after emergence from anesthesia are increased by all opioids to about the same degree. A useful side effect of meperidine is its capacity to reduce shivering, a common problem during emergence from anesthesia; other opioids are not as efficacious against shivering, perhaps due to less κ receptor agonism. Finally, opioids often are administered intrathecally and epidurally for management of acute and chronic pain (see Chapter 20). Neuraxial opioids with or without local anesthetics can provide profound analgesia for many surgical procedures; however, respiratory depression and pruritus usually limit their use to major operations.

Neuromuscular Blocking Agents

The practical aspects of the use of neuromuscular blockers as anesthetic adjuncts are briefly described here. The detailed pharmacology of this drug class is presented in Chapter 11.

Depolarizing (e.g., succinylcholine) and nondepolarizing (e.g., vecuronium) muscle relaxants often are administered during the induction of anesthesia to relax muscles of the jaw, neck, and airway and thereby facilitate laryngoscopy and endotracheal intubation. Nondepolarizing muscle relaxants are generally better tolerated. Barbiturates will precipitate when mixed with muscle relaxants and should be allowed to clear from the intravenous line prior to injection of a muscle relaxant. The action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an acetylcholinesterase inhibitor such as neostigmine or edrophonium (see Chapter 10), in combination with a muscarinic receptor antagonist (e.g., glycopyrrolate or atropine; see Chapter 9) to offset the muscarinic activation resulting from esterase inhibition. Sugammadex, a first-in-class selective relaxant binding agent specific for reversal of rocuronium muscle-relaxing effect, is approved in Europe and awaits FDA approval in the U.S. (Ledowski, 2015).

Anesthetic Toxicity and Cytoprotection

The conventional view of general anesthesia is that anesthetics produce a reversible loss of consciousness and that CNS function returns to basal levels on termination of anesthesia and recovery of anesthesia. Recent data, however, cast doubt on this notion. Exposure of rodents to anesthetic agents during the period of synaptogenesis results in widespread neurodegeneration in the developing brain (Jevtovic-Todorovic et al., 2003). This neuronal injury resulted in disturbed electrophysiologic function and cognitive dysfunction in adolescent and adult rodents exposed to anesthetics during the neonatal period. The cognitive deficits attendant with neonatal anesthetic exposure have been attributed to neuronal apoptosis; however, recently published data have cast doubt on this premise. There is convincing data that exposure to anesthetics in the neonatal period leads to actin cytoskeleton dysregulation and profound synaptic loss; this may contribute to later cognitive and behavioral dysfunction. A variety of agents, including isoflurane, propofol, midazolam, nitrous oxide, and thiopental, manifest this toxicity (Patel and Sun, 2009). The underlying mechanism(s) in animal models are unclear, and the threat to humans is still uncertain.

By contrast, anesthetics reduce ischemic injury to a variety of tissues, including the heart and brain. This protective effect is robust and results in better functional outcomes in comparison to ischemic injury that occurs in the unanesthetized awake subjects. In the brain, several mechanisms for anesthetic-mediated protection have been proposed, including suppression of excitotoxicity from excess glutamate release, reduction in inflammation, and increased prosurvival signaling (Head and Patel, 2007). In the heart, the molecular mechanisms attendant to anesthetic-mediated protection include activation of “classical” preconditioning pathways, including GPCRs, endothelial NO synthase, survival protein kinases, PKC, reactive oxygen species, ATP-dependent K⁺ channels, and the mitochondrial permeable transition pore (Kunst and Klein, 2015).

Therapeutic Gases

Oxygen

Oxygen is essential to life. Hypoxia is a life-threatening condition in which O₂ delivery is inadequate to meet the metabolic demands of the tissues. Hypoxia may result from alterations in tissue perfusion, decreased O₂ tension in the blood, or decreased O₂ carrying capacity. In addition, hypoxia may result from restricted O₂ transport from the microvasculature to cells or impaired utilization within the cell. An inadequate supply of O₂ ultimately results in the cessation of aerobic metabolism and oxidative phosphorylation, depletion of high-energy compounds, cellular dysfunction, and death.

Normal Oxygenation

Oxygen makes up 21% of air, which at sea level represents a partial pressure of 21 kPa (158 mm Hg). While the fraction (percentage) of O₂ remains constant regardless of atmospheric pressure, the PO₂ decreases

with lower atmospheric pressure. Ascent to elevated altitude reduces the uptake and delivery of O₂ to the tissues, whereas increases in atmospheric pressure (e.g., hyperbaric therapy or breathing at depth) raise the PO₂ in inspired air and increase gas uptake. As the air is delivered to the distal airways and alveoli, the PO₂ decreases by dilution with CO₂ and water vapor and by uptake into the blood.

Under ideal conditions, when ventilation and perfusion are well matched, the alveolar PO₂ will be about 14.6 kPa (110 mm Hg). The corresponding alveolar partial pressures of water and CO₂ are 6.2 kPa (47 mm Hg) and 5.3 kPa (40 mm Hg), respectively. Under normal conditions, there is complete equilibration of alveolar gas and lung capillary blood, and the PO₂ in end-capillary blood is typically within a fraction of a kilopascal of that in the alveoli. The PO₂ in arterial blood, however, is further reduced by venous admixture (shunt), the addition of mixed venous blood from the pulmonary artery, which has a PO₂ of about 5.3 kPa (40 mm Hg). Together, the diffusional barrier, ventilation-perfusion mismatches, and the shunt fraction are the major causes of the alveolar-to-arterial O₂ gradient, which is normally 1.3–1.6 kPa (10–12 mm Hg) when air is breathed and 4.0–6.6 kPa (30–50 mm Hg) when 100% O₂ is breathed. O₂ is delivered to the tissue capillary beds by the circulation and again follows a gradient out of the blood and into cells. Tissue extraction of O₂ typically reduces the PO₂ of venous blood by an additional 7.3 kPa (55 mm Hg). Although the PO₂ at the site of cellular O₂ utilization—the mitochondria—is not known, oxidative phosphorylation can continue at a PO₂ of only a few millimeters of mercury.

In the blood, O₂ is carried primarily in chemical combination with hemoglobin and is to a small extent dissolved in solution. The quantity of O₂ combined with hemoglobin depends on the PO₂, as illustrated by the sigmoidal oxyhemoglobin dissociation curve (Figure 21–5). Hemoglobin is about 98% saturated with O₂ when air is breathed under normal circumstances, and it binds 1.3 mL of O₂ per gram when fully saturated. The steep slope of this curve with falling PO₂ facilitates unloading of O₂ from hemoglobin at the tissue level and reloading when desaturated mixed venous blood arrives at the lung. Shifting of the curve to the right with increasing temperature, increasing PCO₂, and decreasing pH, as is found in metabolically active tissues, lowers the O₂ saturation for the same PO₂ and thus delivers additional O₂ where and when it is most needed. However, the flattening of the curve with higher PO₂ indicates that increasing blood PO₂ by inspiring O₂-enriched mixtures can increase the amount of O₂ carried by hemoglobin only minimally. Because of the low solubility of O₂ (0.226 mL/L per kPa or 0.03 mL/L per mm Hg at 37°C), breathing 100% O₂ can increase the amount of O₂ dissolved in blood by only 15 mL/L, less than one-third of normal metabolic demands. However, if the inspired PO₂ is increased to 3 atm (304 kPa) in a hyperbaric chamber, the amount of dissolved O₂ is sufficient to meet normal metabolic demands even in the absence of hemoglobin (Table 21–4).

Oxygen Deprivation. Hypoxemia generally implies a failure of the respiratory system to oxygenate arterial blood. Classically, there are five causes of hypoxemia:

- Low F_{IO₂}
- Hypoventilation
- Ventilation-perfusion mismatch
- Shunt or venous admixture
- Increased diffusion barrier

The term *hypoxia* denotes insufficient oxygenation of the tissues. In addition to failure of the respiratory system to oxygenate the blood adequately, a number of other factors can contribute to hypoxia at the tissue level. These may be divided into categories of O₂ delivery and O₂ utilization. O₂ delivery decreases globally when cardiac output falls or locally when regional blood flow is compromised, such as from a vascular occlusion (e.g., stenosis, thrombosis, or microvascular occlusion) or increased downstream pressure (e.g., compartment syndrome, venous stasis, or venous hypertension). Decreased O₂ carrying capacity of the blood likewise will reduce O₂ delivery, such as occurs with anemia, carbon monoxide poisoning, or hemoglobinopathy. Finally, hypoxia may occur when

Figure 21-5 Oxyhemoglobin dissociation curve for whole blood. The relationship between P_{O_2} and Hb saturation is shown. The P_{50} , or the P_{O_2} resulting in 50% saturation, is indicated. An increase in temperature or a decrease in pH (as in working muscle) shifts this relationship to the right, reducing the hemoglobin saturation at the same P_{O_2} and thus aiding in the delivery of O_2 to the tissues.

transport of O_2 from the capillaries to the tissues is decreased (edema) or utilization of the O_2 by the cells is impaired (CN^- toxicity).

Effects of Hypoxia

Cellular and Metabolic Effects. At the molecular level, nonlethal hypoxia produces a marked alteration in gene expression, mediated in part by hypoxia inducible factor 1 α (Guimarães-Camboa et al., 2015).

When the mitochondrial P_{O_2} falls below about 0.13 kPa (1 mm Hg), aerobic metabolism stops, and the less-efficient anaerobic pathways of glycolysis become responsible for the production of cellular energy. End products of anaerobic metabolism, such as lactic acid, are released into the circulation in measurable quantities. Energy-dependent ion pumps slow, and transmembrane ion gradients dissipate. Intracellular concentrations

of Na^+ , Ca^{2+} , and H^+ increase, finally leading to cell death. The time course of cellular demise depends on the relative metabolic demands, oxygen storage capacity, and anaerobic capacity of the individual organs. Restoration of perfusion and oxygenation prior to hypoxic cell death paradoxically can result in an accelerated form of cell injury (ischemia-reperfusion syndrome), which is thought to result from the generation of highly reactive oxygen free radicals.

Cell and Organ Survival. Ultimately, hypoxia results in the cessation of aerobic metabolism, exhaustion of high-energy intracellular stores, cellular dysfunction, and death. The time course of cellular demise depends on the tissue's relative metabolic requirements, O_2 and energy stores, and anaerobic capacity. Survival times (the time from the onset of circulatory arrest to significant organ dysfunction) range from 1–2 min in the cerebral cortex to around 5 min in the heart and 10 min in the kidneys and liver, with the potential for some degree of recovery if reperfused. Revival times (the duration of hypoxia beyond which recovery is no longer possible) are about four to five times longer.

Organ System Effects. Less-severe degrees of hypoxia have progressive physiological effects on different organ systems (Nunn, 2005).

Respiratory System. Hypoxia stimulates the carotid and aortic baroreceptors to cause increases in both the rate and the depth of ventilation. Minute volume almost doubles when normal individuals inspire gas with a P_{O_2} of 6.6 kPa (50 mm Hg). Dyspnea is not always experienced with simple hypoxia but occurs when the respiratory minute volume approaches half the maximal breathing capacity; this may occur with minimum exertion in patients in whom maximal breathing capacity is reduced by lung disease. In general, little warning precedes the loss of consciousness resulting from hypoxia.

Cardiovascular System. Hypoxia causes reflex activation of the sympathetic nervous system by both autonomic and humoral mechanisms, resulting in tachycardia and increased cardiac output. Peripheral vascular resistance, however, decreases primarily through local autoregulatory mechanisms, with the net result that blood pressure generally is maintained unless hypoxia is prolonged or severe. In contrast to the systemic circulation, hypoxia causes pulmonary vasoconstriction and hypertension, an extension of the normal regional vascular response that matches perfusion with ventilation to optimize gas exchange in the lung (hypoxic pulmonary vasoconstriction).

CNS. The CNS is least able to tolerate hypoxia. Hypoxia is manifest initially by decreased intellectual capacity and impaired judgment and psychomotor ability. This state progresses to confusion and restlessness and ultimately to stupor, coma, and death as the arterial P_{O_2} decreases below 4–5.3 kPa (30–40 mm Hg). Victims often are unaware of this progression.

TABLE 21-4 ■ THE CARRIAGE OF OXYGEN IN BLOOD^a

ARTERIAL P_{O_2} kPa (mm Hg)	ARTERIAL O_2 CONTENT (mL O_2 /L)			MIXED VENOUS P_{O_2} kPa (mm Hg)	MIXED VENOUS O_2 CONTENT (mL O_2 /L)			EXAMPLES
	DISSOLVED	BOUND TO Hb	TOTAL		DISSOLVED	BOUND TO Hb	TOTAL	
4.0 (30)	0.9	109	109.9	2.7 (20)	0.6	59	59.6	High altitude; respiratory failure breathing air
12.0 (90)	2.7	192	194.7	5.5 (41)	1.2	144	145.2	Normal person breathing air
39.9 (300)	9.0	195	204	5.9 (44)	1.3	153	154.3	Normal person breathing 50% O_2
79.7 (600)	18	196	214	6.5 (49)	1.5	163	164.5	Normal person breathing 100% O_2
239 (1800)	54	196	250	20.0 (150)	4.5	196	200.5	Normal person breathing hyperbaric O_2

^aThis table illustrates the carriage of oxygen in the blood under a variety of circumstances. As arterial O_2 tension increases, the amount of dissolved O_2 increases in direct proportion to the P_{O_2} , but the amount of oxygen bound to Hb reaches a maximum of 196 mL O_2 /L (100% saturation of Hb at 15 g/dL). Further increases in O_2 content require increases in dissolved oxygen. At 100% inspired O_2 , dissolved O_2 still provides only a small fraction of total demand. Hyperbaric oxygen therapy is required to increase the amount of dissolved oxygen to supply all or a large part of metabolic requirements. Note that, during hyperbaric oxygen therapy, the hemoglobin in the mixed venous blood remains fully saturated with O_2 . The figures in this table are approximate and are based on the assumptions of 15 g/dL Hb, 50 mL O_2 /L whole-body oxygen extraction, and constant cardiac output. When severe anemia is present, arterial P_{O_2} remains the same, but arterial content is lower; oxygen extraction continues, resulting in lower O_2 content and tension in mixed venous blood. Similarly, as cardiac output falls significantly, the same oxygen extraction occurs from a smaller volume of blood and results in lower mixed venous oxygen content and tension.

Adaptation to Hypoxia

Long-term hypoxia results in adaptive physiological changes; these have been studied most thoroughly in persons exposed to high altitude. Adaptations include increased numbers of pulmonary alveoli, increased concentrations of hemoglobin in blood and myoglobin in muscle, and a decreased ventilatory response to hypoxia. Short-term exposure to high altitude produces similar adaptive changes. In susceptible individuals, however, acute exposure to high altitude may produce *acute mountain sickness*, a syndrome characterized by headache, nausea, dyspnea, sleep disturbances, and impaired judgment progressing to pulmonary and cerebral edema. Mountain sickness is treated with rest and analgesics when mild or supplemental O_2 , descent to lower altitude, or an increase in ambient pressure when more severe. Acetazolamide (a carbonic anhydrase inhibitor) and dexamethasone also may be helpful. The syndrome usually can be avoided by a slow ascent to altitude, adequate hydration, and prophylactic use of acetazolamide or dexamethasone.

Examples of “normal” hypoxia are widespread, and the comparative physiology of hypoxic tolerance offers clues to the mechanisms involved. Aspects of fetal and newborn physiology are strongly reminiscent of adaptation mechanisms found in hypoxia-tolerant animals (Guimarães-Camboa et al., 2015; Mortola, 1999), including shifts in the oxyhemoglobin dissociation curve (fetal hemoglobin), reductions in metabolic rate and body temperature (hibernation-like mode), reductions in heart rate and circulatory redistribution (as in diving mammals), and redirection of energy utilization from growth to maintenance metabolism. These adaptations probably account for the relative tolerance of the fetus and neonate to both chronic (uterine insufficiency) and short-term hypoxia.

Oxygen Inhalation

Physiological Effects. O_2 inhalation is used primarily to reverse or prevent the development of hypoxia. However, when O_2 is breathed in excessive amounts or for prolonged periods, secondary physiological changes and toxic effects can occur.

Respiratory System. Inhalation of O_2 at 1 atm or above causes a small degree of respiratory depression in normal subjects, presumably as a result of loss of tonic chemoreceptor activity. However, ventilation typically increases within a few minutes of O_2 inhalation because of a paradoxical increase in the tension of CO_2 in tissues. This increase results from the increased concentration of oxyhemoglobin in venous blood, which causes less-efficient removal of carbon dioxide from the tissues. Expansion of poorly ventilated alveoli is maintained in part by the nitrogen content of alveolar gas; nitrogen is poorly soluble and thus remains in the air spaces while O_2 is absorbed. High O_2 concentrations delivered to poorly ventilated lung regions dilute the nitrogen content and can promote absorption atelectasis (partial or complete collapse of the lung), occasionally resulting in an increase in shunt and a paradoxical worsening of hypoxemia after a period of O_2 administration.

Cardiovascular System. Heart rate and cardiac output are slightly reduced when 100% O_2 is breathed; blood pressure changes little. Elevated pulmonary artery pressures in patients living at high altitude who have chronic hypoxic pulmonary hypertension may reverse with O_2 therapy or return to sea level. In neonates with congenital heart disease and left-to-right shunting of cardiac output, O_2 supplementation must be regulated carefully because of the risk of further reducing pulmonary vascular resistance and increasing pulmonary blood flow.

Metabolism. Inhalation of 100% O_2 does not produce detectable changes in O_2 consumption, CO_2 production, respiratory quotient, or glucose utilization.

Oxygen Administration

Oxygen is supplied as a compressed gas in steel cylinders; purity of 99% is *medical grade*. For safety, O_2 cylinders and piping are color coded (green in the U.S.), and some form of mechanical indexing of valve connections is used to prevent the connection of other gases to O_2 systems.

Oxygen is delivered by inhalation except during extracorporeal circulation, when it is dissolved directly into the circulating blood. A closed delivery system with an endotracheal tube produces an airtight seal to the

patient's airway, and complete separation of inspired from expired gases can precisely control FiO_2 . In all other systems, such as nasal cannulas and face masks, the actual delivered FiO_2 will depend on the ventilatory pattern (i.e., rate, tidal volume, inspiratory-expiratory time ratio, and inspiratory flow) and delivery system characteristics.

Monitoring of Oxygenation. Monitoring and titration are required to meet the therapeutic goal of O_2 therapy and to avoid complications and side effects. Although cyanosis is a physical finding of substantial clinical importance, it is not an early, sensitive, or reliable index of oxygenation. Noninvasive monitoring of arterial O_2 saturation can be achieved using transcutaneous pulse oximetry, in which O_2 saturation is measured from the differential absorption of light by oxyhemoglobin and deoxyhemoglobin and the arterial saturation determined from the pulsatile component of this signal. Pulse oximetry measures hemoglobin saturation and not PO_2 . It is not sensitive to increases in PO_2 that exceed levels required to saturate the blood fully. Pulse oximetry is useful for monitoring the adequacy of oxygenation during procedures requiring sedation or anesthesia, rapid evaluation and monitoring of potentially compromised patients, and titrating O_2 therapy in situations where toxicity from O_2 or side effects of excess O_2 are of concern. A specific tool for measuring cerebral oxygenation is near-infrared spectroscopy (Guarracino, 2008).

Complications of Oxygen Therapy. In addition to the potential to promote absorption atelectasis and depress ventilation, high flows of dry O_2 can dry out and irritate mucosal surfaces of the airway and the eyes, as well as decrease mucociliary transport and clearance of secretions. Humidified O_2 thus should be used when prolonged therapy (>1 h) is required. Finally, any O_2 -enriched atmosphere constitutes a fire hazard, and appropriate precautions must be taken. Hypoxemia can occur despite the administration of supplemental O_2 . Therefore, it is essential that both O_2 saturation and adequacy of ventilation be assessed frequently.

Therapeutic Uses of Oxygen

Correction of Hypoxia. The primary therapeutic use of O_2 is to correct hypoxia. Hypoxia is most commonly a manifestation of an underlying disease, and administration of O_2 thus should be viewed as temporizing therapy. Efforts must be directed at correcting the cause of the hypoxia. Hypoxia resulting from most pulmonary diseases can be alleviated at least partially by administration of O_2 , allowing time for definitive therapy to reverse the primary process.

Reduction of Partial Pressure of an Inert Gas. Because nitrogen constitutes some 79% of ambient air, it also is the predominant gas in most gas-filled spaces in the body. In situations such as bowel distension from obstruction or ileus, intravascular air embolism, or pneumothorax, it is desirable to reduce the volume of air-filled spaces. Because nitrogen is relatively insoluble, inhalation of high concentrations of O_2 (and thus low concentrations of nitrogen) rapidly lowers the total-body partial pressure of nitrogen and provides a substantial gradient for the removal of nitrogen from gas spaces. Administration of O_2 for air embolism is also beneficial because it helps to relieve localized hypoxia distal to the vascular obstruction. In the case of *decompression sickness*, or *bends*, lowering the inert gas tension in blood and tissues by O_2 inhalation prior to or during barometric decompression reduces the supersaturation that occurs after decompression so that bubbles do not form.

Hyperbaric Oxygen Therapy. O_2 can be administered at greater than atmospheric pressure in hyperbaric chambers (Thom, 2009). Clinical uses of hyperbaric O_2 therapy include the treatment of trauma, burns, radiation damage, infections, nonhealing ulcers, skin grafts, spasticity, and other neurological conditions. Hyperbaric O_2 may be useful in generalized hypoxia. In carbon monoxide poisoning, hemoglobin and myoglobin become unavailable for O_2 binding because of the high affinity of these proteins for carbon monoxide. High PO_2 facilitates competition of O_2 for hemoglobin binding sites as carbon monoxide is exchanged in the alveoli. In addition, hyperbaric O_2 increases the availability of dissolved O_2 in the blood (see Table 21-4). Adverse effects of hyperbaric O_2 therapy include middle ear barotrauma, CNS toxicity, seizures, lung toxicity, and aspiration pneumonia.

Hyperbaric O₂ therapy has two components: increased hydrostatic pressure and increased O₂ pressure. Both factors are necessary for the treatment of decompression sickness and air embolism. The hydrostatic pressure reduces bubble volume, and the absence of inspired nitrogen increases the gradient for elimination of nitrogen and reduces hypoxia in downstream tissues. Increased O₂ pressure at the tissue is the primary therapeutic goal for other indications for hyperbaric O₂. A small increase in Po₂ in ischemic areas enhances the bactericidal activity of leukocytes and increases angiogenesis. Repetitive brief exposures to hyperbaric O₂ may enhance therapy for chronic refractory osteomyelitis, osteoradionecrosis, crush injury, or the recovery of compromised skin and tissue grafts. Increased O₂ tension can be bacteriostatic and useful in the treatment of the spread of infection with *Clostridium perfringens* and clostridial myonecrosis (gas gangrene).

Oxygen Toxicity

Oxygen can have deleterious actions at the cellular level. O₂ toxicity may result from increased production of hydrogen peroxide and reactive intermediates such as superoxide anion, singlet oxygen, and hydroxyl radicals that attack and damage lipids, proteins, and other macromolecules, especially those in biological membranes. A number of factors limit the toxicity of oxygen-derived reactive agents, including enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, which scavenge toxic oxygen by-products, and reducing agents such as iron, glutathione, and ascorbate. These factors, however, are insufficient to limit the destructive actions of oxygen when patients are exposed to high concentrations over an extended time period. Tissues show differential sensitivity to oxygen toxicity, which is likely the result of differences in both their production of reactive compounds and their protective mechanisms.

Respiratory Tract. The pulmonary system is usually the first to exhibit toxicity, a function of its continuous exposure to the highest O₂ tensions in the body. Subtle changes in pulmonary function can occur within 8–12 h of exposure to 100% O₂. Increases in capillary permeability, which will increase the alveolar/arterial O₂ gradient and ultimately lead to further hypoxemia, and decreased pulmonary function can be seen after only 18 h of exposure. Serious injury and death, however, require much longer exposures. Pulmonary damage is directly related to the inspired O₂ tension, and concentrations of less than 0.5 atm appear to be safe over long time periods. The capillary endothelium is the most sensitive tissue of the lung. Endothelial injury results in loss of surface area from interstitial edema and leaks into the alveoli.

Nervous System. Retinopathy of prematurity is an eye disease in premature infants involving abnormal vascularization of the developing retina that can result from O₂ toxicity or relative hypoxia. CNS problems are rare, and toxicity occurs only under hyperbaric conditions where exposure exceeds 200 kPa (2 atm). Symptoms include seizures and visual changes, which resolve when O₂ tension is returned to normal. In premature neonates and those who have sustained in utero asphyxia, hyperoxia and hypocapnia are associated with worse neurologic outcomes.

Carbon Dioxide

Carbon dioxide is produced by metabolism at approximately the same rate as O₂ is consumed. At rest, this value is about 3 mL/kg/min, but it may increase dramatically with exercise. CO₂ diffuses readily from the cells into the blood, where it is carried partly as bicarbonate ion (HCO₃⁻), partly in chemical combination with hemoglobin and plasma proteins, and partly in solution at a partial pressure of about 6 kPa (46 mm Hg) in mixed venous blood. CO₂ is transported to the lung, where it is normally exhaled at the rate it is produced, leaving a partial pressure of about 5.2 kPa (40 mm Hg) in the alveoli and in arterial blood. An increase in PCO₂ results in respiratory acidosis and may be due to decreased ventilation or the inhalation of CO₂, whereas an increase in ventilation results in decreased PCO₂ and respiratory alkalosis. Because CO₂ is freely diffusible, the changes in blood PCO₂ and pH soon are reflected by intracellular changes in PCO₂ and pH and by widespread effects in the body, especially on respiration, circulation, and the CNS.

Respiration

Carbon dioxide is a rapid, potent stimulus to ventilation in direct proportion to the inspired CO₂. CO₂ stimulates breathing by acidifying central chemoreceptors and the peripheral carotid bodies. Elevated PCO₂ causes bronchodilation, whereas hypocarbia causes constriction of airway smooth muscle; these responses may play a role in matching pulmonary ventilation and perfusion.

Circulation

The circulatory effects of CO₂ result from the combination of its direct local effects and its centrally mediated effects on the autonomic nervous system. The direct effect of CO₂ on the heart, diminished contractility, results from pH changes and a decreased myofilament Ca²⁺ responsiveness. The direct effect on systemic blood vessels results in vasodilation. CO₂ causes widespread activation of the sympathetic nervous system. The results of sympathetic nervous system activation generally are opposite to the local effects of carbon dioxide. The sympathetic effects consist of increases in cardiac contractility, heart rate, and vasoconstriction (see Chapter 12). The balance of opposing local and sympathetic effects, therefore, determines the total circulatory response to CO₂. The net effect of CO₂ inhalation is an increase in cardiac output, heart rate, and blood pressure. In blood vessels, however, the direct vasodilating actions of CO₂ appear more important, and total peripheral resistance decreases when the PCO₂ is increased. CO₂ also is a potent coronary vasodilator. Cardiac arrhythmias associated with increased PCO₂ are due to the release of catecholamines.

Hypocarbia results in opposite effects: decreased blood pressure and vasoconstriction in skin, intestine, brain, kidney, and heart. These actions are exploited clinically in the use of hyperventilation to diminish intracranial hypertension.

CNS

Hypercarbia depresses the excitability of the cerebral cortex and increases the cutaneous pain threshold through a central action. This central depression has therapeutic importance. For example, in patients who are hypoventilating from narcotics or anesthetics, increasing PCO₂ may result in further CNS depression, which in turn may worsen the respiratory depression. This positive-feedback cycle can have lethal consequences.

Methods of Administration

Carbon dioxide is marketed in gray metal cylinders as the pure gas or as CO₂ mixed with O₂. It usually is administered at a concentration of 5%–10% in combination with O₂ by means of a face mask. Another method for the temporary administration of CO₂ is by rebreathing, such as from an anesthesia breathing circuit or from something as simple as a paper bag.

Therapeutic Uses

Carbon dioxide is used for insufflation during endoscopic procedures (e.g., laparoscopic surgery) because it is highly soluble and does not support combustion. CO₂ can be used to flood the surgical field during cardiac surgery. Because of its density, CO₂ displaces the air surrounding the open heart so that any gas bubbles trapped in the heart are CO₂ rather than insoluble N₂. It is used to adjust pH during cardiopulmonary bypass procedures when a patient is cooled.

Hypocarbia still has some uses in anesthesia; it constricts cerebral vessels, decreasing brain size slightly, and thus may facilitate the performance of neurosurgical operations. While short-term hypocarbia is effective for this purpose, sustained hypocarbia has been associated with worse outcomes in patients with head injury. Hypocarbia should be instituted with a clearly defined indication and normocarbia should be reestablished as soon the indication for hypocarbia no longer applies.

Nitric Oxide

Nitric oxide is a free-radical gas now known as a critical endogenous cell-signaling molecule with an increasing number of potential therapeutic applications.

Endogenous NO is produced from L-arginine by NO synthases (neural, inducible, and endothelial) (see Chapter 3). In the vasculature, basal production of NO by endothelial cells is a primary determinant of resting vascular tone. NO causes vasodilation of smooth muscle cells and inhibition of platelet aggregation and adhesion. Impaired NO production is implicated in atherosclerosis, hypertension, cerebral and coronary vasospasm, ischemia-reperfusion injury, and inflammation and in mediating central nociceptive pathways. NO is rapidly inactivated in the circulation by oxyhemoglobin and by the reaction of NO with the heme iron, leading to the formation of nitrosyl-hemoglobin. Small quantities of methemoglobin are also produced, and these are converted to the ferrous form of heme iron by cytochrome b5 reductase. The majority of inhaled NO is excreted in the urine in the form of nitrate.

Therapeutic Uses

Inhaled NO selectively dilates the pulmonary vasculature (Cooper, 1999) and has potential as a therapy for numerous diseases associated with increased pulmonary vascular resistance. Inhaled NO is FDA-approved for only one indication, persistent pulmonary hypertension of the newborn.

Diagnostic Uses

Inhaled NO can be used during cardiac catheterization to evaluate the pulmonary vasodilating capacity of patients with heart failure and infants with congenital heart disease. Inhaled NO also is used to determine the diffusion capacity (D_L) across the alveolar-capillary unit. NO is more effective than CO₂ in this regard because of its greater affinity for hemoglobin and its higher water solubility at body temperature. NO is produced from the nasal passages and from the lungs of normal human subjects and can be detected in exhaled gas. The measurement of fractional exhaled NO is a noninvasive marker for airway inflammation with utility in the assessment of respiratory tract diseases, including asthma, respiratory tract infection, and chronic lung disease.

Toxicity

Administered at low concentrations (0.1–50 ppm), inhaled NO appears to be safe and without significant side effects. Pulmonary toxicity can occur with levels higher than 50–100 ppm. NO is an atmospheric pollutant; the Occupational Safety and Health Administration places the 7-hour exposure limit at 50 ppm. Part of the toxicity of NO may be related to its further oxidation to NO₂ in the presence of high concentrations of O₂.

The development of methemoglobinemia is a significant complication of inhaled NO at higher concentrations, and rare deaths have been reported with overdoses of NO. Methemoglobin concentrations should be monitored intermittently during NO inhalation. Inhaled NO can inhibit platelet function and has been shown to increase bleeding time in some clinical studies, although bleeding complications have not been reported. In patients with impaired function of the left ventricle, NO has a potential to further impair left ventricular performance by dilating the pulmonary circulation and increasing the blood flow to the left ventricle, thereby increasing left atrial pressure and promoting pulmonary edema formation.

The most important requirements for safe NO inhalation therapy include the following:

- Continuous measurement of NO and NO₂ concentrations using either chemiluminescence or electrochemical analyzers
- Frequent calibration of monitoring equipment
- Intermittent analysis of blood methemoglobin levels

- The use of certified tanks of NO
- Administration of the lowest NO concentration required for therapeutic effect

Methods of Administration

Courses of treatment of patients with inhaled NO are highly varied, extending from 0.1 to 40 ppm in dose and for periods of a few hours to several weeks in duration. The determination of a dose-response relationship on a frequent basis should assist in the titration of the optimum dose of NO. Commercial NO systems are available that will accurately deliver inspired NO concentrations between 0.1 and 80 ppm and simultaneously measure NO and NO₂ concentrations.

Helium

Helium is an inert gas whose low density, low solubility, and high thermal conductivity provide the basis for its medical and diagnostic uses. Helium can be mixed with O₂ and administered by mask or endotracheal tube. Under hyperbaric conditions, it can be substituted for the bulk of other gases, resulting in a mixture of much lower density that is easier to breathe.

The primary uses of helium are in pulmonary function testing, the treatment of respiratory obstruction, laser airway surgery, as a label in imaging studies, and for diving at depth. Helium is also suited for determinations of residual lung volume, functional residual capacity, and related lung volumes. These measurements require a highly diffusible nontoxic gas that is insoluble and does not leave the lung by the bloodstream so that, by dilution, the lung volume can be measured. Helium can be added to O₂ to reduce turbulence due to airway obstruction because the density of helium is less than that of air, and the viscosity of helium is greater than that of air. Mixtures of helium and O₂ reduce the work of breathing. Helium has high thermal conductivity, making it useful during laser surgery on the airway. Laser-polarized helium is used as an inhalational contrast agent for pulmonary magnetic resonance imaging. Helium also has potential as a cytoprotective agent (Smit et al., 2015).

Hydrogen Sulfide

Hydrogen sulfide, which has a characteristic rotten egg smell, is a colorless, flammable, water-soluble gas that is primarily considered as a toxin due to its capacity to inhibit mitochondrial respiration through blockade of cytochrome c oxidase. Inhibition of respiration can be toxic; however, if depression of respiration occurs in a controlled manner, it may allow nonhibernating species exposed to inhaled H₂S to enter a state akin to suspended animation (i.e., a slowing of cellular activity to a point at which metabolic processes are inhibited but not terminal) and thereby increase tolerance to stress. H₂S activates ATP-dependent K⁺ channels, has vasodilating properties, and serves as a free-radical scavenger. H₂S can protect against whole-body hypoxia, lethal hemorrhage, and ischemia-reperfusion injury in various organs, including the kidney, lung, liver, and heart. Currently, effort is under way for development of gas-releasing molecules that could deliver H₂S and other therapeutic gases to diseased tissue. H₂S in low quantities may have the potential to limit cell death (Lefer, 2007).

Drug Facts for Your Personal Formulary: *General Anesthetics and Therapeutic Gases*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Parenteral Anesthetics		
Propofol Etomidate Ketamine Thiopental	<ul style="list-style-type: none"> Anesthetic induction Rapid-onset and short-duration anesthetics used in procedures for rapid return to preoperative mental status 	<ul style="list-style-type: none"> Highly lipophilic \Rightarrow entry to brain and spinal cord, accumulation in fatty tissues Propofol dosage: \downarrow in elderly due to reduced clearance, \uparrow in young children due to rapid clearance PRIS: rare complication associated with prolonged and high-dose propofol infusion in young or head-injured patients Etomidate: preferred for patients at risk of hypotension or MI; produces hypnosis, no analgesic effects; \uparrow EEG activity, associated with seizures Ketamine: suited for patients at risk for hypotension and asthma and for pediatric procedures; increases HR, BP, CO, CBF, and ICP; emergence delirium, hallucinations, vivid dreams limit use
Barbiturates Methohexital Thiopental	<ul style="list-style-type: none"> Anesthetic induction 	<ul style="list-style-type: none"> Respiratory and EEG depressants Methohexital: more rapid clearance than other barbiturates Thiopental: action terminated by redistribution; good safety record; not available in the U.S. Intra-arterial injection of thiobarbiturates \Rightarrow severe inflammatory and potentially necrotic reaction
Inhalational Anesthetics		
Isoflurane	<ul style="list-style-type: none"> Maintenance of anesthesia Commonly used inhalational anesthetic 	<ul style="list-style-type: none"> Highly volatile at RT; not flammable in air or O_2 \downarrow Ventilation and RBF; \uparrow CBF Induces hypotension and \uparrow coronary blood flow, thus \downarrow myocardial O_2 consumption \downarrow Baroreceptor function Excreted unchanged by the lungs
Enflurane	<ul style="list-style-type: none"> Maintenance of anesthesia 	<ul style="list-style-type: none"> Volatile at RT; store in tightly sealed bottles Slow induction and recovery \downarrow Arterial BP due to vasodilation and \downarrow myocardial contractility Possible effects: \uparrow ICP, seizure activity
Sevoflurane	<ul style="list-style-type: none"> Preferred agent for anesthetic induction Used for outpatient anesthesia (not irritating airway; induction and recovery are rapid) 	<ul style="list-style-type: none"> Reacts exothermically with desiccated CO_2 absorbent Ideal induction agent (pleasant smell, rapid onset) \downarrow AP pressure and CO; potent bronchodilator Preferred for patients with myocardial ischemia Compound A, product of interaction of sevoflurane with the CO_2-absorbent soda lime, is nephrotoxic
Desflurane	<ul style="list-style-type: none"> Used for outpatient surgery (rapid onset, rapid recovery) 	<ul style="list-style-type: none"> Highly volatile at RT; store in tightly sealed bottles Nonflammable in mixtures of air or O_2 An airway irritant
Halothane	<ul style="list-style-type: none"> Maintenance of anesthesia 	<ul style="list-style-type: none"> Highly volatile at RT, light sensitive; store in tightly sealed amber bottles with thymol (preservative) Possible hepatic toxicity has limited its use and is no longer available in the U.S.
Nitrous oxide (N_2O)	<ul style="list-style-type: none"> Weak anesthetic agent used for its significant analgesic effects 	<ul style="list-style-type: none"> Colorless and odorless gas at RT; used as adjunct to other anesthetics. Will expand volume of air-containing cavities; thus, avoid use in obstructions of ear and bowel, and in intraocular and intracranial air bubbles, etc. To avoid diffusional hypoxia, administer 100% O_2 rather than air when discontinuing N_2O Can increase CBF and ICP Clinical use of N_2O is controversial due to potential metabolic effects related to increased homocysteine and changes in DNA and protein synthesis
Xenon	<ul style="list-style-type: none"> Analgesic and anesthetic effects 	<ul style="list-style-type: none"> Rapid induction and emergence from anesthesia In CNS: NMDA receptor antagonist, TREK channel agonist Well tolerated in older patients
Anesthetic Adjuncts • Augment anesthetic effects of general anesthesia		
Benzodiazepines Midazolam, diazepam, lorazepam	Used for anxiolysis, amnesia, preanesthetic sedation, and sedation during procedures not requiring general anesthesia	<ul style="list-style-type: none"> Midazolam most commonly used, followed distantly by diazepam and lorazepam (see Chapters 15 and 19)
α_2 Adrenergic agonists Dexmedetomidine	<ul style="list-style-type: none"> Short-term (<24 h) sedation of critically ill adults Sedation prior to and during surgical or medical procedures in nonintubated patients 	<ul style="list-style-type: none"> Activation of the α_{2A} adrenergic receptor by dexmedetomidine \Rightarrow sedation and analgesia Side effects: hypotension and bradycardia due to decreased catecholamine release in the CNS; nausea and dry mouth

Anesthetic Adjuncts • Augment anesthetic effects of general anesthesia (continued)		
Analgesics <i>Opioids</i> Fentanyl, Sufentanil, Alfentanil, Remifentanyl, Meperidine, Morphine	<ul style="list-style-type: none"> To reduce anesthetic requirement and minimize hemodynamic changes due to painful stimuli 	<ul style="list-style-type: none"> Opioids are the primary analgesics during perioperative period; the choice of opioid is based on duration of action (see Chapter 20) Opioids often are administered intrathecally and epidurally for management of acute and chronic pain
<i>NSAIDs</i> Acetaminophen		<ul style="list-style-type: none"> NSAIDs and acetaminophen are used for minor surgical procedures to control postoperative pain
Neuromuscular Blocking Agents Succinylcholine (Depolarizing) Atracurium, Vecuronium, et al. (Nondepolarizing, Competitive)	<ul style="list-style-type: none"> Skeletal muscle relaxant 	<ul style="list-style-type: none"> Action of nondepolarizing muscle relaxants usually is antagonized, once muscle paralysis is no longer desired, with an AChE inhibitor (e.g., neostigmine or edrophonium; see Chapter 10), in combination with a muscarinic receptor antagonist
THERAPEUTIC GASES

Chapter 22

Local Anesthetics

William A. Catterall and Kenneth Mackie

HISTORY

CHEMISTRY AND STRUCTURE-ACTIVITY RELATIONSHIP

MECHANISM OF ACTION

- Cellular Site of Action
- The Local Anesthetic Receptor Site on Na⁺ Channels
- Frequency and Voltage Dependence
- Differential Sensitivity of Nerve Fibers
- Effect of pH
- Prolongation of Action by Vasoconstrictors

UNDESIRE EFFECTS OF LOCAL ANESTHETICS

- CNS
- Cardiovascular System
- Smooth Muscle
- Neuromuscular Junction and Ganglia
- Hypersensitivity

METABOLISM

TOXICITY

LOCAL ANESTHETICS AND RELATED AGENTS

- Cocaine
- Lidocaine
- Bupivacaine
- Local Anesthetics Suitable for Injection
- Agents Used Primarily to Anesthetize Mucous Membranes and Skin
- Anesthetics With Low Aqueous Solubility
- Agents for Ophthalmic Use
- Biological Toxins: Tetrodotoxin and Saxitoxin

CLINICAL USES OF LOCAL ANESTHETICS

- Topical Anesthesia
- Infiltration Anesthesia
- Field Block Anesthesia
- Nerve Block Anesthesia
- Intravenous Regional Anesthesia (Bier Block)
- Spinal Anesthesia
- Epidural Anesthesia

Local anesthetics bind reversibly to a specific receptor site within the pore of the Na⁺ channels in nerves and block ion movement through this pore. When applied locally to nerve tissue in appropriate concentrations, local anesthetics can act on any part of the nervous system and on every type of nerve fiber, reversibly blocking the action potentials responsible for nerve conduction. Thus, a local anesthetic in contact with a nerve trunk can cause both sensory and motor paralysis in the area innervated. These effects of clinically relevant concentrations of local anesthetics are reversible with recovery of nerve function and no evidence of damage to nerve fibers or cells in most clinical applications.

History

The first local anesthetic, cocaine, was serendipitously discovered to have anesthetic properties in the late 19th century. Cocaine occurs in abundance in the leaves of the coca shrub (*Erythroxylon coca*). For centuries, Andean natives have chewed an alkali extract of these leaves for its stimulatory and euphoric actions. When, in 1860, Albert Niemann isolated cocaine, he tasted his newly isolated compound, noted that it numbed his tongue, and a new era began. Sigmund Freud studied cocaine's physiological actions, and Carl Koller introduced cocaine into clinical practice in 1884 as a topical anesthetic for ophthalmological surgery. Shortly thereafter, Halstead popularized its use in infiltration and conduction block anesthesia.

Chemistry and Structure-Activity Relationship

Cocaine is an ester of benzoic acid and the complex alcohol 2-carbomethoxy, 3-hydroxytropine (Figure 22-1). Because of its toxicity and addictive properties (Chapter 24), a search for synthetic substitutes

for cocaine began in 1892 with the work of Einhorn and colleagues, resulting in the synthesis of procaine, which became the prototype for local anesthetics for nearly half a century. The most widely used agents today are lidocaine, bupivacaine, and tetracaine.

Typical local anesthetics contain hydrophilic and hydrophobic moieties that are separated by an intermediate ester or amide linkage. A broad range of compounds containing these minimal structural features can satisfy the requirements for action as local anesthetics. The hydrophilic group usually is a tertiary amine but also may be a secondary amine; the hydrophobic moiety must be aromatic. The nature of the linking group determines some of the pharmacological properties of these agents. For example, plasma esterases readily hydrolyze local anesthetics with an ester link.

The structure-activity relationship and the physicochemical properties of local anesthetics have been well reviewed (Courtney and Strichartz, 1987). Hydrophobicity increases both the potency and the duration of action of the local anesthetics; association of the drug at hydrophobic sites enhances the partitioning of the drug to its sites of action and decreases the rate of metabolism by plasma esterases and hepatic enzymes. In addition, the receptor site for these drugs on Na⁺ channels is thought to be hydrophobic (see Mechanism of Action), so that receptor affinity for anesthetic agents is greater for the more hydrophobic drugs. Hydrophobicity also increases toxicity, so that the therapeutic index is decreased for more hydrophobic drugs.

Molecular size influences the rate of dissociation of local anesthetics from their receptor sites. Smaller drug molecules can escape from the receptor site more rapidly. This characteristic is important in rapidly firing cells, in which local anesthetics bind during action potentials and dissociate during the period of membrane repolarization. Rapid binding of local anesthetics during action potentials causes the frequency and voltage dependence of their action.

ACh: acetylcholine
CSF: cerebrospinal fluid
CYP: cytochrome P450
EDTA: ethylenediaminetetraacetic acid
GI: gastrointestinal
IFM: isoleucine-phenylalanine-methionine
LA: local anesthetic
NE: norepinephrine
NET: norepinephrine transporter
PKA: protein kinase A, cyclic AMP-dependent protein kinase
PKC: protein kinase C
TRP: transient receptor potential
TRPV channel: TRP vanilloid subtype channel
TTX: tetrodotoxin

Mechanism of Action

Cellular Site of Action

Local anesthetics act at the cell membrane to prevent the generation and the conduction of nerve impulses. Conduction block can be demonstrated in squid giant axons from which the axoplasm has been removed.

Local anesthetics block conduction by decreasing or preventing the large transient increase in the permeability of excitable membranes to Na^+ that normally is produced by a slight depolarization of the membrane (Chapters 8, 11, and 14; Strichartz and Ritchie, 1987). This action of local anesthetics is due to their direct interaction with voltage-gated Na^+ channels. As the anesthetic action progressively develops in a nerve, the threshold for electrical excitability gradually increases, the rate of rise of the action potential declines, impulse conduction slows, and the safety factor for conduction decreases. These factors decrease the probability of propagation of the action potential, and nerve conduction eventually fails.

Local anesthetics can bind to other membrane proteins (Butterworth and Strichartz, 1990). In particular, they can block K^+ channels (Strichartz and Ritchie, 1987). However, because the interaction of local anesthetics with K^+ channels requires higher concentrations of drug, blockade of

conduction is not accompanied by any large or consistent change in resting membrane potential.

Quaternary analogues of local anesthetics block conduction when applied internally to perfused giant axons of squid but are relatively ineffective when applied externally. These observations suggest that the site at which local anesthetics act, at least in their charged form, is accessible only from the inner surface of the membrane (Narahashi and Frazier, 1971; Strichartz and Ritchie, 1987). Therefore, local anesthetics applied externally first must cross the membrane before they can exert a blocking action.

The Local Anesthetic Receptor Site on Na^+ Channels

The major mechanism of action of these drugs involves their interaction with one or more specific binding sites within the Na^+ channel (Butterworth and Strichartz, 1990). The Na^+ channels of the mammalian brain are complexes of glycosylated proteins with an aggregate molecular size in excess of 300,000 Da; the individual subunits are designated α (260,000 Da) and β_1 to β_4 (33,000–38,000 Da). The large α subunit of the Na^+ channel contains four homologous domains (I–IV); each domain is thought to consist of six transmembrane segments in α -helical conformation (S1–S6; Figure 22–2) and an additional, membrane-reentrant pore (P) loop. The Na^+ -selective transmembrane pore of the channel resides in the center of a nearly symmetrical structure formed by the four homologous domains. The voltage dependence of channel opening is hypothesized to reflect conformational changes that result from the movement of “gating charges” within the voltage sensor module of the sodium channel in response to changes in the transmembrane potential. The gating charges are located in the S4 transmembrane helices, which are hydrophobic and positively charged, containing lysine or arginine residues at every third position. These residues are thought to move perpendicular to the plane of the membrane under the influence of the transmembrane potential, initiating a series of conformational changes in all four domains, which leads to the open state of the channel (Figure 22–2) (Catterall, 2000; Yu et al., 2005).

The transmembrane pore of the Na^+ channel is surrounded by the S5 and S6 transmembrane helices and the short membrane-associated segments between them that form the P loop. Amino acid residues in these short segments are the most critical determinants of the ion conductance and selectivity of the channel.

After it opens, the Na^+ channel inactivates within a few milliseconds due to closure of an inactivation gate. This functional gate is formed by the short intracellular loop of protein that connects homologous domains III

Figure 22–1 Structural formulas of selected local anesthetics. Most local anesthetics consist of a hydrophobic (aromatic) moiety (black), a linker region (orange), and a substituted amine (hydrophilic region, red). The structures at the top are grouped by the nature of the linker region. Procaine is a prototypic ester-type local anesthetic; esters generally are rapidly hydrolyzed by plasma esterases, contributing to the relatively short duration of action of drugs in this group. Lidocaine is a prototypic amide-type local anesthetic; these structures generally are more resistant to clearance and have longer durations of action. There are exceptions, including benzocaine (poorly water soluble; used only topically) and the structures with a ketone, an amidine, and an ether linkage. Chloroprocaine has a chlorine atom on C2 of the aromatic ring of procaine.

Figure 22-2 Structure and function of voltage-gated Na^+ channels. **A.** A two-dimensional representation of the α (center), β_1 (left), and β_2 (right) subunits of the voltage-gated Na^+ channel from mammalian brain. The polypeptide chains are represented by continuous lines with length approximately proportional to the actual length of each segment of the channel protein. Cylinders represent regions of transmembrane α helices. Ψ indicates sites of demonstrated N-linked glycosylation. Note the repeated structure of the four homologous domains (I–IV) of the α subunit. **Voltage Sensing.** The S4 transmembrane segments in each homologous domain of the α subunit serve as voltage sensors. (+) represents the positively charged amino acid residues at every third position within these segments. Electrical field (negative inside) exerts a force on these charged amino acid residues, pulling them toward the intracellular side of the membrane; depolarization allows them to move outward and initiate a conformational change that opens the pore. **Pore.** The S5 and S6 transmembrane segments and the short membrane-associated loop between them (P loop) form the walls of the pore in the center of an approximately symmetrical square array of the four homologous domains (see **B**). The amino acid residues indicated by circles in the P loop are critical for determining the conductance and ion selectivity of the Na^+ channel and its ability to bind the extracellular pore-blocking toxins TTX and saxitoxin. **Inactivation.** The short intracellular loop connecting homologous domains III and IV serves as the inactivation gate of the Na^+ channel. It is thought to fold into the intracellular mouth of the pore and occlude it within a few milliseconds after the channel opens. Three hydrophobic residues (IFM) at the position marked **h** appear to serve as an inactivation particle, entering the intracellular mouth of the pore and binding therein to an inactivation gate receptor there. **Modulation.** The gating of the Na^+ channel can be modulated by protein phosphorylation. Phosphorylation of the inactivation gate between homologous domains III and IV by PKC slows inactivation. Phosphorylation of sites in the intracellular loop between homologous domains I and II by either PKC or PKA reduces Na^+ channel activation. (Adapted with permission from Catterall WA. From ionic currents to molecular mechanisms: the structure and function of voltage-gated sodium channels. *Neuron*, 2000, 26:13–25. Copyright © Elsevier). **B.** The four homologous domains of the Na^+ channel α subunit are illustrated as a square array, as viewed looking down on the membrane. The sequence of conformational changes that the Na^+ channel undergoes during activation and inactivation is diagrammed. On depolarization, each of the four homologous domains sequentially undergoes a conformational change to an activated state. After all four domains have activated, the Na^+ channel can open. Within a few milliseconds after opening, the inactivation gate between domains III and IV closes over the intracellular mouth of the channel and occludes it, preventing further ion conductance (see Catterall, 2000).

and IV. This loop folds over the intracellular mouth of the transmembrane pore during the process of inactivation and binds to an inactivation gate “receptor” formed by the intracellular mouth of the pore.

Amino acid residues important for local anesthetic binding are found in the S6 segments in domains I, III, and IV (Ragsdale et al., 1994; Yarov-Yarovoy et al., 2002). Hydrophobic amino acid residues near the center and the intracellular end of the S6 segment may interact directly with

bound local anesthetics, locating the local anesthetic receptor site in the intracellular half of the transmembrane pore of the Na^+ channel, with part of its structure contributed by amino acids in the S6 segments of domains I, III, and IV (Figure 22-3). Ancestral Na^+ channels in bacteria comprise four identical subunits, each similar to one of the four domains of the mammalian Na^+ channel α subunit and containing a similar voltage sensor and pore-lining segment. The three-dimensional structure of an ancestral

Figure 22-3 A pharmacologist's view of the interaction of a local anesthetic with a voltage-gated Na^+ channel. A voltage-gated Na^+ channel may be thought of as an antechamber (*extracellular funnel*) that feeds into a constricted area (*selectivity filter*), which opens onto a larger volume (*central cavity*) that has an exit door (*gate*). Functionally, the channel can exist in a cycle of multiple states, initiated by the local effects of an action potential on the S4 transmembrane segments of the α subunits of segments I–IV, shown in Figure 22–2A. These states are *resting/closed*, *intermediate/closed*, *open*, *inactivated*. LAs bind in the center of the region depicted by the light blue balls. LAs exist in charged and uncharged forms at physiological pH, in accordance with the Henderson-Hasselbalch relationship (Figure 2–2). The uncharged species, LA, can diffuse across the membrane, possibly interacting with the channel protein en route. Within the cell, LA equilibrates with H^+ ; the charged form, LAH^+ , binds in the channel with greater affinity than does the uncharged species. The resting/closed conformation of the channel, in which the positive charges of the S4 segments are pulled toward the cell interior by the resting membrane potential, has a relatively low affinity for LA. The effect of an action potential is to initiate a conformational change in the selectivity funnel region of the channel, moving the positive charges outward and away from the pore interior. As a result, intermediate/closed, open, and inactivated states have a much higher affinity for LA. LAs prevent opening of the intermediate state, may block the channel in the open state, and extend the duration of the inactivated state. Ultimately, however, LA dissociates from its binding site (and the rate of LA's dissociation affects the extent of channel block), and the receptor returns to the resting state. Thus, stimulation of a nerve by an action potential enhances LA binding. With a low frequency of stimulation, LA has time to dissociate and the channels reliably return to their resting state (low affinity for LA). With a high frequency of stimulation, as in nociceptive sensory afferents after a wound, there is insufficient time for LA to fully dissociate; thus, the fraction of channels liganded by LA increases in the continued presence of LA, leading to greater and greater conduction blockade, as explained in the text. The marine neurotoxin TTX binds in the funnel with high affinity ($K_d = 10^{-10}$ nM), as does saxitoxin; both toxins block Na^+ channel activity.

Na^+ channel (Payandeh et al., 2011) revealed the arrangement of its transmembrane segments and the amino acid residues in the local anesthetic binding site in the pore.

Frequency and Voltage Dependence

The degree of block produced by a given concentration of local anesthetic depends on how the nerve has been stimulated and on its resting membrane potential. Thus, a resting nerve is much less sensitive to a local anesthetic than one that is repetitively stimulated; higher frequency of stimulation and more positive membrane potential cause a greater degree of anesthetic block. These frequency- and voltage-dependent effects of local anesthetics occur because the charged form of the local anesthetic molecule gains access to its binding site within the pore primarily when the Na^+ channel is

open and because the local anesthetic binds more tightly to and stabilizes the inactivated state of the Na^+ channel (Butterworth and Strichartz, 1990; Courtney and Strichartz, 1987; Hille, 1977). Remarkably, the conformation of the local anesthetic receptor site is changed considerably in the inactivated state (Payandeh et al., 2012; Figure 22–3D), revealing how preferential binding to inactivated Na^+ channels may occur.

Local anesthetics exhibit frequency and voltage dependence to different extents depending on their pK_a , lipid solubility, molecular size, and binding to different channel states. In general, the frequency dependence of local anesthetic action depends critically on the rate of dissociation from the receptor site in the pore of the Na^+ channel. A high frequency of stimulation is required for rapidly dissociating drugs so that drug binding during the action potential exceeds drug dissociation between

action potentials. Dissociation of smaller and more hydrophobic drugs is more rapid, so a higher frequency of stimulation is required to yield frequency-dependent block. Frequency-dependent block of ion channels is also important for the actions of antiarrhythmic drugs (Chapter 30).

Differential Sensitivity of Nerve Fibers

For most patients, treatment with local anesthetics causes the sensation of pain to disappear first, followed by loss of the sensations of temperature, touch, deep pressure, and finally motor function (Table 22-1). Classical experiments with intact nerves showed that the δ wave in the compound action potential, which represents slowly conducting, small-diameter myelinated fibers, was reduced more rapidly and at lower concentrations of cocaine than was the α wave, which represents rapidly conducting, large-diameter fibers (Gasser and Erlanger, 1929). In general, autonomic fibers, small unmyelinated C fibers (mediating pain sensations), and small myelinated A δ fibers (mediating pain and temperature sensations) are blocked before the larger myelinated A γ , A β , and A α fibers (mediating postural, touch, pressure, and motor information) (Raymond and Gissen, 1987). *The differential rate of block exhibited by fibers mediating different sensations is of considerable practical importance in the use of local anesthetics.*

The precise mechanisms responsible for this apparent specificity of local anesthetic action on pain fibers are not known, but several factors may contribute. The initial hypothesis was that sensitivity to local anesthetic block increases with decreasing fiber size, consistent with high sensitivity for pain sensation mediated by small fibers and low sensitivity for motor function mediated by large fibers (Gasser and Erlanger, 1929). However, when nerve fibers are dissected from nerves to allow direct measurement of action potential generation, no clear correlation of the concentration dependence of local anesthetic block with fiber diameter is observed (Fink and Cairns, 1984; Franz and Perry, 1974; Huang et al., 1997). Therefore, it is unlikely that the fiber size per se determines the sensitivity to local anesthetic block under steady-state conditions. However, the spacing of nodes of Ranvier increases with the size of nerve fibers. Because a fixed number of nodes must be blocked to prevent conduction, small fibers with closely spaced nodes of Ranvier may be blocked more rapidly during treatment of intact nerves because the local anesthetic reaches a critical length of nerve more rapidly. Differences in tissue barriers and location of smaller C fibers and A δ fibers in nerves also may influence the rate of local anesthetic action. Different combinations of Na⁺ channel subtypes

are also expressed in these nerve fibers, but all of these Na⁺ channels have similar affinity for block by local anesthetics.

Effect of pH

Local anesthetics tend to be only slightly soluble as unprotonated amines. Therefore, they generally are marketed as water-soluble salts, usually hydrochlorides. Because local anesthetics are weak bases (typical pK_a values range from 8 to 9), their hydrochloride salts are mildly acidic. This property increases the stability of the local anesthetic esters and the catecholamines added as vasoconstrictors. Under usual conditions of administration, the pH of the local anesthetic solution rapidly equilibrates to that of the extracellular fluids.

Although the unprotonated species of the local anesthetic is necessary for diffusion across cellular membranes, it is the cationic species that interacts preferentially with Na⁺ channels. The results of experiments on anesthetized mammalian nonmyelinated fibers support this conclusion (Ritchie and Greengard, 1966). In these experiments, conduction could be blocked or unblocked merely by adjusting the pH of the bathing medium to 7.2 or 9.6, respectively, without altering the amount of anesthetic present. The primary role of the cationic form also was demonstrated by Narahashi and Frazier, who perfused the extracellular and axoplasmic surface of the giant squid axon with tertiary and quaternary amine local anesthetics and found that the quaternary amines were active only when perfused intracellularly (Narahashi and Frazier, 1971). However, the unprotonated molecular forms also possess some anesthetic activity (Butterworth and Strichartz, 1990). Recent reports indicated that quaternary local anesthetics such as QX-314 can gain access to the cytoplasmic surface of the nerve cell membrane via TRPV1 channels (reviewed by Butterworth and Oxford, 2009). TRP channels, and possibly other ion channels, appear to lose selectivity and permit permeation of molecules like QX-314 in the face of prolonged or intense activation.

Prolongation of Action by Vasoconstrictors

The duration of action of a local anesthetic is proportional to the time of contact with nerve. Consequently, maneuvers that keep the drug at the nerve prolong the period of anesthesia. For example, cocaine inhibits the neuronal membrane transporters for catecholamines, thereby potentiating the effect of NE at α adrenergic receptors in the vasculature, resulting in vasoconstriction and reduced cocaine absorption in vascular beds where α adrenergic effects predominate (Chapters 8 and 12). In clinical practice,

TABLE 22-1 ■ SUSCEPTIBILITY OF NERVE TYPES TO LOCAL ANESTHETICS

CLASSIFICATION	ANATOMIC LOCATION	MYELIN	DIAMETER (μ m)	CONDUCTION VELOCITY (m/s)	FUNCTION	CLINICAL SENSITIVITY TO BLOCK
A fibers						
A α	Afferent to and efferent from muscles and joints	Yes	6–22	10–85	Motor and proprioception	+
A β						++
A γ	Efferent to muscle spindles	Yes	3–6	15–35	Muscle tone	++
A δ	Sensory roots and afferent peripheral nerves	Yes	1–4	5–25	Pain, temperature, touch	+++
B fibers	Preganglionic sympathetic	Yes	<3	3–15	Vasomotor, visceromotor, sudomotor, pilomotor	++++
C fibers						
Sympathetic	Postganglionic sympathetic	No	0.3–1.3	0.7–1.3	Vasomotor, visceromotor, sudomotor, pilomotor	++++
Dorsal root	Sensory roots and afferent peripheral nerves	No	0.4–1.2	0.1–2	Pain, temperature, touch	++++

a vasoconstrictor, usually epinephrine, is often added to local anesthetics. The vasoconstrictor performs a dual service. By decreasing the rate of absorption, it localizes the anesthetic at the desired site and allows the drug's elimination to keep pace with its entry into the systemic circulation, thereby reducing the drug's systemic toxicity. Note, however, that epinephrine dilates skeletal muscle vascular beds via actions at β_2 adrenergic receptors and therefore has the potential to increase systemic toxicity of anesthetic deposited in muscle tissue.

Some of the vasoconstrictor agents may be absorbed systemically, occasionally to an extent sufficient to cause untoward reactions (see the next section). There also may be delayed wound healing, tissue edema, or necrosis after local anesthesia. These effects seem to occur partly because sympathomimetic amines increase the O_2 consumption of the tissue; this, together with the vasoconstriction, leads to hypoxia and local tissue damage. Thus, the use of vasoconstrictors in local anesthetic preparations for anatomical regions with limited collateral circulation is avoided.

Undesired Effects of Local Anesthetics

In addition to blocking conduction in nerve axons in the peripheral nervous system, local anesthetics interfere with the function of all organs in which conduction or transmission of impulses occurs. Thus, these agents affect the CNS, autonomic ganglia, neuromuscular junctions, and all forms of muscle (for a review, see Covino, 1987; Garfield and Gugino, 1987; Gintant and Hoffman, 1987). The danger of such adverse reactions is proportional to the concentration of local anesthetic achieved in the circulation. In general, in local anesthetics with chiral centers, the *S*-enantiomer is less toxic than the *R*-enantiomer (McClure, 1996).

CNS

Following absorption, local anesthetics may cause CNS stimulation, producing restlessness and tremor that may progress to clonic convulsions. In general, the more potent the anesthetic, the more readily convulsions may be produced. Alterations of CNS activity are thus predictable from the local anesthetic agent in question and the blood concentration achieved. Central stimulation is followed by depression; death usually is caused by respiratory failure.

The apparent stimulation and subsequent depression produced by applying local anesthetics to the CNS presumably is due solely to depression of neuronal activity; a selective depression of inhibitory neurons likely accounts for the excitatory phase *in vivo*. Rapid systemic administration of local anesthetics may produce death with no or only transient signs of CNS stimulation. Under these conditions, the concentration of the drug probably rises so rapidly that all neurons are depressed simultaneously. Airway control, along with ventilatory and circulatory support, are essential features of treatment in the late stage of intoxication. Intravenously administered benzodiazepines are the drugs of choice for both the prevention and the arrest of convulsions. Neither propofol nor a rapidly acting barbiturate is preferred; both are more likely to produce cardiovascular depression than a benzodiazepine (Chapter 19).

Although drowsiness is the most frequent complaint that results from the CNS actions of local anesthetics, lidocaine may produce dysphoria or euphoria and muscle twitching. Moreover, lidocaine may produce a loss of consciousness that is preceded only by symptoms of sedation (Covino, 1987). Whereas other local anesthetics also show the effect, cocaine has a particularly prominent effect on mood and behavior. These effects of cocaine and its potential for abuse are discussed in Chapter 24.

Cardiovascular System

Following systemic absorption, local anesthetics act on the cardiovascular system. The primary site of action is the myocardium, where decreases in electrical excitability, conduction rate, and force of contraction occur. In addition, most local anesthetics cause arteriolar dilation. Untoward cardiovascular effects usually are seen only after high systemic concentrations are attained and CNS symptoms are evident. However, on rare occasions, lower doses of some local anesthetics will cause cardiovascular collapse

and death, probably due to either an action on the pacemaker or the sudden onset of ventricular fibrillation. Ventricular tachycardia and fibrillation are relatively uncommon consequences of local anesthetics other than bupivacaine. The antiarrhythmic effects of local anesthetics such as lidocaine and procainamide are discussed in Chapter 30. Finally, it should be stressed that untoward cardiovascular effects of local anesthetic agents may result from their inadvertent intravascular administration, especially if epinephrine is also present.

Smooth Muscle

Local anesthetics depress contractions in the intact bowel and in strips of isolated intestine (Zipf and Dittmann, 1971). They also relax vascular and bronchial smooth muscle, although low concentrations initially may produce contraction (Covino, 1987). Spinal and epidural anesthesia, as well as instillation of local anesthetics into the peritoneal cavity, cause sympathetic nervous system paralysis, which can result in increased tone of GI musculature (described under Clinical Uses). Local anesthetics may increase the resting tone and decrease the contractions of isolated human uterine muscle; however, uterine contractions are seldom depressed directly during intrapartum regional anesthesia.

Neuromuscular Junction and Ganglia

Local anesthetics also affect transmission at the neuromuscular junction. At concentrations at which the muscle responds normally to direct electrical stimulation, procaine can block the response of skeletal muscle to maximal motor-nerve volleys and to ACh. Similar effects occur at autonomic ganglia. These effects are due to block of nicotinic ACh receptors by high concentrations of the local anesthetic (Charnet et al., 1990; Neher and Steinbach, 1978).

Hypersensitivity

Rare individuals are hypersensitive to local anesthetics. The reaction may manifest itself as an allergic dermatitis or a typical asthmatic attack (Covino, 1987). It is important to distinguish allergic reactions from toxic side effects and from the effects of coadministered vasoconstrictors. Hypersensitivity seems to occur more frequently with local anesthetics of the ester type and frequently extends to chemically related compounds. For example, individuals sensitive to procaine also may react to structurally similar compounds (e.g., tetracaine) through reaction to a common metabolite. Although allergic responses to agents of the amide type are uncommon, solutions of such agents may contain preservatives such as methylparaben that may provoke an allergic reaction (Covino, 1987). Local anesthetic preparations containing a vasoconstrictor also may elicit allergic responses due to the sulfite added as an antioxidant for the catecholamine/vasoconstrictor.

Metabolism

Local anesthetics of the ester type (e.g., tetracaine) are hydrolyzed and inactivated primarily by a plasma esterase, probably plasma cholinesterase. The liver also participates in hydrolysis of local anesthetics. Because spinal fluid contains little or no esterase, anesthesia produced by the intrathecal injection of an anesthetic agent will persist until the local anesthetic agent has been absorbed into the circulation. The amide-linked local anesthetics are, in general, degraded by the hepatic CYPs, with the initial reactions involving *N*-dealkylation and subsequent hydrolysis (Arthur, 1987). However, with prilocaine, the initial step is hydrolytic, forming *o*-toluidine metabolites that can cause methemoglobinemia. The extensive use of amide-linked local anesthetics in patients with severe hepatic disease requires caution.

Toxicity

The metabolic fate of local anesthetics is of great practical importance because toxicity can result from an imbalance between their rates of absorption and elimination. The rate of absorption of many local anesthetics into

the systemic circulation can be considerably reduced by the incorporation of a vasoconstrictor agent in the anesthetic solution. However, the rate of degradation of local anesthetics varies greatly, and this is a major factor in determining the safety of a particular agent. Because toxicity is related to the concentration of free drug, binding of the anesthetic to proteins in the serum and to tissues reduces toxicity. For example, in intravenous regional anesthesia of an extremity, about half of the original anesthetic dose still is tissue bound 30 min after the restoration of normal blood flow (Arthur, 1987). Reversing the effects of local anesthetic systemic toxicity is a clinical challenge. One developing approach is promising and unusual: intravenous lipid emulsion therapy (Weinberg, 2012). Whether the lipids simply provide a favorable milieu of micelles into which lipophilic drugs can partition or the effect involves more complex biochemical pathways is not yet clear (Fettiplace et al., 2016).

Plasma binding sites serve to moderate local anesthetic levels on blood. The amide-linked local anesthetics bind extensively (55%–95%) to plasma proteins, particularly α_1 -acid glycoprotein. Many factors increase (e.g., cancer, surgery, trauma, myocardial infarction, smoking, and uremia) or decrease (e.g., oral contraceptives) the level of this glycoprotein, thereby changing the amount of anesthetic delivered to the liver for metabolism and thus influencing systemic toxicity. Age-related changes in protein binding of local anesthetics also occur. The neonate is relatively deficient in plasma proteins that bind local anesthetics and thereby is more susceptible to toxicity. Plasma proteins are not the sole determinant of local anesthetic availability. Uptake by the lung also may play an important role in the distribution of amide-linked local anesthetics. Finally, reduced cardiac output slows delivery of the amide compounds to the liver, reducing their metabolism and prolonging their plasma half-lives.

Local Anesthetics and Related Agents

Cocaine

Chemistry

Cocaine, an ester of benzoic acid and methylecgonine, occurs in abundance in the leaves of the coca shrub. Ecgonine is an amino alcohol base closely related to tropine, the amino alcohol in atropine. It has the same fundamental structure as the synthetic local anesthetics (Figure 20–1).

Pharmacological Actions and Preparations

The clinically desired actions of cocaine are the blockade of nerve impulses as a consequence of its local anesthetic properties and local vasoconstriction secondary to inhibition of the NET (see Table 8–5). Toxicity and its potential for abuse have steadily decreased the clinical uses of cocaine. Its high toxicity is due to reduced catecholamine uptake in both the central and peripheral nervous systems and the resulting prolongation of transmitter dwell time in the synaptic cleft. Cocaine's euphoric properties are due primarily to inhibition of catecholamine uptake, particularly DA, in the CNS. Other local anesthetics do not block the uptake of NE and do not produce the sensitization to catecholamines, vasoconstriction, or mydriasis characteristic of cocaine. Currently, cocaine is used primarily for topical anesthesia of the upper respiratory tract, where its combination of both vasoconstrictor and local anesthetic properties provide anesthesia and shrinking of the mucosa. Cocaine hydrochloride is provided as a 1%, 4%, or 10% solution for topical application. For most applications, the 1% or 4% preparation is preferred to reduce toxicity. Because of its abuse potential, cocaine is listed as a schedule II controlled substance by the U.S. Drug Enforcement Agency.

Lidocaine

Lidocaine, an aminoethylamide (Figure 20–1), is the prototypical amide local anesthetic.

Pharmacological Actions and Preparations

Lidocaine produces faster, more intense, longer-lasting, and more extensive anesthesia than does an equal concentration of procaine. Lidocaine is an alternative choice for individuals sensitive to ester-type local anesthetics.

A lidocaine transdermal patch is used for relief of pain associated with postherpetic neuralgia. The combination of lidocaine (2.5%) and prilocaine (2.5%) under an occlusive dressing (EMLA, others) is used as an anesthetic prior to venipuncture, skin graft harvesting, and infiltration of anesthetics into genitalia. Lidocaine in combination with tetracaine in a formulation that generates a “peel” is approved for topical local analgesia prior to superficial dermatological procedures such as filler injections and laser-based treatments. Lidocaine in combination with tetracaine is also supplied in a formulation that generates heat on exposure to air, which is used prior to venous access and superficial dermatological procedures such as excision, electrodesiccation, and shave biopsy of skin lesions. The mild warming is intended to increase skin temperature by up to 5°C for the purpose of enhancing delivery of local anesthetic into the skin.

ADME

Lidocaine is absorbed rapidly after parenteral administration and from the GI and respiratory tracts. Although it is effective when used without any vasoconstrictor, epinephrine decreases the rate of absorption, thereby decreasing the probability of toxicity and prolonging the duration of action. In addition to preparations for injection, lidocaine is formulated for topical, ophthalmic, mucosal, and transdermal use.

Lidocaine is dealkylated in the liver by CYPs to monoethylglycine xylidide and glycine xylidide, which can be metabolized further to monoethylglycine and xylidide. Both monoethylglycine xylidide and glycine xylidide retain local anesthetic activity. In humans, about 75% of the xylidide is excreted in the urine as the further metabolite 4-hydroxy-2,6-dimethylaniline (Arthur, 1987).

Toxicity

The side effects of lidocaine seen with increasing dose include drowsiness, tinnitus, dysgeusia, dizziness, and twitching. As the dose increases, seizures, coma, and respiratory depression and arrest will occur. Clinically significant cardiovascular depression usually occurs at serum lidocaine levels that produce marked CNS effects. The metabolites monoethylglycine xylidide and glycine xylidide may contribute to some of these side effects.

Clinical Uses

Lidocaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of intermediate duration is needed. Lidocaine also is used as an antiarrhythmic agent (Chapter 30).

Bupivacaine

Bupivacaine has a wide range of clinical uses as a local anesthetic; it has utility in almost any application where a local anesthetic of long duration is needed.

Pharmacological Actions and Preparations

Bupivacaine is a widely used amide local anesthetic; its structure is similar to that of lidocaine except that the amine-containing group is a butyl piperidine (Figure 20–1). Bupivacaine is a potent agent capable of producing prolonged anesthesia. Its long duration of action plus its tendency to provide more sensory than motor block has made it a popular drug for providing prolonged analgesia during labor or the postoperative period. By taking advantage of indwelling catheters and continuous infusions, bupivacaine can be used to provide several days of effective analgesia. Recently, a liposomal bupivacaine preparation has been FDA-approved. While safe and effective, its superiority over conventional bupivacaine and its ideal clinical applications remain to be determined (Uskova and O'Connor, 2015).

ADME

Bupivacaine is more slowly absorbed than lidocaine, so plasma levels increase more slowly following a bupivacaine nerve block or epidural. Conversely, bupivacaine levels fall more slowly following cessation of a continuous bupivacaine infusion than would be predicted from single-injection pharmacokinetics. Bupivacaine is primarily metabolized in the liver by CYP3A4 to pipercolylxylidide, which is then glucuronidated and excreted.

Bupivacaine is more cardiotoxic than equieffective doses of lidocaine. Clinically, this is manifested by severe ventricular arrhythmias and myocardial depression after inadvertent intravascular administration. Although lidocaine and bupivacaine both rapidly block cardiac Na^+ channels during systole, bupivacaine dissociates much more slowly than lidocaine during diastole, so a significant fraction of Na^+ channels at physiological heart rates remains blocked with bupivacaine at the end of diastole (Clarkson and Hondeghem, 1985). Thus, the block by bupivacaine is cumulative and substantially more than predicted by its local anesthetic potency. At least a portion of the cardiac toxicity of bupivacaine may be mediated centrally; direct injection of small quantities of bupivacaine into the medulla can produce malignant ventricular arrhythmias (Thomas et al., 1986). Bupivacaine-induced cardiac toxicity can be difficult to treat, and its severity is enhanced by coexisting acidosis, hypercarbia, and hypoxemia, emphasizing the importance of prompt airway control in resuscitation from bupivacaine overdose.

Local Anesthetics Suitable for Injection

The number of synthetic local anesthetics is so large that it is impractical to consider them all here. Some local anesthetic agents are too toxic to be given by injection. Their use is restricted to topical application to the eye (Chapter 69), the mucous membranes, or the skin (Chapter 70). Many local anesthetics are suitable, however, for infiltration or injection to produce nerve block; some of these also are useful for topical application. The discussion below presents the main categories of local anesthetics; agents are listed alphabetically.

Articaine

Articaine is approved in the U.S. for dental and periodontal procedures. Although it is an amide local anesthetic, it also contains an ester, whose hydrolysis terminates its action. Thus, articaine exhibits rapid onset (1–6 min) and duration of action of about 1 h.

Chloroprocaine

Chloroprocaine is a chlorinated derivative of procaine. Its major assets are its rapid onset and short duration of action and its reduced acute toxicity due to rapid metabolism (plasma $t_{1/2} \sim 25$ sec). Enthusiasm for its use has been tempered by reports of prolonged sensory and motor block after epidural or subarachnoid administration of large doses. This toxicity appears to have been a consequence of low pH and the use of sodium metabisulfite as a preservative in earlier formulations. There are no reports of neurotoxicity with newer preparations of chloroprocaine that contain calcium EDTA as the preservative, although these preparations are not recommended for intrathecal administration. A higher-than-expected incidence of muscular back pain following epidural anesthesia with 2-chloroprocaine has also been reported (Stevens et al., 1993). This back pain is thought to be due to tetany in the paraspinal muscles, which may be a consequence of Ca^{2+} binding by the EDTA included as a preservative; the incidence of back pain appears to be related to the volume of drug injected and its use for skin infiltration.

Mepivacaine

Mepivacaine is an intermediate-acting amino amide with pharmacological properties resembling those of lidocaine. Mepivacaine, however, is more toxic to the neonate and thus is not used in obstetrical anesthesia. The increased toxicity of mepivacaine in the neonate is related to ion trapping of this agent because of the lower pH of neonatal blood and the pK_a of mepivacaine, rather than to its slower metabolism in the neonate. Mepivacaine appears to have a slightly higher therapeutic index in adults than does lidocaine. Its onset of action is similar to, and its duration slightly longer (~20%) than, that of lidocaine in the absence of a coadministered vasoconstrictor. Mepivacaine is not effective as a topical anesthetic.

Prilocaine

Prilocaine is an intermediate-acting amino amide. It has a pharmacological profile similar to that of lidocaine. The primary differences are that it causes little vasodilation and thus can be used without a vasoconstrictor; its increased volume of distribution reduces its CNS toxicity, making it suitable for intravenous regional blocks (described further in the chapter).

The use of prilocaine is largely limited to dentistry because the drug is unique among the local anesthetics in its propensity to cause methemoglobinemia. This effect is a consequence of the metabolism of the aromatic ring to *o*-toluidine. Development of methemoglobinemia is dependent on the total dose administered, usually appearing after a dose of 8 mg/kg. If necessary, it can be treated by the intravenous administration of methylene blue (1–2 mg/kg).

Ropivacaine

The cardiac toxicity of bupivacaine stimulated interest in developing a less-toxic, long-lasting local anesthetic. One result of that search was the development of the amino ethylamide ropivacaine; the *S*-enantiomer was chosen because it has a lower toxicity than the *R*-isomer (McClure, 1996). Ropivacaine is slightly less potent than bupivacaine in producing anesthesia. Ropivacaine appears to be suitable for both epidural and regional anesthesia, with a duration of action similar to that of bupivacaine. Interestingly, it seems to be even more motor-sparing than bupivacaine.

Procaine

Procaine is no longer marketed in the U.S. as a single entity. It is an ingredient of some long-acting intramuscular formulations of penicillin.

Tetracaine

Tetracaine is a long-acting amino ester. It is significantly more potent and has a longer duration of action than procaine. Tetracaine may exhibit increased systemic toxicity because it is more slowly metabolized than the other commonly used ester local anesthetics. Currently, it is widely used in spinal anesthesia when a drug of long duration is needed. Tetracaine also is incorporated into several topical anesthetic preparations. With the introduction of bupivacaine, tetracaine is rarely used in peripheral nerve blocks because of the large doses often necessary, its slow onset, and its potential for toxicity.

Agents Used Primarily to Anesthetize Mucous Membranes and Skin

Some agents are useful as topical anesthetic agents on the skin or mucous membranes, although too irritating or too ineffective to be applied to the eye. These preparations are effective in the symptomatic relief of anal and genital pruritus, poison ivy rashes, and numerous other acute and chronic dermatoses. They sometimes are combined with a glucocorticoid or antihistamine and are available in a number of proprietary formulations.

Dibucaine

Dibucaine is a quinoline derivative. Its toxicity resulted in its removal from the U.S. market as an injectable preparation. It retains wide popularity outside the U.S. as a spinal anesthetic. It currently is available as an over-the-counter ointment for cutaneous use.

Dyclonine

Dyclonine hydrochloride is readily absorbed through the skin and mucous membranes. Its onset is rapid; its duration of action is short. Dyclonine is an active ingredient in a number of over-the-counter medications, including sore throat lozenges, a patch for cold sores, and a 0.75% solution.

Pramoxine

Pramoxine hydrochloride is a surface anesthetic agent that is not a benzoate ester. Its distinct chemical structure may help minimize the danger of cross-sensitivity reactions in patients allergic to other local anesthetics. Pramoxine produces satisfactory surface anesthesia and is reasonably well tolerated on the skin and mucous membranes. It is too irritating to be used on the eye or in the nose, but an otic solution containing chloroxylenol is marketed. Many preparations (currently 284 in the U.S.), including creams, lotions, sprays, gel, wipes, and foams, usually containing 1% pramoxine, are available for topical application.

Anesthetics With Low Aqueous Solubility

Some local anesthetics have low aqueous solubility and consequently are absorbed too slowly to cause classical local anesthetic toxicity. These compounds can be applied directly to wounds and ulcerated surfaces, where they remain localized for long periods of time, producing a sustained

anesthetic action. Chemically, they are esters of para-aminobenzoic acid lacking the terminal amino group possessed by the previously described local anesthetics. The most important member of the series is benzocaine (ethyl aminobenzoate), which is incorporated into a large number of topical preparations. Benzocaine can cause methemoglobinemia (see the discussion of methemoglobinemia in the section on prilocaine); consequently, dosing recommendations must be followed carefully.

Agents for Ophthalmic Use

Anesthesia of the cornea and conjunctiva can be obtained readily by topical application of local anesthetics. However, most of the local anesthetics that have been described are too irritating for ophthalmological use. The two compounds used most frequently today are proparacaine and tetracaine. In addition to being less irritating during administration, proparacaine has the advantage of bearing little antigenic similarity to the other benzoate local anesthetics. Thus, it sometimes can be used in individuals sensitive to the amino ester local anesthetics.

For use in ophthalmology, these local anesthetics are instilled a single drop at a time. If anesthesia is incomplete, successive drops are applied until satisfactory conditions are obtained. The duration of anesthesia is determined chiefly by the vascularity of the tissue; thus, it is longest in normal cornea and shortest in inflamed conjunctiva. In the latter case, repeated instillations may be necessary to maintain adequate anesthesia. Long-term administration of topical anesthesia to the eye has been associated with retarded healing, pitting, and sloughing of the corneal epithelium and predisposition of the eye to inadvertent injury. Thus, these drugs should not be prescribed for self-administration. For issues of drug delivery, pharmacokinetics, and toxicity unique to drugs for ophthalmic use, see Chapter 69.

Biological Toxins: Tetrodotoxin and Saxitoxin

The two biological toxins, tetrodotoxin and saxitoxin, block the pore of the Na^+ channel. Tetrodotoxin is found in the gonads and other visceral tissues of some fish of the order Tetraodontiformes (to which the Japanese *fugu*, or puffer fish, belongs); it also occurs in the skin of some newts of the family Salamandridae and of the Costa Rican frog *Atelopus*. Saxitoxin is elaborated by the dinoflagellates *Gonyaulax catenella* and *G. tamarensis* and retained in the tissues of clams and other shellfish that eat these organisms. Given the right conditions of temperature and light, the *Gonyaulax* may multiply so rapidly as to discolor the ocean, causing the condition known as *red tide*. Shellfish feeding on *Gonyaulax* at this time become extremely toxic to humans and are responsible for periodic outbreaks of paralytic shellfish poisoning (Sakai and Swanson, 2014; Stommel and Watters, 2004). Although these toxins are chemically distinct, they have similar mechanisms of action. Both toxins, in nanomolar concentrations, specifically block the outer mouth of the pore of Na^+ channels in the membranes of excitable cells. As a result, the action potential is blocked. The receptor site for these toxins is formed by amino acid residues in the P loop of the Na^+ channel α subunit (Figure 22-2) in all four domains (Catterall, 2000; Terlau et al., 1991). Not all Na^+ channels are equally sensitive to tetrodotoxin; some Na^+ channels in cardiac myocytes and dorsal root ganglion neurons are resistant, and a tetrodotoxin-resistant Na^+ channel is expressed when skeletal muscle is denervated. Tetrodotoxin and saxitoxin are exceedingly potent; the minimal lethal dose of each in the mouse is about 8 $\mu\text{g}/\text{kg}$. Both toxins have caused fatal poisoning in humans due to paralysis of the respiratory muscles; therefore, the treatment of severe cases of poisoning requires support of respiration. Blockade of vasomotor nerves, together with a relaxation of vascular smooth muscle, seems to be responsible for the hypotension that is characteristic of tetrodotoxin poisoning. Early gastric lavage and pressor support also are indicated. If the patient survives paralytic shellfish poisoning for 24 h, the prognosis is good.

Clinical Uses of Local Anesthetics

Local anesthesia is the loss of sensation in a body part without the loss of consciousness or the impairment of central control of vital functions. It offers two major advantages over general anesthesia. First, physiological

perturbations associated with general anesthesia are avoided. Second, neurophysiological responses to pain and stress can be modified beneficially. However, local anesthetics have the potential to produce deleterious side effects. Proper choice of a local anesthetic and care in its use are the primary determinants in avoiding these problems.

There is a poor relationship between the amount of local anesthetic injected and peak plasma levels in adults. Furthermore, peak plasma levels vary widely depending on the area of injection. They are highest with interpleural or intercostal blocks and lowest with subcutaneous infiltration. Thus, recommended maximum doses serve only as general guidelines. This discussion summarizes the pharmacological and physiological consequences of the use of local anesthetics categorized by method of administration. A more comprehensive discussion of their use and administration is presented in textbooks on regional anesthesia (Cousins et al., 2008).

Topical Anesthesia

Anesthesia of mucous membranes of the nose, mouth, throat, tracheobronchial tree, esophagus, and genitourinary tract can be produced by direct application of aqueous solutions of salts of many local anesthetics or by suspension of the poorly soluble local anesthetics. Tetracaine (2%), lidocaine (2%–10%), and cocaine (1%–4%) typically are used. Cocaine is used only in the nose, nasopharynx, mouth, throat, and ear, where it uniquely produces vasoconstriction as well as anesthesia. The shrinking of mucous membranes decreases operative bleeding while improving surgical visualization. Comparable vasoconstriction can be achieved with other local anesthetics by the addition of a low concentration of a vasoconstrictor such as phenylephrine (0.005%). Epinephrine, topically applied, has no significant local effect and does not prolong the duration of action of local anesthetics applied to mucous membranes because of poor penetration. *Maximal safe total dosages* for topical anesthesia in a healthy 70-kg adult are 300 mg for lidocaine, 150 mg for cocaine, and 50 mg for tetracaine.

Peak anesthetic effect following topical application of cocaine or lidocaine occurs within 2–5 min (3–8 min with tetracaine), and anesthesia lasts for 30–45 min (30–60 min with tetracaine). Anesthesia is entirely superficial; it does not extend to submucosal structures. This technique does not alleviate joint pain or discomfort from subdermal inflammation or injury.

Local anesthetics are absorbed rapidly into the circulation following topical application to mucous membranes or denuded skin. Thus, topical anesthesia always carries the risk of systemic toxic reactions. Systemic toxicity has occurred even following the use of local anesthetics to control discomfort associated with severe diaper rash in infants. Absorption is particularly rapid when local anesthetics are applied to the tracheobronchial tree. Concentrations in blood after instillation of local anesthetics into the airway are nearly the same as those following intravenous injection. Surface anesthetics for the skin and cornea have been described earlier in the chapter.

Eutectic mixtures of local anesthetics lidocaine (2.5%)/prilocaine (2.5%) (EMLA) and lidocaine (7%)/tetracaine (7%) (Pliagis) bridge the gap between topical and infiltration anesthesia. The efficacy of each of these combinations lies in the fact that the mixture has a melting point less than that of either compound alone, existing at room temperature as an oil that can penetrate intact skin. These creams produce anesthesia to a maximum depth of 5 mm and are applied as a cream on intact skin under an occlusive dressing in advance (~30–60 min) of any procedure. These mixtures are effective for procedures involving skin and superficial subcutaneous structures (e.g., venipuncture and skin graft harvesting). Beware: the component local anesthetics will be absorbed into the systemic circulation, potentially producing toxic effects. Guidelines are available to calculate the maximum amount of cream that can be applied and area of skin covered. These mixtures must not be used on mucous membranes or abraded skin, as rapid absorption across these surfaces may result in systemic toxicity.

Infiltration Anesthesia

Infiltration anesthesia is the injection of local anesthetic directly into tissue without taking into consideration the course of cutaneous nerves.

Infiltration anesthesia can be so superficial as to include only the skin. It also can include deeper structures, including intra-abdominal organs, when these too are infiltrated.

The duration of infiltration anesthesia can be approximately doubled by the addition of epinephrine (5 $\mu\text{g/mL}$) to the injection solution; epinephrine also decreases peak concentrations of local anesthetics in blood. *Epinephrine-containing solutions are generally not injected into tissues supplied by end arteries—for example, fingers and toes, ears, the nose, and the penis—because of a concern that the resulting vasoconstriction may cause gangrene.* Similarly, epinephrine should be avoided in solutions injected intracutaneously. Because epinephrine also is absorbed into the circulation, its use should be avoided in those for whom adrenergic stimulation is undesirable.

The local anesthetics most frequently used for infiltration anesthesia are lidocaine (0.5%–1%) and bupivacaine (0.125%–0.25%). When used without epinephrine, up to 4.5 mg/kg of lidocaine or 2 mg/kg of bupivacaine can be employed in adults. When epinephrine is added, these amounts can be increased by one-third. Tumescence anesthesia is a special case of infiltration anesthesia for which large doses and volumes of lidocaine and epinephrine are administered (Lozinski and Huq, 2013).

Infiltration anesthesia and other regional anesthetic techniques have the advantage of providing satisfactory anesthesia without disrupting normal bodily functions. The chief disadvantage of infiltration anesthesia is that relatively large amounts of drug must be used to anesthetize relatively small areas. This is no problem with minor surgery. When major surgery is performed, however, the amount of local anesthetic that is required makes systemic toxic reactions likely. The amount of anesthetic required to anesthetize an area can be reduced significantly and the duration of anesthesia increased markedly by specifically blocking the nerves that innervate the area of interest. This can be done at one of several levels: subcutaneously, at major nerves, or at the level of the spinal roots.

Field Block Anesthesia

Field block anesthesia is produced by subcutaneous injection of a solution of local anesthetic to anesthetize the region distal to the injection. For example, subcutaneous infiltration of the proximal portion of the volar surface of the forearm results in an extensive area of cutaneous anesthesia that starts 2–3 cm distal to the site of injection. The same principle can be applied with particular benefit to the scalp, the anterior abdominal wall, and the lower extremity.

The drugs, concentrations, and doses recommended are the same as for infiltration anesthesia. The advantage of field block anesthesia is that less drug can be used to provide a greater area of anesthesia than when infiltration anesthesia is used. Knowledge of the relevant neuroanatomy obviously is essential for successful field block anesthesia.

Nerve Block Anesthesia

Injection of a solution of a local anesthetic into or about individual peripheral nerves or nerve plexuses produces even greater areas of anesthesia than do the techniques already described. Blockade of mixed peripheral nerves and nerve plexuses also usually anesthetizes somatic motor nerves, producing skeletal muscle relaxation, which is essential for some surgical procedures. The areas of sensory and motor block usually start several centimeters distal to the site of injection. Brachial plexus blocks are particularly useful for procedures on the upper extremity and shoulder. Intercostal nerve blocks are effective for anesthesia and relaxation of the anterior abdominal wall. Cervical plexus block is appropriate for surgery of the neck. Sciatic and femoral nerve blocks are useful for surgery distal to the knee. Other useful nerve blocks prior to surgical procedures include blocks of individual nerves at the wrist and at the ankle, blocks of individual nerves such as the median or ulnar at the elbow, and blocks of sensory cranial nerves.

There are four major determinants of the onset of sensory anesthesia following injection near a nerve: (1) proximity of the injection to the nerve; (2) concentration and volume of drug; (3) degree of ionization of the drug; and (4) time.

Local anesthetic is never intentionally injected into the nerve; this would be painful and could cause nerve damage. Instead, the anesthetic agent is deposited as close to the nerve as possible. Thus, the local anesthetic must diffuse from the site of injection into the nerve on which it acts. The rate of diffusion is determined chiefly by the concentration of the drug, its degree of ionization (ionized local anesthetic diffuses more slowly), its hydrophobicity, and the physical characteristics of the tissue surrounding the nerve. Higher concentrations of local anesthetic will provide a more rapid onset of peripheral nerve block. The utility of higher concentrations, however, is limited by systemic toxicity and by direct neural toxicity of concentrated local anesthetic solutions. For a given concentration, local anesthetics with lower pK_a values tend to have a more rapid onset of action because more drug is uncharged at neutral pH. For example, the onset of action of lidocaine occurs in about 3 min; 35% of lidocaine is in the basic form at pH 7.4. In contrast, the onset of action of bupivacaine requires about 15 min; only 5%–10% of bupivacaine is uncharged at this pH. Increased hydrophobicity might be expected to speed onset by increased penetration into nerve tissue. However, it also will increase binding in tissue lipids. Furthermore, the more hydrophobic local anesthetics also are more potent (and toxic) and thus must be used at lower concentrations, decreasing the concentration gradient for diffusion. Tissue factors also play a role in determining the rate of onset of anesthetic effects. The amount of connective tissue that must be penetrated can be significant in a nerve plexus compared to isolated nerves and can slow or even prevent adequate diffusion of local anesthetic to the nerve fibers.

Duration of nerve block anesthesia depends on the physical characteristics of the local anesthetic used and the presence or absence of vasoconstrictors. Especially important physical characteristics are lipid solubility and protein binding. Local anesthetics can be broadly divided into three categories:

- those with a short (20- to 45-min) duration of action in mixed peripheral nerves, such as procaine;
- those with an intermediate (60- to 120-min) duration of action, such as lidocaine and mepivacaine; and
- those with a long (400- to 450-min) duration of action, such as bupivacaine, ropivacaine, and tetracaine.

Block duration of the intermediate-acting local anesthetics such as lidocaine can be prolonged by the addition of epinephrine (5 $\mu\text{g/mL}$). The degree of block prolongation in peripheral nerves following the addition of epinephrine appears to be related to the intrinsic vasodilating properties of the local anesthetic and thus is most pronounced with lidocaine.

The types of nerve fibers that are blocked when a local anesthetic is injected about a mixed peripheral nerve depend on the concentration of drug used, nerve fiber size, internodal distance, and frequency and pattern of nerve impulse transmission (see the previous sections on Frequency and Voltage Dependence and Differential Sensitivity of Nerve Fibers). Anatomical factors are similarly important. A mixed peripheral nerve or nerve trunk consists of individual nerves surrounded by an investing epineurium. The vascular supply usually is centrally located. When a local anesthetic is deposited about a peripheral nerve, it diffuses from the outer surface toward the core along a concentration gradient. Consequently, nerves in the outer mantle of the mixed nerve are blocked first. These fibers usually are distributed to more proximal anatomical structures than are those situated near the core of the mixed nerve and often are motor. If the volume and concentration of local anesthetic solution deposited about the nerve are adequate, the local anesthetic eventually will diffuse inward in amounts adequate to block even the most centrally located fibers. Lesser amounts of drug will block only nerves in the mantle and the smaller and more sensitive central fibers. Furthermore, because removal of local anesthetics occurs primarily in the core of a mixed nerve or nerve trunk, where the vascular supply is located, the duration of blockade of centrally located nerves is shorter than that of more peripherally situated fibers.

The choice of local anesthetic and the amount and concentration administered are determined by the nerves and the types of fibers to be blocked, the required duration of anesthesia, and the size and health of the patient. For blocks of 2–4 h, lidocaine (1%–1.5%) can be used in the

amounts recommended previously (see Infiltration Anesthesia). Mepivacaine (up to 7 mg/kg of a 1%–2% solution) provides anesthesia that lasts about as long as that from lidocaine. Bupivacaine (2–3 mg/kg of a 0.25%–0.375% solution) can be used when a longer duration of action is required. Addition of 5 µg/mL epinephrine slows systemic absorption and therefore prolongs duration and lowers the plasma concentration of the intermediate-acting local anesthetics.

Peak plasma concentrations of local anesthetics depend on the amount injected, the physical characteristics of the local anesthetic, whether epinephrine is used, the rate of blood flow to the site of injection, and the surface area exposed to local anesthetic. This is of particular importance in the safe application of nerve block anesthesia because the potential for systemic reactions is related to peak free serum concentrations. For example, peak concentrations of lidocaine in blood following injection of 400 mg without epinephrine for intercostal nerve blocks average 7 µg/mL; the same amount of lidocaine used for block of the brachial plexus results in peak concentrations in blood of about 3 µg/mL (Covino and Vassallo, 1976). Therefore, the amount of local anesthetic that can be injected must be adjusted according to the anatomical site of the nerve(s) to be blocked to minimize untoward effects. Addition of epinephrine can decrease peak plasma concentrations by 20%–30%. Multiple nerve blocks (e.g., intercostal block) or blocks performed in vascular regions require reduction in the amount of anesthetic that can be given safely because the surface area for absorption or the rate of absorption is increased.

Intravenous Regional Anesthesia (Bier Block)

The Bier block technique relies on using the vasculature to bring the local anesthetic solution to the nerve trunks and endings. In this technique, an extremity is exsanguinated with an Esmarch (elastic) bandage, and a proximally located tourniquet is inflated to 100–150 mm Hg above the systolic blood pressure. The Esmarch bandage is removed, and the local anesthetic is injected into a previously cannulated vein. Typically, complete anesthesia of the limb ensues within 5–10 min. Pain from the tourniquet and the potential for ischemic nerve injury limit tourniquet inflation to 2 h or less. However, the tourniquet should remain inflated for at least 15–30 min to prevent toxic amounts of local anesthetic from entering the circulation following deflation. Lidocaine, 40–50 mL (0.5 mL/kg in children) of a 0.5% solution without epinephrine, is the drug of choice for this technique. For intravenous regional anesthesia in adults using a 0.5% solution without epinephrine, the dose administered should not exceed 4 mg/kg. A few clinicians prefer prilocaine (0.5%) over lidocaine because of its higher therapeutic index.

The attractiveness of the Bier block lies in its simplicity. Its primary disadvantages are that it can be used only for a few anatomical regions, sensation (pain) returns quickly after tourniquet deflation, and premature release or failure of the tourniquet can produce toxic levels of local anesthetic (e.g., 50 mL of 0.5% lidocaine contains 250 mg of lidocaine). For the last reason and because its longer duration of action offers no advantage, the more cardiotoxic agent bupivacaine is not recommended for this technique. Intravenous regional anesthesia is used most often for surgery of the forearm and hand but can be adapted for the foot and distal leg.

Spinal Anesthesia

Spinal anesthesia follows the injection of local anesthetic into the CSF in the lumbar space. For a number of reasons, including the ability to produce anesthesia of a considerable fraction of the body with a dose of local anesthetic that produces negligible plasma levels, spinal anesthesia remains one of the most popular forms of anesthesia. In most adults, the spinal cord terminates above the second lumbar vertebra; between that point and the termination of the thecal sac in the sacrum, the lumbar and sacral roots are bathed in CSF. Thus, in this region there is a relatively large volume of CSF within which to inject drug, thereby minimizing the potential for direct nerve trauma.

The following is a brief discussion of the physiological effects of spinal anesthesia relating to the pharmacology of the local anesthetics. See more specialized texts (Cousins et al., 2008) for additional details.

Physiological Effects of Spinal Anesthesia

Most of the physiological side effects of spinal anesthesia are a consequence of the sympathetic blockade produced by local anesthetic block of the sympathetic fibers in the spinal nerve roots. A thorough understanding of these physiological effects is necessary for the safe and successful application of spinal anesthesia. Although some effects may be deleterious and require treatment, others can be beneficial for the patient or can improve operating conditions.

Most sympathetic fibers leave the spinal cord between T1 and L2 (see Figure 8–1). Although local anesthetic is injected below these levels in the lumbar portion of the dural sac, cephalad spread of the local anesthetic occurs with all but the smallest volumes injected. This cephalad spread is of considerable importance in the practice of spinal anesthesia and potentially is under the control of numerous variables, of which patient position and baricity (density of the drug relative to the density of the CSF) are the most important (Greene, 1983). The degree of sympathetic block is related to the height of sensory anesthesia; often, the level of sympathetic blockade is several spinal segments higher because the preganglionic sympathetic fibers are more sensitive to low concentrations of local anesthetic. The effects of sympathetic blockade involve both the actions (now partially unopposed) of the parasympathetic nervous system and the response of the unblocked portion of the sympathetic nervous system. Thus, as the level of sympathetic block ascends, the actions of the parasympathetic nervous system are increasingly dominant, and the compensatory mechanisms of the unblocked sympathetic nervous system are diminished. As most sympathetic nerve fibers leave the cord at T1 or below, few additional effects of sympathetic blockade are seen with cervical levels of spinal anesthesia. The consequences of sympathetic blockade will vary among patients as a function of age, physical conditioning, and disease state. Interestingly, sympathetic blockade during spinal anesthesia appears to be minimal in healthy children.

Clinically, the most important effects of sympathetic blockade during spinal anesthesia are on the cardiovascular system. At all but the lowest levels of spinal blockade, some vasodilation will occur. Vasodilation is more marked on the venous than on the arterial side of the circulation, resulting in blood pooling in the venous capacitance vessels. This reduction in circulating blood volume is well tolerated at low levels of spinal anesthesia in healthy patients. With an increasing level of block, this effect becomes more marked, and venous return becomes gravity dependent. If venous return decreases too much, cardiac output and organ perfusion decline precipitously. Venous return can be increased by a modest (10°–15°) head-down tilt or by elevating the legs.

At high levels of spinal blockade, the cardiac accelerator fibers, which exit the spinal cord at T1–T4, will be blocked. This is detrimental in patients dependent on elevated sympathetic tone to maintain cardiac output (e.g., during congestive heart failure or hypovolemia), and it also removes one of the compensatory mechanisms available to maintain organ perfusion during vasodilation. Thus, as the level of spinal block ascends, the rate of cardiovascular compromise can accelerate if not carefully observed and treated. Sudden asystole also can occur, presumably because of loss of sympathetic innervation in the continued presence of parasympathetic activity at the sinoatrial node (Caplan et al., 1988). In the usual clinical situation, blood pressure serves as a surrogate marker for cardiac output and organ perfusion. Treatment of hypotension usually is warranted when the blood pressure decreases to about 30% of resting values.

Therapy is aimed at maintaining brain and cardiac perfusion and oxygenation. To achieve these goals, administration of oxygen, fluid infusion, manipulation of patient position, and the administration of vasoactive drugs are all options. In practice, patients typically are administered a bolus (500–1000 mL) of fluid prior to the administration of spinal anesthesia in an attempt to prevent some of the deleterious effects of spinal blockade. Because the usual cause of hypotension is decreased venous return, possibly complicated by decreased heart rate, drugs with preferential venoconstrictive and chronotropic properties are preferred. For this reason, ephedrine, 5–10 mg intravenously, often is the drug of choice. In addition to the use of ephedrine to treat deleterious effects of sympathetic blockade, direct-acting α_1 adrenergic receptor agonists such as

phenylephrine (Chapter 12) can be administered by either bolus or continuous infusion.

A beneficial effect of spinal anesthesia partially mediated by the sympathetic nervous system is on the intestine. Sympathetic fibers originating from T5 to L1 inhibit peristalsis; thus, their blockade produces a small, contracted intestine. This, together with flaccid abdominal musculature, produces excellent operating conditions for some types of bowel surgery. The consequences of spinal anesthesia on the respiratory system are mostly mediated by effects on the skeletal musculature. Paralysis of the intercostal muscles will reduce a patient's ability to cough and clear secretions, which may produce dyspnea in patients with bronchitis or emphysema. Respiratory arrest during spinal anesthesia seldom occurs due to paralysis of the phrenic nerves or to toxic levels of local anesthetic in the CSF of the fourth ventricle; it is much more likely to be due to medullary ischemia secondary to hypotension.

Pharmacology

Currently in the U.S., the drugs most commonly used in spinal anesthesia are lidocaine, tetracaine, and bupivacaine. The choice of local anesthetic is primarily determined by the desired duration of anesthesia. General guidelines are to use lidocaine for short procedures, bupivacaine for intermediate-to-long procedures, and tetracaine for long procedures. As mentioned, the factors contributing to the distribution of local anesthetics in the CSF have received much attention because of their importance in determining the height of block. The most important pharmacological factors include the amount, and possibly the volume, of drug injected and its baricity. The speed of injection of the local anesthesia solution also may affect the height of the block, just as the position of the patient can influence the rate of distribution of the anesthetic agent and the height of blockade achieved (described in the next section). For a given preparation of local anesthetic, administration of increasing amounts leads to a fairly predictable increase in the level of block attained. For example, 100 mg of lidocaine, 20 mg of bupivacaine, or 12 mg of tetracaine usually will result in a T4 sensory block. More complete tables of these relationships can be found in standard anesthesiology texts.

Epinephrine often is added to spinal anesthetics to increase the duration or intensity of block. Epinephrine's effect on duration of block is dependent on the technique used to measure duration. A commonly used measure of block duration is the length of time it takes for the block to recede by two dermatomes from the maximum height of the block, while a second is the duration of block at some specified level, typically L1. In most studies, addition of 200 μ g of epinephrine to tetracaine solutions prolongs the duration of block by both measures. However, addition of epinephrine to lidocaine or bupivacaine does not affect the first measure of duration but does prolong the block at lower levels. In different clinical situations, one or the other measure of anesthesia duration may be more relevant, and this must be kept in mind when deciding whether to add epinephrine to spinal local anesthetics.

The mechanism of action of vasoconstrictors in prolonging spinal anesthesia is uncertain. It has been hypothesized that these agents decrease spinal cord blood flow, decreasing clearance of local anesthetic from the CSF, but this has not been convincingly demonstrated. Epinephrine and other α adrenergic agonists have been shown to decrease nociceptive transmission in the spinal cord, and studies in genetically modified mice suggested that α_{2A} adrenergic receptors play a principal role in this response (Stone et al., 1997). Such actions may contribute to the beneficial effects of epinephrine, clonidine, and dexmedetomidine when these agents are added to spinal local anesthetics.

Drug Baricity and Patient Position

The baricity of the local anesthetic injected will determine the direction of migration within the dural sac. Hyperbaric solutions will tend to settle in the dependent portions of the sac, while hypobaric solutions will tend to migrate in the opposite direction. Isobaric solutions usually will stay in the vicinity where they were injected, diffusing slowly in all directions. Consideration of the patient position during and after the performance of the block and the choice of a local anesthetic of the appropriate baricity is crucial for a successful block during some surgical procedures.

Lidocaine and bupivacaine are marketed in both isobaric and hyperbaric preparations and, if desired, can be diluted with sterile, preservative-free water to make them hypobaric.

Complications

Persistent neurological deficits following spinal anesthesia are extremely rare. Thorough evaluation of a suspected deficit should be performed in collaboration with a neurologist. Neurological sequelae can be both immediate and late. Possible causes include introduction of foreign substances (such as disinfectants, ultrasound gel, or talc) into the subarachnoid space, infection, hematoma, or direct mechanical trauma. Aside from drainage of an abscess or hematoma, treatment usually is ineffective; thus, avoidance and careful attention to detail while performing spinal anesthesia are necessary.

High concentrations of local anesthetic can cause irreversible block. After administration, local anesthetic solutions are diluted rapidly, quickly reaching nontoxic concentrations. However, there are several reports of transient or longer-lasting neurological deficits following lidocaine spinal anesthesia, particularly with 5% lidocaine HCl (i.e., ~ 180 mM) in 7.5% glucose (Zaric and Pace, 2009).

Spinal anesthesia sometimes is regarded as contraindicated in patients with preexisting disease of the spinal cord. No experimental evidence exists to support this hypothesis. Nonetheless, it is prudent to avoid spinal anesthesia in patients with progressive diseases of the spinal cord. However, spinal anesthesia may be useful in patients with a fixed, chronic spinal cord injury.

A more common sequela following any lumbar puncture, including spinal anesthesia, is a postural headache with classic features. The incidence of headache decreases with increasing age of the patient and decreasing needle diameter. Headache following lumbar puncture must be thoroughly evaluated to exclude serious complications such as meningitis. Treatment usually is conservative, with bed rest and analgesics. If this approach fails, an epidural blood patch with the injection of autologous blood can be performed; this procedure is usually successful in alleviating postdural puncture headaches, although a second blood patch may be necessary. If two epidural blood patches are ineffective in relieving the headache, the diagnosis of postdural puncture headache should be reconsidered. Intravenous caffeine (500 mg as the benzoate salt administered over 4 h) also has been advocated for the treatment of postdural puncture headache; however, the efficacy of caffeine is less than that of a blood patch, and relief usually is transient.

Evaluation of Spinal Anesthesia

Spinal anesthesia is a safe and effective technique, especially during surgery involving the lower abdomen, the lower extremities, and the perineum. It often is combined with intravenous medication to provide sedation and amnesia. The physiological perturbations associated with low spinal anesthesia often have less potential harm than those associated with general anesthesia. The same does not apply for high spinal anesthesia. The sympathetic blockade that accompanies levels of spinal anesthesia adequate for mid- or upper abdominal surgery, coupled with the difficulty in achieving visceral analgesia, is such that equally satisfactory and safer operating conditions can be realized by combining the spinal anesthetic with a "light" general anesthetic or by the administration of a general anesthetic and a neuromuscular blocking agent.

Epidural Anesthesia

Epidural anesthesia is administered by injecting local anesthetic into the epidural space—the space bounded by the ligamentum flavum posteriorly, the spinal periosteum laterally, and the dura anteriorly. Epidural anesthesia can be performed in the sacral hiatus (caudal anesthesia) or in the lumbar, thoracic, or cervical regions of the spine. Its current popularity arises from the development of catheters that can be placed into the epidural space, allowing either continuous infusions or repeated bolus administration of local anesthetics. The primary site of action of epidurally administered local anesthetics is on the spinal nerve roots. However, epidurally administered local anesthetics also may act on the spinal cord and on the paravertebral nerves.

The selection of drugs available for epidural anesthesia is similar to that for major nerve blocks. As for spinal anesthesia, the choice of drugs to be used during epidural anesthesia is dictated primarily by the duration of anesthesia desired. However, when an epidural catheter is placed, short-acting drugs can be administered repeatedly, providing more control over the duration of block. Bupivacaine, 0.5%–0.75%, is used when a long duration of surgical block is desired. Due to enhanced cardiotoxicity in pregnant patients, the 0.75% solution is not approved for obstetrical use. Lower concentrations—0.25%, 0.125%, or 0.0625%—of bupivacaine, often with 2 µg/mL of fentanyl added, frequently are used to provide analgesia during labor. They also are useful preparations for providing postoperative analgesia in certain clinical situations. Lidocaine 2% is the most frequently used intermediate-acting epidural local anesthetic. Chloroprocaine, 2% or 3%, provides rapid onset and a very short duration of anesthetic action. However, its use in epidural anesthesia has been clouded by controversy regarding its potential ability to cause neurological complications if the drug is accidentally injected into the subarachnoid space (discussed previously). The addition of epinephrine frequently prolongs the duration of action and reduces the toxicity of epidurally administered local anesthetics. Addition of epinephrine also makes inadvertent intravascular injection easier to detect and modifies the effect of sympathetic blockade during epidural anesthesia.

For each anesthetic agent, a relationship exists between the volume of local anesthetic injected epidurally and the segmental level of anesthesia achieved. For example, in 20- to 40-year-old, healthy, nonpregnant patients, each 1–1.5 mL of 2% lidocaine will give an additional segment of anesthesia. The amount needed decreases with increasing age and during pregnancy and in children. The concentration of local anesthetic used determines the type of nerve fibers blocked. The highest concentrations are used when sympathetic, somatic sensory, and somatic motor blockade are required. Intermediate concentrations allow somatic sensory anesthesia without muscle relaxation. Low concentrations will block only preganglionic sympathetic fibers. As an example, with bupivacaine these effects might be achieved with concentrations of 0.5%, 0.25%, and 0.0625%, respectively. The total amounts of drug that can be injected with safety at one time are approximately those mentioned in the sections Nerve Block Anesthesia and Infiltration Anesthesia. Performance of epidural anesthesia requires a greater degree of skill than does spinal anesthesia. The technique of epidural anesthesia and the volumes, concentrations, and types of drugs used are described in detail in standard texts on regional anesthesia (Cousins et al., 2008).

A significant difference between epidural and spinal anesthesia is that the dose of local anesthetic used can produce high concentrations in blood following absorption from the epidural space. Peak concentrations of lidocaine in blood following injection of 400 mg (without epinephrine) into the lumbar epidural space average 3–4 µg/mL; peak concentrations of bupivacaine in blood average 1 µg/mL after the lumbar epidural injection of 150 mg. Addition of epinephrine (5 µg/mL) decreases peak plasma concentrations by about 25%. Peak blood concentrations are a function of the total dose of drug administered rather than the concentration or volume of solution following epidural injection (Covino and Vassallo, 1976). The risk of inadvertent intravascular injection is increased in epidural anesthesia, as the epidural space contains a rich venous plexus.

Another major difference between epidural and spinal anesthesia is that there is no zone of differential sympathetic blockade with epidural anesthesia; thus, the level of sympathetic block is close to the level of sensory block. Because epidural anesthesia does not result in the zones of differential sympathetic blockade observed during spinal anesthesia, cardiovascular responses to epidural anesthesia might be expected to be less prominent. In practice, this is not the case; the potential advantage of epidural anesthesia is offset by the cardiovascular responses to the high concentration of anesthetic in blood that occurs during epidural anesthesia. This is most apparent when epinephrine is added to the epidural injection.

The resulting concentration of epinephrine in blood is sufficient to produce significant β_2 adrenergic receptor-mediated vasodilation. As a consequence, blood pressure decreases, even though cardiac output increases due to the positive inotropic and chronotropic effects of epinephrine (Chapter 12). The result is peripheral hyperperfusion and hypotension. Differences in cardiovascular responses to equal levels of spinal and epidural anesthesia also are observed when a local anesthetic such as lidocaine is used without epinephrine. This may be a consequence of the direct effects of high concentrations of lidocaine on vascular smooth muscle and the heart. The magnitude of the differences in responses to equal sensory levels of spinal and epidural anesthesia varies, however, with the local anesthetic used for the epidural injection (assuming no epinephrine is used). For example, local anesthetics such as bupivacaine, which are highly lipid soluble, are distributed less into the circulation than are less lipid-soluble agents such as lidocaine.

High concentrations of local anesthetics in blood during epidural anesthesia are of particular concern when this technique is used to control pain during labor and delivery. Local anesthetics cross the placenta, enter the fetal circulation, and at high concentrations may cause depression of the neonate. The extent to which they do so is determined by dosage, acid-base status, level of protein binding in both maternal and fetal blood, placental blood flow, and solubility of the agent in fetal tissue. These concerns have been lessened by the trend toward using more dilute solutions of bupivacaine for labor analgesia.

Epidural and Intrathecal Opiate Analgesia

Small quantities of opioid injected intrathecally or epidurally produce segmental analgesia (Yaksh and Rudy, 1976). This observation led to the clinical use of spinal and epidural opioids during surgical procedures and for the relief of postoperative and chronic pain (Cousins and Mather, 1984). As with local anesthesia, analgesia is confined to sensory nerves that enter the spinal cord dorsal horn in the vicinity of the injection. Presynaptic opioid receptors inhibit the release of substance P and other neurotransmitters from primary afferents, while postsynaptic opioid receptors decrease the activity of certain dorsal horn neurons in the spinothalamic tracts (Willcockson et al., 1986; see also Chapters 8 and 20). Because conduction in autonomic, sensory, and motor nerves is not affected by the opioids, blood pressure, motor function, and nonnociceptive sensory perception typically are not influenced by spinal opioids. The volume-evoked micturition reflex is inhibited, as manifested by urinary retention. Other side effects include pruritus, nausea, and vomiting in susceptible individuals. Delayed respiratory depression and sedation, presumably from cephalad spread of opioid within the CSF, occur infrequently with the doses of opioids currently used.

Spinally administered opioids by themselves do not provide satisfactory anesthesia for surgical procedures. Thus, opioids have found the greatest use in the treatment of postoperative and chronic pain, providing excellent analgesia following thoracic, abdominal, pelvic, or lower extremity surgery without the side effects associated with high doses of systemically administered opioids. For postoperative analgesia, spinally administered morphine, 0.2–0.5 mg, usually will provide 8–16 h of analgesia. Placement of an epidural catheter and repeated boluses or an infusion of opioid permits an increased duration of analgesia. Morphine, 2–6 mg every 6 h, commonly is used for bolus injections, while fentanyl, 20–50 µg/h, often combined with bupivacaine at 5–20 mg/h, is used for infusions. For cancer pain, repeated doses of epidural opioids can provide analgesia of several months' duration. The dose of epidural morphine is far less than the dose of systemically administered morphine that would be required to provide similar analgesia, thus reducing the complications that usually accompany the administration of high doses of systemic opioids, particularly sedation and constipation. Unfortunately, as with systemic opioids, tolerance will develop to the analgesic effects of epidural opioids, but this usually can be managed by increasing the dose.

Drug Facts for Your Personal Formulary: *Local Anesthetics*

Drugs	Therapeutic Uses or Duration	Clinical Pharmacology and Tips
Topical Anesthesia		
Lidocaine	<ul style="list-style-type: none"> • Superficial anesthesia of mucous membranes 	<ul style="list-style-type: none"> • 2%–10% solution • ~30 min duration • Maximal healthy adult dose, ~4 mg/kg
Cocaine	<ul style="list-style-type: none"> • Superficial anesthesia of mucous membranes of nose, mouth, ear 	<ul style="list-style-type: none"> • 1%–4% solution • ~30 min duration • Maximal healthy adult dose, ~1–3 mg/kg (maximum 400 mg); pediatric dose, < 1 mg/kg • Vasoconstriction + anesthesia
Eutectic mixtures, oil, or cream: Lidocaine (2.5%)/prilocaine (2.5%) (EMLA) or Lidocaine (7%)/tetracaine (7%) (PLIAGIS)	<ul style="list-style-type: none"> • Superficial anesthesia of cutaneous structures 	<ul style="list-style-type: none"> • Effective to ~5-mm depth • Requires 30–60 min of contact to establish effective anesthesia • Should not be used on mucous membranes or abraded skin due to rapid absorption • Consult package insert for maximum dose
Infiltration Anesthesia		
Lidocaine	<ul style="list-style-type: none"> • Superficial anesthesia of cutaneous structures • Addition of dilute sodium bicarbonate (10:1—lidocaine: 8.4% sodium bicarbonate, ~0.75 mg/mL sodium bicarbonate) can lessen pain on injection 	<ul style="list-style-type: none"> • 0.5%–1.0% solution • Maximal healthy adult dose, ~4 mg/kg • Addition of epinephrine (5 µg/mL) increases duration of action and maximal safe lidocaine dose
Bupivacaine	<ul style="list-style-type: none"> • Superficial anesthesia of cutaneous structures 	<ul style="list-style-type: none"> • 0.125%–0.25% solution • Maximal healthy adult dose, ~2 mg/kg • Addition of epinephrine (5 µg/mL) increases duration of action and maximal safe bupivacaine dose
Nerve Block Anesthesia • Use with epinephrine-containing test dose • Risk of intravenous injection		
Articaine	<ul style="list-style-type: none"> • 1 h duration 	<ul style="list-style-type: none"> • For dental and periodontal procedures • 4% solution, typically with epinephrine • Contains both an amide and ester, so degraded in both plasma and liver
Lidocaine, mepivacaine	<ul style="list-style-type: none"> • 1–2 h duration • Addition of epinephrine prolongs duration and increases maximal safe level of drug • Identification of blocked nerves (nerve stimulation or ultrasound) may increase safety and success of block 	Safe doses depend on vascularity of tissue, generally: <ul style="list-style-type: none"> • Lidocaine: 1%–1.5%, maximal healthy adult dose, ~4 mg/kg • Mepivacaine: 1%–2%, maximal healthy adult dose, ~7 mg/kg (maximum 400 mg)
Bupivacaine, ropivacaine	<ul style="list-style-type: none"> • 6–8 h duration • Longer duration of sensory block with bupivacaine than with ropivacaine • Addition of epinephrine prolongs duration and increases maximal safe level of drug 	Safe doses depend on vascularity of tissue, generally: <ul style="list-style-type: none"> • Bupivacaine: 0.25%–0.375%, maximal healthy adult dose, ~2–3 mg/kg (maximum 400 mg) • Ropivacaine: 0.5%–0.75%, maximal healthy adult dose, ~3–4 mg/kg (maximum 200 mg) • Infusions through a catheter placed adjacent to the nerve can provide sustained analgesia • Identification of blocked nerves (nerve stimulation or ultrasound) may increase safety and success of block
Epidural Anesthesia • Use with epinephrine-containing test dose • Risk of intravenous injection • Spread of block dependent on dose and volume injected • Epidural catheter allows repeated dosing • Consider coagulation status of patient		
Chloroprocaine	<ul style="list-style-type: none"> • Short duration • Epinephrine prolongs action 	<ul style="list-style-type: none"> • 2%–3% solution • Possible increased incidence of postprocedure back pain
Lidocaine	<ul style="list-style-type: none"> • Intermediate duration • Epinephrine prolongs action 	<ul style="list-style-type: none"> • 2% solution • Maximal healthy adult dose, ~4 mg/kg
Bupivacaine	<ul style="list-style-type: none"> • Long duration 	<ul style="list-style-type: none"> • 0.5% solution • Maximal healthy adult dose, ~2–3 mg/kg
Ropivacaine	<ul style="list-style-type: none"> • Long duration 	<ul style="list-style-type: none"> • 0.5%–1.0% solution • Maximal healthy adult dose, ~2–3 mg/kg • May have less toxicity than equiefficacious dose of bupivacaine
Spinal Anesthesia • Dose and baricity of anesthetic strongly influence spread • Addition of opioids can prolong analgesia • Consider coagulation status of patient		
Lidocaine	<ul style="list-style-type: none"> • Short duration (60–90 min) 	<ul style="list-style-type: none"> • ~25–50 mg for perineal and lower extremity surgery • Association of spinal lidocaine with transient neurological symptoms
Tetracaine	<ul style="list-style-type: none"> • Long duration (210–240 min) 	<ul style="list-style-type: none"> • Duration increased by epinephrine • ~5 mg for perineal surgery • ~10 mg for lower extremity surgery
Bupivacaine	<ul style="list-style-type: none"> • Long duration (210–240 min) 	<ul style="list-style-type: none"> • ~10 mg for perineal and lower extremity surgery • 15–20 mg for abdominal surgery

Ethanol ($\text{CH}_3\text{CH}_2\text{OH}$), or beverage alcohol, is a two-carbon alcohol that directly affects many different types of neurochemical systems and signaling cascades and has rewarding and addictive properties. It is the oldest recreational drug and likely contributes to more morbidity, mortality, and public health costs than all illicit drugs combined. The current *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* integrates alcohol abuse and alcohol dependence into a single disorder called *alcohol use disorder* (AUD), with mild, moderate, and severe subclassifications (American Psychiatric Association, 2013). This chapter presents an overview of the effects of ethanol on various physiological systems, then focuses on the mechanisms of ethanol's effects in the CNS as the basis for understanding the rewards, disease processes, and treatments for ethanol-related conditions.

Human Consumption of Ethanol: A Brief History and Perspective

The use of alcoholic beverages has been documented as far back as 10,000 BC. By about 3000 BC, the Greeks, Romans, and inhabitants of Babylon were incorporating ethanol into religious festivals, while also using it for pleasure and in medicinal practice. Over the last 2000 years, alcoholic beverages have been identified in most cultures, including pre-Columbian America about AD 200 and the Islamic world in the 8th century.

The dangers of heavy consumption of alcohol have long been recognized by almost all cultures, with most stressing the importance of moderation; yet, problems with ethanol are as ancient as the use of this beverage itself. The increase in ethanol consumption in the 1800s, along with industrialization and the need for a more dependable work force, contributed to the development of more widespread organized efforts to discourage

drunkenness, including a constitutional ban on the sale of alcoholic beverages in the U.S. from 1920 to 1933.

Today, AUD is one of the most prevalent psychiatric disorders worldwide. In the U.S. among adults 18 years and older, AUD is associated with other substance use and psychiatric disorders; despite its prevalence and comorbidity, AUD often goes untreated (Grant et al., 2015). The highest quantities of ethanol intake per occasion are usually observed in the late teens to early 20s (CDC, 2012). Older adults drink more often but consume fewer total drinks each month (White et al., 2015). In the U.S., the per capita consumption of all alcoholic beverages for persons aged 14 and older is equivalent to 2.3 gallons (8.7 L) of absolute alcohol per year (NIAAA, 2015). Among drinkers, as many as half have experienced an alcohol-related problem, such as missing school or work, alcohol-related amnesia (blackouts), or operating a motor vehicle after consuming alcohol (Schuckit, 2009). Roughly one-third of men (36%) and one-quarter of women (23%) meet criteria for a mild, moderate, or severe AUD in their lifetimes (Grant et al, 2015). The CDC estimated that annually in the U.S. the excessive consumption of ethanol contributes to 10% of deaths of working adults 20–64 years old and to one-third of fatal traffic accidents and cost \$249 billion in 2010 (CDC, 2014).

Ethanol Consumption

Compared with other drugs, surprisingly large amounts of ethanol are required for physiological effects. Ethanol is consumed in gram quantities. In contrast, most other drugs with affinities for specific proteins are taken in milligram or microgram doses. The alcohol content of beverages typically ranges from 4% to 6% (volume/volume) for beer, 10% to 15% for wine, and 40% and higher for distilled spirits (the proof of an alcoholic

beverage is twice its percentage of alcohol; e.g., 40% alcohol is 80 proof). A 12-oz bottle of beer (355 mL), a 5-oz glass of wine (148 mL), and a 1.5-oz “shot” of 40% liquor (44 mL) each contain about 14 g ethanol (the density of ethanol is 0.79 g/mL at 25°C), and constitute what is defined as a “standard drink” in the U.S.

Because the ratio of ethanol in end-expiratory alveolar air and blood is relatively consistent, BECs in humans are readily estimated by the measurement of ethanol levels in expired air; the partition coefficient for ethanol between blood and alveolar air is about 2100:1. The legally allowed BEC for operating a motor vehicle is 80 mg% (80 mg ethanol per 100 mL blood; 0.08% w/v) in the United States, which is equivalent to a concentration of 17 mM ethanol in blood. The consumption of one standard drink (a 12-oz bottle of beer, a 5-oz glass of wine, or a 1.5-oz shot of 40% liquor) by a 70-kg person would produce a BEC of about 30 mg%. However, it is important to note that this is an estimation because the BEC is determined by several factors, including the rate of drinking, gender, body weight and water percentage, as well as the rates of metabolism and stomach emptying (see Acute Ethanol Intoxication further in the chapter).

Pharmacological Properties of Ethanol and Methanol

Ethanol

Absorption and Gastric Metabolism

After oral administration, ethanol is absorbed rapidly into the bloodstream from the stomach and small intestine and distributes into total body water (~0.65 L/kg body weight). Due to high surface area, absorption occurs more rapidly from the small intestine than from the stomach; delays in gastric emptying (e.g., due to the presence of food) slow ethanol absorption. Peak blood levels occur about 30 min after ingestion of ethanol when the stomach is empty. Because of first-pass metabolism by gastric and liver ADH, oral ingestion of ethanol leads to lower BECs than would be obtained if the same dose were administered intravenously. The rate of gastric metabolism of ethanol is lower in women than in men (Schuckit, 2006). Other factors also affect absorption and metabolism; for

example, aspirin (1 g) inhibits gastric ADH and increases the bioavailability of ethanol in men.

Liver Metabolism

Only small amounts of ethanol are excreted in urine, sweat, and breath. The main enzymes involved in ethanol metabolism are ADH and ALDH, followed by catalase and CYP2E1. CYPs 1A2 and 3A4 may also participate. Ethanol is metabolized primarily by sequential hepatic oxidation, first to acetaldehyde by ADH and then to acetic acid by ALDH (Figure 23-1). Each metabolic step requires NAD^+ ; thus, oxidation of 1 mol ethanol (46 g) to 1 mol acetic acid requires 2 mol NAD^+ (approximately 1.3 kg). This greatly exceeds the supply of NAD^+ in the liver; thus, the bioavailability of NAD^+ limits ethanol metabolism to about 8 g/h (10 mL/h, 170 mmol/h) in a 70-kg adult. Ethanol metabolism proceeds via zero-order kinetics at BECs greater than 10 mg% and by first-order kinetics at BECs less than 10 mg%.

In addition to limiting the rate of ethanol metabolism, the large increase in the hepatic $\text{NADH}:\text{NAD}^+$ ratio resulting from ethanol oxidation has profound consequences. The function of NAD^+ -requiring enzymes is impaired, resulting in accumulation of lactate, reduced activity of the tricarboxylic acid cycle, and accumulation of acetyl-CoA (which is produced from ethanol-derived acetic acid; Figure 23-1). The combination of increased NADH and elevated acetyl-CoA supports fatty acid synthesis and the storage and accumulation of triacylglycerides; ketone bodies then accrue, exacerbating lactic acidosis.

Although ADH is responsible for the majority of ethanol metabolism, CYP2E1 accounts for about 10%. This constituent of the microsomal ethanol-oxidizing system can be altered by acute or chronic ethanol consumption. Competition between ethanol and other drugs (e.g., phenytoin and warfarin) that are metabolized by CYP2E1 is observed after acute consumption of ethanol. CYP2E1 is also induced by chronic consumption of ethanol, resulting in increased clearance of its substrates and increased susceptibility to certain toxins (e.g., CCl_4 , which CYP2E1 metabolizes and thereby activates to the highly reactive trichloromethyl radical). Ethanol metabolism by the CYP2E1 pathway elevates NADP^+ and limits the availability of NADPH for the regeneration of reduced glutathione, thereby enhancing oxidative stress.

The mechanisms underlying hepatic disease resulting from heavy ethanol use probably reflect a complex combination of these metabolic factors, CYP2E1 induction (and enhanced activation of toxins and production of H_2O_2 and oxygen radicals), and possibly enhanced release of endotoxin as a consequence of ethanol's effect on gram-negative flora in the GI tract. The often-poor nutritional status of alcoholics (malabsorption and lack of vitamins A and D and thiamine), suppression of immune function, and a variety of other generalized effects likely compound the more direct adverse effects of excessive ethanol consumption. An overview of ethanol metabolism and how it can lead to tissue injury is found in the work of Molina et al. (2014).

Genetic Variation in Ethanol Metabolism

Genetic variations in metabolic enzymes for ethanol can alter its metabolism and susceptibility to its effects, thus influencing the risk for developing AUD and other pathology. Linkage analyses indicated that genes clustered in the *ADH* region affect risk for alcohol dependence (Edenberg et al., 2006). SNPs across the *ADH* region show strong evidence of association in and around the *ADH4* gene. In addition, a SNP in the *ADH1B* gene (*ADH1B**2) is found in high frequencies in East Asians that may protect against AUD. This genetic variation produces faster metabolism of ethanol and a transient higher blood level of acetaldehyde, which are associated with a lower risk for heavy drinking and other ethanol-related problems, but a higher risk for esophageal cancer if one drinks. The *ALDH2**2 polymorphism (see discussion that follows) also leads to an increased incidence of esophageal cancer in those who consume alcohol. Another polymorphism (*ADH1B**3) is protective in African Americans and is associated with lower risk of heavy drinking and ethanol-related problems.

Polymorphisms in the *ALDH2* gene are implicated in the development of AUD (Chen et al., 2014). *ALDH2* is the most efficient *ALDH* isozyme in humans for the metabolism of ethanol-derived acetaldehyde. Low levels of acetaldehyde are rewarding and stimulating, while high blood

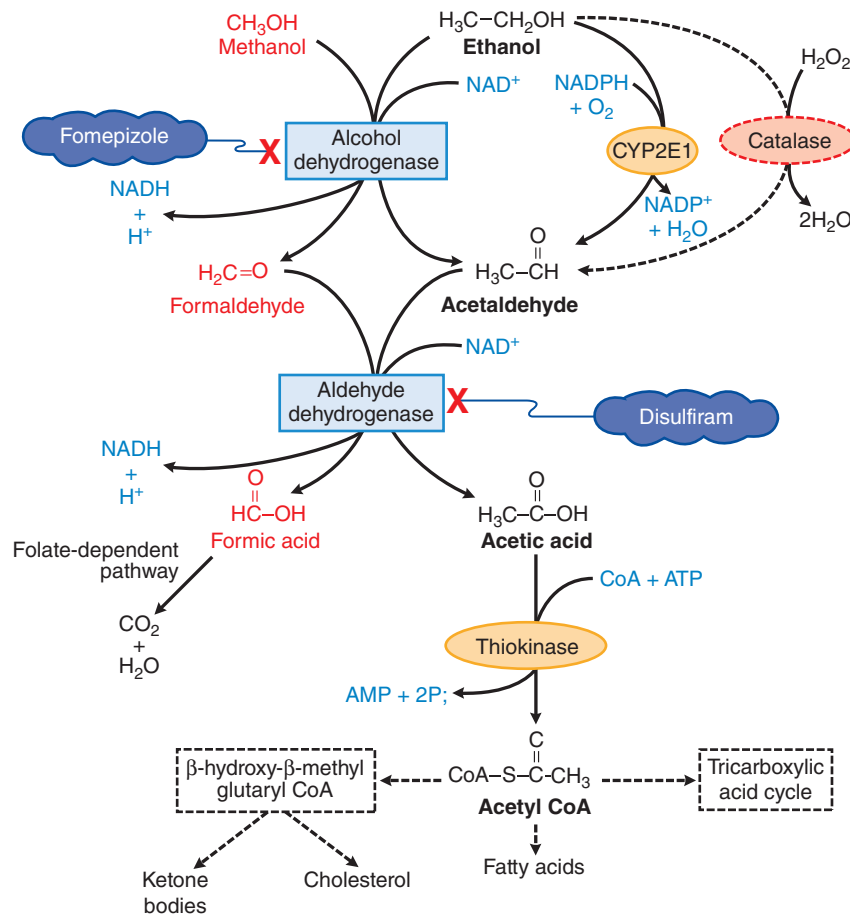

Figure 23–1 Metabolism of ethanol and methanol.

levels produce adverse reactions such as vomiting, diarrhea, and unstable blood pressure; thus, genetic variation in ALDH activity could affect the rewarding or aversive properties of ethanol. A mutation in the *ALDH2* gene (*ALDH2*²) produces an enzyme that is incapable of metabolizing ethanol. Approximately 10% of Asians are homozygous for *ALDH2*² and develop severe adverse reactions after the consumption of one drink or less. Similar adverse reactions occur if ethanol is consumed with the ALDH inhibitor disulfiram. Approximately 30%–40% of Asians are heterozygous for *ALDH2*², and these individuals experience facial flushing and enhanced sensitivity to alcohol but do not necessarily report an overall adverse response to the drug. Thus, several polymorphisms may decrease an individual's risk for developing AUD and other diseases that may be related to the toxic effects of aldehydes. The section Alcohol Use Disorder, Genetics, and Pharmacogenetics provides additional evidence for genetic determinants in AUD.

Methanol

Methanol (CH_3OH), also known as methyl or wood alcohol, is an important industrial reagent and solvent found in products such as paint removers, shellac, and antifreeze. Methanol is added to industrial use ethanol to make it unsafe for human consumption. Ingestion of as little as 10 mg of methanol produces toxicity ranging from blindness to death. The toxic effects of methanol take about 12 or more hours to manifest themselves and are dependent on methanol metabolism to formaldehyde and formic acid (Figure 23–1). Methanol poisoning consists of headache, GI distress, and pain (partially related to pancreatic necrosis), difficulty breathing, restlessness, and blurred vision. The visual disturbances occur from injury to ganglion cells of the retina and the optic nerve by formic acid, which produces inflammation, atrophy, and potential bilateral blindness. Severe metabolic acidosis can develop due to the accumulation of formic acid, and respiratory depression may be severe, resulting in coma or death.

ADME and Treatment of Poisoning

Methanol is rapidly absorbed via oral administration, inhalation, and through the skin, with the last two routes most relevant in industrial settings. Absorption of methanol taken orally typically occurs within 30–60 min. Methanol is metabolized by ADH to formaldehyde, which is then metabolized to formic acid by ALDH. Competition between methanol and ethanol for ADH is the basis for using ethanol to treat methanol poisoning because ethanol slows the rate of formic acid production, lessening the toxicity associated with accidental methanol consumption.

FOMEPIZOLE

Fomepizole (4-methylpyrazole), an ADH inhibitor (Figure 23–1), is also used to treat methanol or ethylene glycol poisoning, applied either alone or in combination with hemodialysis. Plasma levels of 0.8 mg/L are effective in inhibiting ADH. Fomepizole should not be used with ethanol because it prolongs the half-life of ethanol. Treatment of methanol poisoning also consists of treating patients with sodium bicarbonate to combat acidosis.

Effects of Ethanol on Physiological Systems

The Wisdom of Shakespeare

William Shakespeare described the acute pharmacological effects of imbibing ethanol in the Porter scene (act 2, scene 3) of *Macbeth*. The Porter, awakened from an alcohol-induced sleep by Macduff, explains

Porter: ... and drink, sir, is a great provoker of three things.
Macduff: What three things does drink especially provoke?

Porter: Marry, sir, nose-painting [cutaneous vasodilation], sleep [CNS depression], and urine [a consequence of the inhibition of antidiuretic hormone (vasopressin) secretion, exacerbated by volume loading]. Lechery, sir, it provokes and unprovokes: it provokes the desire but it takes away the performance. Therefore much drink may be said to be an equivocator with lechery: it makes him and it mars him; it sets him on and it takes him off; it persuades him and disheartens him, makes him stand to and not stand to [the imagination desires what the corpus cavernosum cannot deliver]; in conclusion, equivocates him in a sleep, and, giving him the lie, leaves him.

More recent research has added details to Shakespeare's enumeration—see the bracketed additions to the Porter's words in the preceding paragraph and the following sections on organ systems—but the most noticeable consequences of the recreational use of ethanol still are well summarized by the gregarious and garrulous Porter, whose delighted and devilish demeanor demonstrates a frequently observed influence of modest concentrations of ethanol on the CNS. The sections that follow detail ethanol's effects on physiological systems.

CNS

Ethanol is primarily a CNS depressant. Ingestion of moderate amounts of ethanol, like that of other sedative/hypnotics such as barbiturates and benzodiazepines, can have anxiolytic actions and produce behavioral disinhibition. Individual signs of intoxication vary from expansive and vivacious effects to uncontrolled mood swings and emotional outbursts that may have violent components. With more severe intoxication, CNS function becomes progressively more impaired, ultimately to the point of general anesthesia. Due to respiratory depression, there is little margin between the concentrations yielding the anesthetic and lethal effects of ethanol.

Acute Ethanol Intoxication

Many factors influence the BEC, including body weight, body composition, and the rate of absorption from the GI tract. In women with smaller body size and a lower body water percentage and, consequently, a lower volume of distribution for ethanol, BECs may be about 30%–50% higher than in men for the same quantity consumed.

Signs of intoxication typical of CNS depression are observed in most people after two or three drinks, with the most prominent effects seen at times of peak BEC, about 30–60 min following consumption on an empty stomach. These symptoms include an initial stimulatory effect (perhaps due to inhibition of CNS inhibitory systems), giddiness, muscle relaxation, and impaired judgment. Higher blood levels (~80 mg/dL or ~17 mM) are associated with slurred speech, incoordination, unsteady gait, and impaired attention; levels between 80 and 200 mg/dL are associated with more intense mood lability and greater cognitive deficits, potentially accompanied by aggressiveness, and anterograde amnesia (an “alcoholic blackout,” i.e., loss of memory of events that transpired while intoxicated). BECs greater than 200 mg/dL can produce nystagmus and sedation, while levels of 300 mg/dL and higher produce failing vital signs, coma, and death. All of these symptoms are likely to be exacerbated and occur at a lower BEC if ethanol is taken along with other CNS depressants (e.g., benzodiazepines or barbiturates) or with any drug or medication that promotes sedation and incoordination (e.g., antihistamines).

The treatment of acute ethanol intoxication is based on the severity of respiratory and CNS depression. If respiratory depression is not severe, careful observation is the primary treatment. Patients with evidence of respiratory depression should be intubated to protect the airway and to provide ventilatory assistance; stomach lavage can also be considered if absorption is not yet complete. Because it is freely miscible with water, ethanol can be removed from the blood by hemodialysis. The usual protocol

involves observing the patient in the emergency room for 4–6 h while the ingested ethanol is metabolized. The symptoms associated with diabetic coma, drug intoxication, cardiovascular accidents, and skull fractures are similar and may be confused with profound alcohol intoxication. Testing for breath odor in a case of suspected intoxication can be misleading because there can be other causes of breath odor similar to that of alcohol (e.g., diabetic ketoacidosis or other metabolic acidosis). Determining blood ethanol levels is necessary to confirm the absence or presence of alcohol intoxication, and diabetes or other underlying conditions should also be considered in patients with positive BECs.

Putative Mechanisms of Ethanol Action in the CNS

Ethanol produces distinct neuroadaptations that depend on acute versus chronic exposure. Ethanol perturbs the balance between excitatory and inhibitory transmission in the brain by either enhancing inhibitory or antagonizing excitatory neurotransmission (Table 23–1). The exact molecular sites responsible for ethanol action in vivo have yet to be resolved, although many ion channels have been implicated, including the ligand-gated NMDA and GABA_A receptor-operated channels, as well as the large conductance Ca²⁺- and voltage-activated K⁺ channel.

Advances in X-ray crystal structures of open and closed states of ion channels combined with structural modeling and site-directed mutagenesis have elucidated selective binding pockets for ethanol in different channel proteins (Howard et al., 2014; Trudell et al., 2014). Ethanol also alters ion channel function indirectly via receptor phosphorylation and trafficking mechanisms (Trudell et al., 2014). Mutant mouse models and genetic association studies in animals and humans further demonstrate a role for ligand-gated ion channels in alcohol dependence. To define the key sites of ethanol action, a combination of functional, structural, behavioral, and genomic approaches will be required.

Addiction, Tolerance, and Dependence

Alcohol use disorder is the chronically relapsing and compulsive use of alcohol, comprising three interacting stages that progressively worsen over time: binge-intoxication, withdrawal-negative affect, and preoccupation-anticipation (“craving”). The neurocircuitry of the basal ganglia is thought to mediate the neurobiological basis of the binge-intoxication stage, including the facilitation of incentive salience, a form of motivational salience associated with reward. The basal ganglia are associated with key functions, including voluntary motor control and procedural learning related to routine behaviors or habits. Release of dopamine and opioid peptides in the ventral striatum (nucleus accumbens) is associated with the reinforcing actions of alcohol (Volkow et al., 2007). Endocannabinoid signaling may also contribute to the motivational and reinforcing properties of ethanol, and ethanol drinking alters

TABLE 23–1 ■ ETHANOL TARGETS ION CHANNELS	
LIGAND- AND VOLTAGE-GATED ION CHANNELS	EFFECTS OF ACUTE ETHANOL
GABA _A receptor-operated channels	Enhancement
Glycine receptor-operated channels	Enhancement
NMDA receptor-operated channels	Inhibition
Nicotinic ACh receptor-operated channels	Enhancement
5HT ₃ receptor-operated channels	Enhancement
G protein–coupled inwardly rectifying K ⁺ channels	Enhancement
Voltage-gated Ca ²⁺ channels	Inhibition
Large conductance, Ca ²⁺ /voltage-activated K ⁺ channels (BK, slo1-containing subunits)	Enhancement

These ligand- and voltage-activated ion channels can be modulated by 50 mM ethanol or less. The enhancement or inhibition of channel function recorded here represents an overall consensus of the acute ethanol effects observed in multiple studies. Results depend on ethanol concentration, time of exposure, channel subunit composition, brain region, cell type, posttranslational modifications, and other factors.

endocannabinoid levels and cannabinoid receptor 1 expression in brain nuclei associated with addiction pathways (Pava and Woodward, 2012). Alcohol use facilitates incentive salience by imparting motivational properties to previously neutral stimuli. Activation of the ventral striatum leads to recruitment of basal ganglia–globus pallidus–thalamic–cortical loops that engage the dorsal striatum habit formation, hypothesized to be the beginning of compulsive-like responding for drugs.

Tolerance rapidly develops to the rewarding effects of alcohol and is defined as a reduced behavioral or physiological response to the same dose of drug, or the requirement of a higher dose to obtain the same effect (see Chapter 24). The major forms of tolerance are *acute* and *chronic*. Acute functional tolerance, also known as the Mellanby effect, occurs within hours of alcohol administration and is due to CNS adaptations to its effects. This is demonstrated by comparing behavioral impairment at the same BECs on the ascending limb of the absorption phase of the BEC–time curve and on the descending limb of the curve, as metabolism reduces the BEC. Behavioral impairment and subjective feelings of intoxication are much greater at a given BEC on the ascending than on the descending limb. Chronic tolerance also develops in the long-term heavy drinker. In contrast to acute tolerance, chronic tolerance has both pharmacodynamic and pharmacokinetic elements, the latter due to induction of alcohol-metabolizing enzymes. In general, the maximum pharmacokinetic tolerance attained would be a doubling of the normal metabolic rate.

Dependence is defined by a withdrawal syndrome observed several hours to days after alcohol consumption is terminated. The symptoms and severity are determined by the amount and duration of drinking and include major motivational changes, sleep disruption, autonomic nervous system (sympathetic) activation, tremors, and, in severe cases, seizures. In addition, two or more days after withdrawal, some individuals experience *delirium tremens*, characterized by hallucinations, delirium, tachycardia, and a potentially fatal fever. Individuals with AUD also show evidence of negative emotional states during acute withdrawal that persist into protracted abstinence; such states include symptoms related to anxiety, dysphoria, and depression. Persistent depression/anxiety-like symptoms may be relevant in the treatment considerations for AUD.

Two processes are thought to form the neurobiological basis for the withdrawal–negative affect stage: a decrease in functioning in reward systems in the ventral striatum and recruitment of the stress systems in the extended amygdala. As dependence develops, brain stress systems, involving corticotropin-releasing factor, norepinephrine, and dynorphin, are recruited (Koob, 2014), producing a powerful motivation for reengaging in drug seeking.

The preoccupation-anticipation (“craving”) stage involves dysregulation of prefrontal cortex circuits, causing loss of executive control. The completion of complex tasks in the AUD brain may involve two opposing systems. A “go” system, consisting of the anterior cingulate cortex and dorsolateral prefrontal cortex, engages habits via the basal ganglia, while the “stop” system, consisting of the ventrolateral prefrontal cortex and orbitofrontal cortex, inhibits the basal ganglia incentive salience system and the extended amygdala stress system (Koob, 2015). Individuals with AUD present with impairments in decision-making, spatial information, and behavioral inhibition, all of which drive craving. Craving can be divided into “reward” craving (drug seeking induced by drugs or stimuli linked to drugs) and “relief” craving (drug seeking induced by an acute stressor or a state of stress) (Heinz et al., 2003). Thus, deficits in prefrontal cortical control of basal ganglia and extended amygdala function may represent a key mechanism to explain individual differences in the predisposition to and perpetuation of addiction. Residual dysregulation of the neurocircuits mediating incentive salience and stress responsivity help perpetuate compulsive drug taking and relapse.

Consequences of Ethanol Consumption on CNS Function

The transient CNS effects of heavy ethanol consumption that produce a “hangover”—the next-morning syndrome of headache, thirst, nausea, and cognitive impairment—may reflect mechanisms associated with ethanol withdrawal, dehydration, or mild acidosis. Insomnia is a common

and persistent problem in AUD, even after weeks of abstinence (Brower, 2015). Insomnia should be treated because it may be a factor contributing to relapse. Ethanol affects respiration and muscle relaxation, and heavy drinking can produce sleep apnea, especially in older alcohol-dependent subjects.

Alcohol use disorder causes shrinkage of the brain due to loss of both white and gray matter, and chronic heavy drinking increases the risk of developing *alcoholic dementia*. The cognitive deficits and brain atrophy observed soon after a heavy drinking period partially reverse over the subsequent weeks to months following abstinence. Furthermore, alcohol abuse reduces overall brain metabolism, which reverses during detoxification. The magnitude of the hypometabolic state is determined by the number of years of use and the patient’s age.

Wernicke-Korsakoff syndrome consists of two neuropsychiatric disorders: Wernicke encephalopathy, which is largely reversible, and Korsakoff psychosis, which is generally not reversible. These syndromes are now considered a unitary disorder called *Wernicke-Korsakoff syndrome* that occurs subsequent to inadequate intake of thiamine, likely due to the poor dietary habits of patients with AUD. Thiamine deficiency, alone, can lead to Wernicke-Korsakoff syndrome (Scalzo et al., 2015).

Wernicke encephalopathy is characterized by a confusional state, ataxia, abnormal eye movements, blurred vision, double vision, nystagmus, and tremor. It is associated with a prolonged history of heavy drinking and an inadequate nutritional state. The neurological syndrome (ataxia, ophthalmoplegia, and nystagmus) can be reversed in its early stages by high doses of thiamine, but the learning and memory impairments respond more slowly and incompletely. Untreated Wernicke encephalopathy leads to death in up to 20% of cases, and 85% of those who survive the encephalopathy go on to develop Korsakoff psychosis, characterized by severe anterograde and retrograde amnesia (Thomson et al., 2012) that is largely irreversible. Wernicke-Korsakoff syndrome is a medical emergency, and early treatment with intravenous thiamine (followed by oral maintenance treatment) is essential to reverse the Wernicke symptoms and prevent progression or reduce the severity of the Korsakoff state.

Neuroendocrine System

Both acute and chronic ethanol exposure alter endocrine regulation via the hypothalamo-pituitary-adrenal, hypothalamo-pituitary-gonadal, and hypothalamo-pituitary-thyroid axes (Molina et al., 2014). Some of the resulting endocrine-related disorders include hypothyroidism, growth retardation, diabetes, as well as hypogonadism and abnormal sexual function, discussed in the next section. Overall, alcohol abuse contributes to an impaired ability to respond to psychological and physical stressors and to maintain homeostasis.

Sexual Function

Many drugs of abuse, including ethanol, have disinhibiting effects that may initially increase libido. Despite the notion that ethanol enhances sexual function, the opposite effect generally prevails, as Shakespeare’s Porter noted. Both acute and chronic ethanol use can lead to impotence in men. Increased BECs lead to decreased sexual arousal, increased ejaculatory latency, and decreased orgasmic pleasure. The incidence of sexual dysfunction may be as high as 70% in those with AUD. In addition, testicular atrophy and decreased fertility may occur. Many females with AUD complain of decreased libido, decreased vaginal lubrication, and menstrual cycle abnormalities. Their ovaries often are small and without follicular development; some data suggest that fertility rates are lower in women with AUD. Gynecomastia is associated with alcoholic liver disease and is related to an increased estrogen-to-testosterone ratio. Altered levels of reproductive hormones also affect bone metabolism.

Bone

Ethanol interferes with Ca^{2+} and bone metabolism by several processes. Acute ethanol exposure transiently decreases parathyroid hormone, resulting in increased loss of calcium. Chronic ethanol intake can disturb

vitamin D metabolism and decrease Ca^{2+} absorption. Ethanol is also directly toxic to bone-forming cells and inhibits their activity. AUD is associated with decreased bone mineral density and mass and increased prevalence of osteoporosis, leading to increased risk of fractures. Anabolic hormones, particularly testosterone, are important in regulating bone remodeling and bone mass. The impaired hypothalamo-pituitary-gonadal axis and decreased testosterone levels observed in AUD further contribute to compromised bone health (Molina et al., 2014).

Body Temperature

Ingestion of ethanol causes a feeling of warmth due to enhanced cutaneous vasodilatation. Heat is transferred from the body core to the periphery and the core temperature falls due to an effect of ethanol on the central temperature-regulating mechanism in the hypothalamus. Intake of high ethanol doses may lead to pronounced decreases in body temperature, especially in cold ambient temperatures. Alcohol is a major risk factor contributing to deaths from hypothermia.

Diuresis

Ethanol inhibits the release of vasopressin (antidiuretic hormone) from the posterior pituitary gland, resulting in enhanced diuresis. Alcohol-dependent individuals in withdrawal exhibit increased vasopressin release and a consequential retention of water, as well as dilutional hyponatremia.

Cardiovascular System

There is a complex J-shaped relationship between ethanol consumption and heart disease, a leading cause of death and disability. In general, light-to-moderate ethanol intake decreases risks for coronary artery disease, congestive heart failure, and stroke, whereas high intake increases cardiovascular risk (O'Keefe et al., 2014). Epidemiological studies suggested that gender, ethanol consumption, and drinking patterns affect the association risk for IHD. AUD elevates the risk for IHD, but there is a beneficial association with IHD risk in people who consume less than 30 g per day without episodes of heavy drinking (Roerecke and Rehm, 2014). However, ethanol consumption recommendations from clinicians should remain guarded when judging the overall risk-benefit relationship given the wide range of effects and potential for other ethanol-related problems, presence of other disease states, and the lack of randomized controlled trials on ethanol's long-term effects. The risk-to-benefit ratio of drinking is also higher in younger individuals.

Serum Lipoproteins and Cardiovascular Effects

Epidemiological studies suggest that wine consumption (20–30 g ethanol per day) may confer a cardioprotective effect, resulting in decreased risk of CHD compared with abstainers. In contrast, daily consumption of greater amounts of ethanol leads to an increased incidence of arrhythmias, cardiomyopathy, and hemorrhagic stroke (Movva and Figueredo, 2013).

One possible mechanism by which ethanol could reduce the risk of CHD is through its effects on blood lipids. Changes in plasma lipoprotein levels, particularly increases in HDL (see Chapter 33), are linked with the protective effects of ethanol. HDL binds cholesterol and returns it to the liver for elimination or reprocessing, decreasing tissue cholesterol accumulation. Ethanol-induced increases in HDL cholesterol could thus decrease cholesterol accumulation in arterial walls, lessening the risk of infarction. HDL is found as two subfractions, HDL2 and HDL3. Increased levels of HDL2 (and possibly HDL3) are associated with reduced risk of myocardial infarction. Levels of both subfractions increase following ethanol consumption and decrease when consumption ceases. In addition to the antiatherogenic effects of low doses of ethanol, the flavonoids found in red wine (and purple grape juice) may play an additional role by protecting LDL from oxidative damage.

Hypertension

Heavy alcohol use can raise diastolic and systolic blood pressure. Consumption of 30 g of ethanol per day is associated with elevations in diastolic-systolic blood pressure, 1.5–2.3 mm Hg in men and 2.1–3.2 mm Hg in women.

Cardiac Arrhythmias and Cardiomyopathy

Ethanol-induced arrhythmias may be related to electrolyte abnormalities, prolongation of the QT interval, and hyperadrenergic states. Atrial arrhythmias associated with chronic alcohol use include supraventricular tachycardia, atrial fibrillation, and atrial flutter. Alcoholic cardiomyopathy is a specific disease that is classified among the acquired forms of dilated cardiomyopathy, causing left ventricular dysfunction and dilatation that may or may not be associated with right ventricular dysfunction. In general, studies suggest that consuming more than 80 g of alcohol per day over at least 5 years, in the absence of other causes of cardiomyopathy, constitutes a diagnosis of alcoholic cardiomyopathy (Guzzo-Merello et al., 2014). Women are more sensitive to alcohol than men and develop alcoholic cardiomyopathy at a lower total dose of ethanol. Lowering blood pressure with angiotensin-converting enzyme inhibitors, in particular, may be beneficial in alcoholic cardiomyopathy (Guzzo-Merello et al., 2014).

Stroke

A meta-analysis showed that low alcohol intake reduces risk of total stroke, ischemic stroke, and stroke mortality, while heavy intake increases risk of total stroke (Zhang et al., 2014). Clinical studies indicated an increased incidence of hemorrhagic and ischemic stroke in persons who drink more than 40–60 g alcohol per day. Proposed etiological factors include the following:

- Alcohol-induced cardiac arrhythmias and associated thrombus formation
- High blood pressure from chronic alcohol consumption and subsequent cerebral artery degeneration
- Acute increases in systolic blood pressure and alterations in cerebral artery tone
- Head trauma

Lungs

As in the heart and other organs, chronic alcohol abuse causes oxidative injury in the lungs. AUD increases risk of acute respiratory distress syndrome and pneumonia (Molina et al., 2014). Alcohol impairs the pulmonary response to injury, infection, and inflammation, resulting in an overall imbalance in the immune response.

Skeletal Muscle

Chronic ethanol abuse is associated with decreased muscle mass and strength, even when adjusted for other factors such as age, nicotine use, and chronic illness. Heavy doses of ethanol may irreversibly damage muscle, reflected by a marked increase in the activity of creatine kinase in plasma. Muscle biopsies from heavy drinkers also reveal decreased glycogen stores and reduced pyruvate kinase activity. Approximately 50% of chronic drinkers have skeletal muscle myopathy, which is much greater than the incidence of alcohol cirrhosis (Molina et al., 2014).

GI Tract and Digestive System

The GI system mediates ethanol absorption and metabolism and is a target for alcohol-induced pathophysiology, such as impaired esophageal and gastric motility, altered acid secretion, impaired nutrient absorption, and disrupted intestinal barrier function.

Esophagus

Alcohol is one of multiple factors associated with esophageal reflux, Barrett esophagus, traumatic rupture of the esophagus, Mallory-Weiss tears, and esophageal cancer. Either tobacco or alcohol use is associated with a 20%–30% increased likelihood of the development of esophageal squamous cell carcinoma; however, the concomitant use of both drugs increases the risk 3-fold. There is little change in esophageal function at low BECs, but at higher BECs peristalsis and lower esophageal sphincter pressure decrease. Patients with chronic reflux esophagitis may respond to proton pump inhibitors, as well as abstinence from alcohol.

Stomach

Heavy ethanol use can disrupt the gastric mucosal barrier and cause acute and chronic gastritis. Ethanol concentrations up to 5% stimulate gastric acid secretion, whereas concentrations above 5% have no effect. Alcohol concentrations above 15% inhibit gastric motility and retard emptying of stomach contents. Clinical symptoms of high concentrations of ethanol intake include acute epigastric pain that is relieved with antacids or histamine H_2 receptor antagonists.

Intestines

Many individuals with AUD have chronic diarrhea caused by malabsorption in the small intestine. The rectal fissures and pruritus ani that are associated with heavy drinking are likely related to chronic diarrhea. Diarrhea is caused by structural and functional changes in the small intestine; for example, the intestinal mucosa has flattened villi, and digestive enzyme levels often are decreased. These changes are usually reversible after a period of abstinence.

Pancreas

Heavy alcohol use is the most common cause of both acute and chronic pancreatitis in the U.S. Acute alcoholic pancreatitis, involving acinar cells, is characterized by the abrupt onset of abdominal pain, nausea, vomiting, and increased levels of serum or urine pancreatic enzymes. Treatment usually involves intravenous fluid replacement (often with nasogastric suction) and opioid pain medication. Similar to alcoholic cirrhosis, chronic pancreatitis results from progressive cellular destruction and fibrosis. Chronic pancreatitis is treated by replacing the resulting endocrine and exocrine deficiencies. Hyperglycemia can develop as a sequela of pancreatitis and often requires insulin to control blood sugar levels (see Chapter 47). Pancreatic enzyme capsules containing lipase, amylase, and proteases may be necessary to treat malabsorption (see Chapter 50). The alcohol-induced risk for chronic pancreatitis is increased in smokers, which further exacerbates the risk of pancreatic cancer (Molina et al., 2014).

Liver

As the main organ involved in ethanol metabolism, the liver is a primary target for the pathological effects of ethanol. Alcohol misuse is responsible for approximately 50% of liver disease in the U.S. Ethanol produces dose-dependent hepatic injuries that progress from fat accumulation (steatosis) and inflammation to collagen deposition (fibrosis) to loss of liver cells (cirrhosis). The clinical stages of alcoholic liver disease are hepatosteatosis, alcoholic hepatitis, and cirrhosis. Accumulation of fat in the liver is an early event and can occur in normal individuals after the ingestion of relatively small amounts of ethanol. The generation of excess NADH, via metabolism of ethanol and acetaldehyde by ADH and ALDH, inhibits the tricarboxylic acid cycle and the oxidation of fat, leading to steatosis (see Figure 23-1). Steatosis is usually reversible with abstinence.

Hepatic stellate cells play an important role in the development of alcohol-mediated liver fibrosis. Fibrosis, resulting from tissue necrosis and chronic inflammation, is the underlying cause of alcoholic cirrhosis. The histological hallmark of cirrhosis is the formation of intracytoplasmic bodies called Mallory bodies, which may be related to an altered intermediate filament cytoskeleton.

Patients with AUD and alcoholic liver disease show changes in the composition of their intestinal microbiomes, increased intestinal permeability, and increased levels of gut-derived microbial products (Hartmann et al., 2015). Chronic ethanol exposure in animals and humans increases the circulating concentration of LPS, and the severity of hepatic injury correlates with serum levels of LPS. LPS activates TLRs and induces a complex signaling cascade, causing release of reactive oxygen species, chemokines, and pro-inflammatory cytokines.

Treatment of alcoholic hepatitis involves abstinence from alcohol and administration of corticosteroids, but corticosteroids only reduce mortality in the short term (Louvet and Mathurin, 2015). Improved treatment options may come from compounds that target the gut microbiome (see previous discussion), liver inflammation/regeneration, and oxidative stress. Probiotics, antibiotics, anti-inflammatory agents, immunosuppressants, growth

factors, and antioxidants are examples of some of the different compounds undergoing clinical trials.

Cancers

Ethanol consumption is strongly linked to cancers of the oral cavity, pharynx, larynx, esophagus, colorectum (especially in men), and breast (women); there is also some evidence for an increased risk of liver cancer (Roswall and Weiderpass, 2015). Alcohol dependence plays a role in approximately 3.6% of all cancer cases and a similar percentage of cancer-related deaths (Boffetta et al., 2006). Two- to three-fold increases in cancer susceptibility are seen in individuals who chronically consume 50 g of alcohol per day, and concomitant smoking has a synergistic effect. As mentioned, individuals deficient in ALDH2 activity are particularly vulnerable to esophageal cancer. A notable complication in the treatment of cancer patients with AUD is that ethanol can interfere in the metabolism of some chemotherapeutic agents. The effects of acetaldehyde, a demonstrated carcinogen in animal models, and oxidative stress are widely cited mechanisms for the increased rate of carcinogenesis among individuals with AUD. Evidence also points to a role for aberrant DNA methylation patterns and other epigenetic modifications that control genome activity as mechanisms in alcohol-induced cancer development and progression. Epigenetics refers to processes that affect gene expression without changes in DNA sequence.

Hematological and Immunological Effects

Chronic excessive ethanol use is associated with different anemias, including microcytic, macrocytic, normochromic, and sideroblastic anemias, the last of which may respond to vitamin B_{12} supplementation. Ethanol use also is associated with reversible thrombocytopenia. Ethanol affects granulocytes and lymphocytes, causing leukopenia, alteration of lymphocyte subsets, decreased T-cell mitogenesis, and changes in immunoglobulin production. In some patients with AUD, depressed leukocyte migration into inflamed areas may contribute to poor resistance to some infections (e.g., *Klebsiella* pneumonia, listeriosis, and tuberculosis). Some effects of ethanol-induced innate immune mechanisms that spread from the periphery to brain are described in the inflammatory sequence of events depicted in the following section.

Neuroimmune Mechanisms

The interplay between brain, behavior, and immunity in the etiology and progression of drug abuse is a rapidly developing area of research. Chronic ethanol consumption increases the levels of innate immune signaling molecules that reach the brain, producing alterations in brain physiology and behavior (Mayfield et al., 2013). Binge drinking increases levels of LPS, disrupting tight junctions and contributing to a leaky gut that permits bacteria and endotoxins to enter the circulation and exacerbate liver inflammation (Crews and Vetreno, 2015). This in turn releases pro-inflammatory cytokines that are transported across the blood-brain barrier, eliciting long-lasting neuroimmune responses. Within brain microglia, the actions of innate immune cytokines, activated TLRs, etc., are amplified via complex signaling loops, one of which leads to activation of the transcription factor NF- κ B. NF- κ B then regulates transcription of pro-inflammatory immune-related genes. Ethanol-induced microglia activation and induction of neuroimmune genes can thus be initiated systemically, through blood-borne molecules, as well as locally in the brain through neuronal-glial signaling. Neuroimmune mechanisms appear to be involved in later stages of heavy drinking and may contribute to neuronal apoptosis. Ethanol-induced neuroimmune activation also occurs in the developing brain, which may be relevant in FASDs (Drew and Kane, 2014).

Teratogenic Effects: Fetal Alcohol Spectrum Disorders

Ethanol is the most common teratogen in humans. Children born to mothers who are heavy drinkers display mental deficits and a common pattern of distinct dysmorphology known as FAS. The diagnosis of FAS

428 is typically based on the observance of a triad of abnormalities associated with a history of prenatal ethanol exposure (Dorrie et al., 2014):

- A cluster of craniofacial abnormalities
- CNS dysfunction (structural or functional)
- Pre- or postnatal growth deficiencies (weight or height)

Fetal alcohol spectrum disorder is not a diagnostic term used by clinicians but rather an umbrella term that encompasses all of the disabilities caused by prenatal alcohol exposure. For example, children who do not meet all of the criteria for a diagnosis of FAS may show physical or mental deficits consistent with partial phenotypes, including *partial FAS*, *ARND*, and *ARBD* (Dorrie et al., 2014). The incidence of FAS is about 0.5–2 per 1000 live births in the general U.S. population, while the incidence of FAS, ARND, and ARBD combined is at least 1%. Higher rates of FAS occur in African and Native American women. Children of binge-drinking mothers show severe mental and behavioral deficits, likely due to the high peak BECs (Dorrie et al., 2014).

The FAS craniofacial abnormalities associated with maternal drinking in the first trimester consist of microcephaly, shortened palpebral fissures, thin upper lip, smooth philtrum, and epicanthal folds. Magnetic resonance imaging studies demonstrate decreased volumes in the basal ganglia, corpus callosum, cerebrum, and cerebellum that correlate with the facial abnormalities. CNS dysfunction attributed to in utero ethanol exposure consists of hyperactivity; attention and mental deficits; learning disabilities; language, memory, and motor disorders; and psychiatric conditions. FAS is the number one preventable cause of cognitive and attention deficits in the Western world, with afflicted children consistently scoring lower than their peers on a variety of IQ tests. Although the evidence is not conclusive, it has been suggested that even moderate alcohol consumption (28 g per day) in the second trimester of pregnancy is correlated with impaired academic performance of children at age 6. Maternal age also may be a factor: Pregnant women over age 30 who drink alcohol create greater risks to their children than do younger women who consume similar amounts of alcohol. In addition, the intake of high amounts of alcohol, particularly during the first trimester, greatly increases the chances of spontaneous abortion. Current recommendations are to drink no alcohol during pregnancy.

Clinical Uses of Ethanol

As mentioned, systemically administered ethanol is confined to the treatment of poisoning by methanol or ethylene glycol. In addition, dehydrated alcohol is injected in close proximity to nerves or sympathetic ganglia to relieve the long-lasting pain related to trigeminal neuralgia, inoperable carcinoma, and other conditions. Epidural, subarachnoid, and lumbar paravertebral injections of ethanol are also administered for inoperable pain. For example, lumbar paravertebral ethanol injections destroy sympathetic ganglia and thereby cause vasodilation and pain relief and promote healing of lesions in patients with vascular disease of the lower extremities.

Drug Interactions

Due to synergistic effects, great care must be taken when using sedatives to treat patients who have ingested heavy doses of ethanol or other CNS depressants. Acute ethanol intoxication decreases general anesthetic requirements, and elective surgery should be postponed in intoxicated patients. In contrast, chronic ethanol exposure increases anesthetic requirements largely due to pharmacodynamic cross-tolerance. An additional complication is the use of neuromuscular blockers and sedative/anesthetic agents in patients with AUD presenting with compromised liver function. This is particularly true for patients administered succinylcholine and benzodiazepines.

Pharmacokinetic interactions between ethanol and other drugs also occur. *Acute administration* of ethanol inhibits the function of enzymes responsible for metabolizing a variety of different drugs, including

codeine, morphine, phenytoin, some benzodiazepines, tolbutamide, and warfarin, among others. Because ethanol inhibits CYP2E1, any drug also metabolized by this CYP isozyme will be metabolized at a slower rate in the presence of ethanol. In contrast, the *chronic administration* of ethanol acts as an enzyme inducer, particularly of CYP2E1, increasing the rate of metabolism of phenytoin, warfarin, propranolol, and benzodiazepines.

Comorbidity of Alcohol Use Disorder With Other Diseases

Many systemic diseases are related to chronic alcohol abuse, such as cardiovascular and liver diseases, as well as several types of cancers. AUD appears to increase the risk for diabetes mellitus, hypertension, stroke, osteoporosis, pancreatitis, and many other diseases. In this section, we focus on comorbid mental health conditions that are often present in patients with AUD or other substance use disorders.

Psychiatric Diseases

Patients diagnosed with a mood or anxiety disorder are about twice as likely to suffer from a drug abuse disorder and vice versa. In addition, AUD or other drug abuse disorders often occur in people with schizophrenia, leading to increased social and medical problems and complicating the course and treatment of schizophrenia. Patients with AUD and comorbid psychiatric disorders require treatment strategies that address both conditions. Although SSRIs have not been shown to be effective treatments for AUD in patients without a comorbid mental disorder, SSRIs and other antidepressants may decrease intake when AUD and depression co-occur; if alcohol use occurs as a consequence of depression, treating the underlying problem can decrease drinking.

Post-Traumatic Stress Disorder

Post-traumatic stress disorder is characterized by extreme hyperarousal and hyperstress responsiveness that contributes in a major way to the classic symptom cluster of reexperiencing, avoidance, and arousal. The prevalence of AUD in individuals with PTSD may be as high as 30% (Ouimette et al., 2005). The study of PTSD neurocircuitry has evolved from animal work on fear circuits and shows significant overlap with the symptoms of hyperresponsiveness to stress observed during alcohol withdrawal. One attractive hypothesis of the functional neurocircuitry changes that occur in PTSD is that of a brain-state shift from mild stress, in which the prefrontal cortex inhibits the amygdala, to extreme stress, in which the amygdala dominates (Pitman et al., 2012). Relative cortical dominance conveys resilience, while relative amygdala dominance conveys vulnerability; similar arguments can be made for the resilience and vulnerability to alcoholism, as elaborated by studies of the neurobiology of the withdrawal–negative affect stage of the alcohol addiction cycle.

Alcohol Use Disorder, Genetics, and Pharmacogenetics

Similar to other complex trait disorders, the development and progression of AUD is influenced by the interaction of multiple genetic and environmental factors. Environmental and cultural factors include stress, drinking patterns within one's culture and peer group, availability of alcohol, and attitudes toward drunkenness. These influences contribute to the initial decision to drink and the transition from casual drinking to alcohol-related problems. The heritability of AUD is estimated to be 50%–60%, as judged by family and twin studies. Long-term alcohol abuse and dependence are linked to persistent changes in gene expression (Mayfield et al., 2008).

As discussed previously, SNPs of *ADH* and *ALDH* may explain why some populations have a lower risk for AUD. Genetic variants of *ADH* that exhibit high activity and variants of *ALDH* that exhibit low activity protect against heavy drinking, likely because ethanol consumption by individuals

expressing these variants results in accumulation of acetaldehyde, producing a variety of unpleasant effects.

Many additional genes modulate responses to ethanol, including variants of the following: μ -opioid receptor (*OPRM1*), dopamine transporter (*SLC6A3*), serotonin transporter (*SLC6A4*), dopamine receptor D2 (*DRD2*), α_2 subunit of the GABA_A receptor (*GABRA2*), and α_3 subunit of the glycine receptor (*GLRA3*) (Jones et al., 2015). Other candidate genes include corticotropin-releasing hormone receptor 1 (*CRHR1*) and corticotropin-releasing hormone binding protein (*CRHBP*), which are important in brain stress pathways. Ethanol also induces the expression of neuroimmune-related genes, producing increased levels of immune markers detectable in postmortem brains from individuals with AUD (e.g., high-mobility group box 1, interleukin 1 β , and TLRs), which may mediate long-term changes in brain function and neurodegeneration. Polymorphisms of genes encoding interleukin 1 β and other immune molecules are associated with susceptibility to alcohol dependence (Crews and Vetreno, 2015).

Some of the pharmacotherapies for AUD, discussed in the next section, may be more effective in individuals carrying particular genetic variants. Clinical advances through pharmacogenetic studies of AUD may make the goal of precision medicine a possibility, but this will require rigorous methodological and statistical analyses. Each individual has unique neurobiological, genetic, and environmental profiles that affect treatment outcome, making individualized strategies not only feasible, but also necessary to move treatment of AUD into mainstream medicine (Litten et al., 2015).

Because AUD involves multifactorial processes with genetic and environmental determinants, as well as neuroadaptations related to disease progression, moving beyond studying the significance of individual candidate genes must include a systems approach to identify the relevant gene and protein networks operating at different stages of the disease. (Gorini et al., 2014).

Pharmacotherapy of Alcohol Use Disorder

Currently, three drugs are FDA approved for the treatment of AUD: disulfiram, naltrexone, and acamprosate (Table 23–2). They have reasonable efficacy, with effect sizes similar to those of antidepressant drugs for depression; unfortunately, they are not routinely prescribed (Jonas et al., 2014). Their efficacies may be influenced by an individual's genetic makeup, and genotyping is likely to become important in future treatment strategies. Benzodiazepines are the treatment of choice for management of acute alcohol withdrawal and to prevent the progression from minor withdrawal symptoms to major ones, such as seizures and delirium tremens (see Chapter 24).

TABLE 23–2 ■ ORAL MEDICATIONS FOR TREATING ALCOHOL ABUSE

MEDICATION	USUAL DOSE	MECHANISM/EFFECT
Disulfiram	250 mg/d (range of 125–500 mg/d)	<ul style="list-style-type: none"> Inhibits ALDH with resulting \uparrow acetaldehyde after drinking. Abstinence is reinforced to avoid the resulting adverse reaction.
Naltrexone	50 mg/d	<ul style="list-style-type: none"> μ-opioid receptor antagonist; may \downarrow drinking through \downarrow feelings of reward with alcohol or \downarrow craving.
Acamprosate	666 mg three times daily	<ul style="list-style-type: none"> Unknown mechanism, may block hyperglutamatergic state and may \downarrow mild protracted abstinence syndromes with \downarrow feelings of a “need” for alcohol.

Disulfiram

Disulfiram (tetraethylthiuram disulfide), the first drug approved to treat alcohol abuse, is relatively nontoxic when taken in the absence of ethanol. It inhibits ALDH activity and increases the blood acetaldehyde concentration by 5–10 times compared to the level measured when ethanol is administered alone. Disulfiram irreversibly inactivates cytosolic and mitochondrial forms of ALDH to varying degrees. It is unlikely that disulfiram itself is responsible for ALDH inactivation in vivo because several active metabolites of the drug, especially diethylthiomethylcarbamate, behave as suicide-substrate inhibitors of ALDH in vitro. These metabolites reach significant concentrations in plasma following the administration of disulfiram.

Alcohol consumption by individuals previously treated with disulfiram gives rise to marked signs and symptoms of acetaldehyde poisoning. At BECs of 5–10 mg%, mild effects are noted, increasing markedly in severity as the BEC reaches 50 mg%. If the patient attains a BEC of 125–150 mg%, loss of consciousness may occur. Within 5–10 min, the face feels hot and soon afterward becomes flushed and scarlet in appearance. As the vasodilation spreads over the whole body, intense throbbing is felt in the head and neck, and a pulsating headache may develop. Respiratory difficulties, nausea, copious vomiting, sweating, thirst, chest pain, considerable hypotension, orthostatic syncope, marked uneasiness, weakness, vertigo, blurred vision, and confusion are observed. The facial flush is then replaced by pallor, and blood pressure may fall to levels seen in shock. Thus, the use of disulfiram requires careful medical supervision and should only be attempted in motivated patients committed to maintaining abstinence. Patients must learn to avoid disguised forms of alcohol that may be present in sauces, fermented vinegar, cough syrups, and even aftershave lotions. Disulfiram treatment results in poor compliance, possibly because of the adverse effects that result if taken with ethanol.

Disulfiram should not be administered until the patient has abstained from alcohol for at least 12 h. In the initial phase of treatment, a maximal daily dose of 500 mg is given for 1–2 weeks. Maintenance dosage then ranges from 125 to 500 mg daily depending on tolerance to side effects. Unless sedation is prominent, the daily dose should be taken in the morning, the time when the resolve not to drink may be strongest. Sensitization to alcohol may last as long as 14 days after the last ingestion of disulfiram because of the slow rate of restoration of ALDH.

Disulfiram or its metabolites can inhibit many enzymes with sulfhydryl groups, producing a wide spectrum of biological effects. Hepatic CYPs are inhibited, thereby interfering with the metabolism of phenytoin, chlordiazepoxide, barbiturates, warfarin, and other drugs.

Naltrexone

Naltrexone, a μ -opioid receptor antagonist, is chemically related to naloxone but has higher oral bioavailability and a longer duration of action when administered orally. It is also approved for treatment of opioid overdose and dependence (see Chapters 18 and 24). There is evidence that naltrexone blocks activation of brain receptors by opioid peptides that are thought to be critical for the rewarding effects of drugs of abuse.

Naltrexone reduces craving and decreases relapse to heavy drinking. Meta-analyses indicated that naltrexone is better than placebo, especially in reducing risk of heavy drinking. It is typically administered after detoxification at a dose of 50 mg/d for several months. Adherence to this regimen is important to ensure the therapeutic value of naltrexone but is a problem for some patients. A long-acting depot formulation of naltrexone is available for monthly injection. Naltrexone implants lasting several months are available outside the U.S.

The most common side effect of naltrexone is nausea, which subsides if the patient abstains from alcohol. There is some evidence of dysphoria associated with administration of naltrexone, and it is contraindicated in patients with depressive disorders. Doses of naltrexone exceeding 300 mg can cause liver damage; the drug is contraindicated in patients with liver failure or acute hepatitis and should be used only after careful consideration in patients with active liver disease. Naltrexone cannot be given to

430 patients taking opioids, but it is used following opioid detoxification for prevention of relapse to opioid dependence.

Acamprosate

Acamprosate (N-acetylhomotaurine) may work by blocking a hyperglutamatergic state in the alcoholic brain, but the exact molecular target has remained elusive. It is FDA-approved for the treatment of AUD and is generally well tolerated by patients, with mild diarrhea being the main side effect. Double-blind, placebo-controlled studies demonstrated that acamprosate decreases drinking frequency and reduces relapse drinking in abstinent individuals but may not be effective in those who are currently drinking or misusing other drugs. Meta-analyses of randomized clinical trials showed that acamprosate is associated with reduced relapse in drinking (Jonas et al., 2014). For dosing, see Table 23–2.

Other Agents

Baclofen (used in France) has shown positive results for the treatment of AUD in some studies but is not FDA-approved for this use. Three other drugs described next, although not FDA-approved for AUD, are either approved in Europe or may prove useful based on emerging evidence.

Nalmefene, an opioid receptor antagonist structurally similar to naltrexone, is used to treat opioid overdose and may also be used to manage addictive behaviors. It is approved in Europe for as-needed use (18 mg) to reduce heavy drinking. It has several advantages over naltrexone, including longer duration of action, lack of dose-dependent liver toxicity, and higher affinity of binding to μ - and κ -opioid receptors.

Nalmefene reduces the total amount of alcohol consumed and the number of heavy drinking days in alcohol-dependent patients (van den Brink et al., 2014). Nalmefene was used for opioid overdose in the U.S. but has been discontinued.

Gabapentin, which interacts with the $\alpha 2\delta$ subunit of neuronal voltage-gated Ca^{2+} channels, is primarily used to treat epileptic seizures and neuropathic pain. A clinical trial showed that gabapentin (particularly the daily 1800-mg dose) improved rates of abstinence and no heavy drinking days in alcohol-dependent adults, decreased the number of heavy drinking days and number of drinks consumed per week, and decreased the severity of craving, insomnia, and dysphoria (Mason et al., 2014). Additional studies are needed to determine if gabapentin or other agents can be repurposed to treat AUD. For additional information on gabapentin, see Chapter 17.

Varenicline, which is approved for smoking cessation, also reduces alcohol consumption in preclinical and clinical models (Rahman et al., 2014). Varenicline acts as a partial agonist at $\alpha 3\beta 4$, $\alpha 4\beta 2$, and $\alpha 6\beta 2$ subtypes of nAChRs and as a high-efficacy agonist at $\alpha 7$ nAChRs. Given the role of nAChRs in mediating the rewarding properties of ethanol and drugs of abuse, their blockade may offer pharmacological targets for treating patients with AUD who are heavy smokers. For more information on varenicline, consult Chapter 11.

Drug Facts for Your Personal Formulary: Drugs Used to Treat Alcohol Use Disorder

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Disulfiram	• AUD	ALDH inhibitor. Causes adverse effects from increased acetaldehyde when taken with alcohol. Poor patient compliance.
Naltrexone	• AUD • Opioid dependence after opioid detoxification	μ -opioid receptor antagonist. Nausea, liver damage at high doses. Available in oral and long-acting injectable formulations. Contraindicated in patients with liver disease or taking opioids concurrently.
Acamprosate	• AUD	Unknown mechanism, may block hyperglutamatergic state. May work best in abstinent alcoholics.
Benzodiazepines	• Management of alcohol withdrawal • Anxiety/panic/seizure disorders • Insomnia • Anesthetic premedication	\uparrow GABA binding at GABA_A receptors. Chlordiazepoxide, lorazepam, diazepam, oxazepam, midazolam, and clorazepate are used in the U.S. to manage alcohol withdrawal symptoms.
Fomepizole	• Methanol poisoning	ADH inhibitor.
Drugs Not FDA Approved for Treatment of AUD But Approved Elsewhere or Found Clinically Useful		
Gabapentin	• AUD • Epileptic seizures and neuropathic pain	Blocks neuronal voltage-gated Ca^{2+} channels. Reduced alcohol cravings in a clinical trial.
Varenicline	• \downarrow alcohol consumption in clinical trials • Smoking cessation	Partial or full agonist at some central nAChR subtypes.
Nalmefene	• AUD • Opioid overdose/dependence	μ - and κ -opioid receptor antagonist. Approved in Europe for as-needed use to decrease drinking. Advantages over naltrexone: no liver toxicity, longer duration of action, higher affinity. Approved for opioid overdose but was discontinued in the U.S.
Baclofen	• AUD • Spasticity	GABA_B receptor agonist, skeletal muscle relaxant, and antispasmodic agent.

Drug Use Disorders and Addiction

Charles P. O'Brien

THE CONFUSING TERMINOLOGY OF DRUG USE DISORDERS

ORIGINS OF SUBSTANCE USE DISORDERS

- Agent (Drug) Variables
- Host (User) Variables
- Environmental Variables

PHARMACOLOGICAL PHENOMENA

- Tolerance
- Physical Dependence
- Withdrawal Syndrome

CLINICAL ISSUES: CNS DEPRESSANTS

- Ethanol
- Benzodiazepines

- Barbiturates
- Nicotine
- Opioids

CLINICAL ISSUES: COCAINE AND OTHER PSYCHOSTIMULANTS

- Cocaine
- Amphetamine and Related Agents
- Caffeine
- Cannabinoids (Marijuana)
- Psychedelic Agents

The Confusing Terminology of Drug Use Disorders

The terminology of drug dependence, abuse, and addiction has long elicited confusion that stems from the fact that repeated use of certain prescribed medications can produce neuroplastic changes resulting in two distinctly abnormal states. The first state is *dependence*, or “physical” dependence, produced when there is progressive pharmacological adaptation to the drug resulting in tolerance. Tolerance is a normal reaction that is often mistaken for a sign of “addiction.” In the tolerant state, repeating the same dose of a drug produces a smaller effect. If the drug is abruptly stopped, a withdrawal syndrome ensues in which the adaptive responses are now unopposed by the drug. The appearance of withdrawal symptoms is the cardinal sign of “physical” dependence. *Addiction*, the second abnormal state produced by repeated drug use, occurs in only a minority of those who initiate drug use; addiction leads progressively to compulsive, out-of-control drug use.

Addiction can be considered as a form of maladaptive memory. Addiction begins with the administration of substances (e.g., cocaine) or behaviors (e.g., the thrill of gambling) that directly and intensely activate brain reward circuits. Activation of these circuits motivates normal behavior, and most humans simply enjoy the experience without being compelled to repeat it. For some (~16% of those who try cocaine), the experience produces strong conditioned associations to environmental cues that signal the availability of the drug or the behavior. The individual becomes drawn into compulsive repetition of the experience, focusing on the immediate pleasure despite negative long-term consequences and neglect of important social responsibilities. The distinction between dependence and addiction is important because patients with pain sometimes are deprived of adequate opioid medication by their physician simply because they have shown evidence of tolerance or they exhibit withdrawal symptoms if the analgesic medication is stopped or reduced abruptly. The most recent revision of the classification system (*Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*; see American Psychiatric Association, 2013) makes a clear distinction between normal tolerance and a drug use disorder involving compulsive drug seeking.

Origins of Substance Use Disorders

Most of those who initiate use of a drug with addiction potential do not develop a drug use disorder. Many variables operate simultaneously to influence the likelihood that a beginning drug user will lose control and develop an addiction. These variables can be organized into three categories: agent (drug), host (user), and environment (Table 24–1).

Agent (Drug) Variables

Reinforcement refers to the capacity of drugs to produce effects that make the user wish to take them again. The more strongly reinforcing a drug is, the greater is the likelihood that the drug will be abused. Reinforcing properties of drugs are associated with their capacity to increase neuronal activity in brain reward areas (see Chapters 13 and 14). Cocaine, amphetamine, ethanol, opiates, cannabinoids, and nicotine reliably increase extracellular fluid DA levels in the ventral striatum, specifically the nucleus accumbens region. In contrast, drugs that block DA receptors generally produce bad feelings (i.e., *dysphoric effects*). Despite strong correlative findings, a precise causal relationship between DA and euphoria/dysphoria has not been established, and other findings emphasize additional roles of 5HT, glutamate, NE, endogenous opioids, and GABA in mediating the reinforcing effects of drugs.

The abuse liability of a drug is enhanced by rapidity of onset. When coca leaves are chewed, cocaine is absorbed slowly; this produces low cocaine levels in the blood and few, if any, behavioral problems. Crack cocaine, sold illegally and at a low price (\$1–\$3 per dose in 2016), is alkaloidal cocaine (free base) that can be readily vaporized by heating. Simply inhaling the vapors produces blood levels comparable to those resulting from intravenous cocaine owing to the large surface area for absorption into the pulmonary circulation following inhalation. Thus, inhalation of crack cocaine is much more addictive than chewing, drinking, or sniffing cocaine. The risk for developing addiction among those who try nicotine is about twice that for those who try cocaine (Table 24–2). This does not imply that the pharmacological addiction liability of nicotine is twice that of cocaine. Rather, there are other variables listed in Table 24–1 in the categories of Agent (e.g., mode of administration), Host, and Environment that influence the development of addiction.

Abbreviations

AIDS: acquired immune deficiency syndrome
CDC: U.S. Centers for Disease Control and Prevention
CNS: central nervous system
DA: dopamine
DAT: dopamine transporter
DEA: Drug Enforcement Agency
DMT: *N, N*-dimethyltryptamine
DOM: dimethoxymethylamphetamine
EEG: electroencephalogram
FDA: U.S. Food and Drug Administration
GABA: γ -aminobutyric acid
GI: gastrointestinal
GPCR: G protein–coupled receptor
5HT: serotonin
LSD: lysergic acid diethylamide
MDA: methylenedioxymphetamine
MDMA: methylenedioxymethamphetamine
MOR: μ opioid receptor
NE: norepinephrine
NMDA: *N*-methyl-D-aspartate
PCP: phenylcyclidine
 Δ -9-THC: Δ -9-tetrahydrocannabinol

TABLE 24–1 ■ MULTIPLE SIMULTANEOUS VARIABLES AFFECTING ONSET AND CONTINUATION OF DRUG ABUSE AND ADDICTION

Agent (drug)
Availability
Cost
Purity/potency
Mode of administration
Chewing (absorption <i>via</i> oral mucous membranes)
Gastrointestinal
Intranasal
Subcutaneous and intramuscular
Intravenous
Inhalation
Speed of onset and termination of effects (pharmacokinetics: combination of agent and host)
Host (user)
Heredity
Innate tolerance
Speed of developing acquired tolerance
Likelihood of experiencing intoxication as pleasure
Metabolism of the drug (nicotine and alcohol data already available)
Psychiatric symptoms
Prior experiences/expectations
Propensity for risk-taking behavior
Environment
Social setting
Community attitudes
Peer influence, role models
Availability of other reinforcers (sources of pleasure or recreation)
Employment or educational opportunities
Conditioned stimuli: environmental cues become associated with drugs after repeated use in the same environment

TABLE 24–2 ■ USE, ADDICTION, AND RISK AMONGST USERS OF TOBACCO, ETHANOL, AND ILLICIT DRUGS IN THE U.S., 1992–1994

AGENT	EVER USED ^a (%)	ADDICTION (%)	RISK OF ADDICTION (%)
Tobacco	75.6	24.1	31.9
Alcohol	91.5	14.1	15.4
Illicit drugs	51.0	7.5	14.7
<i>Cannabis</i>	46.3	4.2	9.1
<i>Cocaine</i>	16.2	2.7	16.7
<i>Stimulants</i>	15.3	1.7	11.2
<i>Anxiolytics</i>	12.7	1.2	9.2
<i>Analgesics</i>	9.7	0.7	7.5
<i>Psychedelics</i>	10.6	0.5	4.9
<i>Heroin</i>	1.5	0.4	23.1
<i>Inhalants</i>	6.8	0.3	3.7

^aThe ever-used and addiction percentages are those of the general population. The risk of addiction is specific to the drug indicated and refers to the percentage who met criteria for addiction among those who reported having used the agent at least once (i.e., each value in the rightmost column was obtained by expressing the number in the Addiction column as a percentage of the number in the Ever Used column, subject to errors of rounding).

Comparative epidemiology of dependence on tobacco, alcohol, controlled substances and the inhalants: basic findings from the National Comorbidity Survey. *Exp Clin Psychopharmacol*, 1994, 2:244–268. This study was repeated in 2001–2003: Degenhardt L, et al. Epidemiological patterns of drug use in the United States: evidence from the National Comorbidity Survey Replication, 2001–2003. doi:10.1016/j.drugalcdep.2007.03.007. Accessed July 10, 2016. The National Institute on Drug Abuse conducted a related study in 2014: available at: <https://www.drugabuse.gov/national-survey-drug-use-health>. Accessed July 10, 2016.

Host (User) Variables

Effects of drugs vary among individuals. Polymorphism of genes that encode enzymes involved in absorption, metabolism, and excretion of a drug and its receptor-mediated responses may contribute to the effects of the drug across the addiction cycle (e.g., euphoria, reinforcement, etc.) (see Chapters 2 through 7). Innate tolerance to alcohol may represent a biological trait that contributes to the development of alcoholism. While innate tolerance increases vulnerability to alcoholism, impaired metabolism may *protect* against it (see Chapter 23). Similarly, individuals who inherit a gene associated with slow nicotine metabolism may experience unpleasant effects when beginning to smoke and reportedly have a lower probability of becoming nicotine dependent.

Psychiatric disorders constitute another category of host variables. People with anxiety, depression, insomnia, or even shyness may find that certain drugs give them relief. However, the apparent beneficial effects are transient, and repeated use of the drug may lead to tolerance and eventually compulsive, uncontrolled drug use. While psychiatric symptoms are seen commonly in drug abusers presenting for treatment, most of these symptoms begin *after* the person starts abusing drugs. Thus, drugs of abuse appear to produce more psychiatric symptoms than they relieve.

Environmental Variables

Initiating and continuing illegal drug use is influenced significantly by societal norms and peer pressure.

Pharmacological Phenomena

Tolerance

Tolerance, the most common response to repetitive use of the same drug, can be defined as the reduction in response to the drug after

Figure 24-1 Shifts in a dose-response curve with tolerance and sensitization. The solid black curve describes the dose-response relationship to initial doses (the “control” curve). With tolerance, there is a shift of the curve to the right such that higher doses are required to achieve equivalent effects. With sensitization, the dose response shifts leftward, and a given dose produces a greater effect than in the control case.

repeated administrations. Consider an idealized drug dose-response curve (Figure 24-1). As the dose of the drug increases, the observed effect of the drug increases. With repeated use of the drug, however, the curve shifts to the right (tolerance). There are many forms of tolerance, likely arising through multiple mechanisms.

Tolerance to some drug effects develops much more rapidly than to other effects of the same drug. For example, tolerance develops rapidly to the euphoria produced by opioids such as heroin, and addicts tend to increase their dose to reexperience that elusive “high.” In contrast, tolerance to the GI effects of opioids develops more slowly. The discrepancy between tolerance to euphorogenic effects (rapid) and tolerance to effects on vital functions such as respiration and blood pressure (slow) can lead to potentially fatal overdoses.

We can define multiple aspects of tolerance and give examples of some general mechanisms and dosing schedules that contribute:

- *Innate tolerance* refers to genetically determined lack of sensitivity to a drug the first time that it is experienced.
- *Acquired tolerance* can be divided into three major types—*pharmacokinetic*, *pharmacodynamic*, and *learned tolerance*—and includes acute, reverse, and cross-tolerance.
 1. *Pharmacokinetic* or *dispositional tolerance* refers to changes in the distribution or metabolism of a drug after repeated administrations, such that a given dose produces a lower blood concentration than the same dose did on initial exposure. The most common mechanism is an increase in the rate of metabolism of the drug. For example, chronic administration of barbiturates induces hepatic CYPs 1A2, 2C9, 2C19, and 3A4, thereby enhancing the metabolism of drugs that are substrates for these enzymes.
 2. *Pharmacodynamic tolerance* refers to adaptive changes that have taken place within systems affected by the drug so that response to a given concentration of the drug is altered (usually reduced). Examples include drug-induced changes in receptor density or efficiency of receptor coupling to signal transduction pathways (see Chapter 3).
 3. *Learned tolerance* refers to a reduction in the effects of a drug due to compensatory mechanisms that are acquired by past experiences. One type of learned tolerance is called *behavioral tolerance*. A common example is learning to walk a straight line despite the motor impairment produced by alcohol intoxication. At higher levels of intoxication, behavioral tolerance is overcome, and the behavioral deficits are obvious.
- *Conditioned tolerance* (situation-specific tolerance) develops when environmental cues or situations consistently are paired with the

administration of a drug. When a drug affects homeostatic balance by producing sedation and changes in blood pressure, pulse rate, gut activity, and so on, there is usually a reflexive counteraction or adaptation in the direction of maintaining the status quo. If a drug always is taken in the presence of specific environmental cues (e.g., smell of drug preparation and sight of syringe), these cues begin to predict the effects of the drug, and the adaptations begin to occur, which will prevent the full manifestation of the drug's effects (i.e., cause tolerance). This mechanism follows classical (Pavlovian) principles of learning and results in drug tolerance under circumstances where the drug is “expected.”

- *Acute tolerance* refers to rapid tolerance developing with repeated use on a single occasion, such as in a “binge.” For example, repeated doses of cocaine over several hours produce a decrease in response to subsequent doses of cocaine during the binge. This is the opposite of *sensitization*, observed with an intermittent-dosing schedule.
- *Sensitization* or *reverse tolerance* refers to an increase in response with repetition of the same dose of the drug. Sensitization results in a shift to the left of the dose-response curve (see Figure 24-1). Sensitization, in contrast to acute tolerance during a binge, requires a longer interval between doses, usually about 1 day. Sensitization can occur with stimulants such as cocaine or amphetamine.
- *Cross-tolerance* occurs when repeated use of a drug in a given category confers tolerance not only to that drug but also to other drugs in the same pharmacological category. Understanding cross-tolerance is important in the medical management of persons dependent on a drug.
- *Detoxification* is a form of treatment of drug dependence that involves giving gradually decreasing doses of the drug to prevent withdrawal symptoms, thereby weaning the patient from the drug of dependence. Detoxification can be accomplished with any medication in the same category as the initial drug of dependence. For example, users of heroin show cross-tolerance to other opioids. Thus, the detoxification of heroin-dependent patients can be accomplished with any medication that activates MORs.

These issues of tolerance, while straightforward, seem to produce a dangerous misunderstanding among self-medicating opioid users. Degrees of tolerance depend on the type of opioid, its half-life, and the route of administration. The typical addicted user is craving the “high” and seems willing to risk overdose by going beyond the safe level. This is especially dangerous when they have progressed to intravenous injection. Accidental overdose has become so common in the U.S. that death in this manner now exceeds the toll for traffic accidents in young people (Rudd et al., 2016).

Physical Dependence

Physical dependence is a state that develops as a result of the adaptation (tolerance) produced by a resetting of homeostatic mechanisms in response to repeated drug use. A person in this adapted or physically dependent state requires continued administration of the drug to maintain normal function. If administration of the drug is stopped abruptly, there is another imbalance, and the affected systems must readjust to a new equilibrium without the drug.

Withdrawal Syndrome

Withdrawal signs and symptoms occur when drug administration in a physically dependent person is terminated abruptly. The appearance of a withdrawal syndrome when administration of the drug is terminated is the only actual evidence of physical dependence. The type of withdrawal symptoms depends on the pharmacological category of the drug of dependence. Thus, withdrawal of a stimulant causes sedation during withdrawal. Withdrawal of an opioid produces craving for the opioid and physical symptoms, such as nausea, vomiting, and diarrhea, that are the opposite of the opioid's effects.

Pharmacokinetic variables are of considerable importance in the amplitude and duration of the withdrawal syndrome. Tolerance, physical dependence, and withdrawal are all biological phenomena. They are the natural consequences of drug use and can be produced in experimental animals and in any human being who takes certain

medications repeatedly. These symptoms in themselves do not imply that the individual is involved in drug misuse or addiction. *Patients who take medicine for appropriate medical indications and in correct dosages still may show tolerance, physical dependence, and withdrawal symptoms* if the drug is stopped abruptly rather than gradually. A physician prescribing a medication that normally produces tolerance must understand the difference between dependence and addiction and be mindful of withdrawal symptoms if the dose is reduced.

Clinical Issues: CNS Depressants

Abuse of multiple drugs in combination is common. Alcohol is so widely available that it is combined with practically all other categories of drugs. Some combinations reportedly are taken because of their interactive effects. When confronted with a patient exhibiting signs of overdose or withdrawal, the physician must be aware of these possible combinations because each drug may require a different and specific treatment.

Ethanol

More than 90% of American adults report experience with ethanol (commonly called “alcohol”). Ethanol is classified as a depressant because it produces sedation and sleep. However, the initial effects of alcohol, particularly at lower doses, often are perceived as stimulation owing to a suppression of inhibitory systems (see Chapter 23). Heavy use of ethanol causes development of tolerance and physical dependence sufficient to produce an alcohol withdrawal syndrome when intake is stopped (Table 24–3).

Tolerance, Physical Dependence, and Withdrawal

The symptoms of mild intoxication by alcohol vary among individuals. Some experience motor incoordination and sleepiness. Others initially become stimulated. As the blood level increases, the sedating effects increase, with eventual coma and death occurring at high blood alcohol levels. The innate tolerance to alcohol varies greatly among individuals and is related to family history of alcoholism (Wilhelmsen et al., 2003). Experience with alcohol can produce greater tolerance (acquired tolerance) such that extremely high blood levels (300–400 mg/dL) can be found in alcoholics who do not appear grossly sedated. In these cases, the lethal dose does not increase proportionately to the sedating dose; thus, the margin of safety is decreased.

Heavy consumers of alcohol acquire tolerance and also develop a state of physical dependence. This often leads to drinking in the morning to restore blood alcohol levels diminished during the night. The alcohol withdrawal syndrome generally depends on the size of the average daily dose and usually is “treated” by resumption of alcohol ingestion. Withdrawal symptoms are experienced frequently but usually are not severe or life threatening until they occur in conjunction with other problems, such as

infection, trauma, malnutrition, or electrolyte imbalance. In the setting of such complications, the syndrome of *delirium tremens* becomes likely.

Alcohol addiction produces cross-tolerance to other sedatives, such as benzodiazepines. This tolerance is operative in abstinent alcoholics, but while the alcoholic is drinking, the sedating effects of alcohol add to those of other sedatives. This is particularly true for benzodiazepines, which are relatively safe in overdose when given alone but potentially are lethal in combination with alcohol. The chronic use of alcohol and other sedatives is associated with the development of depression and the risk of suicide. Cognitive deficits have been reported in alcoholics tested while sober. These deficits usually improve with abstinence. More severe recent memory impairment is associated with specific brain damage caused by nutritional deficiencies common in alcoholics (e.g., thiamine deficiency). Medical complications of alcohol abuse and dependence include liver disease, cardiovascular disease, endocrine and GI effects, and malnutrition, in addition to the CNS dysfunctions outlined previously. Ethanol readily crosses the placental barrier, producing the fetal alcohol syndrome, a major cause of mental retardation (see Chapter 23).

Pharmacological Interventions

Detoxification. Although most mild cases of alcohol withdrawal never come to medical attention, severe cases require general evaluation; attention to hydration and electrolytes; vitamins, especially high-dose thiamine; and a sedating medication that has cross-tolerance with alcohol. To block or diminish the symptoms described in Table 24–3, a short-acting benzodiazepine such as oxazepam can be used at a dose of 15–30 mg every 6–8 h according to the stage and severity of withdrawal; some authorities recommend a long-acting benzodiazepine unless there is demonstrated liver impairment. Anticonvulsants such as carbamazepine have been shown to be effective in alcohol withdrawal, but not as well as benzodiazepines.

Pharmacotherapy. Detoxification is the first step of treatment. Complete abstinence is the objective of long-term treatment, and this is best accomplished by a combination of relapse prevention, anticraving medication, and cognitive behavioral therapy. Disulfiram has been useful in some programs that focus behavioral efforts to promote ingestion of the medication. Disulfiram blocks aldehyde dehydrogenase, resulting in the accumulation of acetaldehyde (Figure 23–1), which produces an unpleasant flushing reaction and nausea when alcohol is ingested. Knowledge that this unpleasant reaction will ensue may help the patient to resist the urge to resume drinking alcohol. However, disulfiram has not proven to be effective in controlled clinical trials because so many patients choose to stop the medication rather than the alcohol.

Naltrexone is an opioid receptor antagonist that blocks the endorphin activation properties of alcohol. Chronic administration of naltrexone decreased the rate of relapse to heavy drinking in randomized clinical trials. The effect varied from strong to weak, but overall, reduction in heavy drinking was a consistent finding (Pettinati et al., 2006).

Naltrexone works best in combination with behavioral treatment programs that encourage adherence to medication and abstinence from alcohol. A depot preparation with a duration of 30 days is now available; it greatly improves medication adherence. Depot naltrexone can also be used in the prevention of relapse in opioid addiction (Lee et al., 2016).

Recent studies of alcohol detoxification have reported that gabapentin can aid in the transition to the abstinent state, possibly by improvement in sleep. Acamprosate, a competitive inhibitor of the NMDA-type glutamate receptor (see Table 23–2), appears to normalize the dysregulated neurotransmission associated with chronic ethanol intake and thereby to attenuate one of the mechanisms that lead to relapse.

Benzodiazepines

Benzodiazepines are used mainly for the treatment of anxiety disorders and insomnia (see Chapters 15 and 17). These agents are widely used, and abuse of prescription benzodiazepines is not uncommon. They may also be combined with alcohol or methadone in the treatment of opioid addiction. The proportion of patients who become tolerant and physically dependent on benzodiazepines increases after several months

TABLE 24–3 ■ ALCOHOL WITHDRAWAL SYNDROME

Alcohol craving
Tremor, irritability
Nausea
Sleep disturbance
Tachycardia
Hypertension
Sweating
Perceptual distortion
Seizures (6–48 h after last drink)
Visual (and occasionally auditory or tactile) hallucinations (12–48 h after last drink)
Delirium tremens (48–96 h after last drink; rare in uncomplicated withdrawal)
Severe agitation, confusion
Fever, profuse sweating
Tachycardia, dilated pupils
Nausea, diarrhea

TABLE 24-4 ■ BENZODIAZEPINE WITHDRAWAL SYMPTOMS**Following moderate-dose usage**

Anxiety, agitation
 Increased sensitivity to light and sound
 Paresthesias, strange sensations
 Muscle cramps
 Myoclonic jerks
 Sleep disturbance
 Dizziness

Following high-dose usage

Seizures
 Delirium

of use, and abrupt reduction of the dose or stopping the medication produces withdrawal symptoms (Table 24-4).

It can be difficult to distinguish benzodiazepine withdrawal symptoms from the reappearance of the anxiety symptoms for which the benzodiazepine was originally prescribed. Some patients may increase their dose over time as tolerance develops to the sedative effects. Antianxiety benefits, however, seem to continue to occur long after tolerance to the sedating effects. Moreover, some patients continue to take the medication for years in appropriate doses according to medical directions and are able to function effectively as long as they take the medication. Patients with a history of alcohol or other drug abuse problems have an increased risk for the development of benzodiazepine abuse and should rarely, if ever, be treated with benzodiazepines on a chronic basis.

Pharmacological Interventions

If patients receiving long-term benzodiazepine treatment by prescription wish to stop their medication, the process may take months of gradual dose reduction. Withdrawal symptoms may occur during this outpatient detoxification, but in most cases the symptoms are mild. Patients who have been on low doses of benzodiazepines for years usually have no adverse effects. If anxiety symptoms return, a nonbenzodiazepine such as buspirone may be prescribed. Some authorities recommend transferring the patient to a benzodiazepine with a long $t_{1/2}$ during detoxification; others recommend the anticonvulsants carbamazepine and phenobarbital. The specific benzodiazepine receptor antagonist flumazenil is useful in the treatment of overdose and in reversing the effects of long-acting benzodiazepines used in anesthesia.

Abusers of high doses of benzodiazepines usually require inpatient detoxification. Frequently, benzodiazepine abuse is part of a combined dependence involving alcohol, opioids, and cocaine. Detoxification can be a complex clinical pharmacological challenge requiring knowledge of the pharmacokinetics of each drug. One approach to complex detoxification is to focus on the CNS depressant drug and temporarily hold the opioid component constant with a low dose of methadone or buprenorphine. A long-acting benzodiazepine such as diazepam or clonazepam or a long-acting barbiturate such as phenobarbital can be used to block the sedative withdrawal symptoms. After detoxification, the prevention of relapse requires a long-term outpatient rehabilitation program similar to the treatment of alcoholism. No specific medications have been found to be useful in the rehabilitation of sedative abusers, but specific psychiatric disorders such as depression or schizophrenia, if present, require appropriate medications.

Barbiturates

Abuse problems with barbiturates resemble those seen with benzodiazepines in many ways, and treatment of abuse and addiction to barbiturates should be handled similarly to interventions for the abuse of alcohol and benzodiazepines. Because drugs in this category frequently are prescribed as hypnotics for patients complaining of insomnia, physicians should be aware of the problems that can develop when the hypnotic

agent is withdrawn and of possible causes for insomnia that are treatable by other means. Insomnia often is a symptom of an underlying chronic problem, such as depression or respiratory dysfunction. Long-term prescription of sedative medications can change the physiology of sleep and should be avoided. When the sedative is stopped, there is a rebound effect with worsened insomnia. Whether from prescribed hypnotic or self-administered alcohol, medication-induced rebound insomnia requires detoxification by gradual dose reduction. Physicians should not recommend a bedtime drink of alcohol to relieve insomnia; the result is usually disordered sleep.

Nicotine

Nicotine and agents for smoking cessation are discussed in Chapter 11. Because nicotine provides the reinforcement for cigarette smoking, the most common cause of preventable death and disease in the U.S., it is arguably the most dangerous dependence-producing drug. Although more than 80% of smokers express a desire to quit, only 35% try to stop each year, and fewer than 5% are successful in unaided attempts to quit.

Tobacco (nicotine) addiction is influenced by multiple variables. Nicotine itself produces reinforcement; users compare nicotine to stimulants such as cocaine or amphetamine, although its effects are of lower magnitude. While there are many casual users of alcohol and cocaine, few individuals who smoke cigarettes smoke a small enough quantity (≤ 5 cigarettes per day) to avoid dependence. Nicotine is absorbed readily through the skin, mucous membranes, and lungs. The pulmonary route produces discernible CNS effects in as little as 7 sec. Thus, each puff produces some discrete reinforcement. With 10 puffs per cigarette, the 1-pack-per-day smoker reinforces the habit 200 times daily.

In dependent smokers, the urge to smoke correlates with a low blood nicotine level, as though smoking were a means to achieve a certain nicotine level and thus avoid nicotine withdrawal symptoms (Table 24-5). Depressed mood (dysthymic disorder, affective disorder) is associated with nicotine dependence, but it is not known whether depression can predispose one to begin smoking or whether depression develops secondarily during the course of nicotine dependence.

Pharmacological Interventions

The nicotine withdrawal syndrome can be alleviated by nicotine replacement therapy (e.g., nicotine inhaler and nasal spray, nicotine gum or lozenge, or nicotine transdermal patch). Different methods of nicotine delivery provide different blood nicotine levels over varying time courses (Figure 24-2). These methods suppress the symptoms of nicotine withdrawal. Although these treatments result in more smokers achieving abstinence, most resume smoking over the ensuing weeks or months. A sustained-release preparation of the antidepressant bupropion (see Chapter 15) improves abstinence rates among smokers and remains a useful option. The cannabinoid CB₁ receptor inverse agonist rimonabant improves abstinence rates and reduces the weight gain seen frequently in ex-smokers; unfortunately, rimonabant was found in clinical trials to be linked to depressive and neurologic symptoms and is not approved in the U.S.

Varenicline, a partial agonist at the $\alpha 4\beta 2$ subtype of the nicotinic acetylcholine receptor, reduces cigarette craving and improves long-term abstinence rates. It has high receptor affinity, thus blocking access to nicotine, so if the treated smoker relapses, there is little reward, and abstinence is more likely to be maintained. In one clinical trial, the abstinence rate for

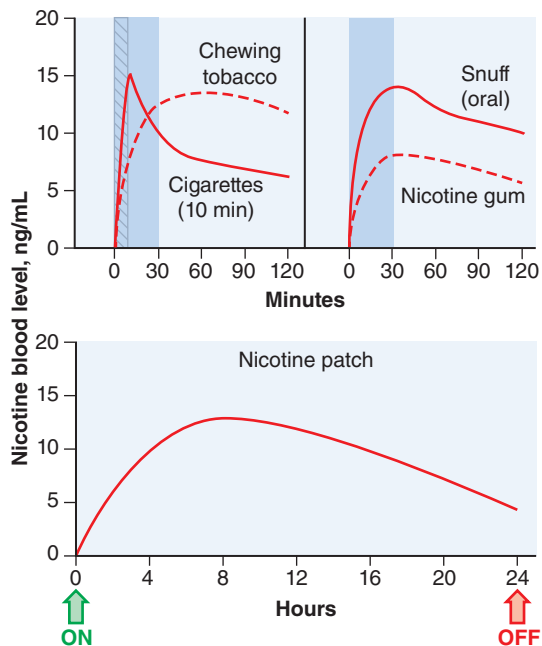

Figure 24-2 Blood levels of nicotine resulting from different delivery systems. In the upper panels, the shaded areas indicate the periods of nicotine delivery (30 min except for cigarettes, 10 min). In the lower panel, the arrows indicate the times of application and removal of a nicotine patch. These idealized curves are based on the findings of experiments by Benowitz et al., 1988, and Srivastava et al., 1991.

varenicline at 1 year was 36.7% versus 7.9% for placebo (Williams et al., 2007). There were initial reports of suicidal ideation in patients treated with this medication, but more recent studies in larger populations have failed to replicate these reports. See Chapter 11 for the pharmacology of varenicline.

Opioids

Opioid drugs are used primarily for the treatment of pain (see Chapter 20). Some of the CNS mechanisms that reduce the perception of pain also produce a state of well-being or euphoria. Thus, opioid drugs also are taken outside medical settings for the purpose of obtaining mood elevation or euphoria. Such use entails a high risk of overdose.

Death by Overdose

Heroin is the most frequently abused illicit opioid. Although there is no legal supply of heroin in the U.S., the drug is widely available on the illicit market. The purity of street heroin in the U.S. has increased over the past decade from about 4 mg heroin per 100-mg bag (range 0–8 mg/100 mg; the rest was nonopioid filler such as quinine) to a purity of 45%–75%, with some samples testing as high as 90%. This increase in purity has led to increased levels of physical dependence among heroin addicts. Users who interrupt regular dosing now develop more severe withdrawal symptoms. The more potent supplies can be smoked or administered nasally (snorted), making heroin use accessible to people who would not insert a needle into their veins. The increased potency of heroin has also contributed to more deaths by overdose.

Legal opioids are also abused. During early 21st century, there was increased interest among members of the medical profession in asking patients about pain, giving it a numerical rating, and treating it aggressively with prescription opioids as the agents of choice. In some cases, there was clear overprescribing, especially of extended-release forms of oxycodone, which have been linked to abuse, addiction, and overdose, and FDA approval of another long-acting formulation of oxycodone has provoked controversy (Manchikanti et al., 2014). Opioid overdose has become a common cause of death in many communities, and the latest

reports are worrisome, indicating that death from opioid overdose is now about 25,000 annually (DEA, 2015; Rudd et al., 2016). In response, the CDC announced more stringent guidelines for physicians to limit the prescription of opioids for chronic pain (Dowell et al., 2016; see Chapter 20).

Tolerance, Dependence, and Withdrawal

Injection of a heroin solution produces a variety of sensations, described as warmth, taste, or high and intense pleasure (“rush”) often compared with sexual orgasm. There are some differences among the opioids in their acute effects; for instance, morphine produces a prominent histamine-releasing effect (causing itching), and meperidine is notable for producing excitation or confusion. Even experienced opioid addicts, however, cannot distinguish between heroin and the common opioid hydromorphone, often used for pain in hospitalized patients. The popularity of heroin may be due to its widespread availability on the illicit market and its rapid onset of effect.

After intravenous injection, the effects begin in less than a minute. Heroin has high lipid solubility, crosses the blood-brain barrier quickly, and is deacetylated to the active metabolites 6-monoacetyl morphine and morphine. After the intense euphoria, which lasts from 45 sec to several minutes, there is a period of sedation and tranquility (“on the nod”) lasting up to an hour. The effects of heroin wear off in 3–5 h, depending on the dose. Experienced users may inject two to four times daily. Thus, the heroin addict is constantly oscillating between being “high” and feeling the sickness of early withdrawal (as depicted in Figure 24-3). This produces many problems in the homeostatic systems regulated at least in part by endogenous opioids.

Based on patient reports, tolerance develops early to the euphoria-producing effects of heroin and other opioids. There also is tolerance to the respiratory depressant, analgesic, sedative, and emetic properties. Heroin users tend to increase their daily dose, depending on their financial resources and the availability of the drug. Overdose is likely to occur when potency of the street sample is unexpectedly high or when the heroin is mixed with a far more potent opioid, such as fentanyl.

Addiction to heroin or other short-acting opioids produces behavioral disruptions and usually becomes incompatible with a productive life. Apart from the behavioral changes and the risk of overdose, chronic use of opioids is relatively nontoxic in and of itself. Nonetheless, the mortality rate for street heroin users is high. Heroin users commonly acquire bacterial infections producing skin abscesses, endocarditis; pulmonary infections, especially tuberculosis; and viral infections producing hepatitis C and AIDS.

Another factor is the use of opioids frequently in combination with other drugs, such as heroin and cocaine (“speedball”). Users report improved euphoria because of the combination, and there is evidence of

Figure 24-3 Comparative time courses of response to heroin and methadone. A person who injects heroin (↑) several times per day oscillates between being sick and being high (red line). In contrast, a methadone patient (purple line) remains in the “normal” range (blue band) with little fluctuation after dosing once per day. Ordinate values represent the subject’s mental and physical state, not plasma levels of the drug.

TABLE 24-6 ■ CHARACTERISTICS OF OPIOID WITHDRAWAL

SYMPTOMS	SIGNS

Protracted withdrawal Anxiety Insomnia Drug craving	Cyclic changes in weight, pupil size, respiratory center sensitivity

an interaction: Cocaine reduces the signs of opiate withdrawal, and heroin may reduce the irritability seen in chronic users of cocaine.

Pharmacological Interventions

Withdrawal and Detoxification. The first stage of treatment addresses physical dependence and consists of detoxification. The opioid withdrawal syndrome (Table 24-6) is unpleasant but not life threatening. It begins within 6–12 h after the last dose of a short-acting opioid and as long as 72–84 h after a long-acting opioid medication. The duration and intensity of the syndrome are related to the clearance of the individual drug. Heroin withdrawal is brief (5–10 days) and intense. Methadone withdrawal is slower in onset and lasts longer.

Opioid withdrawal signs and symptoms can be treated by three different approaches. *The first and most commonly used approach* consists of transfer to a prescription opioid medication and then gradual dose reduction. It is convenient to change the patient from a short-acting opioid such as heroin to a long-acting one such as methadone. The initial dose of methadone is typically 20–30 mg. The first day's total dose can be determined by the response and then reduced by 20% per day during the course of detoxification.

A second approach to detoxification involves the use of oral clonidine, an α_2 adrenergic agonist that decreases adrenergic neurotransmission from the locus ceruleus. This medication is approved for the treatment of hypertension but is commonly used off label to reduce symptoms of opioid withdrawal. Many of the autonomic symptoms of opioid withdrawal result from the loss of opioid suppression of the locus ceruleus system during the abstinence syndrome. Clonidine can alleviate many of these symptoms but not the generalized aches and opioid craving. Lofexidine, a similar medication, is FDA-approved for use as an opioid withdrawal suppressant. With clonidine and lofexidine, the dose must be titrated according to the stage and severity of withdrawal; postural hypotension is commonly a side effect.

A third method of treating opioid withdrawal involves activation of the endogenous opioid system without medication. The techniques proposed include acupuncture and several methods of CNS activation using transcutaneous electrical stimulation. While attractive theoretically, this method is not yet deemed practical.

Long-Term Management. If patients are simply discharged from the hospital after withdrawal from opioids, there is a high probability of a quick return to compulsive opioid use. Numerous factors influence relapse. The withdrawal syndrome does not end in 5–7 days; a *protracted withdrawal syndrome* (see Table 24-6) persists for up to 6 months. Physiological measures tend to oscillate as though a new set point were being established; during this phase, outpatient drug-free treatment has a low probability of success, even when the patient has received intensive prior treatment while protected from relapse in a residential program.

The most successful treatment of heroin addiction consists of stabilization on methadone in accordance with state and federal regulations. Patients who relapse repeatedly during drug-free treatment can be transferred directly to methadone without requiring detoxification. The dose of methadone must be sufficient to prevent withdrawal symptoms for at least 24 h.

The introduction of buprenorphine, a partial agonist at the MOR, represents a major change in the treatment of opiate addiction. This drug produces minimal withdrawal symptoms when discontinued and has a low potential for overdose, a long duration of action, and the ability to block heroin effects. Treatment can take place in a qualified physician's private office rather than in a special center, as required for methadone. When taken sublingually, buprenorphine is active; unfortunately, it also can be dissolved and injected (abused). As a solution to this problem, a buprenorphine-naloxone combination is available. When taken orally (sublingually), the naloxone moiety is not effective, but if the patient abuses the medication by injecting a solution of it, the naloxone will block or diminish the subjective high that could be produced by buprenorphine alone.

Antagonist Treatment. Naltrexone is an antagonist with a high affinity for MOR; it will competitively block the effects of heroin or MOR agonists. Naltrexone will not satisfy craving or relieve protracted withdrawal symptoms, but it can be used after detoxification for patients with high motivation to remain opioid free. Recently, an extended-release depot version of naltrexone has become available (Lee et al., 2016).

Clinical Issues: Cocaine and Other Psychostimulants

Cocaine

In the U.S. in 2014–2015, the number of people aged 12 years or older who are regular users of cocaine (at least monthly) in 2009 was about 1.5 million (FDA, 2016). About 60% of these met the criteria for dependence or abuse defined by the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 2013). Cocaine abuse occurs about twice as frequently in men as in women. Not all users become addicts. A key factor in addiction is the widespread availability of relatively inexpensive cocaine in the alkaloidal form (free base, “crack”), suitable for smoking, and in the hydrochloride powder form, suitable for nasal or intravenous use.

The reinforcing effects of cocaine and cocaine analogues correlate best with their effectiveness in inhibiting DAT, the transporter that recovers DA from the synapse. This leads to increased DA concentrations at critical brain sites. However, cocaine also blocks both NE and 5HT reuptake, and chronic use of cocaine leads to changes in these neurotransmitter systems as well. Cocaine produces a dose-dependent increase in heart rate and blood pressure accompanied by increased arousal, improved performance on tasks of vigilance and alertness, and a sense of self-confidence and well-being. Higher doses produce euphoria, which has a brief duration and often is followed by a desire for more drug. Repeated doses of cocaine may lead to involuntary motor activity, stereotyped behavior, and paranoia. Irritability and increased risk of violence are found among heavy chronic users. The $t_{1/2}$ of cocaine in plasma is about 50 min, but inhalant (crack) users typically desire more cocaine after 10–30 min.

COCAINE

The major route for cocaine metabolism involves hydrolysis of its two ester groups. Tissue esterases and spontaneous hydrolysis remove the

methyl ester to produce benzoylecgonine (30–40%); removal of the benzoyl moiety by butyrylcholinesterase yields ecgonine methyl ester (~50%). As a pharmacokinetic approach to treating cocaine toxicity and abuse, catalytic antibodies and mutations of human butyrylcholinesterase and a bacterial cocaine esterase have been developed that speed cocaine metabolism in animal models (Schindler and Goldberg, 2012).

Benzoylecgonine, produced on loss of the methyl group, represents the major urinary metabolite and can be found in the urine for 2–5 days after a binge. As a result, the benzoylecgonine test is a valid method for detecting cocaine use; the metabolite remains detectable in the urine of heavy users for up to 10 days. Ethanol is frequently abused with cocaine, as it reduces the irritability induced by cocaine. Dual addiction to alcohol and cocaine is common. When cocaine and alcohol are taken concurrently, cocaine may be transesterified to cocaethylene, which is equipotent to cocaine in blocking DA reuptake.

Addiction is the most common complication of cocaine abuse. In general, stimulants tend to be abused much more irregularly than opioids, nicotine, and alcohol. Binge use is common, and a binge may last hours to days, terminating only when supplies of the drug are exhausted.

Toxicity

Other risks of cocaine, beyond the potential for addiction, include cardiac arrhythmias, myocardial ischemia, myocarditis, aortic dissection, cerebral vasoconstriction, and seizures. Death from trauma also is associated with cocaine use. Cocaine may induce premature labor and abruptio placentae. Cocaine has been reported to produce a prolonged and intense orgasm if taken prior to intercourse, and users often indulge in compulsive and promiscuous sexual activity. However, chronic cocaine use reduces sexual drive. Chronic use is also associated with psychiatric disorders, including anxiety, depression, and psychosis.

Tolerance, Dependence, and Withdrawal

In intermittent users of cocaine, the euphoric effect typically is not subject to sensitization. On the contrary, most experienced users become desensitized and, over time, require more cocaine to obtain euphoria (i.e., tolerance develops). Because cocaine typically is used intermittently, even heavy users go through frequent periods of withdrawal or “crash.” The symptoms of withdrawal seen in users admitted to hospitals are listed in Table 24–7. Careful studies of cocaine users during withdrawal showed gradual diminution of these symptoms over 1–3 weeks. Residual depression, often seen after cocaine withdrawal, should be treated with antidepressant agents if it persists (see Chapter 15).

Pharmacological Interventions

Because cocaine withdrawal is generally mild, treatment of withdrawal symptoms usually is not required. The major problem in treatment is not detoxification but helping the patient to resist the urge to resume compulsive cocaine use. Rehabilitation programs involving individual and group psychotherapy based on the principles of Alcoholics Anonymous and behavioral treatments based on reinforcing cocaine-free urine tests result in significant improvement in the majority of cocaine users.

Animal models suggest that enhancing GABAergic inhibition can reduce reinstatement of cocaine self-administration, and a controlled clinical trial of topiramate showed a significant reduction in cocaine use. Topiramate also reduced the relapse rate in alcoholics, prompting current studies in patients dually dependent on cocaine and alcohol. Baclofen, a GABA_B agonist, was found in a single-site trial to reduce relapse in cocaine addicts but was not effective in a multisite trial. Modafinil is currently

being tested in clinical trials of cocaine, methamphetamine, alcohol, and other substance abuse disorders. A mild stimulant approved for treating narcolepsy, modafinil has had several positive clinical trials for use in cocaine withdrawal (Morgan et al., 2016). The medication reduces the euphoria produced by cocaine and relieves cocaine withdrawal symptoms. It remains under investigation for this purpose.

A novel approach to cocaine addiction employs a vaccine that produces cocaine-binding antibodies. Cocaine itself is not antigenic in humans; however, a conjugate of the cocaine metabolite, nor-cocaine, with the B subunit of cholera toxin has been constituted as a vaccine, and it causes a vigorous immune response with the production of antibodies (immunoglobulin G) that neutralize cocaine in the bloodstream. Initial reports were promising, but in a recent trial the vaccine did not demonstrate the expected efficiency (Kosten et al., 2014). For now, behavioral therapy remains the treatment of choice, with medication indicated for specific coexisting disorders such as depression.

Amphetamine and Related Agents

Subjective effects similar to those of cocaine are produced by *amphetamine*, *dextroamphetamine*, *methamphetamine*, *phenmetrazine*, *methylphenidate*, and *diethylpropion*. Amphetamines increase synaptic DA, NE, and 5HT primarily by stimulating presynaptic release of stored neurotransmitter (see Chapter 8). Intravenous or smoked methamphetamine produces an abuse/dependence syndrome similar to that of cocaine, although clinical deterioration may progress more rapidly. Methamphetamine addiction has become a major public health problem in the U.S. Behavioral and medical treatments for methamphetamine addiction are similar to those used for cocaine.

Caffeine

Caffeine, a mild stimulant, is the most widely used psychoactive drug in the world. It is present in soft drinks, coffee, tea, cocoa, chocolate, and numerous prescription and over-the-counter drugs.

Caffeine can inhibit cyclic nucleotide phosphodiesterases, mildly increases NE and DA release, and enhances neural activity in numerous brain areas. Caffeine is absorbed from the digestive tract, is distributed rapidly throughout all tissues, and easily crosses the placental barrier. Caffeine is metabolized largely by CYP1A2, yielding a mean biological half-life of ~5 h, a number that can vary widely. For instance, tobacco smoking reduces it by ~40%; oral contraceptives double it; fluvoxamine increases caffeine's half-life tenfold. Many of caffeine's effects are believed to occur by means of competitive antagonism at adenosine receptors. Adenosine is a neuromodulator (see Chapter 14) that resembles caffeine structurally. The mild sedating effects that occur when adenosine activates particular adenosine receptor subtypes can be antagonized by caffeine. Tolerance occurs rapidly to the stimulating effects of caffeine. Thus, a mild withdrawal syndrome has been produced in controlled studies by abruptly discontinuing the intake of as little as one to two cups of coffee per day. Caffeine withdrawal consists of feelings of fatigue and sedation. With higher doses, headaches and nausea have been reported during withdrawal; vomiting is rare.

Cannabinoids (Marijuana)

The cannabis plant has been cultivated for centuries for its presumed medicinal and psychoactive properties. The smoke from burning cannabis contains many chemicals, including 61 different cannabinoids that have been identified. One of these, Δ^9 -THC, produces most of the characteristic pharmacological effects of smoked marijuana. In the U.S., marijuana use remains prohibited by federal law, but it is approved in thirteen states as medicine and in eight states for recreational purposes. This is leading to increased marijuana use and a greater number of marijuana-associated auto accidents. The issues of whether and how to control the use of marijuana have not been resolved. In addition, the potencies of available botanical forms have generally not been standardized, and the dangers inherent in inhaling a smoke replete with organic molecules have not been defined for marijuana smoke.

TABLE 24–7 ■ COCAINE WITHDRAWAL SYMPTOMS AND SIGNS

Dysphoria, depression
Sleepiness, fatigue
Cocaine craving
Bradycardia

The human cannabinoid endogenous ligand/receptor/signaling systems are described in Chapter 14 (see Figure 14–17). This system is stimulated by exogenous Δ^9 -THC. The pharmacological effects of Δ^9 -THC vary with the dose, route of administration, experience of the user, vulnerability to psychoactive effects, and setting of use. Intoxication with marijuana produces changes in mood, perception, and motivation, but the effects most frequently sought are a “high” and a “mellowing out.” Effects vary with dose, but typically last about 2 h. During the high, cognitive functions, perception, reaction time, learning, and memory are impaired. Coordination and tracking behavior may be impaired for several hours beyond the perception of the high. Marijuana also produces complex behavioral changes such as giddiness and increased hunger. Unpleasant reactions such as panic or hallucinations and even acute psychosis may occur. These reactions are seen commonly with higher doses and with oral ingestion rather than smoked marijuana. Numerous clinical reports suggest that marijuana use may precipitate a recurrence of psychosis in people with a history of schizophrenia. One of the most controversial putative effects of marijuana is the production of an “amotivational syndrome.” This syndrome is not an official diagnosis but has been used to describe young people who drop out of social activities and show little interest in school, work, or other goal-directed activity. At the cellular level, there is no evidence that marijuana damages brain cells or produces any permanent functional changes. There is evidence that the CB₁ receptor, a highly abundant GPCR in the mammalian brain, can deliver neuroprotective signals in animal models of striatal damage (Blázquez et al., 2015).

Marijuana has medicinal effects, including antiemetic properties that relieve side effects of anticancer chemotherapy. It also has muscle-relaxing effects, anticonvulsant properties, and the capacity to reduce the elevated intraocular pressure of glaucoma. These medical benefits come at the cost of the psychoactive effects that often impair normal activities. Dronabinol is an approved formulation of Δ^9 -THC (see Chapters 14 and 50).

Tolerance, Dependence, and Withdrawal

Tolerance to most of the effects of marijuana can develop rapidly after only a few doses, but also disappears rapidly. Withdrawal symptoms are not seen in clinical populations. Human subjects develop a withdrawal syndrome when they receive regular oral doses of the agent (Table 24–8). This syndrome, however, is only seen clinically in persons who use marijuana on a daily basis and then suddenly stop. Marijuana abuse and addiction have no specific treatments. Heavy users may suffer from accompanying depression and thus may respond to antidepressant medication.

Psychedelic Agents

There are two main categories of psychedelic compounds, indoleamines and phenethylamines. The indoleamine hallucinogens include LSD, DMT, and psilocybin. The phenethylamines include mescaline, DOM, MDA, and MDMA. Both groups have a relatively high affinity for 5HT₂ receptors (see Chapter 13), but they differ in their affinity for other subtypes of 5HT receptors. There is a good correlation between the relative affinity of these compounds for 5HT₂ receptors and their potency as hallucinogens in humans. LSD interacts with most brain 5HT receptors as an agonist/partial agonist and elicits sensory distortions (especially visual) and hallucinations at doses as low as 1 μ g/kg. Current hypotheses of the mechanism of action of LSD and other hallucinogens focus on 5HT_{2A} receptor-mediated disruption of thalamic gating with sensory overload of the cortex (Nichols, 2016).

TABLE 24–8 ■ MARIJUANA WITHDRAWAL SYNDROME

Restlessness
Irritability
Mild agitation

Sleep EEG disturbance
Nausea, cramping

LSD

LSD is the most potent hallucinogenic drug, more than 3000 times more potent than mescaline. LSD is sold on the illicit market in a variety of forms. A popular contemporary system involves postage stamp-size papers impregnated with varying doses of LSD (50–300 μ g or more).

The effects of hallucinogenic drugs are variable, even in the same individual on different occasions. LSD is absorbed rapidly after oral administration, with effects beginning at 40–60 min, peaking at 2–4 h, and gradually returning to baseline over 6–8 h. At a dose of 100 μ g, LSD produces perceptual distortions and sometimes hallucinations; mood changes, including elation, paranoia, or depression; intense arousal; and sometimes a feeling of panic. Signs of LSD ingestion include pupillary dilation, increased blood pressure and pulse, flushing, salivation, lacrimation, and hyperreflexia. Visual effects are prominent. Colors seem more intense, and shapes may appear altered. The subject may focus attention on unusual items, such as the pattern of hairs on the back of the hand.

A “bad trip” usually consists of severe anxiety, although at times it can be marked by intense depression and suicidal thoughts. Visual disturbances usually are prominent. There are no documented toxic fatalities from LSD use, but fatal accidents and suicides have occurred during or shortly after intoxication. Prolonged psychotic reactions lasting 2 days or more may occur after the ingestion of a hallucinogen. Schizophrenic episodes may be precipitated in susceptible individuals, and there is some evidence that chronic use of these drugs is associated with the development of persistent psychotic disorders. Claims about the potential of psychedelic drugs for enhancing psychotherapy and for treating addictions and other mental disorders are not supported by controlled studies; there is no generally accepted indication for these drugs as medications.

Tolerance, Physical Dependence, and Withdrawal. Frequent, repeated use of psychedelic drugs is unusual; thus, tolerance is not commonly seen. Tolerance does develop to the behavioral effects of LSD after three or four daily doses, but no withdrawal syndrome has been observed.

Pharmacological Intervention. Because of the unpredictability of psychedelic drug effects, any use carries some risk. Users may require medical attention because of bad trips. Severe agitation may respond to diazepam (20 mg orally). “Talking down” by reassurance also is effective and is the management of first choice. Antipsychotic medications (see Chapter 16) may intensify the experience and thus are contraindicated. A particularly troubling aftereffect of LSD and similar drugs is the occasional occurrence of episodic visual disturbances. These originally were called “flashbacks” and resembled the experiences of prior LSD trips. Flashbacks belong to an official diagnostic category called the *hallucinogen persisting perception disorder*. The symptoms include false fleeting perceptions in the peripheral fields, flashes of color, geometric pseudohallucinations, and positive after-images. The visual disorder appears stable in half the cases and represents an apparently permanent alteration of the visual system. Precipitants include stress, fatigue, emergence into a dark environment, marijuana, antipsychotic agents, and anxiety states.

MDMA (“Ecstasy”) and MDA

MDMA and MDA are phenylethylamines that have stimulant as well as psychedelic effects.

Acute effects are dose dependent and include feelings of energy, altered sense of time, and pleasant sensory experiences with enhanced perception. Negative effects include tachycardia, dry mouth, jaw clenching, and muscle aches. At higher doses, visual hallucinations, agitation, hyperthermia, and panic attacks have been reported. A typical oral dose is one or two 100-mg tablets, producing effects lasting 3–6 h, although dosage and potency of street samples are variable (~100 mg of active drug per tablet).

Phencyclidine

PCP was developed originally as an anesthetic in the 1950s and later was abandoned because of a high frequency of postoperative delirium with hallucinations. It was classified as a dissociative anesthetic because, in the anesthetized state, the patient remains conscious with staring gaze, flat facies, and rigid muscles. PCP became a drug of abuse in the 1970s, first in an oral form and then in a smoked version enabling a better regulation of the dose.

As little as 50 µg/kg produces emotional withdrawal, concrete thinking, and bizarre responses to projective testing. Catatonic posturing also is produced and resembles that of schizophrenia. Abusers taking higher doses may appear to be reacting to hallucinations and may exhibit hostile or assaultive behavior. Anesthetic effects increase with dosage; stupor or coma may occur with muscular rigidity, rhabdomyolysis, and hyperthermia. Intoxicated patients in the emergency room may progress from aggressive behavior to coma, with elevated blood pressure and enlarged, nonreactive pupils. PCP binds with high affinity to sites located in the cortex and limbic structures, blocking NMDA-type glutamate receptors (see Table 14–2 and Figures 14–12 and 14–13). There is evidence that NMDA receptors are involved in ischemic neuronal death caused by high levels of excitatory amino acids; as a result, there is interest in PCP analogues that block NMDA receptors but with fewer psychoactive effects. Both PCP and ketamine (“special K”), another “club drug,” produce similar effects by altering the distribution of the neurotransmitter glutamate.

Medical Intervention. Overdose must be treated by life support; there is no antagonist of PCP effects and no proven way to enhance excretion, although acidification of the urine has been proposed. PCP coma may last 7–10 days. The agitated or psychotic state produced by PCP can be treated with diazepam. Prolonged psychotic behavior requires antipsychotic medication. Because of the anticholinergic activity of PCP, antipsychotic agents with significant anticholinergic effects such as chlorpromazine should be avoided.

Drugs Affecting Renal Excretory Function

Edwin K. Jackson

PART I: RENAL PHYSIOLOGY AND DIURETIC DRUG ACTION

- Renal Anatomy and Physiology
- Principles of Diuretic Action
- Inhibitors of Carbonic Anhydrase
- Osmotic Diuretics
- Inhibitors of $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ Symport: Loop Diuretics, High-Ceiling Diuretics
- Inhibitors of $\text{Na}^+\text{-Cl}^-$ Symport: Thiazide-Type and Thiazide-Like Diuretics
- Inhibitors of Renal Epithelial Na^+ Channels: K^+ -Sparing Diuretics
- Antagonists of Mineralocorticoid Receptors: Aldosterone Antagonists, K^+ -Sparing Diuretics
- Inhibitors of the Nonspecific Cation Channel: Natriuretic Peptides

- Adenosine Receptor Antagonists
- Clinical Use of Diuretics

PART II: WATER HOMEOSTASIS AND THE VASOPRESSIN SYSTEM

- Vasopressin Physiology
- Vasopressin Receptor Agonists
- Diseases Affecting the Vasopressin System
- Clinical Use of Vasopressin Agonists
- Clinical Use of Vasopressin Antagonists

The kidney filters the extracellular fluid volume across the renal glomeruli an average of 12 times a day, and the renal nephrons precisely regulate the fluid volume of the body and its electrolyte content via processes of secretion and reabsorption. Disease states such as hypertension, heart failure, renal failure, nephrotic syndrome, and cirrhosis may disrupt this balance. Diuretics increase the rate of urine flow and Na^+ excretion and are used to adjust the volume or composition of body fluids in these disorders. Precise regulation of body fluid osmolality is also essential. It is controlled by a finely tuned homeostatic mechanism that operates by adjusting both the rate of water intake and the rate of solute-free water excretion by the kidneys—that is, water balance. Abnormalities in this homeostatic system can result from genetic diseases, acquired diseases, or drugs and may cause serious and potentially life-threatening deviations in plasma osmolality.

Part I of this chapter first describes renal physiology, then introduces diuretics with regard to mechanism and site of action, effects on urinary composition, and effects on renal hemodynamics, and then integrates diuretic pharmacology with a discussion of mechanisms of edema formation and the role of diuretics in clinical medicine. Specific therapeutic applications of diuretics are presented in Chapters 28 (hypertension) and 29 (heart failure). *Part II* of this chapter describes the vasopressin system that regulates water homeostasis and plasma osmolality and factors that perturb those mechanisms and examines pharmacological approaches for treating disorders of water balance.

Part I: Renal Physiology and Diuretic Drug Action

Renal Anatomy and Physiology

The basic urine-forming unit of the kidney is the nephron. The initial part of the nephron, the renal (Malpighian) corpuscle, consists of a capsule (Bowman's capsule) and a tuft of capillaries (the glomerulus) residing within the capsule. The glomerulus receives blood from an afferent arteriole, and blood exits the glomerulus via an efferent arteriole. Ultrafiltrate produced by the glomerulus collects in the space between the glomerulus and capsule (Bowman's space) and enters a long tubular portion of the nephron, where the ultrafiltrate is reabsorbed and conditioned. Each human kidney is composed of about 1 million nephrons. Figure 25-1 illustrates subdivisions of the nephron.

Glomerular Filtration

In the glomerular capillaries, a portion of plasma water is forced through a filter that has three basic components: the fenestrated capillary endothelial cells, a basement membrane lying just beneath the endothelial cells, and the filtration slit diaphragms formed by epithelial cells that cover the basement membrane on its urinary space side. Solutes of small size flow with filtered water (solvent drag) into Bowman's space, whereas formed elements and macromolecules are retained by the filtration barrier.

Overview of Nephron Function

The kidney filters large quantities of plasma, reabsorbs substances that the body must conserve, and leaves behind or secretes substances that must be eliminated. The changing architecture and cellular differentiation along the length of a nephron are crucial to these functions (see Figure 25-1). The two kidneys in humans together produce about 120 mL of ultrafiltrate/min, yet only 1 mL of urine/min of urine; more than 99% of the glomerular ultrafiltrate is reabsorbed at a staggering energy cost. The kidneys consume 7% of total-body O_2 intake despite comprising only 0.5% of body weight.

The proximal tubule is contiguous with Bowman's capsule and takes a tortuous path until finally forming a straight portion that dives into the renal medulla. Normally, about 65% of filtered Na^+ is reabsorbed in the proximal tubule, and because this part of the tubule is highly permeable to water, reabsorption is essentially isotonic. Between the outer and inner strips of the outer medulla, the tubule abruptly changes morphology to become the DTL, which penetrates the inner medulla, makes a hairpin turn, and then forms the ATL. At the juncture between the inner and outer medulla, the tubule once again changes morphology and becomes the TAL. Together, the proximal straight tubule, DTL, ATL, and TAL segments are known as the *loop of Henle*.

The DTL is highly permeable to water, yet its permeabilities to NaCl and urea are low. In contrast, the ATL is permeable to NaCl and urea but is impermeable to water. The TAL actively reabsorbs NaCl but is impermeable to water and urea. Approximately 25% of filtered Na^+ is reabsorbed in the loop of Henle, mostly in the TAL, which has a large reabsorptive capacity. The TAL passes between the afferent and efferent arterioles and makes contact with the afferent arteriole by means of a cluster of specialized columnar epithelial cells known as the *macula densa*. The macula densa is strategically located to sense concentrations of NaCl leaving the loop of Henle. If the concentration of NaCl is too

Abbreviations

AA: arachidonic acid
ACTH: corticotropin (previously adrenocorticotrophic hormone)
ADH: antidiuretic hormone
AIP: aldosterone-induced protein
Aldo: aldosterone
Ang: angiotensin
ANP: atrial natriuretic peptide
ATL: ascending thin limb
AVP: arginine vasopressin
BL: basolateral membrane
BNP: brain natriuretic peptide
CA: carbonic anhydrase
cGMP: cyclic guanosine monophosphate
CHF: congestive heart failure
CNGC: cyclic nucleotide-gated cation channel
CNP: C-type natriuretic peptide
CNT: connecting tubule
COX: cyclooxygenase
DAG: diacylglycerol
DCT: distal convoluted tubule
DDAVP: 1-deamino-8-D-*AVP* (desmopressin)
DI: diabetes insipidus
DTL: descending thin limb
ECFV: extracellular fluid volume
ENaC: epithelial Na⁺ channel
ENCC1 or TSC: the absorptive Na⁺-Cl⁻ symporter
ENCC2, NKCC2, or BSC1: the absorptive Na⁺-K⁺-2Cl⁻
ENCC3, NKCC1, or BSC2: the secretory symporter
FDA: Food and Drug Administration
FF: filtration fraction
GFR: glomerular filtration rate
GPCR: G protein-coupled receptor
GTP: guanosine triphosphate
HCTZ: hydrochlorothiazide
HDL: high-density lipoprotein
HSD: 11-β-hydroxysteroid dehydrogenase
IMCD: inner medullary collecting duct
IP₃: inositol trisphosphate
LDL: low-density lipoprotein
LM: luminal membrane
LOX: lipoxygenase
LT: leukotriene
MR: mineralocorticoid receptor
MRA: mineralocorticoid receptor antagonist
mRNA: messenger RNA
NP: natriuretic peptide
NPA: asparagine-proline-alanine
NPR : natriuretic peptide receptor _ (e.g., NPRA, B, or C)
NSAID: nonsteroidal anti-inflammatory drug
OAT: organic anion transporter
PA: phosphatidic acid
PG: prostaglandin
PK_ : protein kinase _ (e.g., PKA, PKB, PKG)
PL_ : phospholipase _ (e.g., PLC, PLD)
PTH: parathyroid hormone
PVN: paraventricular nucleus
RAAS: renin-angiotensin-aldosterone system
RAS: renin-angiotensin system
RBF: renal blood flow
SGK-1: serum and glucocorticoid-stimulated kinase 1
SIADH: syndrome of inappropriate secretion of ADH

SNS: sympathetic nervous system
SON: supraoptic nucleus
TAL: thick ascending limb
TGF: tubuloglomerular feedback
TX: thromboxane
VP: vasopressin
VRUT: vasopressin-regulated urea transporter
vWD: von Willebrand disease
WCV: water channel-containing vesicle

high, the macula densa sends a chemical signal (perhaps adenosine or ATP) to the afferent arteriole of the same nephron, causing it to constrict, thereby reducing the GFR. This homeostatic mechanism, known as *TGF*, protects the organism from salt and volume wasting. The macula densa also regulates renin release from the adjacent juxtaglomerular cells in the wall of the afferent arteriole.

Approximately 0.2 mm past the macula densa, the tubule changes morphology once again to become the DCT. Like the TAL, the DCT actively transports NaCl and is impermeable to water. Because these characteristics impart the capacity to produce dilute urine, the TAL and the DCT are collectively called the *diluting segment of the nephron*, and the tubular fluid in the DCT is hypotonic regardless of hydration status. However, unlike the TAL, the DCT does not contribute to the countercurrent-induced hypertonicity of the medullary interstitium (described in material that follows).

The collecting duct system (segments 10–14 in Figure 25–1) is an area of fine control of ultrafiltrate composition and volume. It is here that final adjustments in electrolyte composition are made, a process modulated by the adrenal steroid *aldosterone*. Vasopressin (also called ADH) modulates water permeability of this part of the nephron as well. The more distal portions of the collecting duct pass through the renal medulla, where the interstitial fluid is markedly hypertonic. In the absence of ADH, the collecting duct system is impermeable to water, and dilute urine is excreted. In the presence of ADH, the collecting duct system is permeable to water, and water is reabsorbed. The movement of water out of the tubule is driven by the steep concentration gradient that exists between tubular fluid and medullary interstitium.

The hypertonicity of the medullary interstitium plays a vital role in the capacity of mammals and birds to concentrate urine, which is accomplished by a combination of the unique topography of the loop of Henle and the specialized permeabilities of the loop's subsegments. The "passive countercurrent multiplier hypothesis" proposes that active transport in the TAL concentrates NaCl in the interstitium of the outer medulla. Because this segment of the nephron is impermeable to water, active transport in the ascending limb dilutes the tubular fluid. As the dilute fluid passes into the collecting duct system, water is extracted if, and only if, ADH is present. Because the cortical and outer medullary collecting ducts have low permeability to urea, urea is concentrated in the tubular fluid. The IMCD, however, is permeable to urea, so urea diffuses into the inner medulla, where it is trapped by countercurrent exchange in the vasa recta (medullary capillaries that run parallel to the loop of Henle). Because the DTL is impermeable to salt and urea, the high urea concentration in the inner medulla extracts water from the DTL and concentrates NaCl in the tubular fluid of the DTL. As the tubular fluid enters the ATL, NaCl diffuses out of the salt-permeable ATL, thus contributing to the hypertonicity of the medullary interstitium.

General Mechanism of Renal Epithelial Transport

There are multiple mechanisms by which solutes may cross cell membranes (see Figure 5–4). The kinds of transport achieved in a nephron segment depend mainly on which transporters are present and whether they are embedded in the luminal or basolateral membrane. Figure 25–2 presents a general model of renal tubular transport that be summarized as follows:

1. Na⁺, K⁺-ATPase (sodium pump) in the basolateral membrane transports Na⁺ into the intercellular and interstitial spaces and K⁺ into the cell,

Figure 25–1 Anatomy and nomenclature of the nephron.

- establishing an electrochemical gradient for Na^+ across the cell membrane directed inward.
- Na^+ can diffuse down this Na^+ gradient across the luminal membrane via Na^+ channels and via membrane symporters that use the energy stored in the Na^+ gradient to transport solutes out of the tubular lumen and into the cell (e.g., Na^+ -glucose, Na^+ - H_2PO_4^- , and Na^+ -amino acid) and antiporters (e.g., Na^+ - H^+) that move solutes into the lumen as Na^+ moves down its gradient and into the cell.
- Na^+ exits the basolateral membrane into intercellular and interstitial spaces via the Na^+ pump.

- The action of Na^+ -linked symporters in the luminal membrane causes the concentration of substrates for these symporters to rise in the epithelial cell. These substrate/solute gradients then permit simple diffusion or mediated transport (e.g., symporters, antiporters, uniporters, and channels) of solutes into the intercellular and interstitial spaces.
- Accumulation of Na^+ and other solutes in the intercellular space creates a small osmotic pressure differential across the epithelial cell. In water-permeable epithelium, water moves into the intercellular spaces driven by the osmotic pressure differential. Water moves through aqueous pores in both the luminal and the basolateral cell membranes,

Figure 25-2 Generic mechanism of renal epithelial cell transport (see text for details). A, antiporter; ATPase, Na^+ , K^+ -ATPase (sodium pump); CH, ion channel; I, membrane-impermeable solutes; P, membrane-permeable solutes; PD, potential difference across indicated membrane or cell; S, symporter; U, uniporter; WP, water pore; X and Y, transported solutes.

- as well as through tight junctions (paracellular pathway). Bulk water flow carries some solutes into the interstitial space by solvent drag.
6. Movement of water into the interstitial space concentrates other solutes in the tubular fluid, resulting in an electrochemical gradient for these substances across the epithelium. Membrane-permeable solutes then move down their electrochemical gradients into the intercellular space by both the transcellular (e.g., simple diffusion, symporters, antiporters, uniporters, and channels) and paracellular pathways. Membrane-impermeable solutes remain in the tubular lumen and are excreted in the urine with an obligatory amount of water.
 7. As water and solutes accumulate in the interstitial space, hydrostatic pressure increases, thus providing a driving force for bulk water flow. Bulk water flow carries solute out of the intercellular space into the interstitial space and, finally, into the peritubular capillaries.

Organic Acid and Organic Base Secretion

The kidney is a major organ involved in the elimination of organic chemicals from the body. Organic molecules may enter the renal tubules by glomerular filtration or may be actively secreted directly into tubules. The

proximal tubule has a highly efficient transport system for organic acids and an equally efficient but separate transport system for organic bases. Current models for these secretory systems are illustrated in Figure 25-3. Both systems are powered by the sodium pump in the basolateral membrane, involve secondary and tertiary active transport, and use a facilitated diffusion step. There are many organic acid and organic base transporters (see Chapter 5). A family of OATs links countertransport of organic anions with dicarboxylates (Figure 25-3A).

Renal Handling of Specific Anions and Cations

Reabsorption of Cl^- generally follows reabsorption of Na^+ . In segments of the tubule with low-resistance tight junctions (i.e., “leaky” epithelium), such as the proximal tubule and TAL, Cl^- movement can occur paracellularly. Cl^- crosses the luminal membrane by antiport with formate and oxalate (proximal tubule), symport with Na^+/K^+ (TAL), symport with Na^+ (DCT), and antiport with HCO_3^- (collecting duct system). Cl^- crosses the basolateral membrane via symport with K^+ (proximal tubule and TAL), antiport with $\text{Na}^+/\text{HCO}_3^-$ (proximal tubule), and Cl^- channels (TAL, DCT, collecting duct system).

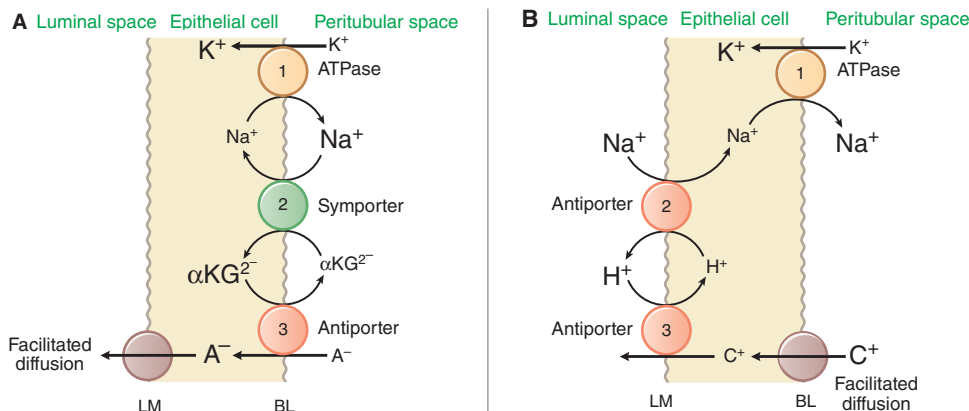

Figure 25-3 Mechanisms of organic acid (A) and organic base (B) secretion in the proximal tubule. The numbers 1, 2, and 3 refer to primary, secondary, and tertiary active transport, respectively. A⁻, organic acid (anion); C⁺, organic base (cation); αKG^{2-} , α -ketoglutarate but also other dicarboxylates. BL and LM indicate basolateral and luminal membranes, respectively.

Of filtered K⁺, 80%–90% is reabsorbed in the proximal tubule (diffusion and solvent drag) and TAL (diffusion), largely through the paracellular pathway. The DCT and collecting duct system secrete variable amounts of K⁺ by a channel-mediated pathway. Modulation of the rate of K⁺ secretion in the collecting duct system, particularly by aldosterone, allows urinary K⁺ excretion to be matched with dietary intake. The transepithelial potential difference V_T , lumen positive in the TAL and lumen negative in the collecting duct system, drives K⁺ reabsorption and secretion, respectively.

Most of the filtered Ca²⁺ (~70%) is reabsorbed by the proximal tubule by passive diffusion through a paracellular route. Another 25% of filtered Ca²⁺ is reabsorbed by the TAL in part by a paracellular route driven by the lumen-positive V_T and in part by active transcellular Ca²⁺ reabsorption modulated by PTH (see Chapter 43). Most of the remaining Ca²⁺ is reabsorbed in DCT by a transcellular pathway. The transcellular pathway in the TAL and DCT involves passive Ca²⁺ influx across the luminal membrane through Ca²⁺ channels (TRPV5, **transient receptor potential cation channel V5**), followed by Ca²⁺ extrusion across the basolateral membrane by a Ca²⁺-ATPase. Also, in DCT and CNT, Ca²⁺ crosses the basolateral membrane by Na⁺-Ca²⁺ exchanger (antiport). P_i is largely reabsorbed (80% of filtered load) by the proximal tubule. The Na⁺-P_i symporter uses the free energy of the Na⁺ electrochemical gradient to transport P_i into the cell. The Na⁺-P_i symporter is inhibited by PTH.

The renal tubules reabsorb HCO₃⁻ and secrete protons (tubular acidification), thereby participating in acid-base balance. These processes are described in the section on carbonic anhydrase inhibitors.

Principles of Diuretic Action

Diuretics are drugs that increase the rate of urine flow; clinically useful diuretics also increase the rate of Na⁺ excretion (natriuresis) and of an accompanying anion, usually Cl⁻. Most clinical applications of diuretics are directed toward reducing extracellular fluid volume by decreasing total-body NaCl content.

Although continued diuretic administration causes a sustained net deficit in total-body Na⁺, the time course of natriuresis is finite because renal compensatory mechanisms bring Na⁺ excretion in line with Na⁺ intake, a phenomenon known as *diuretic braking*. These compensatory mechanisms include activation of the sympathetic nervous system, activation of the renin-angiotensin-aldosterone axis, decreased arterial blood pressure (which reduces pressure natriuresis), renal epithelial cell hypertrophy, increased renal epithelial transporter expression, and perhaps alterations in natriuretic hormones such as ANP. The net effects on extracellular volume and body weight are shown in Figure 25-4.

Diuretics may modify renal handling of other cations (e.g., K⁺, H⁺, Ca²⁺, and Mg²⁺), anions (e.g., Cl⁻, HCO₃⁻, and H₂PO₄⁻), and uric acid. In addition, diuretics may alter renal hemodynamics indirectly. Table 25-1 compares the general effects of the major diuretic classes.

Inhibitors of Carbonic Anhydrase

There are three orally administered carbonic anhydrase inhibitors—*acetazolamide*, *dichlorphenamide*, and *methazolamide* (Table 25-2).

Mechanism and Site of Action

Proximal tubular epithelial cells are richly endowed with the zinc metalloenzyme carbonic anhydrase, which is found in the luminal and basolateral membranes (type IV carbonic anhydrase), as well as in the cytoplasm (type II carbonic anhydrase) (Figure 25-5). Carbonic anhydrase plays a role in NaHCO₃ reabsorption and acid secretion.

Figure 25-4 Changes in extracellular fluid volume and weight with diuretic therapy. The period of diuretic administration is shown in the shaded box along with its effects on body weight in the upper part of the figure and Na²⁺ excretion in the lower half of the figure. Initially, when Na²⁺ excretion exceeds intake, body weight and ECFV decrease. Subsequently, a new steady state is achieved where Na⁺ intake and excretion are equal but at a lower ECFV and body weight. This results from activation of the RAAS and SNS, “the braking phenomenon.” When the diuretic is discontinued, body weight and ECFV rise during a period when Na²⁺ intake exceeds excretion. A new steady state is then reached as stimulation of the RAAS and SNS wane.

TABLE 25-1 ■ EXCRETORY AND RENAL HEMODYNAMIC EFFECTS OF DIURETICS^a

DIURETIC MECHANISM (Primary site of action)	CATIONS					ANIONS			URIC ACID		RENAL HEMODYNAMICS			
	Na ⁺	K ⁺	H ⁺ ^b	Ca ²⁺	Mg ²⁺	Cl ⁻	HCO ₃ ⁻	H ₂ PO ₄ ⁻	ACUTE	CHRONIC	RBF	GFR	FF	TGF
Inhibitors of CA (proximal tubule)	+	++	-	NC	V	(+)	++	++	I	-	-	-	NC	+
Osmotic diuretics (loop of Henle)	++	+	I	+	++	+	+	+	+	I	+	NC	-	I
Inhibitors of Na ⁺ -K ⁺ -2Cl ⁻ symport (thick ascending limb)	++	++	+	++	++	++	+ ^c	+ ^c	+	-	V(+)	NC	V(-)	-
Inhibitors of Na ⁺ -Cl ⁻ symport (distal convoluted tubule)	+	++	+	V(-)	V(+)	+	+ ^c	+ ^c	+	-	NC	V(-)	V(-)	NC
Inhibitors of renal epithelial Na ⁺ channels (late distal tubule, collecting duct)	+	-	-	-	-	+	(+)	NC	I	-	NC	NC	NC	NC
Antagonists of mineralocorticoid receptors (late distal tubule, collecting duct)	+	-	-	I	-	+	(+)	I	I	-	NC	NC	NC	NC

^aExcept for uric acid, changes are for acute effects of diuretics in the absence of significant volume depletion, which would trigger complex physiological adjustments.

^bH⁺ includes titratable acid and NH₄⁺.

^cIn general, these effects are restricted to those individual agents that inhibit carbonic anhydrase. However, there are notable exceptions in which symport inhibitors increase bicarbonate and phosphate (e.g., metolazone, bumetanide). ++, +, (+), -, NC, V, V(+), V(-) and I indicate marked increase, mild-to-moderate increase, slight increase, decrease, no change, variable effect, variable increase, variable decrease, and insufficient data, respectively. For cations and anions, the indicated effects refer to absolute changes in fractional excretion.

TABLE 25-2 ■ INHIBITORS OF CARBONIC ANHYDRASE

DRUG	RELATIVE POTENCY	ORAL AVAILABILITY	t _{1/2} (hours)	ROUTE OF ELIMINATION
Acetazolamide	1	~100%	6-9	R
Dichlorophenamide	30	ID	ID	ID
Methazolamide	>1; <10	~100%	~14	~25% R, ~75% M

ID, insufficient data; M, metabolism; R, renal excretion of intact drug.

Figure 25-5 Sites and mechanisms of action of diuretics. Three important features are noteworthy: 1. Transport of solute across epithelial cells in all nephron segments involves highly specialized proteins, which for the most part are apical and basolateral membrane integral proteins. 2. Diuretics target and block the action of epithelial proteins involved in solute transport. 3. The site and mechanism of action of a given class of diuretics are determined by the specific protein inhibited by the diuretic.

In the proximal tubule, the free energy in the Na^+ gradient established by the basolateral Na^+ pump is used by a Na^+ - H^+ antiporter (Na^+ - H^+ exchanger type 3) in the luminal membrane to transport H^+ into the tubular lumen in exchange for Na^+ . In the lumen, H^+ reacts with filtered HCO_3^- to form H_2CO_3 , which decomposes rapidly to CO_2 and water in the presence of carbonic anhydrase in the brush border. Carbonic anhydrase reversibly accelerates this reaction several thousand fold. CO_2 is lipophilic and rapidly diffuses across the luminal membrane into the epithelial cell, where it reacts with water to form H_2CO_3 , a reaction catalyzed by cytoplasmic carbonic anhydrase. Continued operation of the Na^+ - H^+ antiporter maintains a low proton concentration in the cell, so H_2CO_3 ionizes spontaneously to form H^+ and HCO_3^- , creating an electrochemical gradient for HCO_3^- across the basolateral membrane. The electrochemical gradient for HCO_3^- is used by a Na^+ - HCO_3^- symporter (also known as the Na^+ - HCO_3^- cotransporter) in the basolateral membrane to transport NaHCO_3 into the interstitial space. The net effect of this process is transport of NaHCO_3 from the tubular lumen to the interstitial space, followed by movement of water (isotonic reabsorption). Removal of water concentrates Cl^- in the tubular lumen, and consequently, Cl^- diffuses down its concentration gradient into the interstitium by the paracellular pathway.

Carbonic anhydrase inhibitors potently inhibit both the membrane-bound and cytoplasmic forms of carbonic anhydrase, and can cause nearly complete abolition of NaHCO_3 reabsorption in the proximal tubule. However, due to the large excess of carbonic anhydrase activity in proximal tubules, a large fraction of the enzyme activity must be inhibited before an effect on electrolyte excretion is observed. Although the proximal tubule is the major site of action of carbonic anhydrase inhibitors, carbonic anhydrase also is involved in secretion of titratable acid in the collecting duct system, which is a secondary site of action for this class of drugs.

Effects on Urinary Excretion

Inhibition of carbonic anhydrase is associated with a rapid rise in urinary HCO_3^- excretion to about 35% of filtered load. This, along with inhibition of titratable acid and NH_4^+ secretion in the collecting duct system, results in an increase in urinary pH to about 8 and development of metabolic acidosis. However, even with a high degree of inhibition of carbonic anhydrase, 65% of HCO_3^- is rescued from excretion. The loop of Henle has large reabsorptive capacity and captures most of the Cl^- and a portion of the Na^+ . Thus, only a small increase in Cl^- excretion occurs, HCO_3^- being the major anion excreted along with the cations Na^+ and K^+ . The fractional excretion of Na^+ may be as much as 5%, and the fractional excretion of K^+ can be as much as 70%. The increased excretion of K^+ is in part secondary to increased delivery of Na^+ to the distal nephron, as described in the section on inhibitors of Na^+ channels. The effects of carbonic anhydrase inhibitors on renal excretion are self-limiting, probably because the resulting metabolic acidosis decreases the filtered load of HCO_3^- to the point that the uncatalyzed reaction between CO_2 and water is sufficient to achieve HCO_3^- reabsorption.

Effects on Renal Hemodynamics

By inhibiting proximal reabsorption, carbonic anhydrase inhibitors increase delivery of solutes to the macula densa. This triggers TGF, which increases afferent arteriolar resistance and reduces RBF and GFR.

Other Actions

These agents have extrarenal sites of action. Carbonic anhydrase in the ciliary processes of the eye mediates formation of HCO_3^- in aqueous humor. Inhibition of carbonic anhydrase decreases the rate of formation of aqueous humor and consequently reduces intraocular pressure. Acetazolamide frequently causes paresthesias and somnolence, suggesting an action of carbonic anhydrase inhibitors in the CNS. The efficacy of acetazolamide in epilepsy is due in part to the production of metabolic acidosis; however, direct actions of acetazolamide in the CNS also contribute to its anticonvulsant action. Owing to interference with carbonic anhydrase activity in erythrocytes, carbonic anhydrase inhibitors increase CO_2 levels in peripheral tissues and decrease CO_2 levels in expired gas. Acetazolamide causes vasodilation by opening vascular Ca^{2+} -activated K^+ channels; however, the clinical significance of this effect is unclear.

ADME

See Table 25–2 for pharmacokinetic data.

Therapeutic Uses

The efficacy of carbonic anhydrase inhibitors as single agents is low. The combination of acetazolamide with diuretics that block Na^+ reabsorption at more distal sites in the nephron causes a marked natriuretic response in patients with low basal fractional excretion of Na^+ (<0.2%) who are resistant to diuretic monotherapy. Even so, the long-term usefulness of carbonic anhydrase inhibitors often is compromised by the development of metabolic acidosis. The major indication for carbonic anhydrase inhibitors is open-angle glaucoma (Scozzafava and Supuran, 2014). Two products developed specifically for this use are dorzolamide and brinzolamide, which are available only as ophthalmic drops. Carbonic anhydrase inhibitors also may be employed for secondary glaucoma and preoperatively in acute-angle closure glaucoma to lower intraocular pressure before surgery (see Chapter 69). Orally administered acetazolamide also is used for the treatment of glaucoma (see Chapter 69) and absence seizures (see Chapter 21). Acetazolamide can provide symptomatic relief in patients with high-altitude illness or mountain sickness (Ritchie et al., 2012). Carbonic anhydrase inhibitors are also useful in patients with familial periodic paralysis. Dichlorphenamide is now approved for treating this syndrome. The mechanism for the beneficial effects of carbonic anhydrase inhibitors in altitude sickness and familial periodic paralysis may relate to the induction of a metabolic acidosis. Finally, carbonic anhydrase inhibitors can be useful for correcting metabolic alkalosis, especially one caused by diuretic-induced increases in H^+ excretion.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Serious toxic reactions to carbonic anhydrase inhibitors are infrequent; however, these drugs are sulfonamide derivatives and, like other sulfonamides, may cause bone marrow depression, skin toxicity, sulfonamide-like renal lesions, and allergic reactions. With large doses, many patients exhibit drowsiness and paresthesias. Most adverse effects, contraindications, and drug interactions are secondary to urinary alkalization or metabolic acidosis, including (1) diversion of ammonia of renal origin from urine into the systemic circulation, a process that may induce or worsen hepatic encephalopathy (the drugs are contraindicated in patients with hepatic cirrhosis); (2) calculus formation and ureteral colic owing to precipitation of calcium phosphate salts in alkaline urine; (3) worsening of metabolic or respiratory acidosis (the drugs are contraindicated in patients with hyperchloremic acidosis or severe chronic obstructive pulmonary disease); and (4) reduction of the urinary excretion rate of weak organic bases.

Osmotic Diuretics

Osmotic diuretics (Table 25–3) are freely filtered at the glomerulus, undergo limited reabsorption by the renal tubule, and are relatively inert pharmacologically. Osmotic diuretics are administered in doses large enough to increase significantly the osmolality of plasma and tubular fluid. Of the osmotic diuretics listed, only glycerin and mannitol are currently available in the U.S.

TABLE 25–3 ■ OSMOTIC DIURETICS

DRUG	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION
Glycerin	Orally active	0.5–0.75	~80% M, ~20% U

^aNot available in the U.S.

^bIn renal failure, 6–36 h.

Osmotic diuretics act in both the proximal tubule and the loop of Henle, with the latter the primary site of action. In the proximal tubule, osmotic diuretics act as nonreabsorbable solutes that limit the osmosis of water into the interstitial space and thereby reduce the luminal Na⁺ concentration to the point that net Na⁺ reabsorption ceases. By extracting water from intracellular compartments, osmotic diuretics expand extracellular fluid volume, decrease blood viscosity, and inhibit renin release. These effects increase RBF, and the increase in renal medullary blood flow removes NaCl and urea from the renal medulla, thus reducing medullary tonicity. A reduction in medullary tonicity causes a decrease in the extraction of water from the DTL, which in turn limits the concentration of NaCl in the tubular fluid entering the ATL. This latter effect diminishes the passive reabsorption of NaCl in the ATL. In addition, osmotic diuretics inhibit Mg²⁺ reabsorption in the TAL.

Effects on Urinary Excretion

Osmotic diuretics increase urinary excretion of nearly all electrolytes, including Na⁺, K⁺, Ca²⁺, Mg²⁺, Cl⁻, HCO₃⁻, and phosphate.

Effects on Renal Hemodynamics

Osmotic diuretics increase RBF by a variety of mechanisms, but total GFR is little changed.

ADME

Pharmacokinetic data on the osmotic diuretics are gathered in Table 25–3. Where available, glycerin and isosorbide can be given orally, whereas mannitol and urea must be administered intravenously (with the exception that mannitol powder is used by inhalation for diagnosis of bronchial hyperreactivity).

Therapeutic Uses

One use for mannitol is in the treatment of dialysis disequilibrium syndrome. Overly removing solutes from the extracellular fluid by hemodialysis results in a reduction in the osmolality of extracellular fluid. Consequently, water moves from the extracellular compartment into the intracellular compartment, causing hypotension and CNS symptoms (headache, nausea, muscle cramps, restlessness, CNS depression, and convulsions). Osmotic diuretics increase the osmolality of the extracellular fluid compartment and thereby shift water back into the extracellular compartment. By increasing the osmotic pressure of plasma, osmotic diuretics extract water from the eye and brain. Osmotic diuretics are used to control intraocular pressure during acute attacks of glaucoma and for short-term reductions in intraocular pressure both preoperatively and postoperatively in patients who require ocular surgery. Also, mannitol is used to reduce cerebral edema and brain mass before and after neurosurgery and to control intracranial pressure in patients with traumatic brain injury (Wakai et al., 2013). Mannitol is often used to treat or prevent acute kidney injury; however, it is questionable regarding whether mannitol improves renal outcomes (Nigwekar and Waikar, 2011). Other

FDA-approved uses of mannitol include enhancement of urinary excretion of salicylates, barbiturates, bromides, and lithium following overdose; for the diagnosis of bronchial hyperreactivity (by oral inhalation); and for antihemolytic urologic irrigation during transurethral procedures.

Toxicity, Adverse Effects, Contraindications, and Drug Interactions

Osmotic diuretics are distributed in the extracellular fluid and contribute to the extracellular osmolality. Thus, water is extracted from intracellular compartments, and the extracellular fluid volume becomes expanded. In patients with heart failure or pulmonary congestion, this may cause frank pulmonary edema. Extraction of water also causes hyponatremia, which may explain the common adverse effects, including headache, nausea, and vomiting. Conversely, loss of water in excess of electrolytes can cause hypernatremia and dehydration. Osmotic diuretics are contraindicated in patients who are anuric owing to severe renal disease. Urea may cause thrombosis or pain if extravasation occurs, and it should not be administered to patients with impaired liver function because of the risk of elevation of blood ammonia levels. Both mannitol and urea are contraindicated in patients with active cranial bleeding. Glycerin is metabolized and can cause hyperglycemia.

Inhibitors of Na⁺-K⁺-2Cl⁻ Symport: Loop Diuretics, High-Ceiling Diuretics

The loop and high-ceiling diuretics inhibit activity of the Na⁺-K⁺-2Cl⁻ symporter in the TAL of the loop of Henle, hence the moniker *loop diuretics*. Although the proximal tubule reabsorbs about 65% of filtered Na⁺, diuretics acting only in the proximal tubule have limited efficacy because the TAL has the capacity to reabsorb most of the rejectate from the proximal tubule. In contrast, inhibitors of Na⁺-K⁺-2Cl⁻ symport in the TAL, sometimes called *high-ceiling diuretics*, are highly efficacious because (1) about 25% of the filtered Na⁺ load normally is reabsorbed by the TAL, and (2) nephron segments past the TAL do not possess the resorptive capacity to rescue the flood of rejectate exiting the TAL.

Of the inhibitors of Na⁺-K⁺-2Cl⁻ symport (Table 25–4), only furosemide, bumetanide, ethacrynic acid, and torsemide are available in the U.S. Furosemide and bumetanide contain a sulfonamide moiety. Ethacrynic acid is a phenoxyacetic acid derivative; torsemide is a sulfonylurea. Furosemide and bumetanide are available as oral and injectable formulations. Torsemide is available as an oral formulation; ethacrynate sodium is available as an injectable solution and ethacrynic acid as an oral tablet.

Mechanism and Site of Action

These agents act primarily in the TAL, where the flux of Na⁺, K⁺, and Cl⁻ from the lumen into epithelial cells is mediated by a Na⁺-K⁺-2Cl⁻ symporter (Figure 25–5). Inhibitors of this symporter block its function (Bernstein and Ellison, 2011; Wile, 2012), bringing salt transport in this segment of the nephron to a virtual standstill. There is evidence that these

TABLE 25–4 ■ INHIBITORS OF Na ⁺ -K ⁺ -2Cl ⁻ SYMPORT (LOOP DIURETICS, HIGH-CEILING DIURETICS)

^bNot available in the U.S.

drugs attach to the Cl^- binding site located in the symporter's transmembrane domain; however, more recent studies challenge this view. Inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport also inhibit Ca^{2+} and Mg^{2+} reabsorption in the TAL by abolishing the transepithelial potential difference that is the dominant driving force for reabsorption of these cations.

$\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporters are found in many secretory and absorbing epithelia. There are two varieties of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporters. The “absorptive” symporter (called *ENCC2*, *NKCC2*, or *BSC1*) is expressed only in the kidney, is localized to the apical membrane and subapical intracellular vesicles of the TAL, and is regulated by the cyclic AMP/PKA pathway. The “secretory” symporter (called *ENCC3*, *NKCC1*, or *BSC2*) is a “housekeeping” protein that is expressed widely and, in epithelial cells, is localized to the basolateral membrane. The affinity of loop diuretics for the secretory symporter is somewhat less than for the absorptive symporter (e.g., 4-fold difference for bumetanide). Mutations in the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter cause a form of inherited hypokalemic alkalosis called Bartter syndrome.

Effects on Urinary Excretion

Loop diuretics increase urinary Na^+ and Cl^- excretion profoundly (i.e., up to 25% of the filtered Na^+ load) and markedly increase Ca^{2+} and Mg^{2+} excretion. Furosemide has weak carbonic anhydrase-inhibiting activity and thus increases urinary excretion of HCO_3^- and phosphate. All inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport increase urinary K^+ and titratable acid excretion. This effect is due in part to increased Na^+ delivery to the distal tubule (the mechanism by which increased distal Na^+ delivery enhances K^+ and H^+ excretion is discussed in the section on Na^+ channel inhibitors). Other mechanisms contributing to enhanced K^+ and H^+ excretion include flow-dependent enhancement of ion secretion by the collecting duct, non-osmotic vasopressin release, and activation of the RAS axis.

Acutely, loop diuretics increase uric acid excretion; their chronic administration results in reduced uric acid excretion. Chronic effects of loop diuretics on uric acid excretion may be due to enhanced proximal tubule transport or secondary to volume depletion or to competition between diuretic and uric acid for the organic acid secretory mechanism in the proximal tubule. Asymptomatic hyperuricemia is a common consequence of loop diuretics, but painful episodes of gout are rarely reported (Bruderer et al., 2014). By blocking active NaCl reabsorption in the TAL, inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport interfere with a critical step in the mechanism that produces a hypertonic medullary interstitium. Therefore, loop diuretics block the kidney's ability to concentrate urine. Also, because the TAL is part of the diluting segment, inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport markedly impair the kidney's ability to excrete a dilute urine during water diuresis.

Effects on Renal Hemodynamics

If volume depletion is prevented by replacing fluid losses, inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport generally increase total RBF and redistribute RBF to the midcortex. The mechanism of the increase in RBF is not known but may involve PGs: NSAIDs attenuate the diuretic response to loop diuretics in part by preventing PG-mediated increases in RBF. Loop diuretics block TGF by inhibiting salt transport into the macula densa so that the macula densa no longer detects NaCl concentrations in the tubular fluid. Therefore, unlike carbonic anhydrase inhibitors, loop diuretics do not decrease the GFR by activating TGF. Loop diuretics are powerful stimulators of renin release. This effect is due to interference with NaCl transport by the macula densa and, if volume depletion occurs, to reflex activation of the sympathetic nervous system and stimulation of the intrarenal baroreceptor mechanism.

Other Actions

Loop diuretics, particularly furosemide, acutely increase systemic venous capacitance and thereby decrease left ventricular filling pressure. This effect, which may be mediated by PGs and requires intact kidneys, benefits patients with pulmonary edema even before diuresis ensues. High doses of inhibitors of $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport can inhibit electrolyte transport in many tissues. This effect is clinically important in the inner ear and can result in ototoxicity, particularly in patients with preexisting hearing impairment.

ADME

Table 25–4 presents some pharmacokinetic properties of the agents. Because these drugs are bound extensively to plasma proteins, delivery of these drugs to tubules by filtration is limited. However, they are secreted efficiently by the organic acid transport system in the proximal tubule and thereby gain access to the $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symporter in the luminal membrane of the TAL. Approximately 65% of furosemide is excreted unchanged in urine, and the remainder is conjugated to glucuronic acid in the kidney. Thus, in patients with renal disease, the elimination $t_{1/2}$ of furosemide is prolonged. Bumetanide and torsemide have significant hepatic metabolism, so liver disease can prolong the elimination $t_{1/2}$ of these loop diuretics. Oral bioavailability of furosemide varies (10%–100%). In contrast, oral availabilities of bumetanide and torsemide are reliably high.

As a class, loop diuretics have short elimination half-lives; prolonged-release preparations are not available. Consequently, often the dosing interval is too short to maintain adequate levels of loop diuretics in the tubular lumen. Note that torsemide has a longer $t_{1/2}$ than other agents available in the U.S. As the concentration of loop diuretic in the tubular lumen declines, nephrons begin to avidly reabsorb Na^+ , which often nullifies the overall effect of the loop diuretic on total-body Na^+ . This phenomenon of “postdiuretic Na^+ retention” can be overcome by restricting dietary Na^+ intake or by more frequent administration of the loop diuretic.

Therapeutic Uses

A major use of loop diuretics is in the treatment of acute pulmonary edema. A rapid increase in venous capacitance in conjunction with brisk natriuresis reduces left ventricular filling pressures and thereby rapidly relieves pulmonary edema. Loop diuretics also are used widely for treatment of chronic CHF when diminution of extracellular fluid volume is desirable to minimize venous and pulmonary congestion (see Chapter 29). Diuretics cause a significant reduction in mortality and the risk of worsening heart failure, as well as an improvement in exercise capacity. Although furosemide is the most commonly used loop diuretic for the treatment of heart failure, patients with heart failure have fewer hospitalizations and better quality of life with torsemide than with furosemide, perhaps because of its more reliable absorption and due to other ancillary pharmacological effects (Buggey et al., 2015).

Although diuretics are used widely for treatment of hypertension (see Chapter 28), in patients with normal renal function, $\text{Na}^+-\text{K}^+-2\text{Cl}^-$ symport inhibitors are not considered first-line diuretics for the treatment of hypertension. This is due to the lower antihypertensive efficacy of loop diuretics in such patients and the lack of data demonstrating a reduction in cardiovascular events. However, in patients with a low GFR (<30 mL/min) or with resistant hypertension, loop diuretics are the diuretics of choice.

The edema of nephrotic syndrome often is refractory to less-potent diuretics, and loop diuretics often are the only drugs capable of reducing the massive edema associated with this renal disease. Loop diuretics also are employed in the treatment of edema and ascites of liver cirrhosis; however, care must be taken not to induce volume contraction. In patients with a drug overdose, loop diuretics can be used to induce forced diuresis to facilitate more rapid renal elimination of the offending drug. Loop diuretics, combined with isotonic saline administration to prevent volume depletion, are used to treat hypercalcemia. Loop diuretics interfere with the kidney's capacity to produce concentrated urine. Consequently, loop diuretics combined with hypertonic saline are useful for the treatment of life-threatening hyponatremia. Loop diuretics also are used to treat edema associated with chronic kidney disease, in which the dose-response curve may be right shifted, requiring higher doses of the loop diuretic.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Most adverse effects are due to abnormalities of fluid and electrolyte balance. Overzealous use of loop diuretics can cause serious depletion of total-body Na^+ . This may manifest as hyponatremia or extracellular fluid volume depletion associated with hypotension, reduced GFR, circulatory collapse, thromboembolic episodes, and, in patients with liver disease, hepatic encephalopathy. Increased Na^+ delivery to the

distal tubule, particularly when combined with activation of the renin-angiotensin system, leads to increased urinary K^+ and H^+ excretion, causing a hypochloremic alkalosis. If dietary K^+ intake is not sufficient, hypokalemia may develop, and this may induce cardiac arrhythmias, particularly in patients taking cardiac glycosides. Increased Mg^{2+} and Ca^{2+} excretion may result in hypomagnesemia (a risk factor for cardiac arrhythmias) and hypocalcemia (rarely leading to tetany). Loop diuretics should be avoided in postmenopausal osteopenic women, in whom increased Ca^{2+} excretion may have deleterious effects on bone metabolism.

Loop diuretics can cause ototoxicity that manifests as tinnitus, hearing impairment, deafness, vertigo, and a sense of fullness in the ears. Hearing impairment and deafness are usually, but not always, reversible. Ototoxicity occurs most frequently with rapid intravenous administration and least frequently with oral administration. To avoid ototoxicity, the rate of furosemide infusions should not exceed 4 mg/min. Ethacrynic acid appears to induce ototoxicity more often than do other loop diuretics and should be reserved for use only in patients who cannot tolerate other loop diuretics. Loop diuretics also can cause hyperuricemia (occasionally leading to gout) and hyperglycemia (infrequently precipitating diabetes mellitus) and can increase plasma levels of LDL cholesterol and triglycerides while decreasing plasma levels of HDL cholesterol. Other adverse effects include skin rashes, photosensitivity, paresthesias, bone marrow depression, and GI disturbances. Contraindications to the use of loop diuretics include severe Na^+ and volume depletion, hypersensitivity to sulfonamides (for sulfonamide-based loop diuretics), and anuria unresponsive to a trial dose of loop diuretic.

Drug interactions may occur when loop diuretics are coadministered with the following:

- Aminoglycosides, carboplatin, paclitaxel, and others (synergism of ototoxicity)
- Anticoagulants (increased anticoagulant activity)
- Digitalis glycosides (increased digitalis-induced arrhythmias)
- Lithium (increased plasma levels of Li^+)
- Propranolol (increased plasma levels of propranolol)
- Sulfonylureas (hyperglycemia)
- Cisplatin (increased risk of diuretic-induced ototoxicity)
- NSAIDs (blunted diuretic response and salicylate toxicity with high doses of salicylates)
- Probenecid (blunted diuretic response)
- Thiazide diuretics (synergism of diuretic activity of both drugs, leading to profound diuresis)
- Amphotericin B (increased potential for nephrotoxicity and intensification of electrolyte imbalance)

Inhibitors of Na^+-Cl^- Symport: Thiazide-Type and Thiazide-Like Diuretics

The term *thiazide diuretics* generally refers to all inhibitors of Na^+-Cl^- symport, so named because the original inhibitors of Na^+-Cl^- symport were benzothiadiazine derivatives. The class now includes diuretics that are benzothiadiazine derivatives (*thiazide* or *thiazide-type diuretics*) and drugs that are pharmacologically similar to thiazide diuretics but differ structurally (*thiazide-like diuretics*). Table 25-5 lists diuretics in this drug class that are currently available in the United States.

Mechanism and Site of Action

Thiazide diuretics inhibit $NaCl$ transport in the DCT; the proximal tubule may represent a secondary site of action. Figure 25-5 illustrates the current model of electrolyte transport in the DCT. Transport is powered by a Na^+ pump in the basolateral membrane. Free energy in the electrochemical gradient for Na^+ is harnessed by a Na^+-Cl^- symporter in the luminal membrane that moves Cl^- into the epithelial cell against its electrochemical gradient. Cl^- then exits the basolateral membrane passively by a Cl^- channel. Thiazide diuretics inhibit the Na^+-Cl^- symporter (called *ENCC1* or *TSC*) that is expressed predominantly in kidney and localized to the apical membrane of DCT epithelial cells. Expression of the symporter is regulated by aldosterone. Mutations in the Na^+-Cl^- symporter cause a form of inherited hypokalemic alkalosis called Gitelman syndrome.

Effects on Urinary Excretion

Inhibitors of Na^+-Cl^- symport increase Na^+ and Cl^- excretion. However, thiazides are only moderately efficacious (i.e., maximum excretion of filtered Na^+ load is only 5%) because about 90% of the filtered Na^+ load is reabsorbed before reaching the DCT. Some thiazide diuretics also are weak inhibitors of carbonic anhydrase, an effect that increases HCO_3^- and phosphate excretion and probably accounts for their weak proximal tubular effects. Inhibitors of Na^+-Cl^- symport increase K^+ and titratable acid excretion by the same mechanisms discussed for loop diuresis. Acute thiazide administration increases uric acid excretion. However, uric acid excretion is reduced following chronic administration by similar mechanisms discussed for loop diuretics. In addition, thiazides may be transported from the basolateral compartment to the luminal compartment via the OAT4 antiporter in the apical membrane (Palmer, 2011; see Chapter 5). Acute effects of inhibitors of Na^+-Cl^- symport on Ca^{2+} excretion are variable; when administered chronically, thiazide diuretics decrease Ca^{2+} excretion. The mechanism involves increased proximal reabsorption owing to volume depletion, as well as direct effects of thiazides to increase Ca^{2+} reabsorption in the DCT. Thiazide diuretics may

TABLE 25-5 ■ INHIBITORS OF Na^+-Cl^- SYMPORT (THIAZIDE DIURETICS)

DRUG	RELATIVE POTENCY	ORAL AVAILABILITY	$t_{1/2}$ (hours)	ROUTE OF ELIMINATION
Thiazide diuretics				
Bendroflumethiazide	10	~100%	3–3.9	~30% R, ~70% M
Chlorothiazide	0.1	9%–56% (dose-dependent)	~1.5	R

B, excretion of intact drug into bile; ID, insufficient data; M, metabolism; R, renal excretion of intact drug; U, unknown pathway of elimination.

cause mild magnesuria; long-term use of thiazide diuretics may cause magnesium deficiency, particularly in the elderly. Because inhibitors of $\text{Na}^+\text{-Cl}^-$ symport inhibit transport in the cortical diluting segment, thiazide diuretics attenuate the kidney's ability to excrete dilute urine during water diuresis. However, because the DCT is not involved in the mechanism that generates a hypertonic medullary interstitium, thiazide diuretics do not alter the kidney's ability to concentrate urine during hydropenia. In general, inhibitors of $\text{Na}^+\text{-Cl}^-$ symport do not affect RBF and only variably reduce GFR owing to increases in intratubular pressure. Thiazides have little or no influence on TGF.

ADME

Table 25–5 lists pharmacokinetic parameters of $\text{Na}^+\text{-Cl}^-$ symport inhibitors. Note the wide range of half-lives for these drugs. Sulfonamides, as organic acids, are secreted into the proximal tubule by the organic acid secretory pathway. Because thiazides must gain access to the tubular lumen to inhibit the $\text{Na}^+\text{-Cl}^-$ symporter, drugs such as probenecid can attenuate the diuretic response to thiazides by competing for transport into the proximal tubule. However, plasma protein binding varies considerably among thiazide diuretics, and this parameter determines the contribution that filtration makes to tubular delivery of a specific thiazide.

Therapeutic Uses

Thiazide diuretics are used for the treatment of edema associated with diseases of the heart (CHF), liver (hepatic cirrhosis), and kidney (nephrotic syndrome, chronic renal failure, and acute glomerulonephritis). With the possible exceptions of metolazone and indapamide, most thiazide diuretics are ineffective when the GFR is less than 30–40 mL/min. Thiazide diuretics decrease blood pressure in hypertensive patients and are used widely for the treatment of hypertension in combination with other antihypertensive drugs (Tamargo et al., 2014) (see Chapter 28). Thiazide diuretics are inexpensive, as efficacious as other classes of antihypertensive agents, and well tolerated. Thiazides can be administered once daily, do not require dose titration, and have few contraindications. Moreover, thiazides have additive or synergistic effects when combined with other classes of antihypertensive agents. Although hydrochlorothiazide is the 10th most prescribed drug in the United States and is prescribed 20 times more often than chlorthalidone (Roush et al., 2014), there is strong evidence that chlorthalidone and other thiazide-like diuretics, such as indapamide, reduce blood pressure and cardiovascular events in hypertensive patients more so than does hydrochlorothiazide (Olde Engberink et al., 2015; Roush et al., 2014, 2015). This is likely due to the longer half-life of *thiazide-like* diuretics compared to hydrochlorothiazide, resulting in better 24-h control of arterial blood pressure by chlorthalidone.

Thiazide diuretics, which reduce urinary Ca^{2+} excretion, sometimes are employed to treat Ca^{2+} nephrolithiasis and may be useful for treatment of osteoporosis (see Chapter 44). Thiazide diuretics also are the mainstay for treatment of nephrogenic DI, reducing urine volume by up to 50%. Although it may seem counterintuitive to treat a disorder of increased urine volume with a diuretic, thiazides reduce the kidney's ability to excrete free water: They increase proximal tubular water reabsorption (secondary to volume contraction) and block the ability of the DCT to form dilute urine. This last effect results in an increase in urine osmolality. Because other halides are excreted by renal processes similar to those for Cl^- , thiazide diuretics may be useful for the management of Br^- intoxication.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Thiazide diuretics rarely cause CNS (e.g., vertigo, headache), GI, hematological, and dermatological (e.g., photosensitivity and skin rashes) disorders. The incidence of erectile dysfunction is greater with $\text{Na}^+\text{-Cl}^-$ symport inhibitors than with several other antihypertensive agents (Grimm et al., 1997), but usually is tolerable. As with loop diuretics, most serious adverse effects of thiazides are related to abnormalities of fluid and electrolyte balance. These adverse effects include extracellular volume depletion, hypotension, hypokalemia, hyponatremia, hypochloremia, metabolic alkalosis, hypomagnesemia, hypercalcemia, and hyperuricemia (Palmer,

2011). Thiazide diuretics have caused fatal or near-fatal hyponatremia (Rodenburg et al., 2013), and some patients are at recurrent risk of hyponatremia when rechallenged with thiazides.

Thiazide diuretics also decrease glucose tolerance and unmask latent diabetes mellitus (Palmer, 2011). The mechanism of impaired glucose tolerance appears to involve reduced insulin secretion and alterations in glucose metabolism. Hyperglycemia is reduced when K^+ is given along with the diuretic. Importantly, thiazide-induced diabetes mellitus is not associated with the same cardiovascular disease risk as incident diabetes (Barzilay et al., 2012). Thiazide-induced hypokalemia also impairs the antihypertensive effect and cardiovascular protection afforded by thiazides in patients with hypertension. Thiazide diuretics also may increase plasma levels of LDL cholesterol, total cholesterol, and total triglycerides. Thiazide diuretics are contraindicated in individuals who are hypersensitive to sulfonamides. Thiazide diuretics may diminish the effects of anticoagulants, uricosuric agents used to treat gout, sulfonyleureas, and insulin and may increase the effects of anesthetics, diazoxide, digitalis glycosides, lithium, loop diuretics, and vitamin D. The effectiveness of thiazide diuretics may be reduced by NSAIDs, nonselective or selective COX-2 inhibitors, and bile acid sequestrants (reduced absorption of thiazides). Amphotericin B and corticosteroids increase the risk of hypokalemia induced by thiazide diuretics.

In a potentially lethal interaction, thiazide diuretic-induced K^+ depletion may contribute to fatal ventricular arrhythmias associated with drugs that prolong the QT interval (i.e., quinidine, dofetilide, arsenic trioxide, see also Chapter 30).

Inhibitors of Renal Epithelial Na^+ Channels: K^+ -Sparing Diuretics

Triamterene and amiloride are the only two drugs of this class in clinical use. Both drugs cause small increases in NaCl excretion and usually are employed for their antikaliuretic actions to offset the effects of other diuretics that increase K^+ excretion. Consequently, triamterene and amiloride, along with spironolactone and eplerenone (described in the next section), often are classified as *potassium (K^+)-sparing diuretics*.

Both drugs are organic bases, are transported by the organic base secretory mechanism in the proximal tubule, and have similar mechanisms of action (Figure 25–5). Principal cells in the late distal tubules and collecting ducts (particularly cortical collecting tubules) have, in their luminal membranes, ENaCs that provide a conductive pathway for Na^+ entry into the cell down the electrochemical gradient created by the basolateral Na^+ pump. The higher permeability of the luminal membrane for Na^+ depolarizes the luminal membrane but not the basolateral membrane, creating a lumen-negative transepithelial potential difference. This transepithelial voltage provides an important driving force for the secretion of K^+ into the lumen via K^+ channels (ROMK [Kir1.1] and BK channels) (Garcia and Kaczorowski, 2014) in the luminal membrane; however, the overall regulation of K^+ secretion in the late distal tubule and collecting duct involves multiple signaling mechanisms (Welling, 2013). Carbonic anhydrase inhibitors, loop diuretics, and thiazide diuretics increase Na^+ delivery to the late distal tubule and collecting duct, a situation that often is associated with increased K^+ and H^+ excretion.

Amiloride and triamterene block ENaCs in the luminal membrane of principal cells in late distal tubules and collecting ducts by binding to a site in the channel pore. ENaCs consist of three subunits (α , β , and γ) (Kellenberger and Schild, 2015). Although the α subunit is sufficient for channel activity, maximal Na^+ permeability is induced when all three subunits are coexpressed in the same cell, probably forming a tetrameric structure consisting of two α subunits, one β subunit, and one γ subunit. Incompletely understood, complex mechanisms, including proteolytic cleavage, regulate ENaC activation (Kellenberger and Schild, 2015).

Effects on Urinary Excretion

The late distal tubule and collecting duct have a limited capacity to reabsorb solutes; thus, Na^+ channel blockade in this part of the nephron increases Na^+ and Cl^- excretion rates only mildly (~2% of filtered load).

TABLE 25-6 ■ INHIBITORS OF RENAL EPITHELIAL Na⁺ CHANNELS (K⁺-SPARING DIURETICS)

DRUG	RELATIVE POTENCY	ORAL BIOAVAILABILITY	t _{1/2} (hours)	ROUTE OF ELIMINATION
Amiloride	1	15%–25%	~21	R
Triamterene	0.1	~50%	~4	M

M, metabolism; R, renal excretion of intact drug; however, triamterene is transformed into an active metabolite that is excreted in the urine.

Blockade of Na⁺ channels hyperpolarizes the luminal membrane, reducing the lumen-negative transepithelial voltage. Because the lumen-negative potential difference normally opposes cation reabsorption and facilitates cation secretion, attenuation of the lumen-negative voltage decreases K⁺, H⁺, Ca²⁺, and Mg²⁺ excretion rates. Volume contraction may increase reabsorption of uric acid in the proximal tubule; hence, chronic administration of amiloride and triamterene may decrease uric acid excretion. Amiloride and triamterene have little or no effect on renal hemodynamics and do not alter TGF.

ADME

Table 25-6 lists pharmacokinetic data for amiloride and triamterene. Amiloride is eliminated predominantly by urinary excretion of intact drug. Triamterene is metabolized in the liver to an active metabolite, 4-hydroxytriamterene sulfate, and this metabolite is excreted in urine. Therefore, triamterene toxicity may be enhanced in both hepatic disease and renal failure.

Therapeutic Uses

Because of the mild natriuresis induced by Na⁺ channel inhibitors, these drugs seldom are used as sole agents in treatment of edema or hypertension; their major utility is in combination with other diuretics. Coadministration of a Na⁺ channel inhibitor augments the diuretic and antihypertensive response to thiazide and loop diuretics. More important, the ability of Na⁺ channel inhibitors to reduce K⁺ excretion tends to offset the kaliuretic effects of thiazide and loop diuretics and to result in normal plasma K⁺ values.

Liddle syndrome (described later in this chapter) can be treated effectively with Na⁺ channel inhibitors. Aerosolized amiloride has been shown to improve mucociliary clearance in patients with cystic fibrosis. By inhibiting Na⁺ absorption from the surfaces of airway epithelial cells, amiloride augments hydration of respiratory secretions and thereby improves mucociliary clearance. Amiloride also is useful for lithium-induced nephrogenic DI because it blocks Li⁺ transport into collecting tubule cells (Kortenoeven et al., 2009).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

The most dangerous adverse effect of renal Na⁺ channel inhibitors is hyperkalemia, which can be life threatening. Consequently, amiloride and triamterene are contraindicated in patients with hyperkalemia, as well as in patients at increased risk of developing hyperkalemia (e.g., patients with renal failure, patients receiving other K⁺-sparing diuretics, patients taking angiotensin-converting enzyme inhibitors, or patients taking K⁺ supplements). Even NSAIDs can increase the likelihood of hyperkalemia in patients receiving Na⁺ channel inhibitors. Routine monitoring of the serum K⁺ level is essential in patients receiving K⁺-sparing diuretics. Cirrhotic patients are prone to megaloblastosis because of folic acid deficiency, and triamterene, a weak folic acid antagonist, may increase the likelihood of this adverse event. Triamterene also can reduce glucose tolerance and induce photosensitization and has been associated with interstitial nephritis and renal stones. Both drugs can cause CNS, GI, musculoskeletal, dermatological, and hematological adverse effects. The most common adverse effects of amiloride are nausea, vomiting, diarrhea, and headache; those of triamterene are nausea, vomiting, leg cramps, and dizziness.

Antagonists of Mineralocorticoid Receptors: Aldosterone Antagonists, K⁺-Sparing Diuretics

Mineralocorticoids cause salt and water retention and increase K⁺ and H⁺ excretion by binding to specific MRs. Two MR antagonists are available in the U.S., spironolactone and eplerenone (Table 25-7).

Mechanism and Site of Action

Epithelial cells in late distal tubule and collecting duct (particularly cortical collecting tubule) contain cytosolic MRs with high aldosterone affinity. When aldosterone binds to MRs, the MR-aldosterone complex translocates to the nucleus, where it regulates the expression of multiple gene products called aldosterone-induced proteins (AIPs) (Figure 25-6). AIPs affect the production, destruction, localization, and activation of multiple components of the system that mediates Na⁺ reabsorption in late distal tubules and collecting ducts (Figure 25-6A). Consequently, transepithelial NaCl transport is enhanced, and the lumen-negative transepithelial voltage is increased. The latter effect increases the driving force for K⁺ and H⁺ secretion into the tubular lumen.

Drugs such as spironolactone and eplerenone competitively inhibit the binding of aldosterone to the MR. Unlike the MR-aldosterone complex, the MR-spironolactone or MR-eplerenone complex is not able to induce the synthesis of AIPs. Because spironolactone and eplerenone block the biological effects of aldosterone, these agents also are referred to as *aldosterone antagonists*. MR antagonists are the only diuretics that do not require access to the tubular lumen to induce diuresis.

Both the β and β subunits of ENaC have a specific region in their C terminus called the PY motif. The PY motif interacts with the ubiquitin ligase Nedd4-2 (Figure 25-6B), a protein that ubiquitinates ENaC and targets it for destruction by the proteasome. Aldosterone increases the expression of SGK-1; SGK-1 phosphorylates and inactivates Nedd4-2. Thus, aldosterone results in attenuated internalization and proteasome-mediated degradation of ENaC, leading to increased expression of ENaC in the luminal membrane. Liddle syndrome, an autosomal-dominant, monogenic disease characterized by sodium retention and severe hypertension, is caused by mutations in the PY motif of either the β or γ subunit of ENaC, leading to MR-independent overexpression of ENaC. Thus, Liddle syndrome is responsive to ENaC inhibitors but not to MR antagonists.

TABLE 25-7 ■ MINERALOCORTICOID RECEPTOR ANTAGONISTS (ALDOSTERONE ANTAGONISTS, K⁺-SPARING DIURETICS)

DRUG	ORAL AVAILABILITY	t _{1/2} (hours)	ROUTE OF ELIMINATION
Spironolactone	~65%	~1.6	M
Canrenone ^a	80%	3.7–22	M
Potassium canrenoate ^a	100%	3.7–22	M
Eplerenone	69%	~5	M

M, metabolism.
^aNot available in U.S.

Figure 25-6 Effects of aldosterone on late distal tubule and collecting duct and diuretic mechanism of aldosterone antagonists.

A. Overview of aldosterone's influences on Na^+ retention. Via interaction with the mineralocorticoid receptor (MR), aldosterone affects myriad renal pathways that handle Na^+ . Key to numbered items influenced by ALDO:

1. Activation of membrane-bound Na^+ channels
2. Na^+ channel (ENaC) removal from the membrane inhibited
3. *De novo* synthesis of Na^+ channels
4. Activation of membrane-bound Na^+, K^+ -ATPase
5. Redistribution of Na^+, K^+ -ATPase from cytosol to membrane
6. *De novo* synthesis of Na^+, K^+ -ATPase
7. Changes in permeability of tight junctions
8. Increased mitochondrial production of ATP

Cortisol also has affinity for the mineralocorticoid receptor but is inactivated in the cell by 11- β -hydroxysteroid dehydrogenase (HSD) type II.

B. Details of aldosterone's influences on membrane ENaC. ERK signaling phosphorylates components of ENaC, making them susceptible to interaction with Nedd4-2, a ubiquitin-protein ligase that ubiquitinates ENaC, leading to its degradation. The Nedd4-2 interaction with ENaC occurs via several proline-tyrosine-proline (PY) motifs of ENaC. ALDO enhances expression of the serum and glucocorticoid-induced kinase-1 (SGK1) and the glucocorticoid-induced leucine zipper protein (GILZ; TSC22D3). SGK-1 phosphorylates and inactivates Nedd4-2; 14-3-3 dimers bind to the phosphorylated sites in Nedd4-2 and stabilize them. Phosphorylated Nedd4-2 no longer interacts well with the PY motifs of ENaC. As a result, ENaC is not ubiquitinated and remains in the membrane, leading to increased Na^+ entry into the cell. GILZ stabilizes SGK1, enhancing its effects, and decreases ERK signaling and ENaC phosphorylation, events that prime ENaC for degradation; these effects all lead to less ubiquitination and more active ENaC in the cell membranes of the distal tubule and collecting duct. For details see Ronzaud and Staub (2014) and Ronchetti et al. (2015).

Abbreviations: AIP, aldosterone-induced proteins; ALDO, aldosterone; CH, ion channel; BL, basolateral membrane; LM, luminal membrane; MR, mineralocorticoid receptor.

Effects on Urinary Excretion

The effects of MR antagonists on urinary excretion are similar to those induced by renal ENaC inhibitors. However, unlike Na^+ channel inhibitors, the clinical efficacy of MR antagonists is a function of endogenous aldosterone levels. The higher the endogenous aldosterone level, the greater the effects of MR antagonists on urinary excretion. MR antagonists have little or no effect on renal hemodynamics and do not alter TGF.

Other Actions

Spironolactone has some affinity toward progesterone and androgen receptors and thereby induces side effects such as gynecomastia, impotence, and menstrual irregularities. Owing to its 9,11-epoxide group, eplerenone has very low affinity for progesterone and androgen receptors (<1% and <0.1%, respectively) compared with spironolactone. High spironolactone concentrations can interfere with steroid biosynthesis by inhibiting steroid hydroxylases, but these effects have limited clinical relevance.

ADME

Spironolactone is absorbed partially (~65%), is metabolized extensively (even during its first passage through the liver), undergoes enterohepatic

recirculation, and is highly protein bound. Although spironolactone per se has a short $t_{1/2}$ (~1.6 h), it is metabolized to a number of active compounds (including canrenone; see discussion that follows) that have long half-lives. The $t_{1/2}$ of spironolactone is prolonged to 9 h in patients with cirrhosis. Eplerenone has good oral availability and is eliminated primarily by metabolism by CYP3A4 to inactive metabolites, with a $t_{1/2}$ of about 5 h. Canrenone and K^+ -canrenoate also are in clinical use (not available in the U.S.). Canrenoate is not active but is converted to canrenone.

Therapeutic Uses

The MR antagonists often are coadministered with thiazide or loop diuretics in the treatment of edema and hypertension. Such combinations result in increased mobilization of edema fluid while causing lesser perturbations of K^+ homeostasis. MR antagonists are particularly useful in the treatment of resistant hypertension due to primary hyperaldosteronism (adrenal adenomas or bilateral adrenal hyperplasia) and of refractory edema associated with secondary aldosteronism (cardiac failure, hepatic cirrhosis, nephrotic syndrome, and severe ascites). MR antagonists are considered diuretics of choice in patients with hepatic cirrhosis. MR antagonists, added to standard therapy, substantially reduce morbidity

and mortality in patients with heart failure with reduced ejection fraction (see Chapter 29) (D'Elia and Krum, 2014).

The MR antagonists may reduce mortality in patients with systolic dysfunction following a myocardial infarction if treated within 3 to 6 days (Roush et al., 2014). In patients with diastolic dysfunction with preserved ejection fraction, the use of MR antagonists is controversial. In such patients, MR antagonists improve left ventricular end-diastolic filling, left ventricular remodeling, and neurohumoral activation but do not improve maximal exercise capacity, quality of life, mortality, or hospitalization for heart failure (Edelmann et al., 2013; Pitt et al., 2014). MR antagonists also may reduce ventricular arrhythmias and sudden cardiac death.

The MR antagonists reduce proteinuria in patients with chronic kidney disease, and the use of these drugs in kidney diseases is under intense investigation (Bauersachs et al., 2015). Spironolactone, but not eplerenone, is widely considered to be an antiandrogenic compound and has been used to treat hirsutism and acne; however, evidence for efficacy is weak (Brown et al., 2009), and these uses are not FDA-approved. Biochemical studies suggested that spironolactone is a partial agonist of androgen receptors (Nirdé et al., 2001) and can exert antiandrogenic or androgenic effects depending on context (e.g., the prevailing levels of endogenous androgenic steroids). Indeed, a recent case report described spironolactone-induced worsening of prostate cancer attributed to androgen receptor stimulation (Sundar and Dickinson, 2012).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Hyperkalemia is the principal risk of MR antagonists. Therefore, these drugs are contraindicated in patients with hyperkalemia and in those at increased risk of developing hyperkalemia. MR antagonists also can induce metabolic acidosis in cirrhotic patients. Salicylates may reduce the tubular secretion of canrenone and decrease diuretic efficacy of spironolactone. Spironolactone may alter the clearance of cardiac glycosides. Owing to its affinity for other steroid receptors, spironolactone may cause gynecomastia, impotence, decreased libido, and menstrual irregularities. Spironolactone also may induce diarrhea, gastritis, gastric bleeding, and peptic ulcers (the drug is contraindicated in patients with peptic ulcers). CNS adverse effects include drowsiness, lethargy, ataxia, confusion, and headache. Spironolactone may cause skin rashes and, rarely, blood dyscrasias. Strong inhibitors of CYP3A4 may increase plasma levels of eplerenone, and such drugs should not be administered to patients taking eplerenone and vice versa. Other than hyperkalemia and GI disorders, the rate of adverse events for eplerenone is similar to that of placebo.

Inhibitors of the Nonspecific Cation Channel: Natriuretic Peptides

Four NPs are relevant with respect to human physiology: ANP, BNP, CNP, and urodilatin. The IMCD is a major site of action of NPs.

Three NPs—ANP, BNP, and CNP—share a common homologous 17-member amino acid ring formed by a disulfide bridge between cysteine residues, although they are products of different genes. Urodilatin, also structurally similar, arises from altered processing of the same precursor molecule as ANP and has four additional amino acids at the N terminus. ANP and BNP are produced by the heart in response to wall stretch, CNP is of endothelial and renal cell origin; urodilatin is found in the kidney and urine. NPRs, classified as types A, B, and C, are membrane monospans. NPRA (binds ANP and BNP) and NPRB (binds CNP) have intracellular domains with guanylate cyclase activity and a protein kinase element. NPRC (binds all NPs) has a truncated intracellular domain and may help with NP clearance. The various NPs have somewhat overlapping effects, causing natriuresis, inhibition of production of renin and aldosterone, and vasodilation (the result of cGMP elevation in vascular smooth muscle). A human recombinant BNP, nesiritide, with the same 32-amino acid structure as the endogenous peptide produced by the ventricular myocardium, is available for clinical use.

Mechanism and Site of Action

The IMCD is the final site along the nephron where Na^+ is reabsorbed. Up to 5% of the filtered Na^+ load can be reabsorbed here. The effects of nesiritide and other NPs are mediated via effects of cGMP on Na^+ transporters (Figure 25–7). Two types of Na^+ channels are expressed in IMCD. The first is a high conductance, 28-pS, nonselective, CNGC. This channel is inhibited by intracellular cGMP and by NPs via their capacity to stimulate membrane-bound guanylyl cyclase activity and elevate cellular cGMP. The second type of Na^+ channel expressed in the IMCD is the low-conductance, 4-pS, highly selective Na^+ channel ENaC. The majority of Na^+ reabsorption in the IMCD is mediated via CNGC.

Effects on Urinary Excretion and Renal Hemodynamics

Nesiritide inhibits Na^+ transport in both the proximal nephron but its primary effect is in the IMCD. Urinary Na^+ excretion increases with nesiritide, but the effect may be attenuated by upregulation of Na^+ reabsorption in upstream segments of the nephron. GFR increases in response to nesiritide in normal subjects, but in treated patients with CHF, GFR may increase, decrease, or remain unchanged.

Other Actions

Administration of nesiritide decreases systemic and pulmonary resistances and left ventricular filling pressure and induces a secondary increase in cardiac output.

ADME

Natriuretic peptides are administered intravenously. Nesiritide has a distribution $t_{1/2}$ of 2 min and a mean terminal $t_{1/2}$ of 18 min. Clearance occurs via at least two mechanisms: internalization and subsequent degradation mediated by NPCR, and metabolism by extracellular proteases (Potter, 2011). There is no need to adjust the dose for renal insufficiency.

Therapeutic Uses

Human recombinant ANP (carperitide, available only in Japan) and BNP (nesiritide) are the available therapeutic agents of this class. Urodilatin (ularitide) is in development. Nesiritide is indicated for the management of acutely decompensated CHF. In patients who have dyspnea with minimal activity or at rest, nesiritide reduces pulmonary capillary wedge pressure and improves short-term symptoms of dyspnea. However, the ASCEND-HF trial found that nesiritide does not change mortality and

Figure 25–7 The IMCD Na^+ transport and its regulation. Na^+ enters the IMCD cell in one of two ways: via ENaC and through a CNGC that transports Na^+ , K^+ , and NH_4^+ and is gated by cGMP. Na^+ then exits the cell via the Na^+, K^+ -ATPase. The CNGC is the primary pathway for Na^+ entry and is inhibited by NPs. NPs bind to cell surface NPRs A, B, and C. The A and B receptors are isoforms of particulate guanylyl cyclase that synthesize cGMP. The CNGC is inhibited by cGMP directly and indirectly through PKG. PKG activation also inhibits Na^+ exit via the Na^+, K^+ -ATPase. ENaC is a low-conductance, 4-pS, highly selective Na^+ channel that plays a minor role in IMCD Na^+ transport (see Figure 25–6).

rehospitalization and has only a small effect on dyspnea (O'Connor et al., 2011). Thus, nesiritide is not recommended for routine use in the broad population of patients with acute heart failure (O'Connor et al., 2011).

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Nesiritide can cause hypotension, and there are concerns about adverse renal effects. However, the ASCEND-HF trial did not demonstrate worsening of renal function in nesiritide-treated patients with heart failure (O'Connor et al., 2011).

Adenosine Receptor Antagonists

There are four adenosine receptor subtypes (A_1 , A_{2A} , A_{2B} , and A_3). A_1 , A_{2A} , and A_{2B} receptors regulate aspects of renal physiology. The A_1 receptor is expressed in the proximal tubule and stimulates reabsorption of Na^+ . Consequently, antagonists of A_1 receptors cause diuresis/natriuresis, yet are K^+ sparing. Several naturally occurring methylxanthines (e.g., caffeine, theophylline, and theobromine) are A_1 receptor antagonists (albeit non-selective) and consequently cause diuresis. Pamabrom is a mild diuretic

consisting of a one-to-one mixture of 8-bromotheophylline and 2-amino-2-methyl-1-propanol; 8-bromotheophylline, a methylxanthine, is the active component of pamabrom. Pamabrom is the diuretic ingredient in several over-the-counter products marketed for relief of premenstrual syndrome. Little is known regarding the pharmacology, diuretic mechanism of action, and efficacy of pamabrom. However, because 8-bromotheophylline is a methylxanthine, it is possible that the mild diuresis induced by pamabrom is related to blockade of renal A_1 receptors.

Clinical Use of Diuretics

Site and Mechanism of Diuretic Action

An understanding of the sites and mechanisms of action of diuretics enhances comprehension of the clinical aspects of diuretic pharmacology. Figure 25–5 provides a summary view of the sites and mechanisms of actions of diuretics.

The Role of Diuretics in Clinical Medicine

Figure 25–8 illustrates interrelationships among renal function, Na^+ intake, water homeostasis, distribution of extracellular fluid volume, and

Figure 25–8 Interrelationships amongst renal function, Na^+ intake, water homeostasis, distribution of extracellular fluid volume, and mean arterial blood pressure. Starting at upper left panel (#1), read this figure counterclockwise. Complex interrelationships exist amongst the cardiovascular system, kidneys, CNS, and capillary beds such that perturbations at one of these sites can affect all other sites. A primary law of the kidney is that Na^+ excretion is a steep function of mean arterial blood pressure (MABP) such that small increases in MABP cause marked increases in Na^+ excretion; this is known as the “pressure-natriuresis” relationship (upper left). Over any given time interval, the net change in total-body Na^+ is the dietary Na^+ intake minus the urinary excretion rate and other losses (lower left). If the pressure-natriuresis curve is right-shifted, a net positive Na^+ balance occurs, and the extracellular Na^+ concentration increases, thus stimulating water intake (thirst) and reducing urinary water output (via ADH release). These changes expand the extracellular fluid volume (ECFV), and the enlarged ECFV is distributed amongst many body compartments (lower right). ECFV on the arterial side of the circulation pressurizes the arterial tree (“sensed” ECFV), and increases MABP (upper right), thus increasing Na^+ excretion (and completing the loop). This loop cycles until net Na^+ accumulation is zero; i.e., in the long run, Na^+ intake must equal Na^+ loss.

These considerations explain the fundamental mechanisms of edema formation:

1. Rightward shift of renal pressure natriuresis curve.
2. Excessive dietary Na^+ intake.
3. Increased distribution of ECFV to peritoneal cavity (e.g., liver cirrhosis with increased hepatic sinusoidal hydrostatic pressure) leading to ascites formation.
4. Increased distribution of ECFV to lungs (e.g., left-sided heart failure with increased pulmonary capillary hydrostatic pressure) leading to pulmonary edema.
5. Increased distribution of ECFV to venous circulation (e.g., right-sided heart failure) leading to venous congestion.
6. Peripheral edema caused by altered Starling forces causing increased distribution of ECFV to interstitial space (e.g., diminished plasma proteins in nephrotic syndrome, severe burns, and liver disease).
7. Increased MABP resulting from “Sensed” ECFV on the arterial side of the heart.

These perturbations leading to edema can be addressed by: **A.** Correcting the underlying disease; **B.** Administering diuretics to left-shift the renal pressure-natriuresis relationship; **C.** Restricting dietary Na^+ intake.

ECFV, extracellular fluid volume; MABP, mean arterial blood pressure.

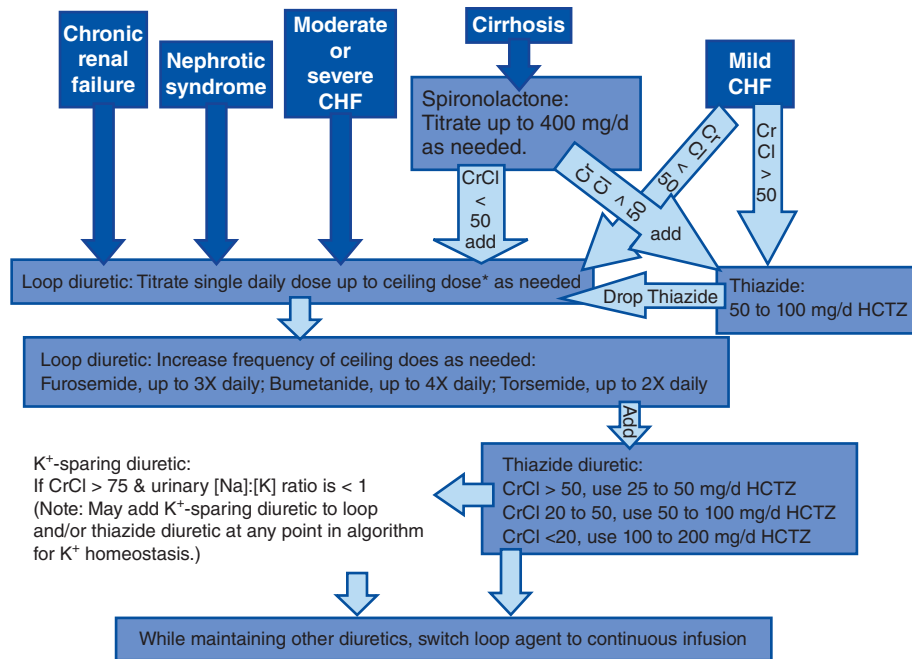

Figure 25–9 “Brater’s algorithm” for diuretic therapy of chronic renal failure, nephrotic syndrome, CHF, and cirrhosis. Follow algorithm until adequate response is achieved. If adequate response is not obtained, advance to the next step. For illustrative purposes, the thiazide diuretic used is HCTZ. An alternative thiazide-type diuretic may be substituted with dosage adjusted to be pharmacologically equivalent to the recommended dose of HCTZ. Do not combine two K^+ -sparing diuretics due to the risk of hyperkalemia. CrCl indicates creatinine clearance in milliliters per minute, and ceiling dose refers to the smallest dose of diuretic that produces a near-maximal effect. *Ceiling doses of loop diuretics and dosing regimens for continuous intravenous infusions of loop diuretics are disease-state specific. Doses are for adults only.

mean arterial blood pressure and suggests three fundamental strategies for mobilizing edema fluid:

- Correction of the underlying disease
- Restriction of Na^+ intake
- Administration of diuretics

Figure 25–9 presents a useful synthesis, Brater’s algorithm, a logically compelling algorithm for diuretic therapy (specific recommendations for drug, dose, route, and drug combinations) in patients with edema caused by renal, hepatic, or cardiac disorders (Brater, 1998).

The clinical situation dictates whether a patient should receive diuretics and what therapeutic regimen should be used (type of diuretic, dose, route of administration, and speed of mobilization of edema fluid). Massive pulmonary edema in patients with acute left-sided heart failure is a medical emergency requiring rapid, aggressive therapy, including intravenous administration of a loop diuretic. In this setting, use of oral diuretics is inappropriate. Conversely, mild pulmonary and venous congestion associated with chronic heart failure is best treated with an oral loop or thiazide diuretic, the dosage of which should be titrated carefully to maximize the benefit-to-risk ratio. Loop and thiazide diuretics decrease morbidity and mortality in patients with heart failure (Faris et al., 2002); MR antagonists also demonstrate reduced morbidity and mortality in patients with heart failure receiving optimal therapy with other drugs (Roush et al., 2014).

Periodic administration of diuretics to cirrhotic patients with ascites may eliminate the necessity for or reduce the interval between paracenteses, adding to patient comfort and sparing protein reserves that are lost during paracenteses. Although diuretics can reduce edema associated with chronic renal failure, increased doses of more powerful loop diuretics usually are required. In nephrotic syndrome, diuretic response often is disappointing. In chronic renal failure and cirrhosis, edema will not pose an immediate health risk but can greatly reduce quality of life. In such cases, only partial removal of edema fluid should be attempted, and fluid should be mobilized slowly using a diuretic regimen that accomplishes the task with minimal perturbation of normal physiology.

Diuretic resistance refers to edema that is or has become refractory to a given diuretic. If diuretic resistance develops against a less-efficacious diuretic, a more efficacious diuretic should be substituted, such as a loop diuretic for a thiazide. However, resistance to loop diuretics can be due to several causes. NSAID coadministration is a common preventable cause of diuretic resistance. PG production, especially PGE_2 , is an important counterregulatory mechanism in states of reduced renal perfusion such as volume contraction, CHF, and cirrhosis characterized by activation of the RAAS and sympathetic nervous system. NSAID administration can block PG-mediated effects that counterbalance the RAAS and sympathetic nervous system, resulting in salt and water retention. Diuretic resistance also occurs with COX-2-selective inhibitors.

In chronic renal failure, a reduction in RBF decreases delivery of diuretics to the kidney, and accumulation of endogenous organic acids competes with loop diuretics for transport at the proximal tubule. Consequently, diuretic concentration at the active site in the tubular lumen is diminished. In nephrotic syndrome, binding of diuretics to luminal albumin was postulated to limit response; however, the validity of this concept has been challenged. In hepatic cirrhosis, nephrotic syndrome, and heart failure, nephrons may have diminished diuretic responsiveness because of increased proximal tubular Na^+ reabsorption, leading to diminished Na^+ delivery to distal nephrons.

Faced with resistance to loop diuretics, the clinician has several options:

- Bed rest may restore drug responsiveness by improving the renal circulation.
- An increase in dose of loop diuretic may restore responsiveness; however, nothing is gained by increasing the dose above that which causes a near-maximal effect (the ceiling dose) of the diuretic.
- Administration of smaller doses more frequently or a continuous intravenous infusion of a loop diuretic will increase the length of time that an effective diuretic concentration is at the active site.
- Use of combination therapy to sequentially block more than one site in the nephron may result in a synergistic interaction between two diuretics. For example, a combination of a loop diuretic with a K^+ -sparing or a

thiazide diuretic may improve therapeutic response; however, nothing is gained by the administration of two drugs of the same type. Thiazide diuretics with significant proximal tubular effects (e.g., metolazone) are particularly well suited for sequential blockade when coadministered with a loop diuretic.

- Reducing salt intake will diminish postdiuretic Na^+ retention, which can nullify previous increases in Na^+ excretion.
- Scheduling of diuretic administration shortly before food intake will provide effective diuretic concentration in the tubular lumen when salt load is highest.

Part II: Water Homeostasis and the Vasopressin System

Vasopressin Physiology

Arginine vasopressin (ADH in humans) is the main hormone that regulates body fluid osmolality. The hormone is released by the posterior pituitary whenever water deprivation causes an increased plasma osmolality or whenever the cardiovascular system is challenged by hypovolemia or hypotension. Vasopressin acts primarily in the renal collecting duct to increase the permeability of the cell membrane to water, thus permitting water to move passively down an osmotic gradient across the collecting duct into the extracellular compartment.

Vasopressin is a potent vasopressor/vasoconstrictor. It is also a neurotransmitter; among its actions in the CNS are apparent roles in the secretion of ACTH and in regulation of the cardiovascular system, temperature, and other visceral functions. Vasopressin also promotes release of coagulation factors by vascular endothelium and increases platelet aggregability.

Anatomy of the Vasopressin System

The antidiuretic mechanism in mammals involves two anatomical components: a CNS component for synthesis, transport, storage, and release of vasopressin and a renal collecting duct system composed of epithelial cells that respond to vasopressin by increasing their water permeability. The CNS component of the antidiuretic mechanism is called the *hypothalamoneurohypophyseal system* and consists of neurosecretory

neurons with perikarya located predominantly in two specific hypothalamic nuclei, the SON and PVN. Long axons of magnocellular neurons in SON and PVN terminate in the neural lobe of the posterior pituitary (neurohypophysis), where they release vasopressin and oxytocin (see Figure 42–1).

Synthesis of Vasopressin

Vasopressin and oxytocin are synthesized mainly in the perikarya of magnocellular neurons in the SON and PVN. However, parvocellular neurons in the PVN also synthesize vasopressin, as do some non-CNS cells (see discussion that follows). Vasopressin synthesis appears to be regulated solely at the transcriptional level. In humans, a 168-amino acid preprohormone (Figure 25–10) is synthesized and then packaged into membrane-associated granules. The prohormone contains three domains: vasopressin (residues 1–9), vasopressin-neurophysin (residues 13–105), and vasopressin-glycopeptide (residues 107–145). The vasopressin domain is linked to the vasopressin-neurophysin domain through a GLY-LYS-ARG-processing signal, and the vasopressin-neurophysin is linked to the vasopressin-glycopeptide domain by an ARG-processing signal. In secretory granules, an endopeptidase, exopeptidase, monooxygenase, and lyase act sequentially on the prohormone to produce vasopressin, vasopressin-neurophysin (sometimes referred to as neurophysin II), and vasopressin-glycopeptide. The synthesis and transport of vasopressin depend on the preprohormone conformation. In particular, vasopressin-neurophysin binds vasopressin and is critical for correct processing, transport, and storage of vasopressin. Genetic mutations in either the signal peptide or vasopressin-neurophysin give rise to central DI.

Vasopressin also is synthesized by the heart and adrenal gland. In the heart, elevated wall stress increases vasopressin synthesis several-fold and may contribute to impaired ventricular relaxation and coronary vasoconstriction. Vasopressin synthesis in the adrenal medulla stimulates catecholamine secretion from chromaffin cells and may promote adrenal cortical growth and stimulate aldosterone synthesis.

Regulation of Vasopressin Secretion

Hyperosmolality. An increase in plasma osmolality is the principal physiological stimulus for vasopressin secretion by the posterior pituitary. The osmolality threshold for secretion is about 280 mOsm/kg. Below the

Figure 25–10 Processing of human AVP preprohormone. More than 40 mutations in the single gene on chromosome 20 that encodes AVP preprohormone give rise to central DI. *Boxes indicate mutations leading to central DI.

threshold, vasopressin is barely detectable in plasma, and above the threshold, vasopressin levels are a steep and relatively linear function of plasma osmolality. Indeed, a 2% elevation in plasma osmolality causes a 2- to 3-fold increase in plasma vasopressin levels, which in turn causes increased solute-free water reabsorption, with an increase in urine osmolality. Increases in plasma osmolality above 290 mOsm/kg lead to an intense desire for water (thirst). Thus, the vasopressin system affords the organism longer thirst-free periods and, in the event that water is unavailable, allows the organism to survive longer periods of water deprivation. Above a plasma osmolality of approximately 290 mOsm/kg, plasma vasopressin levels exceed 5 pM. Since urinary concentration is maximal (~1200 mOsm/kg) when vasopressin levels exceed 5 pM, further defense against hypertonicity depends entirely on water intake rather than on decreases in water loss.

Hepatic Portal Osmoreceptors. An oral salt load activates hepatic portal osmoreceptors, leading to increased vasopressin release. This mechanism augments plasma vasopressin levels even before the oral salt load increases plasma osmolality.

Hypovolemia and Hypotension. Vasopressin secretion is regulated hemodynamically by changes in effective blood volume or arterial blood pressure. Regardless of the cause (e.g., hemorrhage, Na⁺ depletion, diuretics, heart failure, hepatic cirrhosis with ascites, adrenal insufficiency, or hypotensive drugs), reductions in effective blood volume or arterial blood pressure are associated with high circulating vasopressin concentrations. However, unlike osmoregulation, hemodynamic regulation of vasopressin secretion is exponential; that is, small decreases (5%) in blood volume or pressure have little effect on vasopressin secretion, whereas larger decreases (20%–30%) can increase vasopressin levels to 20–30 times normal (exceeding the vasopressin concentration required to induce maximal antidiuresis). Vasopressin is one of the most potent vasoconstrictors known, and the vasopressin response to hypovolemia or hypotension serves as a mechanism to stave off cardiovascular collapse during periods of severe blood loss or hypotension. Hemodynamic regulation of vasopressin secretion does not disrupt osmotic regulation; rather, hypovolemia/hypotension alters the set point and slope of the plasma osmolality–plasma vasopressin relationship.

Neuronal pathways that mediate hemodynamic regulation of vasopressin release are different from those involved in osmoregulation. Baroreceptors in the left atrium, left ventricle, and pulmonary veins sense blood volume (filling pressures), and baroreceptors in the carotid sinus and aorta monitor arterial blood pressure. Nerve impulses reach brainstem nuclei predominantly through the vagal trunk and glossopharyngeal nerve; these signals are ultimately relayed to the SON and PVN.

Hormones and Neurotransmitters. Vasopressin-synthesizing magnocellular neurons have a large array of receptors on both perikarya and nerve terminals; therefore, vasopressin release can be accentuated or attenuated by chemical agents acting at both ends of the magnocellular neuron (Iovino et al., 2014). Also, hormones and neurotransmitters can modulate vasopressin secretion by stimulating or inhibiting neurons in nuclei that project, either directly or indirectly, to the SON and PVN (Iovino et al., 2014). Because of these complexities, modulation of vasopressin secretion by most hormones or neurotransmitters is unclear. Several agents stimulate vasopressin secretion, including acetylcholine (by nicotinic receptors), histamine (by H₁ receptors), dopamine (by both D₁ and D₂ receptors), glutamine, aspartate, cholecystokinin, neuropeptide Y, substance P, vasoactive intestinal polypeptide, PGs, and AngII. Inhibitors of vasopressin secretion include ANP, γ -aminobutyric acid, and opioids (particularly dynorphin via κ receptors). The effects of AngII have received the most attention. AngII synthesized in the brain and circulating AngII may stimulate vasopressin release. Inhibition of the conversion of AngII to AngIII blocks AngII-induced vasopressin release, suggesting that AngIII is the main effector peptide of the brain renin-angiotensin system controlling vasopressin release.

Pharmacological Agents. A number of drugs alter urine osmolality by stimulating or inhibiting vasopressin secretion. In most cases, the mechanism is not known. Stimulators of vasopressin secretion include

vincristine, cyclophosphamide, tricyclic antidepressants, nicotine, epinephrine, and high doses of morphine. Lithium, which inhibits the renal effects of vasopressin, also enhances vasopressin secretion. Inhibitors of vasopressin secretion include ethanol, phenytoin, low doses of morphine, glucocorticoids, fluphenazine, haloperidol, promethazine, oxilorphan, and butorphanol. Carbamazepine has a renal action to produce antidiuresis in patients with central DI but actually inhibits vasopressin secretion by a central action. Ethanol inhibits vasopressin secretion (see Chapter 23).

Vasopressin Receptors

Cellular vasopressin effects are mediated mainly by interactions of the hormone with the three types of receptors: V_{1a}, V_{1b}, and V₂. All are GPCRs. The V_{1a} receptor is the most widespread subtype of vasopressin receptor; it is found in vascular smooth muscle, adrenal gland, myometrium, bladder, adipocytes, hepatocytes, platelets, renal medullary interstitial cells, vasa recta in the renal microcirculation, epithelial cells in the renal cortical collecting duct, spleen, testis, and many CNS structures. V_{1b} receptors have a more limited distribution and are found in the anterior pituitary, several brain regions, pancreas, and adrenal medulla. V₂ receptors are located predominantly in principal cells of the renal collecting duct system but also are present on epithelial cells in TAL and on vascular endothelial cells.

Figure 25–11 summarizes the current model of V₁ receptor-effector coupling. Vasopressin binding to V₁ receptors activates the G_s–PLC–IP₃ pathway, thereby mobilizing intracellular Ca²⁺ and activating PKC, ultimately causing biological effects that include immediate responses (e.g., vasoconstriction, glycogenolysis, platelet aggregation, and ACTH release) and growth responses in smooth muscle cells.

Principal cells in renal collecting duct have V₂ receptors on their basolateral membranes that couple to G_s to stimulate adenylyl cyclase activity (Figure 25–12). The resulting activation of the cyclic AMP/PKA pathway triggers an increased rate of insertion of water channel-containing vesicles (WCVs) into the apical membrane and a decreased rate of endocytosis of WCVs from the apical membrane. Because WCVs contain preformed functional water channels (aquaporin 2), their net shift into apical membranes in response to V₂ receptor stimulation greatly increases water permeability of the apical membrane (Nejsum, 2005) (see Figures 25–12 and 25–13).

V₂ receptor activation also increases urea permeability by 400% in the terminal portions of the IMCD. V₂ receptors increase urea permeability by activating a vasopressin-regulated urea transporter (termed VRUT, UTI, or UTA1), most likely by PKA-induced phosphorylation. Kinetics of vasopressin-induced water and urea permeability differ, and vasopressin-induced regulation of VRUT does not entail vesicular trafficking to the plasma membrane.

V₂ receptor activation also increases Na⁺ transport in TAL and collecting duct. Increased Na⁺ transport in TAL is mediated by three mechanisms that affect the Na⁺–K⁺–2Cl[–] symporter: rapid phosphorylation of the symporter, translocation of the symporter into the luminal membrane, and increased expression of symporter protein. The multiple mechanisms by which vasopressin increases water reabsorption are summarized in Figure 25–14.

Renal Actions of Vasopressin

Several sites of vasopressin action in kidney involve both V₁ and V₂ receptors. V₁ receptors mediate contraction of mesangial cells in the glomerulus and contraction of vascular smooth muscle cells in vasa recta and efferent arterioles. V₁ receptor-mediated reduction of inner medullary blood flow contributes to the maximum concentrating capacity of the kidney. V₁ receptors also stimulate PG synthesis by medullary interstitial cells. Because PGE₂ inhibits adenylyl cyclase in collecting ducts, stimulation of PG synthesis by V₁ receptors may counterbalance V₂ receptor-mediated antidiuresis. V₁ receptors on principal cells in cortical collecting ducts may inhibit V₂ receptor-mediated water flux by activation of PKC. V₂ receptors mediate the most prominent response to vasopressin, which is increased water permeability of the collecting duct at concentrations as low as 50 fM. Thus, V₂ receptor-mediated effects of vasopressin occur at concentrations far lower than are required to engage

Figure 25–11 Mechanism of V_1 receptor-effector coupling. Binding of AVP to V_1 vasopressin receptors (V_1) stimulates membrane-bound phospholipases. Stimulation of G_q activates the $PLC\beta$ - IP_3 /DAG- Ca^{2+} -PKC pathway. Activation of V_1 receptors also causes influx of extracellular Ca^{2+} by an unknown mechanism. PKC and Ca^{2+} /calmodulin-activated protein kinases phosphorylate cell-type-specific proteins, leading to cellular responses. A further component of the AVP response derives from the production of eicosanoids secondary to the activation of PLA_2 ; the resulting mobilization of AA provides substrate for eicosanoid synthesis by the COX and LOX pathways, leading to local production of PGs, TXs, and LT, which may activate myriad signaling pathways, including those linked to G_s and G_i .

V_1 receptor-mediated actions. Other renal actions mediated by V_2 receptors include increased urea transport in the IMCD and increased Na^+ transport in the TAL; both effects contribute to the urine-concentrating ability of the kidney. V_2 receptors also increase Na^+ transport in cortical collecting ducts, and this may synergize with aldosterone to enhance Na^+ reabsorption during hypovolemia.

Pharmacological Modification of the Antidiuretic Response to Vasopressin

The NSAIDs, particularly indomethacin, enhance the antidiuretic response to vasopressin. Because PGs attenuate antidiuretic responses to vasopressin and NSAIDs inhibit PG synthesis, reduced PG production probably accounts for potentiation of vasopressin's antidiuretic response. Carbamazepine and chlorpropamide also enhance antidiuretic effects of vasopressin by unknown mechanisms. In rare instances, chlorpropamide can induce water intoxication. A number of drugs inhibit the antidiuretic actions of vasopressin. Lithium is of particular importance because of its use in the treatment of manic-depressive disorders (Kishore and Ecelbarger, 2013). Acutely, Li^+ appears to reduce V_2 receptor-mediated stimulation of adenylyl cyclase. Also, Li^+ increases plasma levels of PTH, a partial antagonist to vasopressin. In most patients, the antibiotic demeclocycline attenuates the antidiuretic effects of vasopressin, probably owing to decreased accumulation and action of cyclic AMP (Kortenoeven et al., 2013).

Nonrenal Actions of Vasopressin

Cardiovascular System. The cardiovascular effects of vasopressin are complex. Vasopressin is a potent vasoconstrictor (V_1 receptor mediated), and resistance vessels throughout the circulation may be affected. Vascular smooth muscle in the skin, skeletal muscle, fat, pancreas, and thyroid gland appears most sensitive, with significant vasoconstriction also occurring in the GI tract, coronary vessels, and brain. Despite the

potency of vasopressin as a direct vasoconstrictor, vasopressin-induced pressor responses in vivo are minimal and occur only with vasopressin concentrations significantly higher than those required for maximal antidiuresis. To a large extent, this is due to circulating vasopressin actions on V_1 receptors to inhibit sympathetic efferents and potentiate baroreflexes. In addition, V_2 receptors cause vasodilation in some blood vessels.

Vasopressin helps to maintain arterial blood pressure during episodes of severe hypovolemia/hypotension. The effects of vasopressin on the heart (reduced cardiac output and heart rate) are largely indirect and result from coronary vasoconstriction, decreased coronary blood flow, and alterations in vagal and sympathetic tone. Some patients with coronary insufficiency experience angina even in response to the relatively small amounts of vasopressin required to control DI, and vasopressin-induced myocardial ischemia has led to severe reactions and even death.

CNS. Vasopressin likely plays a role as a neurotransmitter or neuromodulator. Although vasopressin can modulate CNS autonomic systems controlling heart rate, arterial blood pressure, respiration rate, and sleep patterns, the physiological significance of these actions is unclear. While vasopressin is not the principal corticotropin-releasing factor, vasopressin may provide for sustained activation of the hypothalamic-pituitary-adrenal axis during chronic stress. Studies in both laboratory animals and humans indicated that vasopressin and oxytocin are key regulators of social and emotional behaviors (Benarroch, 2013). CNS effects of vasopressin appear to be mediated predominantly by V_1 receptors.

Blood Coagulation. Activation of V_2 receptors by desmopressin or vasopressin increases circulating levels of procoagulant factor VIII and of von Willebrand factor. These effects are mediated by extrarenal V_2 receptors. Presumably, vasopressin stimulates secretion of von Willebrand factor and of factor VIII from storage sites in vascular endothelium. However, because release of von Willebrand factor does not occur when desmopressin is applied directly to cultured endothelial cells or to isolated blood vessels, intermediate factors are likely to be involved.

Figure 25-12 Mechanism of V_2 receptor-effector coupling. Binding of AVP to the V_2 receptor activates the G_s -adenylyl cyclase-cAMP-PKA pathway and shifts the balance of aquaporin 2 trafficking toward the apical membrane of the principal cell of the collecting duct, thus enhancing water permeability. Although phosphorylation of Ser256 of aquaporin 2 is involved in V_2 receptor signaling, other proteins located in both the water channel-containing vesicles and the apical membrane of the cytoplasm also may be involved.

Other Nonrenal Effects. At high concentrations, vasopressin stimulates smooth muscle contraction in the uterus (by oxytocin receptors) and GI tract (by V_1 receptors). Vasopressin is stored in platelets, and activation of V_1 receptors stimulates platelet aggregation. Also, activation of V_1 receptors on hepatocytes stimulates glycogenolysis.

Vasopressin Receptor Agonists

A number of vasopressin-like peptides occur naturally across the animal kingdom (Table 25-8); all are nonapeptides. In all mammals except swine, the neurohypophyseal peptide is 8-arginine vasopressin, and the terms vasopressin, AVP, and ADH are used interchangeably. There are also a number of synthetic peptides with receptor-subtype specificity, and one nonpeptide agonist.

Many vasopressin analogues were synthesized with the goal of increasing duration of action and selectivity for vasopressin receptor subtypes (V_1 vs. V_2 receptors, which mediate pressor responses and antidiuretic responses, respectively). Thus, the antidiuretic-to-vasopressor ratio for the V_2 -selective agonist, DDAVP, also called desmopressin, is about 3000 times greater than that for vasopressin; thus, desmopressin is the preferred drug for the treatment of central DI. Substitution of valine for glutamine in position 4 further increases the antidiuretic selectivity, and the antidiuretic-to-vasopressor ratio for deamino [Val⁴, D-Arg⁸]AVP is about 11,000 times greater than that for vasopressin.

Figure 25-13 Structure of aquaporins. Aquaporins have six transmembrane domains, and the NH_2 and $COOH$ termini are intracellular. Loops b and e each contain an NPA sequence. Aquaporins fold with transmembrane domains 1, 2, and 6 in close proximity and transmembrane domains 3, 4 and 5 in juxtaposition. The long b and e loops dip into the membrane, and the NPA sequences align to create a pore through which water can diffuse. Most likely, aquaporins form a tetrameric oligomer. At least seven aquaporins are expressed at distinct sites in the kidney. Aquaporin 1, abundant in the proximal tubule and DTL, is essential for concentration of urine. Aquaporin 2, exclusively expressed in the principal cells of the connecting tubule and collecting duct, is the major vasopressin-regulated water channel. Aquaporin 3 and aquaporin 4 are expressed in the basolateral membranes of collecting duct principal cells and provide exit pathways for water reabsorbed apically by aquaporin 2. Aquaporin 7 is in the apical brush border of the straight proximal tubule. Aquaporins 6–8 are also expressed in kidney; their functions remain to be clarified. Vasopressin regulates water permeability of the collecting duct by influencing the trafficking of aquaporin 2 from intracellular vesicles to the apical plasma membrane (Figure 25-12). AVP-induced activation of the cAMP-PKA pathway also enhances expression of aquaporin 2 mRNA and protein; chronic dehydration thus causes upregulation of aquaporin 2 and water transport in the collecting duct.

Increasing V_1 selectivity has proved more difficult than increasing V_2 selectivity. Vasopressin receptors in the adenohypophysis that mediate vasopressin-induced ACTH release are neither classical V_1 nor V_2 receptors. Because vasopressin receptors in the adenohypophysis appear to share a common signal-transduction mechanism with classical V_1 receptors, and because many vasopressin analogues with vasoconstrictor activity release ACTH, V_1 receptors have been subclassified into V_{1a} (vascular/hepatic) and V_{1b} (pituitary) receptors (also called V_3 receptors). There are selective agonists for V_{1a} and V_{1b} receptors.

The chemical structure of oxytocin is closely related to that of vasopressin: Oxytocin is [Ile³, Leu⁸]AVP. With such structural similarities, it is not surprising that vasopressin and oxytocin agonists and antagonists can bind to each other's receptors. Therefore, most of the available peptide vasopressin agonists and antagonists have some affinity for oxytocin receptors; at high doses, they may block or mimic the effects of oxytocin.

Diseases Affecting the Vasopressin System

Diabetes Insipidus

Diabetes insipidus is a disease of impaired renal water conservation owing either to inadequate vasopressin secretion from the neurohypophysis

Figure 25-14 Mechanisms by which vasopressin increases the renal conservation of water. Red and black arrows denote major and minor pathways, respectively.

(central DI) or to insufficient renal vasopressin response (nephrogenic DI). Very rarely, DI can be caused by an abnormally high degradation rate of vasopressin by circulating vasopressinases. Pregnancy may accentuate or reveal central or nephrogenic DI by increasing plasma levels of vasopressinase and by reducing renal sensitivity to vasopressin. Patients with DI excrete large volumes (>30 mL/kg per day) of dilute (<200 mOsm/kg) urine and, if their thirst mechanism is functioning normally, are polydipsic. Central DI can be distinguished from nephrogenic DI by administration of desmopressin, which will increase urine osmolality in patients with central DI but have little or no effect in patients with nephrogenic DI. DI can be differentiated from primary polydipsia by measuring plasma osmolality, which will be low to low-normal in patients with primary polydipsia and high to high-normal in patients with DI.

Central DI. Head injury, either surgical or traumatic, in the region of the pituitary or hypothalamus may cause central DI. Postoperative central DI may be transient, permanent, or triphasic (recovery followed by permanent relapse). Other causes include hypothalamic or pituitary tumors, cerebral aneurysms, CNS ischemia, and brain infiltrations and infections. Central DI may also be idiopathic or familial. Familial central DI usually is autosomal dominant (chromosome 20), and vasopressin deficiency occurs several months or years after birth and worsens gradually. Autosomal dominant central DI is linked to mutations in the vasopressin pre-hormone gene that cause the prohormone to misfold and oligomerize improperly. Accumulation of mutant vasopressin precursor causes neuronal death, hence the dominant mode of inheritance. Rarely, familial central DI is autosomal recessive owing to a mutation in the vasopressin peptide itself that gives rise to an inactive vasopressin mutant.

Antidiuretic peptides are the primary treatment of central DI, with desmopressin the peptide of choice. For patients with central DI who cannot tolerate antidiuretic peptides because of side effects or allergic reactions, other treatment options are available. Chlorpropamide, an oral sulfonylurea, potentiates the action of small or residual amounts of

circulating vasopressin and will reduce urine volume in more than half of all patients with central DI. Doses of 125–500 mg daily appear effective in patients with partial central DI. If polyuria is not controlled satisfactorily with chlorpropamide alone, addition of a thiazide diuretic to the regimen usually results in an adequate reduction in urine volume. Carbamazepine (800–1000 mg daily in divided doses) also reduces urine volume in patients with central DI. Long-term use may induce serious adverse effects; therefore, carbamazepine is used rarely to treat central DI. These agents are not effective in nephrogenic DI, which indicates that functional V_2 receptors are required for the antidiuretic effect. Because carbamazepine inhibits and chlorpropamide has little effect on vasopressin secretion, it is likely that carbamazepine and chlorpropamide act directly on the kidney to enhance V_2 receptor-mediated antidiuresis.

Nephrogenic DI. Nephrogenic DI may be congenital or acquired. Hypercalcemia, hypokalemia, postobstructive renal failure, Li^+ , foscarnet, clozapine, demeclocycline, and other drugs can induce nephrogenic DI. As many as one in three patients treated with Li^+ may develop nephrogenic DI. X-linked nephrogenic DI is caused by mutations in the gene encoding the V_2 receptor, which maps to Xq28. Mutations in the V_2 receptor gene may cause impaired routing of the V_2 receptor to the cell surface, defective coupling of the receptor to G proteins, or decreased receptor affinity for vasopressin. Autosomal recessive and dominant nephrogenic DI result from inactivating mutations in aquaporin 2. These findings indicate that aquaporin 2 is essential for the antidiuretic effect of vasopressin in humans.

Although the mainstay of treatment of nephrogenic DI is assurance of an adequate water intake, drugs also can be used to reduce polyuria. Amiloride blocks Li^+ uptake by the Na^+ channel in the collecting duct system and may be effective in patients with mild-to-moderate concentrating defects. Thiazide diuretics reduce the polyuria of patients with DI and often are used to treat nephrogenic DI. In infants with nephrogenic DI, use of thiazides may be crucial because uncontrolled polyuria may exceed the child's capacity to imbibe and absorb fluids. It is possible that the natriuretic action of thiazides and resulting extracellular fluid volume depletion play an important role in thiazide-induced antidiuresis. The antidiuretic effects appear to parallel the thiazide's ability to cause natriuresis, and the drugs are given in doses similar to those used to mobilize edema fluid. In patients with DI, a 50% reduction of urine volume is a good response to thiazides. Moderate restriction of Na^+ intake can enhance the antidiuretic effectiveness of thiazides.

A number of case reports described the effectiveness of indomethacin in the treatment of nephrogenic DI; however, other PG synthase inhibitors (e.g., ibuprofen) appear to be less effective. The mechanism of the effect may involve a decrease in GFR, an increase in medullary solute concentration, or enhanced proximal fluid reabsorption. Also, because PGs attenuate vasopressin-induced antidiuresis in patients with at least a partially intact V_2 receptor system, some of the antidiuretic response to indomethacin may be due to diminution of the PG effect and enhancement of vasopressin effects on the principal cells of collecting duct.

Syndrome of Inappropriate Secretion of Antidiuretic Hormone

A disease of impaired water excretion with accompanying hyponatremia and hypoosmolality, SIADH caused by the *inappropriate* secretion of vasopressin. Clinical manifestations of plasma hypotonicity resulting from SIADH may include lethargy, anorexia, nausea and vomiting, muscle cramps, coma, convulsions, and death. A multitude of disorders can induce SIADH, including malignancies, pulmonary diseases, CNS injuries/diseases (e.g., head trauma, infections, and tumors), and general surgery.

Three drug classes are commonly implicated in drug-induced SIADH: psychotropic medications (e.g., selective serotonin reuptake inhibitors, haloperidol, and tricyclic antidepressants), sulfonylureas (e.g., chlorpropamide), and vinca alkaloids (e.g., vincristine and vinblastine). Other drugs strongly associated with SIADH include clonidine, cyclophosphamide, enalapril, felbamate, ifosfamide, methyl dopa, pentamidine,

and vinorelbine. Many other drugs have been implicated. In a normal individual, an elevation in plasma vasopressin per se does not induce plasma hypotonicity because the person simply stops drinking owing to an osmotically induced aversion to fluids. Therefore, plasma hypotonicity only occurs when excessive fluid intake (oral or intravenous) accompanies inappropriate secretion of vasopressin.

Treatment of hypotonicity in the setting of SIADH includes water restriction, intravenous administration of hypertonic saline, loop diuretics (which interfere with kidney's concentrating ability), and drugs that inhibit the effect of vasopressin to increase water permeability in collecting ducts. To inhibit vasopressin's action in collecting ducts, demeclocycline, a tetracycline, has been the preferred drug, but tolvaptan and conivaptan, V_2 receptor antagonists, are now available (see next section and Table 25–9).

Although Li^+ can inhibit the renal actions of vasopressin, it is effective in only a minority of patients, may induce irreversible renal damage when used chronically, and has a low therapeutic index. Therefore, Li^+ should be considered for use only in patients with symptomatic SIADH who cannot be controlled by other means or in whom tetracyclines are contraindicated (e.g., patients with liver disease). It is important to stress that the majority of patients with SIADH do not require therapy because plasma Na^+ stabilizes in the range of 125–132 mM; such patients usually are asymptomatic. Only when symptomatic hypotonicity ensues, generally when plasma Na^+ levels drop below 120 mM, should therapy with demeclocycline be initiated. Because hypotonicity, which causes an influx of water into cells with resulting cerebral swelling, is the cause of symptoms, the goal of therapy is simply to increase plasma osmolality toward normal.

Other Water-Retaining States

In patients with CHF, cirrhosis, or nephrotic syndrome, *effective* blood volume often is reduced, and hypovolemia frequently is exacerbated by the liberal use of diuretics. Because hypovolemia stimulates vasopressin release, patients may become hyponatremic owing to vasopressin-mediated retention of water. The development of potent orally active V_2 receptor antagonists and specific inhibitors of water channels in the collecting duct has provided a new therapeutic strategy not only in patients with SIADH but also in the more common setting of hyponatremia in patients with heart failure, liver cirrhosis, and nephrotic syndrome.

Clinical Use of Vasopressin Agonists

Two antidiuretic peptides are available for clinical use in the U.S.:

- *Vasopressin* (synthetic 8-L-arginine vasopressin) is available as a sterile aqueous solution; it may be administered intravenously, subcutaneously, intramuscularly, intranasally, intraosseously (off label), intra-arterially, or endotracheally (off label; unreliable).
- *Desmopressin acetate* (synthetic DDAVP) is available as a sterile aqueous solution packaged for intravenous or subcutaneous injection, in a solution for intranasal administration with either a nasal spray pump or rhinal tube delivery system, and in tablets for oral administration.

Therapeutic Uses

The therapeutic uses of vasopressin and its congeners can be divided into two main categories according to the vasopressin receptor involved: V_1 receptor mediated and V_2 receptor mediated.

V_1 receptor-mediated therapeutic applications are based on the rationale that V_1 receptors cause GI and vascular smooth muscle contraction. *Vasopressin is the main agent used.* V_1 receptor-mediated GI smooth muscle contraction has been used to treat postoperative ileus and abdominal distension and to displace intestinal gas before abdominal roentgenography to avoid interfering gas shadows. V_1 receptor-mediated vasoconstriction of the splanchnic arterial vessels reduces blood flow to the portal system and thereby attenuates pressure and bleeding in esophageal varices. Although endoscopic variceal banding ligation is the treatment of choice for bleeding esophageal varices, V_1 receptor agonists have been used in an emergency setting until endoscopy can be performed. Simultaneous administration of nitroglycerin with V_1 receptor agonists may attenuate the cardiotoxic effects of V_1 agonists while enhancing their beneficial

splanchnic effects. Also, V_1 receptor agonists have been used during abdominal surgery in patients with portal hypertension to diminish the risk of hemorrhage during the procedure. V_1 receptor-mediated vasoconstriction has been used to reduce bleeding during acute hemorrhagic gastritis, burn wound excision, cyclophosphamide-induced hemorrhagic cystitis, liver transplant, cesarean section, and uterine myoma resection. Vasopressin levels in patients with vasodilatory shock are inappropriately low, and such patients are extraordinarily sensitive to the pressor actions of V_1 receptor agonists. Therefore, V_1 receptor agonists are indicated for the treatment of hypotension in patients with vasodilatory shock that responds insufficiently to therapy with fluids and catecholamines (Sarpa Neto et al., 2012). Vasopressin combined with epinephrine and steroids showed improved outcomes after in-hospital cardiac arrest (Layek et al., 2014).

V_2 receptor-mediated therapeutic applications are based on the rationale that V_2 receptors cause water conservation and release of blood coagulation factors. *Desmopressin is the standard drug of choice.* Central, but not nephrogenic, DI can be treated with V_2 receptor agonists, and polyuria and polydipsia usually are well controlled by these agents. Some patients experience transient DI (e.g., in head injury or surgery in the area of the pituitary); however, therapy for most patients with DI is lifelong. Desmopressin is the drug of choice for the vast majority of patients. The duration of effect from a single intranasal dose is from 6 to 20 h; twice-daily administration is effective in most patients. The usual intranasal dosage in adults is 10–40 µg daily either as a single dose or divided into two or three doses. In view of the high cost of the drug and the importance of avoiding water intoxication, the schedule of administration should be adjusted to the minimal amount required. In some patients, chronic allergic rhinitis or other nasal pathology may preclude reliable peptide absorption following nasal administration. Oral administration of desmopressin in doses of 0.1–1.2 mg/d provides adequate desmopressin blood levels to control polyuria. Subcutaneous or intravenous administration of 2–4 µg daily of desmopressin also is effective in central DI.

Vasopressin has little, if any, place in the long-term therapy of DI because of its short duration of action and V_1 receptor-mediated side

effects. Vasopressin can be used as an alternative to desmopressin in the initial diagnostic evaluation of patients with suspected DI and to control polyuria in patients with DI who recently have undergone surgery or experienced head trauma. Under these circumstances, polyuria may be transient, and long-acting agents may produce water intoxication.

Desmopressin is used in bleeding disorders. In most patients with type I vWD and in some with type II_n vWD, desmopressin will elevate von Willebrand factor and shorten bleeding time. However, desmopressin generally is ineffective in patients with types II_a, II_b, and III vWD. Desmopressin may cause a marked transient thrombocytopenia in individuals with type II_b vWD and is contraindicated in such patients. Desmopressin also increases factor VIII levels in patients with mild-to-moderate hemophilia A. Desmopressin is not indicated in patients with severe hemophilia A, those with hemophilia B, or those with factor VIII antibodies. In patients with renal insufficiency, desmopressin shortens bleeding time and increases circulating levels of factor VIII coagulant activity, factor VIII-related antigen, and ristocetin cofactor. It also induces the appearance of larger von Willebrand factor multimers. Desmopressin is effective in some patients with liver cirrhosis- or drug-induced (e.g., heparin, hirudin, and antiplatelet agents) bleeding disorders. Desmopressin, given intravenously at a dose of 0.3 µg/kg, increases factor VIII and von Willebrand factor for more than 6 h. Desmopressin can be given at intervals of 12–24 h depending on the clinical response and severity of bleeding. Tachyphylaxis to desmopressin usually occurs after several days (owing to depletion of factor VIII and von Willebrand factor storage sites) and limits its usefulness to preoperative preparation, postoperative bleeding, excessive menstrual bleeding, and emergency situations.

Another V_2 receptor-mediated therapeutic application is the use of desmopressin for primary nocturnal enuresis. Bedtime administration of desmopressin tablets provides a high response rate that is sustained with long-term use and that accelerates the cure rate. Intranasal desmopressin is no longer recommended for the treatment of primary nocturnal enuresis because of increased risk of hyponatremia. Desmopressin also relieves post-lumbar puncture headache, probably by causing water retention and thereby facilitating rapid fluid equilibration in the CNS.

When vasopressin and desmopressin are given orally, they are inactivated quickly by trypsin. Inactivation by peptidases in various tissues (particularly liver and kidney) results in a plasma $t_{1/2}$ of vasopressin of 17–35 min. Following intramuscular or subcutaneous injection, antidiuretic effects of vasopressin last 2–8 h. The $t_{1/2}$ of desmopressin is 75 min to 3.5 h.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

Most adverse effects are mediated through V_1 receptor activation on vascular and GI smooth muscle; such adverse effects are much less common and less severe with desmopressin than with vasopressin. After injection of large doses of vasopressin, marked facial pallor owing to cutaneous vasoconstriction is observed commonly. Increased intestinal activity is likely to cause nausea, belching, cramps, and an urge to defecate. Vasopressin should be administered with extreme caution in individuals suffering from vascular disease, especially coronary artery disease. Other cardiac complications include arrhythmia and decreased cardiac output. Peripheral vasoconstriction and gangrene were encountered in patients receiving large doses of vasopressin.

The major V_2 receptor-mediated adverse effect is water intoxication. Many drugs, including carbamazepine, chlorpropamide, morphine, tricyclic antidepressants, and NSAIDs, can potentiate the antidiuretic effects of these peptides. Several drugs, such as Li^+ , demeclocycline, and ethanol, can attenuate the antidiuretic response to desmopressin. Desmopressin and vasopressin should be used cautiously in disease states in which a rapid increase in extracellular water may impose risks (e.g., in angina, hypertension, and heart failure) and should not be used in patients with acute renal failure. Patients receiving desmopressin to maintain hemostasis should be advised to reduce fluid intake. Also, it is imperative that these peptides not be administered to patients with primary or psychogenic polydipsia because severe hypotonic hyponatremia will ensue. Mild facial flushing and headache are the most common adverse effects. Allergic reactions ranging from urticaria to anaphylaxis may occur with desmopressin or vasopressin. Intranasal administration may cause local adverse effects in the nasal passages, such as edema, rhinorrhea, congestion, irritation, pruritus, and ulceration.

Clinical Use of Vasopressin Antagonists

Table 25–9 summarizes the selectivity of vasopressin receptor antagonists. Only tolvaptan and conivaptan are currently available in the United States.

Therapeutic Uses

When the kidney perceives the arterial blood volume to be low (as in the disease states of CHF, cirrhosis, and nephrosis), AVP perpetuates a state

of total body salt and water excess. V_2 receptor antagonists or “aquaretics” may have a therapeutic role in these conditions, especially in patients with concomitant hyponatremia. They are also effective in hyponatremia associated with SIADH. Aquaretics increase renal free water excretion with little or no change in electrolyte excretion. Because they do not affect Na^+ reabsorption, they do not stimulate the TGF mechanism with its associated consequence of reducing GFR.

Tolvaptan is a selective oral V_2 receptor antagonist FDA-approved for clinically significant hypervolemic and euvoletic hyponatremia. Conivaptan is a nonselective V_{1a} receptor/ V_2 receptor antagonist that is FDA-approved for the treatment of hospitalized patients with euvoletic and hypervolemic hyponatremia. Conivaptan is available only for intravenous infusion. Expert panels have yet to reach a consensus regarding the appropriate use of V_2 receptor antagonists (Berl, 2015).

ADME

Tolvaptan has a $t_{1/2}$ of 2.8–12 h and less than 1% is excreted in the urine. Tolvaptan is a substrate and inhibitor of P-glycoprotein and is eliminated entirely by CYP3A4 metabolism. Conivaptan is highly protein bound, has a terminal elimination $t_{1/2}$ of 5–12 h, is metabolized via CYP3A, and is partially excreted by the kidney.

Toxicity, Adverse Effects, Contraindications, Drug Interactions

The most dangerous adverse effect of V_2 receptor antagonists is due to their pharmacological action to increase free water excretion. This may correct hyponatremia too rapidly, resulting in serious and even fatal consequences (osmotic demyelination syndrome). Indeed, tolvaptan is labeled with a black-box warning against too rapid correction of hyponatremia and with the recommendation to initiate therapy in a hospital setting capable of close monitoring of serum Na^+ . V_2 receptor antagonists should not be used with hypertonic saline. Antagonism of V_2 receptors can also cause polyuria, which likely explains the increased incidence of dehydration, hypotension, dizziness, pyrexia, increased thirst, and xerostomia with this class of drugs. Both tolvaptan and conivaptan can cause adverse GI adverse effects. Tolvaptan can cause liver damage; therefore, administration of tolvaptan generally should be limited to 30 days, and tolvaptan should not be used in patients with liver disease. Both tolvaptan and conivaptan can induce headaches, hypokalemia, and hyperglycemia, and both are contraindicated in anuria (no benefit) and in patients receiving drugs that inhibit CYP3A4 (e.g., clarithromycin, ketoconazole).

FUNCTIONS AND EFFECTS OF ANGIOTENSIN II

- Mechanisms by Which Angiotensin II Increases Peripheral Resistance
- Mechanisms by Which Angiotensin II Regulates Renal Function
- Mechanisms by Which Angiotensin II Alters Cardiovascular Structure
- Role of the RAS in Long-Term Maintenance of Arterial Blood Pressure Despite Extremes in Dietary Na⁺ Intake

INHIBITORS OF THE RENIN-ANGIOTENSIN SYSTEM

- Angiotensin-Converting Enzyme Inhibitors
- Angiotensin II Receptor Blockers
- Direct Renin Inhibitors
- Effect of Pharmacological Blood Pressure Reduction on Function of the RAS

The Renin-Angiotensin System

The RAS participates in the pathophysiology of hypertension, congestive heart failure, myocardial infarction, and diabetic nephropathy. This realization has led to a thorough exploration of the RAS and the development of new approaches for inhibiting its actions. This chapter discusses the physiology, biochemistry, and cellular and molecular biology of the classical RAS and novel RAS components and pathways. The chapter also discusses the basic pharmacology of drugs that interrupt the RAS, and the clinical utility of inhibitors of the RAS. Therapeutic applications of drugs covered in this chapter are also discussed in Chapters 27–29.

History

In 1898, Tiegerstedt and Bergman found that crude saline extracts of the kidney contained a pressor substance that they named *renin*. In 1934, Goldblatt and his colleagues demonstrated that constriction of the renal arteries produced persistent hypertension in dogs. In 1940, Braun-Menéndez and his colleagues in Argentina and Page and Helmer in the U.S. reported that renin was an enzyme that acted on a plasma protein substrate to catalyze the formation of the actual pressor material, a peptide, that was named *hypertensin* by the former group and *angiotonin* by the latter. Ultimately, the pressor substance was renamed *angiotensin*, and the plasma substrate was called *angiotensinogen*.

In the mid-1950s, two forms of angiotensin were recognized, a decapeptide (AngI) and an octapeptide (AngII) formed by proteolytic cleavage of AngI by an enzyme termed *ACE*. The octapeptide was the more active form, and its synthesis in 1957 by Schwyzler and by Bumpus made the material available for intensive study. Later research showed that the kidneys are an important site of aldosterone action, and that angiotensin potentially stimulates the production of aldosterone in humans. Moreover, renin secretion increased with depletion of Na⁺. Thus, the RAS became recognized as a mechanism to stimulate aldosterone synthesis and secretion and an important homeostatic mechanism in the regulation of blood pressure and electrolyte composition.

In the early 1970s, polypeptides were discovered that either inhibited the formation of AngII or blocked AngII receptors. These inhibitors

revealed important physiological and pathophysiological roles for the RAS and inspired the development of a new and broadly efficacious class of antihypertensive drugs: the orally active ACE inhibitors. Studies with ACE inhibitors uncovered roles for the RAS in the pathophysiology of hypertension, heart failure, vascular disease, and renal failure. Selective and competitive antagonists of AngII receptors were subsequently developed that yielded losartan, the first orally active, highly selective, and potent nonpeptide AngII receptor antagonist (Dell'Italia, 2011). Subsequently, many other AngII receptor antagonists have been developed; more recently, aliskiren, a direct renin inhibitor, was approved for antihypertensive therapy.

Classical RAS

Through the actions of AngII, the RAS participates in blood pressure regulation, aldosterone release, Na⁺-reabsorption from renal tubules, electrolyte and fluid homeostasis, and cardiovascular remodeling. AngII is derived from angiotensinogen in two proteolytic steps. First, the enzyme renin, released into the circulation from the JG cells in the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, an ACE, located on the endothelial cell lining of the vasculature, removes the carboxy-terminal dipeptide of AngI to produce the octapeptide AngII. These enzymatic steps are summarized in Figure 26–1. AngII acts by binding to two distinct heptaspanning GPCRs, AT₁ and AT₂.

New Paradigms in the RAS

The RAS has expanded from being solely an endocrine system to include a paracrine, autocrine/intracrine hormonal system with several new components and active pathways. The current understanding of the RAS involves local (tissue) RAS; alternative pathways for AngII synthesis (*ACE independent* and *renin independent*); an ACE2/Ang(1–7)/Mas receptor axis that opposes the vasoconstrictor effects of ACE/AngII/AT₁ receptor axis; an AngIV/AT₄ receptor axis that is important in brain functions and cognition; multiple biologically active angiotensin peptides such as Ang(1–9), AngIII, Ang(3–7), angiotensin A, and alamandine; multiple receptors for angiotensin (AT₁, AT₂, AT₄; Mas; and MrgD); and

ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
Ac-SDKP: *N*-acetyl-seryl-aspartyl-lysyl-proline
ACTH: corticotropin (formerly adrenocorticotrophic hormone)
Ang: angiotensin
ARB: angiotensin receptor blocker
ATR: angiotensin receptor
BP: blood pressure
cAMP: cyclic AMP
CNS: central nervous system
COX: cyclooxygenase
DRI: direct renin inhibitor
FDA: Food and Drug Administration
GFR: glomerular filtration rate
GI: gastrointestinal
GPCR: G protein-coupled receptor
HCTZ: hydrochlorothiazide
JG: juxtaglomerular
LDL: low-density lipoprotein
MrgD: Mas-related G protein-coupled receptor D
NE: norepinephrine
NO: nitric oxide
NOS: nitric oxide synthase
NSAID: nonsteroidal anti-inflammatory drug
PAI-1: plasminogen activator inhibitor type 1
PCP: prolylcarboxypeptidase
PG: prostaglandin
PI₃K: phosphoinositide 3-kinase
PL: phospholipase
PRA: plasma renin activity
PRC: plasma renin concentration
(pro)renin: renin and prorenin
PRR: (pro)renin receptor
RAS: renin-angiotensin system
RBF: renal blood flow
ROS: reactive O₂ species
TGF: transforming growth factor
TPR: total peripheral resistance

the PRR. Differential activation of these multiple arms of the RAS may underlie the pathophysiological outcome in cardiovascular and renal disease (Campbell, 2014; Santos, 2014).

Components of the Renin-Angiotensin System

Renin

Renin is the major determinant of the rate of AngII production; its secretion is regulated by several mechanisms (Figures 26–1 through 26–3). Renin is synthesized, stored, and secreted by exocytosis into the renal arterial circulation by the granular JG cells located in the walls of the afferent arterioles that enter the glomeruli. Renin is an aspartyl protease that cleaves the bond between residues 10 and 11 at the amino terminus of angiotensinogen to generate AngI. The active form of renin is a glycoprotein that contains 340 amino acids. It is synthesized as a proenzyme that is processed to prorenin.

Prorenin may be activated in two ways (Figure 26–2): *proteolytically*, by proconvertase 1 or cathepsin B enzymes that remove 43 amino acids (propeptide) from its amino terminus to uncover the active site of renin; and *nonproteolytically*, when prorenin binds to the PRR, resulting in

conformational changes that unfold the propeptide and expose the active catalytic site of the enzyme (Nguyen and Danser, 2008). Both renin and prorenin are stored in the JG cells and, when released, circulate in the blood. The concentration of prorenin in the circulation is about 10-fold greater than that of the active enzyme. The $t_{1/2}$ of circulating renin is about 15 min.

Control of Renin Secretion

Renin is secreted by the granular cells within the JG apparatus and is regulated by the following pathways (Figure 26–3):

1. The macula densa pathway
2. The intrarenal baroreceptor pathway
3. The β_1 adrenergic receptor pathway

The Macula Densa Pathway

The macula densa pathway provides an important function for salt and water regulation by the RAS. The macula densa lies adjacent to the JG cells and is composed of specialized columnar epithelial cells in the wall of that portion of the cortical thick ascending limb that passes between the afferent and efferent arterioles of the glomerulus. A change in NaCl reabsorption by the macula densa results in the transmission to nearby JG cells of chemical signals that modify renin release. Increases in NaCl flux across the macula densa inhibit renin release, whereas decreases in NaCl flux stimulate renin release.

Adenosine, ATP, and PGs modulate the macula densa pathway (Figure 26–4). ATP and adenosine *inhibit renin release* when NaCl transport *increases*. ATP acts via P2Y receptors to enhance Ca²⁺ release, and adenosine acts via the A₁ adenosine receptor to inhibit adenylyl cyclase activity and cyclic AMP production. PGE₂ and PGI₂ *stimulate renin release* when NaCl transport *decreases* through enhancing cyclic AMP formation. PG production is enhanced by inducible cyclooxygenase 2 (COX-2) and nNOS. The expression of COX-2 and nNOS is upregulated by chronic dietary Na⁺ restriction; selective inhibition of either COX-2 or nNOS inhibits renin release (Peti-Peterdi et al., 2010).

Regulation of the macula densa pathway is more dependent on the luminal concentration of Cl[−] than Na⁺. NaCl transport into the macula densa is mediated by the Na⁺-K⁺-2Cl[−] symporter (Figure 26–4), and the half-maximal concentrations of Na⁺ and Cl[−] required for transport via this symporter are 2–3 and 40 mEq/L, respectively. Because the luminal concentration of Na⁺ at the macula densa usually is much greater than the level required for half-maximal transport, physiological variations in luminal Na⁺ concentrations at the macula densa have little effect on renin release (i.e., the symporter remains saturated with respect to Na⁺). Conversely, physiological changes in Cl[−] concentrations (20–60 mEq/L) at the macula densa profoundly affect macula densa-mediated renin release.

The Intrarenal Baroreceptor Pathway

Increases and decreases in blood pressure or renal perfusion pressure in the preglomerular vessels inhibit and stimulate renin release, respectively. The immediate stimulus to secretion is believed to be reduced tension within the wall of the afferent arteriole. The release of renal PGs and biomechanical coupling via stretch-activated ion channels may mediate in part the intrarenal baroreceptor pathway.

The β_1 Adrenergic Receptor Pathway

The β_1 adrenergic receptor pathway is regulated by the release of NE from postganglionic sympathetic nerves; activation of β_1 receptors on JG cells increases cyclic AMP and enhances renin secretion. Treatment with β blockers reduces renin secretion and PRA.

Feedback Regulation

Renin release is subject to feedback regulation (Figure 26–3). Increased renin secretion enhances the formation of AngII, which stimulates AT₁ receptors on JG cells to inhibit renin release, an effect termed *short-loop negative feedback*. Inhibition of renin release due to AngII-dependent increase in blood pressure is termed *long-loop negative feedback*. AngII increases arterial blood pressure via AT₁ receptors; this effect inhibits renin release by the following:

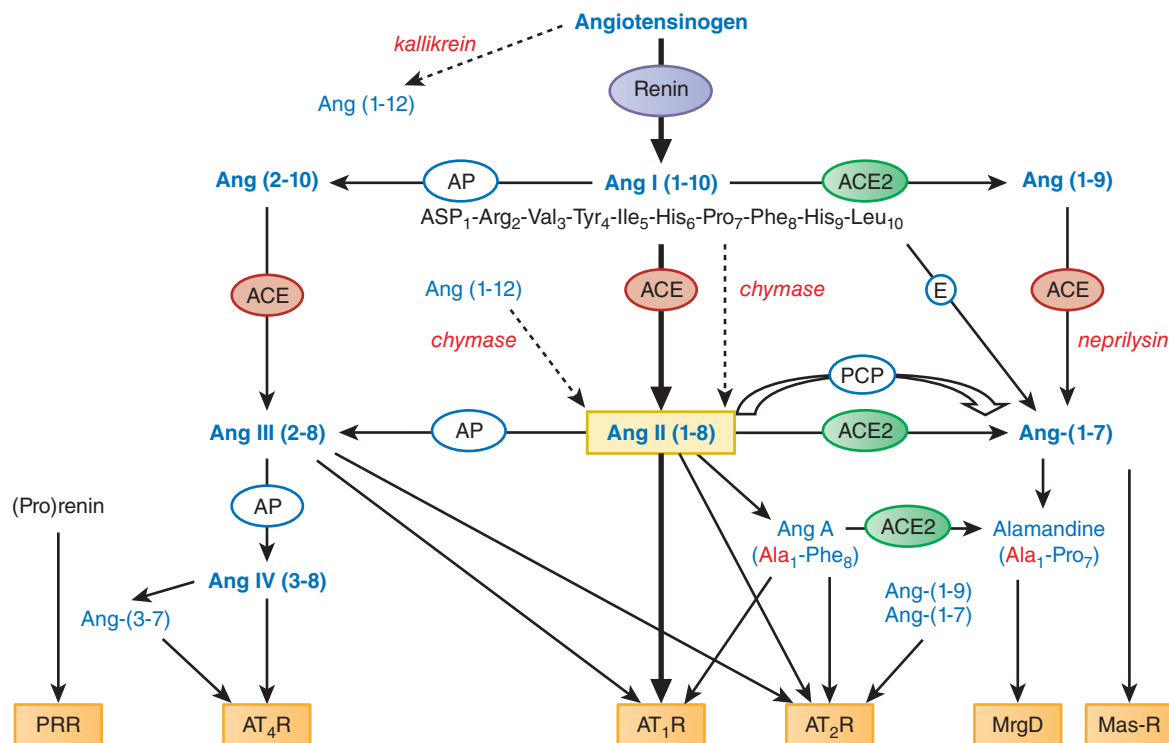

Figure 26-1 Components of the RAS. The heavy arrows show the classical pathway, and the light arrows indicate alternative pathways. Receptors involved: AT_1 , AT_2 , AT_4 , Mas, MrgD, and PRR. AP, aminopeptidase; E, endopeptidases; PCP, prolylcarboxypeptidase.

1. Activating high-pressure baroreceptors, thereby reducing renal sympathetic tone
2. Increasing pressure in the preglomerular vessels
3. Reducing NaCl reabsorption in the proximal tubule (pressure natriuresis), which increases tubular delivery of NaCl to the macula densa

Drugs That Affect Renin Secretion

Renin release is influenced by arterial blood pressure, dietary salt intake, and pharmacological agents (Figures 26-3 and 26-4). Loop diuretics stimulate renin release and increase PRC by decreasing arterial blood pressure and by blocking the reabsorption of NaCl at the macula densa. NSAIDs inhibit PG synthesis and thereby decrease renin release. ACE inhibitors, ARBs, and renin inhibitors interrupt both the short- and long-loop negative-feedback mechanisms and therefore increase renin release and PRC. Centrally acting sympatholytic drugs, as well as β_1 adrenergic

receptor antagonists, decrease renin secretion by reducing activation of β_1 adrenergic receptors on JG cells.

Angiotensinogen

The substrate for renin is angiotensinogen, an abundant globular glycoprotein. AngI is cleaved by renin from the amino terminus of angiotensinogen. Human angiotensinogen contains 452 amino acids and is synthesized as preangiotensinogen, which has a 24- or 33-amino acid signal peptide. Angiotensinogen is synthesized and secreted primarily by the liver, although angiotensinogen transcripts occur in many tissues, including the heart, kidneys, pancreas, adipocytes, and certain regions of the CNS. Biosynthesis of angiotensinogen is stimulated by inflammation, insulin, estrogens, glucocorticoids, thyroid hormone, and AngII. During pregnancy, plasma levels of angiotensinogen increase several-fold owing to increased estrogen.

Figure 26-2 Biological activation of prorenin and pharmacological inhibition of renin. Prorenin is inactive; accessibility of AGT (angiotensinogen) to the catalytic site is blocked by the propeptide (black segment). The blocked catalytic site can be activated nonproteolytically by the binding of prorenin to the PRR or by proteolytic removal of the propeptide. The competitive renin inhibitor aliskiren has a higher affinity ($\sim 0.1 \mu\text{M}$) for the active site of renin than does AGT ($\sim 1 \mu\text{M}$).

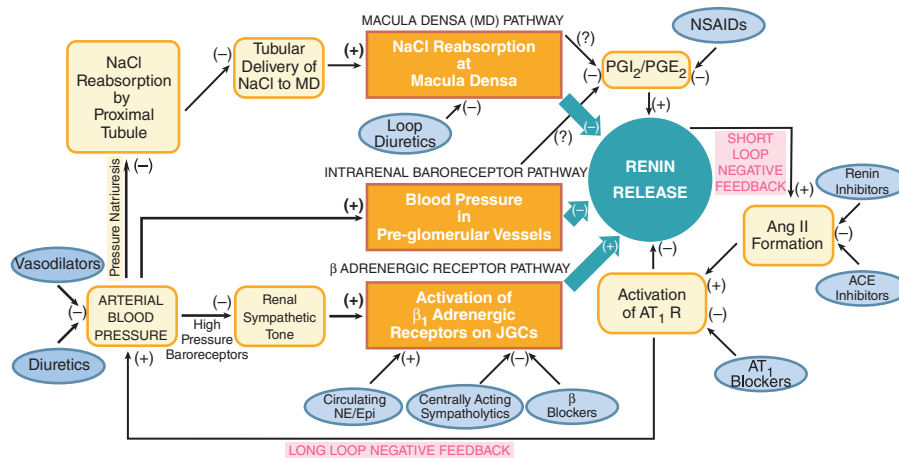

Figure 26-3 Physiological pathways, feedback loops, and pharmacological regulation of the RAS. Schematic portrayal of the three major physiological pathways regulating renin release. See text for details.

Circulating levels of angiotensinogen are approximately equal to the K_m of renin for its substrate ($\sim 1 \mu\text{M}$). Consequently, the rate of AngII synthesis, and therefore blood pressure, can be influenced by changes in angiotensinogen levels. Oral contraceptives containing estrogen increase circulating levels of angiotensinogen and can induce hypertension. A missense mutation in the angiotensinogen gene (M235T in angiotensinogen) that increases plasma levels of angiotensinogen is associated with essential and pregnancy-induced hypertension (Sethi et al., 2003). Urinary angiotensinogen levels are considered an index for local intrarenal RAS activation and are elevated in patients with hypertension and progressive renal disease (Kobori and Urushihara, 2013).

Angiotensin-Converting Enzyme

Angiotensin-converting enzyme (ACE, kininase II, dipeptidyl carboxypeptidase) is an ectoenzyme and glycoprotein with an apparent molecular weight of 170 kDa. Human ACE contains 1277 amino acid residues and has two homologous domains, each with a catalytic site and a Zn^{2+} -binding region. ACE has a large amino-terminal extracellular domain, a short

carboxyl-terminal intracellular domain, and a 22-amino acid transmembrane hydrophobic region that anchors the ectoenzyme. ACE is rather nonspecific and cleaves dipeptide units from substrates with diverse amino acid sequences. Preferred substrates have only one free carboxyl group in the carboxyl-terminal amino acid, and proline must not be the penultimate amino acid; thus, the enzyme does not degrade AngII. ACE is identical to kininase II, the enzyme that inactivates bradykinin and other potent vasodilator peptides. Although slow conversion of AngI to AngII occurs in plasma, the very rapid metabolism that occurs in vivo is due largely to the activity of membrane-bound ACE present on the luminal surface of endothelial cells throughout the vascular system (Guang et al., 2012).

The ACE gene contains an insertion/deletion polymorphism in intron 16 that explains the large phenotypic variance in serum ACE levels. The deletion allele, associated with higher levels of serum ACE and increased metabolism of bradykinin, may confer an increased risk of hypertension, cardiac hypertrophy, atherosclerosis, and diabetic nephropathy (Sayed-Tabatabaei et al., 2006; Hadjadj et al., 2001).

Figure 26-4 Regulation of JG cell renin release by the macula densa. Mechanisms by which the MD regulates renin release. Changes in tubular delivery of NaCl to the MD cause appropriate signals to be conveyed to the JG cells. Sodium depletion upregulates nNOS and COX-2 in the MD to enhance production of PGs. PGs and catecholamines stimulate adenylyl cyclase (AC) and cAMP production and thence renin release from the JG cells. Increased NaCl transport depletes ATP and increases adenosine (ADO) levels. Adenosine diffuses to the JG cells and inhibits cAMP production and renin release via G_i -coupled A_1 receptors. Increased NaCl transport in the MD augments the efflux of ATP, which may inhibit renin release directly by binding to P2Y receptors and activating the G_q -PLC-IP₃-Ca²⁺ pathway in JG cells. Circulating AngII also inhibits renin release on JG cells via G_i -coupled AT_1 receptors.

*Expression upregulated by chronic Na⁺ depletion.

Angiotensin-Converting Enzyme 2

A carboxypeptidase, ACE2, cleaves one amino acid from the carboxyl terminal to convert AngII to Ang(1–7). ACE2 may also convert AngI to Ang(1–9), which is then converted to Ang(1–7) by ACE, neprilysin, and endopeptidases (Santos, 2014). ACE2 contains a single catalytic domain that is 42% identical to the two catalytic domains of ACE. AngII is the preferred substrate for ACE2, with 400-fold higher affinity than AngI (Guang et al., 2012).

The counterregulation of the actions of AngII by ACE2 occur in at least two ways:

1. It decreases AngII levels and limits its effects by metabolizing it to Ang(1–7).
2. It increases levels of Ang(1–7), which acts on Mas receptors to oppose AngII actions (Figure 26–5).

Angiotensin-converting enzyme 2 is not inhibited by the standard ACE inhibitors and has no effect on bradykinin. Reduced expression or deletion of ACE2 is associated with hypertension, defects in cardiac contractility, and elevated levels of AngII. Inhibition of AT₁ receptors by ARBs increases the expression of ACE2. Overexpression of the ACE2 gene decreases blood pressure and prevents AngII-induced cardiac hypertrophy in hypertensive rats. ACE2 is protective against diabetic nephropathy through the Ang(1–7)/Mas receptor pathway (Varagic et al., 2014). Ang(1–9), which is generated from AngI by ACE2, may also have vasodilating and protective effects by activating AT₂ receptors (Etelvino et al., 2014). In addition, ACE2 metabolizes Apelin peptides, serves as a receptor for the severe acute respiratory syndrome coronavirus (SARS), and has been reported to interact with and regulate amino acid transporters (Kuba et al., 2013).

Alternative Pathways for Angiotensin II Biosynthesis

Angiotensin II may be generated through ACE-independent pathways or “ACE escape.” Angiotensinogen is converted to AngI, or directly to AngII

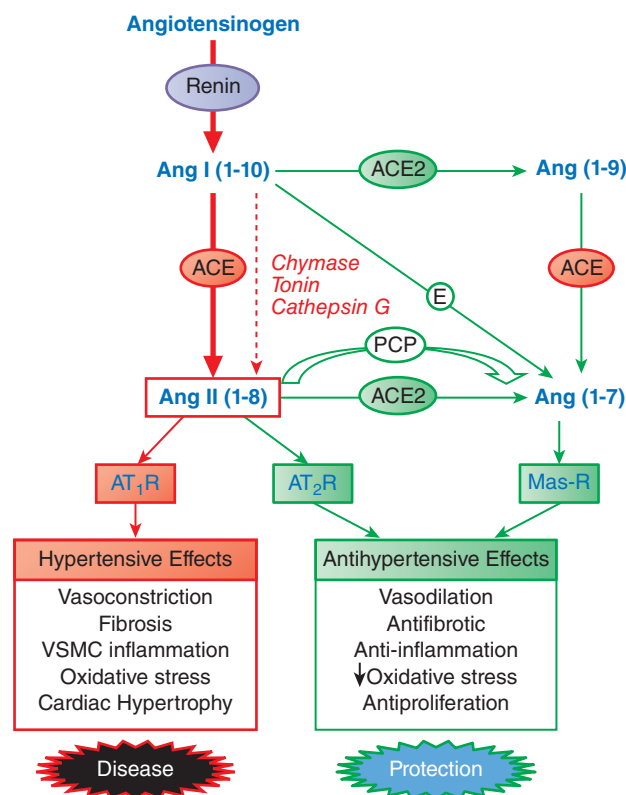

Figure 26–5 Schematic diagram of opposing arms in the RAS. Therapeutic interventions aim to inhibit the ACE/AngII/AT₁ receptor axis (red) and enhance ACE2/Ang(1–7)/Mas receptor axis (green). VSMC: vascular smooth muscle cells.

by cathepsin G and tonin. Enzymes that convert AngI to AngII include cathepsin G, chymostatin-sensitive AngII-generating enzyme, and chymase. Chymase contributes to tissue conversion of AngI and Ang(1–12) to AngII, particularly in the heart and kidneys. The major source of chymase is mast cells (Ferrario et al., 2014; Paul et al., 2006).

Angiotensinases

Angiotensinases include aminopeptidases, endopeptidases, carboxypeptidases, and other peptidases that metabolize angiotensin peptides; none is specific.

Angiotensin Peptides and Their Receptors

Table 26–1 shows the RAS peptides, their receptors, and overall effects of the receptor-peptide interactions.

AngII-AT₁ Receptor Axis

Angiotensin II binds to specific GPCRs, designated AT₁ and AT₂. The hypertensive, renal, and hypertrophic effects of AngII are mediated by activation of the AT₁ receptor (Dell'Italia, 2011). The AT₁ receptor gene contains a polymorphism (A1166C) associated with hypertension, hypertrophic cardiomyopathy, and coronary artery vasoconstriction. Moreover, the C allele synergizes with the ACE deletion allele with regard to increased risk of coronary artery disease (Álvarez et al., 1998). Preeclampsia is associated with the development of agonistic autoantibodies against the AT₁ receptor in some cases (Xia et al., 2013).

AngII-AT₁ Receptor-Effector Coupling. The AT₁ receptors link to a large array of signal transduction systems to produce effects that vary with cell type and that are a combination of primary and secondary responses. AT₁ receptors couple to several heterotrimeric G proteins, including G_q, G_{12/13}, and G_i, and the GPCR characteristics of being substrates for phosphorylation and desensitization by G protein-coupled receptor kinases (GRKs), interacting with β -arrestin, and being subsequently internalized.

In most cell types, AT₁ receptors couple to G_q to activate the PLC β -IP₃-Ca²⁺ pathway. Secondary to G_q activation, activation of PKC, PLA₂, and PLD and eicosanoid production, Ca²⁺-dependent and MAP kinases, Ca²⁺-calmodulin-dependent activation of NOS may occur. Activation of G_i may occur and will reduce the activity of adenylyl cyclase, lowering cellular cyclic AMP content; however, there also is evidence for G_q \rightarrow G_s cross talk such that activation of the AT₁-G_q-PLC pathway enhances cyclic AMP production. The $\beta\gamma$ subunits of G_i and activation of G_{12/13} lead to activation of tyrosine kinases and small G proteins such as Rho. Ultimately, the Jak/STAT pathway may be activated and a variety of transcriptional regulatory

TABLE 26–1 RAS PEPTIDES AND THEIR IDENTIFIED RECEPTORS

RECEPTOR	RAS PEPTIDE	EFFECT
AT ₁	AngII, AngIII, AngA, Ang(1–12)	Vasoconstriction hypertrophy Fibrosis, nephropathy
AT ₂	AngII, AngIII, Ang(1–7), Ang(1–9), AngA	Vasodilation, antihypertrophy, antifibrosis Natriuresis
Mas	Ang(1–7)	Vasodilation, antihypertrophy, antifibrosis Natriuresis
MrgD	Alamandine	Vasodilation, antihypertrophy, antifibrosis
AT ₄	AngIV, Ang(3–7)	Neuroprotection Cognition Renal vasodilation Natriuresis
PRR	Prorenin, renin	Hypertrophy, fibrosis Apoptosis

factors induced. By these mechanisms, angiotensin influences the expression of a host of gene products relating to cell growth and the production of components of the extracellular matrix. Through AT_1 receptors, AngII also stimulates the activity of a membrane-bound NADH/NADPH oxidase that generates ROS. ROS may contribute to some of the biochemical effects (activation of MAP kinase, tyrosine kinase, and phosphatases; inactivation of NO; and expression of monocyte chemoattractant protein-1) and physiological effects (acute effects on renal function, chronic effects on blood pressure, and vascular hypertrophy and inflammation) of AngII (Mehta and Griendling, 2007). The relative importance of these myriad signal transduction pathways in mediating biological responses to AngII is tissue specific. The AT_1 receptor is structurally flexible and may be activated, independently of AngII binding, by conformational changes such as mechanical stress (Kim et al., 2012). Functions of the AT_1 receptor may be modified by dimerization with AT_2 receptor, the bradykinin B_2 receptor, the β_2 adrenergic receptor, and the apelin receptor (Goupil et al., 2013).

AngII- AT_2 Receptor Axis

Activation of the AT_2 receptors counteracts many of the effects of the AT_1 receptors by having antiproliferative, anti-inflammatory, vasodilatory, natriuretic, and antihypertensive effects (Figure 26-5). The AT_2 receptors are distributed widely in fetal tissues, but their distribution is more restricted in adults. Expression of AT_2 receptors is upregulated in cardiovascular diseases, including heart failure, cardiac fibrosis, and ischemic heart disease (Jones et al., 2008). Signaling through the AT_2 receptor is mediated by G protein-dependent (G_{i2} and G_{i3}) and G protein-independent pathways. Consequences of AT_2 receptor activation include activation of phosphotyrosine phosphatases that inhibit MAP kinases and ERK 1/2; inhibition of Ca^{2+} channel functions; and enhancing NO, cyclic GMP, and bradykinin production. The AT_2 receptors can bind the AT_1 receptors to antagonize and reduce their expression; and the AT_2 receptors can form heterodimers with the bradykinin B_2 receptor to enhance NO production (Jones et al., 2008; Padia and Carey, 2013).

Angiotensin (1-7)/Mas Receptor Axis

The ACE2/Ang(1-7)/Mas receptor axis is a negative regulator of the pressor, profibrotic, and antinatriuretic effects of the ACE/AngII/ AT_1 receptor axis of the RAS (Figure 26-5). Ang(1-7) is generated in several ways (Figure 26-1):

- from AngII by ACE2;
- from AngII by carboxypeptidases;
- from AngI by endopeptidases; and
- from AngI by a two-step conversion, by ACE2 to Ang(1-9) and then to Ang(1-7) by ACE or neprilysin.

The antihypertensive effects of Ang(1-7) are mediated through binding to the Mas receptors, although Ang(1-7) can bind and activate AT_2 receptors (Gironacci et al., 2014). Activation of the Mas receptor by Ang(1-7) induces vasodilation, stimulates PI_3K/Akt pathway that promotes NO production, potentiates the vasodilatory effects of bradykinin, and inhibits AngII-induced activation of ERK1/2 and NF κ B; it has antiangiogenic, antiproliferative, and antithrombotic effects; and it is renoprotective and cardioprotective in cardiac ischemia and heart failure (Fraga-Silva et al., 2013; Varagic et al., 2014).

The *Mas* proto-oncogene encodes an orphan GPCR. Knockout of the *Mas* gene in mice causes increased vascular resistance and cardiac dysfunction (Santos, 2014; Varagic et al., 2014). The Mas receptor is present in the brain, and its activation is associated with improved memory and cognition (Gironacci et al., 2014).

The capacity of Ang(1-7) to counterbalance the actions of AngII may depend on the ratio of ACE-AngII- AT_1 receptor activity to ACE2-Ang(1-7)-Mas receptor activity (see Figure 26-5; Santos, 2014; Romero et al., 2015). Pharmacologically enhancing the ACE2-Ang(1-7)-Mas receptor pathway using ACE2 activators and specific Mas receptor agonists could provide new avenues for modulating RAS in cardiovascular and renal disease.

Angiotensin III

Angiotensin III, also called Ang(2-8), can be formed by the action of aminopeptidase A on AngII or by the action of ACE on Ang(2-10). AngIII

binds to both AT_1 and AT_2 receptors, causing effects qualitatively similar to those of AngII. AngII and AngIII stimulate aldosterone secretion with equal potency; however, AngIII is less efficacious in elevating blood pressure (25%) and stimulating the adrenal medulla (10%). Data from model systems make clear that AngIII and the shorter angiotensin-derived peptides have significant activity, especially at the AT_2 receptor, and that there may be instances where AngIII is the active endogenous ligand (Bosnyak et al., 2011).

Angiotensin IV/ AT_4 Receptor Axis

Angiotensin IV, also called Ang(3-8), is formed from AngIII through the catalytic action of aminopeptidase N. Central and peripheral actions of AngIV are mediated through a specific AT_4 receptor that was identified as IRAP (insulin-regulated aminopeptidase) (see Figure 26-1). This receptor is a single transmembrane protein (1025 amino acids) that colocalizes with the glucose transporter type 4. AT_4 receptors are detectable in a number of tissues, such as heart, vasculature, adrenal cortex, and brain regions processing sensory and motor functions. AngIV-dependent AT_4 receptor activation regulates cerebral blood flow, is neuroprotective, and facilitates long-term potentiation, memory consolidation, and cognition (Wright et al., 2013). AngIV binding to the AT_4 receptor inhibits the catalytic activity of IRAP and enables accumulation of various neuropeptides linked to memory potentiation. Other actions include renal vasodilation, natriuresis, neuronal differentiation, hypertrophy, inflammation, and extracellular matrix remodeling. Analogues of AngIV are being developed for their therapeutic potential in Alzheimer disease and head injury (Albiston et al., 2007; Wright et al., 2013).

New Physiologically Active Angiotensin Peptides

New biologically active angiotensin peptides and their receptors have been identified (Table 26-1). These peptides include Ang(1-9), AngA and alamandine, Ang(3-7), and proangiotensin/Ang(1-12) (Ferrario et al., 2014). Ang(1-9) is generated from AngI by the action of ACE2, carboxypeptidase A, and cathepsin. Ang(1-9) has cardioprotective and antipressor effects reportedly mediated through binding to AT_2 receptors and the release of NO (Etelvino et al., 2014). Alamandine is produced from Ang(1-7) by the decarboxylation of the Asp₁ residue into Ala₁ residue on the N-terminal. Alamandine acts through the *MrgD* to mediate vasodilatory and antifibrotic effects similar to Ang(1-7). Alamandine is an ACE substrate and may act as an ACE inhibitor. Alamandine is elevated in patients with chronic renal disease (Etelvino et al., 2014).

Angiotensin A is an octapeptide produced by decarboxylation of the Asp₁ residue of AngII into Ala₁. AngA binds to both AT_1 and AT_2 receptors and has effects similar to, but less potent than, AngII. AngA is reported to be elevated in patients with end-stage renal disease (Ferrario et al., 2014). Ang(3-7) is generated from AngIV and binds AT_4 receptors (Wright et al., 2013). Proangiotensin or Ang(1-12) is generated from angiotensinogen through a nonrenin pathway and can be converted to AngII through action of chymase. Ang(1-12) can bind to the AT_1 receptors and may be a precursor for autocrine/intracrine production of AngII (Ferrario et al., 2014).

Local (Tissue) Renin-Angiotensin System

Local (tissue) RAS is a tissue-based AngII-producing system that plays a role in hypertrophy, nephropathy, inflammation, remodeling, and apoptosis. ACE is present on the luminal face of vascular endothelial cells throughout the circulation; circulating (pro)renin can bind the PRR in the arterial wall and other tissues to mediate local generation of AngII (Campbell, 2014; Paul et al., 2016). Tissue RAS is also an autocrine and intracrine mechanism that can generate AngII and other bioactive angiotensin peptides independently of the renal/hepatic-based system. Many tissues—including the brain, pituitary, blood vessels, heart, kidney, and adrenal gland—produce renin, angiotensinogen, ACE and ACE2, chymase, PRR, and angiotensins I, II, III, IV, Ang(1-7) and the AT_1 , AT_2 , and Mas receptors (Campbell, 2014; Ferrario et al., 2014). Selective activation of the local RAS components is tissue specific and likely affects the pathophysiological outcomes in disease.

The (Pro) Renin Receptor

(Pro)renin/PRR binding enhances tissue-RAS activity and induces profibrotic intracellular signaling events that are independent of AngII production (Figure 26–6). The PRR is abundant in the heart, brain, eye, adrenals, placenta, adipose tissue, liver, and kidneys. The PRR gene is located in the locus p11.4 of the X chromosome and is named ATP6ap2 (ATPase-6 accessory protein 2). Knockout of the PRR gene is lethal, indicating an important role for PRR in development. In humans, mutations in the PRR gene are associated with mental retardation and epilepsy (Nguyen and Danser, 2008). Human PRR is a single transmembrane protein of 350 amino acids (~37 kDa). PRR is composed of N-terminal extracellular domain that binds (pro)renin, a transmembrane domain and a cytosolic domain that are associated with Vacuolar-H⁺-ATPase (V-ATPase) activity (Nguyen, 2011). Cleavage of the extracellular domain of PRR by furin or ADAM19 produces the N-terminal segment, soluble PRR, found in plasma and urine. Increased levels of urinary soluble PRR correlate with elevated urinary angiotensinogen levels, a biomarker of intrarenal RAS activity (Oshima et al., 2014).

(Pro)renin receptor binds (pro)renin with nanomolar affinity and high specificity to enhance the tissue-RAS. Binding of (pro)renin to PRR augments the catalytic activity of renin and induces nonproteolytic activation of prorenin by unfolding the 43 amino acid–prorenin prosegment and exposing the enzymatic cleft (Figure 26–2). Bound, activated (pro)renin

catalyzes the conversion of angiotensinogen to AngI, with the consequent formation of AngII. The binding of (pro)renin to PRR also induces profibrotic signaling events that are *AngII independent* (Figure 26–6), including activation of ERK1/2, p38, tyrosine kinases, COX-2, TGF- β gene expression, and PAI-1 (Nguyen and Danser, 2008). These signaling pathways are not blocked by ACE inhibitors or AT₁ receptor antagonists and are reported to contribute to fibrosis, nephrosis, and end-organ damage (Kaneshiro et al., 2007). Overexpression of the human PRR in transgenic animals increases plasma aldosterone levels in the absence of changes in plasma renin levels and induces hypertension and nephropathy. Rats overexpressing PRR exhibit increased expression of COX-2 in the macula densa and develop proteinuria and glomerulosclerosis that increase with aging (Kaneshiro et al., 2007).

Circulating plasma concentrations of (pro)renin are elevated 100-fold in diabetic patients and are associated with increased risk of nephropathy, renal fibrosis, and retinopathy (Nguyen and Danser, 2008). The blockade of PRR by administration of a peptide antagonist, known as “handle region peptide” (HRP), was reported to be protective in animal models against diabetic nephropathy and retinopathy (Oshima et al., 2014); however, the efficacy and specificity of HRP was not strongly confirmed by other groups (reviewed by Binger and Muller, 2013; Nguyen, 2011). The pathophysiological significance of (pro)renin/PRR interaction outside the local tissue RAS is still unclear (Lu et al., 2016).

The PRR participates in many functions that are independent of (pro)renin binding. PRR functions as an accessory protein essential for V-ATPase activity, which is required for intracellular acidity, receptor-mediated endocytosis, and activation of lysosomal and autophagosomal enzymes (Oshima et al., 2014). Cardiomyocyte-specific PRR knockout mice and podocyte-specific PRR knockout mice develop lethal organ-specific failure due to loss of V-ATPase and the dysregulation of intracellular acidification and autophagic functions (Binger and Muller, 2013). PRR also participates in the activation of Wnt/ β -catenin and Wnt/planar cell polarity signaling pathways that are important in cell polarization in the plane of tissue (Nguyen, 2011). PRR reportedly can regulate LDL uptake and metabolism. In hepatocytes, silencing PRR expression decreased cellular LDL uptake by decreasing expression of LDL receptor and sortilin 1 protein, a regulator of LDL uptake and metabolism and a PRR-interacting protein (Lu et al., 2016). (Pro)renin also binds to mannose-6-phosphate receptor, an insulin-like growth factor II receptor that functions as a clearance receptor (Nguyen and Danser, 2008).

Figure 26–6 (Pro)renin/PRR interaction activates AngII-dependent and AngII-independent signaling pathways. See text for details.

Functions and Effects of Angiotensin II

Angiotensin II increases total peripheral resistance (TPR) and alters renal function and cardiovascular structure (Figure 26–7). Modest increases in plasma concentrations of AngII acutely raise blood pressure; on a molar basis, AngII is about 40 times more potent than NE; the EC₅₀ of AngII for acutely raising arterial blood pressure is about 0.3 nM. When a single moderate dose of AngII is injected intravenously, systemic blood pressure begins to rise within seconds, peaks rapidly, and returns to normal within minutes (Figure 26–8). This *rapid pressor response* to AngII is due to a swift increase in TPR—a response that helps to maintain arterial blood pressure in the face of an acute hypotensive challenge (e.g., blood loss or vasodilation). Although AngII increases cardiac contractility directly (via opening voltage-gated Ca²⁺ channels in cardiac myocytes) and increases heart rate indirectly (via facilitation of sympathetic tone, enhancing adrenergic neurotransmission, and provoking adrenal catecholamine release), the rapid increase in arterial blood pressure activates a baroreceptor reflex that decreases sympathetic tone and increases vagal tone. Thus, depending on the physiological state, AngII may increase, decrease, or not change cardiac contractility, heart rate, and cardiac output. Changes in cardiac output therefore contribute little, if at all, to the rapid pressor response induced by AngII.

AngII also causes a *slow pressor response* that helps to stabilize arterial blood pressure over the long term. A continuous infusion of initially subpressor doses of AngII gradually increases arterial blood pressure, with

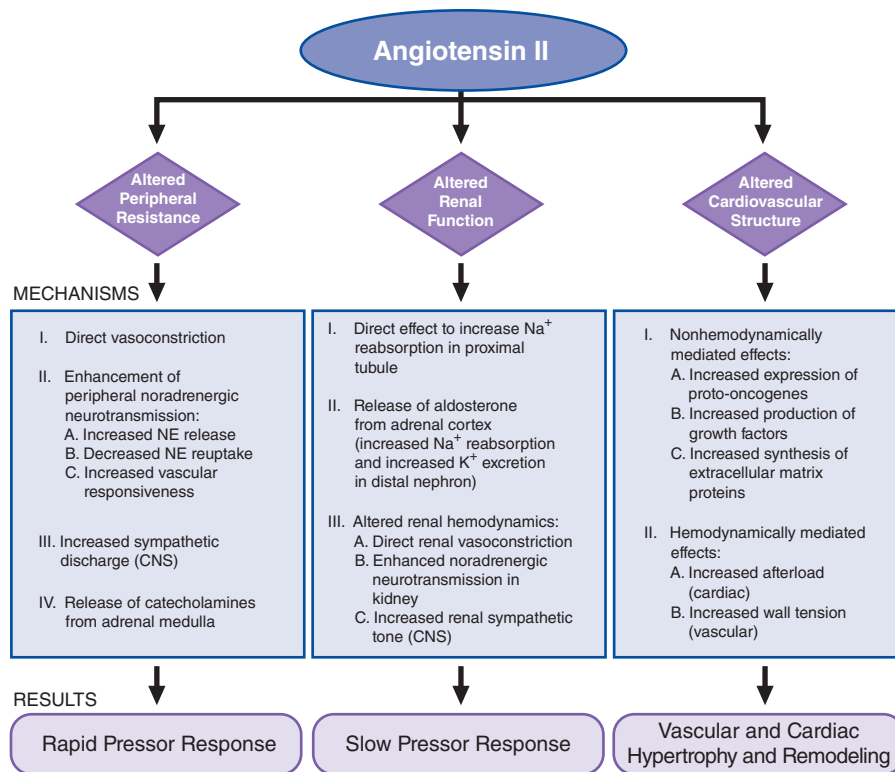

Figure 26–7 Major physiological effects of AngII.

the maximum effect requiring days to achieve. This slow pressor response probably is mediated by a decrement in renal excretory function that shifts the renal pressure–natriuresis curve to the right (see the next section). AngII stimulates the synthesis of endothelin 1 and superoxide anion, which may contribute to the slow pressor response.

In addition to its effects on arterial blood pressure, AngII stimulates remodeling of the cardiovascular system, causing hypertrophy of vascular and cardiac cells and increased synthesis and deposition of collagen by cardiac fibroblasts.

Mechanisms by Which Angiotensin II Increases Total Peripheral Resistance

Angiotensin II increases peripheral resistance via direct and indirect effects on blood vessels (Figure 26–7).

Direct Vasoconstriction

Angiotensin II constricts precapillary arterioles and, to a lesser extent, post-capillary venules by activating AT_1 receptors located on vascular smooth muscle cells and stimulating the G_q -PLC- IP_3 - Ca^{2+} pathway. AngII has differential effects on vascular beds. Direct vasoconstriction is strongest in the kidneys (Figure 26–8) and somewhat less in the splanchnic bed. AngII-induced vasoconstriction is much less in vessels of the brain and still weaker in those of the lung and skeletal muscle. Nevertheless, high circulating concentrations of AngII may decrease cerebral and coronary blood flow.

Enhancement of Peripheral Noradrenergic Neurotransmission

Angiotensin II, binding to AT_1 receptors, augments NE release from sympathetic nerve terminals by inhibiting the reuptake of NE into nerve terminals and by enhancing the vascular response to NE in model systems (see Chapter 12). High concentrations of the peptide stimulate ganglion cells directly.

Effects on the CNS

Angiotensin II increases sympathetic tone. Small amounts of AngII infused into the vertebral arteries cause an increase in arterial blood pressure. This response reflects effects of the hormone on circumventricular nuclei that are not protected by a blood-brain barrier (e.g., area postrema,

subfornical organ, organum vasculosum of the lamina terminalis). Circulating AngII also attenuates baroreceptor-mediated reductions in sympathetic discharge, thereby increasing arterial pressure. The CNS is affected both by blood-borne AngII and by AngII formed within the brain. The brain contains all components of the RAS. AngII also causes a centrally mediated dipsogenic (thirst) effect and enhances the release of vasopressin from the neurohypophysis.

Release of Catecholamines From the Adrenal Medulla

Angiotensin II stimulates the release of catecholamines from the adrenal medulla by promoting Ca^{2+} entry secondary to depolarization of chromaffin cells.

Mechanisms by Which Angiotensin II Regulates Renal Function

Angiotensin II has pronounced effects on renal function, reducing the urinary excretion of Na^+ and water while increasing the excretion of K^+ . The overall effect of AngII on the kidneys is to shift the renal pressure–natriuresis curve to the right (Figure 26–9).

Direct Effects of AngII on Na^+ Reabsorption in the Renal Tubules

Very low concentrations of AngII stimulate Na^+/H^+ exchange in the proximal tubule—an effect that increases Na^+ , Cl^- , and bicarbonate reabsorption. Approximately 20%–30% of the bicarbonate handled by the nephron may be affected by this mechanism. AngII also increases the expression of the Na^+ -glucose symporter in the proximal tubule. Paradoxically, at high concentrations, AngII may inhibit Na^+ transport in the proximal tubule. AngII also directly stimulates the $Na^+-K^+-2Cl^-$ symporter in the thick ascending limb. The proximal tubule secretes angiotensinogen, and the connecting tubule releases renin, so a paracrine tubular RAS may contribute to Na^+ reabsorption.

Release of Aldosterone From the Adrenal Cortex

Angiotensin II stimulates the zona glomerulosa of the adrenal cortex to increase the synthesis and secretion of aldosterone and augments responses to other stimuli (e.g., ACTH, K^+). Increased output of aldosterone is

Figure 26-8 Effect of an intravenous bolus of AngII on arterial BP and RBF. Angiotensin was added at the time indicated by the dashed vertical line.

elicited by concentrations of AngII that have little or no acute effect on blood pressure. Aldosterone acts on the distal and collecting tubules to cause retention of Na^+ and excretion of K^+ and H^+ . The stimulant effect of AngII on aldosterone synthesis and release is enhanced under conditions of hyponatremia or hyperkalemia and is reduced when concentrations of Na^+ and K^+ in plasma are altered in the opposite directions.

Altered Renal Hemodynamics

Angiotensin II reduces renal blood flow and renal excretory function by directly constricting the renal vascular smooth muscle, by enhancing renal sympathetic tone (a CNS effect), and by facilitating renal adrenergic transmission (an intrarenal effect). AngII-induced vasoconstriction of preglomerular microvessels is enhanced by endogenous adenosine owing to signal transduction systems activated by AT_1 and the adenosine A_1 receptor.

Angiotensin II influences the GFR by several mechanisms:

- Constriction of the afferent arterioles, which reduces intraglomerular pressure and tends to reduce GFR
- Contraction of mesangial cells, which decreases the capillary surface area within the glomerulus available for filtration and also tends to decrease GFR
- Constriction of efferent arterioles, which increases intraglomerular pressure and tends to increase GFR

Normally, AngII slightly reduces GFR; however, with renal artery hypotension, the effects of AngII on the efferent arteriole predominate so that AngII increases GFR. Thus, blockade of the RAS may cause acute

Figure 26-9 Pressure-natriuresis curve: effects of Na^+ intake on renin release (AngII formation) and arterial blood pressure. Inhibition of the RAS will cause a large drop in blood pressure in Na^+ -depleted individuals. (Modified with permission from Jackson EK, Branch RA, Margolius HS, Oates JA. Physiological functions of the renal prostaglandin, renin, and kallikrein systems. In: Seldin DW, Giebisch GH, eds. *The Kidney: Physiology and Pathophysiology*. Vol 1. Lippincott Williams & Wilkins, Philadelphia, 1985, 624.)

renal failure in patients with bilateral renal artery stenosis or in patients with unilateral stenosis who have only a single kidney.

Mechanisms by Which Angiotensin II Alters Cardiovascular Structure

Pathological alterations involving cardiovascular hypertrophy and remodeling increase morbidity and mortality. The cells involved include vascular smooth muscle cells, cardiac myocytes, and fibroblasts. AngII induces hypertrophy of cardiac myocytes; stimulates the migration, proliferation, and hypertrophy of vascular smooth muscle cells; increases extracellular matrix production by vascular smooth muscle cells; and increases extracellular matrix production by cardiac fibroblasts. In addition, AngII alters extracellular matrix formation and degradation indirectly by increasing aldosterone production and mineralocorticoid receptor activation. The adverse cardiovascular remodeling induced by AngII can be reduced but not entirely prevented by mineralocorticoid receptor antagonists.

Hemodynamically Mediated Effects of Angiotensin II on Cardiovascular Structure

In addition to the direct cellular effects of AngII on cardiovascular structure, changes in cardiac preload (volume expansion owing to Na^+ retention) and afterload (increased arterial blood pressure) probably contribute to cardiac hypertrophy and remodeling. Arterial hypertension also contributes to hypertrophy and remodeling of blood vessels.

Role of the RAS in Long-Term Maintenance of Arterial Blood Pressure Despite Extremes in Dietary Na^+ Intake

Arterial blood pressure is a major determinant of Na^+ excretion. This is illustrated graphically by plotting urinary Na^+ excretion versus mean arterial blood pressure (Figure 26-9), a plot known as the *renal pressure-natriuresis curve*. Over the long term, Na^+ excretion must equal Na^+ intake; therefore, the set point for long-term levels of arterial blood pressure can be obtained as the intersection of a horizontal line representing Na^+ intake with the renal pressure-natriuresis curve. The RAS plays a major role in maintaining a constant set point for long-term levels of arterial blood pressure despite extreme changes in dietary Na^+ intake. When dietary Na^+ intake is low, renin release is stimulated, and AngII acts on the kidneys to shift the renal pressure-natriuresis curve to the right. Conversely, when dietary Na^+ is high, renin release is inhibited, and the withdrawal of AngII shifts the renal pressure-natriuresis curve to the left. When modulation of the RAS is blocked by drugs, changes in salt intake markedly affect long-term levels of arterial blood pressure.

Figure 26–10 Inhibitors of the RAS.

Other Effects of the RAS

Expression of the RAS is required for the development of normal kidney morphology, particularly the maturational growth of the renal papilla. AngII causes a marked anorexigenic effect and weight loss, and high circulating levels of AngII may contribute to the anorexia, wasting, and cachexia of heart failure (Paul et al., 2006; Yoshida et al., 2013).

Inhibitors of the Renin-Angiotensin System

Drugs that interfere with the RAS play a prominent role in the treatment of cardiovascular disease. Besides β_1 blockers that inhibit renin release, the following three classes of inhibitors of the RAS are utilized therapeutically (Figure 26–10):

- 1. ACE inhibitors
- 2. Angiotensin receptor blockers
- 3. Direct renin inhibitors

All of these classes of agents will reduce the actions of AngII and lower blood pressure, but each has different effects on the individual components of the RAS (Table 26–2). Representative structures of agents inhibiting the RAS and reducing the effects of AngII are shown in Figure 26–11, near the end of the chapter.

Angiotensin-Converting Enzyme Inhibitors

History

In the 1960s, Ferreira and colleagues found that venom extract from the Brazilian pit viper (*Bothrops jararaca*) contains factors that intensify vasodilator responses to bradykinin. These bradykinin-potentiating factors are peptides that inhibit kininase II, an enzyme that inactivates bradykinin. Erdös and coworkers established that ACE and kininase II are the same enzyme, which catalyzes both the synthesis of AngII and the destruction of bradykinin. Based on these findings, the nonapeptide teprotide (snake venom peptide that inhibits kininase II and ACE) was later synthesized and tested in human subjects. It lowered blood pressure in many patients with essential hypertension and exerted beneficial effects in patients with heart failure. The orally effective ACE inhibitor *captopril* was developed by analysis of the inhibitory action of teprotide, inference about the action of ACE on its substrates, and analogy with carboxypeptidase A, which was known to be inhibited by D-benzylsuccinic acid. Ondetti, Cushman, and colleagues argued that inhibition of ACE might be produced by succinyl amino acids that corresponded in length to the dipeptide cleaved by ACE. This led to the synthesis of a series of carboxy alkanoyl and mercapto alkanoyl derivatives that are potent competitive inhibitors of ACE.

Pharmacological Effects

The ACE inhibitors inhibit the conversion of AngI to AngII. Inhibition of AngII production lowers blood pressure and enhances natriuresis. ACE is an enzyme with many substrates; thus, there are other consequences of its inhibition, including inhibition of the degradation of bradykinin, which has beneficial antihypertensive and protective effects. ACE inhibitors increase by 5-fold the circulating levels of the natural stem cell regulator Ac-SDKP, which may also contribute to the cardioprotective effects of ACE inhibitors (Rhaleb et al., 2001). ACE inhibitors will increase renin release and the rate of formation of AngI by interfering with both short- and long-loop negative feedbacks on renin release (Figure 26–3). Accumulating AngI is directed down alternative metabolic routes, resulting in the increased production of vasodilator peptides such as Ang(1–9) and Ang(1–7) (Figures 26–1 and 26–5).

Clinical Pharmacology

The ACE inhibitors can be classified into three broad groups based on chemical structure:

- 1. Sulfhydryl-containing ACE inhibitors structurally related to captopril
- 2. Dicarboxyl-containing ACE inhibitors structurally related to enalapril (e.g., lisinopril, benazepril, quinapril, moexipril, ramipril, trandolapril, perindopril, Figure 26–11)
- 3. Phosphorus-containing ACE inhibitors structurally related to fosinopril

Many ACE inhibitors are ester-containing prodrugs that are 100–1000 times less potent but have better oral bioavailability than the active molecules.

DIRECT RENIN INHIBITOR

Figure 26–11 Structures of representative RAS inhibitors. Enalapril and candesartan cilexetil are pro-drugs, relatively inactive until in vivo esterases remove the region within the red box, replacing it with a hydrogen atom to form the active drug.

Currently, 11 ACE inhibitors are available for clinical use in the U.S. They differ with regard to potency, whether ACE inhibition is primarily a direct effect of the drug itself or the effect of an active metabolite, and pharmacokinetics.

All ACE inhibitors block the conversion of AngI to AngII and have similar therapeutic indications, adverse-effect profiles, and contraindications. Because hypertension usually requires lifelong treatment, quality-of-life issues are an important consideration in comparing anti-hypertensive drugs. With the exceptions of fosinopril, trandolapril, and quinapril (which display balanced elimination by the liver and kidneys), ACE inhibitors are cleared predominantly by the kidneys. Impaired renal function significantly diminishes the plasma clearance of most ACE inhibitors, and dosages of these drugs should be reduced in patients with renal impairment. *Elevated PRA renders patients hyperresponsive to ACE inhibitor-induced hypotension, and initial dosages of all ACE inhibitors should be reduced in patients with high plasma levels of renin (e.g., patients with heart failure and during salt depletion including diuretic use).* ACE inhibitors differ markedly in tissue distribution, and it is possible that this difference could be exploited to inhibit some local (tissue) RAS while leaving others relatively intact.

Captopril. Captopril is a potent ACE inhibitor with a K_i of 1.7 nM. Given orally, captopril is absorbed rapidly and has a bioavailability of about 75%.

Bioavailability is reduced by 25%–30% with food. Peak concentrations in plasma occur within an hour, and the drug is cleared rapidly, with a $t_{1/2}$ of about 2 h. Most of the drug is eliminated in urine, 40%–50% as captopril and the rest as captopril disulfide dimers and captopril–cysteine disulfide. The oral dose of captopril ranges from 6.25 to 150 mg 2–3 times daily, with 6.25 mg thrice daily or 25 mg twice daily appropriate for the initiation of therapy for heart failure or hypertension, respectively.

Enalapril. Enalapril maleate is a prodrug that is hydrolyzed by esterases in the liver to produce enalaprilat, the active dicarboxylic acid. Enalaprilat is a potent inhibitor of ACE with a K_i of 0.2 nM. Enalapril is absorbed rapidly when given orally and has an oral bioavailability of about 60% (not reduced by food). Although peak concentrations of enalapril in plasma occur within an hour, enalaprilat concentrations peak only after 3–4 h. Enalapril has a $t_{1/2}$ of about 1.3 h, but enalaprilat, because of tight binding to ACE, has a plasma $t_{1/2}$ of about 11 h. Elimination is by the kidneys as either intact enalapril or enalaprilat. The oral dosage of enalapril ranges from 2.5 to 40 mg daily, with 2.5 and 5 mg daily appropriate for the initiation of therapy for heart failure and hypertension, respectively.

Enalaprilat. Enalaprilat is not absorbed orally but is available for intravenous administration when oral therapy is not appropriate.

For hypertensive patients, the dosage is 0.625–1.25 mg given intravenously over 5 min. This dosage may be repeated every 6 h.

Lisinopril. Lisinopril is the lysine analogue of enalaprilat; unlike enalapril, lisinopril itself is active. In vitro, lisinopril is a slightly more potent ACE inhibitor than is enalaprilat. Lisinopril is absorbed slowly, variably, and incompletely (~30%) after oral administration (not reduced by food); peak concentrations in plasma are achieved in about 7 h. It is excreted unchanged by the kidney with a plasma $t_{1/2}$ of about 12 h. Lisinopril does not accumulate in tissues. The oral dosage of lisinopril ranges from 5 to 40 mg daily (single or divided dose), with 5 and 10 mg daily appropriate for the initiation of therapy for heart failure and hypertension, respectively. A daily dose of 2.5 mg with close medical supervision is recommended for patients with heart failure who are hyponatremic or have renal impairment.

Benazepril. Cleavage of the ester moiety by hepatic esterases transforms benazepril, a prodrug, into benazeprilat. Benazepril is absorbed rapidly but incompletely (37%) after oral administration (only slightly reduced by food). Benazepril is nearly completely metabolized to benazeprilat and to the glucuronide conjugates of benazepril and benazeprilat, which are excreted into the urine and bile; peak concentrations of benazepril and benazeprilat in plasma are achieved in 0.5–1 and 1–2 h, respectively. Benazeprilat has an effective plasma $t_{1/2}$ of 10–11 h. With the exception of the lungs, benazeprilat does not accumulate in tissues. The oral dosage of benazepril ranges from 5 to 80 mg daily (single or divided dose).

Fosinopril. Cleavage of the ester moiety by hepatic esterases transforms fosinopril into fosinoprilat. Fosinopril is absorbed slowly and incompletely (36%) after oral administration (rate but not extent reduced by food). Fosinopril is largely metabolized to fosinoprilat (75%) and to the glucuronide conjugate of fosinoprilat. These are excreted in both the urine and the bile; peak concentrations of fosinoprilat in plasma are achieved in about 3 h. Fosinoprilat has an effective plasma $t_{1/2}$ of about 11.5 h, a figure not significantly altered by renal impairment. The oral dosage of fosinopril ranges from 10 to 80 mg daily (single or divided dose). The initial dose is reduced to 5 mg daily in patients with Na^+ or water depletion or renal failure.

Trandolapril. An oral dose of trandolapril is absorbed without reduction by food and produces plasma levels of trandolapril (10% bioavailability) and trandolaprilat (70% bioavailability). Trandolaprilat is about 8 times more potent than trandolapril as an ACE inhibitor. Glucuronides of trandolapril and deesterification products are recovered in the urine (33%, mostly trandolaprilat) and feces (66%). Peak concentrations of trandolaprilat in plasma are achieved in 4–10 h.

Trandolaprilat displays biphasic elimination kinetics, with an initial $t_{1/2}$ of about 10 h (the major component of elimination), followed by a more prolonged $t_{1/2}$ (owing to slow dissociation of trandolaprilat from tissue ACE). Plasma clearance of trandolaprilat is reduced by both renal and hepatic insufficiency. The oral dosage ranges from 1 to 8 mg daily (single or divided dose). The initial dose is 0.5 mg in patients who are taking a diuretic or who have renal impairment.

Quinapril. Cleavage of the ester moiety by hepatic esterases transforms quinapril, a prodrug, into quinaprilat. Quinapril is absorbed rapidly (peak concentrations are achieved in 1 h), and the rate, but not extent, of oral absorption (60%) may be reduced by food (delayed peak). Quinaprilat and other minor metabolites of quinapril are excreted in the urine (61%) and feces (37%). Peak concentrations of quinaprilat in plasma are achieved in about 2 h. Conversion of quinapril to quinaprilat is reduced in patients with diminished liver function. The initial $t_{1/2}$ of quinaprilat is about 2 h; a prolonged terminal $t_{1/2}$ of about 25 h may be due to high-affinity binding of the drug to tissue ACE. The oral dosage of quinapril ranges from 5 to 80 mg daily.

Ramipril. Orally administered ramipril is absorbed rapidly (peak concentrations in 1 h; the rate but not extent of its oral absorption (50%–60%) is reduced by food. Ramipril is metabolized to ramiprilat by hepatic esterases and to inactive metabolites that are excreted predominantly by the kidneys. Peak concentrations of ramiprilat in plasma are achieved in

about 3 h. Ramiprilat displays triphasic elimination kinetics ($t_{1/2}$ values: 2–4, 9–18, and more than 50 h). This triphasic elimination is due to extensive distribution to all tissues (initial $t_{1/2}$), clearance of free ramiprilat from plasma (intermediate $t_{1/2}$), and dissociation of ramiprilat from tissue ACE (long terminal $t_{1/2}$). The oral dosage of ramipril ranges from 1.25 to 20 mg daily (single or divided dose).

Moexipril. Moexipril's antihypertensive activity is due to its deesterified metabolite, moexiprilat. Moexipril is absorbed incompletely, with bioavailability as moexiprilat of about 13%. Bioavailability is markedly decreased by food. The time to peak plasma concentration of moexiprilat is almost 1.5 h; the elimination $t_{1/2}$ varies between 2 and 12 h. The recommended dosage range is 7.5–30 mg daily (single or divided doses). The dosage range is halved in patients who are taking diuretics or who have renal impairment.

Perindopril. Perindopril erbumine is a prodrug, and 30%–50% of systemically available perindopril is transformed to perindoprilat by hepatic esterases. Although the oral bioavailability of perindopril (75%) is not affected by food, the bioavailability of perindoprilat is reduced by about 35%. Perindopril is metabolized to perindoprilat and to inactive metabolites that are excreted predominantly by the kidneys. Peak concentrations of perindoprilat in plasma are achieved in 3–7 h. Perindoprilat displays biphasic elimination kinetics with half-lives of 3–10 h (the major component of elimination) and 30–120 h (owing to slow dissociation of perindoprilat from tissue ACE). The oral dosage ranges from 2 to 16 mg daily (single or divided dose).

Therapeutic Uses of ACE Inhibitors

The ACE inhibitors are effective in the treatment of cardiovascular disease, heart failure, and diabetic nephropathy.

ACE Inhibitors in Hypertension. Inhibition of ACE lowers systemic vascular resistance and mean, diastolic, and systolic blood pressures in various hypertensive states except when high blood pressure is due to primary aldosteronism (see Chapter 28). The initial change in blood pressure tends to be positively correlated with PRA and AngII plasma levels prior to treatment. However, some patients may show a sizable reduction in blood pressure that correlates poorly with pretreatment values of PRA. It is possible that increased local (tissue) production of AngII or increased responsiveness of tissues to normal levels of AngII makes some hypertensive patients sensitive to ACE inhibitors despite normal PRA.

The long-term fall in systemic blood pressure observed in hypertensive individuals treated with ACE inhibitors is accompanied by a leftward shift in the renal pressure–natriuresis curve (Figure 26–9) and a reduction in TPR in which there is variable participation by different vascular beds. The kidney is a notable exception: Because the renal vessels are extremely sensitive to the vasoconstrictor actions of AngII, ACE inhibitors increase renal blood flow via vasodilation of the afferent and efferent arterioles. Increased renal blood flow occurs without an increase in GFR; thus, the filtration fraction is reduced.

The ACE inhibitors cause systemic arteriolar dilation and increase the compliance of large arteries, which contributes to a reduction of systolic pressure. Cardiac function in patients with uncomplicated hypertension generally is little changed, although stroke volume and cardiac output may increase slightly with sustained treatment. Baroreceptor function and cardiovascular reflexes are not compromised, and responses to postural changes and exercise are little impaired. Even when substantial lowering of blood pressure is achieved, heart rate and concentrations of catecholamines in plasma generally increase only slightly, if at all. This perhaps reflects an alteration of baroreceptor function with increased arterial compliance and the loss of the normal tonic influence of AngII on the sympathetic nervous system.

Aldosterone secretion is reduced, but not seriously impaired, by ACE inhibitors. Aldosterone secretion is maintained at adequate levels by other steroidogenic stimuli, such as ACTH and K^+ . The activity of these secretagogues on the zona glomerulosa of the adrenal cortex requires very small trophic or permissive amounts of AngII, which always are present because ACE inhibition never is complete. Excessive retention of K^+ is encountered

in patients taking supplemental K^+ , in patients with renal impairment, or in patients taking other medications that reduce K^+ excretion.

The ACE inhibitors alone normalize blood pressure in about 50% of patients with mild-to-moderate hypertension. Ninety percent of patients with mild-to-moderate hypertension will be controlled by the combination of an ACE inhibitor and a Ca^{2+} channel blocker, a β_1 adrenergic receptor blocker, or a diuretic. Diuretics augment the antihypertensive response to ACE inhibitors by rendering the patient's blood pressure renin dependent. Several ACE inhibitors are marketed in fixed-dose combinations with a thiazide diuretic or Ca^{2+} channel blocker for the management of hypertension.

ACE Inhibitors in Left Ventricular Systolic Dysfunction. Unless contraindicated, ACE inhibitors should be given to all patients with impaired left ventricular systolic function whether or not they have symptoms of overt heart failure (see Chapter 29). Several large clinical studies demonstrated that inhibition of ACE in patients with systolic dysfunction prevents or delays the progression of heart failure, decreases the incidence of sudden death and myocardial infarction, decreases hospitalization, and improves quality of life. Inhibition of ACE commonly reduces afterload and systolic wall stress, and both cardiac output and cardiac index increase, as do indices of stroke work and stroke volume. In systolic dysfunction, AngII decreases arterial compliance, and this is reversed by ACE inhibition. Heart rate generally is reduced. Systemic blood pressure falls, sometimes steeply at the outset, but tends to return toward initial levels. Renovascular resistance falls sharply, and renal blood flow increases. Natriuresis occurs as a result of the improved renal hemodynamics, the reduced stimulus to the secretion of aldosterone by AngII, and the diminished direct effects of AngII on the kidney. The excess volume of body fluids contracts, which reduces venous return to the right side of the heart. A further reduction results from venodilation and an increased capacity of the venous bed.

Although AngII has little acute venoconstrictor activity, long-term infusion of AngII increases venous tone, perhaps by central or peripheral interactions with the sympathetic nervous system. The response to ACE inhibitors also involves reductions of pulmonary arterial pressure, pulmonary capillary wedge pressure, and left atrial and left ventricular filling volumes and pressures. Consequently, preload and diastolic wall stress are diminished. The better hemodynamic performance results in increased exercise tolerance and suppression of the sympathetic nervous system. Cerebral and coronary blood flows usually are well maintained, even when systemic blood pressure is reduced. In heart failure, ACE inhibitors reduce ventricular dilation and tend to restore the heart to its normal elliptical shape. ACE inhibitors may reverse ventricular remodeling via changes in preload/afterload by preventing the growth effects of AngII on myocytes and by attenuating cardiac fibrosis induced by AngII and aldosterone.

ACE Inhibitors in Acute Myocardial Infarction. The beneficial effects of ACE inhibitors in acute myocardial infarction are particularly large in hypertensive and diabetic patients. Unless contraindicated (e.g., cardiogenic shock or severe hypotension), ACE inhibitors should be started immediately during the acute phase of myocardial infarction and can be administered along with thrombolytics, aspirin, and β adrenergic receptor antagonists (ACE Inhibitor Myocardial Infarction Collaborative Group, 1998). In high-risk patients (e.g., large infarct, systolic ventricular dysfunction), ACE inhibition should be continued long term (see Chapters 27 and 28).

ACE Inhibitors in Patients Who Are at High Risk of Cardiovascular Events. Patients at high risk of cardiovascular events benefit considerably from treatment with ACE inhibitors (Heart Outcomes Prevention Study Investigators, 2000). ACE inhibition significantly decreases the rate of myocardial infarction, stroke, and death in patients who do not have left ventricular dysfunction but have evidence of vascular disease or diabetes and one other risk factor for cardiovascular disease. In patients with coronary artery disease but without heart failure, ACE inhibition reduces cardiovascular disease death and myocardial infarction (European Trial, 2003).

ACE Inhibitors in Diabetes Mellitus and Renal Failure. Diabetes mellitus is the leading cause of renal disease. In patients with type 1

diabetes mellitus and diabetic nephropathy, ACE inhibitors prevent or delay the progression of renal disease, affording renoprotection, as defined by changes in albumin excretion. The renoprotective effects of ACE inhibitors in type 1 diabetes are in part independent of blood pressure reduction. In addition, ACE inhibitors may decrease retinopathy progression in type 1 diabetics and attenuate the progression of renal insufficiency in patients with a variety of nondiabetic nephropathies (Ruggenenti et al., 2010).

Several mechanisms participate in the renal protective effects of ACE inhibitors. Increased glomerular capillary pressure induces glomerular injury, and ACE inhibitors reduce this parameter by decreasing arterial blood pressure and by dilating renal efferent arterioles. ACE inhibitors increase the permeability selectivity of the filtering membrane, thereby diminishing exposure of the mesangium to proteinaceous factors that may stimulate mesangial cell proliferation and matrix production, two processes that contribute to expansion of the mesangium in diabetic nephropathy. Because AngII is a growth factor, reductions in the intrarenal levels of AngII may further attenuate mesangial cell growth and matrix production. ACE inhibitors increase Ang(1–7) levels by preventing its metabolism by ACE. Ang(1–7) binds to Mas receptors and has protective and antifibrotic effects (Santos, 2014). In the setting of diabetes, at the level of renal epithelial podocytes, activation of AT₁ receptors leads to activation of protein kinase signaling cascades, cytoskeletal rearrangements, retraction of podocyte processes, and a reduction in proteins of the slit diaphragm, all resulting in increased permeability of the renal epithelium to proteins (proteinuria). ACE inhibitors reduce these effects of AngII (Márquez et al., 2015).

ACE Inhibitors in Scleroderma Renal Crisis. The use of ACE inhibitors considerably improves survival of patients with scleroderma renal crisis.

Adverse Effects of ACE Inhibitors

In general, ACE inhibitors are well tolerated. The drugs do not alter plasma concentrations of uric acid or Ca^{2+} and may improve insulin sensitivity and glucose tolerance in patients with insulin resistance and decrease cholesterol and lipoprotein (a) levels in proteinuric renal disease.

Hypotension. A steep fall in blood pressure may occur following the first dose of an ACE inhibitor in patients with elevated PRA. Care should be exercised in patients who are salt depleted, are on multiple antihypertensive drugs, or have congestive heart failure.

Cough. In 5%–20% of patients, ACE inhibitors induce a bothersome, dry cough mediated by the accumulation in the lungs of bradykinin, substance P, or PGs. Thromboxane antagonism, aspirin, and iron supplementation reduce cough induced by ACE inhibitors. ACE dose reduction or switching to an ARB is sometimes effective. Once ACE inhibitors are stopped, the cough disappears, usually within 4 days.

Hyperkalemia. Significant K^+ retention is rarely encountered in patients with normal renal function. However, ACE inhibitors may cause hyperkalemia in patients with renal insufficiency or diabetes or in patients taking K^+ -sparing diuretics, K^+ supplements, β receptor blockers, or NSAIDs.

Acute Renal Failure. Inhibition of ACE can induce acute renal insufficiency in patients with bilateral renal artery stenosis, stenosis of the artery to a single remaining kidney, heart failure, or volume depletion owing to diarrhea or diuretics.

Angioedema. In 0.1%–0.5% of patients, ACE inhibitors induce rapid swelling in the nose, throat, mouth, glottis, larynx, lips, or tongue. Once ACE inhibitors are stopped, angioedema disappears within hours; meanwhile, the patient's airway should be protected, and if necessary, epinephrine, an antihistamine, or a glucocorticoid should be administered. African Americans have a 4.5 times greater risk of ACE inhibitor-induced angioedema than Caucasians. Although rare, angioedema of the intestine (visceral angioedema) characterized by emesis, watery diarrhea, and abdominal pain also has been reported. ACE inhibitor-associated angioedema is a class effect, and patients who develop this adverse event should not be prescribed any other drugs within the ACE inhibitor class.

Fetopathic Potential. If a pregnancy is diagnosed, it is imperative that ACE inhibitors be discontinued as soon as possible. ACE inhibitors and ARBs have been associated with renal developmental defects when administered in the third trimester of pregnancy, and potentially earlier. The fetopathic effects may be due in part to fetal hypotension. This possible adverse effect should be discussed with any woman of childbearing potential, as should the necessity of appropriate birth control measures.

Skin Rash. The ACE inhibitors occasionally cause a maculopapular rash that may itch, but that may resolve spontaneously or with antihistamines.

Other Side Effects. Extremely rare but reversible side effects include *dyseusia* (an alteration in or loss of taste), *neutropenia* (symptoms include sore throat and fever), *glycosuria* (spillage of glucose into the urine in the absence of hyperglycemia), *anemia*, and *hepatotoxicity*.

Drug Interactions. Antacids may reduce the bioavailability of ACE inhibitors; capsaicin may worsen ACE inhibitor-induced cough; NSAIDs, including aspirin, may reduce the antihypertensive response to ACE inhibitors; and K^+ -sparing diuretics and K^+ supplements may exacerbate ACE inhibitor-induced hyperkalemia. ACE inhibitors may increase plasma levels of digoxin and lithium and hypersensitivity reactions to allopurinol.

Angiotensin II Receptor Blockers

HISTORY

Attempts to develop therapeutically useful AngII receptor antagonists date to the early 1970s. Initial endeavors concentrated on angiotensin peptide analogues. Saralasin, 1-sarcosine, 8-isoleucine AngII, and other 8-substituted angiotensins are potent AngII receptor antagonists but were of no clinical value because of lack of oral bioavailability and unacceptable partial agonist activity. A breakthrough came in the early 1980s with the synthesis and testing of a series of imidazole-5-acetic acid derivatives that attenuated pressor responses to AngII in rats. Two compounds, S-8307 and S-8308, proved to be highly specific, albeit very weak, nonpeptide AngII receptor antagonists that were devoid of partial agonist activity (Dell'Italia, 2011). Through a series of stepwise modifications, the orally active, potent, and selective nonpeptide AT_1 receptor antagonist losartan was developed and approved for clinical use in the U.S. in 1995. Since then, seven additional AT_1 receptor antagonists (see Drug Facts for Your Personal Formulary table) have been approved. Although these AT_1 receptor antagonists are devoid of partial agonist activity, structural modifications as minor as a methyl group can transform a potent antagonist into an agonist (Perlman et al., 1997).

Pharmacological Effects

The AngII receptor blockers bind to the AT_1 receptor with high affinity and are more than 10,000-fold selective for the AT_1 receptor over the AT_2 receptor. Although binding of ARBs to the AT_1 receptor is competitive, the inhibition by ARBs of biological responses to AngII often is functionally insurmountable. Insurmountable antagonism has the theoretical advantage of sustained receptor blockade even with increased levels of endogenous ligand and with missed doses of drug. ARBs inhibit most of the biological effects of AngII, which include AngII-induced (1) contraction of vascular smooth muscle; (2) rapid pressor responses; (3) slow pressor responses; (4) thirst; (5) vasopressin release; (6) aldosterone secretion; (7) release of adrenal catecholamines; (8) enhancement of noradrenergic neurotransmission; (9) increases in sympathetic tone; (10) changes in renal function; and (11) cellular hypertrophy and hyperplasia. ARBs reduce arterial blood pressure in animals with renovascular and genetic hypertension, as well as in transgenic animals overexpressing the renin gene. ARBs, however, have little effect on arterial blood pressure in animals with low-renin hypertension (e.g., rats with hypertension induced by NaCl and deoxycorticosterone) (Csajka et al., 1997).

Do ARBs Have Therapeutic Efficacy Equivalent to That of ACE Inhibitors?

Although both ARBs and ACE inhibitors of drugs block the RAS, they differ in several important aspects:

- ARBs reduce activation of AT_1 receptors more effectively than do ACE inhibitors. ACE inhibitors reduce the biosynthesis of AngII by the action of ACE, but do not inhibit AngII generation via chymase and other ACE-independent AngII-producing pathways. ARBs block the actions of AngII via the AT_1 receptor regardless of the biochemical pathway leading to AngII formation.
- In contrast to ACE inhibitors, ARBs permit activation of AT_2 receptors. ACE inhibitors increase renin release, but block the conversion of AngI to AngII. ARBs also stimulate renin release; however, with ARBs, this translates into a several-fold increase in circulating levels of AngII. Because ARBs block AT_1 receptors, this increased level of AngII is available to activate AT_2 receptors.
- ACE inhibitors and ARBs increase Ang(1–7) levels by different mechanisms. ACE is involved in the clearance of Ang(1–7), so inhibition of ACE increases Ang(1–7) levels. With ARBs, AngII, the preferred substrate of ACE2, is converted to Ang(1–7).
- ACE inhibitors increase the levels of a number of ACE substrates, including bradykinin and Ac-SDKP.

Whether the pharmacological differences between ARBs and ACE inhibitors result in significant differences in therapeutic outcomes is an open question.

Clinical Pharmacology

Oral bioavailability of ARBs generally is low (<50%) except for azilsartan (~60%) and irbesartan (~70%), and protein binding is high (>90%).

Candesartan Cilexetil. Candesartan cilexetil is an inactive ester prodrug that is completely hydrolyzed to the active form, candesartan, during absorption from the GI tract (Figure 26–11). Peak plasma levels are obtained 3–4 h after oral administration; the plasma $t_{1/2}$ is about 9 h. Plasma clearance of candesartan is due to renal elimination (33%) and biliary excretion (67%). The plasma clearance of candesartan is affected by renal insufficiency but not by mild-to-moderate hepatic insufficiency. Candesartan cilexetil should be administered orally once or twice daily for a total daily dose of 4–32 mg.

Eprosartan. Peak plasma levels are obtained 1–2 h after oral administration; the plasma $t_{1/2}$ is 5–9 h. Eprosartan is metabolized in part to the glucuronide conjugate. Clearance is by renal elimination and biliary excretion. The plasma clearance of eprosartan is affected by both renal insufficiency and hepatic insufficiency. The recommended dosage of eprosartan is 400–800 mg/d in one or two doses.

Irbesartan. Peak plasma levels are obtained about 1.5–2 h after oral administration; the plasma $t_{1/2}$ is 11–15 h. Irbesartan is metabolized in part to the glucuronide conjugate, and the parent compound and its glucuronide conjugate are cleared by renal elimination (20%) and biliary excretion (80%). The plasma clearance of irbesartan is unaffected by either renal or mild-to-moderate hepatic insufficiency. The oral dosage of irbesartan is 150–300 mg once daily.

Losartan. Approximately 14% of an oral dose of losartan is converted by CYP2C9 and CYP3A4 to the 5-carboxylic acid metabolite, EXP 3174, which is more potent than losartan as an AT_1 receptor antagonist. Peak plasma levels of losartan and EXP 3174 occur about 1–3 h after oral administration, and the plasma half-lives are 2.5 and 6–9 h, respectively. The plasma clearances of losartan and EXP 3174 are via the kidney and liver (metabolism and biliary excretion) and are affected by hepatic but not renal insufficiency. Losartan should be administered orally once or twice daily for a total daily dose of 25–100 mg. Losartan is a competitive antagonist of the thromboxane A_2 receptor and attenuates platelet aggregation. EXP 3179, another metabolite of losartan without angiotensin receptor effects, reduces COX-2 messenger RNA upregulation and COX-dependent PG generation (Krämer et al., 2002) (Figure 26–11).

Olmesartan Medoxomil. Olmesartan medoxomil is an inactive ester prodrug that is completely hydrolyzed to the active form, olmesartan, during absorption from the GI tract. Peak plasma levels are obtained 1.4–2.8 h after oral administration; the plasma $t_{1/2}$ is 10–15 h. Plasma clearance of olmesartan is due to both renal elimination and biliary excretion. Although renal impairment and hepatic disease decrease the plasma clearance of olmesartan, no dose adjustment is required in patients with mild-to-moderate renal or hepatic impairment. The oral dosage of olmesartan medoxomil is 20–40 mg once daily.

Telmisartan. Peak plasma levels are obtained 0.5–1 h after oral administration; the plasma $t_{1/2}$ is about 24 h. Telmisartan is cleared from the circulation mainly by biliary secretion of intact drug. The plasma clearance of telmisartan is affected by hepatic but not renal insufficiency. The recommended oral dosage of telmisartan is 40–80 mg once daily.

Valsartan. Peak plasma levels occur 2–4 h after oral administration; food markedly decreases absorption; the plasma $t_{1/2}$ is about 9 h. Valsartan is cleared from the circulation by the liver (~70% of total clearance), and hepatic insufficiency will reduce clearance. The oral dosage of valsartan is 80–320 mg once daily.

Azilsartan Medoxomil. The prodrug is hydrolyzed in the GI tract into the active form, azilsartan. The drug is available in 40- and 80-mg once-daily doses. At the recommended dose of 80 mg once a day, azilsartan medoxomil is superior to the maximal doses of valsartan and olmesartan in lowering blood pressure. Bioavailability of azilsartan is about 60% and is not affected by food. Peak plasma concentrations C_{max} are achieved within 1.5–3 h. The elimination $t_{1/2}$ is about 11 h. Azilsartan is metabolized mostly by CYP2C9 into inactive metabolites. Elimination of the drug is 55% in feces and 42% in urine. About 15% of the dose is eliminated as unchanged azilsartan in urine. Plasma clearance is not affected by renal or hepatic insufficiency.

Angiotensin Receptor–Neprilysin Inhibitor. A combination of sacubitril and valsartan, marketed as Entresto, is a first-in-class drug that combines the AT_1 receptor antagonistic moiety of valsartan with the neprilysin inhibitor moiety of sacubitril. The complex (sacubitril, valsartan, Na^+ , and water [1:1:3:2.5]) dissociates into sacubitril and valsartan after oral administration. Sacubitril bioavailability is about 60%, and it is highly protein bound (94%–97%). Sacubitril is further metabolized by esterases into the active metabolite LBQ657, which has a $t_{1/2}$ of 11 h. The neprilysin inhibitor blocks the breakdown of natriuretic peptides ANP, BNP, and CNP, as well as AngI and bradykinin. The drug combination lowers vascular resistance and increases blood flow. In clinical trial, this combination agent was reported to be superior to enalapril in decreasing the risk of deaths from cardiovascular causes and heart failure by 20% (McMurray et al., 2014).

Entresto is approved for treatment of heart failure with reduced ejection fraction, with a recommended dose of 100–400 mg daily, divided into two doses. Because the ACE/neprilysin inhibitor omapatrilat demonstrated an increased risk of angioedema, use of Entresto is contraindicated in conjunction with an ACE inhibitor or in patients with a history of angioedema during ACE inhibitor or ARB use. The drug should not be used in conjunction with an ARB or ACE inhibitor, and in patients with diabetes should not be used in conjunction with aliskiren. Potential adverse effects discussed for valsartan also apply to this sacubitril-valsartan combination.

A New Class of ARBs in Development. A β -arrestin-biased AT_1 receptor blocker, TRV027 is a ligand that binds AT_1 receptor and blocks G protein-coupled signaling while engaging β -arrestin. β -Arrestin functions as an adaptor protein that participates in receptor desensitization and internalization. In animal models, β -arrestin-biased AT_1 receptor ligand increases myocyte contractility and protects against apoptosis (Kim et al., 2012). In phase II clinical studies, TRV027 decreased mean arterial pressure and was well tolerated. The safety and efficacy of TRV027 is being tested in the BLAST-HF study in patients with acute heart failure (Felker et al., 2015).

Therapeutic Uses of ARBs

All ARBs are approved for the treatment of hypertension. ARBs are renoprotective in type 2 diabetes mellitus, and many experts now consider them the drugs of choice for renoprotection in diabetic patients.

Irbesartan and losartan are approved for diabetic nephropathy, losartan is approved for stroke prophylaxis, and valsartan and candesartan are approved for heart failure and to reduce cardiovascular mortality in clinically stable patients with left ventricular failure or left ventricular dysfunction following myocardial infarction. The efficacy of ARBs in lowering blood pressure is comparable with that of ACE inhibitors and other established antihypertensive drugs, with a favorable adverse-effect profile. ARBs also are available as fixed-dose combinations with HCTZ or amlodipine (see Chapters 27–29).

The Losartan Intervention for Endpoint (LIFE) Reduction in Hypertension Study demonstrated the superiority of an ARB compared with a β_1 adrenergic receptor antagonist with regard to reducing stroke in hypertensive patients with left ventricular hypertrophy (Dahlöf et al., 2002). Also, irbesartan appears to maintain sinus rhythm in patients with persistent, long-standing atrial fibrillation (Madrid et al., 2002). Losartan is reported to be safe and highly effective in the treatment of portal hypertension in patients with cirrhosis and portal hypertension without compromising renal function (Schneider et al., 1999).

The ELITE (Evaluation of Losartan in the Elderly) study and a follow-up study (ELITE II) concluded that in elderly patients with heart failure, losartan is as effective as captopril in improving symptoms (Pitt et al., 2000). The VALIANT (Valsartan in Acute Myocardial Infarction) trial demonstrated that valsartan is as effective as captopril in patients with myocardial infarction complicated by left ventricular systolic dysfunction with regard to all-cause mortality (Pfeffer et al., 2003). Both valsartan and candesartan reduce mortality and morbidity in patients with heart failure (reviewed by Makani et al., 2013). Current recommendations are to use ACE inhibitors as first-line agents for the treatment of heart failure and to reserve ARBs for treatment of heart failure in patients who cannot tolerate or have an unsatisfactory response to ACE inhibitors.

The ARBs are renoprotective in type 2 diabetes mellitus, and many experts now consider them the drugs of choice for renoprotection in diabetic patients.

Dual Inhibition of the RAS. At present, there is contradictory evidence regarding the advisability of combining an ARB and an ACE inhibitor in patients with heart failure, with one study indicating that a combination of ARB and ACE inhibitors decreases morbidity and mortality in patients with heart failure, and another showing that combination therapy is associated with increased adverse effects and no added benefits (Dell'Italia, 2011; Makani et al., 2013; ONTARGET Investigators, 2008).

Adverse Effects

The ARBs are generally well tolerated. The incidence of angioedema and cough with ARBs is less than that with ACE inhibitors. As with ACE inhibitors, ARBs have teratogenic potential and should be discontinued in pregnancy. In patients whose arterial blood pressure or renal function is highly dependent on the RAS (e.g., renal artery stenosis), ARBs can cause hypotension, oliguria, progressive azotemia, or acute renal failure. ARBs may cause hyperkalemia in patients with renal disease or in patients taking K^+ supplements or K^+ -sparing diuretics. ARBs enhance the blood pressure-lowering effect of other antihypertensive drugs, a desirable effect but one that may necessitate dosage adjustment. There are rare postmarketing reports of anaphylaxis, abnormal hepatic function, hepatitis, neutropenia, leukopenia, agranulocytosis, pruritus, urticaria, hyponatremia, alopecia, and vasculitis, including Henoch-Schönlein purpura.

Direct Renin Inhibitors

Angiotensinogen is the only specific substrate for renin. DRIs inhibit the cleavage of AngI from angiotensinogen by renin, an enzymatic reaction that is the rate-limiting step for the subsequent generation of AngII. Aliskiren is the only DRI approved for clinical use.

HISTORY

Earlier renin inhibitors were orally inactive peptide analogues of the prorenin propeptide or analogues of renin-substrate cleavage site. Orally active, first-generation renin inhibitors (*enalikiren*, *zankiren*, *CGP38560A*, and *remikiren*) were effective in reducing AngII levels, but none of them made it past clinical trials due to their low potency, poor bioavailability, and short $t_{1/2}$. Low-molecular-weight renin inhibitors were designed based on molecular modeling and crystallographic structural information of renin-substrate interaction (Wood et al., 2003). This led to the development of aliskiren, a second-generation renin inhibitor that is FDA approved for the treatment of hypertension. Aliskiren has blood pressure-lowering effects similar to those of ACE inhibitors and ARBs.

Pharmacological Effects

Aliskiren is a low-molecular-weight nonpeptide and a potent competitive inhibitor of renin. It binds the active site of renin to block conversion of angiotensinogen to AngI, thus reducing the consequent production of AngII. Aliskiren has a 10,000-fold higher affinity to renin ($IC_{50} \sim 0.6$ nM) than to any other aspartic peptidases. In healthy volunteers, aliskiren (40–640 mg/d) induces a dose-dependent decrease in blood pressure, reduces PRA and AngI and AngII levels, but increases PRC by 16- to 34-fold due to the loss of the short-loop negative feedback by AngII (Figure 26–3; Table 26–2). Aliskiren also decreases plasma and urinary aldosterone levels and enhances natriuresis (Nussberger et al., 2002).

Clinical Pharmacology

Aliskiren is recommended as a single oral dose of 150 or 300 mg/d. Bioavailability of aliskiren is low (~2.5%), but its high affinity and potency compensate for the low bioavailability. Peak plasma concentrations are

reached within 3–6 h. The $t_{1/2}$ is 20–45 h. Steady state in plasma is achieved in 5–8 days. Plasma protein binding is 50% and is independent of concentration. Aliskiren is a substrate for P-glycoprotein, which contributes low bioavailability. Fatty meals significantly decrease the absorption of aliskiren. Hepatic metabolism by CYP3A4 is minimal. Elimination is mostly as unchanged drug in feces. About 25% of the absorbed dose appears in the urine as the parent drug.

Therapeutic Uses of Aliskiren

Therapeutic uses of aliskiren are discussed in Chapter 28.

Adverse Effects and Contraindications

Aliskiren is well tolerated, and adverse events are mild or comparable to placebo with no gender difference. Adverse effects include mild GI symptoms such as diarrhea at high doses (600 mg daily), abdominal pain, dyspepsia, and gastroesophageal reflux; headache; nasopharyngitis; dizziness; fatigue; upper respiratory tract infection; back pain; angiodema; and cough (much less common than with ACE inhibitors). Other adverse effects include rash, hypotension, hyperkalemia in diabetics on combination therapy, elevated uric acid, renal stones, and gout. Like other RAS inhibitors, aliskiren is not recommended in pregnancy.

Drug Interactions. Aliskiren does not interact with drugs that interact with CYPs. Aliskiren reduces absorption of furosemide by 50%. Irbesartan reduces the C_{max} of aliskiren by 50%. Aliskiren plasma levels are increased by drugs, such as ketoconazole, atorvastatin, and cyclosporine, that inhibit P-glycoprotein.

Effect of Pharmacological Blood Pressure Reduction on Function of the RAS

The RAS responds to alterations in blood pressure with compensatory changes (Figure 26–3). Thus, pharmacological agents that lower blood

Drug Facts for Your Personal Formulary: *Inhibitors of the RAS*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Angiotensin-Converting Enzyme Inhibitors • Inhibit the conversion of AngI to AngII		
Captopril Lisinopril Enalapril Benazepril Quinapril Ramipril Moexipril	<ul style="list-style-type: none">• Inhibit AngII production, thus lowering arteriolar resistance• Hypertension• Acute myocardial infarction• Congestive heart failure• Diabetic nephropathy• Scleroderma renal crisis	<ul style="list-style-type: none">• Antihypertensive effects potentiated by inhibition of ACE-catalyzed breakdown of bradykinin• Antihypertensive effects potentiated by increase in Ang(1–7) levels and activation of Ang(1–7)/Mas receptor pathway• Increase PRC and PRA• Adverse effects include cough in 5%–20% of patients, angioedema, hypotension, hyperkalemia, skin rash, neutropenia, anemia, fetopathic syndrome• Contraindicated in patients with renal artery stenosis and should be used with caution in patients with impaired renal function or hypovolemia• Should be stopped during pregnancy
Enalaprilat (IV)		<ul style="list-style-type: none">• Intravenous administration
Fosinopril Trandolapril Perindopril		<ul style="list-style-type: none">• Undergo both hepatic and renal elimination and should be used with caution in patients with renal or hepatic impairment
Angiotensin Receptor Blockers • Block AT₁ receptors		
Losartan Valsartan Eprosartan Irbesartan Candesartan Olmesartan Telmisartan Azilsartan	<ul style="list-style-type: none">• Block the vasoconstrictor and profibrotic effects of AngII by inhibiting AT₁ receptors while permitting vasodilation through activation of AT₂ receptors• Hypertension• Congestive heart failure• Diabetic nephropathy	<ul style="list-style-type: none">• Antihypertensive effects potentiated by activation of the AT₂ receptors• Antihypertensive effects potentiated by ACE2-dependent conversion of AngII to Ang(1–7) and activation of vasodilation via Ang(1–7)/Mas receptor pathway• Increase PRC and PRA• Adverse effects include hyperkalemia and hypotension• Contraindicated in patients with renal insufficiency• Should be stopped during pregnancy
Direct Renin Inhibitors • Inhibit renin and thus the conversion of angiotensinogen to AngI		
Aliskiren	<ul style="list-style-type: none">• Decrease AngI and AngII levels• Hypertension	<ul style="list-style-type: none">• Therapeutic value unclear; no evidence for superiority over ACEIs or ARBs• Increase PRC but decrease PRA• Contraindicated in diabetic nephropathy, pregnancy or renal insufficiency

pressure will alter the feedback loops that regulate the RAS and cause changes in the levels and activities of the system's components. These changes, summarized in Table 26-2, should be taken into account when interpreting laboratory evaluation of patients. Furthermore, during aliskiren treatment, the assay for PRA will be inhibited by persistence of aliskiren in this ex vivo reaction, whereas the renin concentration radioimmunoassay will not be inhibited.

Chapter 27

Treatment of Ischemic Heart Disease

Thomas Eschenhagen

PATHOPHYSIOLOGY OF ISCHEMIC HEART DISEASE

PATHOPHYSIOLOGY OF ANGINA PECTORIS

PHARMACOTHERAPY OF ISCHEMIC HEART DISEASE

- Organic Nitrates
- Ca^{2+} Channel Blockers
- β Adrenergic Receptor Antagonists (β blockers)
- Antiplatelet, Anti-integrin, and Antithrombotic Agents
- Other Antianginal Agents

THERAPEUTIC STRATEGIES

- Stable Coronary Artery Disease
- Acute Coronary Syndromes
- Claudication and Peripheral Vascular Disease

MECHANOPHARMACOLOGICAL THERAPY: DRUG-ELUTING ENDOVASCULAR STENTS

Pathophysiology of Ischemic Heart Disease

The pathophysiological understanding of ischemic heart disease has seen major changes over the past two decades—from a concept of localized calcification causing progressive constrictions of coronary arteries, ischemia, and exercise-induced angina pectoris to a systemic inflammatory disease of the arteries, including the coronaries (therefore the CAD name). A key finding in this change of paradigm was that most infarct-causing occlusions occur at small-to-medium plaques (“active plaques”) by thrombosis rather than at hemodynamically relevant stenoses by progressive narrowing. Thus, in addition to the mere size of an obstructing plaque, the inflammatory activity of the atherosclerotic process, the stability of the plaque, and platelet reactivity appear to determine the prognosis (Libby et al., 2002).

Atherosclerosis encompasses increased lipid deposition in the subendothelial space (early plaque), endothelial dysfunction with decreased production of NO, less vasodilation and increased risk of platelet adhesion, influx of lipid scavenger cells (mainly macrophages), necrosis, sterile inflammation, proliferation of smooth muscle cells, and calcification and narrowing of the blood vessel by increasing plaque formation. If the endothelium covering the plaque or the cell layer enclosing the necrotic core of the plaque disrupt, thrombogenic materials such as collagen are presented to the bloodstream, causing platelet adhesion, fibrin deposition, thrombus formation, and closure of the blood vessel.

Triggering factors can be not only acute inflammation (e.g., influenza), but also blood pressure peaks during physical exercise or emotional stress (e.g., demonstrated during a life-threatening emergency and in avid fans during football games). Importantly, the process is dynamic, and the net thrombus formation is the result of the balance between thrombosis and thrombolysis by the fibrinolytic system (plasminogen). The degree and the duration of coronary obstruction and thereby of the ischemia of downstream myocardium (and its size) determine the degree of necrosis of muscle tissue, that is, infarct size.

Taken together, important factors that determine the progress of CAD are the concentration of lipids in the blood, endothelial function, blood pressure (as a mechanical factor predisposing to plaque rupture), the activity of the inflammatory system, and the reactivity of pro- and antithrombotic systems. Patients with CAD should be advised not only to exercise regularly, stop smoking, and have blood pressure and body weight well controlled, but also to be treated with statins, aspirin, and β adrenergic receptor antagonists (β blockers) and have annual vaccinations

against influenza. The widespread implementation of this combination drug regimen and the considerably improved treatment of ACSs likely account for the continuous reduction in MIs and age-corrected cardiovascular lethality in Western countries (–42% between 2000 and 2011; Mozaffarian et al., 2015). Interestingly, the incidence of the classical large STEMI is declining as that of smaller non-STEMI increases. This raises the hypothesis that the dominant pathogenesis of acute coronary thrombosis may have changed from the rupture of lipid-rich, inflammatory plaques (in the prestatin era) to the erosion of stable plaques (Libby and Pasterkamp, 2015).

Antiplatelet agents, fibrinolytic drugs, anticoagulants, and statins (HMG-CoA reductase inhibitors) are systematically discussed in Chapters 32 and 33. This chapter concentrates on pharmacotherapy for angina pectoris and myocardial ischemia.

Pathophysiology of Angina Pectoris

Angina pectoris, the primary symptom of ischemic heart disease, is caused by transient episodes of myocardial ischemia that are due to an imbalance in the myocardial oxygen supply-demand relationship. This imbalance may be caused by an increase in myocardial oxygen demand (which is determined by heart rate, ventricular contractility, and ventricular wall tension) or by a decrease in myocardial oxygen supply (primarily determined by coronary blood flow, but occasionally modified by the oxygen-carrying capacity of the blood), or sometimes by both (Figure 27–1). Because blood flow is inversely proportional to the fourth power of the artery’s luminal radius, the progressive decrease in vessel radius that characterizes coronary atherosclerosis can impair coronary blood flow and lead to symptoms of angina when myocardial O_2 demand increases, as with exertion (the so-called typical and most prevalent form of angina pectoris). In some patients, anginal symptoms may occur without any increase in myocardial O_2 demand, but rather as a consequence of an abrupt reduction in blood flow, as might result from coronary thrombosis (unstable angina or ACS) or localized vasospasm (variant or Prinzmetal angina). Regardless of the precipitating factors, the sensation of angina is similar in most patients. Typical angina is experienced as a heavy, pressing substernal discomfort (rarely described as a “pain”), often radiating to the left shoulder, flexor aspect of the left arm, jaw, or epigastrium. However, a significant minority of patients note discomfort in a different location or of a different character. Women, the elderly, and diabetics are more

Abbreviations

ACE:	angiotensin-converting enzyme
ACEI:	angiotensin-converting enzyme inhibitor
ACS:	acute coronary syndrome
ALDH2:	mitochondrial aldehyde dehydrogenase
ARB:	angiotensin receptor blocker
AV:	atrioventricular
CABG:	coronary artery bypass grafting
CAD:	coronary artery disease
COX-1:	cyclooxygenase isoform 1
CYP:	cytochrome P450
EC₅₀:	half-maximal effective concentration
EMA:	European Medicines Agency
eNOS:	endothelial NOS
FDA:	U.S. Food and Drug Administration
FFA:	free fatty acid
GI:	gastrointestinal
GTN:	glyceryl trinitrate (nitroglycerin)
HCM:	hypertrophic cardiomyopathy
HCN:	hyperpolarization-activated cyclic nucleotide-gated
HMG-CoA:	3-hydroxy-3-methylglutaryl coenzyme A
iNOS:	inducible NOS
IP₃:	inositol 1,4,5-trisphosphate
ISDN:	isosorbide dinitrate
ISMN:	isosorbide-5-mononitrate
MI:	myocardial infarction
nNOS:	neuronal NOS
NO:	nitric oxide
NOS:	nitric oxide synthase
NSTEMI:	non-ST-elevation myocardial infarction
PDE:	cyclic nucleotide phosphodiesterase
Pgp:	P-glycoprotein
PLC:	phospholipase C
rTPA:	recombinant tissue plasminogen activator
SA:	sinoatrial
SNS:	sympathetic nervous system
STEMI:	ST-segment elevation myocardial infarction
Tn:	troponin
TxA₂:	thromboxane A ₂

likely to experience myocardial ischemia with atypical symptoms. In most patients with typical angina, whose symptoms are provoked by exertion, the symptoms are relieved by rest or by administration of sublingual nitroglycerin.

Angina pectoris is a common symptom, affecting 8 million Americans (Mozaffarian et al., 2015). Angina pectoris may occur in a stable

pattern over many years or may become unstable, increasing in frequency or severity and even occurring at rest. In typical stable angina, the pathological substrate is usually fixed atherosclerotic narrowing of an epicardial coronary artery, on which exertion or emotional stress superimposes an increase in myocardial O₂ demand. In variant angina, focal or diffuse coronary vasospasm episodically reduces coronary flow. Patients also may display a mixed pattern of angina with the addition of altered vessel tone on a background of atherosclerotic narrowing. In most patients with unstable angina, rupture of an atherosclerotic plaque, with consequent platelet adhesion and aggregation, decreases coronary blood flow. Superimposed thrombosis may lead to the complete abrogation of blood flow. Atherosclerotic plaques with thinner fibrous caps appear to be more “vulnerable” to rupture.

Myocardial ischemia also may be *silent*, with electrocardiographic, echocardiographic, or radionuclide evidence of ischemia appearing in the absence of symptoms. While some patients have only silent ischemia, most patients who have silent ischemia have symptomatic episodes as well. The precipitants of silent ischemia appear to be the same as those of symptomatic ischemia. We now know that the *ischemic burden* (i.e., the total time a patient is ischemic each day) is greater in many patients than was recognized previously. In most trials, the agents that are efficacious in typical angina also are efficacious in reducing silent ischemia. β Blockers appear to be more effective than the Ca²⁺ channel blockers in the prevention of episodes. Therapy directed at abolishing all silent ischemia has not been shown to be of additional benefit over conventional therapy.

Pharmacotherapy of Ischemic Heart Disease

The principal pharmacological agents used in the treatment of angina are nitrovasodilators, β blockers (see Chapter 12), and Ca²⁺ channel blockers. In patients with typical exercise-induced angina on the basis of CAD, these antianginal agents improve the balance of myocardial O₂ supply and O₂ demand principally by reducing myocardial O₂ demand by decreasing heart rate, myocardial contractility, or ventricular wall stress. Increased O₂ supply by dilating the coronary vasculature may play an additional role and is the major effect of nitrovasodilators and Ca²⁺ channel blockers in variant angina.

By contrast, the principal therapeutic goal in ACSs with unstable angina is to prevent or reduce coronary thrombus formation and increase myocardial blood flow; strategies include the use of antiplatelet agents and *heparin*, often accompanied by efforts to restore flow by mechanical means, including percutaneous coronary interventions using coronary stents, or (less commonly) emergency coronary bypass surgery. The principal therapeutic aim in variant or Prinzmetal angina is to prevent coronary vasospasm.

Antianginal agents may provide prophylactic or symptomatic treatment, but β blockers also reduce mortality, apparently by decreasing the incidence of sudden cardiac death associated with myocardial ischemia and infarction. The chronic use of organic nitrate vasodilators, which are highly efficacious in treatment of angina, is not associated with

Figure 27-1 Pharmacological modification of the major determinants of myocardial O₂ supply. When myocardial O₂ requirements exceed O₂ supply, an ischemic episode results. This figure shows the primary hemodynamic sites of action of pharmacological agents that can reduce O₂ demand (left side) or enhance O₂ supply (right side). Some classes of agents have multiple effects. Stents, angioplasty, and coronary bypass surgery are mechanical interventions that increase O₂ supply. Both pharmacotherapy and mechanotherapy attempt to restore a dynamic balance between O₂ demand and O₂ supply.

improvements in cardiac mortality, and some investigators have suggested that chronic use of nitroglycerin may have adverse cardiovascular effects (Parker, 2004).

Besides symptomatic relief from angina pain conferred by antianginal drugs, patients with CAD should be treated with drugs that can reduce the progression of atherosclerosis and reduce the risk of coronary thrombosis and MI. *Aspirin* is used routinely in patients with myocardial ischemia, and daily aspirin at low doses reduces the incidence of clinical events (Fihn et al., 2012). The optimal dose appears to be between 75 and 150 mg/d (Montalescot et al., 2013), although most large studies have been done with a 325-mg dose. The oral ADP receptor antagonist clopidogrel was slightly superior to aspirin in patients with chronic atherosclerotic vascular disease and had a favorable safety profile (CAPRIE Steering Committee, 1996). When used in combination with aspirin in patients with ACS, clopidogrel reduced the cardiovascular death rate by 20%, but increased the incidence of major bleeding events by 38% (Yusuf et al., 2001). In patients with stable cardiovascular disease, clopidogrel conferred no benefit over aspirin and was associated with signs of harm in patients with multiple risk factors (Bhatt et al., 2006). Guidelines therefore recommend clopidogrel only as an alternative in patients with aspirin intolerance and advise against the routine use of dual platelet inhibition in patients with stable disease (Fihn et al., 2012; Montalescot et al., 2013). In contrast, dual platelet inhibition is routinely given in patients who underwent coronary artery stenting. The recommended time (1–12 months) varies depending on the intervention (e.g., bare metal vs. drug-eluting stent) and the risk profile of patients. The newer ADP receptor antagonists prasugrel and ticagrelor have a more useful pharmacokinetic profile and seem to have a better benefit/risk ratio than clopidogrel in the postintervention treatment phase (Cannon et al., 2010; Wiviott et al., 2007) but are not generally recommended as alternatives to clopidogrel in patients with stable CAD. Statins reduce mortality in patients with CAD. Although high-risk patients (including those with high plasma LDL cholesterol levels) have the greatest absolute benefit, the relative risk reduction of approximately 25% appears largely independent of baseline cholesterol blood levels. Statins should therefore be given to all patients with CAD. It is unclear whether ACEIs or angiotensin receptor blockers (see Chapter 26) reduce mortality or other end points in patients with CAD when given routinely in addition to aspirin, statins, and β blockers, but they are recommended for subgroups of patients with CAD with reduced left ventricular systolic function, hypertension, diabetes, or chronic kidney disease (Montalescot et al., 2013).

Coronary artery bypass surgery and percutaneous coronary interventions such as angioplasty and coronary artery stent deployment commonly complement pharmacological treatment. In some subsets of patients, percutaneous or surgical revascularization may have a survival advantage over medical treatment alone (Kappetein et al., 2011). Intracoronary drug delivery using drug-eluting coronary stents represents an intersection of mechanical and pharmacological approaches in the treatment of CAD.

Organic Nitrates

The organic nitrate agents are prodrugs that are sources of NO. NO activates the soluble isoform of guanylyl cyclase, thereby increasing intracellular levels of cGMP. In turn, cGMP promotes the dephosphorylation of the myosin light chain and the reduction of cytosolic Ca^{2+} and leads to the relaxation of smooth muscle cells in a broad range of tissues (see Figures 3-13, 3-17, and 44-7). The NO-dependent relaxation of vascular smooth muscle leads to vasodilation; NO-mediated guanylyl cyclase activation also inhibits platelet aggregation and relaxes smooth muscle in the bronchi and GI tract.

The broad biological response to nitrovasodilators reflects the existence of endogenous NO-modulated regulatory pathways. The endogenous synthesis of NO in humans is catalyzed by a family of NOSs that oxidize the amino acid L-arginine to form NO, plus L-citrulline as a coproduct. There are three distinct mammalian NOS isoforms: *nNOS*, *eNOS*, and *iNOS* (see Chapter 3), and they are involved in processes as diverse as neurotransmission, vasomotion, and immunomodulation. In several vascular disease

states, pathways of endogenous NO-dependent regulation appear to be deranged (reviewed in [Dudzinski et al., 2006]).

HISTORICAL PERSPECTIVE

Nitroglycerin was first synthesized in 1846 by Sobrero, who observed that a small quantity placed on the tongue elicited a severe headache. The explosive properties of nitroglycerin also were soon noted, and control of this unstable compound for military and industrial use was not realized until Alfred Nobel devised a process to stabilize the nitroglycerin and patented a specialized detonator in 1863. The vast fortune that Nobel accrued from the nitroglycerin detonator patent provided the funds later used to establish the Nobel prizes. In 1857, T. Lauder Brunton of Edinburgh (no relation to the editor of this volume) administered *amyl nitrite*, a known vasodepressor, by inhalation and noted that anginal pain was relieved within 30–60 sec. The action of amyl nitrite was transitory, however, and the dosage was difficult to adjust. Subsequently, William Murrell surmised that the action of nitroglycerin mimicked that of amyl nitrite and established the use of sublingual nitroglycerin for relief of the acute anginal attack and as a prophylactic agent to be taken prior to exertion. The empirical observation that organic nitrates could dramatically and safely alleviate the symptoms of angina pectoris led to their widespread acceptance by the medical profession. Indeed, Alfred Nobel himself was prescribed nitroglycerin by his physicians when he developed angina in 1890. Basic investigations defined the role of NO in both the vasodilation produced by nitrates and endogenous vasodilation. The importance of NO as a signaling molecule in the cardiovascular system and elsewhere was recognized by the awarding of the 1998 Nobel Prize in Medicine/Physiology to the pharmacologists Robert Furchgott, Louis Ignarro, and Ferid Murad.

Chemistry

Organic nitrates are polyol esters of nitric acid, whereas organic nitrites are esters of nitrous acid (Table 27-1). Nitrate esters ($-\text{C}-\text{O}-\text{NO}_2$) and nitrite esters ($-\text{C}-\text{O}-\text{NO}$) are characterized by a sequence of carbon-oxygen-nitrogen, whereas nitro compounds possess carbon-nitrogen bonds ($\text{C}-\text{NO}_2$). Thus, GTN is not a nitro compound, and it is erroneously called nitroglycerin; however, this nomenclature is both widespread and official. Amyl nitrite is a highly volatile liquid that must be administered by inhalation and is of limited therapeutic utility. Organic nitrates of low molecular mass (such as GTN) are moderately volatile, oily liquids, whereas the high-molecular-mass nitrate esters (e.g., erythrityl tetranitrate, ISDN, and isosorbide mononitrate) are solids. In the pure form (without an inert carrier such as lactose), nitroglycerin is explosive. The organic nitrates and nitrites, collectively termed *nitrovasodilators*, must be metabolized (reduced) to produce gaseous NO, which appears to be the active principle of this class of compounds. NO gas also can be directly administered by inhalation.

Pharmacological Properties

Mechanism of Action. Nitrites, organic nitrates, nitroso compounds, and a variety of other nitrogen oxide-containing substances (including *nitroprusside*; see further in the chapter) lead to the formation of the reactive gaseous free radical NO and related NO-containing compounds. NO gas also may be administered by inhalation. Surprisingly, more than 140 years after its introduction in the therapy of angina pectoris, the mode of action of organic nitrates is still incompletely understood (Mayer and Beretta, 2008). Established mechanisms of GTN bioactivation and action include a nonenzymatic reaction with L-cysteine, formation of nitrite and NO by ALDH2 (Chen et al., 2002), activation of soluble guanylyl cyclase, and generation of cGMP. The bioactivation of other nitrovasodilators such as ISDN and ISMN is ALDH2 independent, suggesting the involvement of other enzymes, such as CYPs, xanthine oxidoreductase, and cytosolic ALDH isoforms (Munzel et al., 2014). The action of NO on soluble

guanylyl cyclase seems to be elicited in substantial part by S-nitrosothiol. The different ALDH2 dependence of GTN and ISDN is clinically relevant because individuals of Asian origin carry an inactive ALDH2 variant and do not respond adequately to GTN but do respond to ISDN (Stamler, 2008).

The NO-stimulated elevation of cGMP activates PKG and modulates the activities of cyclic nucleotide PDEs (PDEs 2, 3, and 5) in a variety of cell types. In smooth muscle, the net result is reduced phosphorylation of myosin light chain, reduced Ca^{2+} concentration in the cytosol, and relaxation (Figure 44-7). Reduced phosphorylation of myosin light chain is the result of decreased myosin light-chain kinase activity and increased myosin light-chain phosphatase activity and promotes vasorelaxation and smooth muscle relaxation in many tissues. cGMP is a substrate for PDE 5, whose inhibition by sildenafil and related compounds potentiates the action of nitrovasodilators (see *Toxicity and Untoward Responses*).

Hemodynamic Effects. The nitrovasodilators promote relaxation of vascular smooth muscle. For reasons not understood, GTN dilates large blood vessels (>200-µm diameter) more potently than small vessels, explaining why low doses of GTN preferentially dilate veins and conductance arteries and leave the tone of the small-to-medium arterioles (that regulate resistance) unaffected. This profile has important consequences for the antianginal efficacy of nitrovasodilators. At low-to-medium doses, preferential venodilation decreases venous return, leading to a fall in left and right ventricular chamber size and end-diastolic pressures, reduced wall stress, and thereby reduced cardiac O_2 demand (see discussion that follows). Systemic vascular resistance and arterial pressure are not or only mildly decreased, leaving coronary perfusion pressure unaffected. Heart rate remains unchanged or may increase slightly in response to a decrease in blood pressure. Pulmonary vascular resistance and cardiac output are slightly reduced. Doses of GTN that do not alter systemic arterial pressure may still produce arteriolar dilation in the face and neck, resulting in a facial flush, or dilation of meningeal arterial vessels, causing headache.

Higher doses of organic nitrates cause further venous pooling and may decrease arteriolar resistance as well, thereby decreasing systolic and diastolic blood pressure and causing pallor, weakness, dizziness, and activation of compensatory sympathetic reflexes. This can happen to such an extent that coronary flow is compromised, and the sympathetic increase in myocardial O_2 demand overrides the beneficial action of the

nitrovasodilators, leading to ischemia. In addition, sublingual nitroglycerin administration may produce bradycardia and hypotension, probably owing to activation of the Bezold-Jarisch reflex.

In patients with autonomic dysfunction and an inability to increase sympathetic outflow (multiple-system atrophy and pure autonomic failure are the most common forms, much less commonly seen in the autonomic dysfunction associated with diabetes), the fall in blood pressure consequent to the venodilation produced by nitrates cannot be compensated. In these clinical contexts, nitrates may reduce arterial pressure and coronary perfusion pressure significantly, producing potentially life-threatening hypotension and even aggravating angina.

ADME. As outlined previously, nitrovasodilators differ in their dependence on ALDH2 for bioactivation (note ALDH2 deficiency in many Asians). In addition, their pharmacokinetic profiles exhibit therapeutically relevant differences in sublingual resorption, onset of action, and half-life (Table 27-1).

Nitroglycerin. Peak concentrations of GTN are found in plasma within 4 min of sublingual administration; the drug has a $t_{1/2}$ of 1–3 min. The onset of action of GTN may be even more rapid if delivered as a sublingual spray rather than as a sublingual tablet. Glyceryl dinitrate metabolites, which have about one-tenth the vasodilator potency, appear to have half-lives of about 40 min.

Isosorbide Dinitrate. Sublingual administration of ISDN produces maximal plasma concentrations of the drug by 6 min, and the fall in concentration is rapid ($t_{1/2}$ of about 45 min). The primary initial metabolites, isosorbide-2-mononitrate and ISMN, have longer half-lives (3–6 h) and are presumed to contribute to the therapeutic efficacy of the drug. ISDN is therefore suitable both for standby and sustained therapy.

Isosorbide-5-Mononitrate. This agent is available in tablet form. ISMN does not undergo significant first-pass metabolism, so it has high bioavailability after oral administration, but its onset of action is too slow for acute treatment of angina.

Inhaled NO. Nitric oxide gas administered by inhalation appears to exert most of its therapeutic effects on the pulmonary vasculature because of the rapid inactivation of NO by hemoglobin in the blood. It is approved for the treatment of pulmonary hypertension in hypoxemic neonates, where it reduced morbidity and mortality (Bloch et al., 2007), and is currently tested in patients with pulmonary arterial hypertension.

Mechanisms of Antianginal Efficacy of Organic Nitrates

When GTN is injected directly into the coronary circulation of patients with CAD, anginal attacks (induced by electrical pacing) are not aborted even when coronary blood flow is increased. In contrast, sublingual administration of GTN does relieve anginal pain in the same patients, indicating that the major antianginal effect of nitrovasodilators is mediated by preload reduction rather than coronary artery dilation.

This interpretation is supported by studies in exercising patients showing that angina occurs at the same value of the *triple product* (Aortic pressure \times Heart rate \times Ejection time, which is roughly proportional to myocardial consumption of O_2) with or without nitroglycerin. Thus, the beneficial effect of nitroglycerin has to result from reduced cardiac O_2 demand rather than an increase in the delivery of O_2 to ischemic regions of myocardium. However, these results do not preclude the possibility that a favorable redistribution of blood flow to ischemic subendocardial myocardium may contribute to relief of pain in a typical anginal attack, and they do not preclude the possibility that direct coronary vasodilation may be the major effect of nitroglycerin in situations where vasospasm compromises myocardial blood flow.

Effects on Myocardial O_2 Requirements. The major determinants of myocardial O_2 consumption are left ventricular wall tension, heart rate, and myocardial contractility (Figure 27-1). Ventricular wall tension is affected by preload and afterload. *Preload* is determined by the diastolic pressure that distends the ventricle (ventricular end-diastolic pressure). Increasing end-diastolic volume augments the ventricular wall tension (by the law of Laplace, tension is proportional to pressure times radius). Increasing venous capacitance with nitrates decreases venous return to the heart, decreases ventricular end-diastolic volume, and thereby decreases O_2 consumption. An additional benefit of reducing preload is that it increases the pressure gradient for perfusion across the ventricular wall, which favors subendocardial perfusion. *Afterload* is the impedance against which the ventricle must eject. In the absence of aortic valvular disease, afterload is related to peripheral resistance. Decreasing peripheral arteriolar resistance reduces afterload and thus myocardial work and O_2 consumption. The distensibility of the large conductance arteries such as the aorta may play an additional role.

Nitrovasodilators preferentially decrease preload by dilating venous capacitance vessels. The decrease in afterload is generally small and mainly observed at higher doses. The effect on aortic stiffness appears complex (Soma et al., 2000). NO and nitrovasodilators can directly modulate the inotropic or chronotropic state of the heart via cGMP and its stimulatory effect on PDE2 (thereby reducing cAMP) or an inhibitory effect on the cAMP-specific PDE3 (thereby increasing cAMP). An inotropic response depends on the extent to which the PDE isoforms are expressed in the appropriate cells and in the proper subcellular compartment (Steinberg and Brunton, 2001). Small NO concentrations favor a positive inotropic effect (Kojda et al., 1997); however, the effect size is small and its significance unclear. Because nitrates affect several of the primary determinants of myocardial O_2 demand, their net effect usually is to decrease myocardial O_2 consumption. In addition, an improvement in the lusitropic state of the heart may be seen with more rapid early diastolic filling. This may be secondary to the relief of ischemia rather than primary, or it may be due to a reflex increase in sympathetic activity. Nitrovasodilators also increase cGMP in platelets, with consequent inhibition of platelet function. While this may contribute to their antianginal efficacy, the effect appears to be modest and in some settings may be confounded by the potential of nitrates to alter the pharmacokinetics of heparin, reducing its antithrombotic effect.

Effects on Total and Regional Coronary Blood Flow. When considering the effect of vasodilators in the ischemic heart, it is important to realize that myocardial ischemia itself is a powerful stimulus to coronary vasodilation and part of an autoregulatory mechanism. In the presence of atherosclerotic coronary artery narrowing, ischemia distal to the lesion stimulates vasodilation of downstream resistance arterioles and thereby helps maintain adequate perfusion of the ischemic area under rest. If the stenosis is severe, much of the capacity to dilate is used to maintain resting

blood flow. Further dilation may not be possible, neither under exercise nor with therapeutically applied vasodilators. In contrast, nonselective vasodilators such as adenosine or dipyridamole (which inhibits adenosine transmembrane transport and thereby increases extracellular concentrations) can worsen the perfusion of ischemic areas by dilating the relatively constricted arterioles of the healthy myocardium, leading to redistribution of blood flow away from the ischemic myocardium ("steal phenomenon"). Accordingly, dipyridamole is not used therapeutically but can be used as a stress test to provoke angina pectoris (Bodi et al., 2007).

Nitrovasodilators, in contrast, do not have a major effect on the smaller resistance arteries (and therefore do not cause steal phenomena) but can dilate the large, epicardial sections of the coronary arteries upstream of a stenosis and also in a stenosis (concept of the "dynamic stenosis"; Brown et al., 1981) and thereby increase blood flow distal to the narrowing. Collateral flow to ischemic regions also is increased. As outlined previously, GTN also reduces wall stress that opposes blood flow to the subendocardium, which is particularly sensitive to ischemia.

In patients with angina owing to coronary artery spasm, the capacity of nitrovasodilators to dilate epicardial coronary arteries, particularly regions affected by spasm, is the primary mechanism of their beneficial effect.

Other Effects. The nitrovasodilators also relax smooth muscles of the bronchial tract, the gallbladder, biliary ducts, and sphincter of Oddi and the GI tract. Spontaneous motility decreased by nitrates both in vivo and in vitro. The effect may be transient and incomplete in vivo, but abnormal "spasm" frequently is reduced. Indeed, many incidences of atypical chest pain and "angina" are due to biliary or esophageal spasm, and these also can be relieved by nitrates. Nitrates can also relax ureteral and uterine smooth muscle, but these responses are of uncertain clinical significance.

Tolerance

Frequently repeated or continuous exposure to high doses of nitrovasodilators lead to tolerance, that is, marked attenuation in the magnitude of most of their pharmacological effects. The magnitude of tolerance is a function of dosage and frequency of use. Tolerance may result from a reduced capacity of the vascular smooth muscle to convert nitroglycerin to NO, *true vascular tolerance*, or to the activation of mechanisms extraneous to the vessel wall, *pseudotolerance* (Munzel et al., 1995). Multiple mechanisms have been proposed to account for nitrate tolerance, including volume expansion, neurohumoral activation, cellular depletion of sulfhydryl groups, and the generation of free radicals (Parker and Parker, 1998). A reactive intermediate formed during the generation of NO from organic nitrates may itself damage and inactivate the enzymes of the activation pathway (Munzel et al., 1995; Parker, 2004). Inactivation of ALDH2 (Sydow et al., 2004) and S-nitrosylation of soluble guanylyl cyclase (Sayed et al., 2008) are seen in models of nitrate tolerance and could explain cross-tolerance to different (nitro)vasodilators. Other changes observed in the setting of nitroglycerin tolerance include an enhanced response to vasoconstrictors such as angiotensin II, serotonin, and phenylephrine. Prolonged administration of GTN is associated with plasma volume expansion, which may be reflected by a decrease in hematocrit. Unfortunately, attempts to prevent nitrate tolerance based on these mechanisms (e.g., antioxidants, coapplication of vasodilators or diuretics) failed in clinical trials.

A clinically important lesson of research on nitrate tolerance is that prolonged treatment with nitrates may not only induce a loss of response to nitrates, but also actually decrease angina threshold in the interval (Parker et al., 1995). A special form of GTN tolerance is observed in individuals exposed to GTN in the manufacture of explosives. If protection is inadequate, workers may experience severe headaches, dizziness, and postural weakness during the first several days of employment ("Monday disease"). Tolerance then develops and can lead to organic nitrate dependence. Workers without demonstrable organic vascular disease have been reported to have an increase in the incidence of ACSs during the 24- to 72-h periods away from the work environment. It seems prudent not to withdraw nitrates abruptly from a patient who has received such therapy chronically.

Therapy should be designed to prevent tolerance. High doses should be avoided and therapy interrupted for 8–12 h daily, which allows the return of efficacy. In patients with exertional angina, it is usually most convenient to omit dosing at night either by adjusting dosing intervals of oral or buccal preparations or by removing cutaneous GTN. Patients whose anginal pattern suggests its precipitation by increased left ventricular filling pressures (e.g., in association with orthopnea or paroxysmal nocturnal dyspnea) may benefit from continuing nitrates at night and omitting them during a quiet period of the day. Some patients develop an increased frequency of nocturnal angina when a nitrate-free interval is employed using GTN patches; such patients may require another class of antianginal agent during this period. Continuous intravenous administration of GTN regularly induces tolerance and should therefore be avoided. Tolerance also has been seen with ISMN and ISDN; an eccentric twice-daily dosing schedule appears to maintain efficacy (Parker and Parker, 1998). Molsidomine, a direct NO donor, is approved in many European countries and is claimed to induce less tolerance than the organic nitrates, but the supporting evidence is weak. A recent study failed to demonstrate beneficial effects of molsidomine on endothelial dysfunction (Barbato et al., 2015).

Toxicity and Untoward Responses

Untoward responses to the therapeutic use of organic nitrates are almost all secondary to actions on the cardiovascular system. Headache is common and can be severe, usually decreasing over a few days if treatment is continued and often controlled by decreasing the dose. Transient episodes of dizziness, weakness, and other manifestations associated with postural hypotension may develop, particularly if the patient is standing immobile, and may progress occasionally to loss of consciousness, a reaction that appears to be accentuated by alcohol. It also may be seen with very low doses of nitrates in patients with autonomic dysfunction. Even in severe nitrate syncope, positioning and other measures that facilitate venous return are the only therapeutic measures required. All the organic nitrates occasionally can produce drug rash.

Interaction of Nitrates With PDE5 Inhibitors. Erectile dysfunction is a frequently encountered problem whose risk factors parallel those of CAD. Thus, many men desiring therapy for erectile dysfunction already may be receiving (or may require, especially if they increase physical activity) antianginal therapy. The combination of sildenafil and other PDE5 inhibitors with organic nitrate vasodilators can cause extreme hypotension.

Cells in the corpus cavernosum produce NO during sexual arousal in response to nonadrenergic, noncholinergic neurotransmission (Burnett et al., 1992). NO stimulates the formation of cGMP, which leads to relaxation of smooth muscle of penile arteries that fill the corpus cavernosum, leading to engorgement of the corpus cavernosum and erection. The accumulation of cGMP is enhanced by inhibition of the cGMP-specific PDE5 family. Sildenafil and congeners inhibit PDE5 and have been demonstrated to improve erectile function in patients with erectile dysfunction. Not surprisingly, PDE5 inhibitors have assumed the status of widely used recreational drugs. Sildenafil is also FDA and EMA approved in patients with pulmonary arterial hypertension in whom the drug decreased pulmonary vascular resistance and enhanced exercise capacity. PDE5 inhibitors also are being studied in patients with congestive heart failure, but a recent trial in patients with preserved ejection fraction failed (Redfield et al., 2013; Chapter 28). Tadalafil and vardenafil share similar therapeutic efficacy and side-effect profiles with sildenafil; tadalafil has a longer time to onset of action and a longer therapeutic $t_{1/2}$ than the other PDE5 inhibitors (Table 45–1). Sildenafil has been the most thoroughly characterized of these compounds, but all three PDE5 inhibitors are contraindicated for patients taking organic nitrate vasodilators, and the PDE5 inhibitors should be used with caution in patients taking α - or β blockers (see Chapter 12).

The side effects of sildenafil and other PDE5 inhibitors are largely predictable on the basis of their effects on PDE5. Headache, flushing, and rhinitis may be observed, as well as dyspepsia owing to relaxation of the lower esophageal sphincter. Sildenafil and vardenafil also weakly inhibit PDE6, the enzyme involved in photoreceptor signal

transduction (Figure 69–9), and can produce visual disturbances, most notably changes in the perception of color hue or brightness. In addition to visual disturbances, sudden one-sided hearing loss has also been reported. Tadalafil inhibits PDE11, a widely distributed PDE isoform, but the clinical importance of this effect is not clear. The most important toxicity of all these PDE5 inhibitors is hemodynamic. When given alone to men with severe CAD, these drugs induce only a modest (<10%) decrease of blood pressure (Herrmann et al., 2000). However, PDE5 inhibitors and nitrates act synergistically to cause profound increases in cGMP and dramatic reductions in blood pressure (>25 mm Hg). *PDE5 inhibitors should therefore not be prescribed to patients receiving any form of nitrate* (Cheitlin et al., 1999); in prescribing nitrates, the physician should warn the patient that PDE5 inhibitors and nitrates must not be used concurrently, and that no PDE5 inhibitor should be used in the 24 h prior to initiating nitrate therapy. A period of longer than 24 h may be needed following administration of a PDE5 inhibitor for safe use of nitrates, especially with tadalafil, due to its prolonged $t_{1/2}$. In the event that patients develop significant hypotension following combined administration of sildenafil and a nitrate, fluids and a adrenergic receptor agonists, if needed, may be used for support.

Sildenafil, tadalafil, and vardenafil are metabolized via CYP3A4, and their toxicity may be enhanced in patients who receive inhibitors of this enzyme, including macrolide and imidazole antibiotics, and antiretroviral agents (see individual chapters and Chapter 6). PDE5 inhibitors also may prolong cardiac repolarization by blocking the I_{Kr} . Although these interactions and effects are important clinically, the overall incidence and profile of adverse events observed with PDE5 inhibitors, when used without nitrates, are consistent with the expected background frequency of the same events in the treated population. In patients with CAD whose exercise capacity indicates that sexual activity is unlikely to precipitate angina and who are not currently taking nitrates, the use of PDE5 inhibitors can be considered.

Therapeutic Uses

Stable Angina Pectoris. Diseases that predispose to CAD and angina should be treated as part of a comprehensive therapeutic program with the primary goal being to prolong life. Conditions such as hypertension, anemia, thyrotoxicosis, obesity, heart failure, cardiac arrhythmias, and acute emotional stress can precipitate anginal symptoms in many patients. Patients should be counseled to stop smoking, lose weight, and maintain a low-fat, high-fiber diet; hypertension and hyperlipidemia should be corrected; and daily aspirin (or clopidogrel if aspirin is not tolerated) and statins (see Chapter 33) should be prescribed. Exposure to sympathomimetic agents (e.g., those in nasal decongestants and other sources) and serotonin receptor agonists used in the treatment of migraine (sumatriptan and similar) should be avoided. The use of drugs that modify the perception of pain is a poor approach to the treatment of angina because the underlying myocardial ischemia is not relieved.

Table 27–1 lists the preparations and dosages of the nitrites and organic nitrates. The rapidity of onset, the duration of action, and the likelihood of developing tolerance are related to the method of administration.

Short-Acting Nitrates for Standby Therapy. GTN is the most commonly used drug for the rapid release of angina and can be applied as tablets, capsules, sublingual powder, spray, and aerosol. The onset of action is within 1–2 min (fastest with the spray), and the effects are undetectable by 1 h after administration. An initial dose of 0.3 mg GTN often relieves pain within 3 min. ISDN, but not ISMN, is an alternative to GTN. It has a slower onset of action (3–4 min), but a longer duration (>1 h). Anginal pain may be prevented when the drugs are used prophylactically immediately prior to exercise or stress. The smallest effective dose should be prescribed. Patients should be instructed to seek medical attention immediately if three tablets of GTN taken over a 15-min period do not relieve a sustained attack because this situation may be indicative of MI, unstable angina, or another cause of the pain.

Longer-Acting Nitrates for the Prophylaxis of Angina. Nitrates can also be used to provide prophylaxis against anginal episodes in patients who have more than occasional angina. However, such patients should

be offered revascularizing therapy. Moreover, chronic treatment with nitrates is not associated with a prognostic benefit and may induce tolerance and endothelial dysfunction as discussed previously. Nitrates must therefore be considered a second choice compared to β blockers. Sustained-release oral preparations of ISDN, ISMN, and GTN are available. Sustained-release ISDN and ISMN are typically given in two doses administered 6–7 h apart, followed by a nitrate-free interval of at least 8 h.

Variant (Prinzmetal) Angina. The large coronary arteries normally contribute little to coronary resistance. However, in variant angina, coronary constriction results in reduced blood flow and ischemic pain. Multiple mechanisms have been proposed to initiate vasospasm, including endothelial cell injury. Whereas long-acting nitrates alone are occasionally efficacious in abolishing episodes of variant angina, additional therapy with Ca^{2+} channel blockers usually is required. Ca^{2+} channel blockers, but not nitrates, have been shown to influence mortality and the incidence of MI favorably in variant angina; they should generally be included in therapy.

Congestive Heart Failure. The utility of nitrovasodilators to relieve pulmonary congestion and to increase cardiac output in congestive heart failure is addressed in Chapter 28.

Unstable Angina Pectoris (Acute Coronary Syndromes, see discussion that follows). Resistance to nitrates classifies angina symptoms as “unstable” and is a characteristic feature of ACSs, typically caused by transient or permanent thrombotic occlusion of coronary vessels. Nitrates do not modify this process specifically and are second-line drugs.

Ca^{2+} Channel Blockers

Voltage-gated Ca^{2+} channels (L-type or slow channels) mediate the entry of extracellular Ca^{2+} into smooth muscle and cardiac myocytes and SA and AV nodal cells in response to electrical depolarization. In both smooth muscle and cardiac myocytes, Ca^{2+} is a trigger for contraction, albeit by different mechanisms. Ca^{2+} channel antagonists, also called Ca^{2+} entry blockers or Ca^{2+} channel blockers, inhibit Ca^{2+} influx. In vascular smooth muscle, this leads to relaxation, especially in arterial beds, in cardiac myocytes to negative inotropic effects. All Ca^{2+} channel blockers exert these two principal actions, but the ratio differs according to the class as does the presence of chronotropic and dromotropic effects.

HISTORICAL PERSPECTIVE

The work in the 1960s of Fleckenstein and colleagues led to the concept that drugs can alter cardiac and smooth muscle contraction by blocking the entry of Ca^{2+} into myocytes (Fleckenstein et al., 1969). Godfraind and associates showed that the effect of the diphenylpiperazine analogues in preventing agonist-induced vascular smooth muscle contraction could be overcome by raising the concentration of Ca^{2+} in the extracellular medium (Godfraind et al., 1986). Hass and Hartfelder reported in 1962 that verapamil, a coronary vasodilator, possessed negative inotropic and chronotropic effects that were not seen with other vasodilatory agents, such as GTN. In 1967, Fleckenstein suggested that the negative inotropic effect resulted from inhibition of excitation-contraction coupling and that the mechanism involved reduced movement of Ca^{2+} into cardiac myocytes. Verapamil was the first clinically available Ca^{2+} channel blocker; it is a congener of papaverine. Many other Ca^{2+} entry blockers with a wide range of structures are now available.

Chemistry

The multiple Ca^{2+} channel blockers that are approved for clinical use in the U.S. have diverse chemical structures. Clinically used Ca^{2+} channel blockers include the phenylalkylamine verapamil, the benzothiazepine diltiazem, and numerous dihydropyridines, including amlodipine, clevidipine, felodipine, isradipine, lercanidipine, nicardipine, nifedipine, nimodipine, and nisoldipine. The structures and relative specificities of representative drugs are shown in Table 27–2. Although these drugs are commonly grouped together as “calcium channel blockers,” there are fundamental differences among verapamil, diltiazem, and the dihydropyridines with respect to pharmacodynamics, drug interactions, and toxicities.

Mechanisms of Action

An increased concentration of cytosolic Ca^{2+} causes increased contraction in both cardiac and vascular smooth muscle cells. In cardiac myocytes, the entry of extracellular Ca^{2+} causes a larger Ca^{2+} release from intracellular stores (Ca^{2+} -induced Ca^{2+} release) and thereby initiates the contraction twitch. In smooth muscle cells, entry of Ca^{2+} plays a dominant role, but the release of Ca^{2+} from intracellular storage sites also contributes

TABLE 27–2 ■ COMPARATIVE CV EFFECTS OF Ca^{2+} CHANNEL BLOCKERS^a

DRUG CLASS: EXAMPLE	VASODILATION	↓ CARDIAC CONTRACTILITY	↓ AUTOMATICITY (SA NODE)	↓ CONDUCTION (AV NODE)

to contraction of vascular smooth muscle, particularly in some vascular beds. In contrast to cardiac muscle, smooth muscles typically contract tonically. Cytosolic Ca^{2+} concentrations can be increased by diverse contractile stimuli in vascular smooth muscle cells. Many hormones and autoids increase Ca^{2+} influx through so-called receptor-operated channels, whereas increases in external concentrations of K^+ and depolarizing electrical stimuli increase Ca^{2+} influx through voltage-gated, or “potential operated,” channels. The Ca^{2+} channel blockers produce their effects by binding to the α_1 subunit of the L-type voltage-gated Ca^{2+} channels and reducing Ca^{2+} flux through the channel. The vascular and cardiac effects of some of the Ca^{2+} channel blockers are summarized in the next section and in Table 27–2.

Voltage-gated channels contain domains of homologous sequence that are arranged in tandem within a single large subunit. In addition to the major channel-forming subunit (termed α_1), Ca^{2+} channels contain several other associated subunits (termed α_2 , β , γ , and δ) (Schwartz, 1992). Voltage-gated Ca^{2+} channels have been divided into at least three subtypes based on their conductances and sensitivities to voltage (Schwartz, 1992; Tsien et al., 1988). The channels best characterized to date are the L, N, and T subtypes. Only the L-type channel is sensitive to the dihydropyridine Ca^{2+} channel blockers. All approved Ca^{2+} channel blockers bind to the α_1 subunit of the L-type Ca^{2+} channel, which is the main pore-forming unit of the channel. This approximately 250,000-Da subunit is associated with a disulfide-linked $\alpha_2\delta$ subunit of about 140,000 Da and a smaller intracellular β subunit. The α_1 subunits share a common topology of four homologous domains, each of which is composed of six putative transmembrane segments (S1–S6). The α_2 , δ , and β subunits modulate the α_1 subunit (see Figure 14–2). The phenylalkylamine Ca^{2+} channel blocker verapamil binds to transmembrane segment 6 of domain IV (IVS6), the benzothiazepine Ca^{2+} channel blocker diltiazem binds to the cytoplasmic bridge between domain III (IIIS) and domain IV (IVS), and the dihydropyridine Ca^{2+} channel blockers (nifedipine and several others) bind to transmembrane segments of both domains III and IV. These three separate receptor sites are linked allosterically.

Pharmacological Actions

Vascular Tissue. Depolarization of vascular smooth muscle cells depends primarily on the influx of Ca^{2+} . At least three distinct mechanisms may be responsible for contraction of vascular smooth muscle cells. First, voltage-gated Ca^{2+} channels open in response to depolarization of the membrane, and extracellular Ca^{2+} moves down its electrochemical gradient into the cell. After closure of Ca^{2+} channels, a finite period of time is required before the channels can open again in response to a stimulus. Second, agonist-induced contractions that occur without depolarization of the membrane result from stimulation of the G_q -PLC- IP_3 pathway, resulting in the release of intracellular Ca^{2+} from the sarcoplasmic reticulum (Chapter 3). Emptying of intracellular Ca^{2+} stores may trigger further influx of extracellular Ca^{2+} (store-operated Ca^{2+} entry), but its relevance in smooth muscle is unresolved. Third, receptor-operated Ca^{2+} channels allow the entry of extracellular Ca^{2+} in response to receptor occupancy. An increase in cytosolic Ca^{2+} results in enhanced binding of Ca^{2+} to calmodulin. The Ca^{2+} -calmodulin complex in turn activates myosin light-chain kinase, with resulting phosphorylation of the myosin light chain. Such phosphorylation promotes interaction between actin and myosin and leads to sustained contraction of smooth muscle. Ca^{2+} channel blockers inhibit the voltage-dependent Ca^{2+} channels in vascular smooth muscle and decrease Ca^{2+} entry. All Ca^{2+} channel antagonists relax arterial smooth muscle and thereby decrease arterial resistance, blood pressure, and cardiac afterload. Although experimentally large conductance veins of pig appear similarly or even more sensitive to Ca^{2+} channel blockers than arteries (Magnon et al., 1995), Ca^{2+} channel blockers do not affect cardiac preload significantly when given at normal doses in patients. This suggests that capacitance veins that determine venous return to the heart are resistant to the relaxing effect of Ca^{2+} channel antagonists.

Cardiac Cells. The mechanisms of excitation-contraction coupling in cardiac myocytes of the working myocardium differ from those in

vascular smooth muscle in that increases in intracellular Ca^{2+} are fast and transient (Chapter 28). They are initiated by a fast and short (<5 ms) Na^+ influx through voltage-gated Na^+ channels that causes depolarization of the membrane and opening of L-type Ca^{2+} channels. Repolarizing K^+ currents terminate the cardiac action potential and Ca^{2+} influx. Within the cardiac myocyte, Ca^{2+} binds to troponin C, relieving the inhibitory effect of the troponin complex on the contractile apparatus and permitting productive interaction of actin and myosin, leading to contraction. By inhibiting Ca^{2+} influx, Ca^{2+} channel blockers reduce the peak size of the systolic Ca^{2+} transient and thereby produce a negative inotropic effect. Although this is true of all classes of Ca^{2+} channel blockers, the greater degree of peripheral vasodilation seen with the dihydropyridines is accompanied by a baroreceptor reflex-mediated increase in sympathetic tone sufficient to overcome the negative inotropic effect.

In the SA and AV nodes, depolarization largely depends on the movement of Ca^{2+} through the slow channel. The effect of a Ca^{2+} channel blocker on AV conduction and on the rate of the sinus node pacemaker depends on whether the agent delays the recovery of the slow channel (Schwartz, 1992). Although nifedipine reduces the slow inward current in a dose-dependent manner, it does not affect the rate of recovery of the slow Ca^{2+} channel. Although nifedipine has clear negative chronotropic effects in isolated preparations (at ~5-fold higher concentrations than needed for negative inotropy), at doses used clinically, nifedipine does not directly affect pacemaking or conduction through the AV node. Rather, it stimulates the heart indirectly by eliciting reflex sympathetic activation in response to a lowering of blood pressure (Figure 27–2).

In contrast, verapamil not only reduces the magnitude of the Ca^{2+} current through the slow channel, but also decreases the rate of recovery of the channel. In addition, channel blockade caused by verapamil (and to a lesser extent by diltiazem) is enhanced as the frequency of stimulation increases, a phenomenon known as *frequency dependence* or *use dependence*. Verapamil and diltiazem depress the rate of the sinus node pacemaker and slow AV conduction at clinically used doses; the latter effect is the basis for their use in the treatment of supraventricular tachyarrhythmias (see Chapter 30). Verapamil also inhibits fast Na^+ and repolarizing K^+ currents (I_{Kr}). The contribution of these actions to the clinical profile is unclear, but note that verapamil, despite the effect on I_{Kr} , has not been associated with torsades des pointes arrhythmias as have other I_{Kr} blockers.

Integrated Cardiovascular Effects of Different Ca^{2+} Channel Antagonists. The hemodynamic profiles of the Ca^{2+} channel blockers approved for clinical use differ and depend mainly on the ratio of vasodilating and negative inotropic and chronotropic effects on the heart (Figure 27–2). The dihydropyridines dilate blood vessels at several-fold lower concentrations than those required for decreasing myocardial force; the ratio is close to one for diltiazem and verapamil. The published selectivity values differ widely, depending on the type of blood vessel and the mode of precontraction used for the comparison (Table 27–2 and Figure 27–3). The differences between the relatively vasoselective dihydropyridines and the much less-selective diltiazem and verapamil have important consequences because the decrease in arterial blood pressure elicits reflex sympathetic activation, resulting in the stimulation of heart rate, AV conduction velocity, and myocardial force, just the opposite of the direct effect of Ca^{2+} channel blockers. While direct and indirect effects normally balance each other in case of verapamil and diltiazem, sympathetic stimulation often prevails in dihydropyridines, causing an increase in heart rate and contractility. Cardiac depressant effects of dihydropyridines may be unmasked, though, in the presence of β blockers and in patients with heart failure.

The dihydropyridines in clinical use—amlodipine, clevidipine, felodipine, isradipine, lercanidipine, nicardipine, nifedipine, nimodipine, and nisoldipine—share most pharmacodynamic properties. Differences with regard to vascular selectivity or subvascular selectivity have been intensely addressed in the past, but claims of large vasoselectivity factors were based on indirect comparisons (Godfraind et al., 1992). Overall, the clinical relevance of vasoselectivity ratios appears questionable; actual differences are probably not great (Figure 27–3). In any event, the drugs exert their

Figure 27-2 Comparison of the integrated actions of Ca^{2+} channel blockers. Due to different potencies and efficacies at various sites of action within the cardiovascular system, dihydropyridines produce integrated effects that are not identical to those of verapamil and diltiazem. Verapamil can have direct inhibitory effects on the SNS. The thickness of the arrow indicates the relative strength of the effect.

antianginal effect mainly by peripheral arterial vasodilation and afterload reduction and not by coronary artery dilation (exception in variant angina).

Verapamil, like the dihydropyridines, causes little effect on venous return and preload, but has more direct negative inotropic and chronotropic effects than the dihydropyridines at doses that produce arteriolar dilation and afterload reduction (Figure 27-2). Thus, the consequences of a reflex increase in adrenergic tone are generally offset by the direct cardiodepressant effects of the drug. In patients without heart failure, oral administration of verapamil reduces peripheral vascular resistance and blood pressure with minimal changes in heart rate. Ventricular performance is not impaired and actually may improve, especially if ischemia limits performance. In contrast, in patients with heart failure, intravenous verapamil can cause a marked decrease in contractility and left ventricular function. The antianginal effect of verapamil, like that of all Ca^{2+} channel blockers, is due primarily to a reduction in myocardial O_2 demand. The negative dromotropic effect has no relevance for the improvement of

exercise but can cause second-degree AV block, particularly when given in combination with β blockers (contraindicated). Diltiazem's effects lie in between those of dihydropyridines and verapamil.

The effects of Ca^{2+} channel blockers on diastolic ventricular relaxation (the lusitropic state of the ventricle) are complex. Nifedipine, diltiazem, and verapamil impaired parameters of ventricular relaxation in dogs, especially when given into the coronary arteries (Walsh and O'Rourke, 1985). However, reflex stimulation of sympathetic tone accelerates relaxation, which may outweigh a direct negative lusitropic effect. Likewise, a reduction in afterload will improve the lusitropic state. In addition, if ischemia is improved, the negative lusitropic effect will be reduced. The sum total of these effects in any given patient cannot be determined a priori.

ADME and Drug Interactions. Ca^{2+} channel blockers exhibit clinically relevant differences in pharmacokinetics (Figure 27-4). Immediate-release nifedipine is quickly absorbed after oral intake and produces only a briefly elevated blood level of the drug ($t_{1/2} \sim 1.8$ h) that is associated with an

Figure 27-3 Potency of Ca^{2+} channel blockers at different sites. Effects were assessed on the contractile force of human right atrial appendages (A) and human arteries from aortic vasa vasorum precontracted with high- K^+ concentrations (B). Felodipine (black), nifedipine (blue), amlodipine (green) are more potent on vascular muscle, inhibiting contraction of atrial muscle at concentrations about 10 times higher than those needed to reduce contraction in vascular tissue. Verapamil (red) inhibits atrial muscle force development at 20% of the concentration required to reduce contraction in vascular tissue. The vascular selectivities of the various Ca^{2+} channel blockers (EC_{50} on atrial appendage/ EC_{50} on vasa vasorum) are as follows: felodipine, 12; nifedipine, 7; amlodipine, 5; verapamil, 0.2. (Figure is based on data of Angus et al., 2000.)

Figure 27-4 Minimizing daily fluctuations in C_p values of Ca^{2+} channel blockers. Graphs show plasma levels (C_p values) of amlodipine (left) and of nifedipine (right) in immediate-release (red) and slow-release (black) preparations; doses were administered at zero time. Plasma levels of amlodipine and nifedipine slow-release formulations were assessed after repeated application; thus, C_p values do not start at zero. Note the much smaller differences between trough and peak plasma concentrations in case of amlodipine compared to the rapid and brief pulse in plasma concentration of immediate-release nifedipine and the relatively large fluctuations even with the slow-release form of nifedipine. The plasma $t_{1/2}$ of amlodipine is about 39 h; that of nifedipine is about 1.8 h. A large fluctuation in C_p may result in adverse effects at the maximum and lack of efficacy at the minimum (see Figure 2-9A). (For original data, see Bainbridge et al., 1993; Debbas et al., 1986; and van Harten et al., 1987.)

abrupt decrease in blood pressure, reflex activation of the sympathetic nervous system, and tachycardia. This can cause a typical flush and can increase the risk of angina pectoris by abruptly decreasing coronary perfusion pressure concomitantly with tachycardia. Sustained-release preparations of nifedipine somewhat reduce fluctuations of plasma concentration. By contrast, amlodipine has slow absorption and a prolonged effect. With a plasma $t_{1/2}$ of 35–50 h, plasma levels and effect increase over 7–10 days of daily administration of a constant dose, resulting in a C_p with modest peaks and troughs. Such a profile allows the body to adapt and is associated with less reflex tachycardia. Felodipine, nitrendipine, lercanidipine, and isradipine have similar profiles for chronic treatment (Table 27-2). Clevidipine is available for intravenous administration and has a very rapid ($t_{1/2} \sim 2$ min) onset and offset of action. It is metabolized by esterases in blood. It may be useful in controlling blood pressure in severe or perioperative hypertension as an alternative to GTN, sodium nitroprusside, or nicardipine.

The bioavailability of all Ca^{2+} channel blockers is reduced, in some cases markedly, by first-pass metabolism by CYP3A4 enzymes in the intestinal epithelium and the liver. This has two consequences:

- The bioavailability of these drugs may be increased by strong inhibitors of CYP3A4, such as macrolide and imidazole antibiotics, antiretroviral agents, and grapefruit juice (see Chapter 6). Bioavailability is reduced by inducers of CYP3A4, such as rifampin, carbamazepine, and hypericum (St. John's wort).
- Some Ca^{2+} channel blockers (particularly verapamil) are strong CYP3A4 inhibitors and cause clinically relevant drug interactions with other CYP3A4 substrates, such as simvastatin and atorvastatin.

Moreover, verapamil is a relatively efficient inhibitor of the intestinal and renal ABC transport protein Pgp (also called MDR1 and ABCB1; see Chapter 5) and can thereby increase plasma levels of digoxin, cyclosporine, and loperamide and other agents that are exported by Pgp. This high potential of verapamil for drug-drug interactions is a clear disadvantage and one of the reasons for its declining use. In patients with hepatic cirrhosis, the bioavailabilities and half-lives of the Ca^{2+} channel blockers may be increased, and dosage should be decreased accordingly. The half-lives of these agents also may be longer in older patients.

Toxicity and Untoward Responses. The profile of adverse reactions to the Ca^{2+} channel blockers varies among the drugs in this class. Immediate-release capsules of nifedipine often cause headache, flushing, and dizziness and can actually worsen myocardial ischemia. Dizziness and flushing

are much less of a problem with the sustained-release formulations and with the dihydropyridines having a long $t_{1/2}$ and providing more constant plasma drug concentrations. Peripheral edema may occur in some patients with Ca^{2+} channel blockers but is not the result of generalized fluid retention; rather, it most likely results from increased hydrostatic pressure in the lower extremities owing to precapillary dilation and reflex postcapillary constriction (Epstein and Roberts, 2009). Other adverse effects of these drugs are due to actions in nonvascular smooth muscle. For example, Ca^{2+} channel blockers can cause or aggravate gastroesophageal reflux. Constipation is a common side effect of verapamil but occurs less frequently with other Ca^{2+} channel blockers. Urinary retention is a rare adverse effect. Uncommon adverse effects include rash and elevations of liver enzymes.

Although bradycardia, transient asystole, and exacerbation of heart failure have been reported with verapamil, these responses usually have occurred after intravenous administration of verapamil in patients with disease of the SA node, AV nodal conduction disturbances, or in the presence of β -blockade. The use of intravenous verapamil with an intravenous β blocker is contraindicated because of the increased propensity for AV block or severe depression of ventricular function. Patients with ventricular dysfunction, SA or AV nodal conduction disturbances, and systolic blood pressures below 90 mmHg should not be treated with verapamil or diltiazem, particularly intravenously. Verapamil may also exacerbate AV nodal conduction disturbances observed with digoxin, both for pharmacodynamic and pharmacokinetic reasons (Pgp inhibition; see previous discussion). When used with quinidine, verapamil may cause excessive hypotension, again due to pharmacodynamic and pharmacokinetic reasons (quinidine is CYP3A4 substrate and Pgp inhibitor).

Therapeutic Uses

Variant Angina. Variant angina results from reduced blood flow (a consequence of transient localized vasoconstriction) rather than increased O_2 demand. Drug-induced causes (e.g., cocaine, amphetamines, sumatriptan, and related antimigraine drugs) should be excluded. Ca^{2+} channel blockers are effective in about 90% of patients (Montalescot et al., 2013). These agents are considered first-line treatment and may be combined with nitrovasodilators (Amsterdam et al., 2014).

Exertional Angina. Ca^{2+} channel blockers also are effective in the treatment of exertional, or exercise-induced, angina. Numerous double-blind, placebo-controlled studies have shown that these drugs decrease the number of anginal attacks and attenuate exercise-induced ST-segment depression, but evidence for life-prolonging efficacy is lacking. They are therefore considered the drugs of choice if β blockers do not achieve sufficient symptomatic benefit or are not tolerated (Montalescot et al., 2013).

The Ca^{2+} channel blockers reduce the *double product*, Heart rate \times Systolic blood pressure, an approximate index of myocardial O_2 demand. Because these agents reduce the level of the double product at a given external workload, and because the value of the double product at peak exercise is not altered, the beneficial effect of Ca^{2+} channel blockers likely derives from a decrease in O_2 demand rather than an increase in coronary flow.

Concurrent therapy of a dihydropyridine with a β blocker has proven more effective than either agent given alone in exertional angina, presumably because the β blocker suppresses reflex tachycardia. This concurrent drug therapy is particularly attractive because the dihydropyridines do not delay AV conduction and will not enhance the negative dromotropic effects associated with β receptor blockade. In contrast, the concurrent administration of verapamil or diltiazem with a β blocker is contraindicated for the potential for AV block, severe bradycardia, and decreased left ventricular function.

Unstable Angina (Acute Coronary Syndrome). In the past, Ca^{2+} channel blockers were routinely administered in patients presenting with unstable angina and ACS without persistent ST elevation. Reports about trends for harm with immediate-release nifedipine or nifedipine infusion in the absence of β blockers have led to the recommendation not to use dihydropyridines without concurrent therapy with β blockers.

Verapamil and diltiazem are recommended only for patients who continue to show signs of ischemia, do not tolerate β blockers, have no clinically significant left ventricular dysfunction, and show no signs of disturbed AV conduction (Amsterdam et al., 2014).

Other Uses. The use of verapamil and diltiazem (but not dihydropyridines) as antiarrhythmic agents in supraventricular tachyarrhythmias is discussed in Chapter 30; their use for the treatment of hypertension is discussed in Chapter 28. Ca^{2+} channel blockers are contraindicated in patients with heart failure with reduced ejection fraction, but amlodipine and felodipine did not worsen the prognosis and can therefore be administered if indicated for other reasons (Chapter 29). Verapamil improves left ventricular outflow obstruction and symptoms in patients with HCM. Diltiazem has shown early promising results in a clinical study in asymptomatic HCM mutation carriers (Ho et al., 2015). Verapamil also has been used in the prophylaxis of migraine headaches but is considered a second-choice drug. Nimodipine has been approved for use in patients with neurological deficits secondary to cerebral vasospasm after the rupture of a congenital intracranial aneurysm, but clinical evidence for greater effectiveness than verapamil or magnesium is sparse. Nifedipine, diltiazem, amlodipine, and felodipine appear to provide symptomatic relief in Raynaud disease. The Ca^{2+} channel blockers cause relaxation of the myometrium in vitro and may be effective in reducing preterm uterine contractions in preterm labor (see Chapter 44).

β Blockers

β blockers are the only drug class that is effective in reducing the severity and frequency of attacks of exertional angina and in improving survival in patients who have had an MI. They are therefore recommended as first-line treatment of patients with stable CAD (Montalescot et al., 2013) and unstable angina/ACS (Hamm et al., 2011). Recent meta-analyses raised doubts about the mortality-reducing effects of β blockers in the MI reperfusion era (Bangalore et al., 2014); however, some of the results, such as the slightly increased heart failure frequency in patients receiving β blockers, contradicted numerous well-controlled prospective trials (see Chapter 29) and raised doubts about the validity of the analysis. Thus, the issue has not been definitively resolved. β Blockers are not useful for vasospastic angina and, if used in isolation, may worsen that condition. β Blockers appear equally effective in the treatment of exertional angina (Fihn et al., 2012; Montalescot et al., 2013), but very short-acting agents or drug formulations giving rise to large fluctuations of plasma concentrations (e.g., unformulated metoprolol) should be avoided for treatment of chronic CAD.

The effectiveness of β blockers in the treatment of exertional angina is attributable primarily to a fall in myocardial O_2 consumption at rest and during exertion. The decrease in myocardial O_2 consumption is due to a negative chronotropic effect (particularly during exercise), a negative inotropic effect, and a reduction in arterial blood pressure (particularly systolic pressure) during exercise. A decrease in heart rate prolongs the time of myocardial perfusion during diastole. Moreover, there is evidence that β blockers can increase blood flow toward ischemic regions by increasing coronary collateral resistance and preventing blood from being shunted away from the ischemic myocardium during maximal coronary vasodilation (Billinger et al., 2001), a “reverse steal or Robin Hood phenomenon” (see previous discussion).

Not all actions of β blockers are beneficial in all patients. The decreases in heart rate and contractility cause increases in the systolic ejection period and left ventricular end-diastolic volume; these alterations tend to increase O_2 consumption. However, the net effect of β blockade usually is to decrease myocardial O_2 consumption, particularly during exercise. Nevertheless, in patients with limited cardiac reserve who are critically dependent on adrenergic stimulation, β blockade can result in profound decreases in left ventricular function. Despite this, several β blockers demonstrably reduce mortality in patients with congestive heart failure, and β blockers have become standard therapy for many such patients (see Chapters 12 and 29).

Numerous β blockers are approved for clinical use. Standard compounds for the treatment of angina are β_1 -selective and without intrinsic

sympathomimetic activity (e.g., atenolol, bisoprolol, or metoprolol). Chapter 12 presents their pharmacology in detail.

Antiplatelet, Anti-integrin, and Antithrombotic Agents

Antiplatelet agents represent the cornerstone of therapy for ACS (Amsterdam et al., 2014; Roffi et al., 2015) and are systematically discussed in Chapter 32. They interfere either with two signaling pathways (TxA_2 and ADP) that cooperatively promote platelet aggregation in an auto- and paracrine manner or with a major common pathway of platelet aggregation, the GpIIb/IIIa fibrinogen receptor. Aspirin inhibits platelet aggregation by irreversibly inactivating the thromboxane-synthesizing COX-1 in platelets, thereby reducing production of TxA_2 . Aspirin, given at doses of 160–325 mg at the onset of treatment of ACS, improves survival (Yeghiazarians et al., 2000). The thienopyridines are ADP receptor (P2Y_{12} receptor) antagonists that block the proaggregatory effect of ADP, which is stored in vesicles within platelets and released when platelets adhere to prothrombotic structures. The proaggregatory synergism of TxA_2 and ADP on platelet aggregation and thrombus formation accounts for the potentiating effect of adding a thienopyridine to aspirin.

The addition of the thienopyridine clopidogrel to aspirin therapy reduces mortality in patients with ACS. Newer thienopyridines (prasugrel, ticagrelor, cangrelor) with favorable pharmacokinetic properties have been approved for the treatment of ACS. All three appear superior to clopidogrel in treating patients with ACS; contributing factors likely include faster onset of action and less-variable pharmacokinetics. Ticagrelor is a direct, reversible P2Y_{12} receptor antagonist, while clopidogrel and prasugrel are both prodrugs. The hepatic activation of prasugrel is more stable and faster than that of clopidogrel. Cangrelor is the first P2Y_{12} receptor antagonist for intravenous application, producing very rapid inhibition of platelet aggregation. Recent guidelines recommend ticagrelor and prasugrel as the primary choice in patients with ACS and clopidogrel as an alternative in patients who cannot receive the former or are on oral anticoagulation therapy (e.g., for stroke prevention in atrial fibrillation). The place of cangrelor is not yet fully defined (Roffi et al., 2015).

The optimal timing of the initiation of dual platelet treatment is controversial and depends on the likely clinical course. If conservative treatment is likely and the patient is not at an increased risk of bleeding, aspirin and a parenteral anticoagulant (see discussion that follows) should be given as soon as possible, with the addition of a P2Y_{12} receptor antagonist as soon as the diagnosis of NSTEMI has been made. Dual platelet inhibition for 1 year is currently recommended for all patients after NSTEMI or STEMI and revascularization, independently of the type of revascularization and type of stent used (Roffi et al., 2015). Due to the irreversible (aspirin, clopidogrel, and prasugrel) or prolonged (ticagrelor) modes of action, the risk of bleeding remains increased for extended periods after withdrawal of these drugs. Nonemergency major noncardiac surgeries should therefore be postponed for 5 (ticagrelor, clopidogrel) or 7 days (prasugrel, aspirin) after intake of the last dose.

Anti-integrin agents directed against the platelet integrin GpIIb/IIIa (including abciximab, tirofiban, and eptifibatide) are highly effective by blocking the final effector pathway of platelet aggregation; however, these agents have a small therapeutic index and must be administered parenterally. Meta-analyses of studies in patients with ACS showed that the use of GpIIb/IIIa inhibitors in addition to heparin was associated with about a 10% reduction in mortality, but with an increase in bleeding. Because most of these trials were conducted before the widespread use of the newer and more effective thienopyridines prasugrel and ticagrelor, the current value of the GpIIb/IIIa antagonists is not clear. Guidelines recommend them in patients on prasugrel or ticagrelor only in bailout situations (Roffi et al., 2015).

Heparin, in its unfractionated form and as low-molecular-weight heparin (e.g., enoxaparin), also reduces symptoms and prevents infarction in unstable angina (Yeghiazarians et al., 2000). Fondaparinux, a heparinoid pentasaccharide, antithrombin III-dependent Factor Xa inhibitor has the best efficacy-safety profile of all anticoagulants and is therefore currently

first choice. Thrombin inhibitors, such as hirudin or bivalirudin, directly inhibit even clot-bound thrombin, are not affected by circulating inhibitors, and function independently of antithrombin III. Bivalirudin provides no benefit over heparin in ACS (Valgimigli et al., 2015). Thrombolytic agents such as rTPA are of no benefit in unstable angina. The new oral anticoagulants (factor IIa inhibitor dabigatran and factor Xa inhibitors rivaroxaban, apixaban, and edoxaban) have no established place in the treatment of CAD.

Other Antianginal Agents

Ranolazine

Ranolazine is FDA and EMA approved as a second-line agent for the treatment of chronic angina. The drug may be used with a variety of other agents, including β blockers, Ca^{2+} channel blockers, ACEIs, ARBs, and therapeutic agents for lowering lipids and reducing platelet aggregation.

Mechanism of Action. The mechanism of ranolazine's therapeutic efficacy in angina is uncertain. Its anti-ischemic and antianginal effects occur independently of reductions in heart rate and arterial blood pressure or changes in coronary blood flow. Ranolazine inhibits several cardiac ion fluxes, including I_{Kr} and I_{Na} . Preferential inhibition of late I_{Na} may explain its cardiac effects (Hasenfuss and Maier, 2008). The late I_{Na} contributes to arrhythmias in patients with the rare long QT 3 syndrome (Chapter 30), and is increased in heart failure and ischemia. Reduction of the late I_{Na} could explain in part the elevated cytosolic Na^+ concentrations in cardiac myocytes in these conditions, leading to higher diastolic Ca^{2+} concentrations, Ca^{2+} overload, arrhythmias, and problems with diastolic relaxation. Inhibition of late I_{Na} by ranolazine could reduce $[\text{Na}^+]_i$ -dependent Ca^{2+} overload and its detrimental effects on myocardial ATP hydrolysis and cardiac function.

Other mechanisms of action have been proposed. Ranolazine reduces cardiac fatty acid oxidation and stimulates glucose metabolism without inhibiting carnitine palmitoyl transferase 1, and on this basis ranolazine was initially categorized as a metabolic modulator (McCormack et al., 1998). However, the effect is small, occurs at ranolazine concentrations more than 5-fold higher than do therapeutic effects, and can be assessed in the absence of fatty acid oxidation (Belardinelli et al., 2006). Ranolazine has weak β receptor blocking activity (Letienne et al., 2001) that may contribute to its anti-anginal activity.

In a large prospective trial of patients with incomplete revascularization after percutaneous coronary intervention, anti-ischemic therapy with ranolazine did not improve the prognosis of these high-risk patients (Weisz et al., 2016). Clinical trials are currently testing ranolazine in HCM and heart failure with preserved ejection fraction.

ADME and Adverse Effects. Ranolazine, supplied as extended-release tablets, is administered without regard to meals at 500 to 1000 mg twice daily; higher doses are poorly tolerated. The drug's oral bioavailability is about 75%; inhibitors of Pgp (e.g., digoxin, cyclosporine; see Chapter 5) can increase absorption of ranolazine and increase exposure to both ranolazine and the competing drug. Ranolazine's terminal $t_{1/2}$ is about 7 h; with repeated dosing, a steady-state C_p is reached in 3 days. Ranolazine is metabolized mainly by CYP3A4 and to a lesser extent by CYP2D6; unchanged drug (5%) and metabolites are excreted in the urine. Ranolazine should not be used together with strong CYP3A4 inhibitors (e.g., macrolide and imidazole antibiotics, HIV protease inhibitors), and doses need to be limited when moderate CYP3A4 inhibitors such as verapamil, diltiazem, and erythromycin are used in combination. Inducers of CYP3A4 (e.g., rifampin, carbamazepine, and hypericum) can decrease ranolazine plasma levels, requiring dose adjustment. Ranolazine can affect plasma levels of other CYP3A4 substrates, including doubling levels of simvastatin and its active metabolite and requiring dose adjustment; dose reduction may be needed for other CYP3A4 substrates (e.g., lovastatin), especially for those with a narrow therapeutic range (e.g., cyclosporine, tacrolimus, sirolimus). Coadministration of ranolazine may increase exposure to other substrates of CYP2D6, such as tricyclic antidepressants and antipsychotic agents.

The most frequent adverse effects are dizziness, headache, nausea, and constipation. Some CNS effects (e.g., dizziness, blurry vision, and confusional state) are reminiscent of class I antiarrhythmics. QT prolongations have to be considered, but no torsades des pointes arrhythmias or related events have been reported.

Ivabradine

Ivabradine is EMA approved for treating stable angina and heart failure in patients in whom β blockers are not tolerated or are insufficiently effective in reducing heart rate and FDA-approved only for the treatment of heart failure (Chapter 29). Ivabradine is a selective blocker of hyperpolarization-activated HCN ion channels involved in the generation of automaticity in the SA node. By reducing the pacemaker current I_f through HCN channels, the compound dose dependently reduces heart rate and, differently from β blockers, does not affect cardiac contractile force. The antianginal effect is explained solely by reduction of heart rate and thereby O_2 demand (Figure 27-1).

A typical, often transient, side effect are phosphenes, transient enhanced lightness in restricted areas of the visual field, that are explained by effects on retinal HCN channels (3%–5% of cases). In a recent study in patients with chronic angina and normal left ventricular function, the addition of ivabradine to β blockers did not confer benefit but was associated with a trend for more cardiovascular end points and an increase in symptomatic bradycardia, atrial fibrillation, and QT prolongation (Fox et al., 2014). The data raise doubts about the hypothesis that heart rate reduction per se is associated with better cardiovascular outcome and has led to restrictions on use of ivabradine (e.g., contraindication for concurrent therapy with verapamil or diltiazem).

Nicorandil

Nicorandil is a nitrate ester of nicotinamide developed as an antianginal agent and currently is approved in many Asian and European countries (but not in the U.S. and Germany) for the treatment of stable angina pectoris. Nicorandil is not available in the U.S.

Mechanism of Action and Pharmacological Effects. Nicorandil has nitrate-like (cGMP-dependent) properties and acts as an agonist at ATP-sensitive potassium (K_{ATP}) channels. Its vasodilating action is potentiated by PDE5 inhibitors and only partially blocked by inhibitors of K_{ATP} channels, such as glibenclamide, suggesting that both properties participate in nicorandil's effect. Nicorandil dilates both arterial and venous vascular beds, leading to decreases in afterload and preload of the heart. In the absence of direct effects on contractile force of the ventricles, the decrease in afterload causes cardiac output to increase. The last effect is stronger than that seen after administration of nitrovasodilators and partially explained by (reflex) tachycardia. Thus, the hemodynamic profile of nicorandil lies in between that of nitrovasodilators and dihydropyridine Ca^{2+} channel blockers. Its antianginal effect is described to be stable, but early studies reported a clear decrease or loss of antianginal effect after 2 weeks of oral treatment (Meany et al., 1989; Rajaratnam et al., 1999).

Experimental and clinical studies indicated that nicorandil has cardioprotective effects (Matsubara et al., 2000), mimicking that of ischemic preconditioning, a phenomenon that short periods of ischemia preceding prolonged stopping of perfusion (as in MI) reduce myocardial injury. While the exact mechanisms are not fully understood, a central role of mitochondrial K_{ATP} channels is assumed (Ardehali and O'Rourke, 2005; Sato et al., 2000). Retrospective studies indicated a survival-prolonging effect of chronic treatment with nicorandil in patients with stable CAD, but sufficiently powered prospective studies are lacking.

ADME and Adverse Effects. Nicorandil is rapidly absorbed after sublingual or oral administration and has a short $t_{1/2}$ (1 h), which does not provide relevant trough levels at the usual regimen of twice-daily dosing at 20 mg/dose. Besides nitrate-like headache and hypotension (note contraindication of concurrent PDE5 inhibitors), nicorandil has been associated with the appearance of ulcerations. They were first described in 1997 (Boulinguez et al., 1997) as large, painful buccal aphthosis and seem to extend to a 40%–60% increased risk of GI ulcerations and perforations (Lee et al., 2015).

Trimetazidine

Trimetazidine was developed as an antianginal agent. Its effect is thought to be due to inhibition of long-chain 3-ketoacyl coenzyme A thiolase, the final enzyme in the FFA β -oxidation pathway. This leads to a partial shift from FFA to glucose oxidation in the heart, which provides less ATP but requires less O_2 and may therefore be beneficial in ischemia (Ussher et al., 2014). Numerous small studies provided evidence for the efficacy of the compound to reduce angina and increase exercise tolerance, particularly in patients with diabetes and heart failure (e.g., Tuunanen et al., 2008); as with nicorandil, large randomized studies to define the true therapeutic value of this compound are lacking.

Trimetazidine can cause GI upset, nausea, and vomiting, and, rarely, it has been associated with thrombocytopenia, agranulocytosis, and liver dysfunction. More important, trimetazidine may increase the risk of movement disorders such as Parkinson disease, particularly in older patients with decreased kidney function. This serious effect has led to use restrictions by the EMA and the recommendation to use trimetazidine only as second-line treatment of stable angina in patients inadequately controlled by or intolerant to first-line antianginal therapies. Trimetazidine is not available in the U.S.

Therapeutic Strategies

Stable Coronary Artery Disease

Guidelines

Task forces from the American College of Cardiology and the American Heart Association (Fihn et al., 2012) and the European Society of Cardiology (Montalescot et al., 2013) have published guidelines that are useful in the selection of appropriate initial therapy for patients with chronic stable angina pectoris. All patients with CAD should receive at least one drug for angina relief in addition to fast- and short-acting nitrovasodilators (GTN, ISDN) and, for event prevention, aspirin and a statin. ACEIs should be considered in patients with CAD who have left ventricular dysfunction or diabetes (Table 27-3).

The evidence for clinically relevant differences between the three main classes of antianginal drugs is not compelling. A meta-analysis of publications that compared two or more antianginal therapies concluded that β blockers are associated with fewer episodes of angina per week and a lower rate of withdrawal due to adverse events than is nifedipine. However, differences did not extend to Ca^{2+} channel blockers other than nifedipine. Of note, no significant differences were observed in outcome between *long-acting* nitrates, Ca^{2+} channel blockers, and β blockers. Nevertheless,

guidelines recommend that β blockers be considered first-line treatment of chronic angina relief; Ca^{2+} channel blockers with heart rate-lowering effects (diltiazem, verapamil) are alternatives. Dihydropyridines should be considered in patients who do not tolerate β blockers. In case of persistent angina, a combination of a dihydropyridine and a β blocker should be considered.

Second-Line Treatment

Longer-acting organic nitrates/nitrate formulation (e.g., cutaneous GTN) or ranolazine, and, in non-U.S. countries, ivabradine, trimetazidine, and nicorandil may be considered as adjunct therapy in patients whose angina is not adequately controlled by first-line drugs. β Blockers can block the baroreceptor-mediated reflex tachycardia and positive inotropic effects that may occur with nitrates, whereas nitrates, by increasing venous capacitance, can attenuate the increase in left ventricular end-diastolic volume associated with β -blockade. Concurrent administration of nitrates also can alleviate the increase in coronary vascular resistance associated with blockade of β adrenergic receptors. Ranolazine and trimetazidine have a direct effect on the myocardium and likely act independently of hemodynamic effects. They can therefore be well combined with all other antianginal drugs where permitted. Ivabradine is a possible alternative to β blockers but is associated with toxicity when added to β blockers, verapamil, or diltiazem (Fox et al., 2014).

Ca^{2+} Channel Blockers and Nitrates. In severe exertional or vasospastic angina, the combination of a nitrate and a Ca^{2+} channel blocker may provide additional relief over that obtained with either type of agent alone. Because nitrates primarily reduce preload, whereas Ca^{2+} channel blockers reduce afterload, the net effect on reduction of O_2 demand should be additive; however, excessive vasodilation and hypotension can occur.

Acute Coronary Syndromes

The term ACS refers to chest pain with or without MI (i.e., myocardial necrosis). The latter diagnosis is essentially based on the presence or absence of increases in plasma levels of cardiac troponin (I or T). With tests becoming more and more sensitive, the number of MI diagnoses has increased, while that of unstable angina (i.e., chest pain without necrosis) has decreased. The term *unstable angina pectoris* is used for angina symptoms that present for the first time, change their usual pattern, occur at rest, or are resistant to nitrates.

Common to most clinical presentations of ACS is a disruption of a coronary plaque, leading to local platelet aggregation and thrombosis at the arterial wall, with subsequent partial or total occlusion of the vessel. Less commonly, vasospasm in minimally atherosclerotic coronary vessels

TABLE 27-3 ■ MANAGEMENT OF PATIENTS WITH STABLE CORONARY ARTERY DISEASE

TREATMENT LEVEL	ANGINA RELIEF	EVENT PREVENTION
All patients	Short-acting nitrates as standby medication	Education: Lifestyle management, control of risk factors
First-line treatment	β Blockers or diltiazem/verapamil	Aspirin + statins; consider ACEIs or ARBs
	Long-acting dihydropyridine if heart rate low or there are issues of intolerance/contraindications	
	β Blockers + dihydropyridines if angina persists	
	For vasospastic angina, consider dihydropyridines or long-acting nitrates; avoid β blockers	
Second-line treatment (first line in some cases, according to comorbidities and tolerance)	Add or switch to ivabradine, long-acting nitrates, nicorandil, ranolazine ^a , or trimetazidine ^a	Consider clopidogrel in cases of aspirin intolerance
Invasive therapy	Consider angiography and stenting or CABG	

^aIn patients with diabetes mellitus.

may account for unstable angina. The pathophysiological principles that underlie therapy for exertional angina—which are directed at decreasing myocardial O_2 demand—have limited efficacy in the treatment of ACSs characterized by an insufficiency of myocardial O_2 (blood) supply. The most important interventions are as follows:

- Antiplatelet agents, including aspirin and thienopyridines (e.g., clopidogrel, prasugrel, or ticagrelor)
- Antithrombin agents such as heparin or fondaparinux
- Anti-integrin therapies that directly inhibit platelet aggregation mediated by glycoprotein GPIIb/IIIa
- Primary angioplasty with percutaneously deployed intracoronary stents or, if not possible for logistical reasons, fibrinolysis with rTPA
- Coronary bypass surgery for selected patients

The β blockers reduce O_2 consumption and arrhythmias and have been associated with a moderate reduction in mortality in ACS but should be avoided in patients with compromised ventricular function or decreased blood pressure (Roffi et al., 2015). Nitrates are useful in reducing vasospasm and in reducing myocardial O_2 consumption by decreasing ventricular wall stress. Intravenous administration of nitroglycerin allows high concentrations of drug to be attained rapidly. Because nitroglycerin is degraded rapidly, the dose can be titrated quickly and safely using intravenous administration. If coronary vasospasm is present, intravenous nitroglycerin is likely to be effective, although the addition of a Ca^{2+} channel blocker may be required to achieve complete control in some patients. If a patient has consumed a PDE5 inhibitor within the preceding 24 h, there is a risk of profound hypotension, and nitrates should be withheld in favor of an alternate antianginal therapy.

While these principles apply to the entire group of patients with ACS, specific treatment algorithms and the value of different drug classes in ACS depend on the exact diagnosis and should be chosen according to recent guidelines (Amsterdam et al., 2014; Roffi et al., 2015).

ST-elevation myocardial infarction is generally due to a complete obstruction of a large coronary artery. The mainstay in these patients is immediate reperfusion by primary angioplasty and stenting or, in the absence of invasive options, fibrinolytic therapy.

Non-ST-elevation myocardial infarction can present with variable symptoms and electrocardiographic signs and is likely due to transient obstruction of larger coronary arteries or occlusion of small branches, leading to disseminated myocardial necrosis. Primary angioplasty is also indicated in these patients.

Unstable angina is differentiated from NSTEMI by the absence of increased plasma troponin concentrations. These patients have a better long-term prognosis and benefit less from early invasive procedures and intensified antiplatelet therapy. Mainstays are β blockers and nitrovasodilators (in the absence of contraindications such as hypotension). Short-acting Ca^{2+} channel blockers (e.g., nifedipine; see Figure 27–4) should normally be avoided in ACS because of a strong reflex activation of the sympathetic nervous system, but they are the first choice if vasospasm is the underlying cause.

Claudication and Peripheral Vascular Disease

Most patients with peripheral vascular disease also have CAD, and the therapeutic approaches for peripheral and coronary arterial diseases overlap (Rooke et al., 2011). Mortality in patients with peripheral vascular disease is most commonly due to cardiovascular disease (Regensteiner and Hiatt, 2002), and treatment of CAD remains the central focus of therapy. Many patients with advanced peripheral arterial disease are more limited by the consequences of peripheral ischemia than by myocardial ischemia. In the cerebral circulation, arterial disease may be manifest as stroke or transient ischemic attacks. The painful symptoms of peripheral arterial disease in the lower extremities (claudication) typically are provoked by exertion, with increases in skeletal muscle O_2 demand exceeding blood flow that is impaired by proximal stenoses. When flow to the extremities becomes critically limiting, peripheral ulcers and rest pain from tissue ischemia can become debilitating.

Most of the therapies shown to be efficacious for treatment of CAD also have a salutary effect on progression of peripheral artery disease (Hirsch et al., 2006). Antiplatelet therapy using aspirin (75–325 mg) and clopidogrel (75 mg) are recommended, although the evidence for beneficial effects on cardiovascular or total mortality are mixed (Rooke et al., 2011). Oral anticoagulation is ineffective and increases bleeding risks. ACEIs and statins have been recommended for patients with peripheral artery disease (Hirsch et al., 2006), but the evidence for prognostic benefits is much weaker than in CAD. Interestingly, neither intensive treatment of diabetes mellitus nor antihypertensive therapy appears to alter the progression of symptoms of claudication. Other risk factor and lifestyle modifications remain cornerstones of therapy for patients with claudication; physical exercise, rehabilitation, and smoking cessation (possibly supported by drug treatment with varenicline or bupropion) have proven efficacy.

Drugs used specifically in the treatment of lower extremity claudication include pentoxifylline and cilostazol. Pentoxifylline is a methylxanthine derivative that is called a *rheologic modifier* for its effects on increasing the deformability of red blood cells. However, the effects of pentoxifylline on lower extremity claudication appear to be modest and not sufficiently supported by prospective evidence (Salhiyyah et al., 2015).

Cilostazol is an inhibitor of PDE3 and promotes accumulation of intracellular cAMP in many cells, including blood platelets. Cilostazol-mediated increases in cAMP inhibit platelet aggregation and promote vasodilation. The drug is metabolized by CYP3A4 and has important drug interactions with other drugs metabolized via this pathway (see Chapter 6). Cilostazol has been mainly studied in Asian populations and seems to improve symptoms of claudication, but the effect on cardiovascular mortality remains unclear (Bedenis et al., 2014). As a PDE3 inhibitor, cilostazol is in the same drug class as milrinone, which had been used orally as an inotropic agent for patients with heart failure. Milrinone therapy was associated with an increase in sudden cardiac death, and the oral form of the drug was withdrawn from the market. Concerns about several other inhibitors of PDE3 (inamrinone, flosequinan) followed. Cilostazol therefore is labeled as being contraindicated in patients with heart failure, although it is not clear that cilostazol itself leads to increased mortality in such patients. Cilostazol has been reported to increase nonsustained ventricular tachycardia; headache is the most common side effect.

Other treatments for claudication, including naftidrofuryl, propionyl levocarnitine, and prostaglandins, have been explored in clinical trials, and there is some evidence that some of these therapies may be efficacious.

Mechanopharmacological Therapy: Drug-Eluting Endovascular Stents

Intracoronary stents can ameliorate angina and reduce adverse events in patients with ACSs. However, the long-term efficacy of intracoronary stents is limited by subacute luminal restenosis within the stent, which, in bare metal stents, occurs in 20%–30% of patients during the first 6–9 months of follow-up (Montalescot et al., 2013). The pathways that lead to “in-stent restenosis” are complex, but smooth muscle proliferation within the lumen of the stented artery is a common pathological finding. Local antiproliferative therapies at the time of stenting have been explored over many years; several drug-eluting stents and, more recently, biodegradable stents have been introduced in the market. The drugs currently used in intravascular stents are paclitaxel, sirolimus (rapamycin), and the two sirolimus derivatives everolimus and zatarolimus. Paclitaxel is a tricyclic diterpene that inhibits cellular proliferation by binding to and stabilizing polymerized microtubules. Sirolimus is a hydrophobic macrolide that binds to the cytosolic immunophilin FKBP12; the FKBP12-sirolimus complex inhibits the protein kinase mTOR, the mammalian target of rapamycin (see Figure 35–2), thereby inhibiting cell cycle progression (Figure 65–2). Paclitaxel and sirolimus differ markedly in their mechanisms of action but share common chemical properties as hydrophobic small molecules. Stent-induced damage to the vascular endothelial cell

layer can lead to thrombosis. The inhibition of cellular proliferation by paclitaxel and sirolimus or derivatives not only affects vascular smooth muscle cell proliferation but also attenuates the formation of an intact endothelial layer within the stented artery and thereby markedly reduces the rate of restenosis compared with bare metal stents. Dual antiplatelet therapy (aspirin, typically with clopidogrel) is recommended for one year

after intracoronary stenting with drug-eluting stents, similar to bare metal stents. Evidence for the benefit of even longer periods is limited.

Chapter 28

Treatment of Hypertension

Thomas Eschenhagen

EPIDEMIOLOGY AND TREATMENT ALGORITHMS

- Principles of Antihypertensive Therapy

DIURETICS

- Benzothiadiazines and Related Compounds
- Other Diuretic Antihypertensive Agents
- K⁺-Sparing Diuretics
- Diuretic-Associated Drug Interactions

SYMPATHOLYTIC AGENTS

- β adrenergic receptor antagonist (β Blockers)
- α_1 adrenergic receptor antagonist (α_1 Blockers)
- Combined α_1 and β Blockers
- Centrally Acting Sympatholytic Drugs

Ca²⁺ CHANNEL BLOCKERS

INHIBITORS OF THE RENIN-ANGIOTENSIN SYSTEM

- Angiotensin-Converting Enzyme Inhibitors

- AT₁ Receptor Blockers
- Direct Renin Inhibitors

VASODILATORS

- Hydralazine
- K_{ATP} Channel Openers: Minoxidil
- Sodium Nitroprusside
- Diazoxide

NONPHARMACOLOGICAL THERAPY OF HYPERTENSION

SELECTION OF ANTIHYPERTENSIVE DRUGS IN INDIVIDUAL PATIENTS

ACUTE ANTIHYPERTENSIVE TREATMENT

RESISTANT HYPERTENSION

Epidemiology and Treatment Algorithms

Hypertension is the most common cardiovascular disease. Elevated arterial pressure causes hypertrophy of the left ventricle and pathological changes in the vasculature. As a consequence, hypertension is the principal cause of stroke; a major risk factor for CAD and its attendant complications, MI and sudden cardiac death; and a major contributor to heart failure, renal insufficiency, and dissecting aneurysm of the aorta. The prevalence of hypertension increases with age; for example, about 50% of people between the ages of 60 and 69 years old have hypertension, and the prevalence further increases beyond age 70. According to a recent survey in the U.S., 81.5% of those with hypertension are aware they have it, 74.9% are being treated, yet only 52.5% are considered controlled (Go et al., 2014). The success of hypertension treatment programs, such as one organized in a large integrated healthcare delivery system in the U.S. (Jaffe et al., 2013), show that these figures can be substantially improved by electronic hypertension registries tracking hypertension control rates, regular feedback to providers, development and frequent updating of an evidence-based treatment guideline, promotion of single-pill combination therapies, and follow-up blood pressure checks. Between 2001 and 2009, this program increased the number of patients with a diagnosis of hypertension by 78%, as well as the proportion of subjects meeting target blood pressure goals from 44% to more than 84% (Jaffe et al., 2013).

Hypertension is defined as a sustained increase in blood pressure of 140/90 mmHg or higher, a criterion that characterizes a group of patients whose risk of hypertension-related cardiovascular disease is high enough to merit medical attention. Actually, the risk of both fatal and nonfatal cardiovascular disease in adults is lowest with systolic blood pressures of less than 120 mmHg and diastolic blood pressures less than 80 mmHg; these risks increase incrementally as systolic and diastolic blood pressures rise. Recognition of this continuously increasing risk prevents a simple definition of hypertension (Go et al., 2014) (Table 28-1). Although many of the clinical trials classified the severity of hypertension by diastolic

pressure, progressive elevations of systolic pressure are similarly predictive of adverse cardiovascular events; at every level of diastolic pressure, risks are greater with higher levels of systolic blood pressure. Indeed, in patients more than 50 years old, systolic blood pressures predict adverse outcomes better than do diastolic pressures. Pulse pressure, defined as the difference between systolic and diastolic pressure, may add additional predictive value (Pastor-Barriuso et al., 2003). This may be at least in part due to higher-than-normal pulse pressure indicating adverse remodeling of blood vessels, representing an accelerated decrease in blood vessel compliance normally associated with aging and atherosclerosis. Isolated systolic hypertension (sometimes defined as systolic blood pressure greater than 140–160 mmHg with diastolic blood pressure less than 90 mmHg) is largely confined to people older than 60 years.

The presence of pathological changes in certain target organs heralds a worse prognosis than the same level of blood pressure in a patient lacking these findings. For instance, retinal hemorrhages, exudates, and papilledema in the eyes indicate a far worse short-term prognosis for a given level of blood pressure. Left ventricular hypertrophy defined by electrocardiogram, or more sensitively by echocardiography or cardiac magnetic resonance imaging, is associated with a substantially worse long-term outcome that includes a higher risk of sudden cardiac death. The risk of cardiovascular disease, disability, and death in hypertensive patients also is increased markedly by concomitant cigarette smoking, diabetes, or elevated LDL; the coexistence of hypertension with these risk factors increases cardiovascular morbidity and mortality to a degree that is compounded by each additional risk factor.

The purpose of treating hypertension is to decrease cardiovascular risk; thus, other dietary and pharmacological interventions may be required to treat these additional risk factors. Effective pharmacological treatment of patients with hypertension decreases morbidity and mortality from cardiovascular disease, reducing the risk of strokes, heart failure, and CAD (Rosendorff et al., 2015). The reduction in risk of MI may be less significant.

Abbreviations

ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
Aldo: aldosterone
AngII: angiotensin II
ANP: atrial natriuretic peptide
ARB: angiotensin receptor blocker
AT₁: type 1 receptor for angiotensin II
ATPase: adenosine triphosphatase
AV: atrioventricular
BB: β blocker
β blocker: β adrenergic receptor antagonist
BNP: brain natriuretic peptide
BP: blood pressure
CAD: coronary artery disease
CCB: Ca²⁺ channel blocker
CNS: central nervous system
COX-2: cyclooxygenase 2
DOPA: 3,4-dihydroxyphenylalanine
DRI: direct renin inhibitor
ENaC: epithelial Na⁺ channel
ESC: European Society of Cardiology
GI: gastrointestinal
GFR: glomerular filtration rate
HDL: high-density lipoprotein
HF: heart failure
HTN: hypertension
ISA: intrinsic sympathomimetic activity
ISDN: isosorbide dinitrate
JNC8: Eighth Joint National Committee
MI: myocardial infarction
MRA: mineralocorticoid receptor antagonist
NCC: NaCl cotransporter
NE: norepinephrine
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
RAAS: renin-angiotensin-aldosterone system
RAS: renin-angiotensin system
SA: sinoatrial
SNS: sympathetic nervous system
VMAT2: vesicular catecholamine transporter 2

Principles of Antihypertensive Therapy

Nonpharmacological therapy, or lifestyle-related changes, is an important component of treatment of all patients with hypertension (James et al., 2014; Mancia et al., 2013). In some grade 1 hypertensives (Figure 28–1), blood pressure may be adequately controlled by a combination of weight loss (in overweight individuals), restricting sodium intake (to 5–6 g/d), increasing aerobic exercise (>30 min/d), moderating consumption of alcohol (ethanol/day ≤ 20–30 g in men [two drinks], ≤ 10–20 g in women [one drink]), smoking cessation, increased consumption of fruits, vegetables, and low-fat dairy products.

The majority of patients require drug therapy for adequate blood pressure control (Figure 28–1). Optimal blood pressure goals for drug therapy are still debated, and current guidelines from cardiovascular societies differ slightly (James et al., 2014). Recently, a large comparative study in nondiabetics with increased cardiovascular risk was prematurely stopped because the group of patients treated with antihypertensives to a systolic blood pressure target of 120 mmHg, with an average of 2.8 drugs, experienced a 25% lower rate of cardiovascular end points and total mortality than the group targeted to the current standard goal target of 140 mmHg

TABLE 28–1 ■ AMERICAN HEART ASSOCIATION CRITERIA FOR HYPERTENSION IN ADULTS

CLASSIFICATION	BLOOD PRESSURE (mmHg)	
	SYSTOLIC	DIASTOLIC
Normal	<120	and < 80
Prehypertension	120–139	or 80–89
Hypertension, stage 1	140–159	or 90–99
Hypertension, stage 2	≥160	or ≥ 100
Hypertensive crisis	>180	or > 110

(SPRINT Research Group, 2015). The rate of adverse effects such as hypotension and worsening of renal function were higher in the intensified treatment group, yet this did not translate to a signal for real harm. The data will likely lead to a reexamination of current guideline-recommended blood pressure targets.

Arterial pressure is the product of cardiac output and peripheral vascular resistance (Figure 28–2). Drugs lower blood pressure by actions on peripheral resistance, cardiac output, or both. Drugs may decrease the cardiac output by inhibiting myocardial contractility or by decreasing ventricular filling pressure. Reduction in ventricular filling pressure may be achieved by actions on the venous tone or on blood volume via renal effects. Drugs can decrease peripheral resistance by acting on smooth muscle to cause relaxation of resistance vessels or by interfering with the activity of systems that produce constriction of resistance vessels (e.g., the sympathetic nervous system, the RAS). In patients with isolated systolic hypertension, complex hemodynamics in a rigid arterial system contribute to increased blood pressure; drug effects may be mediated not only by changes in peripheral resistance but also via effects on large artery stiffness (Franklin, 2000).

Antihypertensive drugs can be classified according to their sites or mechanisms of action (Table 28–2, Figure 28–2). The hemodynamic consequences of long-term treatment with antihypertensive agents (Table 28–3) provide a rationale for potential complementary effects of concurrent therapy with two or more drugs. Concurrent use of drugs from different classes is a strategy for achieving effective control of blood pressure while minimizing dose-related adverse effects.

It generally is not possible to predict the responses of individuals with hypertension to any specific drug. For example, for some antihypertensive drugs, about two-thirds of patients will have a meaningful clinical response, whereas about one-third of patients will not respond to the same drug. Racial origin and age may have modest influence on the likelihood of a favorable response to a particular class of drugs. Polymorphisms in genes involved in the metabolism of antihypertensive drugs have been identified in the CYPs (phase I metabolism) and in phase II metabolism, such as catechol-O-methyltransferase (see Chapters 6 and 7). While these polymorphisms can change the pharmacokinetics of specific drugs quite markedly (e.g., five times higher plasma concentrations of metoprolol in CYP2D6 poor metabolizers), differences in efficacy are smaller (Rau et al., 2009) and of unknown clinical relevance. Polymorphisms that influence pharmacodynamic responses to antihypertensive drugs, including ACE inhibitors and diuretics, have also been identified, but evidence for clinically meaningful differences in drug response is sparse. Genome-wide scanning has identified several genetic variants associated with hypertension, but the effect sizes are much smaller than that of clinically established risk factors such as overweight.

Diuretics

An early strategy for the management of hypertension was to alter Na⁺ balance by restriction of salt in the diet. Pharmacological alteration of Na⁺ balance became practical with the development of the orally active thiazide diuretics (see Chapter 25). These and related diuretic agents have

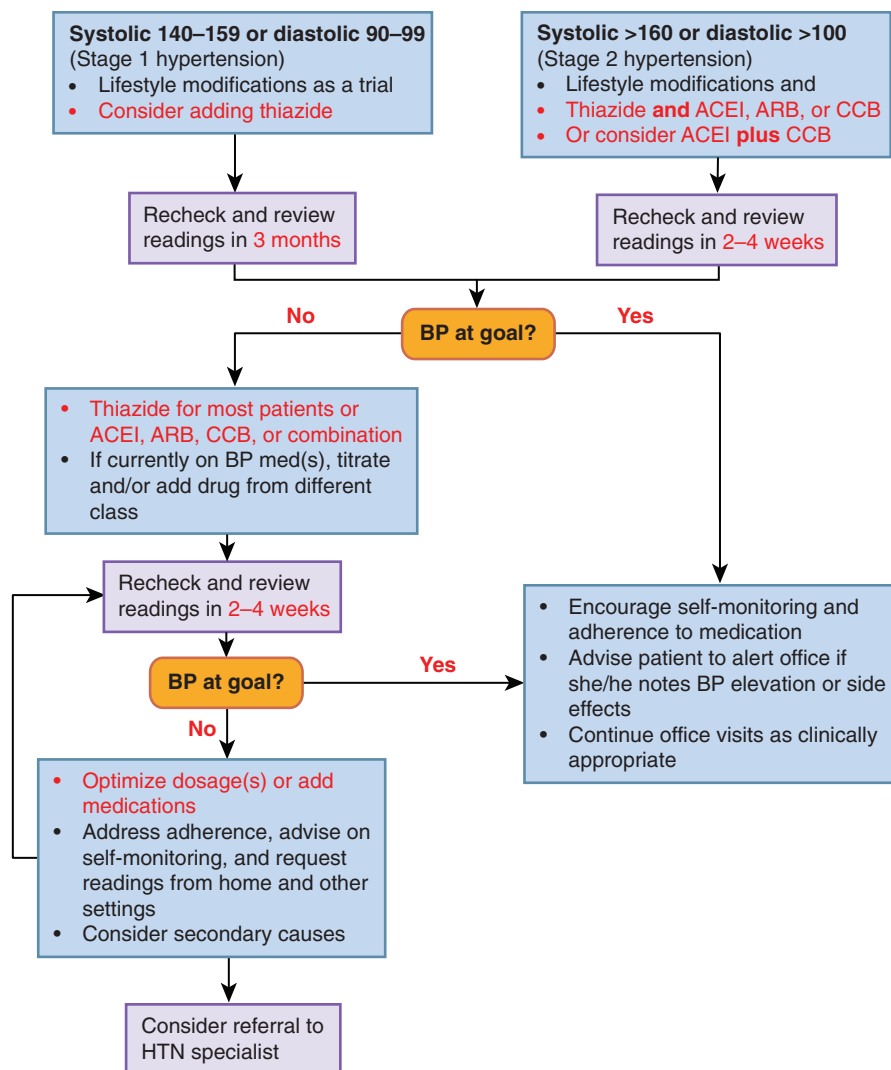

Figure 28–1 Treatment algorithm for adults with hypertension. Algorithm is based on recommendations of the American Heart Association and the American College of Cardiology (Go et al., 2013).

antihypertensive effects when used alone, and they enhance the efficacy of virtually all other antihypertensive drugs. Thus, this class of drugs remains important in the treatment of hypertension.

The exact mechanism for reduction of arterial blood pressure by diuretics is not certain. The initial action of thiazide diuretics decreases extracellular volume by interacting with a thiazide-sensitive NCC (SLC12A3) expressed in the distal convoluted tubule in the kidney, enhancing Na^+ excretion in the urine, and leading to a decrease in cardiac output. However, the hypotensive effect is maintained during long-term therapy due to decreased vascular resistance; cardiac output returns to pretreatment values, and extracellular volume returns to almost normal due to compensatory responses such as activation of the RAS. The explanation for the long-term vasodilation induced by thiazide diuretics is unknown. *Hydrochlorothiazide* may open Ca^{2+} -activated K^+ channels, leading to hyperpolarization of vascular smooth muscle cells, which leads in turn to closing of L-type Ca^{2+} channels and lower probability of opening, resulting in decreased Ca^{2+} entry and reduced vasoconstriction. Hydrochlorothiazide also inhibits vascular carbonic anhydrase, which, hypothetically, could alter smooth muscle cell systolic pH and thereby cause opening of Ca^{2+} -activated K^+ channels with the consequences noted previously.

The relevance of these findings—largely assessed in vitro—to the observed antihypertensive effects of thiazides is speculative. The major action of these drugs on SLC12A3—expressed predominantly in the distal convoluted tubules and not in vascular smooth muscle or the

heart—suggests that these drugs decrease peripheral resistance as an indirect effect of negative Na^+ balance. That thiazides lose efficacy in treating hypertension in patients with coexisting renal insufficiency is compatible with this hypothesis. Moreover, carriers of rare functional mutations in SLC12A3 that decrease renal Na^+ reabsorption have lower blood pressure than appropriate controls (Ji et al., 2008); in a sense, this is an experiment of nature that may mimic the therapeutic effect of thiazides.

Benzothiadiazines and Related Compounds

Benzothiadiazines (“thiazides”) and related diuretics are the most frequently used class of antihypertensive agents in the U.S. Following the discovery of *chlorothiazide*, a number of oral diuretics were developed that have an arylsulfonamide structure and block the NCC. Some of these are not benzothiadiazines but have structural features and molecular functions that are similar to the original benzothiadiazine compounds; consequently, they are designated as members of the thiazide class of diuretics. For example, chlorthalidone (also written as chlortalidone), one of the nonbenzothiadiazines, is widely used in the treatment of hypertension, as is indapamide.

Regimen for Administration of the Thiazide-Class Diuretics in Hypertension

Because members of the thiazide class have similar pharmacological effects, they generally have been viewed as interchangeable with appropriate

Figure 28–2 Principles of blood pressure regulation and its modification by drugs. Cardiac output and peripheral arteriolar resistance, the major determinants of arterial blood pressure, are regulated by myriad mechanisms, including the SNS (main peripheral neurotransmitter NE), the balance between salt intake by the intestine (GI) and salt excretion by the kidneys, the RAAS (main agonists AngII and Aldo), and natriuretic peptides produced in the heart (ANP and BNP). Sensors (green circles) provide afferent input on pressure in the heart and great vessels and on salt concentrations in the kidney. Note positive feedback between the SNS and RAAS via β_1 -stimulated renin release and AngII-stimulated NE release. Drug classes are indicated in boldface type at their main site of action. Arrows indicate blood pressure-increasing (red) and -decreasing (green) effects. Neprilysin inhibitors (e.g., sacubitril) are in clinical testing for hypertension and have been approved for the treatment of heart failure (in combination with an ARB).

adjustment of dosage (see Chapter 25). However, the pharmacokinetics and pharmacodynamics of these drugs differ, so they may not necessarily have the same clinical efficacy in treating hypertension. In a direct comparison, the antihypertensive efficacy of chlorthalidone was greater than that of hydrochlorothiazide, particularly during the night (Ernst et al., 2006), suggesting the much longer $t_{1/2}$ of chlorthalidone (>24 h) compared to hydrochlorothiazide (several hours) gave more stable blood pressure reductions. In light of the considerable clinical trial data supporting the capacity of chlorthalidone to diminish adverse cardiovascular events—in comparison to that available for currently used low doses of hydrochlorothiazide—there is a growing concern that chlorthalidone may be an underutilized drug in hypertensive patients requiring a diuretic.

Antihypertensive effects can be achieved in many patients with as little as 12.5 mg daily of chlorthalidone or hydrochlorothiazide. Furthermore, when used as monotherapy, the maximal daily dose of thiazide-class diuretics usually should not exceed 25 mg of hydrochlorothiazide or chlorthalidone (or equivalent). Even though more diuresis can be achieved with higher doses, some evidence suggests that doses higher than this are not generally more efficacious in lowering blood pressure in patients with normal renal function. Low doses of either thiazide reduce the risk of adverse effects such as K^+ wasting and inhibition of uric acid excretion, indicating an improved risk-to-benefit ratio at low doses of a thiazide. However, other studies suggested that low doses of hydrochlorothiazide

have inadequate effects on blood pressure when monitored in a detailed manner (Lacourciere et al., 1995).

Clinical trials of antihypertensive therapy in the elderly demonstrated the best outcomes for cardiovascular morbidity and mortality when 25 mg of hydrochlorothiazide or chlorthalidone was the maximum dose given; if this dose did not achieve the target blood pressure reduction, a second drug was initiated (1991; Dahlöf et al., 1991). A case-control study found a dose-dependent increase in the occurrence of sudden death at doses of hydrochlorothiazide greater than 25 mg daily (Siscovick et al., 1994), supporting the hypothesis that higher diuretic doses are associated with increased cardiovascular mortality as long as hypokalemia is not corrected. Thus, if adequate blood pressure reduction is not achieved with the 25-mg daily dose of hydrochlorothiazide or chlorthalidone, the addition of a second drug is indicated rather than an increase in the dose of diuretic.

Urinary K^+ loss can be a problem with thiazides. ACE inhibitors and ARBs will attenuate diuretic-induced loss of K^+ to some degree, and this is a consideration if a second drug is required to achieve further blood pressure reduction beyond that attained with the diuretic alone. Because the diuretic and hypotensive effects of these drugs are greatly enhanced when they are given in combination, care should be taken to initiate combination therapy with low doses of each of these drugs (Vlasses et al., 1983). Administration of ACE inhibitors or ARBs together with other

TABLE 28-2 ■ CLASSES OF ANTIHYPERTENSIVE DRUGS**Diuretics** (Chapter 25)

- *Thiazides and related agents*: chlorothiazide, chlorthalidone, hydrochlorothiazide, indapamide
- *Loop diuretics*: bumetanide, furosemide, torsemide
- *K⁺-sparing diuretics*: amiloride, triamterene, MRA spironolactone

Sympatholytic drugs (Chapter 12)

- *β Blockers*: atenolol, bisoprolol, esmolol, metoprolol, nadolol, nebivolol, propranolol, timolol
- *α Blockers*: prazosin, terazosin, doxazosin, phenoxybenzamine
- *Mixed α/β blockers*: labetalol, carvedilol
- *Centrally acting sympatholytic agents*: clonidine, guanabenz, guanfacine, methyldopa, moxonidine, reserpine

Ca²⁺ channel blockers (Chapter 27): amlodipine, clevidipine, diltiazem, felodipine, isradipine, lercanidipine, nicardipine, nifedipine,^a nisoldipine, verapamil

Renin-angiotensin antagonists (Chapter 26)

- *Angiotensin-converting enzyme inhibitors*: benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, trandolapril
- *AngII receptor blockers*: candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan
- *Direct renin inhibitor*: aliskiren

Vasodilators (Chapters 27 and 28)

- *Arterial*: diazoxide, fenoldopam, hydralazine, minoxidil
- *Arterial and venous*: nitroprusside

^aOnly extended-release nifedipine is approved for hypertension.

K⁺-sparing agents or with K⁺ supplements requires great caution; combining K⁺-sparing agents with each other or with K⁺ supplementation can cause potentially dangerous hyperkalemia in some patients.

In contrast to the limitation on the dose of thiazide-class diuretics used as monotherapy, the treatment of severe hypertension that is unresponsive to three or more drugs may require larger doses of the thiazide-class diuretics. Indeed, hypertensive patients may become refractory to drugs that block the sympathetic nervous system or to vasodilator drugs,

because these drugs engender a state in which the blood pressure is very volume dependent. Therefore, it is appropriate to consider the use of thiazide-class diuretics in doses of 50 mg of daily hydrochlorothiazide equivalent when treatment with appropriate combinations and doses of three or more drugs fails to yield adequate control of the blood pressure. Alternatively, there may be a need to use higher-capacity diuretics such as furosemide, especially if renal function is not normal.

The effectiveness of thiazides as diuretics or antihypertensive agents is progressively diminished when the glomerular filtration rate falls below 30 mL/min. One exception is metolazone, which retains efficacy in patients with this degree of renal insufficiency.

Most patients will respond to thiazide diuretics with a reduction in blood pressure within about 4–6 weeks. Therefore, doses should not be increased more often than every 4–6 weeks. There is no way to predict the antihypertensive response from the duration or severity of the hypertension in a given patient, although diuretics are unlikely to be effective as sole therapy in patients with stage 2 hypertension (Table 28-1). Because the effect of thiazide diuretics is additive with that of other antihypertensive drugs, combination regimens that include these diuretics are common and rational. A wide range of fixed-dose combination products containing a thiazide are marketed for this purpose. Diuretics also have the advantage of minimizing the retention of salt and water that is commonly caused by vasodilators and some sympatholytic drugs. Omitting or underutilizing a diuretic is a frequent cause of “resistant hypertension.”

Adverse Effects and Precautions

The adverse effects of diuretics are discussed in Chapter 25. Some of these determine whether a patient can tolerate and adhere to diuretic treatment.

The K⁺ depletion produced by thiazide-class diuretics is dose dependent and variable among individuals, such that a subset of patients may become substantially K⁺ depleted on diuretic drugs. Given chronically, even small doses lead to some K⁺ depletion, which is a well-known risk factor for ventricular arrhythmias by reducing cardiac repolarization reserve. The last has recently been used to explain that insults in a particular repolarization current do not necessarily result in QT interval prolongation, the principle clinical measure of repolarization (see Chapter 30). Hypokalemia directly reduces repolarization reserve by decreasing several K⁺ conductances (inward rectifier I_{K1}, delayed rectifier I_{Kr}, and the transient outward current I_{to}) and increases the binding activity of I_{Kr}-inhibiting drugs such as dofetilide (Yang and Roden, 1996). Hypokalemia also reduces

^aHeart rate can be increased at rest and decreased under exercise as a result of ISA. During rest, ISA may increase resting heart rate; during exercise, β adrenergic antagonism predominates, attenuating heart rate acceleration by NE.

the activity of the Na^+, K^+ -ATPase (the Na^+ pump), causing intracellular accumulation of Na^+ and Ca^{2+} , further increasing the risk of afterdepolarizations (Pezhouman et al., 2015). Consequently, hypokalemia increases the risk of drug-induced polymorphic ventricular tachycardia (torsade de pointes; see Chapter 30) and the risk for ischemic ventricular fibrillation, the leading cause of sudden cardiac death and a major contributor to cardiovascular mortality in treated hypertensive patients. There is a positive correlation between diuretic dose and sudden cardiac death and an inverse correlation between the use of adjunctive K^+ -sparing agents and sudden cardiac death (Siscovick et al., 1994). Thus, hypokalemia needs to be avoided by, for example, combining a thiazide with inhibitors of the RAS or with a K^+ -sparing diuretic.

Thiazides have residual carbonic anhydrase-inhibiting activity, thereby reducing Na^+ reabsorption in the proximal tubule. The increased presentation of Na^+ at the macula densa leads to a reduced glomerular filtration rate via tubuloglomerular feedback. While this effect is clinically not meaningful in patients with normal renal function, it reduces diuretic effectiveness and may gain importance in patients with reduced kidney function. RAS inhibitors and Ca^{2+} channel blockers interfere with tubuloglomerular feedback, providing one explanation for the synergistic effect on blood pressure. Erectile dysfunction is a troublesome adverse effect of the thiazide-class diuretics, and physicians should inquire specifically regarding its occurrence in conjunction with treatment with these drugs. Gout may be a consequence of the hyperuricemia induced by these diuretics. The occurrence of either of these adverse effects is a reason for considering alternative approaches to therapy. However, precipitation of acute gout is relatively uncommon with low doses of diuretics. Hydrochlorothiazide may cause rapidly developing, severe hyponatremia in some patients. Thiazides inhibit renal Ca^{2+} excretion, occasionally leading to hypercalcemia; although generally mild, this can be more severe in patients subject to hypercalcemia, such as those with primary hyperparathyroidism. The thiazide-induced decreased Ca^{2+} excretion may be used therapeutically in patients with osteoporosis or hypercalciuria.

Thiazide diuretics have also been associated with changes in plasma lipids and glucose tolerance that have led to some concern. The clinical significance of the changes has been disputed because the clinical studies demonstrated comparable efficacy of the thiazide diuretic chlorthalidone in reducing cardiovascular risk (ALLHAT Officers, 2002).

All thiazide-like drugs cross the placenta. While they have no direct adverse effects on the fetus, administration of a thiazide during pregnancy increases a risk of transient volume depletion that may result in placental hypoperfusion. Because the thiazides appear in breast milk, they should be avoided by nursing mothers.

Other Diuretic Antihypertensive Agents

The thiazide diuretics are more effective antihypertensive agents than are the loop diuretics, such as furosemide and bumetanide, in patients who have normal renal function. This differential effect is most likely related to the short duration of action of loop diuretics. In fact, a single daily dose of loop diuretics does not cause a significant net loss of Na^+ for an entire 24-h period because the strong initial diuretic effect is followed by a rebound mediated by activation of the RAS. Unfortunately, loop diuretics are frequently and inappropriately prescribed as a once-a-day medication in the treatment not only of hypertension, but also of congestive heart failure and ascites. The high efficacy of loop diuretics to produce a rapid and profound natriuresis can be detrimental for the treatment of hypertension. When a loop diuretic is given twice daily, the acute diuresis can be excessive and lead to more side effects than occur with a slower-acting, milder thiazide diuretic. Loop diuretics may be particularly useful in patients with azotemia or with severe edema associated with a vasodilator such as minoxidil.

K^+ -Sparing Diuretics

Amiloride and triamterene are K^+ -sparing diuretics that have little value as antihypertensive monotherapy but are important in combination with thiazides to antagonize urinary K^+ loss and the concomitant risk of ventricular arrhythmias. They act by reversibly inhibiting the ENaC in the

distal tubule membrane, the transporter responsible for the reabsorption of Na^+ in exchange for K^+ . The importance of ENaC for hypertension is illustrated by the fact that an inherited form of hypertension, Liddle syndrome, is due to hyperactivity of ENaC. Gene expression of ENaC is mineralocorticoid sensitive, explaining the antihypertensive and K^+ -sparing effect of another class of K^+ -sparing diuretics, the MRAs spironolactone and eplerenone. In contrast to the immediate and short-term inhibition of ENaC by amiloride and triamterene, the action of MRAs is delayed for about 3 days and is long lasting because MRAs regulate the density of the channel protein in the tubule membrane.

The MRAs have a particular role in hypertension and heart failure (see Chapter 27) because small doses of spironolactone are often highly effective in patients with “resistant hypertension.” First described decades ago (Ramsay et al., 1980), the concept was recently validated in a prospective, placebo-controlled trial comparing spironolactone (25–50 mg) with bisoprolol or doxazosin as add-ons in patients with uncontrolled hypertension despite triple standard antihypertensive therapy (Williams et al., 2015). Spironolactone had about a 2-fold larger blood pressure-lowering effect (8.7 vs. 4.8 and 4 mmHg, respectively). The efficacy of the MRA spironolactone in resistant hypertension supports a primary role of Na^+ retention in this condition. Some of the effect may be related to the so-called aldosterone-escape phenomenon, or a return to pre-RAS-inhibitor plasma aldosterone levels with extended time of treatment, observed under treatment with RAS inhibitors. Primary hyperaldosteronism occurs in a significant fraction of patients with resistant hypertension (Calhoun et al., 2002).

Spironolactone has some significant adverse effects, especially in men (e.g., erectile dysfunction, gynecomastia, benign prostatic hyperplasia). Eplerenone is a more specific, though less-potent, MRA with reduced side effects.

All K^+ -sparing diuretics should be used cautiously, with frequent measurements of plasma K^+ concentrations in patients predisposed to hyperkalemia. Patients should be cautioned regarding the possibility that concurrent use of K^+ -containing salt substitutes could produce hyperkalemia. Renal insufficiency is a relative contraindication to the use of K^+ -sparing diuretics. Concomitant use of an ACE inhibitor or an ARB magnifies the risk of hyperkalemia with these agents.

Diuretic-Associated Drug Interactions

Because the antihypertensive effects of diuretics are additive with those of other antihypertensive agents, a diuretic commonly is used in combination with other drugs. The K^+ - and Mg^{2+} -depleting effects of the thiazides and loop diuretics can potentiate arrhythmias that arise from digitalis toxicity. Corticosteroids can amplify the hypokalemia produced by the diuretics. NSAIDs (see Chapter 38) that inhibit the synthesis of prostaglandins reduce the antihypertensive effects of diuretics and all other antihypertensives. The renal effects of selective COX-2 inhibitors are similar to those of the traditional NSAIDs. NSAIDs and RAS inhibitors reduce plasma concentrations of aldosterone and can potentiate the hyperkalemic effects of a K^+ -sparing diuretic. All diuretics can decrease the clearance of Li^+ , resulting in increased plasma concentrations of Li^+ and potential toxicity.

Sympatholytic Agents

With the demonstration in 1940 that bilateral excision of the thoracic sympathetic chain could lower blood pressure, there was a search for effective chemical sympatholytic agents. Many of the early sympatholytic drugs were poorly tolerated and had limiting adverse side effects, particularly on mood. A number of sympatholytic agents are currently in use (Table 28–2). Antagonists of α and β adrenergic receptors have been mainstays of antihypertensive therapy.

β Blockers

β Adrenergic receptor antagonists (β blockers) were not expected to have antihypertensive effects when they were first investigated in patients with

angina, their primary indication. However, *pronethalol*, a drug that was never marketed, was found to reduce arterial blood pressure in hypertensive patients with angina pectoris. This antihypertensive effect was subsequently demonstrated for *propranolol* and all other β blockers. The basic pharmacology of these drugs is discussed in Chapter 12; characteristics relevant to their use in hypertension are described here.

Locus and Mechanism of Action

Antagonism of β adrenergic receptors affects the regulation of the circulation through a number of mechanisms, including a reduction in myocardial contractility and heart rate (i.e., cardiac output; see Figure 27-1). Antagonism of β_1 receptors of the juxtaglomerular complex reduces renin secretion and RAS activity. This action likely contributes to the antihypertensive action. Some members of this large, heterogeneous class of drugs have additional effects unrelated to their capacity to bind to β adrenergic receptors. For example, *labetalol* and *carvedilol* are also α_1 blockers, and *nebivolol* promotes endothelial cell–dependent vasodilation via activation of NO production (Pedersen and Cockcroft, 2006) (see Figure 12-4).

Pharmacodynamic Differences

The β blockers vary in their selectivity for the β_1 receptor subtype, presence of partial agonist or intrinsic sympathomimetic activity, and vasodilating capacity. While all of the β blockers are effective as antihypertensive agents, these differences influence the clinical pharmacology and spectrum of adverse effects of the various drugs. The antihypertensive effect resides in antagonism of the β_1 receptor, while major unwanted effects result from antagonism of β_2 receptors (e.g., peripheral vasoconstriction, bronchoconstriction, hypoglycemia). Standard therapies are β_1 blockers without intrinsic sympathomimetic activity (e.g., *atenolol*, *bisoprolol*, *metoprolol*). They produce an initial reduction in cardiac output (mainly β_1) and a reflex-induced rise in peripheral resistance, with little or no acute change in arterial pressure. In patients who respond with a reduction in blood pressure, peripheral resistance gradually returns to pretreatment values or less. Generally, persistently reduced cardiac output and possibly decreased peripheral resistance account for the reduction in arterial pressure. Nonselective β blockers (e.g., *propranolol*) have stronger adverse effects on peripheral vascular resistance by also blocking β_2 receptors that normally mediate vasodilation. Vasodilating β blockers (e.g., *carvedilol*, *nebivolol*) may be preferred in patients with peripheral artery disease. Drugs with intrinsic sympathomimetic activity (e.g., *pindolol*, *xamoterol*) are not recommended for the treatment of hypertension or any other cardiovascular disease because they actually increase nighttime mean heart rate due to their direct partial agonistic activity.

Pharmacokinetic Differences

Lipophilic β blockers (*metoprolol*, *bisoprolol*, *carvedilol*, *propranolol*) appear to have more antiarrhythmic efficacy than the hydrophilic compounds (*atenolol*, *nadolol*, *labetalol*), possibly related to a central mode of action. Many β blockers have relatively short plasma half-lives and require more than once-daily dosing (*metoprolol*, *propranolol*, *carvedilol*), a significant disadvantage in the treatment of hypertension. They should generally be prescribed in sustained-release forms. *Bisoprolol* and *nebivolol* have $t_{1/2}$ values of 10–12 h and thus achieve sufficient trough levels at once-daily dosing. Hepatic metabolism of *metoprolol*, *carvedilol*, and *nebivolol* is CYP2D6 dependent. The relevance is probably greatest in case of *metoprolol*, for which CYP2D6 poor metabolizers (~7% of the Caucasian population) show 5-fold higher drug exposure and 2-fold higher heart rate decreases than the majority of extensive metabolizers (Rau et al., 2009).

Effectiveness in Hypertension

Meta-analyses have suggested that β blockers reduce the incidence of MI similar to other antihypertensives but are only be about half as effective in preventing stroke (Lindholm et al., 2005). This has led to downgrading of this class of drugs in certain national guidelines (e.g., U.K. standards); however, many of the studies supporting this conclusion were conducted with *atenolol*, which may not be the ideal β blocker. *Atenolol* may not lower central (aortic) blood pressure as effectively as it appears when conventionally measured in the brachial artery using a

standard arm cuff (Williams et al., 2006). Indeed, *atenolol*, in contrast to *bisoprolol*, *carvedilol*, *metoprolol*, or *nebivolol*, has not been positively tested in heart failure trials. Prospective studies of hypertensive agents have not compared different β blockers head to head; therefore, the clinical relevance of pharmacological differences in this heterogeneous drug class remains unclear. Results of a detailed meta-analysis of 147 randomized trials of blood pressure reduction showed that, regardless of blood pressure before treatment, lowering systolic blood pressure by 10 mmHg or diastolic blood pressure by 5 mmHg using any of the main classes of antihypertensive drugs significantly reduced coronary events and stroke without an increase in nonvascular mortality (Law et al., 2009).

Adverse Effects and Precautions

The adverse effects of β blockers are discussed in Chapter 12. These drugs should be avoided in patients with reactive airway disease (e.g., asthma) or with SA or AV nodal dysfunction or in combination with other drugs that inhibit AV conduction, such as *verapamil*. The risk of hypoglycemic reactions may be increased in diabetics taking insulin, but type 2 diabetes is not a contraindication. β Blockers increase concentrations of triglycerides in plasma and lower those of HDL cholesterol without changing total cholesterol concentrations. The long-term consequences of these effects are unknown.

Sudden discontinuation of β blockers can produce a withdrawal syndrome that is likely due to upregulation of β receptors during blockade, causing enhanced tissue sensitivity to endogenous catecholamines—potentially exacerbating the symptoms of CAD. The result, especially in active patients, can be rebound hypertension. Thus, β blockers should not be discontinued abruptly, except under close observation; dosage should be tapered gradually over 10–14 days prior to discontinuation.

Epinephrine can produce severe hypertension and bradycardia when a nonselective β blocker is present. The hypertension is due to the unopposed stimulation of α adrenergic receptors when vascular β_2 receptors are blocked. The bradycardia is the result of reflex vagal stimulation. Such paradoxical hypertensive responses to β blockers have been observed in patients with hypoglycemia or pheochromocytoma, during withdrawal from *clonidine*, following administration of epinephrine as a therapeutic agent, or in association with the illicit use of cocaine.

Therapeutic Uses

The β blockers provide effective therapy for all grades of hypertension. Marked differences in their pharmacokinetic properties should be considered; once-daily dosing is preferred for better compliance. Populations that tend to have a lesser antihypertensive response to β blockers include the elderly and African Americans. However, intraindividual differences in antihypertensive efficacy are generally much larger than statistical evidence of differences between racial or age-related groups. Consequently, these observations should not discourage the use of these drugs in individual patients in groups reported to be less responsive.

The β blockers usually do not cause retention of salt and water, and administration of a diuretic is not necessary to avoid edema or the development of tolerance. However, diuretics do have additive antihypertensive effects when combined with β blockers. The combination of a β blocker, a diuretic, and a vasodilator is effective for patients who require a third antihypertensive drug. β Blockers (i.e., *bisoprolol*, *carvedilol*, *metoprolol*, or *nebivolol*) are highly preferred drugs for hypertensive patients with conditions such as MI, ischemic heart disease, or congestive heart failure and may be preferred for younger patients with signs of increased sympathetic drive. However, for other hypertensive patients, particularly older patients with a high risk for stroke, enthusiasm for their early use in treatment has diminished.

α_1 Blockers

The availability of drugs that selectively block α_1 adrenergic receptors without affecting α_2 adrenergic receptors adds another group of antihypertensive agents. The pharmacology of these drugs is discussed in detail in Chapter 12. *Prazosin*, *terazosin*, and *doxazosin* are the agents available

for the treatment of hypertension. Phenoxybenzamine, an irreversible α_1 blocker ($\alpha_1 > \alpha_2$), is used in the treatment of catecholamine-producing tumors (pheochromocytoma).

Pharmacological Effects

Initially, α_1 blockers reduce arteriolar resistance and increase venous capacitance; this causes a sympathetically mediated reflex increase in heart rate and plasma renin activity. During long-term therapy, vasodilation persists, but cardiac output, heart rate, and plasma renin activity return to normal. Renal blood flow is unchanged during therapy with an α_1 blocker. The α_1 blockers cause a variable amount of postural hypotension, depending on the plasma volume. Retention of salt and water occurs in many patients during continued administration, and this attenuates the postural hypotension. The α_1 blockers reduce plasma concentrations of triglycerides and total LDL cholesterol and increase HDL cholesterol. These potentially favorable effects on lipids persist when a thiazide-type diuretic is given concurrently. The long-term consequences of these small, drug-induced changes in lipids are unknown.

Therapeutic Uses

α_1 Blockers are not recommended as monotherapy for hypertensive patients, primarily as a consequence of the ALLHAT study (see further discussion). Consequently, they are used primarily in conjunction with diuretics, β blockers, and other antihypertensive agents. β Blockers enhance the efficacy of α_1 blockers. α_1 Blockers are not the drugs of choice in patients with pheochromocytoma because a vasoconstrictor response to epinephrine can still result from activation of unblocked vascular α_2 adrenergic receptors. α_1 Blockers are attractive drugs for hypertensive patients with benign prostatic hyperplasia because they also improve urinary symptoms.

Adverse Effects

The use of doxazosin as monotherapy for hypertension increases the risk for developing congestive heart failure (ALLHAT Officers, 2002). This may be a class effect that represents an adverse effect of all of the α_1 blockers and has led to recommendations not to use this class of drugs in patients with heart failure. Interpretation of the outcome of the ALLHAT study is controversial, but the commonly held belief that the higher rate of apparent heart failure development in the groups of patients treated with a nondiuretic was caused by withdrawal of prestudy diuretics has not been substantiated (Davis et al., 2006).

A major precaution regarding the use of the α_1 blockers for hypertension is the so-called first-dose phenomenon, in which symptomatic orthostatic hypotension occurs within 30–90 min (or longer) of the initial dose of the drug or after a dosage increase. This effect may occur in up to 50% of patients, especially in patients who are already receiving a diuretic. After the first few doses, patients develop a tolerance to this marked hypotensive response.

Combined α_1 and β Blockers

Carvedilol (see Chapter 12) is a nonselective β blocker with α_1 -antagonist activity. Carvedilol is approved for the treatment of hypertension and symptomatic heart failure. The ratio of α_1 - to β -antagonist potency for carvedilol is approximately 1:10. The drug dissociates slowly from its receptor, explaining why the duration of action is longer than the short $t_{1/2}$ (2.2 h) and why its effect can hardly be overcome by catecholamines. Carvedilol undergoes oxidative metabolism and glucuronidation in the liver; the oxidative metabolism occurs via CYP2D6. As with labetalol, the long-term efficacy and side effects of carvedilol in hypertension are predictable based on its properties as a β and α_1 blocker. Carvedilol reduces mortality in patients with congestive heart failure (Chapter 29). Due to the vasodilating effect, it is a β blocker of choice in patients with peripheral artery disease.

Labetalol (see Chapter 12) is an equimolar mixture of four stereoisomers. One isomer is an α_1 blocker, another is a nonselective β blocker with partial agonist activity, and the other two isomers are inactive. Labetalol has efficacy and adverse effects that would be expected with any combination of an α_1 and a β blocker. It has the disadvantages that are inherent

in fixed-dose combination products: The extent of α_1 - to β -blockade is somewhat unpredictable and varies from patient to patient. Labetalol is FDA-approved for eclampsia, preeclampsia, hypertension, and hypertensive emergencies. The main indication for labetalol is hypertension in pregnancy, for which it is one of the few compounds known to be safe (Magee et al., 2016).

Centrally Acting Sympatholytic Drugs

Methyldopa

Methyldopa, a centrally acting antihypertensive agent, is a prodrug that exerts its antihypertensive action via an active metabolite. Although used frequently as an antihypertensive agent in the past, methyldopa's adverse effect profile limits its current use largely to treatment of hypertension in pregnancy, where it has a record for safety.

Methyldopa (α -methyl-3,4-dihydroxy-L-phenylalanine), an analogue of DOPA, is metabolized by the L-aromatic amino acid decarboxylase in adrenergic neurons to α -methyldopamine, which then is converted to α -methylnorepinephrine, the pharmacologically active metabolite. α -Methylnorepinephrine is stored in the secretory vesicles of adrenergic neurons, substituting for NE, such that the stimulated adrenergic neuron now discharges α -methylnorepinephrine instead of NE. α -Methylnorepinephrine acts in the CNS to inhibit adrenergic neuronal outflow from the brainstem, probably via acting as an agonist at presynaptic α_2 adrenergic receptors in the brainstem, attenuating NE release and thereby reducing the output of vasoconstrictor adrenergic signals to the peripheral sympathetic nervous system.

ADME. Because methyldopa is a prodrug that is metabolized in the brain to the active form, its C_p has less relevance for its effects than that for many other drugs. C_{pmax} occurs 2–3 h following an oral dose. The drug is eliminated with a $t_{1/2}$ of about 2 h. Methyldopa is excreted in the urine primarily as the sulfate conjugate (50%–70%) and as the parent drug (25%). Other minor metabolites include methyldopamine, methylnorepinephrine, and their O-methylated products. The $t_{1/2}$ of methyldopa is prolonged to 4–6 h in patients with renal failure.

Despite its rapid absorption and short $t_{1/2}$, the peak effect of methyldopa is delayed for 6–8 h, even after intravenous administration, and the duration of action of a single dose is usually about 24 h; this permits once- or twice-daily dosing. The discrepancy between the effects of methyldopa and the measured concentrations of the drug in plasma is most likely related to the time required for transport into the CNS, conversion to the active metabolite storage of α -methyl NE, and its subsequent release in the vicinity of relevant α_2 receptors in the CNS. Methyldopa is a good example of a complex relationship between a drug's pharmacokinetics and its pharmacodynamics. Patients with renal failure are more sensitive to the antihypertensive effect of methyldopa, but it is not known if this is due to alteration in excretion of the drug or to an increase in transport into the CNS.

Therapeutic Uses. Methyldopa is a preferred drug for treatment of hypertension during pregnancy based on its effectiveness and safety for both mother and fetus (Magee et al., 2016). The usual initial dose of methyldopa is 250 mg twice daily; there is little additional effect with doses greater than 2 g/d. Administration of a single daily dose of methyldopa at bedtime minimizes sedative effects, but administration twice daily is required for some patients.

Adverse Effects and Precautions. Methyldopa produces sedation that is largely transient. A diminution in psychic energy may persist in some patients, and depression occurs occasionally. Methyldopa may produce dryness of the mouth. Other adverse effects include diminished libido, parkinsonian signs, and hyperprolactinemia that may become sufficiently pronounced to cause gynecomastia and galactorrhea. Methyldopa may precipitate severe bradycardia and sinus arrest.

Methyldopa also produces some adverse effects that are not related to its therapeutic action in the CNS. Hepatotoxicity, sometimes associated with fever, is an uncommon but potentially serious toxic effect of methyldopa. At least 20% of patients who receive methyldopa for a year

develop a positive Coombs test (antiglobulin test) that is due to autoantibodies directed against the Rh antigen on erythrocytes. The development of a positive Coombs test is not necessarily an indication to stop treatment with methyl dopa; however, 1%–5% of these patients will develop a hemolytic anemia that requires prompt discontinuation of the drug. The Coombs test may remain positive for as long as a year after discontinuation of methyl dopa, but the hemolytic anemia usually resolves within a matter of weeks. Severe hemolysis may be attenuated by treatment with glucocorticoids. Adverse effects that are even rarer include leukopenia, thrombocytopenia, red cell aplasia, lupus erythematosus–like syndrome, lichenoid and granulomatous skin eruptions, myocarditis, retroperitoneal fibrosis, pancreatitis, diarrhea, and malabsorption.

Clonidine and Moxonidine

The detailed pharmacology of the α_2 adrenergic agonists clonidine and moxonidine is discussed in Chapter 12. These drugs stimulate α_{2A} adrenergic receptors in the brainstem, resulting in a reduction in sympathetic outflow from the CNS (MacMillan et al., 1996). The hypotensive effect correlates directly with the decrease in plasma concentrations of NE. Patients who have had a spinal cord transection above the level of the sympathetic outflow tracts do not display a hypotensive response to clonidine. At doses higher than those required to stimulate central α_{2A} receptors, these drugs can activate α_{2B} receptors on vascular smooth muscle cells (MacMillan et al., 1996). This effect accounts for the initial vasoconstriction that is seen when overdoses of these drugs are taken and may be responsible for the loss of therapeutic effect that is observed with high doses. A major limitation in the use of these drugs is the paucity of information about their efficacy in reducing the risk of cardiovascular consequences of hypertension.

Pharmacological Effects. The α_2 adrenergic agonists lower arterial pressure by effects on both cardiac output and peripheral resistance. In the supine position, when the sympathetic tone to the vasculature is low, the major effect is a reduction in heart rate and stroke volume; however, in the upright position, when sympathetic outflow to the vasculature is normally increased, these drugs reduce vascular resistance. This action may lead to postural hypotension. The decrease in cardiac sympathetic tone leads to a reduction in myocardial contractility and heart rate that could promote congestive heart failure in susceptible patients.

Therapeutic Uses. The CNS effects are such that this class of drugs is not a leading option for monotherapy of hypertension. Indeed, there is no fixed place for these drugs in the treatment of hypertension. They effectively lower blood pressure in some patients who have not responded adequately to combinations of other agents. The greater clinical experience exists with clonidine. A recent study with moxonidine in patients with hypertension and paroxysmal atrial fibrillation indicated that the drug reduced the incidence of atrial fibrillation (Giannopoulos et al., 2014). Clonidine may be effective in reducing early morning hypertension in patients treated with standard antihypertensives. Overall, enthusiasm for α_2 receptor antagonists is diminished by the relative absence of evidence demonstrating reduction in risk of adverse cardiovascular events.

Clonidine has been used in hypertensive patients for the diagnosis of pheochromocytoma. The failure of clonidine to suppress the plasma concentration of NE to less than 500 pg/mL 3 h after an oral dose of 0.3 mg of clonidine suggests the presence of such a tumor. A modification of this test, wherein overnight urinary excretion of NE and epinephrine is measured after administration of a 0.3-mg dose of clonidine at bedtime, may be useful when results based on plasma NE concentrations are equivocal.

Adverse Effects and Precautions. Many patients experience persistent and sometimes intolerable adverse effects with these drugs. Sedation and xerostomia are prominent adverse effects. The xerostomia may be accompanied by dry nasal mucosa, dry eyes, and swelling and pain of the parotid gland. Postural hypotension and erectile dysfunction may be prominent in some patients. Clonidine may produce a lower incidence of dry mouth and sedation when given transdermally, perhaps because high peak concentrations are avoided. Moxonidine has additional activity at central imidazoline receptors and may produce less sedation than clonidine, but

direct comparisons are lacking. Less-common CNS side effects include sleep disturbances with vivid dreams or nightmares, restlessness, and depression. Cardiac effects related to the sympatholytic action of these drugs include symptomatic bradycardia and sinus arrest in patients with dysfunction of the SA node and AV block in patients with AV nodal disease or in patients taking other drugs that depress AV conduction. Some 15%–20% of patients who receive transdermal clonidine may develop contact dermatitis.

Sudden discontinuation of clonidine and related α_2 adrenergic agonists may cause a withdrawal syndrome consisting of headache, apprehension, tremors, abdominal pain, sweating, and tachycardia. Arterial blood pressure may rise to levels above those present prior to treatment, but the withdrawal syndrome may occur in the absence of an overshoot in pressure. Symptoms typically occur 18–36 h after the drug is stopped and are associated with increased sympathetic discharge, as evidenced by elevated plasma and urine concentrations of catecholamines and metabolites. The frequency of occurrence of the withdrawal syndrome is not known, but withdrawal symptoms are likely dose related and more dangerous in patients with poorly controlled hypertension. Rebound hypertension also has been seen after discontinuation of transdermal administration of clonidine (Metz et al., 1987).

Treatment of the withdrawal syndrome depends on the urgency of reducing the arterial blood pressure. In the absence of life-threatening target organ damage, patients can be treated by restoring the use of clonidine. If a more rapid effect is required, *sodium nitroprusside* or a combination of an α and β blocker is appropriate. β Blockers should not be used alone in this setting because they may accentuate the hypertension by allowing unopposed α adrenergic vasoconstriction caused by activation of the sympathetic nervous system and elevated circulating catecholamines.

Because perioperative hypertension has been described in patients in whom clonidine was withdrawn the night before surgery, surgical patients who are being treated with an α_2 adrenergic agonist either should be switched to another drug prior to elective surgery or should receive their morning dose or transdermal clonidine prior to the procedure. All patients who receive one of these drugs should be warned of the potential danger of discontinuing the drug abruptly, and patients suspected of being noncompliant with medications should not be given α_2 adrenergic agonists for hypertension.

Adverse drug interactions with α_2 adrenergic agonists are rare. Diuretics predictably potentiate the hypotensive effect of these drugs. Tricyclic antidepressants may inhibit the antihypertensive effect of clonidine, but the mechanism of this interaction is not known.

Reserpine

Reserpine is an alkaloid extracted from the root of *Rauwolfia serpentina*, a climbing shrub indigenous to India. Ancient Hindu Ayurvedic writings describe medicinal uses of the plant; Sen and Bose described its use in the Indian biomedical literature. However, rauwolfia alkaloids were not used in Western medicine until the mid-1950s. Reserpine was the first drug found to interfere with the function of the sympathetic nervous system in humans, and its use began the modern era of effective pharmacotherapy of hypertension.

Mechanism of Action. Reserpine binds tightly to adrenergic storage vesicles in central and peripheral adrenergic neurons and remains bound for prolonged periods of time. The interaction inhibits the vesicular catecholamine transporter VMAT2, so that nerve endings lose their capacity to concentrate and store NE and dopamine. Catecholamines leak into the cytoplasm, where they are metabolized. Consequently, little or no active transmitter is released from nerve endings, resulting in a pharmacological sympathectomy. Recovery of sympathetic function requires synthesis of new storage vesicles, which takes days to weeks after discontinuation of the drug. Because reserpine depletes amines in the CNS as well as in the peripheral adrenergic neuron, it is probable that its antihypertensive effects are related to both central and peripheral actions.

Pharmacological Effects. Both cardiac output and peripheral vascular resistance are reduced during long-term therapy with reserpine.

ADME. Few data are available on the pharmacokinetic properties of reserpine because of the lack of an assay capable of detecting low concentrations of the drug or its metabolites. Reserpine that is bound to isolated storage vesicles cannot be removed by dialysis, indicating that the binding is not in equilibrium with the surrounding medium. Because of the irreversible nature of reserpine binding, the amount of drug in plasma is unlikely to bear any consistent relationship to drug concentration at the site of action. Free reserpine is entirely metabolized; therefore, none of the parent drug is excreted unchanged.

Toxicity and Precautions. Most adverse effects of reserpine are due to its effect on the CNS. Sedation and inability to concentrate or perform complex tasks are the most common adverse effects. More serious is the occasional psychotic depression that can lead to suicide. Depression usually appears insidiously over many weeks or months and may not be attributed to the drug because of the delayed and gradual onset of symptoms. Reserpine must be discontinued at the first sign of depression. Reserpine-induced depression may last several months after the drug is discontinued. The risk of depression is likely dose related. Depression is uncommon, but not unknown, with doses of 0.25 mg/d or less. The drug should never be given to patients with a history of depression. Other adverse effects include nasal stuffiness and exacerbation of peptic ulcer disease, which is uncommon with small oral doses.

Therapeutic Uses. Reserpine at low doses, in combination with diuretics, is effective in the treatment of hypertension, especially in the elderly. Several weeks are necessary to achieve maximum effect. In elderly patients with isolated systolic hypertension, reserpine (at 0.05 mg/d) was used as an alternative to atenolol together with a diuretic (Perry et al., 2000; SHEP Cooperative Research Group, 1991). However, with the availability of newer drugs that have proven life-prolonging effects and are well tolerated, the use of reserpine has largely diminished, and it is no longer recommended for the treatment of hypertension (Mancia et al., 2013).

Ca²⁺ Channel Blockers

The Ca²⁺ channel-blocking agents are an important group of drugs for the treatment of hypertension. The general pharmacology of these drugs is presented in Chapter 27. The basis for their use in hypertension comes from the understanding that hypertension generally is the result of increased peripheral vascular resistance. Because contraction of vascular smooth muscle is dependent on the free intracellular concentration of Ca²⁺, inhibition of transmembrane movement of Ca²⁺ through voltage-sensitive Ca²⁺ channels can decrease the total amount of Ca²⁺ that reaches intracellular sites. Indeed, all of the Ca²⁺ channel blockers lower blood pressure by relaxing arteriolar smooth muscle and decreasing peripheral vascular resistance. As a consequence of a decrease in peripheral vascular resistance, the Ca²⁺ channel blockers evoke a baroreceptor reflex-mediated sympathetic discharge. In the case of the dihydropyridines, tachycardia may occur from the adrenergic stimulation of the SA node; this response is generally quite modest except when the drug is administered rapidly. Tachycardia is typically minimal or absent with verapamil and diltiazem because of the direct negative chronotropic effect of these two drugs. Indeed, the concurrent use of a β blocker may magnify negative chronotropic effects of these drugs or cause heart block in susceptible patients. Consequently, the concurrent use of β blockers with either verapamil or diltiazem should be avoided.

The Ca²⁺ channel blockers are among the preferred drugs for the treatment of hypertension, both as monotherapy and in combination with other antihypertensives, because they have a well-documented effect on cardiovascular end points and total mortality. The combination of amlodipine and the ACE inhibitors perindopril proved superior to the combination of the β blocker atenolol and hydrochlorothiazide (Dahlof et al., 2005), and amlodipine was superior to hydrochlorothiazide as the combination partner for the ACEI benazepril (Jamerson et al., 2008).

The Ca²⁺ channel blockers most studied and used for the treatment of hypertension are long-acting dihydropyridines with sufficient 24-h

efficacy at once-daily dosing (e.g., amlodipine, felodipine, lercanidipine, and sustained-release formulations of others). Peripheral edema (ankle edema) are the main unwanted effects. Fewer patients appear to experience this harmless, but possibly distracting, side effect with newer compounds such as lercanidipine (Makarounas-Kirchmann et al., 2009), but the commonly used combination with RAS inhibitors has the same effect (Messerli et al., 2000). Immediate-release nifedipine and other short-acting dihydropyridines have no place in the treatment of hypertension. Verapamil and diltiazem also have short half-lives, more cardiac side effects, and a high drug interaction potential (verapamil > diltiazem) and are therefore not first-line antihypertensives.

Compared with other classes of antihypertensive agents, there may be a greater frequency of achieving blood pressure control with Ca²⁺ channel blockers as monotherapy in elderly subjects and in African Americans, population groups in which the low renin status is more prevalent. However, intrasubject variability is more important than relatively small differences between population groups. Ca²⁺ channel blockers are effective in lowering blood pressure and decreasing cardiovascular events in the elderly with isolated systolic hypertension (Staessen et al., 1997) and may be a preferred treatment in these patients.

Inhibitors of the Renin-Angiotensin System

Angiotensin II is an important regulator of cardiovascular function (see Chapter 26). The capacity to reduce the effects of AngII with pharmacological agents has been an important advance in the treatment of hypertension and its sequelae. Chapter 26 presents the basic physiology of the RAS and the pharmacology of inhibitors of the RAS. Table 26–2 summarizes the effects of a variety of antihypertensive agents on components of the RAS and warrants careful study.

Angiotensin-Converting Enzyme Inhibitors

The ability to reduce levels of AngII with orally effective ACE inhibitors represents an important advance in the treatment of hypertension. Captopril was the first such agent to be developed for the treatment of hypertension. Since then, enalapril, lisinopril, quinapril, ramipril, benazepril, moexipril, fosinopril, trandolapril, and perindopril have become available. These drugs are useful for the treatment of hypertension because of their efficacy and a favorable adverse effect profile that enhances patient adherence. Chapter 26 presents the pharmacology of ACE inhibitors in detail.

The ACE inhibitors appear to confer a special advantage in the treatment of patients with diabetes, slowing the development and progression of diabetic glomerulopathy. They also are effective in slowing the progression of other forms of chronic renal disease, such as glomerulosclerosis, which coexists with hypertension in many patients. An ACE inhibitor is the preferred initial agent in these patients. Patients with hypertension and ischemic heart disease are candidates for treatment with ACE inhibitors. Administration of ACE inhibitors in the immediate post-MI period has been shown to improve ventricular function and reduce morbidity and mortality (see Chapter 27).

The endocrine consequences of inhibiting the biosynthesis of AngII are of importance in a number of facets of hypertension treatment. Because ACE inhibitors blunt the rise in aldosterone concentrations in response to Na⁺ loss, the normal role of aldosterone to oppose diuretic-induced natriuresis is diminished. Consequently, ACE inhibitors tend to enhance the efficacy of diuretic drugs. This means that even very small doses of diuretics may substantially improve the antihypertensive efficacy of ACE inhibitors; conversely, the use of high doses of diuretics together with ACE inhibitors may lead to excessive reduction in blood pressure and to Na⁺ loss in some patients.

Attenuation of aldosterone production by ACE inhibitors also influences K⁺ homeostasis; there is a small and clinically unimportant rise in serum K⁺ when these agents are used alone in patients with normal renal function. However, substantial retention of K⁺ can occur in some patients with renal insufficiency. Furthermore, the potential for developing hyperkalemia should be considered when ACE inhibitors are used with other drugs that can cause K⁺ retention, including the K⁺-sparing

diuretics (amiloride, triamterene, and the MRAs spironolactone and eplerenone), NSAIDs, K⁺ supplements, and β blockers. Some patients with diabetic nephropathy may be at greater risk of hyperkalemia.

There are several cautions in the use of ACE inhibitors in patients with hypertension. Cough is a common (~5%) adverse effect and a reason to switch to AT₁ receptor blockers. Angioedema is a rare but serious and potentially fatal adverse effect of the ACE inhibitors. Patients starting treatment with these drugs should be explicitly warned to discontinue their use with the advent of any signs of angioedema. Due to the risk of severe fetal adverse effects, ACE inhibitors are contraindicated during pregnancy, a fact that should be communicated to women of childbearing age.

In most patients, there is little or no appreciable change in glomerular filtration rate following the administration of ACE inhibitors. However, in renovascular hypertension, the glomerular filtration rate is generally maintained as the result of increased resistance in the postglomerular arteriole caused by AngII. Accordingly, in patients with bilateral renal artery stenosis or stenosis in a sole kidney, the administration of an ACE inhibitor will reduce the filtration fraction and cause a substantial reduction in glomerular filtration rate. In some patients with preexisting renal disease, the glomerular filtration may decrease with an ACE inhibitor. Thus, it should be kept in mind that ACE inhibitors, while inhibiting the progression of chronic kidney disease, carry a risk of reversible drug-induced impairment of glomerular filtration. Serum creatinine levels and K⁺ should therefore be monitored in the first weeks after establishing therapy. Increases of serum creatinine of greater than 20% predict the presence of renal artery stenosis (van de Ven et al., 1998) and are a reason to discontinue the treatment with ACE inhibitors.

The ACE inhibitors lower the blood pressure to some extent in most patients with hypertension. Following the initial dose of an ACE inhibitor, there may be a considerable fall in blood pressure in some patients; this response to the initial dose is a function of plasma renin activity prior to treatment. The potential for a large initial drop in blood pressure is the reason for using a low dose to initiate therapy, especially in patients who may have a very active RAS supporting blood pressure, such as patients with diuretic-induced volume contraction or congestive heart failure. It should also be realized that, generally, no reason exists for normalizing blood pressure in a few days in patients with a lifelong disease. Attempts to do so increase the frequency of side effects and decrease compliance. With continuing treatment, there usually is a progressive fall in blood pressure that in most patients does not reach a maximum for several weeks. The blood pressure seen during chronic treatment is not strongly correlated with the pretreatment plasma renin activity. Young and middle-aged Caucasian patients have a higher probability of responding to ACE inhibitors; elderly African American patients as a group are more resistant to the hypotensive effect of these drugs. While most ACE inhibitors are approved for once-daily dosing for hypertension, a significant fraction of patients has a response that lasts less than 24 h and may require twice-daily dosing for adequate control of blood pressure (e.g., enalapril, ramipril). Captopril, with its very short duration of action, is not a good choice in the treatment of hypertension.

AT₁ Receptor Blockers

The importance of AngII in regulating cardiovascular function has led to the development of nonpeptide antagonists of the AT₁ subtype of AngII receptor. Losartan, candesartan, irbesartan, valsartan, telmisartan, olmesartan, and eprosartan have been approved for the treatment of hypertension. The pharmacology of AT₁ receptor blockers is presented in detail in Chapter 26. By antagonizing the effects of AngII, these agents relax smooth muscle and thereby promote vasodilation, increase renal salt and water excretion, reduce plasma volume, and decrease cellular hypertrophy. Given the central role of AT₁ receptors for the action of AngII, it is not surprising that AT₁ receptor blockers have the same pharmacological profile as ACE inhibitors with one notable exception. AT₁ receptor blockers do not inhibit the ACE-mediated degradation of bradykinin and substance P and thereby cause no cough.

Initial hopes for superiority of AT₁ receptor blockers over ACE inhibitors have not been fulfilled. They were based on the idea that the AT₂

subtype elicits beneficial effects of AngII (e.g., antigrowth and antiproliferative responses). Because the AT₁ receptor mediates feedback inhibition of renin release, renin and AngII concentrations are increased during AT₁ receptor antagonism, leading to increased stimulation of uninhibited AT₂ receptors. Despite considerable interest, not much evidence supports any extra benefit from AT₁ blockade versus ACE inhibition, and attempts to show greater reductions in cardiovascular events by AT₁ receptor blockers or by the combination of an AT₁ receptor blocker plus an ACE inhibitor over ACE inhibitor alone failed. ON-TARGET, one of the largest studies to date in patients with high vascular risk (70% hypertension) showed that telmisartan caused less cough and angioedema than ramipril (1.1% vs. 4.2%, and 0.1% vs. 0.3%) but had identical efficacy. The combination, although not more efficacious, was associated with greater worsening of renal function (13.5% vs. 10.2%), hypotension, and syncope (Yusuf et al., 2008).

Therapeutic Uses

The AT₁ receptor blockers have a sufficient 24-h effect at once-daily dosing (except losartan). The full effect of AT₁ receptor blockers on blood pressure typically is not observed until about 4 weeks after the initiation of therapy. If blood pressure is not controlled by an AT₁ receptor blocker alone, a second drug acting by a different mechanism (e.g., a diuretic or Ca²⁺ channel blocker) may be added. The combination of an ACE inhibitor and an AT₁ receptor blocker is not recommended for the treatment of hypertension.

Adverse Effects and Precautions

Adverse effects of ACE inhibitors that result from inhibiting AngII-related functions (see previous discussion and Chapter 26) also occur with AT₁ receptor blockers. These include hypotension, hyperkalemia, and reduced renal function, including that associated with bilateral renal artery stenosis and stenosis in the artery of a solitary kidney. Hypotension is most likely to occur in patients in whom the blood pressure is highly dependent on AngII, including those with volume depletion (e.g., with diuretics), renovascular hypertension, cardiac failure, and cirrhosis; in such patients, initiation of treatment with low doses and attention to blood volume are essential. Hyperkalemia may occur in conjunction with other factors that alter K⁺ homeostasis, such as renal insufficiency, ingestion of excess K⁺, and the use of drugs that promote K⁺ retention. Cough and angioedema occur rarely. ACE inhibitors and AT₁ receptor blockers should not be administered during pregnancy and should be discontinued as soon as pregnancy is detected.

Direct Renin Inhibitors

Aliskiren, the first orally effective direct renin inhibitor is FDA-approved for the treatment of hypertension. The detailed pharmacology of aliskiren is covered in Chapter 26. Aliskiren is an effective antihypertensive drug but has not been studied sufficiently in monotherapy of hypertension. A large study comparing a placebo or aliskiren added to a background of an ARB or an ACE inhibitor was stopped prematurely for a trend toward increased cardiovascular events in the aliskiren treatment group (McMurray et al., 2012). The combination also induced more renal worsening, hypotension, and hyperkalemia. This mirrors previous studies with ARB/ACE inhibitor combinations and indicates that complete blockade of the RAS system achieves more harm than benefit.

Pharmacology

The initial renin inhibitors were peptide analogues of sequences either in renin itself or included the renin cleavage site in angiotensinogen. While effective in inhibiting renin and lowering blood pressure, these peptide analogues were effective only parenterally. However, aliskiren is effective following oral administration; it directly and competitively inhibits the catalytic activity of renin, leading to diminished production of AngI, AngII, and aldosterone—with a resulting fall in blood pressure. Aliskiren along with ACE inhibitors and AT₁ receptor blockers lead to an adaptive increase in the plasma concentrations of renin; however, because aliskiren inhibits renin activity, plasma renin activity does not increase as occurs with these other classes of drugs (Table 26–2). Nevertheless, the

aldosterone escape known from ACE inhibitors and AT₁ receptor blockers has also been observed under continuous treatment with aliskiren (Bomback et al., 2012).

ADME

Aliskiren is poorly absorbed, with an oral bioavailability of less than 3%. Taking the drug with a high-fat meal may substantially decrease plasma concentrations. Aliskiren has an elimination $t_{1/2}$ of at least 24 h. Elimination of the drug may be primarily through hepatobiliary excretion with limited metabolism via CYP3A4.

Therapeutic Uses

Given the unclear effectiveness and safety of aliskiren monotherapy, the place of this drug in the treatment of hypertension remains clouded. The combination of aliskiren with other RAS inhibitors is contraindicated, and the European Society of Cardiology guideline does not recommend its use (Mancia et al., 2013).

Toxicity and Precautions

Aliskiren is generally well tolerated. Diarrhea may occur, especially at higher-than-recommended doses. The incidence of cough may be higher than for placebo but substantially less than found with ACE inhibitors. Aliskiren has been associated with several cases of angioedema in clinical trials (Frampton and Curran, 2007). Drugs acting on the RAS may damage the fetus and should not be used in pregnant women.

Vasodilators

Hydralazine

Hydralazine (1-hydrazinophthalazine) was one of the first orally active antihypertensive drugs to be marketed in the U.S.; however, the drug initially was used infrequently because of tachycardia and tachyphylaxis. With a better understanding of the compensatory cardiovascular responses that accompany use of arteriolar vasodilators, hydralazine was combined with sympatholytic agents and diuretics with greater therapeutic success. Nonetheless, its role in the treatment of hypertension has markedly diminished with the introduction of new classes of antihypertensive agents.

Mechanism of Action

Hydralazine directly relaxes arteriolar smooth muscle with little effect on venous smooth muscle. The molecular mechanisms mediating this action are not clear but may ultimately involve a reduction in intracellular Ca²⁺ concentrations. While a variety of changes in cellular signaling pathways are influenced by hydralazine, precise molecular targets that explain its capacity to dilate arteries remain uncertain. Potential mechanisms include inhibition of inositol triphosphate–induced release of Ca²⁺ from intracellular storage sites, opening of high-conductance Ca²⁺-activated K⁺ channels in smooth muscle cells, and activation of an arachidonic acid, COX, and prostacyclin pathway that would explain sensitivity to NSAIDs (Maille et al., 2016).

Hydralazine-induced vasodilation is associated with powerful stimulation of the sympathetic nervous system, likely due to baroreceptor-mediated reflexes, resulting in increased heart rate and contractility, increased plasma renin activity, and fluid retention. These effects tend to counteract the antihypertensive effect of hydralazine.

Pharmacological Effects

Most of the effects of hydralazine are confined to the cardiovascular system. The decrease in blood pressure after administration of hydralazine is associated with a selective decrease in vascular resistance in the coronary, cerebral, and renal circulations, with a smaller effect in skin and muscle. Because of preferential dilation of arterioles over veins, postural hypotension is not a common problem; hydralazine lowers blood pressure similarly in the supine and upright positions.

ADME

Following oral administration, hydralazine is well absorbed via the GI tract. Hydralazine is *N*-acetylated in the bowel and the liver, contributing

to the drug's low bioavailability (16% in fast acetylators and 35% in slow acetylators). The rate of acetylation is genetically determined; about half of the U.S. population acetylates rapidly, and half does so slowly. The acetylated compound is inactive; thus, the dose necessary to produce a systemic effect is larger in fast acetylators. Because the systemic clearance exceeds hepatic blood flow, extrahepatic metabolism must occur. Indeed, hydralazine rapidly combines with circulating α -keto acids to form hydrazones, and the major metabolite recovered from the plasma is hydralazine pyruvic acid hydrazone. This metabolite has a longer $t_{1/2}$ than hydralazine but appears to be relatively inactive. Although the rate of acetylation is an important determinant of the bioavailability of hydralazine, it does not play a role in the systemic elimination of the drug, probably because hepatic clearance is so high that systemic elimination is principally a function of hepatic blood flow. The peak concentration of hydralazine in plasma and the peak hypotensive effect of the drug occur within 30–120 min of ingestion. Although its $t_{1/2}$ in plasma is about 1 h, the hypotensive effect of hydralazine can last as long as 12 h. There is no clear explanation for this discrepancy.

Therapeutic Uses

Hydralazine is no longer a first-line drug in the treatment of hypertension on account of its relatively unfavorable adverse-effect profile. The drug has a role as a combination pill containing isosorbide dinitrate (BiDiI) in the treatment of heart failure (see Chapter 29). Hydralazine may have utility in the treatment of some patients with severe hypertension, can be part of evidence-based therapy in patients with congestive heart failure (in combination with nitrates for patients who cannot tolerate ACE inhibitors or AT₁ receptor blockers), and may be useful in the treatment of hypertensive emergencies, especially preeclampsia, in pregnant women. Hydralazine should be used with great caution in elderly patients and in hypertensive patients with CAD because of the possibility of precipitating myocardial ischemia due to reflex tachycardia. The usual oral dosage of hydralazine is 25–100 mg twice daily. Off-label twice-daily administration is as effective as administration four times a day for control of blood pressure, regardless of acetylator phenotype. The maximum recommended dose of hydralazine is 200 mg/d to minimize the risk of drug-induced lupus syndrome.

Toxicity and Precautions

Two types of adverse effects occur after the use of hydralazine. The first, which are extensions of the pharmacological effects of the drug, include headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, and angina pectoris. Myocardial ischemia can occur on account of increased O₂ demand induced by the baroreceptor reflex–induced stimulation of the sympathetic nervous system. Following parenteral administration to patients with CAD, the myocardial ischemia may be sufficiently severe and protracted to cause frank MI. For this reason, parenteral administration of hydralazine is not advisable in hypertensive patients with CAD, hypertensive patients with multiple cardiovascular risk factors, or older patients. In addition, if the drug is used alone, there may be salt retention with development of high-output congestive heart failure. When combined with a β blocker and a diuretic, hydralazine is better tolerated, although adverse effects such as headache are still commonly described and may necessitate discontinuation of the drug.

The second type of adverse effect is caused by immunological reactions, of which the drug-induced lupus syndrome is the most common. Administration of hydralazine also can result in an illness that resembles serum sickness, hemolytic anemia, vasculitis, and rapidly progressive glomerulonephritis. The mechanism of these autoimmune reactions is unknown, although it may involve the drug's capacity to inhibit DNA methylation (Arce et al., 2006). The drug-induced lupus syndrome usually occurs after at least 6 months of continuous treatment with hydralazine, and its incidence is related to dose, gender, acetylator phenotype, and race. In one study, after 3 years of treatment with hydralazine, drug-induced lupus occurred in 10% of patients who received 200 mg daily, 5% who received 100 mg daily, and none who received 50 mg daily (Cameron and Ramsay, 1984). The incidence is four times higher in women than in men, and the syndrome is seen more commonly in Caucasians than in African Americans. The rate of conversion to a positive antinuclear antibody

test is faster in slow acetylators than in rapid acetylators, suggesting that the native drug or a nonacetylated metabolite is responsible. However, the majority of patients with positive antinuclear antibody tests do not develop the drug-induced lupus syndrome, and hydralazine need not be discontinued unless clinical features (arthralgia, arthritis, and fever) of the syndrome appear. Discontinuation of the drug is all that is necessary for most patients with the hydralazine-induced lupus syndrome, but symptoms may persist in a few patients, and administration of corticosteroids may be necessary.

Hydralazine also can produce a pyridoxine-responsive polyneuropathy. The mechanism appears to be related to the ability of hydralazine to combine with pyridoxine to form a hydrazone. This side effect is unusual with doses of 200 mg/d or less.

K_{ATP} Channel Openers: Minoxidil

The discovery in 1965 of the hypotensive action of minoxidil was a significant advance in the treatment of hypertension; the drug has proven to be efficacious in patients with the most severe and drug-resistant forms of hypertension.

Locus and Mechanism of Action

Minoxidil is not active *in vitro* but must be metabolized by hepatic sulfotransferase to the active molecule, minoxidil *N*-O sulfate; the formation of this active metabolite is a minor pathway in the metabolic disposition of minoxidil. Minoxidil sulfate relaxes vascular smooth muscle in isolated systems where the parent drug is inactive. Minoxidil sulfate activates the ATP-modulated K⁺ channel permitting K⁺ efflux, and causes hyperpolarization and relaxation of smooth muscle.

Pharmacological Effects

Minoxidil produces arteriolar vasodilation with essentially no effect on the capacitance vessels; the drug resembles hydralazine and diazoxide in this regard. Minoxidil increases blood flow to skin, skeletal muscle, the GI tract, and the heart more than to the CNS. The disproportionate increase in blood flow to the heart may have a metabolic basis in that administration of minoxidil is associated with a reflex increase in myocardial contractility and in cardiac output. The cardiac output can increase markedly, as much as 3- to 4-fold. The principal determinant of the elevation in cardiac output is the action of minoxidil on peripheral vascular resistance to enhance venous return to the heart; by inference from studies with other drugs, the increased venous return probably results from enhancement of flow in the regional vascular beds, with a fast time constant for venous return to the heart (Ogilvie, 1985). The adrenergically mediated increase in myocardial contractility contributes to the increased cardiac output but is not the predominant causal factor.

The effects of minoxidil on the kidney are complex. Minoxidil is a renal artery vasodilator, but systemic hypotension produced by the drug occasionally can decrease renal blood flow. Renal function usually improves in patients who take minoxidil for the treatment of hypertension, especially if renal dysfunction is secondary to hypertension. Minoxidil is a potent stimulator of renin secretion. This effect is mediated by a combination of renal sympathetic stimulation and activation of the intrinsic renal mechanisms for regulation of renin release.

Discovery of K⁺_{ATP} channels in a variety of cell types and in mitochondria is prompting consideration of K⁺_{ATP} channel modulators as therapeutic agents in many cardiovascular diseases (Pollesello and Mebazaa, 2004). Minoxidil, similar to other K⁺_{ATP} channel openers such as diazoxide, pinacidil, and nicorandil, may have protective effects on the heart during ischemia/reperfusion (Sato et al., 2004). It also promotes the synthesis of vascular elastin in rats (Slove et al., 2013), a potentially interesting therapeutic effect.

ADME

Minoxidil is well absorbed from the GI tract. Although peak concentrations of minoxidil in blood occur 1 h after oral administration, the maximal hypotensive effect of the drug occurs later, possibly because formation of the active metabolite is delayed.

The bulk of the absorbed drug is eliminated as a glucuronide; about 20% is excreted unchanged in the urine. The extent of biotransformation of minoxidil to its active metabolite, minoxidil *N*-O sulfate, has not been evaluated in humans. Minoxidil has a plasma *t*_{1/2} of 3–4 h, but its duration of action is 24 h and occasionally even longer. It has been proposed that persistence of minoxidil in vascular smooth muscle is responsible for this discrepancy, but without knowledge of the pharmacokinetic properties of the active metabolite, an explanation for the prolonged duration of action cannot be given.

Therapeutic Uses

Systemic minoxidil is best reserved for the treatment of severe hypertension that responds poorly to other antihypertensive medications, especially in male patients with renal insufficiency. Minoxidil has been used successfully in the treatment of hypertension in both adults and children. Minoxidil should never be used alone; it must be given concurrently with a diuretic to avoid fluid retention, with a sympatholytic drug (e.g., β blocker) to control reflex cardiovascular effects and an inhibitor of the RAS to prevent remodeling effects on the heart. The drug usually is administered either once or twice a day, but some patients may require more frequent dosing for adequate control of blood pressure. The initial daily dose of minoxidil may be as little as 1.25 mg, which can be increased gradually to 40 mg in one or two daily doses.

Adverse Effects and Precautions

The adverse effects of minoxidil, which can be severe, fall into three major categories: fluid and salt retention, cardiovascular effects, and hypertrichosis. Retention of salt and water results from increased proximal renal tubular reabsorption, which is secondary to reduced renal perfusion pressure and to reflex stimulation of renal tubular α adrenergic receptors. Similar antinatriuretic effects can be observed with the other arteriolar dilators (e.g., diazoxide and hydralazine). Although administration of minoxidil causes increased secretion of renin and aldosterone, this is not an important mechanism for retention of salt and water in this case. Fluid retention usually can be controlled by the administration of a diuretic. However, thiazides may not be sufficiently efficacious, and it may be necessary to use a loop diuretic, especially if the patient has any degree of renal dysfunction.

The cardiac consequences of the baroreceptor-mediated activation of the sympathetic nervous system during minoxidil therapy are similar to those seen with hydralazine; there is an increase in heart rate, myocardial contractility, and myocardial O₂ consumption. Thus, myocardial ischemia can be induced by minoxidil in patients with CAD. The cardiac sympathetic responses are attenuated by concurrent administration of a β blocker. The adrenergically induced increase in renin secretion also can be ameliorated by a β blocker or an ACE inhibitor, with enhancement of blood pressure control.

The increased cardiac output evoked by minoxidil has particularly adverse consequences in those hypertensive patients who have left ventricular hypertrophy and diastolic dysfunction. Such poorly compliant ventricles respond suboptimally to increased volume loads, with a resulting increase in left ventricular filling pressure. This probably is a major contributor to the increased pulmonary artery pressure seen with minoxidil (and hydralazine) therapy in hypertensive patients and is compounded by the retention of salt and water caused by minoxidil. Cardiac failure can result from minoxidil therapy in such patients; the potential for this complication can be reduced but not prevented by effective diuretic therapy. Pericardial effusion is an uncommon but serious complication of minoxidil. Mild and asymptomatic pericardial effusion is not an indication for discontinuing minoxidil, but the situation should be monitored closely to avoid progression to tamponade. Effusions usually clear when the drug is discontinued but can recur if treatment with minoxidil is resumed.

Flattened and inverted T waves frequently are observed in the electrocardiogram following the initiation of minoxidil treatment. These are not ischemic in origin and are seen with other drugs that activate K⁺ channels. In model systems, *pinacidil* is associated with a lowered ventricular fibrillation threshold and increased spontaneous ventricular fibrillation in the ischemic canine heart, and minoxidil causes cardiac antiarrhythmias

in the rabbit; whether such findings translate to events in humans is unknown.

Excess hair growth occurs in patients who receive minoxidil for an extended period and is probably a consequence of K^+ channel activation. Growth of hair occurs on the face, back, arms, and legs and is particularly offensive to women. Frequent shaving or depilatory agents can be used to manage this problem. Topical minoxidil is marketed over the counter for the treatment of male pattern baldness and hair thinning and loss on the top of the head in women. The topical use of minoxidil also can cause measurable cardiovascular effects in some individuals.

Other side effects of the drug are rare and include rashes, Stevens-Johnson syndrome, glucose intolerance, serosanguineous bullae, formation of antinuclear antibodies, and thrombocytopenia.

Sodium Nitroprusside

Although sodium nitroprusside has been known since 1850 and its hypotensive effect in humans was described in 1929, its safety and usefulness for the short-term control of severe hypertension were not demonstrated until the mid-1950s. Several investigators subsequently demonstrated that sodium nitroprusside also was effective in improving cardiac function in patients with left ventricular failure (see Chapter 29).

Sodium nitroprusside

Mechanism of Action

Nitroprusside is a nitrovasodilator that acts by releasing NO. NO activates the guanylyl cyclase–cyclic guanosine monophosphate–protein kinase G pathway, leading to vasodilation, mimicking the production of NO by vascular endothelial cells, which is impaired in many hypertensive patients. The mechanism of release of NO from nitroprusside is not clear and likely involves both enzymatic and nonenzymatic pathways. Tolerance develops to *nitroglycerin* but not to nitroprusside. The pharmacology of the organic nitrates, including nitroglycerin, is presented in Chapter 27.

Pharmacological Effects

Nitroprusside dilates both arterioles and venules, and the hemodynamic response to its administration results from a combination of venous pooling and reduced arterial impedance. In subjects with normal left ventricular function, venous pooling affects cardiac output more than does the reduction of afterload; cardiac output tends to fall. In contrast, in patients with severely impaired left ventricular function and diastolic ventricular distention, the reduction of arterial impedance is the predominant effect, leading to a rise in cardiac output (see Chapter 29).

Sodium nitroprusside is a nonselective vasodilator, and regional distribution of blood flow is little affected by the drug. In general, renal blood flow and glomerular filtration are maintained, and plasma renin activity increases. Unlike minoxidil, hydralazine, diazoxide, and other arteriolar vasodilators, sodium nitroprusside usually causes only a modest increase in heart rate and an overall reduction in myocardial O_2 demand.

ADME

Sodium nitroprusside is an unstable molecule that decomposes under strongly alkaline conditions or when exposed to light. The drug must be protected from light and given by continuous intravenous infusion to be effective. Its onset of action is within 30 sec; the peak hypotensive effect occurs within 2 min, and when the infusion of the drug is stopped, the effect disappears within 3 min.

Sodium nitroprusside is available in vials that contain 50 mg. The contents of the vial should be dissolved in 2–3 mL of 5% dextrose in water. Because the compound decomposes in light, only fresh solutions should be used, and the bottle should be covered with an opaque wrapping. The drug must be administered as a controlled continuous infusion, and the

patient must be closely observed. The majority of hypertensive patients respond to an infusion of 0.25–1.5 $\mu\text{g}/\text{kg}/\text{min}$. Higher infusion rates are necessary to produce controlled hypotension in normotensive patients under surgical anesthesia. Patients who are receiving other antihypertensive medications usually require less nitroprusside to lower blood pressure. If infusion rates of 10 $\mu\text{g}/\text{kg}/\text{min}$ do not produce adequate reduction of blood pressure within 10 min, the rate of administration of nitroprusside should be reduced to minimize potential toxicity.

The metabolism of nitroprusside by smooth muscle is initiated by its reduction, which is followed by the release of cyanide and then NO. Cyanide is further metabolized by hepatic rhodanase to form thiocyanate, which is eliminated almost entirely in the urine. The mean elimination $t_{1/2}$ for thiocyanate is 3 days in patients with normal renal function and much longer in patients with renal insufficiency.

Therapeutic Uses

Sodium nitroprusside is used primarily to treat hypertensive emergencies but also can be used in situations when short-term reduction of cardiac preload or afterload is desired. Nitroprusside has been used to lower blood pressure during acute aortic dissection; to improve cardiac output in congestive heart failure, especially in hypertensive patients with pulmonary edema that does not respond to other treatment (see Chapter 29); and to decrease myocardial O_2 demand after acute MI. In addition, nitroprusside is used to induce controlled hypotension during anesthesia to reduce bleeding in surgical procedures. In the treatment of acute aortic dissection, it is important to administer a β blocker with nitroprusside because reduction of blood pressure with nitroprusside alone can increase the rate of rise in pressure in the aorta as a result of increased myocardial contractility, thereby enhancing propagation of the dissection.

Toxicity and Precautions

The short-term adverse effects of nitroprusside are due to excessive vasodilation, with hypotension and its consequences. Close monitoring of blood pressure and the use of a continuous variable-rate infusion pump will prevent an excessive hemodynamic response to the drug in the majority of cases.

Less commonly, toxicity may result from conversion of nitroprusside to cyanide and thiocyanate. Toxic accumulation of cyanide leading to severe lactic acidosis usually occurs when sodium nitroprusside is infused at a rate greater than 5 $\mu\text{g}/\text{kg}/\text{min}$ but also can occur in some patients receiving doses on the order of 2 $\mu\text{g}/\text{kg}/\text{min}$ for a prolonged period. The limiting factor in the metabolism of cyanide appears to be the availability of sulfur-containing substrates in the body (i.e., mainly thiosulfate). The concomitant administration of sodium thiosulfate can prevent accumulation of cyanide in patients who are receiving higher-than-usual doses of sodium nitroprusside; the efficacy of the drug is unchanged. The risk of thiocyanate toxicity increases when sodium nitroprusside is infused for more than 24–48 h, especially if renal function is impaired. Signs and symptoms of thiocyanate toxicity include anorexia, nausea, fatigue, disorientation, and toxic psychosis. The plasma concentration of thiocyanate should be monitored during prolonged infusions of nitroprusside and should not be allowed to exceed 0.1 mg/mL. Rarely, excessive concentrations of thiocyanate may cause hypothyroidism by inhibiting iodine uptake by the thyroid gland. In patients with renal failure, thiocyanate can be removed readily by hemodialysis.

Nitroprusside can worsen arterial hypoxemia in patients with chronic obstructive pulmonary disease because the drug interferes with hypoxic pulmonary vasoconstriction and therefore promotes mismatching of ventilation with perfusion.

Diazoxide

Diazoxide was used in the treatment of hypertensive emergencies but fell out of favor at least in part due to the risk of marked falls in blood pressure when large bolus doses of the drug were used. Other drugs are now preferred for parenteral administration in the control of hypertension. Diazoxide also is administered orally to treat patients with various forms of hypoglycemia (see Chapter 47).

Nonpharmacological Therapy of Hypertension

Nonpharmacological approaches to the treatment of hypertension may suffice in patients with modestly elevated blood pressure. Such approaches also can augment the effects of antihypertensive drugs in patients with more marked initial elevations in blood pressure. The indications and efficacy of various lifestyle modifications in hypertension were reviewed in recent guidelines (James et al., 2014; Mancia et al., 2013).

- Reduction in body weight for people who are modestly overweight or frankly obese may be useful (Goodpaster et al., 2010).
- Restricting sodium consumption lowers blood pressure in some patients.
- Restriction of ethanol intake to modest levels (daily consumption < 20 g in women, < 40 g in men) may lower blood pressure.
- Increased physical activity improves control of hypertension.
- Renal denervation may be effective in patients with well-defined resistant hypertension (Azizi et al., 2015).
- Bariatric surgery in grossly overweight individuals may normalize blood pressure and increase life expectancy (Sjostrom et al., 2007).

Selection of Antihypertensive Drugs in Individual Patients

Choice of antihypertensive drugs for individual patients may be complex; there are many sources of influence that modify therapeutic decisions. While results derived from randomized, controlled clinical trials are the optimal foundation for rational therapeutics, sorting through the multiplicity of those results and addressing how to apply them to an individual patient can be vexing. While therapeutic guidelines can be useful in reaching appropriate therapeutic decisions, it often is difficult for clinicians to apply guidelines at the point of care, and guidelines often do not provide enough information about recommended drugs. In addition, intense marketing of specific drugs to both clinicians and patients may confound optimal decision-making. Moreover, persuading patients to continue taking drugs that may be expensive for an asymptomatic disease is a challenge. Clinicians may be reluctant to prescribe and patients reluctant to consume the number of drugs that may be necessary to adequately control blood pressure. For these and other reasons, perhaps one-half of patients being treated for hypertension have not achieved therapeutic goals in blood pressure lowering.

Choice of an antihypertensive drug should be driven by the likely benefit in an individual patient, taking into account concomitant diseases such as diabetes mellitus, problematic adverse effects of specific drugs, and cost. The last factor is losing relevance as the most important antihypertensive drug classes (diuretics, Ca^{2+} channel blockers, ACE inhibitors/ AT_1 receptor blockers, and β blockers) are out of patent protection and available as low-cost generics.

After a long debate about blood pressure-independent effects of certain antihypertensive drug classes, there is a consensus that blood pressure lowering per se is the most important goal of antihypertensive treatment. This conclusion is based on a number of large comparative prospective trials that, overall, did not show major differences in outcome depending on drug class (reviewed by Mancia et al., 2013). The JNC8 guidelines formulated a preference for an initial therapy with thiazide diuretics, Ca^{2+} channel blockers, and ACE inhibitor/ARB in the general non-black population (including diabetics) and a preference for thiazides and Ca^{2+} channel blockers in black patients (James et al., 2014). The ESC guidelines state that “although meta-analyses occasionally appear, claiming superiority of one class of agents over another for some outcomes, this largely depends on the selection bias of trials, and the largest meta-analyses available do not show clinically relevant differences between drug classes.” They conclude “that diuretics (including thiazides, chlorthalidone and indapamide), β blockers, calcium channel blockers, ACE inhibitors and AT_1 -receptor blockers are all suitable for the initiation and maintenance of antihypertensive treatment, either as monotherapy or in some

combinations” (Mancia et al., 2013). Major guideline recommendations around the world have been recently compared (Kjeldsen et al., 2014) and are the basis of recommendations for a compilation of drug choices in Table 28–4.

A number of pharmacological principles should be considered for optimizing the antihypertensive drug regimen.

1. **Pharmacokinetics:** Hypertension is a chronic, often lifelong disease without major symptoms but with serious complications, making compliance to antihypertensive drugs a factor of utmost prognostic importance. Antihypertensives should be chosen that exhibit relatively even plasma concentrations at once-daily dosing, achieving sufficient 24-h control of blood pressure and trough-peak effect ratios greater than 50%. The longer the half-life, the less the variation of plasma concentrations (e.g., chlorthalidone vs. hydrochlorothiazide). Drugs with stable pharmacokinetics, that is, low drug interaction potential and no pharmacogenetic influence, are preferred (e.g., bisoprolol vs. metoprolol).
2. **Drug combinations:** Two-thirds of patients with hypertension require two or more antihypertensives for sufficient blood pressure control (<140/90 mmHg). It is therefore reasonable to start combining drugs at low-to-medium doses instead of increasing the dose of a single drug. Prescribing fixed drug combinations (e.g., a Ca^{2+} channel blocker + ACE inhibitor or an ACE inhibitor + diuretic) improves compliance.
3. **Strength of scientific evidence:** Data from large prospective trials provide a high level of confidence for a beneficial risk-benefit ratio and are a reason to use one drug over another.

TABLE 28–4 ■ ANTIHYPERTENSIVE AGENTS PREFERRED IN SPECIFIC PATIENT POPULATIONS

MEDICAL CONDITION	PREFERRED ANTIHYPERTENSIVE AGENTS
Left ventricular hypertrophy	ACEI, ARB, CCB
Asymptomatic atherosclerosis	CCB
Microalbuminuria	ACEI, ARB
Renal dysfunction	ACEI, ARB
Previous stroke	ACEI, ARB, diuretics
Previous myocardial infarction	ACEI, ARB, BB
Coronary artery disease	ACEI, ARB, BB
Angina pectoris	BB, CCB
Heart failure	ACEI, ARB, BB, diuretics, MRA
Aortic aneurysm	BB
Atrial fibrillation, prevention	ACEI, ARB, BB
Atrial fibrillation, rate control	BB, CCB (nondihydropyridines)
End-stage renal disease, proteinuria	ACEI
Peripheral artery disease	ACEI, CCB
Isolated systolic hypertension	ACEI, ARB, CCB, diuretics
Metabolic syndrome	ACEI, ARB, CCB
Diabetes mellitus	ACEI, ARB, CCB, diuretics
Diabetes mellitus with proteinuria	ACEI, ARB
Hyperaldosteronism	MRA
Pregnancy	BB, CCB, α -methyl dopa
Black ethnicity	CCB, diuretics

The drug choices depicted represent a combined view from nine guidelines that differ; thus, the table is, necessarily, a didactic simplification (for details, consult Kjeldsen et al., 2014).

4. **Pharmacodynamic considerations:** Although not formally tested in prospective trials, certain drug combinations make more sense than others. Thiazide diuretics increase the antihypertensive actions of all other classes, but their combination with RAS inhibitors makes particular sense as their K^+ -sparing effect and thus their main risk are reduced by members of this class.
5. **Adverse drug effects and contraindications:** The major classes of antihypertensives are generally well tolerated and, in placebo-controlled trials, showed rates of adverse effects in the range of placebo with some notable exceptions that need to be taken into consideration when choosing a specific drug for a specific patient (Table 28–5). The rate of adverse effects such as hypotension or bradycardia can be largely reduced by starting antihypertensives at low doses and employing a slow dose-escalation strategy.
6. **Compelling indications:** A number of compelling indications exist for specific antihypertensive agents on account of other serious, underlying cardiovascular disease (Table 28–4). These include heart failure, CAD, post-MI, chronic kidney disease, or diabetes. For example, a hypertensive patient with congestive heart failure ideally should be treated with a diuretic, β blocker, ACE inhibitor/AT₁ receptor blocker, and, in selected patients, spironolactone because of the benefit of these drugs in congestive heart failure, even in the absence of hypertension (see Chapter 29). Similarly, ACE inhibitors/AT₁ receptor blockers should be first-line drugs in the treatment of diabetics with hypertension in view of these drugs' well-established benefits in diabetic nephropathy.
7. **Comorbidities:** Some patients have other diseases that could influence the choice of antihypertensive drugs. For example, a hypertensive patient with symptomatic benign prostatic hyperplasia might benefit from having an α_1 blocker as part of his therapeutic program because α_1 blockers are efficacious in both diseases. Similarly, a patient with recurrent migraine attacks might particularly benefit from use of a β blocker because a number of drugs in this class are efficacious in preventing migraine attacks. Women with a high risk of osteoporosis may benefit from the Ca^{2+} -increasing effect of thiazide diuretics. On the other hand, in pregnant hypertensives, some drugs that are otherwise little used (e.g., methyldopa) may be preferred and popular drugs (e.g., ACE inhibitors) need to be avoided on account of concerns about safety.
8. **Second- and third-line hypertensives:** In the vast majority of cases, hypertension can well be controlled by antihypertensives of the five major classes with or without spironolactone at low doses. However, patients with chronic kidney disease often require the additional use of drugs such as hydralazine or minoxidil. The place of clonidine/moxonidine or α_1 blockers in the treatment of hypertension is not well defined.

Acute Antihypertensive Treatment

The considerations mentioned apply to patients with hypertension who need treatment to reduce long-term risk, not patients in immediately life-threatening settings due to hypertension. While there are limited

TABLE 28–5 ■ COMPELLING AND POSSIBLE CONTRAINDICATIONS^a TO ANTIHYPERTENSIVE DRUGS

DRUG CLASS	COMPELLING	POSSIBLE CONTRAINDICATION/PRECAUTION
Diuretics (thiazides)	Gout	Metabolic syndrome Glucose intolerance Pregnancy Hypercalcemia Hypokalemia Erectile dysfunction
Mineralocorticoid receptor antagonists (MRA)	Hyperkalemia Serum creatinine >2.5 mg/dL in men, >2.0 mg/dL in women)	Situations associated with higher risk of hyperkalemia (ACEI, ARB, diabetes)
ACE inhibitors	Pregnancy Angioneurotic edema Hyperkalemia Bilateral renal artery stenosis	Women with child-bearing potential
Angiotensin receptor blockers	Pregnancy Hyperkalemia Bilateral renal artery stenosis	Women with child-bearing potential
Ca^{2+} channel blockers (dihydropyridines)		Tachycardia/arrhythmia Heart failure
Ca^{2+} channel blockers (verapamil, diltiazem)	AV block (grade 2-3) Severe LV dysfunction Heart failure	Co-medication with CYP3A4- or Pgp-dependent drugs (e.g. statins, digoxin)
β Blockers	Asthma AV block (grade 2-3)	Metabolic syndrome Glucose intolerance Athletes and physically active patients Chronic obstructive lung disease Psoriasis Depression
α Blockers	Heart failure	
Central sympatholytic drugs	Depression AV block (grade 2-3)	Erectile dysfunction Xerostomia

^aPossible contraindications and precautions noted in column 3 are not formal contraindications, but rather patient characteristics that should be considered on an individual basis and that may mitigate against use of a class of drugs (e.g., metabolic syndrome and glucose intolerance for diuretics and β blockers). Similarly, some patients with chronic obstructive lung disease can be treated with β_1 blockers without deterioration of lung function, whereas other patients may experience significant bronchoconstriction with β blockers.

clinical trial data, clinical judgment favors rapidly lowering blood pressure in patients with life-threatening complications of hypertension, such as encephalopathy or pulmonary edema due to severe hypertension. However, rapid reduction in blood pressure has considerable risks for the patients; if blood pressure is decreased too quickly or extensively, cerebral blood flow may diminish due to adaptations in the cerebral circulation that protect the brain from the sequelae of very high blood pressures. The temptation to treat patients merely on the basis of increased blood pressure should be resisted. Appropriate therapeutic decisions need to encompass how well a patient's major organs are reacting to the very high blood pressures. While many drugs have been used parenterally to rapidly decrease blood pressure in emergencies (including nitroprusside, enalaprilat, esmolol, fenoldopam, labetalol, clevidipine and nicardipine, hydralazine, and phentolamine), the clinical significance of differing actions of many of these drugs in this setting is largely unknown (Perez et al., 2009).

Resistant Hypertension

Some patients with hypertension fail to respond to recommended antihypertensive treatments. There are many potential explanations. To achieve stringent control of hypertension, many patients require two, three, or four appropriately selected drugs used at optimal doses. Exhibiting an

abundance of caution and therapeutic inertia, clinicians may be reluctant to prescribe sufficient numbers of medications that exploit the drugs' full dose-response curves; conversely, patients may not adhere to the recommended pharmacological regimen. Sometimes, multiple drugs in the same therapeutic class that act by the same mechanism are combined; that is generally not a rational approach. Excess salt intake and the tendency of some antihypertensive drugs, especially vasodilators, to promote salt retention may mitigate falls in blood pressure; consequently, inadequate diuretic treatment commonly is found in patients with resistant hypertension. A relevant fraction of patients with resistant hypertension has primary hyperaldosteronism and benefits from the addition of daily spironolactone at 25–50 mg (Williams et al., 2015). Patients may take prescription drugs, over-the-counter drugs, or herbal preparations that oppose the actions of antihypertensive drugs (e.g., NSAIDs, sympathomimetic decongestants, cyclosporine, erythropoietin, ephedra [also called ma huang], or licorice). Illicit drugs such as cocaine and amphetamines may raise blood pressure. The physician must inquire about a patient's other medications and supplements and individualize the antihypertensive regimen.

- Heart Failure Staging
- Prevention and Treatment

DRUG TREATMENT OF CHRONIC SYSTOLIC HEART FAILURE (STAGES B AND C)

- Treatment Principle I: Neurohumoral Modulation
- Treatment Principle II: Preload Reduction
- Treatment Principle III: Afterload Reduction
- Treatment Principle IV: Increasing Cardiac Contractility
- Treatment Principle V: Heart Rate Reduction

DRUG TREATMENT OF ACUTELY DECOMPENSATED HEART FAILURE

- Diuretics
- Vasodilators
- Positive Inotropic Agents
- Myofilament Calcium Sensitizers (Levosimendan, Pimobendan)
- Other Drugs Used in Heart Failure
- Role of Standard Combination Therapy

LESSONS FROM HEART FAILURE DRUG DEVELOPMENT

- Lessons From Failed Drugs
- Lessons From Treating Acute Heart Failure
- Recent Developments; Novel Approaches

Heart failure is responsible for more than half a million deaths annually in the U.S. Its prevalence is increasing worldwide, likely due to improved survival of those who have had an acute myocardial infarction and an aging population. Median survival rates after the first hospitalization associated with heart failure are worse than those of most cancers, but have improved over the past 30 years (1.3 to 2.3 years in men and 1.3 to 1.7 years in women) (Jhund et al., 2009). This positive trend was associated with a 2- to 3-fold higher prescription rate of ACEIs and ARBs, β receptor antagonists (β blockers), and MRAs, suggesting that improved drug therapy has contributed to enhanced survival of heart failure.

Pathophysiology of Heart Failure

Definitions

Heart failure is a state in which the heart is unable to pump blood at a rate commensurate with the requirements of the body's tissues or can do so only at elevated filling pressure. This leads to symptoms that define the heart failure syndrome clinically. Low output (forward failure) causes fatigue, dizziness, muscle weakness, and shortness of breath, which is aggravated by physical exercise. Increased filling pressure leads to congestion of the organs upstream of the heart (backward failure), clinically apparent as peripheral or pulmonary edema, maldigestion, and ascites.

Most patients with heart failure are diagnosed exclusively on the basis of symptoms; that is, their heart function has never been directly measured (e.g., by echocardiography). Under these circumstances, it is not possible to differentiate between HFrEF (or systolic heart failure) and HFpEF (or diastolic heart failure, see discussion that follows). Other diseases associated with similar symptoms can therefore be wrongly categorized as heart failure (e.g., chronic obstructive pulmonary disease).

Common Final Pathway of Multiple Cardiac Diseases

Heart failure is not a single disease entity but a clinical syndrome that represents the final pathway of multiple cardiac diseases. The most common reason for systolic heart failure today is ischemic heart disease

causing either acute (myocardial infarction) or chronic loss of viable heart muscle mass. Other reasons include chronic arterial hypertension and valvular diseases (both are decreasing in incidence due to improved therapy), genetically determined primary heart muscle defects (cardiomyopathies), viral infections (cytomegalovirus and possibly parvovirus), and toxins. The last encompass excessive alcohol, cocaine, amphetamines, and cancer drugs such as doxorubicin or trastuzumab, the monoclonal antibody directed against the growth factor receptor Her-2/Erb-B2 (see Chapter 67).

Pathophysiological Mechanisms

The pathophysiology of systolic heart failure is relatively well understood. The mechanisms of HFpEF are much less clear, but surely differ and are discussed further in this chapter. The pathophysiology of heart failure is complex and involves four major interrelated systems (Figure 29–1):

- the heart itself
- the vasculature
- the kidney
- neurohumoral regulatory circuits

The Heart Itself: Cardiomyopathy of the Overload

Any overload of the myocardium—loss of relevant muscle mass, which overloads the remaining healthy myocardium; chronic hypertension; or valvular defects—will eventually lead to the organ's failure to produce sufficient cardiac output. This concept can be extended to the genetically determined cardiomyopathies in which essentially any defect in an organelle of cardiac myocytes can lead to primary myocyte contractile dysfunction and then, secondarily, to the picture commonly seen in the cardiomyopathy of the overload. Not surprisingly, the most common cardiomyopathies (HCM, DCM) are due to mutations in genes encoding proteins of the contractile machinery, the sarcomere, proteins anchoring the sarcomere to the plasma membrane, or proteins mediating and maintaining cell-cell contact.

The overload (or the primary contractile defect) leads to alterations of the heart that can partially compensate but that come at a price. Because cardiac myocytes essentially stop replicating in the early postnatal period,

Abbreviations

ACC: American College of Cardiology
ACE: angiotensin-converting enzyme
ACEI: angiotensin-converting enzyme inhibitor
ACh: acetylcholine
ADH: antidiuretic hormone (vasopressin)
ADR: adverse drug reaction
AF: atrial fibrillation
AHA: American Heart Association
AngII: angiotensin II
ANP: atrial natriuretic peptide
ARB: AT₁ angiotensin receptor antagonist (blocker)
ARNI: angiotensin receptor/neprilysin inhibitor
AV: atrioventricular
AVP: arginine vasopressin
BB: β blocker
BNP: brain-type natriuretic peptide
CAD: coronary artery disease
CCB: calcium channel blocker
CG: cardiac glycoside
CHF: congestive heart failure
CM: cardiomyopathy
CNP: C-type natriuretic peptide
COX: cyclooxygenase
CPT1: Carnitine palmitoyltransferase 1
CRT: cardiac resynchronization therapy
CYP: cytochrome P450
DCM: dilated cardiomyopathy
DM: diabetes mellitus
ECG: electrocardiogram
EF: ejection fraction
EMA: European Medicines Agency
eNOS: endothelial nitric oxide synthase
EPI: epinephrine
ESC: European Society of Cardiology
ET: endothelin
FDA: Food and Drug Administration
GC: guanylyl cyclase
GDMT: guideline-directed medical therapy
GFR: glomerular filtration rate
GI: gastrointestinal
GPCR: G protein-coupled receptor
GTN: glycerol trinitrate
HCM: hypertrophic cardiomyopathy
HCN: hyperpolarization-activated, cyclic nucleotide-gated cation channel
HF: heart failure
HFpEF: heart failure with preserved ejection fraction (diastolic heart failure)
HFREF: heart failure with reduced ejection fraction (systolic heart failure)
HMG CoA: 3-hydroxy-3-methylglutaryl coenzyme A
HRQOL: health-related quality of life
HTN: hypertension
ICD: implantable cardioverter-defibrillator
ISDN: isosorbide 2,5'-dinitrate
ISMN: isosorbide 5'-mononitrate
LV: left ventricular
LVH: left ventricular hypertrophy
MCS: mechanical circulatory support
MI: myocardial infarction
MRA: mineralocorticoid receptor antagonist

NCX: Na⁺/Ca²⁺ exchanger
NE: norepinephrine
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
NYHA: New York Heart Association
PD: pharmacodynamic
PDE: cyclic nucleotide phosphodiesterase
PKA: protein kinase A
PLB: phospholamban
PLM: phospholemman
RAAS: renin-angiotensin-aldosterone system
ROS: reactive oxygen species
RyR: ryanodine receptor
SERCA: sarco/endoplasmic reticulum Ca²⁺ ATPase
sGC: soluble guanylyl cyclase
SL: sarcolemma
SNS: sympathetic nervous system
SR: sarcoplasmic reticulum
TnC: troponin C
TNF: tumor necrosis factor
Tnl: inhibitory subunit of troponin

the usual response to overload is not myocyte division but rather hypertrophy, growing in size and assembling more sarcomeres that can contribute to contractile force development. Whereas hypertrophy is principally a normal response to physiological needs such as body growth, pregnancy, and physical exercise ("physiological hypertrophy"), hypertrophy in response to chronic overload comes with features that make it a major risk factor for the development of heart failure ("pathological hypertrophy"). A direct consequence of cardiac myocyte hypertrophy is a reduced capillary/myocyte ratio (i.e., less O₂ and nutrient supply per myocyte), causing an energy deficit and metabolic reprogramming. Altered gene expression of ion channels, Ca²⁺-regulating proteins, and contractile proteins can be interpreted as partially beneficial, energy-saving adaptations; on the other hand, the adaptations also aggravate contractile failure and favor arrhythmias. Concurrently, fibroblasts proliferate and deposit increased amounts of extracellular matrix (e.g., collagen). This fibrosis in heart failure also favors arrhythmias, increases the stiffness of the heart, and interrupts myocyte-to-myocyte communication (coordinated conduction and force transmission). Finally, overload leads to cardiac myocyte death by apoptosis or necrosis. Collectively, these adverse adaptations are called *pathological remodeling*.

Some of these alterations are direct, heart-intrinsic consequences of overload (e.g., hypertrophy, altered gene expression); others are secondary to neurohumoral activation and thereby susceptible to neurohumoral blocking agents (see discussion that follows and Figure 29-1).

The Vasculature

A critical parameter of cardiac function is the stiffness of the vasculature. It determines the resistance against which the heart has to expel the blood and increases with aging. Heart failure may be the consequence of premature aging of the vasculature (Strait and Lakatta, 2012). Aging-induced loss of elasticity of the great blood vessels reduces their compliance, that is, the elasticity that permits vessels to extend in systole and contract in diastole. Good compliance reduces peak systolic pressure and increases diastolic pressure, which favors perfusion in diastole. It is negatively correlated with pulse pressure, that is, the difference between systolic and diastolic blood pressure, which is low in children and high in the elderly. Arterial hypertension and diabetes mellitus are the major reasons for premature stiffening of blood vessels, which imposes increased afterload to the heart and contributes to heart failure. Theoretically, stiffening and loss of compliance could be directly tackled by drugs (see section Recent Developments; Novel Approaches).

Another critical aspect of vascular function is the ability to adapt the vessel diameter to hemodynamic and neurohumoral stimuli, a function

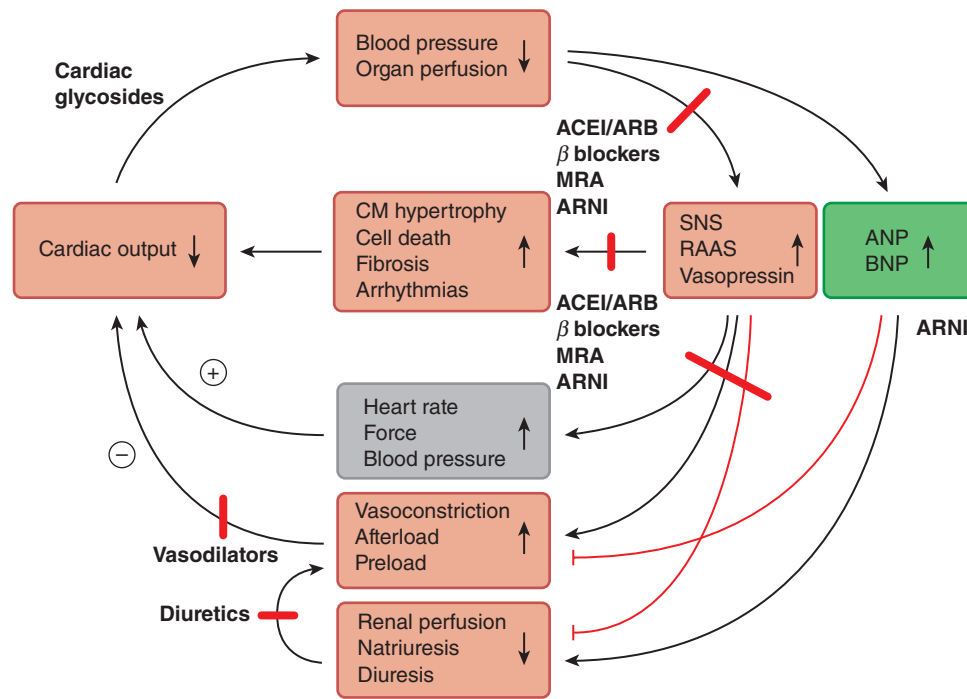

Figure 29-1 Pathophysiologic mechanisms of systolic heart failure (HFrEF) and therapeutic interventions. Any major decrease in cardiac contractile function leads to activation of neurohumoral systems, including the SNS, the RAAS, and vasopressin (ADH) secretion, which acutely stabilize blood pressure and organ perfusion by stimulating cardiac output, constricting resistance vessels, decreasing kidney perfusion, and increasing Na^+ and H_2O retention. Unfortunately, these responses are maladaptive, causing chronic overloading and overstimulation of the failing heart. Direct hypertrophic, pro-apoptotic, fibrotic, and arrhythmogenic effects of NE and AngII further accelerate the deleterious process. Note that the concomitant activation of the ANP/BNP system is the consequence of stretch and increased wall stress in the heart and has opposite and beneficial effects. See Abbreviations list at beginning of chapter.

that is governed by cross talk between luminal endothelial and underlying smooth muscle cells (Chapter 28). The main signaling pathway involves receptors that increase intracellular Ca^{2+} levels in endothelial cells, which activates eNOS to produce NO. This gaseous transmitter diffuses into smooth muscle cells and activates sGC to produce cGMP, which causes relaxation of vascular smooth muscle. Heart failure is always accompanied by endothelial dysfunction, which is a disturbed balance between vasodilating NO and proconstrictor ROS. ROS, by inactivating the two critical enzymes eNOS and sGC and converting NO in peroxynitrite, a strong ROS, favor vasoconstriction. Several common cardiovascular drugs (ACEIs/ARBs, MRAs, statins) improve endothelial function by reducing ROS production. PDE5 inhibitors have similar consequences by inhibiting cGMP degradation in smooth muscle cells and thereby promoting relaxation.

The Kidney

The kidney regulates Na^+ and H_2O excretion and thereby intravascular volume. Under normal conditions, autoregulatory and neurohumoral mechanisms ensure an adequate GFR and diuresis over a wide range of renal perfusion pressures. Prominent mechanisms with relevance for heart failure are (1) the AngII-mediated regulation of filtration rate by regulating the diameter of efferent glomerular arteriole; (2) the regulation of kidney perfusion by a balance between constrictor-promoting effects of AngII (via AT_1 receptors) and vasopressin (AVP, via V_1 receptors) and the vasodilating influence of prostaglandins (hence the deleterious effects of NSAIDs); (3) the aldosterone-mediated regulation of Na^+ reabsorption in the distal tubule; and (4) AVP-regulated water transport in the collecting ducts (via V_2 receptors). In heart failure, all mechanisms are dysregulated and constitute therapeutic targets of ACEIs/ARBs, MRAs, and diuretics. Newer agents, such as adenosine A_1 receptor antagonists and AVP receptor antagonists, have failed to exert therapeutic benefit in clinical studies.

Neurohumoral Regulation and HFrEF

The decrease in cardiac output in heart failure leads to the activation of the SNS and the RAAS and increases in plasma levels of AVP and ET

(Figure 29-1). This concerted response ensures the perfusion of centrally important organs such as the brain and the heart (at the expense of kidney, liver, and skeletal muscle perfusion) in situations of acute blood loss. These responses are components of the “fight-or-flight response” and provide useful short-term physiological responses to alarm and danger. Chronically, however, neurohumoral activation exerts deleterious effects that constitute a vicious cycle in heart failure. Vasoconstriction initially not only stabilizes blood pressure but also increases afterload, which is the resistance against which the heart works to expel blood (see Figures 29-4 and 27-1). Because of the decreased contractile reserve, the failing heart is particularly sensitive to increases in afterload (see Figure 29-4); such increases further decrease cardiac output. Decreased kidney perfusion and increased aldosterone production reduce diuresis and promote volume overload, which increases cardiac preload, dilation, and ventricular wall stress, a major determinant of cardiac O_2 consumption. Tachycardic and positive inotropic actions of catecholamines not only acutely increase cardiac output but also promote arrhythmias and increase O_2 consumption in a failing, energy-depleted heart. AngII, NE, and ET accelerate pathological cardiac remodeling (hypertrophy, fibrosis, and cell death). Aldosterone has prominent profibrotic actions. This spectrum of adverse consequences of chronic neurohumoral activation explains why inhibitors of these systems (ACEIs/ARBs, β blockers, and MRAs) exert long-term, life-prolonging effects in heart failure and are the cornerstones of current therapy.

Unexpectedly, ET and AVP receptor antagonists provide no beneficial effect in patients with heart failure, despite promising results in preclinical studies. Clinical trials suggested that neurohumoral activation in response to altered cardiac function may be sufficiently inhibited by the standard combination therapy, leaving no room for improvement from the addition of ET and AVP antagonists; however, recent data indicate that additional benefit may accrue via another therapeutic route: a drug combination called ARNIs. The FDA has approved a fixed-dose combination of the ARB valsartan with the neprilysin inhibitor sacubitril. Valsartan blocks AT_1 receptors, reducing the deleterious effects of AngII.

Figure 29–2 Pathophysiological mechanisms of diastolic heart failure HFpEF and possible therapeutic interventions. Unlike the case with HFrEF, the pharmacological agents shown have not been proven to have clinical efficacy toward HFpEF, although these agents can help to control underlying diseases, such as hypertension, diabetes, and obesity. Only exercise training has proven effective in increasing maximal exercise capacity. RAGE; receptor for advanced glycosylation end-products.

Sacubitril inhibits the degradation of the natriuretic peptides ANP and BNP. The valsartan-sacubitril combination appears superior to the ACEI enalapril, reducing the rates of hospitalization and death from all cardiovascular causes in patients with HFrEF (Hubers and Brown, 2016).

This finding reflects the fact that neurohumoral activation in heart failure includes one system that exerts beneficial effects: the natriuretic peptides. Normally, ANP and BNP are expressed in the atria and released on increased preload (stretch). During heart failure, ANP and BNP are also produced by the ventricles, such that plasma levels are elevated. Indeed, BNP is used as a biomarker of heart failure. ANP and BNP stimulate the plasma membrane guanylyl cyclase. In the kidney, elevated cGMP has diuretic effects. Elevated cellular cGMP mediates vasodilation in the vasculature and, in the heart, antihypertrophic, antifibrotic, and compliance-increasing effects related to phosphorylation of titin. Enhancing these effects by inhibiting the degradation of ANP/BNP likely explains the clinical benefits of sacubitril-valsartan.

Heart Failure With Preserved Ejection Fraction

Systematic echocardiographic determination of left ventricular EF in thousands of patients with heart failure revealed that about 50% had no reduction; that is, they exhibited EF values greater than 50%. Still, patients had typical heart failure symptoms, including acute decompensation with pulmonary edema and a survival prognosis not much better or even identical to patients with reduced EF (systolic heart failure or HFrEF). These data point to a different pathophysiology in which abnormalities of the diastolic and not the systolic component of cardiac function prevail. Due to difficulties in defining diastolic function by standard techniques, the term *HFpEF* has been introduced and applies to patients with typical heart failure symptoms and “normal” (>50%) or only mildly reduced EF.

Even more than HFrEF, HFpEF is a multifactorial disease (Figure 29–2). HFpEF is typically associated with arterial hypertension, ischemic heart disease, diabetes mellitus, and obesity (metabolic syndrome); it is more frequent in women than men and shows a strong increase in prevalence

with age. Hearts of patients with HFpEF are generally not dilated, wall thickness is enlarged (hypertrophy), and left atrial size often is enlarged as a sign of chronically elevated end-diastolic pressures. Central to the pathophysiology of HFpEF is, presumably, compromised diastolic relaxation of the left ventricle, which causes congestion of the lung, shortness of breath, or pulmonary edema. Clinical decompensation is often associated with strongly elevated blood pressure.

Molecular alterations include increased myocardial fibrosis (causing a permanent relaxation deficit) as well as more dynamic changes, such as reduced phosphorylation of titin, the sarcomeric protein that spans the large region from the Z to the M band. Titin contains several molecular spring domains whose elastic modulus determines the passive tension of cardiomyocytes, particularly at low-to-medium levels of stretch. At higher levels of stretch, the extracellular matrix becomes involved. Titin stiffness is determined by its isoforms and by cGMP-dependent phosphorylation, suggesting that agents that increase cellular cGMP might be beneficial in HFpEF. However, the PDE5 inhibitor sildenafil, which preserves and elevates cellular cGMP in some cells (see Chapters 3, 31, and 45), failed to show benefit (Redfield et al., 2013). This lack of efficacy is, unfortunately, also true for all other pharmacological interventions in HFpEF, including ACEIs, ARBs, and spironolactone. Exercise training is presently the only intervention that significantly increases maximal physical activity in HFpEF patients. In the absence of evidence-based clinical trial data, current therapy recommendations concentrate on optimal treatment of the underlying diseases, such as hypertension, diabetes, and obesity.

Heart Failure Staging

Heart failure was one of the first diseases for which guidelines described specific therapies for each stage of the disease. An early classification of the stages of heart failure was that of the NYHA, a classification still in use: class I (left ventricular dysfunction, no symptoms); class II (symptoms at medium-to-high levels of physical exercise); class III (symptoms at low levels of physical exercise); and class IV (symptoms at rest or daily life

physical activities such as brushing teeth). The more recent guidelines of the AHA and ACC extended this classification by taking into account that

- heart failure is part of the cardiovascular continuum with preventable risk factors (stage A)
- an asymptomatic stage exists that requires treatment to delay transition to symptomatic heart failure (stage B)
- patients oscillate between different degrees of symptoms and therefore between class II and III (class C, which generally includes NYHA class II/III patients)
- a final stage of the disease requires different treatment and special considerations, such as heart transplantation and left ventricular assist device implantation (stage D).

This chapter uses the AHA/ACC classification (Yancey et al., 2013) but also considers the recent guidelines of the European Society of Cardiology (Ponikowski et al., 2016), which provide more specific treatment algorithms, and the 2016 AHA/ACC update (Yancy et al., 2016). Treatment guidelines are summarized in Figure 29–3.

Prevention and Treatment

Ischemic heart disease, hypertension, and valvular diseases are the most prevalent causes of heart failure. People at high risk (stage A) should therefore be consequently treated with drugs with an established effect on the natural course of these diseases, in conjunction with appropriate lifestyle changes. Studies in thousands of patients have reproducibly shown that blood pressure lowering in hypertensive patients and lipid-lowering with statins in dyslipidemic patients reduce not only the incidence of myocardial infarction and death but also the incidence of heart failure. The data are weaker for antidiabetic drugs, but consensus exists that blood glucose should be controlled with a hemoglobin A_{1c} goal of 7%–7.5%.

Treatment of heart failure has seen a dramatic change over the past decades. Until the late 1980s, drugs and drug dosing were symptom oriented and based on pathophysiological considerations of *acute* systolic heart failure. Treatment was mainly directed toward symptom relief and short-term improvement of hemodynamic function. With the era of

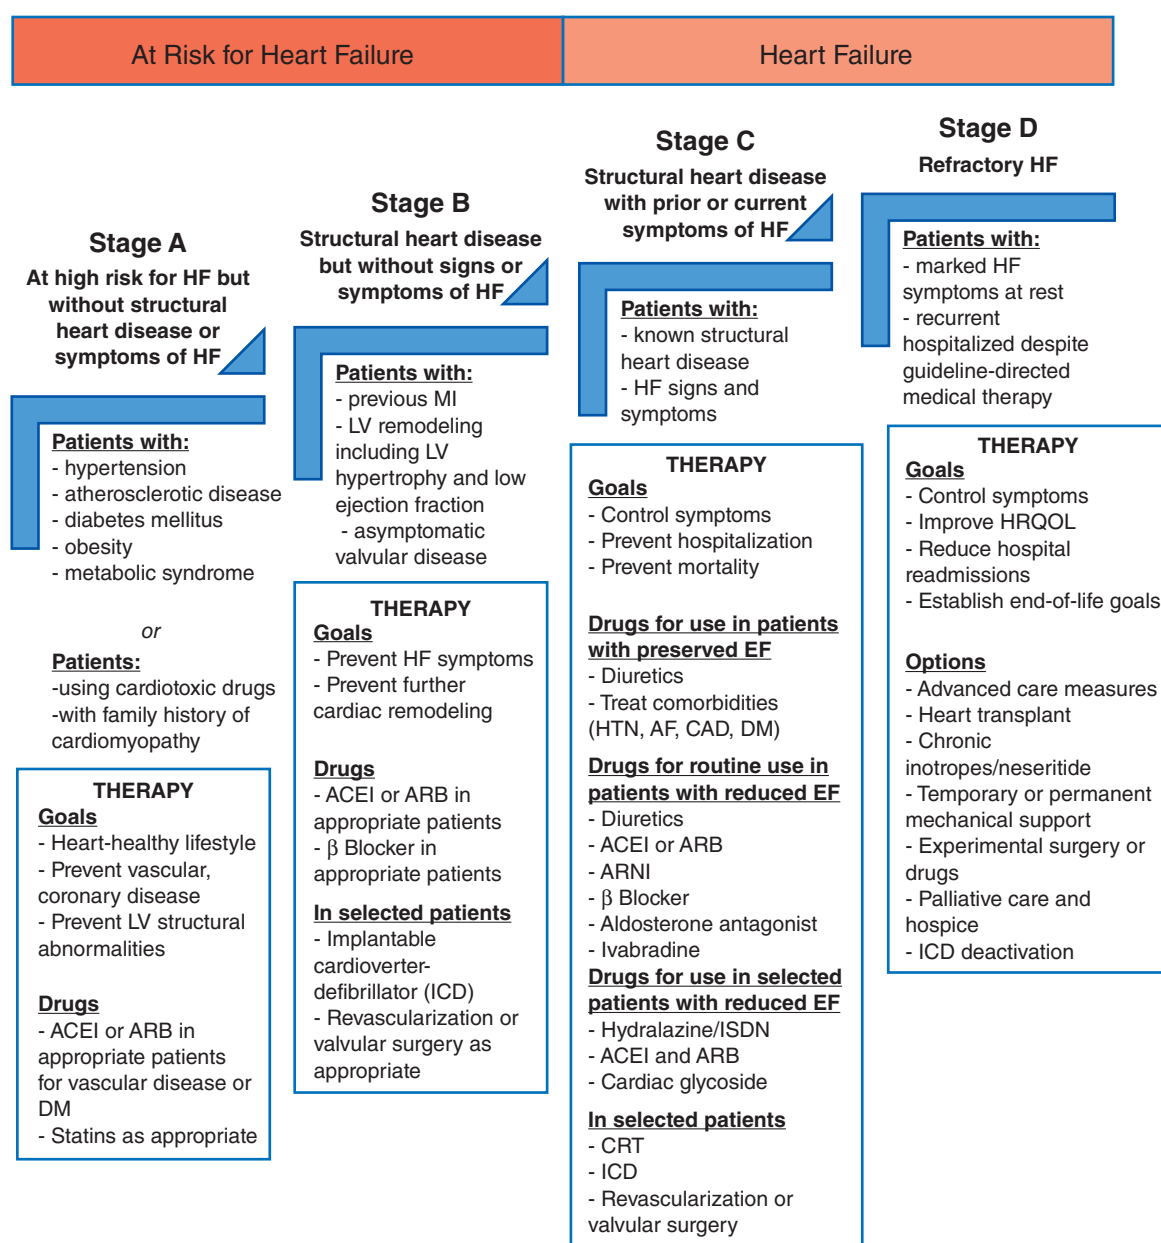

Figure 29–3 AHA/ACC 2013 Heart Failure Treatment Guidelines: stages in the development of HF and recommended therapy by stage. (See Yancy et al., 2013 and 2016, for details.)

TABLE 29–1 ■ LANDMARK STUDIES IN THE TREATMENT OF PATIENTS WITH CHRONIC HEART FAILURE WITH REDUCED EJECTION FRACTION

STUDY (as cited in Bibliography)	STUDY POPULATION	NO. OF SUBJECTS	BASELINE DRUGS (% of patients on each)	DRUG EFFECT (on all-cause mortality)
Cohn et al., 1986	Men, impaired cardiac function and exercise capacity	642	CG, D	ISDN/hydralazine ↓ 34% Prazosin +/- vs. placebo
CONSENSUS Trial Study Group, 1987	Severe HF, NYHA class IV	253	D 100, CG 93, BB 2, spironolactone 52, vasodilators ~ 50	Enalapril ↓ 40% vs. placebo
SOLVD Investigators, 1991	NYHA II–III, left EF < 35%	2569	D 86, CG 67, BB 7.5, vasodilators 51	Enalapril ↓ 16% vs. placebo
SOLVD Investigators, 1992	NYHA I, left EF < 35%	4228	Vasodilators 46, D 17, CG 13	Enalapril ↓ 8% (n.s.) vs. placebo (heart failure development ↓ 20%)

randomized clinical trials, which mainly tested effects of drugs on long-term morbidity (hospitalizations) and mortality, much of the former beliefs have proven to be wrong. For example, positive inotropic drugs (sympathomimetics and PDE inhibitors) that exert acute symptomatic benefit reduce life expectancy when given chronically. In contrast, β blockers decrease cardiac output acutely and may make people feel weak at the start of therapy but prolong life expectancy when given in increasing doses for extended periods. Vasodilators once seemed a logical choice for heart failure, but pure vasodilators such as the α_1 receptor antagonist prazosin or the nitrate ISDN, in combination with the vasodilator hydralazine, do not positively affect the prognosis in Caucasians (see further discussion). Thus, clinical trials have established important principles for assessing efficacy of therapies for heart failure:

1. Drugs for the treatment of chronic heart failure should reduce the patient morbidity and mortality.
2. Short-term drug effects poorly predict the outcome of randomized clinical trials and optimal therapies for heart failure.
3. Considerations of stage of disease are critical.
4. New drugs for heart failure should be compared to the most effective current combination therapy, a principle often ignored in preclinical animal work.
5. Nonpharmacological treatment options such as cardiac resynchronization devices and intracardiac defibrillator/cardioverters are important for their documented lifesaving effect in selected patient populations.

Attention to these principles for assessing long-term efficacy of heart failure therapies has provided evidence-based principles of treatment.

HISTORICAL PERSPECTIVE

A series of landmark studies over three decades has established the current thinking on the treatment of patients with chronic HFrEF. These studies are not reviewed here, but interested readers may wish to consult the evidence that supports current therapies. These studies, often indicated by an acronym, are summarized in Table 29–1.

Drug Treatment of Chronic Systolic Heart Failure (Stages B and C)

Treatment Principle I: Neurohumoral Modulation

Dampening neurohumoral activation and its deleterious consequences on the heart, blood vessels, and kidney is the cornerstone of heart failure therapy. Therapy consists of ACEIs/ARBs, β blockers, and MRAs. Further activation of the natriuretic peptide system adds benefit (Figure 29–1). A systematic discussion of the drugs is found in Chapters 12, 25, 26, 27, and 28.

Angiotensin-Converting Enzyme Inhibitors

Angiotensin II, the most active angiotensin peptide, is largely derived from angiotensinogen in two proteolytic steps. First, *renin*, an enzyme released from the kidneys, cleaves the decapeptide AngI from the amino terminus of angiotensinogen (renin substrate). Then, ACE removes a carboxy-terminal dipeptide (His⁹-Leu¹⁰) from AngI, yielding the active octapeptide, AngII (Figure 26–1). Thus, ACEIs reduce circulating levels of AngII. All patients with heart failure (stages B and C; NYHA I–IV) should receive an ACEI.

Mechanism of Action. AngII interacts with two heptahelical GPCRs, AT₁ and AT₂, and has four major cardiovascular actions that are all mediated by the AT₁ receptor:

- vasoconstriction
- stimulation of aldosterone release from the adrenal glands
- direct hypertrophic and proliferative effects on cardiomyocytes and fibroblasts, respectively
- stimulation of NE release from sympathetic nerve endings and the adrenal medulla

Physiological Effects. The ACEIs lower the circulating level of AngII and thereby reduce its deleterious effects. Thus, ACEIs not only act as vasodilators but also reduce aldosterone levels and thereby act as an indirect diuretic, have direct antiremodeling effects on the heart, and produce sympatholytic effects (thus moderating the reflex tachycardia that accompanies vasodilation and the lowering of blood pressure).

The ACEIs have important renal effects. When renal perfusion pressure is reduced, AngII constricts renal efferent arterioles, and this serves to maintain glomerular filtration pressure and GFR. Thus, under circumstances in which renal perfusion pressure is compromised, inhibition of the RAAS may induce a sudden and marked decrease in GFR. For this reason, ACEIs are contraindicated in bilateral renal artery stenosis. Likewise, because patients with heart failure often have low renal perfusion pressures, aggressive treatment with ACEIs may induce acute renal failure. To avoid this, for patients with heart failure patients, ACEIs should be initiated at very low doses; blood pressure, blood creatinine, and K^+ levels should be monitored; and the ACEI dose slowly increased over weeks toward target levels (for agents that have been carefully evaluated in clinical trials; Table 29–2). The potentially dangerous acute effects become beneficial with long-term use of ACEIs because the (small) chronic lowering of glomerular pressures protects the glomerulus from fibrotic degeneration.

The ACEI-induced lowering of aldosterone levels causes reduced expression of the aldosterone-dependent epithelial Na^+ channel (ENaC) in the distal tubule (see Figure 25–6). This target of K^+ -sparing diuretics (see discussion that follows) normally mediates Na^+ reabsorption and K^+ excretion. Lower levels of ENaC lead to less absorption of Na^+ and less excretion of K^+ . Thus, ACEIs favor hyperkalemia, which can be detrimental in patients with renal insufficiency but is normally beneficial for patients with heart failure who more often present with hypokalemia, a condition that promotes cardiac arrhythmias. ACEIs shift the balance of vascular smooth muscle tone toward vasodilation and thereby increase renal blood flow, another reason for their chronic protective effects on the kidney. This effect also explains why NSAIDs, which reduce the production of vasodilating prostaglandins, antagonize effects of ACEIs and should be avoided in patients with heart failure.

Other Actions, Good and Adverse. Angiotensin-converting enzyme has other actions, including the inactivation of bradykinin and substance P. ACEIs increase bradykinin and substance P levels, with two prominent consequences: cough, the most frequent ADR (~5%); and angioedema, a rare (~0.7%), but life-threatening condition presenting with swelling of the skin and mucous membranes of the throat and asphyxia (three times more common amongst African Americans). Experimental evidence suggests that increases in bradykinin contribute to the therapeutic efficacy of ACEIs and may explain why ARBs, which do not increase bradykinin (and therefore cause no cough), have not been consistently associated with improved survival in patients with HFrEF (Ponikowski et al., 2016).

The ACEIs are generally well tolerated in the majority of patients. Important ADRs are the following:

- dry cough, necessitating a change to ARBs;
- creatinine plasma concentration increase (<20%, normal; 20%–50%: careful observation and reduction of ACEI dosage; > 50%, stop ACEI and consult specialist for diagnosis of renal artery);
- hyperkalemia (small increase normal, but requires careful observation in patients with diabetes, renal insufficiency, or comedication with MRAs, K^+ -sparing diuretics, or NSAIDs);
- angioedema (stop drug immediately, treat with antihistamines, corticosteroids, or, in severe case, EPI); and
- allergic skin reactions.

Angiotensin Receptor Antagonists

The ARBs are systematically discussed in Chapter 26. They are highly selective, competitive receptor antagonists at the AT_1 receptor, which mediates the major effects of AngII. They are therapeutic alternatives to ACEIs and second choice in all stages of heart failure in patients who do not tolerate ACEIs. Given the central role of the AT_1 receptor for the actions of AngII, it is not surprising that ARBs show the same pharmacological profile as ACEIs with the exception of not inducing cough. The unopposed activity of AT_2 receptor pathways in the presence of AT_1 blockade by an ARB seems to confer no therapeutic advantage to ARBs over ACEIs. Moreover, the addition of an ARB to therapy with an ACEI does not affect the prognosis of patients with heart failure but does increase hypotension, hyperkalemia, and renal dysfunction. A negative interaction between ACEIs and ARBs appears to extend to patients with higher renal risk. There is, therefore, no routine indication for this combination.

β Adrenergic Receptor Antagonists

Major Effects of β Adrenergic Antagonists. The sympathetic neurotransmitters NE (released at adrenergic nerve varicosities) and EPI (secreted by the adrenal medulla) are strong stimuli of heart function. They increase heart rate (positive chronotropic effect) and force of contraction (positive inotropic effect) and thereby augment cardiac output. They quicken the rate of force development (increased $+dP/dt$, positive clinotropy) and accelerate cardiac muscle relaxation (greater $-dP/dt$, positive lusitropic effect, which aids ventricular filling during diastole. Acceleration of the atrial-ventricular conduction rate (positive dromotropic effect) shortens the heart cycle and allows higher beating rates. Catecholamines enhance cardiac myocyte automaticity and lower the

TABLE 29–2 ■ PROPERTIES AND THERAPEUTIC DAILY DOSES OF ACEIs AND ARBs APPROVED AND CLINICALLY EVALUATED FOR THE THERAPY OF HFrEF^a

CLASS/ Drug	HALF-LIFE (h)	STARTING DOSE (mg)	TARGET DOSE (mg)	IMPORTANT ADVERSE EFFECTS, INTERACTIONS, AND CONTRAINDICATIONS
ACE inhibitors				
Captopril	1.7	3 × 6.25	3 × 50	Adverse effects: Cough (~5%), ↑ serum creatinine (<25% is normal; if > 50%, possibility of renal artery stenosis), hyperkalemia, hypotension, angioedema Interactions: Increased rate of hyperkalemia in combination with K ⁺ -sparing diuretics, K ⁺ supplements, cyclosporine, NSAIDs (PD), reduced efficacy in combination with NSAIDs (PD), ↑ [Li ⁺] in serum (PK), ↑ hypoglycemic risk in combination with insulin or oral antidiabetics; increased effect in renal insufficiency (PK) Contraindications: Bilateral renal artery stenosis
Enalapril	11	2 × 2.5	2 × 20

threshold for arrhythmias (positive bathmotropic effect). All these acute effects are mediated by β_1 receptors and, to a smaller extent, β_2 receptors. Extracardiac effects include bronchodilation (β_2), vasodilation (β_2) as well as vasoconstriction (α_1 receptors, which dominate at higher concentrations of catecholamines), stimulation of hepatic glycogen metabolism and gluconeogenesis (β_2), and, importantly, stimulation of renin release from the macula densa (β_1). Thus, activation of the SNS coactivates the RAAS, and, as outlined previously, activation of the RAAS activates the SNS by stimulation of NE release (see Chapters 12 and 26).

The β blockers competitively reduce β receptor-mediated actions of catecholamines and thus, depending on the activation level of the SNS, reduce heart rate and force, slow relaxation, slow AV conduction, suppress arrhythmias, lower renin levels, and, depending on their selectivity for the β_1 receptor, permit more or less bronchoconstriction, vasoconstriction, and lowering of hepatic glucose production.

Why Use β Blockers in Heart Failure? In light of the above actions, the efficacy of β blockers in heart failure came as a surprise and had to overcome resistance in the medical community. How can a drug with cardiodepressant actions on heart function be beneficial in a clinical situation in which the heart is already dysfunctional and depending on catecholamines to maintain cardiac output? The first therapeutic application of β blockers at low doses was to a Swedish cohort of patients with heart failure with cardiac decompensation and heart rate greater than 120 beats/min; the goal was to reduce heart rate and cardiac energy consumption (Waagstein et al., 1975). The success of the experiment led to large clinical trials that showed an impressive 35% prolongation of life expectancy in patients treated with β blockers (Table 29–1), on top of effects of ACEIs, diuretics, and digoxin.

Key to the understanding of the success of β blockers in heart failure were two lessons. *First*, therapy must be initiated in a clinically stable condition and at very low doses (1/8 of target), and dose escalation requires time (e.g., doubling every 4 weeks in ambulatory settings; “start low, go slow”). Under these conditions, the heart has time to adapt to decreasing stimulation by catecholamines and to find a new equilibrium at a lower adrenergic drive. Importantly, β blockers do not fully block the receptors; rather, they are competitive antagonists that shift the concentration-response curve of catecholamines to the right (see Figure 3–4).

Second, although the acute effects of catecholamines can be lifesaving, that level of β adrenergic stimulation applied chronically, as the SNS does in response to heart failure, is deleterious. Positive chronotropic, inotropic, and lusitropic effects all come at the price of overproportional increase in energy consumption. This is irrelevant in situations of acute blood loss or other stresses, but critical if persistent. The heart reacts to chronic sympathetic stimulation by a heart failure-specific gene program (e.g., downregulation of β adrenergic receptor density; upregulation of inhibitory G proteins; and decreases of SR Ca^{2+} -ATPase, the fast isoform of myosin heavy chain, and repolarizing K^+ currents), changes that come at the price of decreased dynamic range and increased propensity for arrhythmias. Reversal of the heart failure gene program by β blockers (Lowes et al., 2002) likely contributes to the paradoxical increase in left ventricular EF after 3–6 months of therapy and to the reduced rate of arrhythmogenic sudden cardiac death noted in the large studies. In a simple view, β blockers protect the heart from the adverse long-term consequences

of adrenergic overstimulation, for example, increased energy consumption, fibrosis, arrhythmias, and cell death. Lower heart rates not only save energy but also improve contractile function because the failing heart, in contrast to the healthy human heart, has a negative force-frequency relation (Pieske et al., 1995). In addition, β blockers improve perfusion of the myocardium by prolonging diastole, thereby reducing ischemia.

Available Agents. Four β blockers have been successfully tested in randomized clinical trials (Table 29–1): the β_1 -selective agents metoprolol (MERIT-HF Investigators, 1999) and bisoprolol (CIBIS-II Investigators, 1999) and the third-generation agents with additional actions, carvedilol and nebivolol. Carvedilol is a nonselective β blocker and an α_1 receptor antagonist. Nebivolol (Flather et al., 2005) is β_1 selective and has additional vasodilatory actions that may be NO mediated (Figure 12–4; Table 12–4). Early evidence of superiority of carvedilol over metoprolol (Poole-Wilson et al., 2003) has not been confirmed.

Pharmacokinetic Considerations. There are important pharmacokinetic differences amongst these β blockers (Table 29–3), distinctions that are relevant because successful therapy of heart failure (and most other chronic cardiovascular diseases) requires stable plasma concentrations over the entire day (trough levels before next dose application > 50% of maximum).

Metoprolol has a too short $t_{1/2}$ (3–5 h) and should be prescribed only as the zero-order prolonged-release formulation used by all successful clinical studies. Standard extended-release formulations likely do not suffice. A further disadvantage of metoprolol is its dependency on the polymorphic CYP2D6 for its metabolism. CYP2D6 “poor metabolizers,” about 8% of the Caucasian population, exhibit C_{pmax} levels of metoprolol 5-fold higher than those of standard metabolizers; in a prospective longitudinal study, that difference correlated with 2-fold differences in heart rate responses (Rau et al., 2009). Bisoprolol has a sufficiently long plasma $t_{1/2}$ (10–12 h) for once-daily dosing and is not metabolized by CYP2D6. Carvedilol has a shorter $t_{1/2}$ (6–10 h) and requires twice-daily dosing. An advantageous peculiarity of carvedilol is that it dissociates only slowly from β receptors and therefore acts longer than its plasma $t_{1/2}$ suggests. Carvedilol metabolism depends on CYP2D6, but less so than metoprolol. Nebivolol plasma concentrations are 10- to 15-fold higher in CYP2D6 poor metabolizers, but this is without clinical consequence, likely because the first metabolite is similarly active as the parent compound. Nebivolol is not approved in the U.S. for the treatment of heart failure, but it is approved in 71 countries worldwide, including Europe (patients > 70 years of age).

Clinical Use. All patients with symptomatic heart failure (stage C, NYHA II–IV) and all patients with left ventricular dysfunction (stage B, NYHA I) after myocardial infarction should be treated with a β blocker. The therapy with β blockers should be initiated only in clinically stable patients at very low doses, generally 1/8 of the final target dose, and titrated upward every 4 weeks. Even when initiated properly, a tendency to retain fluid exists that may require diuretic dose adjustment. The improvement of left ventricular function generally takes 3–6 months, and in this period, patients should be carefully monitored.

The β blockers should not be administered in new-onset or acutely decompensated heart failure. If patients are hospitalized with acute decompensation under current therapy with β blockers, doses often have to be

TABLE 29–3 ■ PROPERTIES AND THERAPEUTIC DOSES OF β BLOCKERS APPROVED AS THERAPY OF HFrEF

β BLOCKER	β_1 SELECTIVE	VASODILATION	HALF-LIFE (h)	START DOSE (mg)	TARGET DOSE (mg)	METABOLISM BY CYPs ^a
Bisoprolol	Yes	No	10–12	1 × 1.25	1 × 10	None
Carvedilol	No	Yes	6–10	2 × 3.125	2 × 25	CYP2D6
Metoprolol succinate ^a	Yes	No	>12 ^b	1 × 12.5 ^a	1 × 200	CYP2D6
Nebivolol	Yes	Yes	10	1 × 1.25	1 × 10	CYP2D6

^aCYP2D6 indicates dependence on polymorphic CYP2D6 metabolism, likely less relevant for nebivolol because the first metabolite is active.

^bClinical studies in heart failure have mainly used metoprolol succinate in a slow-release formulation (zero order of kinetics); metoprolol, itself, has a $t_{1/2}$ of 3–5 h.

reduced or the drug discontinued until clinical stabilization, after which therapy should again be initiated.

Precautions. Formally, β blockers have long lists of adverse drug responses and contraindications. Practically, however, they are generally well tolerated if properly initiated. If doses are increased too rapidly, fall of blood pressure, fluid retention, and dizziness are common and require dose reduction.

The major cardiovascular responses associated with use of β blockers are the following:

- **Heart rate lowering**, a desirable effect that indicates proper dosing (no decrease indicates insufficient dosing). A reasonable target resting heart rate is 60–70/min.
- **AV block** (beware preexisting conduction disturbance; consider pacemaker implantation).
- **Bronchoconstriction.** Allergic asthma is a contraindication for all β blocker use; however, chronic obstructive lung disease is not, because the β_2 receptor–dependent dynamic range is low in these patients, and studies have documented safety. Nonetheless, only β_1 -selective compounds should be used in patients with chronic obstructive pulmonary disease.
- **Peripheral vasoconstriction (cold extremities).** Initial vasoconstriction turns into vasodilation under chronic therapy with β blockers. Cold extremities are generally not a problem in patients with heart failure. Yet, patients with peripheral artery disease or symptoms of claudication or Raynaud disease should be carefully monitored and treated with carvedilol if a β blocker is employed.

Mineralocorticoid Receptor Antagonists

The third group of drugs with a documented life-prolonging effect in patients with heart failure is MRAs. They should be given in low doses to all patients in stage C (NYHA class II–IV), that is, with symptomatic HFrEF, despite the fact that the combination of ACEIs/ARBs, and MRA is formally contraindicated due to the risk of hyperkalemia. The safety of a low-dose MRA (25 mg vs. a standard of 100 mg spironolactone) was demonstrated in a large randomized trial in a patient cohort with severe heart failure (NYHA III–IV), with the MRA added to ACEIs, diuretics, and digoxin (Pitt, 2004). Later studies with eplerenone in less-severe heart failure essentially confirmed the efficacy of this class of drugs.

Mechanism of Action. The MRAs act as antagonists of nuclear receptors of aldosterone (Figure 25-6). They are K^+ -sparing diuretics (see discussion that follows) but gained more importance in the treatment of heart failure for their additional efficacy in suppressing the consequences of neurohumoral activation. Aldosterone, as the second major actor of the RAAS, promotes Na^+ and fluid retention, loss of K^+ and Mg^{2+} , sympathetic activation, parasympathetic inhibition, myocardial and vascular fibrosis, baroreceptor dysfunction, and vascular damage, all adverse effects in the setting of heart failure. Aldosterone plasma levels decrease under therapy with ACEIs or ARBs, but quickly increase again, a phenomenon called *aldosterone escape*. It is likely explained by incomplete blockade of the RAAS (e.g., AngI can be converted to AngII by chymase, in addition to ACE; see Figure 26-1) and by the fact that aldosterone secretion is regulated not only by AngII but also by sodium and potassium plasma Na^+ and K^+ . MRAs inhibit all the effects of aldosterone, of which the reduction in fibrosis is most pronounced in animal models.

Clinical Use; Adverse Responses. Currently, two MRAs are available, spironolactone and eplerenone. Only eplerenone is FDA-approved for the therapy of heart failure because no economic interest exists for the approval of spironolactone, which is free of patent protection. Nevertheless, guidelines recommend both. Spironolactone is a nonspecific steroid hormone receptor antagonist with similar affinity for progesterone and androgen receptors; it causes gynecomastia (painful breast swelling, 10% of patients) in men and dysmenorrhea in women. Eplerenone is selective for the mineralocorticoid receptor and therefore does not cause gynecomastia.

The most important ADR of both MRAs is hyperkalemia. Under the well-controlled conditions of clinical trials, serious hyperkalemia (>5.5 mmol/L) occurred in 12% in the eplerenone group and in 7% in

the placebo group (Zannad et al., 2011). Rates may be higher in clinical practice when risk conditions, comedication, and dose restrictions are not well controlled (Juurlink et al., 2004). Guidelines for the use of MRAs in patients with heart failure are:

- Administer no more than 50 mg/d.
- Do not use if the GFR is less than 30 mL/min (creatinine ~ 2 mg/dL).
- Be careful with elderly patients, in whom improvement in prognosis may be less relevant than prevention of serious side effects.
- Be careful with diabetics, who carry a higher risk of hyperkalemia.
- Do not combine with NSAIDs, which are contraindicated in heart failure but are frequently prescribed for chronic degenerative diseases of the musculoskeletal system.
- Do not combine with other K^+ -sparing diuretics.

Angiotensin Receptor and Neprilysin Inhibitors

The latest addition to standard combination therapy of heart failure is sacubitril/valsartan. It is made by cocrystallizing the well-known ARB valsartan with sacubitril, a prodrug that, after deesterization, inhibits neprilysin, a peptidase mediating the enzymatic degradation and inactivation of natriuretic peptides (ANP, BNP, CNP), bradykinin, and substance P. Thus, the drug combines inhibition of the RAAS with activation of a beneficial axis of neurohumoral activation, the natriuretic peptides. Consequently, the ARNI is expected to promote the beneficial effects natriuresis, diuresis, and vasodilation of arterial and venous blood vessels and to inhibit thrombosis, fibrosis, cardiac myocyte hypertrophy, and renin release. Augmentation of ANP/BNP levels by inhibiting degradation is probably a better pharmacological principle than giving the agonist BNP (nesiritide; see under acute heart failure) directly because it enhances *endogenous* regulation of plasma and tissue levels. Sacubitril/valsartan causes smaller increases in bradykinin and substance P than omapatrilat, an earlier drug combining a neprilysin inhibitor and an ACEI. This difference may explain why sacubitril/valsartan is not associated with an increased rate of angioedema, the adverse effect that stopped the development of omapatrilat. A large head-to-head comparison study in patients with stable heart failure showed superiority of sacubitril/valsartan over enalapril (McMurray et al., 2014).

Treatment Principle II: Preload Reduction

Fluid overload with increased filling pressures (increased preload) and dilation of the ventricles in heart failure is the consequence of decreased kidney perfusion and activation of the RAAS. Normally, increased preload and stretch of the myofilaments increase contractile force in an autoregulatory manner, the positive force-length relationship or Frank-Starling mechanism. However, the failing heart in congestion operates at the flat portion of this relationship (Figure 29-4) and cannot generate sufficient force with increasing preload, leading to edema in the lungs and the periphery.

Diuretics increase Na^+ and water excretion by inhibiting transporters in the kidney and thereby improve symptoms of CHF by moving patients to lower cardiac filling pressures along the same ventricular function curve. Diuretics are an integral part of the combination therapy of symptomatic forms of heart failure. Prognostic efficacy of diuretics in heart failure will remain an academic question, simply because randomization for a trial of diuretics would be ethically impermissible. Diuretics should *not* be given to patients without congestion because they activate the RAAS and may accelerate a vicious downward spiral. On the other hand, in severe heart failure, diuretic resistance may occur for various reasons and cause clinical deterioration (Table 29-4).

Loop Diuretics

Loop diuretics (furosemide, torsemide, bumetanide; Table 29-5) inhibit the Na^+ - K^+ -2Cl symporter in the ascending limb of the loop of Henle, where up to 15% of the primary filtrate (~ 150 L/d) is reabsorbed, explaining their strong diuretic action. The increase in Na^+ and fluid delivery to distal nephron segments has two consequences:

- It is sensed in the macula densa and normally activates tubuloglomerular feedback to decrease GFR. This autoregulation explains the quick

Figure 29-4 Hemodynamic responses to pharmacologic interventions in heart failure. The relationships between diastolic filling pressure (preload) and stroke volume (ventricular performance) are illustrated for a normal heart (green line; the Frank-Starling relationship) and for a patient with heart failure with systolic dysfunction (red line). Note that positive inotropic agents (I), such as CGs or dobutamine, move patients to a higher ventricular function curve (lower dashed line), resulting in greater cardiac work for a given level of ventricular filling pressure. Vasodilators (V), such as ACEIs or nitroprusside, also move patients to improved ventricular function curves while reducing cardiac filling pressures. Diuretics (D) improve symptoms of CHF by moving patients to lower cardiac filling pressures along the same ventricular function curve.

loss of efficacy of older diuretics of the carbonic anhydrase inhibitor class (e.g., acetazolamide), acting in the proximal tubule. Thiazides (see discussion that follows) are derived from this class and cause a small decrease in the GFR. Loop diuretics inhibit the feedback mechanism because it is mediated by the Na^+ - K^+ -2Cl symporter; they exhibit stable action and do not affect the GFR.

- It leads to increased ENaC-mediated reabsorption of Na^+ and, in exchange, to more K^+ excretion in the distal tubule, explaining the main side effect, hypokalemia.

The bioavailability of orally administered furosemide ranges from 40% to 70%. High drug doses are often required to initiate diuresis in patients with worsening symptoms or in those with impaired GI absorption, as may occur in severely hypervolemic patients with CHF-induced GI edema. Oral bioavailabilities of bumetanide and torasemide are greater than 80%, and as a result, these agents are more consistently absorbed than furosemide. Furosemide and bumetanide are short-acting drugs.

TABLE 29-4 ■ CAUSES OF DIURETIC RESISTANCE IN HEART FAILURE

Noncompliance with medical regimen; excess dietary Na^+ intake
Decreased renal perfusion and glomerular filtration rate due to Excessive vascular volume depletion and hypotension due to aggressive diuretic or vasodilator therapy Decline in cardiac output due to worsening heart failure, arrhythmias, or other primary cardiac causes Selective reduction in glomerular perfusion pressure following initiation (or dose increase) of ACEI therapy
Nonsteroidal anti-inflammatory drugs
Primary renal pathology (e.g., cholesterol emboli, renal artery stenosis, drug-induced interstitial nephritis, obstructive uropathy)
Reduced or impaired diuretic absorption due to gut wall edema and reduced splanchnic blood flow

The $t_{1/2}$ of furosemide in normal kidney function is about 1 h (increases in terminal kidney failure to > 24 h), and rebound Na^+ retention normally requires dosing twice a day or more. Bumetanide reaches maximal plasma concentrations in 0.5–2 h and has a $t_{1/2}$ of 1–1.5 h. Torasemide has a slower onset of action (maximal effect 1–2 h after ingestion) and a plasma $t_{1/2}$ of 3–4 h. Kidney failure does not critically affect the elimination of bumetanide or torasemide.

Thiazide Diuretics

Thiazide diuretics (hydrochlorothiazide, chlorthalidone; Table 29-5) have a limited role in heart failure for their low maximal diuretic effect and loss of efficacy at a GFR below 30 mL/min. However, combination therapy with loop diuretics is often effective in those refractory to loop diuretics alone, as refractoriness is often caused by upregulation of the Na^+ -Cl cotransporter in the distal convoluted tubule, the main target of thiazide diuretics (see Chapter 25). Thiazides are associated with a greater degree of K^+ wasting per fluid volume reduction than loop diuretics, and combination therapy requires careful monitoring of K^+ loss.

K^+ -Sparing Diuretics

K^+ -Sparing diuretics (see Chapter 25) inhibit apical Na^+ channels in distal segments of the tubulus directly (ENaC; e.g., amiloride, triamterene) or reduce its gene expression (MRAs spironolactone and eplerenone). These agents are weak diuretics, but they are often used in the treatment of hypertension in combination with thiazides or loop diuretics to reduce K^+ and Mg^{2+} wasting. The prognostic efficacy of MRAs, which is at least partially independent of its K^+ -sparing activity, make amiloride and triamterene largely dispensable in the therapy of heart failure. They should not be combined with ACEIs and MRAs.

Treatment Principle III: Afterload Reduction

The failing heart is exquisitely sensitive to increased arterial resistance (i.e., afterload) (Figure 29-5). Vasodilators, therefore, should have beneficial effects on patients with heart failure by reducing afterload and allowing the heart to expel blood against lower resistance. However, clinical trials with pure vasodilators were mainly disappointing, whereas inhibitors of the RAAS, vasodilators with a broader mode of action, were successful. Likely reasons include reflex tachycardia and tachyphylaxis (prazosin, ISDN) and negative inotropic effects (dihydropyridine calcium channel antagonists).

Hydralazine–Isosorbide Dinitrate

A remarkable exception is the therapeutic effect of a fixed combination of hydralazine and ISDN. In a pioneering trial, Cohn and colleagues showed moderate efficacy of this combination in patients with heart failure (Cohn et al., 1986). The benefit was restricted to improvement in the cohort of African Americans. In a second trial in African Americans only, the combination conferred a 43% survival benefit (Taylor et al., 2004). It was FDA-approved in 2006, the first ethnically restricted approval.

As an orally available organic nitrate, ISDN, similar to GTN and ISMN, preferentially dilates large blood vessels, for instance, venous capacitance and arterial conductance vessels (Chapter 27). The main effect is “venous pooling” and reduction of diastolic filling pressure (preload) with little effect on systemic vascular resistance (which is regulated by small-to-medium arterioles). Sustained monotherapy is compromised by nitrate tolerance (i.e., loss of effect and induction of a pro-constrictory state with high levels of ROS). Hydralazine is a direct vasodilator whose mechanism of action remains unresolved (Chapter 28). It was suggested that hydralazine prevents nitrate tolerance by reducing ROS-mediated inactivation of NO (Munzel et al., 2005), an action that could explain the efficacy of this drug combination in heart failure amongst African Americans. A test of this hypothesis in patients with NYHA class II–III heart failure (Chirkov et al., 2010) failed to confirm the hypothesis. The relevant differences in responsiveness between African American and Caucasian patients with heart failure have not been explained.

The fixed-combination formulation in use contains 37.5 mg hydralazine and 20 mg ISDN and is uptitrated to a target dose of 2 tablets, thrice

TABLE 29-5 ■ PROPERTIES AND THERAPEUTIC DOSES OF DIURETICS FOR THE THERAPY OF HF_rEJ^a

DIURETIC	START DOSE (mg)	COMMON DAILY DOSE (mg)	TIME TO START OF EFFECT (h)	HALF-LIFE (h)	ADVERSE EFFECTS AND INTERACTIONS
Loop diuretics					
Bumetanide	0.5–1	1–5	0.5	1–1.5	Adverse effects: Hypokalemia, hyponatremia, hypomagnesemia, hyperuricemia, hypocalcemia (loop diuretics, hypercalcemia (thiazides), glucose intolerance Interactions: ↑[Li+] in serum (PK) and cardiac glycoside toxicity (PD, hypokalemia), anion exchanger resins (PK), non-steroidal anti-inflammatory drugs (NSAID), and glucocorticoids (PD) can ↓ effect of diuretics.
Furosemide	20–40	40–240	0.5	1	
Torsemide	5–10	10–20	1	3–4	
Thiazides					
Chlorthalidone	50	50–100	2	50	
Hydrochlorothiazide	25	12.5–100	1–2	6–8	
Potassium-sparing diuretics					
Eplerenone, spironolactone	50 ^b	100–200 ^b	2–6	24–36	Adverse effects: Hyperkalemia (all), gynecomasty, erectile dysfunction, and menstrual bleeding disorders (spironolactone) Interactions: ↑ Risk of hyperkalemia when given with ACE or ARB (use 50% lower dose), also with cyclosporine and NSAIDs Contraindication: Renal insufficiency with creatinine clearance < 30 mL/min
Amiloride	5 ^b	10–20 ^b	2	10–24	
Triamterene	50 ^b	200 ^b	2	8–16	

^aDosing recommendations were adapted from ESC guidelines (Ponikowski et al., 2016). ^b50% dose reduction when co-administered with RAS blocker.

daily. Patients will also generally be taking a β blocker. Hypotension may be dose limiting. Frequent adverse effects include dizziness and headache. Adherence to the thrice-daily dosing regimen may impose practical problems (Cohn et al., 1986), and hydralazine doses greater than 200 mg have been associated with lupus erythematosus.

Treatment Principle IV: Increasing Cardiac Contractility

The failing heart is unable to generate force sufficient to meet the needs of the body for perfusion of oxygenated blood (Figure 29-1). Historically, physicians attempted to stimulate force generation with positive inotropic drugs. Unfortunately, when used chronically, these agents do not improve life expectancy or cardiac performance. Rather, chronic use of positive inotropes is associated with excess mortality. Of the available inotropic agents, only CGs are used in the treatment of chronic heart failure; this is for two reasons: history and one large trial in patients with NYHA class II–III heart failure showing that digoxin reduced the rate of heart failure–associated hospitalizations without increasing mortality (Table 29-1).

Inotropic Agents and the Regulation of Cardiac Contractility

Cardiac myocytes contract and develop force in response to membrane depolarization and subsequent increases in intracellular Ca²⁺ concentrations (Figure 29-6). The mechanisms of this *excitation-contraction coupling* are the basis for understanding the mode of action of positive inotropic drugs and cardiac myocyte function in general. Most currently employed positive inotropes and novel compounds in development act by increasing the concentration of free intracellular Ca²⁺ ([Ca²⁺]_i). Ca²⁺ “sensitizers” (e.g., levosimendan) sensitize myofilaments to Ca²⁺; that is, they shift the sigmoidal relationship between free Ca²⁺ concentration and force to the left.

Na⁺/K⁺ ATPase Inhibitors. Cardiac glycosides inhibit the plasma membrane Na⁺/K⁺ ATPase, a key enzyme that actively pumps Na⁺ out and K⁺ into the cell and thereby maintains the steep concentration gradients of Na⁺ and K⁺ across the plasma membrane. Inhibition of this enzyme slightly reduces the Na⁺ gradient across the myocyte membrane, reducing the driving force for Ca²⁺ extrusion by the NCX, thereby providing more Ca²⁺ for storage in the SR and subsequent release to activate contraction. The details are explained by Figure 29-6 and its legend.

cAMP-Dependent Inotropes. The strongest stimulation of the heart is achieved by receptor-mediated stimulation of adenylyl cyclase. This explains the use of dobutamine, EPI, and NE in cardiogenic shock (see discussion that follows). Inhibition of cAMP degradation by PDE inhibitors such as milrinone or enoximone elevates cellular cAMP concentrations and activates the cAMP-PKA pathway and other cAMP-responsive systems (see Chapter 3). This concerted action results in higher peak Ca²⁺ concentrations in systole and thereby peak force (Figure 29-6). All cAMP-dependent inotropes hasten contraction (positive inotropic effect) and relaxation (positive lusitropic effect), allowing sufficient perfusion of the ventricles in diastole under catecholamine stimulation and with the concomitant tachycardia. On the downside, acceleration of contraction during catecholamine stimulation, by promoting net Ca²⁺ entry per unit of time, increases the utilization of ATP for Ca²⁺ reuptake into the SR via the SERCA and to restore the membrane potential by the activity of the Na⁺/K⁺ ATPase.

Myofilament Ca²⁺ Sensitizers. Calcium sensitizers increase the affinity of the myofilaments for Ca²⁺, for example, by inducing a conformational change in TnC. They enhance force for a given [Ca²⁺]_i and do not elevate [Ca²⁺]_i with its potentially deleterious pro-arrhythmic and energy-increasing consequences. But, increased myofilament Ca²⁺ sensitivity also causes reduced dissociation of Ca²⁺ from the myofilaments in

Figure 29-5 Stroke volume versus afterload (outflow resistance): effects of heart failure. Increasing the resistance to ventricular outflow, a basic determinant of afterload, has little effect on stroke volume in normal hearts until high levels of outflow resistance (top curve). However, in patients with systolic ventricular dysfunction (lower curves), an increase in outflow resistance elicits a noticeable decrease in cardiac performance (= stroke volume) that is progressive with increasing failure. Such an increase in outflow resistance can occur as a compensatory response by the SNS and RAAS to decreased cardiac function and depressed arterial pressure as a result of heart failure. A higher resistance to ventricular outflow increases peak pressure development in the left ventricle in opening the aortic valve, thereby increasing ventricular wall stress and end-systolic volume. This can cause end-diastolic volume to increase. In the normal heart, increasing ventricular stretch enhances cardiac contractile performance (stroke volume); this is the Frank-Starling effect (inset). However, in the failing heart, the positive contractile response embodied in the Frank-Starling effect is poor and provides only a small increase in stroke volume. Reducing outflow resistance with agents that reduce systemic vascular resistance, such as arterial vasodilators, can shift cardiac performance to a larger stroke volume in patients with myocardial dysfunction (from A to B). Such an increase in stroke volume may provide sufficient output and compensate for the decrease in systemic vascular resistance and moderate the fall in systemic arterial pressure due to the vasodilator. For details, see Figure 29-4 and the work of Klabunde (2015).

diastole and prolongation of relaxation (“negative lusitropic effect”). This effect can aggravate the already-compromised diastolic function in heart failure. It could also lead to delayed Ca^{2+} release from myofilaments in diastole and arrhythmias (Schober et al., 2012). Calcium sensitizers failed to improve prognosis in clinical trials of patients with chronic heart failure. However, levosimendan is approved in some countries for the treatment of acute heart failure. It has additional selective and potent inhibitory effects on PDE III, whose positive lusitropic consequence appears to antagonize the negative lusitropic effect of Ca^{2+} sensitization. Agonists of G_q -coupled receptors (α_1 , AT_1 , ET_A) also increase myofilament Ca^{2+} sensitivity, likely due to increased myosin light chain phosphorylation. The positive inotropic effect is smaller than that of β receptor stimulation, develops more slowly, and is independent of cAMP.

Cardiac Glycosides

Actions and Therapeutic Use of Digoxin. Positive Inotropic Effect. CGs at therapeutic concentrations mildly inhibit the cardiac Na^+/K^+ ATPase, causing an increase in intracellular $[\text{Na}^+]_i$. Increased $[\text{Na}^+]_i$ inhibits Ca^{2+} extrusion via the NCX resulting in higher intracellular $[\text{Ca}^{2+}]_i$ and enhanced contractility (Figure 29-6). The increased contractility and hence cardiac output provides symptomatic relief in patients with heart failure (Figure 29-1). With the main trigger for neurohumoral activation removed, sympathetic nerve tone and, consequently, heart rate and peripheral vascular resistance drop. These decreases in preload and afterload reduce chamber dilation and thereby wall stress, a strong determinant of myocardial O_2 consumption. Increased renal perfusion lowers renin production and increases diuresis, further decreasing preload.

HISTORICAL PERSPECTIVE

The British botanist William Withering (1741–1799) systematically described the actions of *Digitalis purpurea* in patients with heart failure (“dropsy”) and gave exact dosing recommendations (Skou 1986). Oswald Schmiedeberg (1833–1921), working in Strasbourg, France, isolated the first chemical entities from foxglove leaves; one of these entities was digitoxin. Until diuretics became available, CGs were the only heart failure drugs. CGs encompass many chemical entities, but only digoxin, its derivatives β -acetyl digoxin, methylidigoxin, and digitoxin are in clinical use in most countries. Until the 1980s, CGs were dosed according to therapeutic effects (e.g., improved diuresis [Withering considered CGs as diuretics], reduction of heart size [verifiable by X-ray], or alterations of the surface ECG) and to symptoms of overdosing, such as nausea and altered color perception (yellow-green). Now, serum digoxin concentrations can be measured by radioimmunoassay. Digoxin has therapeutic efficacy (including a small survival benefit) only at serum concentrations between 0.5 and 0.8 ng/mL (Rathore et al., 2003). Concentrations greater than 1.2 ng/mL are associated with increased mortality. Serum digoxin concentrations greater than 0.8 ng/mL should be avoided.

Electrophysiological Actions. CGs at therapeutic concentrations shorten action potentials by accelerating the inactivation of L-type Ca^{2+} channels due to higher $[\text{Ca}^{2+}]_i$. Shorter action potentials (= refractory period) favor reentry arrhythmias, a reason that CGs promote atrial fibrillation. With the loss of intracellular K^+ and increase in intracellular Na^+ , the resting membrane potential (determined largely by the K^+ current, now diminished) moves to less-negative values with two consequences. Diastolic depolarization and automaticity are enhanced, and, due to partial inactivation of Na^+ channels, impulse propagation is strongly reduced. Both phenomena promote reentry arrhythmias. At even higher CG concentrations, SR Ca^{2+} overload reaches a point at which Ca^{2+} is spontaneously released at amounts large enough to initiate Ca^{2+} waves and, via the NCX, depolarization of the cell (Figure 29-6). The typical ECG signs at this stage of CG intoxication are extrasystoles and bigeminy with a high risk of ventricular fibrillation.

Extracardiac Effects. CGs also inhibit Na^+/K^+ ATPase in other excitable tissues. (1) At low plasma concentrations, CGs stimulate vagal efferents and sensitize baroreceptor reflex mechanisms, causing increased parasympathetic and decreased sympathetic tone. The beneficial effect of digoxin at low plasma concentrations (Rathore et al., 2003), at which positive inotropic effects are minor, suggests that the neurohumoral actions of CGs may be therapeutically more relevant than the direct positive inotropic effects. (2) CGs at higher plasma concentrations increase Ca^{2+} concentrations in vascular smooth muscle cells and cause vasoconstriction. In patients with heart failure, vasodilation normally prevails due to the decrease in sympathetic nervous tone, but the direct vascular effect explains mesenteric artery ischemia or occlusion, a rare but severe adverse effect of CGs.

Indirect Actions. The vagotonic and sympatholytic effects of CGs cause bradycardia and AV prolongation (negative dromotropic effect) and can promote atrial flutter and fibrillation. Fibrillation is explained by the ACh-induced shortening of atrial action potentials, which is further enhanced by the direct CG effect described previously. On the other hand, CGs are therapeutically used for frequency control of permanent atrial fibrillation because of their negative dromotropic effects.

Interactions With K^+ , Ca^{2+} , and Mg^{2+} . Hyperkalemia reduces and hypokalemia increases the binding affinity of CG to the Na^+/K^+ ATPase. In addition, hypokalemia reduces repolarizing K^+ currents, with the consequence of increased spontaneous diastolic depolarization and automaticity. Hypokalemia is therefore a major risk factor for arrhythmogenic effects of CGs. Hypercalcemia as well as hypomagnesemia favor SR Ca^{2+} overload and spontaneous Ca^{2+} release events. Control of serum electrolytes is therefore mandatory.

Figure 29–6 Cardiac excitation-contraction coupling and its regulation by positive inotropic drugs. The cardiac cycle is initiated by membrane depolarization, which causes the opening of voltage-dependent Na^+ and L-type Ca^{2+} channels, permitting Na^+ and Ca^{2+} flow down their electrochemical gradients into the myocyte. Thus, Na^+ and Ca^{2+} enter the cardiac myocyte during each cycle of membrane depolarization, triggering the release, through the RyR, of larger amounts of Ca^{2+} from internal stores in the SR. The resulting increase in intracellular Ca^{2+} interacts with troponin C and activates interactions between actin and myosin that result in sarcomere shortening. The electrochemical gradient for Na^+ across the sarcolemma is maintained by active transport of Na^+ out of the cell by the sarcolemmal Na^+/K^+ ATPase (NKA). The bulk of cytosolic Ca^{2+} (70%) is pumped back into the SR by a Ca^{2+} -ATPase, SERCA2. The remainder is removed from the cell by either a sarcolemmal Ca^{2+} -ATPase or a high-capacity NCX. The NCX exchanges three Na^+ for a Ca^{2+} , using the electrochemical potential of Na^+ to drive Ca^{2+} extrusion. The β adrenergic agonists (acting at βAR , the β adrenergic receptor) and PDE inhibitors, by increasing intracellular cAMP levels, activate PKA, which phosphorylates PLB in the SR, the α subunit of the L-type Ca^{2+} channel, and regulatory components of the RyR, as well as TnI. As a result, the probabilities of opening of the L-type Ca^{2+} channel and the RyR2 Ca^{2+} channel are increased; SERCA2 inhibition by PLB is released, with the result that SERCA2 accumulates Ca^{2+} into the SR faster, more avidly, and to a higher concentration; and relaxation occurs at slightly higher $[\text{Ca}^{2+}]$, due to slightly reduced sensitivity of the troponin complex to Ca^{2+} . The net effect of these phosphorylations is a positive inotropic effect: a faster rate of tension development to a higher level of tension, followed by a faster rate of relaxation. CGs, by inhibiting the Na^+/K^+ ATPase, reduce Na^+ extrusion from the cell, thereby permitting $[\text{Na}^+]_{\text{in}}$ to rise, reducing the inward gradient for Na^+ that drives Ca^{2+} extrusion by NCX. As a consequence, Ca^{2+} accumulates in the SR, and a positive inotropic effect follows, as noted previously for the effect of increased cellular cAMP. See the text for details of additional effects of CGs. Note that, under steady-state conditions, the amount of Ca^{2+} leaving the cell exactly matches the amount entering it. As NCX exchanges three Na^+ for every Ca^{2+} , it creates a depolarizing current. This makes not only the direction of transport dependent on the chemical gradients of Na^+ and Ca^{2+} across the membrane but also the membrane potential. Thus, the direction of $\text{Na}^+/\text{Ca}^{2+}$ exchange may briefly reverse during depolarization, when the electrical gradient across the sarcolemma is transiently reversed. PLM is a tonic inhibitor of the Na^+/K^+ ATPase, which supplies the driving force (an appropriately low $[\text{Na}^+]_{\text{in}}$) for maintaining low diastolic Ca^{2+} . Phosphorylation of PLM by PKA removes this inhibitory influence, thereby stimulating the activity of the Na^+/K^+ ATPase and limiting $[\text{Na}^+]_{\text{in}}$ and $[\text{Ca}^{2+}]_{\text{in}}$. This may reduce the tendency toward arrhythmias during adrenergic stimulation (see Pavlovic et al., 2013).

Adverse Effects. The therapeutic index of CG is extremely narrow, about 2, as documented in the DIG trial: plasma concentrations between 0.5 and 0.8 ng/mL are associated with beneficial effects, and concentrations of 1.2 ng/mL and greater are associated with a tendency toward increased mortality (Rathore et al., 2003). The most frequent and most serious adverse effects are arrhythmias. In CG overdosing, patients exhibit arrhythmias (90%), GI symptoms (~55%), and neurotoxic symptoms (~12%). The most frequent causes of toxicity are renal insufficiency and overdosing.

Cardiac toxicity in healthy persons presents as extreme bradycardia, atrial fibrillation, and AV block, whereas ventricular arrhythmias are rare. In patients with structural heart disease, frequent signs of CG toxicity are ventricular extrasystoles, bigeminy, ventricular tachycardia, and fibrillation. In principle, however, every type of arrhythmia can be CG induced. GI adverse effects are anorexia, nausea, and vomiting, mainly as a result of CG effects on chemosensors in the area postrema. Spastic contraction of the mesenteric artery can rarely lead to severe diarrhea and

life-threatening necrosis of the intestine. Headache, fatigue, and sleeplessness can be early symptoms of CG toxicity.

Typical, albeit not too common (10%), are visual effects: altered color perception and coronas (halos). Some have speculated that the visual effects of digitalis intoxication contributed to the qualities of late paintings by Vincent van Gogh, who may have been treated for neurological complaints with foxglove by Dr. Paul Gachet, whose portraits by van Gogh (painted in June 1890) show the doctor seated next to a sprig of the plant, a natural source of CGs and used widely in the 19th century (Lee, 1981).

Therapy of CG Toxicity. Cessation of CG medication normally suffices as therapy of CG toxicity. However, severe arrhythmias, such as extreme bradycardia or complex ventricular arrhythmias, require active therapy.

- Extreme sinus bradycardia, sinoatrial block, or AV block grade II or III: Atropine (0.5–1 mg) IV. If not successful, a temporary pacemaker may be necessary.

- Tachycardic ventricular arrhythmias and hypokalemia: K^+ infusion (40–60 mmol/d). Consider that high K^+ can aggravate AV conduction defects.
- An effective antidote for digoxin toxicity is antidigoxin immunotherapy. Purified Fab fragments from ovine antidigoxin antisera (Digibind) are usually dosed by the estimated total dose of digoxin ingested to achieve a fully neutralizing effect.

Treatment Principle V: Heart Rate Reduction

Heart rate is a strong determinant of cardiac energy consumption, and higher heart rates in patients with heart failure are associated with poor prognosis (Bohm et al., 2010). Partial agonists at β receptors such as xamoterol increase nocturnal heart rate (i.e., they prevent the physiological dip) and are associated with excess mortality in patients with heart failure (Xamoterol Study Group, 1990). Conversely, β blockers lower heart rate and improve survival prognosis.

Ivabradine

The circumstantial evidence for beneficial effects of heart rate lowering led to the development of ivabradine, a selective inhibitor of cardiac pacemaker channels (HCNs). The compound is approved in Europe for the treatment of heart failure and stable angina pectoris in patients not tolerating β blockers or in whom β blockers did not sufficiently lower heart rate ($<75/\text{min}$). Approval was based on a study showing a decrease in hospitalization and heart failure mortality, but not total or cardiovascular mortality (Swedberg et al., 2010). Of note, the effect of ivabradine was not superior to that of digoxin in an earlier study (Digitalis Investigation Group, 1997). In a recent large study in patients with stable angina (85% on β blockers), ivabradine conferred no benefit but led to phosphenes (typical transient enhanced brightness in a restricted area of the visual field) and increased the rate of bradycardia, atrial fibrillation, and QT prolongation (Fox et al., 2014), casting doubts about the role of the compound in ischemic heart disease. Ivabradine is not approved in the U.S.

Drug Treatment of Acutely Decompensated Heart Failure

Acutely decompensated heart failure is a leading cause of hospitalization in patients older than 65 and represents a sentinel prognostic event in the natural course of the disease, with a high recurrence rate and a 1-year mortality rate of about 30%. Even in decompensated heart failure, about 50% of patients exhibit preserved left ventricular function (HFpEF). The HFpEF cohort is older, more likely to be female and hypertensive, and with less coronary artery disease than the HFrEF cohort. Therapeutically, it is important to quickly identify and treat specific reasons for decompensation. These include, besides acute myocardial ischemia, uncorrected high blood pressure, atrial fibrillation and other arrhythmias, pulmonary embolism, and kidney failure, as well as several pharmacological reasons: nonadherence to heart failure medication and Na^+ /fluid restriction, negative inotropic drugs (e.g., verapamil, diltiazem, nifedipine, β blockers), and NSAIDs and COX-2 inhibitors.

The therapy of acutely decompensated heart failure aims at fast symptom relief, short-term survival, fast recompensation, and reduction of readmission rates. It is less evidence-based than the therapy of chronic heart failure, and no single drug given to patients experiencing acute decompensation has yet been shown to improve the long-term prognosis. The main principles (besides nonpharmacological treatment modalities such as O_2 and noninvasive or [rarely] invasive ventilatory support) are diuretics and vasodilators, with positive inotropes in selected cases and mechanical support systems as an ultimate step.

Diuretics

Patients with dyspnea and signs of fluid overload/congestion should be promptly treated with an intravenous loop diuretic such as furosemide that exerts an acute vasodilator and slightly delayed but still fast diuretic effect. Optimal doses and regimens need to be adapted to the clinical picture. An

intravenous bolus of 40–80 mg furosemide is a common starting dose, often continued by an infusion of furosemide at a daily dose equal to the (oral) daily dose prescribed before hospitalization. Doses may need to be escalated according to symptoms and diuresis. Additional use of a thiazide diuretic in small doses can break a relative resistance to loop diuretics but requires careful monitoring of K^+ losses. Excessive doses of furosemide must be avoided because they can cause hypotension, a reduction in GFR, electrolyte disturbance, and further neurohumoral activation.

Vasodilators

Vasodilators such as *nitroglycerin* and *nitroprusside* reduce preload and afterload. The reduction in preload (= diastolic filling pressure) moves the patient to the left on the stroke volume-preload relationship, similar to the effect of diuretic-induced volume reduction (Figure 29–3). The accompanying reduction in chamber dimension reduces wall stress and thus O_2 consumption. The additional reduction in afterload allows the heart to expel blood against a lower output resistance (Figure 29–4). These mechanisms explain why vasodilators (which have no inotropic efficacy and lower blood pressure) increase stroke volume. Yet, robust evidence for symptomatic benefit or improved clinical outcome is lacking. They are probably best suited for patients with hypertension and should be avoided in patients with systolic blood pressure less than 110 mm Hg (Ponikowski et al., 2016). The main risk is hypotension, which is negatively associated with favorable outcomes in patients with acutely decompensated heart failure (Patel et al., 2014).

Neseritide, recombinant human BNP, dilates arterial and venous blood vessels by stimulating the membrane-bound guanylyl cyclase to produce more cGMP. By this mechanism, it decreases preload and afterload and reduces pulmonary capillary wedge pressure. It is approved for the treatment of acutely decompensated heart failure in the U.S., but not in several European countries. Early clinical studies and a meta-analysis raised concerns that the use of neseritide was associated with an increased risk for renal failure and death when compared to a noninotrope control therapy (Sackner-Bernstein et al., 2005). This risk was not confirmed in a more recent study (O'Connor et al., 2011), but beneficial effects (dyspnea relief) were also modest.

Positive Inotropic Agents

Stimulating the heart's force of contraction in a situation of critically diminished cardiac output may appear to be the most intuitive intervention. Yet, inotropes in acutely decompensated heart failure are associated with worse outcome and should therefore be restricted to patients with critically low cardiac output and perfusion of vital organs. Hypotension less than 85 mm Hg has been suggested as a practical limit (Ponikowski et al., 2016). Reasons for the adverse consequences of positive inotropes are probably complex. All inotropic agents increase cardiac energy expenditure (greater and faster force development \Rightarrow more ATP consumption \Rightarrow greater O_2 demand), which carries the risk of diffuse cardiac myocyte death. In acutely decompensated heart failure, the risk is exaggerated by the low perfusion pressure, any preexisting coronary artery disease, and the likely presence of cardiac myocyte hypertrophy and myocyte-endothelial cell mismatch. Tachycardia, aggravated by many inotropes, adds to the problem by strongly increasing energy expenditure and reducing the time for coronary perfusion in diastole. All positive inotropes increase the risk of arrhythmias.

Dobutamine

Dobutamine is the β adrenergic agonist of choice for the management of patients with acute CHF with systolic dysfunction. Dobutamine has relatively well-balanced cardiac and vascular actions: stimulation of cardiac output with less tachycardia than EPI and with a concomitant decrease in pulmonary artery wedge pressure. Dobutamine is a racemic mixture of (–) and (+) enantiomers. The (–) enantiomer is a potent agonist at α_1 adrenergic receptors and a weak agonist at β_1 and β_2 receptors. The (+) enantiomer is a potent β_1 and β_2 agonist without much activity at α_1 adrenergic receptors. Dobutamine has no activity at dopamine receptors. At infusion rates that result in a positive inotropic effect in humans, the β_1 adrenergic effect

in the myocardium predominates. In the vasculature, the α_1 adrenergic agonist effect of the (–) enantiomer appears to be offset by the vasodilating effects of the (+) enantiomer at β_2 receptors. Thus, the principal hemodynamic effect of dobutamine is an increase in stroke volume from positive inotropy, augmented by a small decrease in systemic vascular resistance and, therefore, afterload. Lowering of pulmonary artery capillary pressure is considered an advantage compared to other catecholamines, as is the smaller chronotropic effect (reasons for which are not clear).

Continuous dobutamine infusions are typically initiated at 2–3 $\mu\text{g/kg/min}$ and uptitrated until the desired hemodynamic response is achieved. Pharmacologic tolerance may limit infusion efficacy beyond 4 days; therefore, addition or substitution a PDE3 inhibitor may be necessary to maintain adequate circulatory support. The major side effects of dobutamine are tachycardia and supraventricular/ventricular arrhythmias, which may require a reduction in dosage. The concurrent use of β blockers is a common cause of blunted clinical responsiveness to dobutamine. It can be overcome by higher doses in case of bisoprolol and metoprolol, but not as easily for carvedilol, which has a very slow dissociation rate.

Epinephrine

The natural sympathetic agonist is mainly produced by the adrenal gland and systemically released. It is a balanced β_1 , β_2 , and α_1 adrenergic agonist and has a similar net hemodynamic effect as dobutamine, but with a stronger tachycardic effect, which makes it a second-choice inotrope in acutely decompensated heart failure.

Norepinephrine

The main sympathetic neurotransmitter released from sympathetic nerve endings is a potent β_1 and α_1 agonist and weak β_2 receptor agonist. This profile causes the positive inotropism accompanied by prominent vasoconstriction and increased afterload. Vasoconstriction of coronary blood vessels promotes ischemia; increased afterload may impede cardiac output (Figure 29–4). However, the stronger blood pressure-increasing effect of NE may be needed in persistent hypotension despite adequate cardiac filling pressures. Moreover, the increase in mean blood pressure leads to a reflex increase in parasympathetic nervous tone that can antagonize the direct tachycardic effect of NE and actually cause bradycardia.

Dopamine

The pharmacologic and hemodynamic effects of DA vary with concentration. Low doses ($\leq 2 \mu\text{g/kg lean body mass/min}$) induce cAMP-dependent vascular smooth muscle vasodilation by direct stimulation of D2 receptors. Activation of D2 receptors on sympathetic nerves in the peripheral circulation also inhibits NE release and reduces α adrenergic stimulation of vascular smooth muscle, particularly in splanchnic and renal arterial beds. This is the pharmacological basis for the “low-dose DA infusion” historically used to increase renal blood flow and maintain an adequate GFR and diuresis in hospitalized patients with CHF with impaired renal function refractory to diuretics. However, mainly negative clinical studies argue against the validity of this concept (Chen et al., 2013; Vargo et al., 1996). At intermediate infusion rates (2–5 $\mu\text{g/kg/min}$), dopamine directly stimulates cardiac β receptors to enhance myocardial contractility. At higher infusion rates (5–15 $\mu\text{g/kg/min}$), α adrenergic receptor stimulation-mediated peripheral arterial and venous constriction occurs. The complex profile and negative clinical data on low-dose infusion make DA a second or third choice in the treatment of heart failure.

Phosphodiesterase Inhibitors

The cAMP-PDE inhibitors decrease cellular cAMP degradation, resulting in elevated levels of cAMP. This results in positive inotropic and chronotropic effects in the heart and dilation of resistance and capacitance vessels, effectively decreasing preload and afterload (thus the term *inodilator*). PDE inhibitors may be more advantageous than catecholamines in patients on β blockers and in patients with high systemic or pulmonary artery resistance. Hypotension is often dose limiting; tachycardic and arrhythmogenic effects are similar to those of catecholamines.

Milrinone and Enoximone. Parenteral formulations of milrinone and enoximone are used for short-term circulation support in advanced CHF.

Enoximone (not available in the U.S.) is a relative selective inhibitor of PDE3, the cGMP-inhibited cAMP PDE and main isoform involved in inotropic control in human heart. Milrinone inhibits human heart PDE3 and PDE4 with similar potency (Bethke et al., 1992). By increasing intracellular cAMP concentrations, they have similar actions as the β receptor agonists dobutamine and EPI, but tend to lower systemic and pulmonary vascular resistance more than do the catecholamines. It should be kept in mind that PDE inhibitors potentiate the actions of β receptor agonists, both beneficial and detrimental. The loading dose of milrinone is ordinarily 25–75 $\mu\text{g/kg}$, and the continuous infusion rate ranges from 0.375 to 0.75 $\mu\text{g/kg/min}$. Bolus doses of enoximone at 0.5–1.0 mg/kg over 5–10 min are followed by an infusion of 5–20 $\mu\text{g/kg/min}$. The elimination half-lives of milrinone and enoximone in normal individuals are 0.5–1 h and 2–3 h, respectively, but can be increased in patients with severe CHF.

Myofilament Calcium Sensitizers (Levosimendan, Pimobendan)

In some countries but not in the U.S., calcium sensitizers are approved for the short-term treatment of acutely decompensated heart failure (e.g., levosimendan in Sweden, pimobendan in Japan). Calcium sensitizers increase the sensitivity of contractile myofilaments to Ca^{2+} by binding to and inducing a conformational change in the thin-filament regulatory protein troponin C. This causes an increased force for a given cytosolic Ca^{2+} concentration, theoretically without raising the $[\text{Ca}^{2+}]_{\text{cytosol}}$. However, a variety of other effects has been ascribed to pimobendan and levosimendan, including inhibition of PDEs, inhibition of the production of pro-inflammatory cytokines, and opening of ATP-dependent potassium channels. Clinical data provide evidence for symptomatic benefit and reductions in the length of stay in the hospital but do not support a better safety profile of levosimendan compared to catecholamines or classical PDE inhibitors (Mebazaa et al., 2007). Increased rates of arrhythmia and death are likely related to the PDE3 inhibitor activity of these compounds.

Other Drugs Used in Heart Failure

The vasopressin receptor antagonist tolvaptan is FDA-approved for the treatment of therapy-resistant hyponatremia, a common and difficult-to-treat complication in decompensated heart failure. Studies in a more general cohort of patients with heart failure failed to show convincing beneficial effects of this compound. Severe thirst and dehydration are common side effects. Heparin or other anticoagulants are routinely used in hospitalized patients with heart failure to prevent thromboembolism.

Role of Standard Combination Therapy

The majority of patients hospitalized with acutely decompensated heart failure have preexisting heart failure and respective maintenance therapy. Guidelines suggest reviewing a patient's existing therapy on admission to determine whether recent changes in the medication could be causally related to an exacerbation of cardiac disease. If not, the standard heart failure medication (ACEI, β blocker, MRA, diuretic) should be continued in the absence of hemodynamic instability or contraindications (Yancey et al., 2013).

Lessons From Heart Failure Drug Development

Heart failure is an attractive but difficult indication for drug development. The number of drug development failures over the past two decades largely exceeded that of successes, indicating our incomplete understanding of the pathophysiology of heart failure, but sometimes also signaling problematic trial design. Even negative trials have helped to better understand the disease. Examples of drugs that have been tested in large prospective trials and failed are listed in Table 29–6.

Lessons From Failed Drugs

The failure of *positive inotropic agents* (PDE inhibitors, catecholamines, calcium sensitizers, mixed-acting compounds such as flosequinan or

TABLE 29–6 ■ FAILURES IN DRUG DEVELOPMENT FOR HEART FAILURE

DRUG (type)	YEAR OF PUBLICATION	REASON FOR FAILURE
Milrinone (PDE inhibitor)	1991	Increased mortality
Pimobendan (PDE inhibitor)	1996	Trend toward increased mortality
Flosequinan (unclear)	1993	Increased mortality
Vesnarinone (unclear)	1998	Increased mortality, arrhythmias
Moxonidine (central antisymphathetic)	1998	Increased mortality
Infliximab (TNF α blocker)	2003	Increased mortality
Etanercept (TNF α blocker)	2004	Trend toward increased mortality
Bosentan (ET receptor blocker)	2005	Liver toxicity, trend toward benefit over time (?)
Etomoxir (CPT1 blocker)	2007	Liver toxicity
Omapatrilat (dual ACEI and neprilysin inhibitor)	2002	Angioedema, no clear benefit
ARB + ACEI	2003 and 2008	No benefit, more angioedema and renal side effects
Rosuvastatin (HMG CoA reductase inhibitor)	2007	No benefit
Tolvaptan (vasopressin V2 receptor blocker)	2009	No benefit
Rolophylline (adenosine A ₁ receptor blocker)	2009	No benefit, seizures

vesnarinone; Cohn et al., 1998) to improve long-term outcome of patients with heart failure has induced a paradigm shift toward drugs that unload the heart and reduce neurohumoral activation, the current standard. It demonstrated that further stimulating the failing heart may transiently improve symptoms but increase mortality. But, simply reducing the load without protecting the heart from the adverse consequences of the activated SNS and RAAS also seems inefficient, as exemplified by the neutral effect of the α_1 receptor antagonist *prazosin* in the VeHeFT-I trial (Cohn et al., 1986). *Moxonidine*, a centrally acting α_2 /imidazole agonist with similar sympatholytic actions as clonidine, should have had efficacy similar to that of β blockers, but moxonidine increased mortality in a larger prospective trial (Cohn et al., 2003). It is unclear whether doses and dose titration were too aggressive or whether the principle of central sympatholysis is unsafe in heart failure. Multiple lines of laboratory and clinical evidence suggested that heart failure has an important inflammatory component; yet, two blockers of TNF, *infliximab* and *etanercept*, induced harm rather

than benefit in patients with chronic heart failure (Chung et al., 2003; Mann et al., 2004).

Endothelin 1, a potent vasoconstrictor, is upregulated in heart failure and could play an adverse role in heart failure, similar to that of AngII. Nonselective ET receptor antagonists such as *bosentan* had striking efficacy in postinfarct rodent models and are successfully used in pulmonary hypertension (Chapter 31). However, bosentan showed no efficacy in patients with chronic heart failure (Packer et al., 2005). *Omapatrilat*, a dual inhibitor of ACE and neprilysin, can decrease AngII and increase ANP/BNP, conditions promoting vasodilation, diuresis, and antihypertrophic effects; however, expectations that omapatrilat would be more efficacious than an ACEI in heart failure were not confirmed in a prospective study (Packer et al., 2002).

Numerous clinical trials have tested the idea that adding an ARB or the renin inhibitor *aliskiren* to standard therapy that includes an ACEI would be beneficial by more completely inhibiting the RAAS. With the exception of one trial (McMurray et al., 2003), studies of these combinations consistently showed a lack of benefit and an increase in adverse effects, particularly decreased renal function and hyperkalemia. The premise was that if some inhibition of the RAAS is good, more would be better; perhaps the premise was wrong.

Statins were proposed to have anti-inflammatory, antihypertrophic, and pro-angiogenic effects independent of their cholesterol-lowering effect (Liao and Laufs, 2005). Trials testing this hypothesis by adding statins to standard treatment of chronic heart failure demonstrated that the combination was safe but had no added beneficial effect on mortality (Kjekshus et al., 2007). An antagonist of the V₂ vasopressin receptor tolvaptan was ineffective in patients with chronic stable heart failure (Udelson et al., 2007). The discrepancy to several positive preclinical and early clinical studies suggests that the vasopressin axis of the neurohumoral activation program in heart failure may be sufficiently addressed by standard combination therapy, leaving no room for further improvement.

Lessons From Treating Acute Heart Failure

The drugs currently recommended (furosemide, nitroglycerin, dobutamine) for the treatment of acutely decompensated heart failure have never been tested in adequately powered prospective clinical trials. All novel drugs tested either in comparison to standard inotropes or noninotropes or as an add-on have failed to show convincing superiority or benefit in terms of symptoms, duration of hospitalization, and 30-day mortality. The A₂ adenosine receptor antagonist *rolophylline* should produce several beneficial effects on the kidney, including inhibition of tubular reabsorption of Na⁺ and water, dilation of the afferent arteriole, and inhibition of tubuloglomerular feedback, but its addition to standard therapy in patients with acute heart failure with impaired kidney function produced no salutary renal or cardiac effects and caused unacceptable adverse effects such as seizures, a typical side effect of central A₁ adenosine antagonism known also from theophylline (Massie et al., 2010).

Recent Developments; Novel Approaches

Numerous pharmacological and nonpharmacological treatment options are being tested in preclinical and clinical studies (<https://www.clinicaltrials.gov>). They range from cell and gene therapies to food supplements (vitamins, polyunsaturated fatty acid) and intravenous iron to classical small molecules. In the CUPID2 trial, gene therapy, in the form of an intracoronary infusion of adeno-associated virus 1/SERCA2, did not provide any benefit in HFrEF (Greenberg et al., 2016). *Serelaxin*, recombinant human *relaxin* 2, is a naturally occurring peptide with 53 amino acids discovered in 1926 as an ovarian hormone inducing relaxation of the uterus during pregnancy. Its actions on the cardiovascular system include increased arterial compliance, cardiac output, and renal blood flow, characteristics of a promising drug for the treatment of acutely decompensated heart failure. However, the promising results of an earlier study (Teerlink et al., 2013) were not confirmed in a larger phase III trial (announced online March 2017).

Guanylyl cyclases are established targets for natriuretic peptides (the membrane form, mGC) and NO and organic nitrates (the soluble form,

sGC). *Riociguat* is a direct, heme-dependent stimulator of sGC; *cinaciguat* is a heme-independent activator of sGC. Oxidative inactivation of sGC is believed to be a common pathology in cardiovascular disease and a reason for endothelial dysfunction. sGC activators have maintained (or even enhanced) effects at sGC enzymes inactivated by oxidation. Riociguat is approved for the treatment of pulmonary artery hypertension and chronic thromboembolic pulmonary hypertension (see Chapter 31). A prospective study with cinaciguat was prematurely stopped because the drug not only lowered pulmonary wedge pressure and increased cardiac output, but also markedly increased the rate of symptomatic hypotension (Erdmann et al., 2013), a classical problem of vasodilator therapy in acute heart failure.

Heart failure is often associated with anemia, a predictor of a poor prognosis. Yet, correction of anemia by an erythropoietin derivative,

darbapoetin alpha, did not affect any clinical end point but increased the rate of thromboembolic events and ischemic strokes in patients with heart failure and mild-to-moderate anemia (Swedberg et al., 2013). However, intravenous iron, added to standard therapy in patients with NYHA class II–III heart failure, iron deficiency, and hemoglobin levels of 9.5–13.5 g/dL, improved quality of life, NYHA class, and physical exercise capacity (Anker et al., 2009). The beneficial effects seemed to be independent of the presence of anemia and may be related to other roles of iron in the body. Larger prospective studies are needed to confirm the effects.

Acknowledgment: Henry Ooi, Wilson Colucci, Bradley A. Maron, James C. Fang, and Thomas P. Rocco have contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: Heart Failure Drugs

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Inhibitors of the Renin-Angiotensin System		
ACE Inhibitors Benazepril Captopril Enalapril Lisinopril Quinapril Ramipril	<ul style="list-style-type: none"> Heart failure Hypertension Diabetic nephropathy 	<ul style="list-style-type: none"> First choice in treating heart failure Short-acting captopril only for initiation of therapy; enalapril requires twice-daily dosing Cough in 5%–10% of patients; angioedema Hypotension, hyperkalemia, skin rash, neutropenia, anemia, fetopathic syndrome Contraindicated in patients with renal artery stenosis; caution in patients with impaired renal function or hypovolemia
Fosinopril Trandolapril Perindopril		<ul style="list-style-type: none"> Both hepatic and renal elimination, caution in patients with renal or hepatic impairment
Angiotensin Receptor Blockers Candesartan Eprosartan Irbesartan Losartan Olmesartan Telmisartan Valsartan	<ul style="list-style-type: none"> Hypertension Heart failure Diabetic nephropathy 	<ul style="list-style-type: none"> Only in cases of intolerance to ACEI Unwanted effects as ACEI, but no cough or angioedema No evidence for superiority over ACEI In combination with ACEI more harm than benefit
β Blockers		
Bisoprolol Carvedilol Metoprolol Nebivolol	<ul style="list-style-type: none"> Heart failure Hypertension Widely used for angina, prevention of arrhythmias, rate control in atrial fibrillation, migraine 	<ul style="list-style-type: none"> First choice in the treatment of heart failure Start low (1/10 target dose), go slow (2- to 4-weekly doubling) Adverse effects: bradycardia, AV block, bronchospasm, peripheral vasoconstriction, worsening of acute heart failure, depression, worsening of psoriasis Polymorphic CYP2D6 metabolism (metoprolol)
Mineralocorticoid Receptor Antagonists		
Eplerenone Spironolactone	<ul style="list-style-type: none"> Heart failure Hypertension Hyperaldosteronism, hypokalemia, ascites 	<ul style="list-style-type: none"> First choice in treating symptomatic heart failure Low doses (25–50 mg) Most serious side effect is hyperkalemia Spironolactone causes painful breast swelling and impotence in men, dysmenorrhea in women due to nonselective binding to sex hormone receptors
Neprilysin Inhibitor/Angiotensin Receptor Blocker		
Sacubitril/valsartan	<ul style="list-style-type: none"> Heart failure 	<ul style="list-style-type: none"> Superior to the ACEI enalapril May become first choice in treating heart failure ↓ Degradation of natriuretic peptides, ↑ their beneficial actions Hypotension
Diuretics		
Thiazide Type Chlorothiazide Hydrochlorothiazide Thiazide-like Chlorthalidone Indapamide Metolazone	<ul style="list-style-type: none"> Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease, and nephrotic syndrome Hypertension Nephrogenic diabetes insipidus Kidney stones caused by Ca²⁺ crystals 	<ul style="list-style-type: none"> Symptomatic treatment of milder forms of heart failure Loose efficacy at GFR < 30–40 mL/min (exception indapamide and metolazone) Potentiate effect of loop diuretics in severe heart failure (sequential tubulus blockade) Risk for hypokalemia and arrhythmia when combined with QT-prolonging drugs

Drug Facts for Your Personal Formulary: *Heart Failure Drugs (continued)*

Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Loop Diuretics Bumetanide Furosemide Torasemide	<ul style="list-style-type: none"> Acute pulmonary edema (intravenous) Edema associated with congestive heart failure, liver cirrhosis, chronic kidney disease, and nephrotic syndrome Hyponatremia Hypercalcemia Hypertension with renal insufficiency 	<ul style="list-style-type: none"> Symptomatic treatment of severe heart failure and acute decompensation Often required in treating severe chronic heart failure, twice-daily dosing or more Torsemide may be superior to furosemide in heart failure Risk for hypokalemia and arrhythmia when combined with QT-prolonging drugs
Vasodilators		
ISDN/hydralazine	<ul style="list-style-type: none"> Heart failure in African Americans 	<ul style="list-style-type: none"> Approved only for African Americans Adverse effects: headache, nausea, flushing, hypotension, palpitations, tachycardia, dizziness, angina pectoris; \Rightarrow use in combination with β blocker Compliance problems Lupus syndrome
Positive Inotropes		
Digoxin Digitoxin	<ul style="list-style-type: none"> Heart failure 	<ul style="list-style-type: none"> Not first choice in treating heart failure May exert benefits in heart failure and atrial fibrillation Low therapeutic index: proarrhythmic, nausea, diarrhea, visual disturbances Digoxin kidney dependent, digitoxin not Half-life 1.5 (digoxin) or 7 days (digitoxin) Plasma concentration: 0.5–0.8 ng/mL (digoxin) or 10–25 ng/mL (digitoxin)
Heart Rate Reduction		
Ivabradine	<ul style="list-style-type: none"> Heart failure 	<ul style="list-style-type: none"> Not first choice in treating heart failure May exert benefits in patients not tolerating β blockers or having heart rate > 75 under β blockers Unwanted effects: bradycardia, QT prolongation, atrial fibrillation, phosphenes
Intravenous Vasodilators: Acute decompensated heart failure		
Nitroglycerin Sodium nitroprusside	<ul style="list-style-type: none"> Acute decompensated heart failure 	<ul style="list-style-type: none"> May \uparrow cardiac output in acute congestion (\uparrow filling pressure and dilation) via \downarrow preload and afterload NO releaser, stimulates soluble guanylyl cyclase Avoid if systolic blood pressure < 110 mmHg Prognostic benefit unclear
Nesiritide	<ul style="list-style-type: none"> Acute decompensated heart failure 	<ul style="list-style-type: none"> Recombinant human BNP Stimulates membrane-bound guanylyl cyclase May \uparrow cardiac output via \downarrow preload and afterload Therapeutic benefit unclear
Intravenous Positive Inotropes: Acutely decompensated heart failure		
Dobutamine Dopamine Epinephrine Norepinephrine	<ul style="list-style-type: none"> Acute decompensated heart failure 	<ul style="list-style-type: none"> β_1 receptor-mediated stimulation of cardiac output and, depending on drug, complex vascular actions Last option in patients with systolic blood pressure < 85 mmHg \uparrow Cardiac energy consumption and risk of arrhythmia Use of catecholamines correlates with poor prognosis; use lowest possible doses for shortest possible time Dobutamine causes less tachycardia than EPI and less afterload increase than NE Role of low-dose dopamine unclear
Enoximone Milrinone	<ul style="list-style-type: none"> Acute decompensated heart failure 	<ul style="list-style-type: none"> PDE3/4 inhibitors, \uparrow cellular cAMP \uparrow Cardiac output and dilate blood vessels ("inodilator") May be used in patients on β blockers and with high peripheral and pulmonary arterial resistance Blood pressure decrease is dose limiting Risks and prognostic effects: same as catecholamines (above)
Levosimendan	<ul style="list-style-type: none"> Acute decompensated heart failure 	<ul style="list-style-type: none"> Combined Ca^{2+} sensitizer (troponin C binding) and PDE3 inhibitor \uparrow Cardiac output and \downarrow vascular resistance ("inodilator") Advantages over catecholamines or simple PDE inhibitors unclear

Chapter 30

Antiarrhythmic Drugs

Bjorn C. Knollmann and Dan M. Roden

PRINCIPLES OF CARDIAC ELECTROPHYSIOLOGY

- The Cardiac Cell at Rest: a K^+ -Permeable Membrane
- The Cardiac Action Potential
- Maintenance of Intracellular Ion Homeostasis
- Genetic Arrhythmia Diseases
- Action Potential Heterogeneity in the Heart
- Impulse Propagation and the Electrocardiogram
- Refractoriness and Conduction Failure

MECHANISMS OF CARDIAC ARRHYTHMIAS

- Enhanced Automaticity
- Afterdepolarizations and Triggered Automaticity
- Reentry
- Common Arrhythmias and Their Mechanisms

MECHANISMS OF ANTIARRHYTHMIC DRUG ACTION

- State-Dependent Ion Channel Block
- Classifying Antiarrhythmic Drugs

PRINCIPLES IN THE CLINICAL USE OF ANTIARRHYTHMIC DRUGS

- 1. Identify and Remove Precipitating Factors
- 2. Establish the Goals of Treatment

- 3. Minimize Risks
- 4. Consider the Electrophysiology of the Heart as a "Moving Target"

ANTIARRHYTHMIC DRUGS

- Adenosine
- Amiodarone
- Bretylium
- Digoxin
- Disopyramide
- Dofetilide

Cardiac cells undergo depolarization and repolarization about 60 times per minute to form and propagate cardiac action potentials. The shape and duration of each action potential are determined by the activity of ion channel protein complexes in the membranes of individual cells, and the genes encoding most of these proteins and their regulators now have been identified. Action potentials in turn provide the primary signals to release Ca^{2+} from intracellular stores and to thereby initiate contraction. Thus, each normal heartbeat results from the highly integrated electrophysiological behavior of multiple proteins on the surface and within multiple cardiac cells. Disordered cardiac rhythm can arise from influences such as inherited variation in ion channel or other genes, ischemia, sympathetic stimulation, or myocardial scarring. Available antiarrhythmic drugs suppress arrhythmias by blocking flow through specific ion channels or by altering autonomic function. An increasingly sophisticated understanding of the molecular basis of normal and abnormal cardiac rhythm may lead to identification of new targets for antiarrhythmic drugs and perhaps improved therapies (Dobrev et al., 2012; Van Wagoner et al., 2015).

Arrhythmias can range from incidental, asymptomatic clinical findings to life-threatening abnormalities. Mechanisms underlying cardiac arrhythmias have been identified in cellular and animal experiments. For some human arrhythmias, precise mechanisms are known, and treatment can be targeted specifically to those mechanisms. In other cases, mechanisms can be only inferred, and the choice of drugs is based largely on results of prior experience. Antiarrhythmic drug therapy has two goals: termination of an ongoing arrhythmia or prevention of an arrhythmia. Unfortunately, antiarrhythmic drugs may not only help control arrhythmias but also can cause them, even during long-term therapy. Thus, prescribing antiarrhythmic drugs requires that precipitating factors be

excluded or minimized, that a precise diagnosis of the type of arrhythmia (and its possible mechanisms) be made, that the prescriber has reason to believe that drug therapy will be beneficial, and that the risks of drug therapy can be minimized.

Principles of Cardiac Electrophysiology

The flow of ions across cell membranes generates the currents that make up cardiac action potentials. Factors that determine the magnitude of individual currents and their modulation by drugs include transmembrane potential, time since depolarization, or the presence of specific ligands (Nerbonne and Kass, 2005; Priori et al., 1999). Further, because the function of many channels is time and voltage dependent, even a drug that targets a single ion channel may, by altering the trajectory of the action potential, alter the function of other channels. Most antiarrhythmic drugs affect more than one ion current, and many exert ancillary effects, such as modification of cardiac contractility or autonomic nervous system function. Thus, antiarrhythmic drugs usually exert multiple actions and can be beneficial or harmful in individual patients (Priori et al., 1999; Roden, 1994).

The Cardiac Cell at Rest: a K^+ -Permeable Membrane

Ions move across cell membranes in response to electrical and concentration gradients, not through the lipid bilayer but through specific ion channels or transporters. The normal cardiac cell at rest maintains a transmembrane potential approximately 80 to 90 mV negative to the exterior; this gradient is established by pumps, especially the Na^+ , K^+ -ATPase, and fixed anionic charges within cells. There are both an electrical and a

Abbreviations

AF: atrial fibrillation/flutter
4-AP: 4-aminopyridine
AV: atrioventricular
 β blocker: β adrenergic receptor antagonist
CPVT: catecholaminergic polymorphic ventricular tachycardia
DAD: delayed afterdepolarization
DC: direct current
EAD: early afterdepolarization
ECG: electrocardiogram
ERP: effective refractory period
GX: glycine xylidide
HERG: *human ether-a-go-go related gene*
ICD: implantable cardioverter-defibrillator
IV: intravenous
LQTS: long QT syndrome
LV: left ventricle
NCX: Na^+ - Ca^{2+} exchanger
PSVT: paroxysmal supraventricular tachycardia
RV: right ventricle
RyR2: ryanodine receptor type 2
SA: sinoatrial
SERCA2: SR- Ca^{2+} ATPase
SR: sarcoplasmic reticulum
VF: ventricular fibrillation
VT: ventricular tachycardia
WPW: Wolff-Parkinson-White

concentration gradient that would move Na^+ ions into resting cells (Figure 30-1). However, Na^+ channels, which allow Na^+ to move along this gradient, are closed in the cardiac cell at rest, so Na^+ does not enter normal resting cardiac cells. In contrast, a specific type of K^+ channel protein (the inward rectifier channel) remains open at negative resting

Figure 30-1 Electrical and chemical gradients for K^+ and for Na^+ in a resting cardiac cell. Inward rectifier K^+ channels are open (left), allowing K^+ ions to move across the membrane and the transmembrane potential to approach E_{K} . In contrast, Na^+ does not enter the cell despite a large net driving force because Na^+ channel proteins are in the closed conformation (right) in resting cells.

potentials. Hence, K^+ can move through these channels across the cell membrane at negative potentials in response to either electrical or concentration gradients (Figure 30-1). For each individual ion, there is an equilibrium potential E_x at which there is no net driving force for the ion to move across the membrane. E_x can be calculated using the Nernst equation:

$$E_x = -(RT/FZx) \ln([x]_i/[x]_o) \quad (30-1)$$

where Zx is the valence of the ion, T is the absolute temperature, R is the gas constant, F is Faraday's constant, $[x]_o$ is the extracellular concentration of the ion, and $[x]_i$ is the intracellular concentration. For typical values for K^+ , $[\text{K}]_o = 4 \text{ mM}$ and $[\text{K}]_i = 150 \text{ mM}$, the calculated K^+ equilibrium potential E_{K} is -96 mV . There is thus no net force driving K^+ ions into or out of a cell when the transmembrane potential is -96 mV , which is close to the resting potential. If $[\text{K}]_o$ is elevated to 10 mM , as might occur in diseases such as renal failure or myocardial ischemia, the calculated E_{K} rises to -70 mV . In this situation, there is excellent agreement between changes in theoretical E_{K} owing to changes in $[\text{K}]_o$ and the actual measured transmembrane potential, indicating that the normal cardiac cell at rest is permeable to K^+ (because inward rectifier channels are open) and that $[\text{K}]_o$ is the major determinant of resting potential.

The Cardiac Action Potential

Transmembrane current through voltage-gated ion channels is the primary determinant of cardiac action potential morphology and duration. Channels are macromolecular complexes consisting of a pore-forming transmembrane structure (which may be a single protein, often termed an α subunit, or a multimer), as well as function-modifying β subunits and other accessory proteins. Common features of the pore-forming structure include a voltage-sensing domain, a selectivity filter, a conducting pore, and an inactivating particle (Figure 30-2; see also Figure 22-2). In response to changes in local transmembrane potential, ion channels undergo conformational changes, allowing for, or preventing, the flow of ions through the conducting pore along their electrochemical gradient, generally in time-, voltage-, or ligand-dependent fashion.

To initiate an action potential, a cardiac myocyte at rest is depolarized above a threshold potential, usually via gap junctions by a neighboring myocyte. On membrane depolarization, Na^+ channel proteins change conformation from the "closed" (resting) state to the "open" (conducting) state (Figure 30-2), allowing up to 10^7 Na^+ ions/s to enter each cell and moving the transmembrane potential toward E_{Na} ($+65 \text{ mV}$). This surge of Na^+ ions lasts only about a millisecond, after which the Na^+ channel protein rapidly changes conformation from the open state to an "inactivated," nonconducting state (Figure 30-2). The maximum upstroke slope of phase 0 (dV/dt_{max} , or V_{max}) of the action potential (Figure 30-3) is largely governed by

Figure 30-2 Voltage-dependent conformational changes determine current flow through Na^+ channels. At hyperpolarized potentials, the channel is in a closed conformation, and no current can flow (left). As depolarization begins, the voltage sensor (indicated here as ++++) moves, thus altering channel conformation and opening the pore, allowing conduction (middle). As depolarization is maintained, an intracellular particle blocks current flow, making the channel nonconducting in this inactivated state (right).

Na^+ current and is a major determinant of conduction velocity of a propagating action potential. Under normal conditions, Na^+ channels, once inactivated, cannot reopen until they reassume the closed conformation. However, a small population of Na^+ channels may continue to open during the action potential plateau in some cells (Figure 30–3), providing further inward current, often termed a “late” Na^+ current. As the cell membrane repolarizes, the negative membrane potential moves Na^+ channel proteins from inactivated to closed conformations, from which they are again available to open and depolarize the cell. The relationship between Na^+ channel availability and transmembrane potential is an important determinant of conduction and refractoriness in many cells, as discussed in the material that follows.

The changes in transmembrane potential generated by the inward Na^+ current produce, in turn, a series of openings (and in some cases subsequent inactivation) of other channels (Figure 30–3). For example, when a cell is depolarized by the Na^+ current, “transient outward” K^+ channels quickly change conformation to enter an open, or conducting, state; because the transmembrane potential at the end of phase 0 is positive to E_{K} , the opening of transient outward channels results in an outward, or repolarizing, K^+ current (termed I_{TO}), which contributes to the phase 1 “notch” seen in some action potentials (e.g., more prominent in epicardium than in endocardium). Transient outward K^+ channels, like Na^+ channels, inactivate rapidly. During the phase 2 plateau of a normal cardiac action potential, inward, depolarizing currents, primarily through L-type Ca^{2+} channels, are balanced by outward, repolarizing currents primarily through K^+ (“delayed rectifier”) channels. Delayed rectifier currents (collectively termed I_{K}) increase with time, whereas Ca^{2+} currents inactivate (and so decrease with time); as a result, cardiac cells repolarize (phase 3) several hundred milliseconds after the initial Na^+ channel opening.

Figure 30–3 The relationship between an action potential from the conducting system and the time course of the currents that generate it. The current magnitudes are not to scale; the Na^+ current is ordinarily 50 times larger than any other current, although the portion that persists into the plateau (phase 2) is small. Multiple types of Ca^{2+} current, transient outward current I_{TO} , and delayed rectifier I_{K} have been identified. Each represents a different channel protein, usually associated with ancillary (function-modifying) subunits. 4-AP is a widely used in vitro blocker of K^+ channels. I_{TO2} may be a Cl^- current in some species. Components of I_{K} have been separated on the basis of how rapidly they activate: slowly (I_{Ks}), rapidly (I_{Kr}), or ultrarapidly (I_{Kur}). The voltage-activated, time-independent current may be carried by Cl^- (I_{Cl}) or K^+ (I_{Kp} , p for plateau). The genes encoding the major pore-forming proteins have been cloned for most of the channels shown here and are listed in the right-hand column.

A common mechanism whereby drugs prolong cardiac action potentials and provoke arrhythmias is inhibition of a specific delayed rectifier current, I_{Kr} , generated by expression of *KCNH2* (formerly termed the *HERG*). The ion channel protein generated by *KCNH2* expression differs from other ion channels in important structural features that make it much more susceptible to drug block; understanding these structural constraints is an important first step to designing drugs lacking I_{Kr} -blocking properties (Mitcheson et al., 2000). Avoiding I_{Kr} /*KCNH2* channel block has become a major issue in drug development (Roden, 2004).

Maintenance of Intracellular Ion Homeostasis

With each action potential, the cell interior gains Na^+ ions and loses K^+ ions. An ATP-requiring Na^+ - K^+ exchange mechanism, or pump, is activated in most cells to maintain intracellular homeostasis. This Na^+ , K^+ -ATPase extrudes three Na^+ ions for every two K^+ ions shuttled from the exterior of the cell to the interior; as a result, the act of pumping itself is electrogenic, generating a net outward (repolarizing) current.

Normally, intracellular Ca^{2+} is maintained at very low levels (<100 nM). In cardiac myocytes, the entry of Ca^{2+} during each action potential through L-type Ca^{2+} channels is a signal to the SR to release its Ca^{2+} stores, and thus initiate Ca^{2+} -dependent contraction, a process termed excitation-contraction coupling. The efflux of Ca^{2+} from the SR occurs through ryanodine receptor release channels (RyR2) and subsequent removal of intracellular Ca^{2+} occurs by both SERCA2, which moves Ca^{2+} ions back into the SR, and an electrogenic NCX on the cell surface, which exchanges three Na^+ ions from the exterior for each Ca^{2+} ion extruded.

Genetic Arrhythmia Diseases

Rare congenital arrhythmia diseases such as the LQTS and CPVT can cause sudden death due to fatal arrhythmias, often in young subjects. The identification of disease genes not only has resulted in improved care of affected patients and their families but also has contributed importantly to our understanding of the normal action potential, arrhythmia mechanisms, and potential antiarrhythmic drug targets (Keating and Sanguinetti, 2001). For example, mutations in the cardiac Na^+ channel gene *SCN5A* can cause one form of LQTS by destabilizing fast inactivation, increasing late Na^+ current, thereby prolonging action potentials, and thus the QT interval (as discussed in material that follows). Drugs inhibiting this abnormal current may be antiarrhythmic in this form of LQTS (Remme and Wilde, 2013), and drugs increasing late Na^+ current may cause arrhythmias (Yang et al., 2014). Inhibitors may include not only antiarrhythmics such as mexiletine or flecainide discussed in this chapter, but also the antianginal agent ranolazine (see Chapter 28), which appears to be a late Na^+ current blocker.

Similarly, mutations in the *RyR2* gene encoding an intracellular Ca^{2+} release channel (or less commonly in other genes regulating *RyR2* function) cause CPVT by generating “leaky” *RyR2* channels, perturbing intracellular Ca^{2+} homeostasis and causing DAD-dependent arrhythmias described further in this chapter. Drugs such as flecainide and propafenone that inhibit these abnormal *RyR2* channels appear to prevent CPVT in mouse models and in humans (Watanabe et al., 2009). Intriguingly, some arrhythmias in acquired heart disease have been attributed to increased late Na^+ current or leaky *RyR2* channels. Thus, studies in the rare congenital arrhythmia syndromes may point to new avenues for drug development in more common arrhythmias in acquired heart disease (Knollmann and Roden, 2008; Priori et al., 1999).

Action Potential Heterogeneity in the Heart

The general description of the action potential and the currents that underlie it must be modified for certain cell types (Figure 30–4), primarily due to variability in the expression of ion channels and electrogenic ion transport pumps. The resultant diversity of action potentials in different regions of the heart plays a role in understanding the pharmacological profiles of antiarrhythmic drugs. In the ventricle, action potential duration varies across the wall of each chamber, as well as apicobasally, largely as a consequence of varying densities of repolarizing currents. In the

Figure 30-4 Normal impulse propagation. A schematic of the human heart with example action potentials from different regions of the heart (top) for a normal beat and their corresponding contributions to the macroscopic ECG (bottom). neighboring His-Purkinje conduction system, action potentials are longer, probably due to decreased K^+ currents, increased “late” Na^+ currents, and differences in intercellular Ca^{2+} handling (Dun and Boyden, 2008).

Atrial cells have shorter action potentials than ventricular cells because of larger early repolarization currents such as I_{TO} . Atrial cells also express an additional repolarizing K^+ channel that is activated by the neurotransmitter acetylcholine and accounts for action potential shortening with vagal stimulation. Cells of the sinus and AV nodes lack substantial Na^+ currents, and depolarization is achieved by inward current generated by opening of Ca^{2+} channels. In addition, these cells, as well as cells from the conducting system, normally display the phenomenon of spontaneous diastolic, or phase 4, depolarization and thus spontaneously reach threshold for regeneration of action potentials. The rate of spontaneous firing usually is fastest in sinus node cells, which therefore serve as the natural pacemaker of the heart. The slow diastolic depolarization that underlies pacemaker activity is generated by a nonselective channel that conducts both Na^+ and K^+ and is activated at hyperpolarized membrane potentials (Cohen and Robinson, 2006). In diseased cells, pacemaker-like activity can arise from spontaneous Ca^{2+} release from the SR, followed by membrane depolarization due to activation of NCX.

Certain ion channels are expressed only in some tissues or become active only under specific pathophysiologic conditions. For example, the T-type Ca^{2+} channel may be important in diseases such as hypertension and play a role in pacemaker activity (Ono and Iijima, 2010). A T-type-selective Ca^{2+} channel antagonist, *mibefradil* was commercially available briefly in the late 1990s but was withdrawn because of concerns over potentially life-threatening pharmacokinetic interactions with many other drugs. A second example is a channel that transports Cl^- ions and results in repolarizing currents (I_{Cl}) (Duan, 2013); some of these are observed only in association with pathophysiological conditions. A third example is the K^+ channel that are quiescent when intracellular ATP stores are normal and become active when these stores are depleted. Such ATP-inhibited K^+ channel may become particularly important in repolarizing cells during states of metabolic stress such as myocardial ischemia (Tamargo et al., 2004).

Impulse Propagation and the Electrocardiogram

Normal cardiac impulses originate in the sinus node. Impulse propagation in the heart depends on the magnitude of the depolarizing current (usually Na^+ current) and the geometry and density of cell-cell electrical connections (Kleber and Saffitz, 2014). Cardiac cells are relatively long and thin and well coupled through specialized gap junction proteins at their ends, whereas lateral (“transverse”) gap junctions are sparser. As a result, impulses spread along cells two to three times faster than across cells. This “anisotropic” (direction-dependent) conduction may be a factor in the genesis of certain arrhythmias described in the material that follows (Priori et al., 1999).

Once impulses leave the sinus node, they propagate rapidly throughout the atria, resulting in atrial systole and the P wave of the surface ECG (Figure 30-4). Propagation slows markedly through the AV node, where the inward current (through Ca^{2+} channels) is much smaller than the Na^+ current in atria, ventricles, or the subendocardial conducting system. This conduction delay, represented as the PR interval on the ECG, allows the atrial contraction to propel blood into the ventricle, thereby optimizing cardiac output.

Once impulses exit the AV node, they enter the conducting system, where Na^+ currents are larger than in any other tissue, and propagation is correspondingly faster, up to 0.75 m/s longitudinally. Activation spreads from the His-Purkinje system on the endocardium of the ventricles throughout the rest of the ventricles, stimulating coordinated ventricular contraction. This electrical activation manifests itself as the QRS complex on the ECG. Ventricular repolarization is presented on the surface ECG as the T wave. The time from initial depolarization in the ventricle until the end of repolarization is termed the QT interval. Lengthening of ventricular action potentials prolongs the QT interval and may be associated with arrhythmias in LQTS and other settings.

Refractoriness and Conduction Failure

In atrial, ventricular, and His-Purkinje cells, if a restimulation occurs very early during the plateau of an action potential, no Na^+ channels are

available to open, so no inward current results, and no new action potential is generated: At this point, the cell is termed *refractory* (Figure 30-5). On the other hand, if a stimulus occurs after the cell has repolarized completely, Na^+ channels have recovered from inactivation, and a normal Na^+ channel-dependent upstroke results with the same amplitude as the previous upstroke (Figure 30-5A). When a stimulus occurs during phase 3 of the action potential, the upstroke of the premature action potential is slower and of smaller magnitude. The magnitude depends on the number of Na^+ channels that have recovered from inactivation (Figure 30-5A), which in turn is dependent on the membrane potential. Thus, refractoriness is determined by the voltage-dependent recovery of Na^+ channels from inactivation.

Refractoriness frequently is measured by assessing whether premature stimuli applied to tissue preparations (or the whole heart) result in propagated impulses. While the magnitude of the Na^+ current is one major determinant of propagation of premature beats, cellular geometry also is important in multicellular preparations. Propagation from cell to cell requires current flow from the first site of activation and consequently can fail if inward current is insufficient to drive activation in many neighboring cells. The *ERP* is the longest interval at which a premature stimulus fails to generate a propagated response and often is used to describe drug effects in intact tissue.

The situation is different in tissue whose depolarization is largely controlled by Ca^{2+} channel current, such as the AV node. Because Ca^{2+} channels have a slower recovery from inactivation, these tissues are often referred to as *slow response* (Figure 30-5C), in contrast to *fast response* in the remaining cardiac tissues. Even after a Ca^{2+} channel-dependent action potential has repolarized to its initial resting potential, not all Ca^{2+} channels are available for reexcitation. Therefore, an extra stimulus applied shortly after repolarization is complete generates a reduced Ca^{2+} current, which may propagate slowly to adjacent cells prior to extinction. An extra stimulus applied later will result in a larger Ca^{2+} current

and faster propagation. Thus, in Ca^{2+} channel-dependent tissues, which include not only the AV node but also tissues whose underlying characteristics have been altered by factors such as myocardial ischemia, refractoriness is prolonged, and propagation occurs slowly. Conduction that exhibits such dependence on the timing of premature stimuli is termed *decremental*. Slow conduction in the heart, a critical factor in the genesis of reentrant arrhythmias (see further discussion), also can occur when Na^+ currents are depressed by disease or membrane depolarization (e.g., elevated $[\text{K}]_o$), resulting in decreased steady-state Na^+ channel availability (Figure 30-5B).

Mechanisms of Cardiac Arrhythmias

An arrhythmia is by definition a perturbation of the normal sequence of impulse initiation and propagation. Failure of impulse initiation, in the sinus node, may result in slow heart rates (bradyarrhythmias), whereas failure in the normal propagation of action potentials from atrium to ventricle results in dropped beats (commonly referred to as heart block) and usually reflects an abnormality in either the AV node or the His-Purkinje system. These abnormalities may be caused by drugs (Table 30-1) or by structural heart disease; in the latter case, permanent cardiac pacing may be required.

Abnormally rapid heart rhythms (tachyarrhythmias) are common clinical problems that may be treated with antiarrhythmic drugs. Three major underlying mechanisms have been identified: enhanced automaticity, triggered automaticity, and reentry. These are often interrelated mechanisms as abnormal beats arising from one mechanism can elicit a second; for example, a triggered automatic beat can initiate reentry.

Enhanced Automaticity

Enhanced automaticity may occur in cells that normally display spontaneous diastolic depolarization—the sinus and AV nodes and the His-Purkinje system. β Adrenergic stimulation, hypokalemia, and mechanical stretch of cardiac muscle cells increase phase 4 slope and so accelerate pacemaker rate, whereas *acetylcholine* reduces pacemaker rate both by decreasing phase 4 slope and by hyperpolarization (making the maximum diastolic potential more negative). In addition, automatic behavior may occur in sites that ordinarily lack spontaneous pacemaker activity; for example, depolarization of ventricular cells (e.g., by ischemia) may produce “abnormal” automaticity. When impulses propagate from a region of enhanced normal or abnormal automaticity to excite the rest of the heart, more complex arrhythmias may result from the induction of reentry.

Afterdepolarizations and Triggered Automaticity

Under some pathophysiological conditions, a normal cardiac action potential may be interrupted or followed by an abnormal depolarization (Figure 30-6). If this abnormal depolarization reaches threshold, it may, in turn, give rise to secondary upstrokes that can propagate and create abnormal rhythms. These abnormal secondary upstrokes occur only after an initial normal, or “triggering,” upstroke and thus are termed *triggered rhythms*.

Two major forms of triggered rhythms are recognized. In the first case, under conditions of intracellular or SR Ca^{2+} overload (e.g., myocardial ischemia, adrenergic stress, digitalis intoxication, or CPVT), a normal action potential may be followed by a DAD (Figure 30-6A); as discussed previously, enhanced NCX current is thought to be a common mechanism underlying DADs. If this afterdepolarization reaches threshold, a secondary triggered beat or beats may occur. DAD amplitude is increased in vitro by rapid pacing, and clinical arrhythmias thought to correspond to DAD-mediated triggered beats are more frequent when the underlying cardiac rate is rapid (Priori et al., 1999).

In the second type of triggered activity, the key abnormality is marked prolongation of the cardiac action potential. When this occurs, phase 3 repolarization may be interrupted by an EAD (Figure 30-6B). EAD-mediated triggering in vitro and clinical arrhythmias are most common when the

Figure 30-5 Qualitative differences in responses of nodal and conducting tissues to premature stimuli. **A.** With a very early premature stimulus (black arrow) in ventricular myocardium, all Na^+ channels still are in the inactivated state, and no upstroke results. As the action potential repolarizes, Na^+ channels recover from the inactivated to the resting state, from which opening can occur. The phase 0 upstroke slopes of the premature action potentials (purple) are greater with later stimuli because recovery from inactivation is voltage-dependent. **B.** The relationship between transmembrane potential and degree of recovery of Na^+ channels from inactivation. The dotted line indicates 25% recovery. Most Na^+ channel-blocking drugs shift this relationship to the left. **C.** In Ca^{2+} -dependent slow-response tissues such as the AV node, premature stimuli delivered even after full repolarization of the action potential are depressed; recovery from inactivation is time-dependent.

TABLE 30-1 ■ DRUG-INDUCED CARDIAC ARRHYTHMIAS

ARRHYTHMIA	DRUG	LIKELY MECHANISM	TREATMENT*	CLINICAL FEATURES
Sinus bradycardia, AV block	Digoxin	↑Vagal tone	Antidigoxin antibodies, temporary pacing	Atrial tachycardia may also be present
Sinus bradycardia, AV block	Verapamil, diltiazem	Ca ²⁺ channel block	Ca ²⁺ , temporary pacing	
Sinus bradycardia	β Blockers	Sympatholytic	Isoproterenol	
AV block	Clonidine Methyldopa		Temporary pacing	
Sinus tachycardia Any other tachycardia	β Blocker withdrawal	Upregulation of β receptors with chronic therapy; β blocker withdrawal → ↑β effects	β Blockade	Hypertension, angina also possible
↑Ventricular rate in atrial flutter	Quinidine Flecainide Propafenone	Conduction slowing in atrium, with enhanced (quinidine) or unaltered AV conduction	AV nodal blockers	QRS complexes often widened at fast rates
↑Ventricular rate in atrial fibrillation in patients with WPW syndrome	Digoxin Verapamil	↓ Accessory pathway refractoriness	IV procainamide DC cardioversion	Ventricular rate can exceed 300 beats/min
Multifocal atrial tachycardia	Theophylline	↑Intracellular Ca ²⁺ and DADs	Withdraw theophylline ?Verapamil	Often in advanced lung disease
Polymorphic VT with ↑QT interval (torsades de pointes)	Quinidine Sotalol Procainamide Disopyramide Dofetilide Ibutilide “Noncardioactive” drugs (see text) Amiodarone (rare)	EAD-related triggered activity	Cardiac pacing Isoproterenol Magnesium	Hypokalemia, bradycardia frequent Related to ↑ plasma concentrations, except for quinidine
Frequent or difficult to terminate VT (“incessant” VT)	Flecainide Propafenone Quinidine (rarer)	Conduction slowing in reentrant circuits	Na ⁺ bolus reported effective in some cases	Most often in patients with advanced myocardial scarring
Atrial tachycardia with AV block; ventricular bigeminy, others	Digoxin	DAD-related triggered activity (± ↑ vagal tone)	Antidigoxin antibodies	Coexistence of abnormal impulses with abnormal sinus or AV nodal function
Ventricular fibrillation	Inappropriate use of IV verapamil	Severe hypotension and/or myocardial ischemia	Cardiac resuscitation (DC cardioversion)	Misdiagnosis of VT as PSVT and inappropriate use of verapamil

*In each of these cases, recognition and withdrawal of the offending drug(s) are mandatory ↑, increase; ↓, decrease; ?, unclear.

underlying heart rate is slow, extracellular K⁺ is low, and certain drugs that prolong action potential duration (antiarrhythmics and others) are present. EAD-related triggered upstrokes probably reflect inward current through Na⁺ or Ca²⁺ channels. Due to their intrinsically longer action potential, EADs are induced more readily in Purkinje cells and in endocardial than in epicardial cells.

When cardiac repolarization is markedly prolonged, polymorphic ventricular tachycardia with a long QT interval, termed *torsades de pointes*, may occur. This arrhythmia is thought to be caused by EADs, which trigger functional reentry (discussed next) owing to heterogeneity of action potential durations across the ventricular wall (Priori et al., 1999). Congenital LQTS, a disease in which *torsades de pointes* causes syncope or death, is most often caused by mutations in the genes encoding the Na⁺ channels (10%) or the channels underlying the repolarizing currents I_{Kr} and I_{Ks} (80-90%) (Nerbonne and Kass, 2005).

Reentry

Reentry occurs when a cardiac impulse travels in a path such as to return to its original site and reactivate the original site, thus perpetuating rapid

reactivation independent of normal sinus node function. Key features enabling reentrant excitation are a pathway; heterogeneity of electrophysiologic properties, notably refractoriness, along the pathway; and slow conduction.

Anatomically Defined Reentry

The prototypical example of reentry is the WPW syndrome in which patients have an accessory connection between the atrium and ventricle (Figure 30-7). With each sinus node depolarization, impulses can excite the ventricle via the normal structures (AV node) or the accessory pathway, and this often results in an unusual and characteristic QRS complex in normal sinus rhythm. Importantly, the electrophysiological properties of the AV node and accessory pathways are different: Accessory pathways usually consist of nonnodal tissue with longer refractory periods and without decremental conduction. Thus, with a premature atrial beat (e.g., from abnormal automaticity), conduction may fail in the accessory pathway but continue, albeit slowly, in the AV node and then through the His-Purkinje system; there the propagating impulse may encounter the ventricular end of the accessory pathway when it is no longer refractory. The likelihood

Figure 30-6 Afterdepolarizations and triggered activity. **A.** Delayed afterdepolarization arising after full repolarization. DADs are typically caused by spontaneous Ca^{2+} release from the SR under conditions of Ca^{2+} overload. The extracytosolic Ca^{2+} is removed from the cytosol by the electrogenic Na-Ca exchanger, which produces Na^+ influx and causes a cell membrane depolarization in the form of a DAD. A DAD that reaches threshold results in a triggered upstroke (black arrow, right). **B.** Early afterdepolarization interrupting phase 3 repolarization. Multiple ion channels and transporters can contribute to EADs (e.g., Na^+ channel, L-type Ca^{2+} channel, Na-Ca exchanger). Under some conditions, triggered beat(s) can arise from an EAD (black arrow, right).

that the accessory pathway is no longer refractory increases as AV nodal conduction slows, demonstrating how slow conduction enables reentry. When the impulse reenters the atrium, it then can reenter the ventricle via the AV node, reenter the atrium via the accessory pathway, and so on (Figure 30-7).

Reentry of this type, referred to as *AV reentrant tachycardia*, is determined by the following:

1. The presence of an anatomically defined circuit
2. Heterogeneity in refractoriness among regions in the circuit
3. Slow conduction in one part of the circuit

Similar “anatomically defined” reentry commonly occurs in the region of the AV node (*AV nodal reentrant tachycardia*), in the atrium (*atrial flutter*), and in scarred ventricle (*ventricular tachycardia*). The term *PSVT* includes both AV reentry and AV nodal reentry, which share many clinical features.

Figure 30-7 Atrioventricular reentrant tachycardia in the WPW syndrome. In these patients, an accessory AV connection is present (light blue). A premature atrial impulse blocks in the accessory pathway (1) and propagates slowly through the AV node and conducting system. On reaching the accessory pathway (by now no longer refractory), the impulse reenters the atrium (2), where it then can reenter the ventricle via the AV node and become self-sustaining (see Figure 30-9C). AV nodal blocking drugs readily terminate this tachycardia. Recurrences can be prevented by drugs that prevent atrial premature beats, by drugs that alter the electrophysiological characteristics of tissue in the circuit (e.g., they prolong AV nodal refractoriness), and by nonpharmacological ablation techniques that selectively destroy the accessory pathway.

While antiarrhythmic drugs or electrical cardioversion are used to terminate reentry acutely (discussed further in the chapter and Table 30-2), the primary therapy for anatomically defined reentry is radio-frequency ablation because its consistent pathway often makes it possible to identify and ablate critical segments of this pathway effectively, curing the patient and obviating the need for long-term drug therapy. Radio-frequency ablation is carried out through a catheter advanced to the interior of the heart and requires minimal convalescence.

Functionally Defined Reentry

Reentry also may occur in the absence of a distinct, anatomically defined pathway (Figure 30-8). For example, a premature beat from within the ventricular wall may encounter refractory tissue in only one direction, allowing for conduction throughout the rest of the wall until the originally refractory area recovers, reexcites, and then propagates back through the original location of the premature beat. Another example is localized ischemia or other electrophysiological perturbations that result in an area of sufficiently slow conduction in the ventricle that impulses exiting from that area find the rest of the myocardium reexcitable, in which case reentry may ensue. Atrial fibrillation and VF are extreme examples of “functionally defined” reentry: Cells are reexcited as soon as they are repolarized sufficiently to allow enough Na^+ channels to recover from inactivation. The abnormal activation pathway subsequently provides abnormal spatial heterogeneity of repolarization that can cause other reentrant circuits to form. In atrial fibrillation, these can persist for years, and rotor-like activity can sometimes be recorded, presumably reflecting reentrant circuits that can be transiently stable or meander around the atrium.

Common Arrhythmias and Their Mechanisms

The primary tool for diagnosis of arrhythmias is the ECG. More sophisticated approaches sometimes are used, such as recording from specific regions of the heart during artificial induction of arrhythmias by specialized pacing techniques. Table 30-2 lists common arrhythmias, their likely mechanisms, and approaches that should be considered for their acute termination and for long-term therapy to prevent recurrence. Examples of some arrhythmias discussed here are shown in Figure 30-9. Some arrhythmias, notably VF, are treated not pharmacologically but with DC cardioversion—the application of a large electric current across the chest. This technique also can be used to immediately restore normal rhythm in less-serious cases; if the patient is conscious, a brief period of general anesthesia is required. ICDs, devices that are capable of detecting VF and automatically delivering a defibrillating shock, are used increasingly in patients judged to be at high risk for VF. Often, drugs are used with these devices if defibrillating shocks, which are painful, occur frequently.

Mechanisms of Antiarrhythmic Drug Action

Antiarrhythmic drugs almost invariably have multiple effects in patients, and their effects on arrhythmias can be complex. A drug can modulate other targets in addition to its primary site of action. At the same time, a single arrhythmia may result from multiple underlying mechanisms (e.g., torsades de pointes [Figure 30-9H] can result either from increased Na^+ channel late currents or decreased inward rectifier currents). Thus, antiarrhythmic therapy should be tailored to target the most relevant underlying arrhythmia mechanism, where it is known. Drugs may be antiarrhythmic by suppressing the initiating mechanism or by altering reentrant circuits. In some cases, drugs may suppress an initiator but nonetheless promote reentry (see discussion that follows).

Drugs may slow automatic rhythms by altering any of the four determinants of spontaneous pacemaker discharge (Figure 30-10): (1) increase maximum diastolic potential, (2) decrease phase 4 slope, (3) increase threshold potential, or (4) increase action potential duration. *Adenosine* and *acetylcholine* may increase maximum diastolic potential, and β blockers (see Chapter 12) may decrease phase 4 slope. Blockade of Na^+ or Ca^{2+} channels usually results in altered threshold, and blockade of cardiac K^+ channels prolongs the action potential.

TABLE 30-2 ■ A MECHANISTIC APPROACH TO ANTIARRHYTHMIC THERAPY

ARRHYTHMIA	COMMON MECHANISM	ACUTE THERAPY ^a	CHRONIC THERAPY ^a
Premature atrial, nodal, or ventricular depolarizations	Unknown	None indicated	None indicated
Atrial fibrillation	Disorganized “functional” reentry Continual AV node stimulation and irregular, often rapid, ventricular rate	1. Control ventricular response: AV node block ^b 2. Restore sinus rhythm: DC cardioversion	1. Control ventricular response: AV nodal block ^b 2. Maintain normal rhythm: K ⁺ channel block, Na ⁺ channel block, Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ sec
Atrial flutter	Stable reentrant circuit in the right atrium Ventricular rate often rapid and irregular	Same as atrial fibrillation Same as atrial fibrillation	Same as atrial fibrillation AV nodal blocking drugs especially desirable to avoid \uparrow ventricular rate Ablation in selected cases ^c
Atrial tachycardia	Enhanced automaticity, DAD-related automaticity, or reentry in atrium	Adenosine sometimes effective Same as atrial fibrillation	Same as atrial fibrillation Ablation of tachycardia “focus” ^t
AV nodal reentrant tachycardia (PSVT)	Reentrant circuit within or near AV node	AV nodal block ^b Less commonly: \uparrow vagal tone (digitalis, edrophonium, phenylephrine)	*AV nodal block Flecainide Propafenone *Ablation ^c
Arrhythmias associated with WPW syndrome: 1. AV reentry (PSVT) 2. Atrial fibrillation with atrioventricular conduction via accessory pathway	Reentry (Figure 30-7) Very rapid rate due to nondecremental properties of accessory pathway	Same as AV nodal reentry *DC cardioversion *Procainamide Lidocaine	K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ sec *Ablation ^c K ⁺ channel block Na ⁺ channel block with $\tau_{\text{recovery}} > 1$ sec (AV nodal blockers can be harmful)
VT in patients with remote myocardial infarction	Reentry near the rim of the healed myocardial infarction	Amiodarone Procainamide DC cardioversion Adenosine ^e	*ICD ^d Amiodarone K ⁺ channel block Na ⁺ channel block
VT in patients without structural heart disease	DADs triggered by \uparrow sympathetic tone	Verapamil ^e β Blockers ^e *DC cardioversion	Verapamil ^e β Blockers ^e
VF	Disorganized reentry	Lidocaine Amiodarone Procainamide Pacing	*ICD ^d Amiodarone K ⁺ channel block Na ⁺ channel block
Torsades de pointes, congenital or acquired; (often drug related)	EAD-related triggered activity	Magnesium Isoproterenol	β Blockade Pacing

^aIndicates treatment of choice. ^aAcute drug therapy is administered intravenously; chronic therapy implies long-term oral use. ^bAV nodal block can be achieved clinically by adenosine, Ca²⁺ channel block, β adrenergic receptor blockade, or increased vagal tone (a major antiarrhythmic effect of digitalis glycosides). ^cAblation is a procedure in which tissue responsible for the maintenance of a tachycardia is identified by specialized recording techniques and then selectively destroyed, usually by high-frequency radio waves delivered through a catheter placed in the heart. ^dICD, implanted cardioverter-defibrillator: a device that can sense VT or VF and deliver pacing and/or cardioverting shocks to restore normal rhythm. ^eThese may be harmful in reentrant VT and so should be used for acute therapy only if the diagnosis is secure.

Antiarrhythmic drugs may suppress arrhythmias owing to DADs or EADs by two major mechanisms:

1. inhibition of the development of afterdepolarizations; and
2. interference with the inward current (usually through Na⁺ or Ca²⁺ channels), which is responsible for the upstroke

Thus, arrhythmias owing to DADs (i.e., due to *digitalis* toxicity or CPVT) may be inhibited by *verapamil* (which blocks the development of DAD by reducing Ca²⁺ influx into the cell, thereby decreasing SR Ca²⁺ load and the likelihood of spontaneous Ca²⁺ release from the SR) or by Na⁺ channel-blocking drugs, which elevate the threshold required to produce the abnormal upstroke. In CPVT, more effective than *verapamil* is combined RyR2 and Na⁺ channel block by agents such as *flecainide* or *propafenone*. Similarly, two approaches are used in arrhythmias related to EAD-triggered beats (Tables 30-1 and 30-2). EADs can be inhibited by shortening action potential duration; in practice, heart rate is

accelerated by *isoproterenol* infusion or by pacing. Triggered beats arising from EADs can be inhibited by Mg²⁺ without normalizing repolarization in vitro or QT interval through mechanisms that are not well understood. In most forms of congenital LQTS, torsades de pointes occurs with adrenergic stress; therapy includes β adrenergic blockade (which does not shorten the QT interval but may prevent EADs) as well as pacing to shorten action potentials.

In anatomically determined reentry, drugs may terminate the arrhythmia by blocking propagation of the action potential. Conduction usually fails in a “weak link” in the circuit. In the example of the WPW-related arrhythmia described previously, the weak link is the AV node, and drugs that prolong AV nodal refractoriness and slow AV nodal conduction, such as Ca²⁺ channel blockers, β blockers, or adenosine, are likely to be effective. On the other hand, slowing conduction in functionally determined reentrant circuits may change the pathway without extinguishing the circuit. In fact, slow conduction generally promotes the development of reentrant

Figure 30-8 Two types of reentry. The border of a propagating wavefront is denoted by a heavy black arrowhead. In anatomically defined reentry (top), a fixed pathway is present (e.g., Figure 30-7). The black area denotes tissue in the reentrant circuit that is completely refractory because of the recent passage of the propagating wavefront; the gray area denotes tissue in which depressed upstrokes can be elicited (see Figure 30-5A), and the dark red area represents tissue in which restimulation would result in action potentials with normal upstrokes. The dark red area is termed an *excitable gap*. In functionally defined, or “leading circle,” reentry (bottom), there is no anatomic pathway and no excitable gap. Rather, the circulating wavefront creates an area of inexcitable tissue at its core. In this type of reentry, the circuit does not necessarily remain in the same anatomic position during consecutive beats. During mapping of excitation sequences in the heart, this type of activity may be manifest as one or more “rotors.”

arrhythmias, whereas the most likely approach for terminating functionally determined reentry is prolongation of refractoriness (Knollmann and Roden, 2008; Priori et al., 1999; Task Force, 1991). In atrial and ventricular myocytes, refractoriness can be prolonged by delaying the recovery of Na^+ channels from inactivation. Drugs that act by blocking Na^+ channels generally shift the voltage dependence of recovery from block (Figure 30-5B) and so prolong refractoriness (Figure 30-11).

Drugs that increase action potential duration without direct action on Na^+ channels (e.g., by blocking delayed rectifier currents) also will prolong refractoriness (Figure 30-11). Particularly in SA or AV nodal tissues, Ca^{2+} channel blockade prolongs refractoriness. Drugs that interfere with cell-cell coupling also theoretically should increase refractoriness in multicellular preparations; *amiodarone*, a drug with a multiplicity of electrophysiological actions that may be antiarrhythmic, may exert this effect in diseased tissue. Acceleration of conduction in an area of slow conduction also could inhibit reentry; *lidocaine* may exert such an effect, and peptides that suppress experimental arrhythmias by increasing gap junction conductance have been described. Arrhythmia-prone hearts often display abnormal anatomy and histology, notably enhanced fibrosis, and some evidence suggests anti-inflammatory or antifibrotic

interventions could thus be antiarrhythmic by preventing these changes (Van Wagoner et al., 2015).

State-Dependent Ion Channel Block

Knowing the structural and molecular determinants of ion channel permeation and drug block has provided key information for analyzing the actions of available and new antiarrhythmic compounds (MacKinnon, 2003). A key concept is that ion channel–blocking drugs bind to specific sites on the ion channel proteins to modify function (e.g., decrease current). The affinity of the ion channel protein for the drug on its target site generally varies as the ion channel protein shuttles among functional conformations (or ion channel “states”; see Figure 30-2). Physicochemical characteristics, such as molecular weight and lipid solubility, are important determinants of this state-dependent binding. State-dependent binding has been studied most extensively in the case of Na^+ channel–blocking drugs. Most useful agents of this type block open or inactivated Na^+ channels and have little affinity for channels in the resting state. Most Na^+ channel blockers bind to a local anesthetic binding site in the pore of Nav1.5 (Fozzard et al., 2005). Thus, during each action potential, drugs bind to Na^+ channels and block them, and with each diastolic interval, drugs dissociate, and the block is released. Allosteric mechanisms have also been described whereby drug binding to a site distant from the pore nevertheless alters channel conformation and thus permeation through the pore.

As illustrated in Figure 30-12, the dissociation rate is a key determinant of steady-state block of Na^+ channels. When heart rate increases, the time available for dissociation decreases, and steady-state Na^+ channel block increases. The rate of recovery from block also slows as cells are depolarized, as in ischemia. This explains the finding that Na^+ channel blockers depress Na^+ current, and hence conduction, to a greater extent in ischemic tissues than in normal tissues. Open- versus inactivated-state block also may be important in determining the effects of some drugs. Increased action potential duration, which results in a relative increase in time spent in the inactivated state, may increase block by drugs that bind to inactivated channels, such as lidocaine or amiodarone.

The rate of recovery from block often is expressed as a time constant (τ_{recovery} , the time required to complete approximately 63% of an exponentially determined process to be complete). In the case of drugs such as lidocaine, τ_{recovery} is so short ($\ll 1$ sec) that recovery from block is very rapid, and substantial Na^+ channel block occurs only in rapidly driven tissues, particularly in ischemia. Conversely, drugs such as *flecainide* have such long τ_{recovery} values (>10 sec) that roughly the same numbers of Na^+ channels are blocked during systole and diastole. As a result, slowing of conduction occurs even in normal tissues at normal rates.

Classifying Antiarrhythmic Drugs

Classifying drugs by common electrophysiological properties emphasizes the connection between basic electrophysiological actions and antiarrhythmic effects (Vaughan Williams, 1992). To the extent that the clinical actions of drugs can be predicted from their basic electrophysiological properties, such classification schemes have merit. However, as each compound is better characterized in a range of in vitro and in vivo test systems, it becomes apparent that differences in pharmacological effects occur even among drugs that share the same classification, some of which may be responsible for the observed clinical differences in responses to drugs of the same broad “class” (Table 30-3).

An alternative way of approaching antiarrhythmic therapy is to attempt to classify arrhythmia mechanisms and then to target drug therapy to the electrophysiological mechanism most likely to terminate or prevent the arrhythmia (Priori et al., 1999; Task Force, 1991) (Table 30-2). This approach has been further enhanced by an increasing understanding of arrhythmia mechanisms in genetic diseases such as LQTS and CPVT, so a genetic framework represents a complementary approach for improving antiarrhythmic drug development and therapy (Knollmann and Roden, 2008).

Figure 30-9 Electrocardiograms showing normal and abnormal cardiac rhythms. The P, QRS, and T waves in normal sinus rhythm are shown in panel A. Panel B shows a premature beat arising in the ventricle (arrow). PSVT is shown in panel C; this is most likely reentry using an accessory pathway (see Figure 30-7) or reentry within or near the AV node. In atrial fibrillation (panel D), there are no P waves, and the QRS complexes occur irregularly (and at a slow rate in this example); electrical activity between QRS complexes shows small undulations (arrow) corresponding to fibrillatory activity in the atria. In atrial flutter (panel E), the atria beat rapidly, approximately 250 beats/min (arrows) and the ventricular rate is variable. If a drug that slows the rate of atrial flutter is administered, 1:1 AV conduction (panel F) can occur. In monomorphic VT (panel G), identical wide QRS complexes occur at a regular rate, 180 beats per min. The electrocardiographic features of the torsades de pointes syndrome (panel H) include a very long QT interval (>600 ms in this example, arrow) and VT in which each successive beat has a different morphology (polymorphic VT). Panel I shows the disorganized electrical activity characteristic of VF.

Na⁺ Channel Block

The extent of Na⁺ channel block depends critically on heart rate and membrane potential, as well as on drug-specific physicochemical characteristics that determine τ_{recovery} (Figure 30-12). The description that follows applies when Na⁺ channels are blocked, that is, at rapid heart rates in diseased tissue with a rapid-recovery drug such as *lidocaine* or even at normal rates in normal tissues with a slow-recovery drug such as *flecainide*. When Na⁺ channels are blocked, threshold for excitability is decreased; that is, greater membrane depolarization is required to open enough Na⁺ channels to overcome K⁺ currents at the resting membrane potential and elicit an action potential. This change in threshold probably contributes to the clinical finding that Na⁺ channel blockers tend to increase both pacing threshold and the energy required to defibrillate the fibrillating heart. These deleterious effects may be important if antiarrhythmic drugs are used in patients with pacemakers or implanted defibrillators. Na⁺ channel block decreases conduction velocity in nonnodal tissue and increases QRS duration. Usual doses of flecainide prolong QRS intervals by 25% or more during normal rhythm, whereas lidocaine increases QRS intervals only at very fast heart rates. Drugs with τ_{recovery} values greater than 10 sec (e.g., flecainide) also tend to prolong the PR interval; it is not known whether this represents additional Ca²⁺ channel block (see discussion that follows) or block of fast-response tissue in the region of the AV node. Drug effects on the PR interval also are highly modified by autonomic effects. For example, *quinidine* actually tends to shorten the PR interval largely as a result of its vagolytic properties. Action potential duration is either unaffected or is shortened by Na⁺ channel block; some Na⁺ channel-blocking drugs do prolong cardiac action potentials but by other mechanisms, usually K⁺ channel block (Table 30-3).

By increasing threshold, Na⁺ channel block decreases automaticity (Figure 30-10B) and can inhibit triggered activity arising from DADs or EADs. Many Na⁺ channel blockers also decrease phase 4 slope (Figure 30-10A). In anatomically defined reentry, Na⁺ channel blockers

may decrease conduction sufficiently to extinguish the propagating reentrant wavefront. However, as described previously, conduction slowing owing to Na⁺ channel block may exacerbate reentry. Block of Na⁺ channels also shifts the voltage dependence of recovery from inactivation (Figure 30-5B) to more negative potentials, thereby tending to increase refractoriness. Thus, whether a given drug exacerbates or suppresses reentrant arrhythmias depends on the balance between its effects on refractoriness and on conduction in a particular reentrant circuit. *Lidocaine* and *mexiletine* have short τ_{recovery} values and are not useful in atrial fibrillation or flutter, whereas *quinidine*, *flecainide*, *propafenone*, and similar agents are effective in some patients. Many of these agents owe part of their antiarrhythmic activity to blockade of K⁺ channels.

Na⁺ Channel Blocker Toxicity

Conduction slowing in potential reentrant circuits can account for toxicity of drugs that block the Na⁺ channel (Table 30-1). For example, Na⁺ channel block decreases conduction velocity and hence slows atrial flutter rate. Normal AV nodal function permits a greater number of impulses to penetrate the ventricle, and heart rate actually may increase (Figure 30-9). Thus, with Na⁺ channel blocker therapy, atrial flutter rate may drop from 300 per min, with 2:1 or 4:1 AV conduction (i.e., a heart rate of 150 or 75 beats per min), to 220 per min, but with 1:1 transmission to the ventricle (i.e., a heart rate of 220 beats per min), with potentially disastrous consequences. This form of drug-induced arrhythmia is especially common during treatment with quinidine because the drug also increases AV nodal conduction through its vagolytic properties; flecainide, propafenone, and occasionally amiodarone also have been implicated. Therapy with Na⁺ channel blockers in patients with reentrant ventricular tachycardia after a myocardial infarction can increase the frequency and severity of arrhythmic episodes. Although the mechanism is unclear, slowed conduction allows the reentrant wavefront to persist within the tachycardia circuit. Such drug-exacerbated arrhythmia can be difficult to

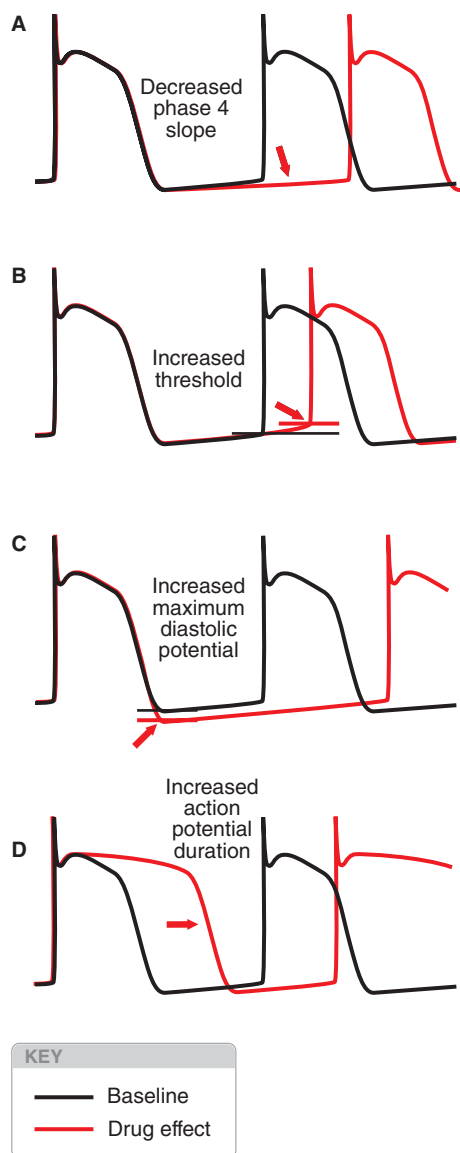

Figure 30-10 Four ways to reduce the rate of spontaneous discharge. The horizontal lines in panels B and C mark the threshold potentials for triggering an action potential before and after drug application.

Figure 30-11 Two ways to increase refractoriness. In this figure, the black dot indicates the point at which a sufficient number of Na^+ channels (an arbitrary 25%; see Figure 30-5B) have recovered from inactivation to allow a premature stimulus to produce a propagated response in the absence of a drug. Block of Na^+ channels (A) shifts voltage dependence of recovery (see Figure 30-5B) and so delays the point at which 25% of channels have recovered (red diamond), prolonging the ERP. Note that if the drug also dissociates slowly from the channel (see Figure 30-12), refractoriness in fast-response tissues actually can extend beyond full repolarization ("postrepolarization refractoriness"). Drugs that prolong the action potential (B) also will extend the point at which an arbitrary percentage of Na^+ channels have recovered from inactivation, even without directly interacting with Na^+ channels.

Figure 30-12 Recovery from block of Na^+ channels during diastole. This recovery is the critical factor determining extent of steady-state Na^+ channel block. Na^+ channel blockers bind to (and block) Na^+ channels in the open or inactivated states, resulting in phasic changes in the extent of block during the action potential. As shown in the middle panel, a decrease in the rate of recovery from block increases the extent of block. Different drugs have different rates of recovery, and depolarization reduces the rate of recovery. The right panel shows that increasing heart rate, which results in relatively less time spent in the rest state and also increases the extent of block. TABLE 30-3 ■ MAJOR ELECTROPHYSIOLOGIC ACTIONS OF ANTIARRHYTHMIC DRUGS

DRUG	Na ⁺ CHANNEL BLOCK		↑APD	Ca ²⁺ CHANNEL BLOCK	AUTONOMIC EFFECTS	OTHER EFFECTS
	τ_{RECOVERY}^1 , SECONDS	STATE DEPENDENCE ¹				
Lidocaine	0.1	I > O				
Phenytoin	0.2	I				
Mexiletine ^a	0.3					
Procainamide	1.8	O	√		Ganglionic blockade (especially intravenous)	√: Metabolite prolongs APD
Quinidine	3	O	√	(x)	α Blockade, vagolytic Anticholinergic	
Disopyramide ^b	9	O	√		Anticholinergic	
Propafenone ^b	11	O ≈ I	√		β Blockade (variable clinical effect)	√ RyR2 channel block
Flecainide ^a	11	O	(x)	(x)		
β Blockers: Propranolol ^b					β Blockade	Na ⁺ channel block in vitro
Sotalol ^b			√		β Blockade	
Amiodarone, dronedarone	1.6	I	√	(x)	Noncompetitive β blockade	Antithyroid action
Dofetilide			√			
Ibutilide			√			
Verapamil ^a				√		
Diltiazem ^a				√		
Digoxin					√: Vagal stimulation	√: Inhibition of Na ⁺ , K ⁺ -ATPase
Adenosine					√: Adenosine receptor activation	√: Activation of outward K ⁺ current
Magnesium				?√		Mechanism not well understood

√Indicates an effect that is important in mediating the clinical action of a drug. (x)Indicates a demonstrable effect whose relationship to drug action in patients is less well established. ^aIndicates drugs prescribed as racemates, and the enantiomers are thought to exert similar electrophysiologic effects. ^bIndicates racemates for which clinically relevant differences in the electrophysiologic properties of individual enantiomers have been reported (see text). One approach to classifying drugs is:

Class	Major action
I	Na ⁺ channel block
II	β blockade
III	action potential prolongation (usually by K ⁺ channel block)
IV	Ca ²⁺ channel block

Drugs are listed here according to this scheme. It is important to bear in mind, however, that many drugs exert multiple effects that contribute to their clinical actions. It is occasionally clinically useful to subclassify Na⁺ channel blockers by their rates of recovery from drug-induced block (τ_{recovery}) under physiologic conditions. Because this is a continuous variable and can be modulated by factors such as depolarization of the resting potential, these distinctions can become blurred: class Ib, $\tau_{\text{recovery}} < 1$ s; class Ia, $\tau_{\text{recovery}} 1$ –10 s; class Ic, $\tau_{\text{recovery}} > 10$ s. These class and subclass effects are associated with distinctive ECG changes, characteristic “class” toxicities, and efficacy in specific arrhythmia syndromes (see text). ¹These data are dependent on experimental conditions, including species and temperature. The τ_{recovery} values cited here are from Courtney (1987). O, open-state blocker; I, inactivated-state blocker.

manage, and deaths owing to intractable drug-induced ventricular tachycardia have been reported. In this setting, Na⁺ infusion may be beneficial. Drug-exacerbated ventricular tachycardia or VF also likely accounts for increased mortality with Na⁺ channel blockers compared to placebo in patients convalescing from acute myocardial infarction in the CAST (Echt et al., 1991). Several Na⁺ channel blockers (e.g., procainamide and quinidine) have been reported to exacerbate neuromuscular paralysis by D-tubocurarine (see Chapter 11).

Action Potential Prolongation

Most drugs that prolong the action potential do so by blocking I_{Kr} (Roden et al., 1993), although increased late Na⁺ current also produces this effect (Lu et al., 2012; Yang et al., 2014). Both drug effects increase action potential duration and reduce normal automaticity (Figure 30-10D). Increased action potential duration, seen as an increase in QT interval, increases refractoriness (Figure 30-11) and therefore should be an effective way

of treating reentry (Task Force, 1991). Experimentally, K⁺ channel block produces a series of desirable effects: reduced defibrillation energy requirement, inhibition of VF owing to acute ischemia, and increased contractility (Roden, 1993; Singh, 1993). As shown in Table 30-3, many K⁺ channel-blocking drugs also interact with β adrenergic receptors (sotalol) or other channels (e.g., amiodarone and quinidine). Amiodarone and sotalol appear to be at least as effective as drugs with predominant Na⁺ channel-blocking properties in both atrial and ventricular arrhythmias. “Pure” action potential-prolonging drugs (e.g., dofetilide and ibutilide) also are available (Murray, 1998; Torp-Pedersen et al., 1999).

Toxicity of Drugs That Prolong the Action Potential

Most of these agents disproportionately prolong cardiac action potentials and the QT interval when underlying heart rate is slow and can cause torsades de pointes (Table 30-1, Figure 30-9). While this effect usually is seen with QT-prolonging antiarrhythmic drugs, it can occur more rarely

with drugs that are used for noncardiac indications. For such agents, the risk of torsades de pointes may become apparent only after widespread use postmarketing, and recognition of this risk has been a common cause for drug withdrawal (Roden, 2004). Sex hormones modify cardiac ion channels and help account for the clinically observed increased incidence of drug-induced torsades de pointes in women (Tadros et al., 2014).

Ca²⁺ Channel Block

The major electrophysiological effects resulting from block of cardiac Ca²⁺ channels are in nodal tissues. Dihydropyridines, such as nifedipine, which are used commonly in angina and hypertension (see Chapters 27 and 28), preferentially block Ca²⁺ channels in vascular smooth muscle; their cardiac electrophysiological effects, such as heart rate acceleration, result principally from reflex sympathetic activation secondary to peripheral vasodilation. Only verapamil, diltiazem, and bepridil (no longer available in the U.S.) block Ca²⁺ channels in cardiac cells at clinically used doses. These drugs generally slow heart rate (Figure 30–10A), although hypotension, if marked, can cause reflex sympathetic activation and tachycardia. The velocity of AV nodal conduction decreases, so the PR interval increases. AV nodal block occurs as a result of decremental conduction, as well as increased AV nodal refractoriness. These effects form the basis of the antiarrhythmic actions of Ca²⁺ channel blockers in reentrant arrhythmias whose circuit involves the AV node, such as AV reentrant tachycardia (Figure 30–7).

Another important indication for antiarrhythmic therapy is to reduce the ventricular rate in atrial flutter or fibrillation. Parenteral verapamil and diltiazem are approved for temporary control of rapid ventricular rate in atrial flutter or fibrillation and for rapid conversion of PSVT to sinus rhythm (where their use has largely been supplanted by adenosine). Oral verapamil or diltiazem may be used to control the ventricular rate in chronic atrial flutter or fibrillation and for prophylaxis of repetitive PSVT. Unlike β blockers, Ca²⁺ channel blockers have not been shown to reduce mortality after myocardial infarction (Singh, 1990). In contrast to other Ca²⁺ channel blockers, bepridil increases action potential duration in many tissues and can exert an antiarrhythmic effect in atria and ventricles. However, because bepridil can cause torsades de pointes, it is not prescribed widely and has been discontinued in the U.S.

Verapamil and Diltiazem

The major adverse effect of intravenous verapamil or diltiazem is hypotension, particularly with bolus administration. This was a particular problem when the drugs were used mistakenly in patients with ventricular tachycardia (in which Ca²⁺ channel blockers usually are not effective) misdiagnosed as PSVT; the drugs are now rarely used for this indication. Hypotension also is frequent in patients receiving other vasodilators and in patients with underlying left ventricular dysfunction, which the drugs can exacerbate. Severe sinus bradycardia or AV block also occurs, especially in susceptible patients, such as those also receiving β blockers. With oral therapy, these adverse effects tend to be less severe. Constipation can occur with oral verapamil.

Verapamil is prescribed as a racemate. L-Verapamil is the more potent Ca²⁺ channel blocker. However, with oral therapy, the L-enantiomer undergoes more extensive first-pass hepatic metabolism. For this reason, a given concentration of verapamil prolongs the PR interval to a greater extent when administered intravenously (where concentrations of the L- and D-enantiomers are equivalent) than when administered orally. Diltiazem also undergoes extensive first-pass hepatic metabolism, and both drugs have metabolites that exert Ca²⁺ channel-blocking actions. In clinical practice, adverse effects during therapy with verapamil or diltiazem are determined largely by underlying heart disease and concomitant therapy; plasma concentrations of these agents are not measured routinely. Both drugs can increase serum digoxin concentration, although the magnitude of this effect is variable; excess slowing of ventricular response may occur in patients with atrial fibrillation.

Blockade of β Adrenergic Receptors

β Adrenergic stimulation increases the magnitude of the Ca²⁺ current and slows its inactivation; increases the magnitude of the repolarizing

current I_{Ks} ; increases pacemaker current (thereby increasing sinus rate; DiFrancesco, 1993); increases the Ca²⁺ stored in the SR (thereby increasing likelihood of spontaneous Ca²⁺ release and DADs); and under pathophysiological conditions, can increase both DAD- and EAD-mediated arrhythmias. The increases in plasma epinephrine associated with severe stress (e.g., acute myocardial infarction or resuscitation after cardiac arrest) lower serum K⁺, especially in patients receiving chronic diuretic therapy. β blockers inhibit these effects and can be antiarrhythmic by reducing heart rate, decreasing intracellular Ca²⁺ overload, and inhibiting afterdepolarization-mediated automaticity. Epinephrine-induced hypokalemia appears to be mediated by β_2 adrenergic receptors and is blocked by “noncardioselective” antagonists such as propranolol (see Chapter 12). In acutely ischemic tissue, β blockers increase the energy required to fibrillate the heart, an antiarrhythmic action. These effects may contribute to the reduced short-term and long-term mortality observed in trials of chronic therapy with β blockers—after myocardial infarction (Singh, 1990).

As with Ca²⁺ channel blockers and digitalis, β blockers increase AV nodal conduction time (increased PR interval) and prolong AV nodal refractoriness; hence, they are useful in terminating reentrant arrhythmias that involve the AV node and in controlling ventricular response in atrial fibrillation or flutter. In many (but not all) patients with the congenital LQTS, in all patients with the CPVT syndrome, as well as in many other patients, arrhythmias are triggered by physical or emotional stress; β blockers may be useful in these cases (Roden and Spooner, 1999; Schwartz et al., 2000). β blockers also reportedly are effective in controlling arrhythmias owing to Na⁺ channel blockers; this effect may be due in part to slowing of the heart rate, which then decreases the extent of rate-dependent conduction slowing by Na⁺ channel block.

Adverse effects of β blockade include fatigue, bronchospasm, hypotension, impotence, depression, aggravation of heart failure, worsening of symptoms owing to peripheral vascular disease, and masking of the symptoms of hypoglycemia in diabetic patients (see Chapter 12). In patients with arrhythmias owing to excess sympathetic stimulation (e.g., pheochromocytoma or clonidine withdrawal), β blockers can result in unopposed α adrenergic stimulation, with resulting severe hypertension or α adrenergic-mediated arrhythmias. In such patients, arrhythmias should be treated with both α and β blockers or with a drug such as labetalol that combines α - and β -blocking properties. Abrupt discontinuation of chronic β -blocker therapy can lead to “rebound” symptoms, including hypertension, increased angina, and arrhythmias; thus, β blockers are tapered over 2 weeks prior to discontinuation of chronic therapy (see Chapters 12 and 27–29).

Selected β Blockers

It is likely that most β blockers share antiarrhythmic properties. Some, such as propranolol, also exert Na⁺ channel-blocking effects at high concentrations. Similarly, drugs with intrinsic sympathomimetic activity may be less useful as antiarrhythmics (Singh, 1990). Acebutolol is as effective as quinidine in suppressing ventricular ectopic beats, an arrhythmia that many clinicians no longer treat. Sotalol (see its discussion in a separate section) is more effective for many arrhythmias than other β blockers, probably because of its K⁺ channel-blocking actions. Esmolol (see separate discussion that follows) is a β_1 -selective agent that has a very short elimination half-life. Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired. Some β blockers (e.g., propranolol) are CYP2D6 substrates; thus, efficacy may vary across individuals (Chapter 7). Many clinicians now favor nadolol when β blockade is needed in congenital arrhythmias (CPVT, LQTS).

Principles in the Clinical Use of Antiarrhythmic Drugs

Drugs that modify cardiac electrophysiology often have a very narrow margin between the doses required to produce a desired effect and those associated with adverse effects. Moreover, antiarrhythmic drugs can induce new arrhythmias with possibly fatal consequences. Nonpharmacological

560 treatments, such as cardiac pacing, electrical defibrillation, or ablation of targeted regions, are indicated for some arrhythmias; in other cases, no therapy is required, even though an arrhythmia is detected. Therefore, the fundamental principles of therapeutics described here must be applied to optimize antiarrhythmic therapy.

1. Identify and Remove Precipitating Factors

Factors that commonly precipitate cardiac arrhythmias include hypoxia, electrolyte disturbances (especially hypokalemia), myocardial ischemia, and certain drugs. Antiarrhythmics, including cardiac glycosides, are not the only drugs that can precipitate arrhythmias (Table 30–1). For example, *theophylline* can cause multifocal atrial tachycardia, which sometimes can be managed simply by reducing the dose of theophylline. Torsades de pointes can arise during therapy not only with action potential–prolonging antiarrhythmics but also with other “noncardiovascular” drugs not ordinarily classified as having effects on ion channels (Roden, 2004). The incidence can vary from 1% to 3% in patients receiving sotalol or dofetilide to very rare (<1/50,000) with some noncardiovascular drugs. Drugs with a very wide range of clinical indications have been implicated: These include some antibiotics (including antibacterials, antiprotozoals, antivirals, and antifungals), antipsychotics, antihistamines, antidepressants, and methadone. The website <https://crediblemeds.org> maintains a list of drugs (and levels of evidence) that have been implicated in this adverse effect.

2. Establish the Goals of Treatment

Some Arrhythmias Should Not Be Treated: The CAST Example

Abnormalities of cardiac rhythm are readily detectable by a variety of recording methods. However, the mere detection of an abnormality does not equate with the need for therapy. This was illustrated in CAST. The presence of asymptomatic ventricular ectopic beats is a known marker for increased risk of sudden death owing to VF in patients convalescing from myocardial infarction. In CAST, patients whose ventricular ectopic beats were suppressed by the potent Na⁺ channel blocker encainide (no longer marketed) or flecainide were randomly assigned to receive those drugs or placebo. Unexpectedly, the mortality rate was 2- to 3-fold higher among patients treated with the drugs than those treated with placebo (Echt et al., 1991). While the explanation for this effect is not known, several lines of evidence suggest that, in the presence of these drugs, transient episodes of myocardial ischemia or sinus tachycardia can cause marked conduction slowing (because these drugs have a very long τ_{recovery}), resulting in fatal reentrant ventricular tachyarrhythmias.

One consequence of this pivotal clinical trial was to reemphasize the concept that therapy should be initiated only when a clear benefit to the patient can be identified. When symptoms are obviously attributable to an ongoing arrhythmia, there usually is little doubt that termination of the arrhythmia will be beneficial; when chronic therapy is used to prevent recurrence of an arrhythmia, the risks may be greater (Roden, 1994). *Among the antiarrhythmic drugs discussed here, only β adrenergic blockers and, to a lesser extent, amiodarone (Connolly, 1999) demonstrably reduce mortality during long-term therapy.*

Symptoms Due to Arrhythmias

Some patients with an arrhythmia may be asymptomatic; in this case, establishing any benefit for treatment will be difficult. Some patients may present with presyncope, syncope, or even cardiac arrest, which may be due to brady- or tachyarrhythmias. Other patients may present with a sensation of irregular heartbeats (i.e., palpitations) that can be minimally symptomatic in some individuals and incapacitating in others. The irregular heartbeats may be due to intermittent premature contractions or to sustained arrhythmias such as atrial fibrillation (which results in an irregular ventricular rate) (Figure 30–9). Finally, patients may present with symptoms owing to decreased cardiac output attributable to arrhythmias. The most common symptom is breathlessness either at rest or on exertion. Occasionally, sustained or frequent tachycardias may produce no “arrhythmia” symptoms (such as palpitations) but will depress

contractile function; these patients may present with heart failure due to “tachycardia-induced cardiomyopathy,” a condition that can be controlled by treating the arrhythmia.

Choosing Among Therapeutic Approaches

In choosing among available therapeutic options, it is important to establish clear therapeutic goals. For example, three options are available in patients with atrial fibrillation: (1) reduce the ventricular response using AV nodal-blocking agents such as digitalis, verapamil, diltiazem, or β blockers (Table 30–1); (2) restore and maintain normal rhythm using drugs such as flecainide or amiodarone; or (3) decide not to implement antiarrhythmic therapy, especially if the patient truly is asymptomatic. Most patients with atrial fibrillation also benefit from anticoagulation to reduce stroke incidence regardless of symptoms (Dzeshka and Lip, 2015) (see Chapter 32).

Factors that contribute to choice of therapy include not only symptoms but also the type and extent of structural heart disease, the QT interval prior to drug therapy, the coexistence of conduction system disease, and the presence of noncardiac diseases (Table 30–4). In the rare patient with the WPW syndrome and atrial fibrillation, the ventricular response can be extremely rapid and can be accelerated paradoxically with digitalis or Ca²⁺ channel blockers; deaths owing to drug therapy have been reported under these circumstances.

The frequency and reproducibility of arrhythmia should be established prior to initiating therapy because inherent variability in the occurrence of arrhythmias can be confused with a beneficial or adverse drug effect. Techniques for this assessment include recording cardiac rhythm for prolonged periods or evaluating the response of the heart to artificially induced premature beats. It is important to recognize that drug therapy may be only partially effective. A marked decrease in the duration

TABLE 30–4 ■ PATIENT-SPECIFIC ANTIARRHYTHMIC DRUG CONTRAINDICATIONS

CONDITION	EXCLUDE/USE WITH CAUTION
Cardiac	
Heart failure	Disopyramide, flecainide
Sinus or AV node dysfunction	Digoxin, verapamil, diltiazem, β blockers, amiodarone
Wolff–Parkinson–White syndrome (risk of extremely rapid rate if atrial fibrillation develops)	Digoxin, verapamil, diltiazem
Infranodal conduction disease	Na ⁺ channel blockers, amiodarone
Aortic/subaortic stenosis	Bretylium
History of myocardial infarction	Flecainide
Prolonged QT interval	Quinidine, procainamide, disopyramide, sotalol, dofetilide, ibutilide, amiodarone
Cardiac transplant	Adenosine
Noncardiac	
Diarrhea	Quinidine
Prostatism, glaucoma	Disopyramide
Arthritis	Chronic procainamide
Lung disease	Amiodarone
Tremor	Mexiletine
Constipation	Verapamil
Asthma, peripheral vascular disease, hypoglycemia	β blockers, propafenone

of paroxysms of atrial fibrillation may be sufficient to render a patient asymptomatic even if an occasional episode still can be detected.

3. Minimize Risks

Antiarrhythmic Drugs Can Cause Arrhythmias

One well-recognized risk of antiarrhythmic therapy is the possibility of provoking new arrhythmias, with potentially life-threatening consequences. Antiarrhythmic drugs can provoke arrhythmias by different mechanisms (Table 30–1). These drug-provoked arrhythmias must be recognized because further treatment with antiarrhythmic drugs often exacerbates the problem, whereas withdrawal of the causative agent is curative. Thus, establishing a precise diagnosis is critical, and targeting therapies at underlying mechanisms of the arrhythmias may be required. For example, treating a ventricular tachycardia with verapamil not only may be ineffective but also can cause catastrophic cardiovascular collapse.

Monitoring of Plasma Concentration

Some adverse effects of antiarrhythmic drugs result from excessive plasma drug concentrations. Measuring plasma concentration and adjusting the dose to maintain the concentration within a prescribed therapeutic range may minimize some adverse effects. In many patients, serious adverse reactions relate to interactions involving antiarrhythmic drugs (often at usual plasma concentrations), transient factors such as electrolyte disturbances or myocardial ischemia, and the type and extent of the underlying heart disease (Roden, 1994). Factors such as generation of unmeasured active metabolites, variability in elimination of enantiomers (which may exert differing pharmacological effects), and disease- or enantiomer-specific abnormalities in drug binding to plasma proteins can complicate the interpretation of plasma drug concentrations.

Patient-Specific Contraindications

Another way to minimize the adverse effects of antiarrhythmic drugs is to avoid certain drugs in certain patient subsets altogether. For example, patients with a history of congestive heart failure are particularly prone to develop heart failure during *disopyramide* therapy. In other cases, adverse effects of drugs may be difficult to distinguish from exacerbations of underlying disease. Amiodarone may cause interstitial lung disease; its use therefore is undesirable in a patient with advanced pulmonary disease in whom the development of this potentially fatal adverse effect would be difficult to detect. Specific diseases that constitute relative or absolute contraindications to specific drugs are listed in Table 30–4.

4. Consider the Electrophysiology of the Heart as a “Moving Target”

Cardiac electrophysiology varies dynamically in response to external influences such as changing autonomic tone, myocardial ischemia, and myocardial stretch (Priori et al., 1999). For example, myocardial ischemia results in changes in extracellular K^+ that make the resting potential less negative, inactivate Na^+ channels, decrease Na^+ current, and slow conduction. In addition, myocardial ischemia can result in the formation and release of metabolites such as lysophosphatidylcholine, which can alter ion channel function; ischemia also may activate channels that otherwise are quiescent, such as the ATP-inhibited K^+ channels. Thus, in response to myocardial ischemia, a normal heart may display changes in resting potential, conduction velocity, intracellular Ca^{2+} concentrations, and repolarization, any one of which then may create arrhythmias or alter response to antiarrhythmic therapy.

Antiarrhythmic Drugs

Summaries of important electrophysiological and pharmacokinetic features of the drugs considered here are presented in Tables 30–3 and 30–5. Ca^{2+} channel blockers and β blockers are discussed in Chapters 12 and 27 to 29. The drugs are presented in alphabetical order. Prescribing patterns have changed over the past several decades in part because fewer suppliers market older drugs, such as quinidine or procainamide, which are therefore increasingly difficult to obtain, a problem for a small number of patients who may still benefit from treatment (Inama et al., 2010; Viskin et al., 2013).

Adenosine

Adenosine is a naturally occurring nucleoside that is administered as a rapid intravenous bolus for the acute termination of reentrant supraventricular arrhythmias (Link, 2012). Rare cases of ventricular tachycardia in patients with otherwise-normal hearts are thought to be DAD mediated and can be terminated by adenosine. Adenosine also has been used to produce controlled hypotension during some surgical procedures and in the diagnosis of coronary artery disease. Intravenous ATP appears to produce effects similar to those of adenosine.

Pharmacological Effects

The effects of adenosine are mediated by its interaction with specific G protein–coupled adenosine receptors. Adenosine activates acetylcholine-sensitive K^+ current in the atrium and sinus and AV nodes, resulting in shortening of action potential duration, hyperpolarization, and slowing of normal automaticity (Figure 30–10C). Adenosine also inhibits the electrophysiological effects of increased intracellular cyclic AMP that occur with sympathetic stimulation. Because adenosine thereby reduces Ca^{2+} currents, it can be antiarrhythmic by increasing AV nodal refractoriness and by inhibiting DADs elicited by sympathetic stimulation.

Administration of an intravenous bolus of adenosine to humans transiently slows sinus rate and AV nodal conduction velocity and increases AV nodal refractoriness. A bolus of adenosine can produce transient sympathetic activation by interacting with carotid baroreceptors; a continuous infusion can cause hypotension.

Adverse Effects

A major advantage of adenosine therapy is that adverse effects are short-lived because the drug is transported into cells and deaminated so rapidly. Transient asystole (lack of any cardiac rhythm whatsoever) is common but usually lasts less than 5 sec and is in fact the therapeutic goal. Most patients feel a sense of chest fullness and dyspnea when therapeutic doses (6 to 12 mg) of adenosine are administered. Rarely, an adenosine bolus can precipitate atrial fibrillation, presumably by heterogeneously shortening atrial action potentials, or bronchospasm.

Clinical Pharmacokinetics

Adenosine is eliminated with a half-life of seconds by carrier-mediated uptake, which occurs in most cell types, including the endothelium, followed by metabolism by adenosine deaminase. Adenosine probably is the only drug whose efficacy requires a rapid bolus dose, preferably through a large central intravenous line; slow administration results in elimination of the drug prior to its arrival at the heart.

The effects of adenosine are potentiated in patients receiving *dipyridamole*, an adenosine-uptake inhibitor, and in patients with cardiac transplants owing to denervation hypersensitivity. Methylxanthines (see Tables 14-7, 40-2, and 40-3, and Figure 40-5) such as theophylline and caffeine block adenosine receptors; therefore, larger-than-usual doses are required to produce an antiarrhythmic effect in patients who have consumed these agents in beverages or as therapy.

Amiodarone

Amiodarone exerts a multiplicity of pharmacological effects, none of which is clearly linked to its arrhythmia-suppressing properties. Amiodarone is a structural analogue of thyroid hormone, and some of its antiarrhythmic

TABLE 30-5 ■ PHARMACOKINETIC CHARACTERISTICS AND DOSES OF ANTIARRHYTHMIC DRUGS

DRUG	BIOAVAILABILITY	PROTEIN BINDING >80%	ELIMINATION			ELIMINATION ^a t _{1/2}	ACTIVE METABOLITE(S)	THERAPEUTIC ^b PLASMA CONCENTRATION	USUAL DOSES ^c

√ Indicates an effect that affects the clinical action of the drug. (x): metabolite or route of elimination probably of minor clinical importance. ^aThe elimination $t_{1/2}$ is one, but not the only, determinant of how frequently a drug must be administered to maintain a therapeutic effect and avoid toxicity (Chapter 2). For some drugs with short elimination half-lives, infrequent dosing is nevertheless possible, e.g., verapamil. Formulations that allow slow release into the GI tract of a rapidly eliminated compound (available for many drugs, including procainamide, disopyramide, verapamil, diltiazem, and propranolol) also allow infrequent dosing. ^bThe therapeutic range is bounded by a plasma concentration below which no therapeutic effect is likely, and an upper concentration above which the risk of adverse effects increases. Many serious adverse reactions to antiarrhythmic drugs can occur at “therapeutic” concentrations in susceptible individuals. When only an upper limit is cited, a lower limit has not been well defined. Variable generation of active metabolites may further complicate the interpretation of plasma concentration data (Chapter 2). ^cOral doses are presented unless otherwise indicated. Doses are presented as suggested ranges in adults of average build; lower doses are less likely to produce toxicity. Lower maintenance dosages may be required in patients with renal or hepatic disease. Loading doses are only indicated when a therapeutic effect is desired before maintenance therapy would bring drug concentrations into a therapeutic range—that is, for acute therapy (e.g., lidocaine, verapamil, adenosine) or when the elimination $t_{1/2}$ is extremely long (amiodarone). ^d Bioavailability reduced by incomplete absorption. ^eIndicates suggested dosage using slow-release formulation. IV, intravenous.

actions and its toxicity may be attributable to interaction with nuclear thyroid hormone receptors. Amiodarone is highly lipophilic, is concentrated in many tissues, and is eliminated extremely slowly; consequently, adverse effects may resolve very slowly. In the U.S., the drug is indicated for oral therapy in patients with recurrent ventricular tachycardia or VF resistant to other drugs. In addition, the intravenous form is a first-line drug for management of ventricular tachycardia or VF causing cardiac arrest (Dorian et al., 2002). Trials of oral amiodarone have shown a modest beneficial effect on mortality after acute myocardial infarction (Amiodarone Trials Meta-Analysis Investigators, 1997). Despite uncertainties about its mechanisms of action and the potential for serious toxicity, amiodarone is used widely in the treatment of common arrhythmias such as atrial fibrillation (Roy et al., 2000).

Pharmacological Effects

Studies of the acute effects of amiodarone in *in vitro* systems are complicated by its insolubility in water, necessitating the use of solvents such as dimethyl sulfoxide, which can have electrophysiological effects on its own. Amiodarone's effects may be mediated by perturbation of the lipid environment of the ion channels. Amiodarone blocks inactivated Na^+ channels and has a relatively rapid rate of recovery (time constant ≈ 1.6 sec) from block. It also decreases Ca^{2+} current and transient outward delayed rectifier and inward rectifier K^+ currents and exerts a non-competitive adrenergic-blocking effect. Amiodarone potentially inhibits abnormal automaticity and, in most tissues, prolongs action potential duration. Amiodarone decreases conduction velocity by Na^+ channel block and by a poorly understood effect on cell-cell coupling that may be especially important in diseased tissue. Prolongations of the PR, QRS, and QT intervals and sinus bradycardia are frequent during chronic therapy. Amiodarone prolongs refractoriness in all cardiac tissues; Na^+ channel block, delayed repolarization owing to K^+ channel block, and inhibition of cell-cell coupling all may contribute to this effect.

Adverse Effects

Hypotension owing to vasodilation and depressed myocardial performance are frequent with the intravenous form of amiodarone and may be due in part to the solvent. While depressed contractility can occur during long-term oral therapy, it is unusual. Despite administration of high doses that would cause serious toxicity if continued long term, adverse effects are unusual during oral drug-loading regimens, which typically require several weeks. Occasional patients develop nausea during the loading phase, which responds to a decrease in daily dose.

Adverse effects during long-term therapy reflect both the size of daily maintenance doses and the cumulative dose, suggesting that tissue accumulation may be responsible. The most serious adverse effect during chronic amiodarone therapy is pulmonary fibrosis, which can be rapidly progressive and fatal. Underlying lung disease, doses of 400 mg/d or more, and recent pulmonary insults such as pneumonia appear to be risk factors. Serial chest X-rays or pulmonary function studies may detect early amiodarone toxicity, but monitoring plasma concentrations has not been useful. With low doses, such as 200 mg/d or less as used in atrial fibrillation, pulmonary toxicity is less common (Zimetbaum, 2007). Other adverse effects during long-term therapy include corneal microdeposits (which often are asymptomatic), hepatic dysfunction, neuromuscular symptoms (most commonly peripheral neuropathy or proximal muscle weakness), photosensitivity, and hypo- or hyperthyroidism. The multiple effects of amiodarone on thyroid function are discussed further in Chapter 43. Treatment consists of withdrawal of the drug and supportive measures, including corticosteroids, for life-threatening pulmonary toxicity; reduction of dosage may be sufficient if the

drug is deemed necessary and the adverse effect is not life threatening. Despite the marked QT prolongation and bradycardia typical of chronic amiodarone therapy, torsades de pointes and other drug-induced tachyarrhythmias are unusual.

Clinical Pharmacokinetics

Amiodarone's oral bioavailability is about 30%, presumably due to poor absorption. This incomplete bioavailability is important in calculating equivalent dosing regimens when converting from intravenous to oral therapy. The drug distributes into lipid; heart tissue-to-plasma concentration ratios of greater than 20:1 and lipid-to-plasma ratios of greater than 300:1 have been reported. After the initiation of amiodarone therapy, increases in refractoriness, a marker of pharmacological effect, require several weeks to develop. Amiodarone undergoes hepatic metabolism by CYP3A4 to desethyl-amiodarone, a metabolite with pharmacological effects similar to those of the parent drug. When amiodarone therapy is withdrawn from a patient who has been receiving therapy for several years, plasma concentrations decline with a half-life of weeks to months. The mechanisms of amiodarone and desethyl-amiodarone elimination are not well established.

A therapeutic plasma amiodarone concentration range of 0.5 to 2 $\mu\text{g/mL}$ has been proposed. However, efficacy apparently depends as much on duration of therapy as on plasma concentration, and elevated plasma concentrations do not predict toxicity. Because of amiodarone's slow accumulation in tissue, a high-dose oral loading regimen (e.g., 800 to 1600 mg/d) usually is administered for several weeks before maintenance therapy is started. The maintenance dose is adjusted based on adverse effects and the arrhythmias being treated. If the presenting arrhythmia is life threatening, dosages of more than 300 mg/d normally are used unless unequivocal toxicity occurs. On the other hand, maintenance doses of 200 mg/d or less are used if recurrence of an arrhythmia would be tolerated, as in patients with atrial fibrillation, because amiodarone slows the ventricular rate during atrial fibrillation.

Dosage adjustments are not required in hepatic, renal, or cardiac dysfunction. Amiodarone potentially inhibits the hepatic metabolism or renal elimination of many compounds. Mechanisms identified to date include inhibition of CYP3A4, CYP2C9, and P-glycoprotein (see Chapters 5 and 6). Dosages of warfarin, other antiarrhythmics (e.g., flecainide, procainamide, and quinidine), or digoxin usually require reduction during amiodarone therapy.

Bretylum

Bretylum is a quaternary ammonium compound that prolongs cardiac action potentials and interferes with reuptake of norepinephrine by sympathetic neurons. In the past, bretylum was used to treat VF and prevent its recurrence; the drug is currently not available in the U.S.

Digoxin

DIGOXIN

Pharmacological Effects

Digitalis glycosides exert positive inotropic effects and have been used in heart failure; now, they are rarely prescribed (see Chapter 29). Their inotropic action results from increased intracellular Ca^{2+} , which also forms the basis for arrhythmias related to cardiac glycoside intoxication. Cardiac glycosides increase phase 4 slope (i.e., increase the rate of automaticity), especially if $[\text{K}]_o$ is low. These drugs (e.g., digoxin) also exert prominent vagotonic actions, resulting in inhibition of Ca^{2+} currents in the AV node and activation of acetylcholine-mediated K^+ currents in the atrium. Thus, the major “indirect” electrophysiological effects of cardiac glycosides are hyperpolarization, shortening of atrial action potentials, and increases in AV nodal refractoriness. The last action accounts for the utility of digoxin in terminating reentrant arrhythmias involving the AV node and in controlling ventricular response in patients with atrial fibrillation. Cardiac glycosides may be especially useful in the last situation because many such patients have heart failure, which can be exacerbated by other AV nodal-blocking drugs such as Ca^{2+} channel blockers or β blockers. However, sympathetic drive is increased markedly in many patients with advanced heart failure, so digitalis is not very effective in decreasing the rate; on the other hand, even a modest decrease in rate can ameliorate heart failure.

Similarly, in other conditions in which high sympathetic tone drives rapid AV conduction (e.g., chronic lung disease and thyrotoxicosis), digitalis therapy may be only marginally effective in slowing the rate. In heart transplant patients, in whom innervation has been ablated, cardiac glycosides are ineffective for rate control. Increased sympathetic activity and hypoxia can potentiate digitalis-induced changes in automaticity and DADs, thus increasing the risk of digitalis toxicity. A further complicating feature in thyrotoxicosis is increased digoxin clearance.

The major ECG effects of cardiac glycosides are PR prolongation and a nonspecific alteration in ventricular repolarization (manifested by depression of the ST segment), whose underlying mechanism is not well understood.

Adverse Effects

Because of the low therapeutic index of cardiac glycosides, their toxicity is a common clinical problem (see Chapter 29). Arrhythmias, nausea, disturbances of cognitive function, and blurred or yellow vision are the usual manifestations. Elevated serum concentrations of digitalis, hypoxia (e.g., owing to chronic lung disease), and electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, and hypercalcemia) predispose patients to digitalis-induced arrhythmias. While digitalis intoxication can cause virtually any arrhythmia, certain types of arrhythmias are characteristic. Arrhythmias that should raise a strong suspicion of digitalis intoxication are those in which DAD-related tachycardias occur along with impairment of sinus node or AV nodal function. Atrial tachycardia with AV block is classic, but ventricular bigeminy (sinus beats alternating with beats of ventricular origin), “bidirectional” ventricular tachycardia (a rare entity), AV junctional tachycardias, and various degrees of AV block also can occur. With severe intoxication (e.g., with suicidal ingestion), severe hyperkalemia owing to poisoning of Na^+ , K^+ -ATPase and profound bradyarrhythmias, which may be unresponsive to pacing therapy, are seen. In patients with elevated serum digitalis levels, the risk of precipitating VF by DC cardioversion probably is increased; in those with therapeutic blood levels, DC cardioversion can be used safely.

Minor forms of cardiac glycoside intoxication may require no specific therapy beyond monitoring cardiac rhythm until symptoms and signs of toxicity resolve. Sinus bradycardia and AV block often respond to intravenous atropine, but the effect is transient. Mg^{2+} has been used successfully in some cases of digitalis-induced tachycardia. Any serious arrhythmia should be treated with antidigoxin Fab fragments (Digibind, Digifab), which are highly effective in binding digoxin and digitoxin and greatly enhance their renal excretion (see Chapter 29). Serum glycoside concentrations rise markedly with antidigitalis antibodies, but these represent bound (pharmacologically inactive) drug. Temporary cardiac pacing may be required for advanced sinus node or AV node dysfunction. Digitalis exerts direct arterial vasoconstrictor effects, which can be especially

deleterious in patients with advanced atherosclerosis who receive intravenous drug; mesenteric and coronary ischemia have been reported.

Clinical Pharmacokinetics

The only digitalis glycoside used in the U.S. is digoxin. Digitoxin (various generic preparations) also is used for chronic oral therapy outside the U.S. Digoxin tablets are incompletely (75%) bioavailable. In some patients, intestinal microflora may metabolize digoxin, markedly reducing bioavailability. In these patients, higher-than-usual doses are required for clinical efficacy; toxicity is a serious risk if antibiotics are administered that destroy intestinal microflora. Inhibition of P-glycoprotein (see further discussion) also may play a role in cases of toxicity. Digoxin is 20% to 30% protein bound.

The antiarrhythmic effects of digoxin can be achieved with intravenous or oral therapy. However, digoxin undergoes relatively slow distribution to effector site(s); therefore, even with intravenous therapy, there is a lag of several hours between drug administration and the development of measurable antiarrhythmic effects such as PR interval prolongation or slowing of the ventricular rate in atrial fibrillation. To avoid intoxication, a loading dose of approximately 0.6 to 1 mg digoxin is administered over 24 h. Measurement of postdistribution serum digoxin concentration and adjustment of the daily dose (0.0625 to 0.5 mg) to maintain concentrations of 0.5 to 2 ng/mL are useful during chronic digoxin therapy (Table 30–5). Some patients may require and tolerate higher concentrations, but with an increased risk of adverse effects.

The elimination half-life of digoxin ordinarily is about 36 h, so maintenance doses are administered once daily. Renal elimination of unchanged drug accounts for about 80% of digoxin elimination. Digoxin doses should be reduced (or dosing interval increased) and serum concentrations monitored closely in patients with impaired excretion owing to renal failure or in patients who are hypothyroid. Digitoxin undergoes primarily hepatic metabolism and may be useful in patients with fluctuating or advanced renal dysfunction. Digitoxin metabolism is accelerated by drugs such as phenytoin and rifampin that induce hepatic metabolism. Digitoxin's elimination half-life is even longer than that of digoxin (about 7 days); it is highly protein bound, and its therapeutic range is 10 to 30 ng/mL.

Amiodarone, quinidine, verapamil, diltiazem, cyclosporine, itraconazole, propafenone, and flecainide decrease digoxin clearance, likely by inhibiting P-glycoprotein, the major route of digoxin elimination (Fromm et al., 1999). New steady-state digoxin concentrations are approached after four to five half-lives (i.e., in about a week). Digitalis toxicity results so often with quinidine or amiodarone that it is routine to decrease the dose of digoxin if these drugs are started. In all cases, digoxin concentrations should be measured regularly and the dose adjusted if necessary. Hypokalemia, which can be caused by many drugs (e.g., diuretics, amphotericin B, and corticosteroids), will potentiate digitalis-induced arrhythmias.

Disopyramide

Disopyramide exerts electrophysiological effects very similar to those of quinidine, but the drugs have different adverse effect profiles. Disopyramide can be used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF. Because of its negative inotropic effects, it is sometimes used in hypertrophic cardiomyopathy. Disopyramide is prescribed as a racemate.

Pharmacological Actions and Adverse Effects

The *in vitro* electrophysiological actions of S-(+)-disopyramide are similar to those of quinidine. The R-(–)-enantiomer produces similar Na^+ channel block but does not prolong cardiac action potentials. Unlike quinidine, racemic disopyramide does not antagonize α adrenergic receptors, but does exert prominent anticholinergic actions that account for many of its adverse effects. These include precipitation of glaucoma, constipation, dry mouth, and urinary retention; the last is most common in males with prostatism but also can occur in females. Disopyramide can cause torsades de pointes and also commonly depresses contractility, which can precipitate heart failure. In patients with hypertrophic cardiomyopathy, this depression contractility may be exploited to therapeutic

Clinical Pharmacokinetics

Disopyramide is well absorbed. Binding to plasma proteins is concentration dependent, so a small increase in total concentration may represent a disproportionately larger increase in free drug concentration. Disopyramide is eliminated by both hepatic metabolism (to a weakly active metabolite) and renal excretion of unchanged drug. The dose should be reduced in patients with renal dysfunction. Higher-than-usual dosages may be required in patients receiving drugs that induce hepatic metabolism, such as phenytoin.

Dofetilide

Dofetilide prolongs action potentials and the QT interval by potentially blocking the I_{Kr} channel. Increased late Na^+ current, likely due to inhibition of phosphoinositide 3-kinase (Yang et al., 2014), may also contribute. The drug has virtually no extracardiac pharmacological effects. Dofetilide is effective in maintaining sinus rhythm in patients with atrial fibrillation. In the DIAMOND studies (Torp-Pedersen et al., 1999), dofetilide did not affect mortality in patients with advanced heart failure or in those convalescing from acute myocardial infarction. Dofetilide currently is available through a restricted distribution system that includes only physicians, hospitals, and other institutions that have received special educational programs covering proper dosing and in-hospital treatment initiation.

Adverse Effects

Torsades de pointes occurred in 1%–3% of patients in clinical trials where strict exclusion criteria (e.g., hypokalemia) were applied and continuous ECG monitoring was used to detect marked QT prolongation in the hospital. Other adverse effects were no more common than with placebo during premarketing clinical trials.

Clinical Pharmacokinetics

Most of a dose of dofetilide is excreted unchanged by the kidneys. In patients with mild-to-moderate renal failure, decreases in dosage based on creatinine clearance are required to minimize the risk of torsades de pointes. The drug should not be used in patients with advanced renal failure or with inhibitors of renal cation transport. Dofetilide also undergoes minor hepatic metabolism.

Dronedarone

Dronedarone is a noniodinated benzofuran derivative of amiodarone that is FDA-approved for the treatment of atrial fibrillation and atrial flutter. In randomized placebo-controlled trials, it was effective in maintaining sinus rhythm and reducing the ventricular response rate during episodes of atrial fibrillation (Patel et al., 2009). Compared to amiodarone, dronedarone treatment is associated with significantly fewer adverse events, but it is also significantly less effective in maintaining sinus rhythm. Dronedarone decreased hospital admissions compared to placebo in patients with a history of atrial fibrillation (Hohnloser et al., 2009). In other studies, however, the drug increased mortality in patients with permanent atrial fibrillation (Connolly et al., 2011) and in those with severe heart failure (Kober et al., 2008).

Pharmacological Effects

Like amiodarone, dronedarone is a blocker of multiple ion currents, including the rapidly activating delayed-rectifier K^+ current (I_{Kr}), the slowly activating delayed-rectifier K^+ current (I_{Ks}), the inward rectifier K^+ current (I_{K1}), the acetylcholine-activated K^+ current, the peak Na^+ current, and the L-type Ca^{2+} current. It has stronger antiadrenergic effects than amiodarone.

Adverse Effects and Drug Interactions

The most common adverse reactions are diarrhea, nausea, abdominal pain, vomiting, and asthenia. Dronedarone causes dose-dependent prolongation of the QTc interval, but torsades de pointes is rare. Dronedarone is metabolized by CYP3A and is a moderate inhibitor of CYP3A, CYP2D6, and P-glycoprotein. Potent CYP3A4 inhibitors such as ketoconazole may

increase dronedarone exposure by as much as 25-fold. Consequently, dronedarone should not be coadministered with potent CYP3A4 inhibitors (e.g., antifungals, macrolide antibiotics). Coadministration with other drugs metabolized by CYP2D6 (e.g., metoprolol) or P-glycoprotein (e.g., digoxin) may result in increased drug concentrations. Dronedarone may cause severe liver injury; the FDA recommends monitoring of hepatic enzymes.

Esmolol

Esmolol is a β_1 -selective agent that is metabolized by erythrocyte esterases and so has a very short elimination half-life (9 min). Intravenous esmolol is useful in clinical situations in which immediate β adrenergic blockade is desired (e.g., for rate control of rapidly conducted atrial fibrillation). Because of esmolol's very rapid elimination, adverse effects due to β adrenergic blockade—should they occur—dissipate rapidly when the drug is stopped. Although methanol is a metabolite of esmolol, methanol intoxication has not been a clinical problem. The pharmacology of esmolol is described in further detail in Chapter 12.

Flecainide

The effects of flecainide therapy are thought to be attributable to the drug's very long τ_{recovery} from Na^+ channel block. Suppression of DADs triggered by $RyR2$ Ca^{2+} release may also contribute to flecainide's antiarrhythmic effect. In CAST, flecainide increased mortality in patients convalescing from myocardial infarction (Echt et al., 1991). However, it continues to be approved for certain arrhythmias in patients in whom structural heart disease is absent (Henthorn et al., 1991); this includes the maintenance of sinus rhythm in patients with supraventricular arrhythmias, including atrial fibrillation, as well as life-threatening ventricular arrhythmias, such as sustained ventricular tachycardia. Clinical case series suggested long-term flecainide efficacy in two congenital ventricular arrhythmia syndromes: type 3 LQTS due to mutations that cause late Na^+ currents and CPVT due to mutations that cause "leaky" $RyR2$ SR Ca^{2+} release channels. Supported by data from a recent randomized clinical trial (Kannankeril et al., 2017), flecainide has become the drug of choice for preventing arrhythmias in CPVT patients uncontrolled by β blockers.

Pharmacological Effects

Flecainide blocks Na^+ current and delayed rectifier K^+ current (I_{Kr}) in vitro at similar concentrations, 1 to 2 μM . It also blocks Ca^{2+} currents in vitro. Action potential duration is shortened in Purkinje cells, probably owing to block of late-opening Na^+ channels, but is prolonged in ventricular cells, probably owing to block of delayed rectifier current. Flecainide does not cause EADs in vitro but has been associated with rare cases of torsades de pointes. In atrial tissue, flecainide disproportionately prolongs action potentials at fast rates, an especially desirable antiarrhythmic drug effect; this effect contrasts with that of quinidine, which prolongs atrial action potentials to a greater extent at slower rates. Flecainide prolongs the duration of PR, QRS, and QT intervals even at normal heart rates. Flecainide is also an open channel blocker of $RyR2$ Ca^{2+} release channels and prevents arrhythmogenic Ca^{2+} release from the SR and hence DADs in isolated myocytes (Hilliard et al., 2010). The $RyR2$ channel block by flecainide targets directly the underlying molecular defect in patients with mutations in the $RyR2$ gene and the cardiac calsequestrin gene, which may explain why flecainide suppresses ventricular arrhythmias in patients with CPVT refractory to β blocker therapy (Watanabe et al., 2009; Kannankeril et al., 2017).

Adverse Effects

Flecainide produces few subjective complaints in most patients; dose-related blurred vision is the most common noncardiac adverse effect. It can exacerbate congestive heart failure in patients with depressed left ventricular performance. The most serious adverse effects are provocation or exacerbation of potentially lethal arrhythmias. These include acceleration of ventricular rate in patients with atrial flutter, increased frequency of episodes of reentrant ventricular tachycardia, and increased mortality in patients convalescing from myocardial infarction. As discussed previously, it is likely that all these effects can be attributed to Na^+

channel block. Flecainide also can cause heart block in patients with conduction system disease.

Clinical Pharmacokinetics

Flecainide is well absorbed. The elimination $t_{1/2}$ is shorter with urinary acidification (10 h) than with urinary alkalization (17 h), but it is nevertheless sufficiently long to allow dosing twice daily (Table 30–5). Elimination occurs by both renal excretion of unchanged drug and hepatic metabolism to inactive metabolites. The latter is mediated by the polymorphically distributed enzyme CYP2D6. However, even in patients in whom this pathway is absent because of genetic polymorphism or inhibition by other drugs (e.g., quinidine or fluoxetine), renal excretion ordinarily is sufficient to prevent drug accumulation. In the rare patient with renal dysfunction and lack of active CYP2D6, flecainide may accumulate to toxic plasma concentrations. Flecainide is a racemate, but there are no differences in the electrophysiological effects or disposition kinetics of its enantiomers. Some reports have suggested that plasma flecainide concentrations greater than 1 $\mu\text{g/mL}$ should be avoided to minimize the risk of flecainide toxicity; however, in susceptible patients, the adverse electrophysiological effects of flecainide therapy can occur at therapeutic plasma concentrations.

Ibutilide

Ibutilide is an I_{Kr} blocker that in some systems also activates an inward Na^+ current (Murray, 1998). The action potential–prolonging effect of the drug may arise from either mechanism. Ibutilide is administered as a rapid infusion (1 mg over 10 min) for the immediate conversion of atrial fibrillation or flutter to sinus rhythm. The drug's efficacy rate is higher in patients with atrial flutter (50%–70%) than in those with atrial fibrillation (30%–50%). In atrial fibrillation, the conversion rate is lower in those in whom the arrhythmia has been present for weeks or months compared with those in whom it has been present for days. The major toxicity with ibutilide is torsades de pointes, which occurs in up to 6% of patients and requires immediate cardioversion in up to one-third of these. The drug undergoes extensive first-pass metabolism, so it is not used orally. It is eliminated by hepatic metabolism and has a $t_{1/2}$ of 2–12 h (average 6 h).

Lidocaine

Lidocaine is a local anesthetic that also is useful in the acute intravenous therapy of ventricular arrhythmias. When lidocaine was administered to all patients with suspected myocardial infarction, the incidence of VF was reduced. However, survival to hospital discharge tended to be decreased, perhaps because of lidocaine-exacerbated heart block or congestive heart failure. Therefore, lidocaine no longer is administered routinely to all patients in coronary care units.

Pharmacological Effects

Lidocaine blocks both open and inactivated cardiac Na^+ channels. In vitro studies suggested that lidocaine-induced block reflects an increased likelihood that the Na^+ channel protein assumes a nonconducting conformation in the presence of drug (Balser et al., 1996). Recovery from block is rapid, so lidocaine exerts greater effects in depolarized (e.g., ischemic) or rapidly driven tissues. Lidocaine is not useful in atrial arrhythmias, possibly because atrial action potentials are so short that the Na^+ channel is in the inactivated state only briefly compared with diastolic (recovery) times, which are relatively long. In some studies, lidocaine increased current through inward rectifier channels, but the clinical significance of this effect is not known. Lidocaine can hyperpolarize Purkinje fibers depolarized by low $[\text{K}]_o$ or stretch; the resulting increased conduction velocity may be antiarrhythmic in reentry.

Lidocaine decreases automaticity by reducing the slope of phase 4 and altering the threshold for excitability. Action potential duration usually is unaffected or is shortened; such shortening may be due to block of the few Na^+ channels that inactivate late during the cardiac action potential. Lidocaine usually exerts no significant effect on PR or QRS duration; QT is unaltered or slightly shortened. The drug exerts little effect

on hemodynamic function, although rare cases of lidocaine-associated exacerbations of heart failure have been reported, especially in patients with very poor left ventricular function. For additional information on lidocaine, see Chapter 22 on local anesthetics.

Adverse Effects

When a large intravenous dose of lidocaine is administered rapidly, seizures can occur. When plasma concentrations of the drug rise slowly above the therapeutic range, as may occur during maintenance therapy, tremor, dysarthria, and altered levels of consciousness are more common. Nystagmus is an early sign of lidocaine toxicity.

Clinical Pharmacokinetics

Lidocaine is well absorbed but undergoes extensive though variable first-pass hepatic metabolism; thus, oral use of the drug is inappropriate. In theory, therapeutic plasma concentrations of lidocaine may be maintained by intermittent intramuscular administration, but the intravenous route is preferred (Table 30–5). Lidocaine's metabolites, GX and monoethyl GX, are less potent as Na^+ channel blockers than the parent drug. GX and lidocaine appear to compete for access to the Na^+ channel, suggesting that with infusions during which GX accumulates, lidocaine's efficacy may be diminished. With infusions lasting longer than 24 h, the clearance of lidocaine falls—an effect that may result from competition between parent drug and metabolites for access to hepatic drug-metabolizing enzymes.

Plasma concentrations of lidocaine decline biexponentially after a single intravenous dose, indicating that a multicompartment model is necessary to analyze lidocaine disposition. The initial drop in plasma lidocaine following intravenous administration occurs rapidly, with a $t_{1/2}$ of about 8 min, and represents distribution from the central compartment to peripheral tissues. The terminal elimination $t_{1/2}$ of about 2 h represents drug elimination by hepatic metabolism. Lidocaine's efficacy depends on maintenance of therapeutic plasma concentrations in the central compartment. Therefore, the administration of a single bolus dose of lidocaine can result in transient arrhythmia suppression that dissipates rapidly as the drug is distributed and concentrations in the central compartment fall. To avoid this distribution-related loss of efficacy, a loading regimen of 3 to 4 mg/kg over 20–30 min is used (e.g., an initial 100 mg followed by 50 mg every 8 min for three doses). Subsequently, stable concentrations can be maintained in plasma with an infusion of 1 to 4 mg/min, which replaces drug removed by hepatic metabolism. The time to steady-state lidocaine concentrations is approximately 8–10 h. If the maintenance infusion rate is too low, arrhythmias may recur hours after the institution of apparently successful therapy. On the other hand, if the rate is too high, toxicity may result. In either case, routine measurement of plasma lidocaine concentration at the time of expected steady state is useful in adjusting maintenance infusion rate.

In heart failure, the central volume of distribution is decreased, so the total loading dose should be decreased. Because lidocaine clearance also is decreased, the rate of the maintenance infusion should be decreased. Lidocaine clearance also is reduced in hepatic disease, during treatment with *cimetidine* or β blockers, and during prolonged infusions. Frequent measurement of plasma lidocaine concentration and dose adjustment to ensure that plasma concentrations remain within the therapeutic range (1.5 to 5 $\mu\text{g/mL}$) are necessary to minimize toxicity in these settings. Lidocaine is bound to the acute-phase reactant α_1 -acid glycoprotein. Diseases such as acute myocardial infarction are associated with increases in α_1 -acid glycoprotein and protein binding and hence a decreased proportion of free drug. These findings may explain why some patients require and tolerate higher-than-usual total plasma lidocaine concentrations to maintain antiarrhythmic efficacy.

Magnesium

The intravenous administration of 1 to 2 g MgSO_4 reportedly is effective in preventing recurrent episodes of torsades de pointes, even if the serum Mg^{2+} concentration is normal (Brugada, 2000). However, controlled studies of this effect have not been performed. The mechanism of action is unknown because the QT interval is not shortened; an effect on the inward current,

possibly a Ca^{2+} current, responsible for the triggered upstroke arising from EADs (black arrow, Figure 30–6B) is possible. Intravenous Mg^{2+} also has been used successfully in arrhythmias related to digitalis intoxication.

Large placebo-controlled trials of intravenous Mg^{2+} to improve outcome in acute myocardial infarction have yielded conflicting results (ISIS-4 Collaborative Group, 1995; Woods and Fletcher, 1994). While oral Mg^{2+} supplements may be useful in preventing hypomagnesemia, there is no evidence that chronic Mg^{2+} ingestion exerts a direct antiarrhythmic action.

Mexiletine

Mexiletine is an analogue of lidocaine that has been modified to reduce first-pass hepatic metabolism and permit chronic oral therapy. The electrophysiological actions are similar to those of lidocaine. Tremor and nausea, the major dose-related adverse effects, can be minimized by taking the drugs with food.

Mexiletine undergoes hepatic metabolism, which is inducible by drugs such as phenytoin. Mexiletine is approved for treating ventricular arrhythmias; combinations of mexiletine with quinidine or sotalol may increase efficacy while reducing adverse effects. In vitro studies and clinical case series have suggested a role for mexiletine (or flecainide; see previous discussion) in correcting the aberrant late inward Na^+ current in type 3 congenital LQTS (Napolitano et al., 2006).

Procainamide

Procainamide is an analogue of the local anesthetic procaine (see Figure 22–1). It exerts electrophysiological effects similar to those of quinidine but lacks quinidine's vagolytic and α adrenergic blocking activity. Procainamide is better tolerated than quinidine when given intravenously. Loading and maintenance intravenous infusions are used in the acute therapy of many supraventricular and ventricular arrhythmias. However, long-term oral treatment is poorly tolerated and often is stopped owing to adverse effects.

Pharmacological Effects

Procainamide is a blocker of open Na^+ channels with an intermediate τ_{recovery} from block. It also prolongs cardiac action potentials in most tissues, probably by blocking outward K^+ current(s). Procainamide decreases automaticity, increases refractory periods, and slows conduction. The major metabolite, *N*-acetyl procainamide, lacks the Na^+ channel-blocking activity of the parent drug but is equipotent in prolonging action potentials. Because the plasma concentrations of *N*-acetyl procainamide often exceed those of procainamide, increased refractoriness and QT prolongation during chronic procainamide therapy may be partly attributable to the metabolite. However, it is the parent drug that slows conduction and produces QRS interval prolongation. Although hypotension may occur at high plasma concentrations, this effect usually is attributable to ganglionic blockade rather than to any negative inotropic effect, which is minimal.

Adverse Effects

Hypotension and marked slowing of conduction are major adverse effects of high concentrations ($>10 \mu\text{g/mL}$) of procainamide, especially during intravenous use. Dose-related nausea is frequent during oral therapy and may be attributable in part to high plasma concentrations of *N*-acetyl procainamide. Torsades de pointes can occur, particularly when plasma concentrations of *N*-acetyl procainamide rise to greater than $30 \mu\text{g/mL}$. Procainamide produces potentially fatal bone marrow aplasia in 0.2% of patients; the mechanism is not known, but high plasma drug concentrations are not suspected.

During long-term therapy, most patients will develop biochemical evidence of the drug-induced lupus syndrome, such as circulating antinuclear antibodies. Therapy need not be interrupted merely because of the presence of antinuclear antibodies. However, 25%–50% of patients eventually develop symptoms of the lupus syndrome; common early symptoms are rash and small-joint arthralgias. Other symptoms of lupus, including pericarditis with tamponade, can occur, although renal involvement is unusual. The lupus-like symptoms resolve on cessation of therapy

or during treatment with *N*-acetyl procainamide (see discussion that follows).

Clinical Pharmacokinetics

Procainamide is eliminated rapidly ($t_{1/2} \sim 3\text{--}4 \text{ h}$) by both renal excretion of unchanged drug and hepatic metabolism. The major pathway for hepatic metabolism is conjugation by *N*-acetyl transferase, whose activity is determined genetically, to form *N*-acetyl procainamide. *N*-Acetyl procainamide is eliminated by renal excretion ($t_{1/2} \sim 6\text{--}10 \text{ h}$) and is not significantly converted back to procainamide. Because of the relatively rapid elimination rates of both the parent drug and its major metabolite, oral procainamide usually is administered as a slow-release formulation. In patients with renal failure, procainamide or *N*-acetyl procainamide can accumulate to potentially toxic plasma concentrations. Reduction of procainamide dose and dosing frequency and monitoring of plasma concentrations of both compounds are required in this situation. Because the parent drug and metabolite exert different pharmacological effects, the past practice of using the sum of their concentrations to guide therapy is inappropriate.

In individuals who are “slow acetylators,” the procainamide-induced lupus syndrome develops more often and earlier during treatment than among rapid acetylators. In addition, the symptoms of procainamide-induced lupus resolve during treatment with *N*-acetyl procainamide. Both these findings support results of in vitro studies suggesting that it is chronic exposure to the parent drug (or an oxidative metabolite) that results in the lupus syndrome; these findings also provided one rationale for the further development of *N*-acetyl procainamide and its analogues as antiarrhythmic agents (Roden, 1993).

Propafenone

Propafenone is a Na^+ channel blocker with a relatively slow time constant for recovery from block (Funch-Brentano et al., 1990). Some data suggest that, like flecainide, propafenone also blocks K^+ channels. Its major electrophysiological effect is to slow conduction in fast-response tissues. The drug is prescribed as a racemate; while the enantiomers do not differ in their Na^+ channel-blocking properties, *S*-(+)-propafenone is a β adrenergic receptor antagonist in vitro and in some patients. Propafenone prolongs PR and QRS durations. Chronic therapy with oral propafenone is used to maintain sinus rhythm in patients with supraventricular tachycardias, including atrial fibrillation; like other Na^+ channel blockers, it also can be used in ventricular arrhythmias, but with only modest efficacy. *R*-(-) propafenone blocks RyR2 channels and may be an alternative to flecainide in CPVT (Hwang et al, 2011).

Adverse Effects

Adverse effects during propafenone therapy include acceleration of ventricular response in patients with atrial flutter, increased frequency or severity of episodes of reentrant ventricular tachycardia, exacerbation of heart failure, and the adverse effects of β adrenergic blockade, such as sinus bradycardia and bronchospasm (see previous discussion and Chapter 12).

Clinical Pharmacokinetics

Propafenone is well absorbed and is eliminated primarily by CYP2D6-mediated hepatic metabolism (see Chapter 6). In most subjects (“extensive metabolizers”), propafenone undergoes extensive first-pass hepatic metabolism to 5-hydroxy propafenone, a metabolite equipotent to propafenone as a Na^+ channel blocker but much less potent as a β adrenergic receptor antagonist. A second metabolite, *N*-desalkyl propafenone, is formed by non-CYP2D6-mediated metabolism and is a less-potent blocker of Na^+ channels and β adrenergic receptors. CYP2D6-mediated metabolism of propafenone is saturable, so small increases in dose can increase plasma propafenone concentration disproportionately. In “poor metabolizer” subjects, in whom CYP2D6 activity is low or absent, first-pass hepatic metabolism is much less than in extensive metabolizers, and plasma propafenone concentrations will be much higher after an equal dose. The incidence of adverse effects during propafenone therapy is significantly higher in poor metabolizers.

CYP2D6 activity can be inhibited markedly by a number of drugs, including quinidine and fluoxetine. In extensive metabolizer subjects receiving such drugs or in poor metabolizer subjects, plasma propafenone concentrations of more than 1 $\mu\text{g/mL}$ are associated with clinical effects of β adrenergic receptor blockade, such as reduction of exercise heart rate. It is recommended that dosage in patients with moderate-to-severe liver disease should be reduced to approximately 20%–30% of the usual dose, with careful monitoring. It is not known if propafenone doses must be decreased in patients with renal disease. A slow-release formulation allows twice-daily dosing.

Quinidine

As early as the 18th century, the bark of the cinchona plant was used to treat “rebellious palpitations” (Levy and Azoulay, 1994). Studies in the early 20th century identified quinidine, a diastereomer of the antimalarial quinine, as the most potent of the antiarrhythmic substances extracted from the cinchona plant, and by the 1920s, quinidine was used as an antiarrhythmic agent. Quinidine is used to maintain sinus rhythm in patients with atrial flutter or atrial fibrillation and to prevent recurrence of ventricular tachycardia or VF (Grace and Camm, 1998). Quinidine may be especially useful in preventing recurrent VF in unusual congenital arrhythmias syndromes such as Brugada syndrome or short QT syndrome (Inama et al., 2010; Viskin et al., 2013).

Pharmacological Effects

Quinidine blocks Na^+ current and multiple cardiac K^+ currents. It is an open-state blocker of Na^+ channels, with a τ_{recovery} in the intermediate (~3-sec) range; as a consequence, QRS duration increases modestly, usually by 10%–20%, at therapeutic dosages. At therapeutic concentrations, quinidine commonly prolongs the QT interval up to 25%, but the effect is highly variable. At concentrations as low as 1 μM , quinidine blocks Na^+ current and the rapid component of delayed rectifier (I_{Kr}); higher concentrations block the slow component of delayed rectifier, inward rectifier, transient outward current, and L-type Ca^{2+} current.

Quinidine's Na^+ channel-blocking properties result in an increased threshold for excitability and decreased automaticity. As a consequence of its K^+ channel-blocking actions, quinidine prolongs action potentials in most cardiac cells, most prominently at slow heart rates. In some cells, such as midmyocardial cells and Purkinje cells, quinidine consistently elicits EADs at slow heart rates, particularly when $[\text{K}]_o$ is low (Priori et al., 1999). Quinidine prolongs refractoriness in most tissues, probably as a result of both prolongation of action potential duration and Na^+ channel blockade.

In intact animals and humans, quinidine also produces α adrenergic receptor blockade and vagal inhibition. Thus, the intravenous use of quinidine is associated with marked hypotension and sinus tachycardia. Quinidine's vagolytic effects tend to inhibit its direct depressant effect on AV nodal conduction, so the effect of drug on the PR interval is variable. Moreover, quinidine's vagolytic effect can result in increased AV nodal transmission of atrial tachycardias such as atrial flutter (Table 30–1).

Adverse Effects

Noncardiac. Diarrhea is the most common adverse effect during quinidine therapy, occurring in 30%–50% of patients; the mechanism is not known. Diarrhea usually occurs within the first several days of quinidine therapy but can occur later. Diarrhea-induced hypokalemia may potentiate torsades de pointes due to quinidine.

A number of immunological reactions can occur during quinidine therapy. The most common is thrombocytopenia, which can be severe but which resolves rapidly with discontinuation of the drug. Hepatitis, bone marrow depression, and lupus syndrome occur rarely. None of these effects is related to elevated plasma quinidine concentrations.

Quinidine also can produce cinchonism, a syndrome that includes headache and tinnitus. In contrast to other adverse responses to quinidine therapy, cinchonism usually is related to elevated plasma quinidine concentrations and can be managed by dose reduction.

Cardiac. Of patients receiving quinidine therapy, 2%–8% will develop marked QT interval prolongation and torsades de pointes. In contrast to effects of sotalolol, *N*-acetyl procainamide, and many other drugs, quinidine-associated torsades de pointes generally occurs at therapeutic or even subtherapeutic plasma concentrations. The reasons for individual susceptibility to this adverse effect are not known.

At high plasma concentrations of quinidine, marked Na^+ channel block can occur, with resulting ventricular tachycardia. This adverse effect occurs when very high doses of quinidine are used to try to convert atrial fibrillation to normal rhythm; this aggressive approach to quinidine dosing has been abandoned, and quinidine-induced ventricular tachycardia is unusual.

Quinidine can exacerbate heart failure or conduction system disease. However, in most patients with congestive heart failure, quinidine is well tolerated, perhaps because of its vasodilating actions.

Clinical Pharmacokinetics

Quinidine is well absorbed and is 80% bound to plasma proteins, including albumin and, like lidocaine, the acute-phase reactant α_1 -acid glycoprotein. As with lidocaine, greater-than-usual doses (and total plasma quinidine concentrations) may be required to maintain therapeutic concentrations of free quinidine in high-stress states such as acute myocardial infarction. Quinidine undergoes extensive hepatic oxidative metabolism, and approximately 20% is excreted unchanged by the kidneys. One metabolite, 3-hydroxyquinidine, is nearly as potent as quinidine in blocking cardiac Na^+ channels and prolonging cardiac action potentials. Concentrations of unbound 3-hydroxyquinidine equal to or exceeding those of quinidine are tolerated by some patients. Other metabolites are less potent than quinidine, and their plasma concentrations are lower; thus, they are unlikely to contribute significantly to the clinical effects of quinidine.

There is substantial individual variability in the range of dosages required to achieve therapeutic plasma concentrations of 2 to 5 $\mu\text{g/mL}$. Some of this variability may be assay dependent because not all assays exclude quinidine metabolites. In patients with advanced renal disease or congestive heart failure, quinidine clearance is decreased only modestly. Thus, dosage requirements in these patients are similar to those in other patients.

Drug Interactions

Quinidine is a potent inhibitor of CYP2D6. As a result, the administration of quinidine to patients receiving drugs that undergo extensive CYP2D6-mediated metabolism may result in altered drug effects owing to accumulation of parent drug and failure of metabolite formation. For example, inhibition of CYP2D6-mediated metabolism of *codeine* to its active metabolite *morphine* results in decreased analgesia. On the other hand, inhibition of CYP2D6-mediated metabolism of propafenone results in elevated plasma propafenone concentrations and increased β adrenergic receptor blockade. Quinidine reduces the clearance of digoxin; inhibition of P-glycoprotein-mediated digoxin transport has been implicated (Fromm et al., 1999). Dextromethorphan, a CYP2D6 substrate that undergoes extensive first-pass bioinactivation, has shown promise in treatment of various neurological disorders, notably pseudobulbar affect. A combination of dextromethorphan and very low-dose quinidine (30 mg) inhibits the first-pass metabolism, achieves higher systemic concentrations than monotherapy, and is now approved for use in pseudobulbar affect (Olney and Rosen, 2010).

Quinidine metabolism is induced by drugs such as *phenobarbital* and *phenytoin*. In patients receiving these agents, very high doses of quinidine

570 may be required to achieve therapeutic concentrations. If therapy with the inducing agent is then stopped, quinidine concentrations may rise to very high levels, and its dosage must be adjusted downward. Cimetidine and verapamil also elevate plasma quinidine concentrations, but these effects usually are modest.

Sotalol

Sotalol is a nonselective β adrenergic receptor antagonist that also prolongs cardiac action potentials by inhibiting delayed rectifier and possibly other K⁺ currents (Hohnloser and Woosley, 1994). Sotalol is prescribed as a racemate; the L-enantiomer is a much more potent β adrenergic receptor antagonist than the D-enantiomer, but the two are equipotent as K⁺ channel blockers. In the U.S., sotalol is approved for use in patients with both ventricular tachyarrhythmias and atrial fibrillation or flutter. Clinical trials suggest that it is at least as effective as most Na⁺ channel blockers in ventricular arrhythmias.

Sotalol prolongs action potential duration throughout the heart and QT interval on the ECG. It decreases automaticity, slows AV nodal conduction, and prolongs AV refractoriness by blocking both K⁺ channels and β adrenergic receptors, but it exerts no effect on conduction velocity in fast-response tissue. Sotalol causes EADs and triggered activity in

vitro and can cause torsades de pointes, especially when the serum K⁺ concentration is low. Unlike the situation with quinidine, the incidence of torsades de pointes (1.5%–2% incidence) seems to depend on the dose of sotalol; indeed, torsades de pointes is the major toxicity with sotalol overdose. Occasional cases occur at low dosages, often in patients with renal dysfunction, because sotalol is eliminated by renal excretion of unchanged drug. The other adverse effects of sotalol therapy are those associated with β adrenergic receptor blockade (see previous discussion and Chapter 12).

Vernakalant

Vernakalant is an inhibitor of multiple ion channels and prolongs atrial refractory periods without significantly affecting ventricular refractoriness. Intravenous vernakalant has modest efficacy in terminating atrial fibrillation (Roy et al., 2008) and is available for this indication in several European countries, but not the U.S. Consult the 12th edition of this text for more information on this drug.

Acknowledgment: Kevin J Simpson and Robert S. Kass contributed to this chapter in the previous edition of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: Antiarrhythmic Agents		
Antiarrhythmic Drug	Therapeutic Uses	Major Toxicity and Clinical Pearls
Class IA: Na ⁺ Channel Blockers • Slow to intermediate off rate • Concomitant class III action (prolong QT)		
Procainamide	<ul style="list-style-type: none">• Acute treatment of AF, VT, and VF• Chronic treatment to prevent AF, VT, and VF	<ul style="list-style-type: none">• 40% of patients discontinue within 6 months of therapy due to side effects: hypotension (especially from intravenous use), nausea• QT prolongation and torsades de pointes due to accumulation of active N-acetyl metabolite• Lupus-like syndrome (25%–50% with chronic use), especially in genetic slow acetylators• Oral drug no longer widely available
Quinidine	<ul style="list-style-type: none">• Chronic treatment to prevent AF, VT, and VF	<ul style="list-style-type: none">• Diarrhea (30%–50% of patients); diarrhea-induced hypokalemia may potentiate torsades de pointes• Marked QT prolongation and high risk (~1%–5%) of torsades de pointes at therapeutic or subtherapeutic concentrations• Immune thrombocytopenia (~1%)• Cinchonism: tinnitus, flushing, blurred vision, dizziness, diarrhea• Potent inhibitor of CYP2D6 and ABCB1: altered effects of digitalis, many antidepressants, and others
Disopyramide	<ul style="list-style-type: none">• Chronic treatment to prevent AF, VT, and VF	<ul style="list-style-type: none">• Anticholinergic effects (dry eyes, urinary retention, constipation)• Long QT (torsades de pointes)• Depression of contractility can precipitate or worsen heart failure; paradoxically, this can be useful in hypertrophic cardiomyopathy to reduce outflow tract obstruction
Class IB: Na ⁺ Channel Blockers • Fast off rate • Little effect on ECG		
Lidocaine	<ul style="list-style-type: none">• Acute treatment of VT and VF	<ul style="list-style-type: none">• CNS: seizures and tinnitus• CNS: tremor, hallucinations, drowsiness, coma
Mexiletine	<ul style="list-style-type: none">• Chronic treatment to prevent VT and VF	<ul style="list-style-type: none">• Tremor and nausea
Class IC: Na ⁺ Channel Blockers • Slow off rate • Prolong PR and broaden QRS intervals		
Flecainide	<ul style="list-style-type: none">• Chronic treatment to prevent PSVT, AF, VT, and VF in the absence of structural heart disease• Available in some countries for intravenous use in PSVT, AF• Useful in CPVT uncontrolled by β-blockers	<ul style="list-style-type: none">• Much better tolerated than class IA or IB agents• Risk of severe proarrhythmia in patients with structural heart disease; increased mortality in patients with myocardial infarction (CAST)• Blurred vision• Can worsen heart failure

Class IC: Na ⁺ Channel Blockers • Slow off rate • Prolong PR and broaden QRS intervals (continued)		
Propafenone	<ul style="list-style-type: none"> Chronic treatment to prevent PSVT, AF, VT, and VF in the absence of structural heart disease Available in some countries for intravenous use in PSVT, AF Alternative to flecainide for CPVT 	<ul style="list-style-type: none"> Also has β adrenergic blocking effects (worsening of heart failure and bronchospasm), especially prominent in CYP2D6 poor metabolizers Risk of severe proarrhythmia in patients with structural heart disease
Class II: β Blockers		
Nadolol Propranolol Metoprolol Many others	<ul style="list-style-type: none"> Chronic treatment to prevent arrhythmias in congenital LQTS and CPVT Rate control in AF Widely used for other indications (angina, hypertension, migraine, etc.) 	<ul style="list-style-type: none"> β Adrenergic blocking effects (worsening of heart failure, bradycardia, bronchospasm) Nadolol preferred by many for LQTS and CPVT
Esmolol	<ul style="list-style-type: none"> Acute treatment to control rate in AF 	<ul style="list-style-type: none"> Ultrashort $t_{1/2}$, intravenous use only
Class III: K ⁺ Channel Blocker • Increase refractory period (prolong QT)		
Amiodarone	<ul style="list-style-type: none"> Drug of choice for acute treatment of VT and VF and to slow ventricular rate and convert AF Chronic treatment to prevent AF, VT, and VF 	<ul style="list-style-type: none"> Hypotension, depressed ventricular function and torsades de pointes (rare) with intravenous administration Pulmonary fibrosis with chronic therapy, which can be fatal (requires periodic monitoring of lung function) Many other adverse effects: corneal microdeposits, hepatotoxicity, neuropathies, photosensitivity, thyroid dysfunction Note: tissue half-life of several months Inhibitor of many drug-metabolizing and transport systems, with high potential for drug interactions
Dronedrone	<ul style="list-style-type: none"> Chronic treatment to prevent AF 	<ul style="list-style-type: none"> Amiodarone analogue with lower efficacy than amiodarone GI disturbances, risk for fatal hepatotoxicity Increases mortality in patients with severe heart failure
Sotalol	<ul style="list-style-type: none"> Chronic treatment to prevent AF, VT, and VF 	<ul style="list-style-type: none"> Also has β adrenergic blocking effects High risk (~1%–5%) of torsades de pointes
Dofetilide	<ul style="list-style-type: none"> Chronic treatment to prevent AF 	<ul style="list-style-type: none"> Few adverse effects except high risk (~1%–5%) of torsades de pointes
Ibutilide	<ul style="list-style-type: none"> Acute treatment to convert AF 	<ul style="list-style-type: none"> High risk (~1%–5%) of torsades de pointes
Class IV: Ca ²⁺ Channel Blockers • Nondihydropyridine • Inhibit SA and AV nodes • Prolong PR		
Diltiazem, Verapamil	<ul style="list-style-type: none"> Acute intravenous use to convert PSVT and for rate control in AF Chronic treatment to prevent PSVT and control rate in AF 	<ul style="list-style-type: none"> Hypotension (intravenous) Sinus bradycardia or AV block especially in combination with β-blockers Constipation Worsening of heart failure
Antiarrhythmic Drugs With Miscellaneous Mechanisms		
Adenosine (activates A receptors)	Drug of choice for acute treatment PSVT	<ul style="list-style-type: none"> Short $t_{1/2}$ (<5 sec) Transient asystole Transient dyspnea Transient atrial fibrillation (rare)
MgSO ₄	<ul style="list-style-type: none"> Acute treatment of torsades de pointes 	
Digoxin (Na ⁺ -K ⁺ -ATPase inhibitor)	<ul style="list-style-type: none"> Ventricular rate control in atrial fibrillation Modest positive inotropic effect 	<ul style="list-style-type: none"> Adverse effects common and include GI symptoms, visual/cognitive dysfunction, and arrhythmias, typically supraventricular arrhythmias with heart block or atrial or ventricular extrasystoles Severe toxicities (e.g., with overdose) can be treated with antibody Probably mortality neutral

Introduction to Pulmonary Hypertension

The pulmonary circulation plays a unique and essential role in gas exchange and, in particular, oxygenation of venous blood. It is a low-resistance and low-pressure circulatory system; the mean PAP in a healthy man is about 12 mm Hg. PAP is a function of CO and PVR. PH is defined as the mean PAP of 25 mm Hg or greater at rest. In patients with PH, pressure overload (i.e., increased afterload) places additional stress on the RV, leading to RV dysfunction and hypertrophy, and in some cases right heart failure. Patients present with a range of symptoms, including dyspnea, fatigue, chest pain, and syncope. PH is a complication of many chronic diseases and is estimated to affect as much as 10%–20% of the general population (McLaughlin et al., 2009).

Pulmonary Hypertension Classification

Pulmonary hypertension is a primary disorder of the pulmonary vasculature and a complication of other cardiopulmonary, vascular, and inflammatory diseases. Based on shared pathophysiological and pathological characteristics as well as response to therapies, PH can be classified into five groups (Simonneau et al., 2013):

1. PAH
2. PH owing to left heart disease
3. PH owing to lung diseases or hypoxia
4. Chronic thromboembolic PH
5. PH with unclear multifactorial mechanisms

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension is a rare, progressive, and fatal disease in which vascular changes in the small arteries and arterioles lead to progressive increases in PVR, resulting in increased PAP (McLaughlin et al., 2009). In patients with PAH, elevated afterload increases stress on the RV, leading to right heart dysfunction and failure, the major cause of morbidity and mortality in this population. The disease is defined clinically by hemodynamic parameters measured during a right heart catheterization: mean PAP 25 mm Hg or greater, accompanied by normal pulmonary venous pressure measured as pulmonary artery occlusion pressure or left ventricular end-diastolic pressure of 15 mm Hg or less. The median survival in untreated disease is 2.8 years, yet with modern therapies, the median survival has been estimated to be about 9 years (Benza et al., 2012). This group of patients is the most well-studied subset and the primary target of available therapeutics (Frumkin, 2012).

Pulmonary Hypertension Associated With Other Disease States

Other PH groups represent the majority of recognized cases of PH. The presence of PH in these more common diseases portends a much poorer prognosis, often identifying people with multiple comorbidities, late-stage presentations, or more severe disease. While recognition of PH in heart and lung disease carries important prognostic implications, to date there are no approved targeted therapies for PH in these other disease states, with the exception of CTEPH. While surgical pulmonary thromboendarterectomy is the treatment of choice in CTEPH, nonsurgical patients or those with persistent PH following surgery respond to pulmonary vasodilator therapy (Fedullo et al., 2011; Ghofrani, et al., 2013).

Routes of Drug Delivery to the Pulmonary Circulation

The pulmonary circulation permits delivery of drugs through multiple routes. The pulmonary circulation runs in series with the systemic circulation, receiving the entire CO in each cardiac cycle. Thus, exposure of pulmonary tissue to drugs is excellent and reliable. Continuous intravenous infusion is used to deliver high concentrations of drugs that exhibit short half-lives to the pulmonary circulation while avoiding first-pass metabolism. Alternatively, drug administration by subcutaneous pump may be used to lower risk of adverse effects. Oral delivery remains a safe, effective, and reliable route for many classes of drugs used to treat PAH. The small pulmonary arteries and precapillary arterioles are also unique in their close proximity to the alveoli and lower airways. Hence, inhalational delivery of therapeutic compounds can directly target the lung vasculature and pulmonary circulation, limit systemic side effects, and preferentially affect well-ventilated parts of the lung to improve ventilation-perfusion matching (see Chapter 40).

Mechanisms of Pulmonary Arterial Hypertension

Pulmonary arterial hypertension is thought to arise from pathophysiological changes in the small pulmonary arteries and arterioles. Regardless of the initial etiological trigger, the putative mechanisms contributing to elevated PVR and PAP include the following:

- pulmonary vascular remodeling
- sustained pulmonary vasoconstriction
- in situ thrombosis
- pulmonary vascular wall stiffening

Abbreviations

ATPase: adenosine triphosphatase
BMPR2: bone morphogenetic protein receptor type 2
[Ca²⁺]_{cyt}: cytosolic free Ca²⁺ concentration
CCB: calcium channel blocker
COPD: chronic obstructive pulmonary disease
CTEPH: chronic thromboembolic pulmonary hypertension
CYP: cytochrome P450
DAG: diacylglycerol
EC: endothelial cell
ECE: endothelin-converting enzyme
EGF: epidermal growth factor
ERA: endothelin receptor antagonist
ET: endothelin-1
FDA: Food and Drug Administration
HCN: hyperpolarization-activated cyclic nucleotide-gated
HIV: human immunodeficiency virus
HPAP: heritable pulmonary arterial hypertension
HPV: hypoxic pulmonary vasoconstriction
5HT: serotonin
IP₃: inositol triphosphate
IPAH: idiopathic pulmonary arterial hypertension
IPR: prostacyclin receptor
LV: left ventricle
mGC: membrane guanylate cyclase
6MWT: six-minute walk testing
NO: nitric oxide
NO₂: nitric dioxide
NYHA: New York Heart Association
PA: pulmonary artery
PAEC: pulmonary arterial endothelial cell
PAH: pulmonary arterial hypertension
Pao₂: partial pressure of arterial O₂
PAOP: pulmonary artery occlusion pressure
PAP: pulmonary arterial pressure
PASMC: pulmonary artery smooth muscle cell
PDE: phosphodiesterase
PDGF: platelet-derived growth factor
PGI₂: prostacyclin, prostaglandin I₂
PH: pulmonary hypertension
PIP₂: phosphatidylinositol 4,5-bisphosphate
PKA: protein kinase A
PKG: protein kinase G
PLC: phospholipase C
PVR: pulmonary vascular resistance
RAP: right atrial pressure
ROC: receptor-operated Ca²⁺ channel
RV: right ventricle
RVF: right ventricular failure
RVH: right ventricular hypertrophy
RVSP: right ventricular systolic pressure
sGC: soluble guanylate cyclase
SR: sarcoplasmic reticulum
SVR: systemic vascular resistance
TKR: tyrosine kinase receptor
TxA₂: thromboxane A₂
VDCC: voltage-dependent Ca²⁺ channel
VEGF: vascular endothelial growth factors
VIP: vasoactive intestinal peptide
VSM: vascular smooth muscle

Each of these mechanisms (Figure 31–1) can contribute to the development and progression of PAH and forms the basis for drug therapy for this disease. Accordingly, an effective therapy for PAH would (1) cause pulmonary vasodilation; (2) exert antiproliferative or proapoptotic effects on highly proliferative cells in the pulmonary vascular wall (e.g., fibroblasts, myofibroblasts, and smooth muscle cells); (3) prevent or resolve in situ thrombosis in small arteries and precapillary arterioles; (4) exert antifibrotic effects to attenuate extracellular matrix stiffness; and (5) reduce pulmonary vascular wall stiffness due to myogenic tone and cholesterol-associated membrane stiffness (Mandegar et al., 2004; Morrell et al., 2009).

Although the cellular and molecular mechanisms leading to these changes in the pulmonary vasculature are complex, an imbalance of vasoactive mediators, mitogenic and angiogenic factors, and pro- and antiapoptotic proteins plays an important role in PAH development. Relative deficiencies of vasodilators (e.g., NO and prostacyclin) deleteriously accompany an excess of vasoconstrictors (e.g., ET-1 and TxA₂). NO released by the vascular ECs normally promotes the production of cyclic GMP in the PASMCs, resulting in PASMC relaxation and pulmonary vasodilation. PGI₂, also released from the vascular endothelium, promotes the synthesis of cAMP, causing PASMC relaxation and pulmonary vasodilation. In addition, NO and PGI₂ both have antiproliferative and anticoagulant effects that inhibit concentric pulmonary vascular wall thickening and in situ thrombosis. ET-1 is a potent vasoconstrictor secreted by ECs; it exerts vasoconstrictive and proliferative effects on PASMCs. Other vasoactive mediators such as TxA₂, 5HT, and VIP appear to play a role in the development of PAH, but the therapeutic potential of targeting these substances has not been well established. Table 31–1 summarizes the changes in these vasoactive mediators and the likely contributions of those changes to the development of PAH.

Sustained vasoconstriction and pulmonary vascular remodeling also result from functional and transcriptional changes in membrane receptors and ion channels on the surface of PASMCs. Several GPCRs and TKRs are implicated in the development and progression of PAH. Increased cytosolic [Ca²⁺] is an important common pathway by which receptor activation and downstream cellular signaling cascades exert their effects in the pulmonary vasculature. A rise in [Ca²⁺]_{cyt} in PASMCs is a major trigger for PASMC contraction and an important mediator for PASMC proliferation, migration, and vascular remodeling. In addition, ion channels, particularly Ca²⁺-permeable cation channels and K⁺-permeable channels (e.g., KCNA5 and KCNK3) in the plasma membrane of PASMCs, can directly influence [Ca²⁺]_{cyt} (Mandegar et al., 2004). Ion channels and transporters, such as VDCCs, ROCs, store-operated Ca²⁺ channels, and the Na⁺-Ca²⁺ exchanger, are implicated in the development of PAH; all are potential therapeutic targets. Downregulation of K⁺-permeable channels in PASMCs leads to membrane depolarization and opening of VDCCs, enhancing Ca²⁺ influx, with a consequent increase in [Ca²⁺]_{cyt} and further sustained vasoconstriction and vascular remodeling (Kuhre et al., 2012).

Clinical Use of Drugs for Pulmonary Hypertension

Treatment of PAH must include a proper assessment of symptoms, functional classification, and RV performance for optimal selection of appropriate agents. The most widely used criterion for initiating treatment is the presence of symptoms and impairments in functional capacity, as measured by functional classification. This classification measures the physical limitations imposed on a particular patient from the disease, progressing from class I through class IV (from no impairment through mounting functional limitation to inability to perform physical activity). Clinical trials suggested that class II patients may benefit from therapy, with greater benefit seen in class III. While overall number of patients is low, patients with the most severe functional impairments, class IV, fare far worse. RV dysfunction results from increased PVR, in part, and is the major contributor to morbidity and mortality in this population; therefore, assessment of the RV often is used in conjunction with functional assessment to guide therapy (Figure 31–2).

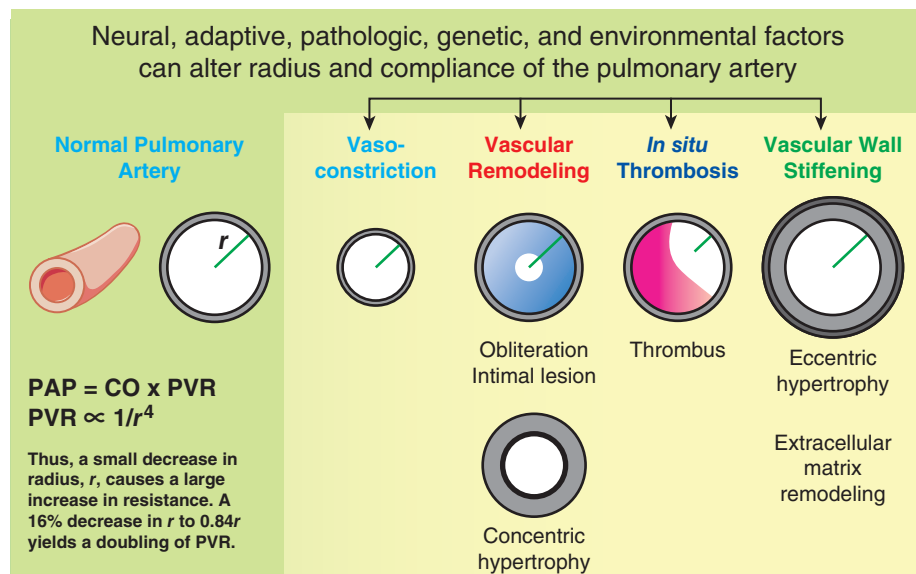

Figure 31-1 Major pathogenic components in the development of PAH. Vascular remodeling occurs as changes in the intraluminal radius with or without changes in the vascular wall thickness. Changes in intraluminal radius of small pulmonary arteries and arterioles have dramatic effects on the PVR. Pathogenic factors contributing to the development and progression of PAH include sustained vasoconstriction, pulmonary vascular remodeling, in situ thrombosis, and vascular wall stiffening.

Goals of treatment include improvement in symptoms, such as dyspnea, fatigue, chest pain, or syncope; improved functional capacity, including 6-min walk distance; and improvement in pulmonary and RV hemodynamics. Oral formulations, either ERAs, PDE5 inhibitors, or sGC stimulators, are usually employed as first-line agents due to ease of use. Treatment of the most severe PAH patients generally involves parenteral therapy with epoprostenol or treprostinil, the most potent pulmonary vasodilators, yet controversy exists on the initial treatment of patients with moderate-to-severe functional limitations. Sequential combination therapy with the addition of separate classes of medications is often utilized for severe or progressive disease (Ghofrani and Humbert, 2014). Modest effects with single agents may be enhanced with the use of up-front combinations and could lead to more dramatic improvements in both symptoms and hemodynamics (Sitbon et al., 2014; Galie et al., 2015).

Pulmonary hypertension is a complex disease process often complicating common diseases of the heart and lungs and heralding poor outcomes. Despite this, PAH, and more recently CTEPH, are the only two subtypes of PH with safe and effective pharmacotherapy. Supportive care therapies described in other chapters include volume management with diuretics (e.g., furosemide), anticoagulants (e.g., warfarin) for patients at high risk for thrombotic disease, supplemental oxygen therapy for hypoxic patients,

and inotropic therapy (e.g., digoxin) to improve cardiac contractility in patients with RV dysfunction.

Pharmacotherapy for Pulmonary Hypertension

Pharmacotherapy for PH targets the major pathogenic mechanisms of the disease—pulmonary vascular remodeling (e.g., concentric pulmonary vascular thickening and intraluminal obliteration), sustained pulmonary vasoconstriction, in situ thrombosis, and pulmonary vascular wall stiffening—with the goals of attenuating the development and progression of PAH and reversing these pathologic changes in patients with established PAH. Currently available PAH therapeutics are classified based on their cellular and molecular mechanisms (see Humbert and Ghofrani, 2016):

- NO and stimulators of cGMP and PKG signaling
- membrane receptor agonists
- membrane receptor antagonists
- ion channel blockers and openers

Stimulators of cGMP and PKG Signaling

Nitric oxide is synthesized mainly in vascular ECs and diffuses into vascular smooth muscle cells (PASMCs) to activate sGC. Activated sGC generates cGMP, which in turn is inactivated by cyclic nucleotide PDE5 to 5'-GMP (Figure 31-3). cGMP is an important intracellular second messenger that signals through (1) cGMP-dependent PKG, the principal downstream mediator of cGMP, and (2) cyclic nucleotide-gated and hyperpolarization-activated cyclic nucleotide-gated (HCN) channels (Craven and Zagotta, 2006). Increased cellular cGMP exerts relaxant and antiproliferative effects on PASMCs and myofibroblasts through activation of cGMP-gated K^+ channels, inhibition of Ca^{2+} -permeable channels (e.g., L-type VDCCs, transient receptor potential cation channels), and attenuation of several specific intracellular signaling cascades that are related to cell proliferation, growth, and migration (cAMP [via activated PKA] has similar effects). The drugs currently available for the treatment of PAH in this category include inhaled NO, stimulators and activators of sGC, and inhibitors of PDE5.

The enzymic catalysts of cGMP formation in tissues are sGC and particulate (plasma membrane) mGC. NO stimulates sGC, while the natriuretic peptides stimulate mGC (see Chapter 3 for information on the structure and mechanisms of activation of these enzymes). The sGC is

TABLE 31-1 ROLES OF VASOACTIVE MEDIATORS IN PAH

Figure 31-2 Clinical use of PAH drugs based on functional class. Treatment of PAH is generally based on the patient's functional classification at the time of presentation. Four functional classes have been defined for PAH: (I) no symptoms or functional limitation; (II) slight limitation of physical activity; (III) marked limitation of physical activity; and (IV) symptoms with any activity or at rest. In patients with no functional limitation, there is no specific therapy that has shown benefit in clinical trials. Expert guidelines recommend only supportive care and physical rehabilitation in this group. Patients with symptoms consistent with functional classes II and III have the best evidence for therapeutic benefits. First-line therapeutics include oral agents such as ERAs, PDE5 inhibitors, sGC stimulators, and the IPR antagonist selexipag. Inhaled PGI₂ analogues can also be considered. The oral formulation of treprostinil has been approved for use in minimally symptomatic individuals but should be reserved for use only as monotherapy. The most severely limited patients, those in functional class IV, or those with evidence of right heart dysfunction should be started on the most potent vasodilators, which include the intravenous and subcutaneous formulations of PGI₂ analogues. Alternatively, combination therapy using multiple agents has been shown to be effective in small clinical trials and one phase 3 clinical trial combining ambrisentan and tadalafil. *approved for monotherapy only.

the source of cGMP synthesis on which therapeutics agents for PAH rely. In the lung, activation of the cGMP-PKG pathway causes relaxation of smooth muscle, inhibits proliferation of bronchial smooth muscle and vascular smooth muscle cells, and has an antiproliferative effect (and can induce apoptosis) in pulmonary vascular smooth muscle cells and ECs (Figure 31-3).

Nitric Oxide

Nitric oxide is biosynthesized from the terminal nitrogen of L-arginine by the enzyme nitric oxide synthase (see Chapter 3). Endogenous NO levels are reduced in patients with PAH, PH associated with connective tissue disease, COPD, and interstitial lung disease (Girgis et al., 2005; Kawaguchi et al., 2006).

ADME. NO is a soluble gas. *Inhaled NO* is a gaseous blend of NO and N₂ (0.01% and 99.99%, respectively, for 100 ppm NO). NO must be compressed and stored with an inert gas such as N₂ to minimize the exposure to O₂, decreasing the risk of the accumulation of NO₂. Inhaled NO increases the PaO₂ by preferentially vasodilating better-ventilated lung regions from poorly inflated lung areas (i.e., with low ventilation/perfusion [V/Q]

ratios). Inhaled NO is generally administered continuously or with a pulsing device that is rapidly triggered with the onset of inspiration; careful monitoring of response is warranted (Griffiths and Evans, 2005). Inhaled NO is a selective pulmonary vasodilator. Its acute and relatively specific effects on PAP and PVR are due to its route of administration and short half-life (2–6 sec), which is primarily a result of the rapid inactivation of NO by hemoglobin binding and oxidation to nitrite; the nitrite interacts with oxyhemoglobin, leading to the formation of nitrate and met-hemoglobin (Bueno et al., 2013). Nitrate has been identified as the predominant NO metabolite excreted in the urine, accounting for more than 70% of the NO dose inhaled (Ichinose et al., 2004).

Clinical Use. NO can acutely lower PAP and PVR without altering systemic arterial pressure. Inhaled NO is used for the treatment of term and near-term neonates with persistent pulmonary hypertension of the newborn and acute hypoxemic respiratory failure (Abman, 2013). Acute vasodilator testing is another well-established but off-label use of inhaled NO in adult patients with PAH. Vasodilator testing is performed in the course of deciding whether a patient might derive clinical benefit from

Figure 31-3 Stimulators of NO/cGMP signaling. NO stimulates sGC to produce cGMP, which has vasodilating effects through decreased $[Ca^{2+}]_{\text{cyt}}$ as well as anticoagulant and antiproliferative effects that are both dependent and independent of $[Ca^{2+}]_{\text{cyt}}$. cGMP is degraded primarily by PDE5 in PSMCs, which is targeted by the PDE5 inhibitors sildenafil and tadalafil.

Ca^{2+} channel blockade therapy (e.g., *nifedipine*) (Abman, 2013). In the treatment of PH, a 30% decrease in PVR during the inhalation of NO (10 ppm for 10 min) has been used to identify an association with vascular responsiveness and a favorable response to CCBs in a small cohort of patients with primary PH (McLaughlin et al., 2009).

Adverse Effects and Precautions. High doses of inhaled NO (500–1000 ppm) are lethal. However, NO doses of less than 40 ppm are well tolerated chronically for up to 6 months and do not cause methemoglobinemia in adults who have normal methemoglobin reductase activity (Griffiths and Evans, 2005). In neonates, methemoglobin accumulation has been investigated during the first 12 h of exposure to 0, 5, 20, and 80 ppm of inhaled NO (Abman, 2013). Methemoglobin concentrations increased during the first 8 h of NO exposure. The mean methemoglobin level remained below 1% in the placebo group and in the 5- and 20-ppm groups, but reached approximately 5% in the 80-ppm inhaled NO group.

Drug interactions between properly dosed NO and other medications are not expected, but side effects may include noisy breathing, hematuria, or possibly atelectasis. Overdosage with inhaled NO manifests as elevations in methemoglobin and pulmonary toxicities associated with inspired NO_2 , including acute respiratory distress syndrome. Elevations in methemoglobin reduce the O_2 delivery capacity of the circulation. Based on clinical studies, NO_2 levels greater than 3 ppm or methemoglobin levels greater than 7% are treated by reducing the dose of, or discontinuing, inhaled NO therapy (Abman, 2013). Methemoglobinemia that does not resolve after reduction or discontinuation of inhaled NO therapy can be treated with intravenous vitamin C, intravenous methylene blue, or blood transfusion, based on the clinical situation.

Inhaled NO gas has limitations: Dosing must be individualized and frequently adjusted; delivery is cumbersome and expensive; off-target effects from reactive nitrogen species are possible; and rebound PH may appear when the NO administration is interrupted. The oxidative product of NO metabolism, the inorganic anion nitrite NO_2^- is relatively stable compared to NO ($t_{1/2} = 51$ min); NO_2^- can be reduced back to NO under physiological and pathological hypoxia by enzymatic and nonenzymatic processes and thus can serve as an intravascular endocrine reservoir of potential NO bioactivity (Bueno et al., 2013). Other NO donor drugs such as sodium nitroprusside and nitroglycerin offer protective benefits in PVR or remodeling, but when administered intravenously, however, these drugs have limited use given their significant systemic vasodilating effects.

Riociguat

In patients with NO deficiency due to dysfunctional endothelial nitric oxide synthase or arginine insufficiency, activation of sGC increases signaling through the cGMP-PKG pathway and exerts a therapeutic effect (Stasch and Evgenov, 2013). Riociguat, a direct activator of sGC, has recently been approved.

Mechanism of Action. Riociguat is the first-in-class stimulator of sGC. The agent exhibits a dual mode of action; it sensitizes sGC to endogenous NO, and it also directly stimulates sGC independently of NO.

ADME. The drug has excellent oral absorption, and the plasma concentration peaks approximately 1.5 h after oral intake (Stasch and Evgenov, 2013). Food does not affect the bioavailability of riociguat; its volume of distribution is about 30 L. Riociguat is metabolized by CYPs 1A1, 3A, 2C8, and 2J2. The action of CYP1A1 forms the major and active metabolite, M1, which is converted to an inactive *N*-glucuronide. The terminal elimination half-life is about 12 h in patients with PAH (7 h in healthy subjects) (Stasch and Evgenov, 2013).

Clinical Use. Riociguat at doses up to 2.5 mg given three times daily for 12 weeks increased walking distance and significantly delayed time to clinical worsening for patients with PAH (Ghofrani, 2013). Riociguat was also effective in patients with CTEPH, for whom improvements in walking distance were apparent from week 2 onward (Ghofrani, et al., 2013).

Adverse Reactions and Precautions. Concurrent use of riociguat with nitroglycerin or PDE5 inhibitors can cause severe hypotension and syncope (Stasch and Evgenov, 2013). Serious adverse effects include embryo-fetal toxicity, hypotension, and bleeding. Other common adverse reactions include headache, dyspepsia, dizziness, nausea, diarrhea, vomiting, anemia, reflux, constipation, palpitations, nasal congestion, epistaxis, dysphagia, abdominal distension, and peripheral edema (Ghofrani, et al., 2013; Ghofrani, et al., 2013; Stasch and Evgenov, 2013).

PDE5 Inhibitors

Cyclic nucleotide PDEs comprise a superfamily of enzymes that hydrolyze 3'-5' cyclic nucleotides to their cognate 5' monophosphates (Omori and Kotera, 2007). PDE5, an isoform that is relatively specific for cGMP, is abundant in PSMCs (Kass et al., 2007). The physiological importance of PDE5 in the regulation of smooth muscle tone has been most effectively demonstrated by the successful clinical use of its specific inhibitors in the treatment of erectile dysfunction and PAH (Galiè et al., 2005; Ravipati et al., 2007).

Sildenafil. Mechanism of Action. Sildenafil, which structurally mimics the purine ring of cGMP, is a competitive and selective inhibitor of PDE5. Sildenafil has a relatively high selectivity (>1000-fold) for human PDE5 over other PDEs. By inhibiting cGMP hydrolysis, sildenafil elevates cellular levels of cGMP and augments signaling through the cGMP-PKG pathway, provided guanylyl cyclase is active.

ADME. The drug is rapidly absorbed and reaches a peak plasma concentration 1 h after oral administration. Sildenafil is cleared by the hepatic CYP3A (major route) and CYP2C9 (minor). Sildenafil and its major active metabolite, *N*-desmethyl sildenafil, have terminal half-lives of about 4 h. Both the parent compound and the major metabolite are highly bound to plasma proteins (96%) (Cockrill and Waxman, 2013). Metabolites are predominantly excreted into the feces (73%–88%) and to a lesser extent into the urine; unmetabolized drug is not detected in urine or feces (Muirhead et al., 2002). Clearance is reduced in the elderly (>65 years), leading to an increase in area-under-the-curve values for the parent drug and the *N*-desmethyl metabolite.

Clinical Use and Adverse Effects and Precautions. Sildenafil, 5 to 20 mg three times per day improves exercise capacity, functional class, and hemodynamics. In addition to improved exercise capacity and hemodynamic parameters, sildenafil (initiated at 20 mg three times daily, titrated to 40–80 mg three times daily) plus long-term epoprostenol therapy also resulted in delayed time to clinical worsening of PAH in clinical studies.

Dose adjustments for reduced renal and hepatic function are usually not necessary except for severe hepatic and renal impairment (Cockrill and Waxman, 2013). Concomitant administration of potent CYP3A inducers (e.g., bosentan) will generally cause substantial decreases in plasma levels of sildenafil. The mean reduction in the bioavailability of sildenafil (80 mg three times a day) when coadministered with epoprostenol was 28% (Cockrill and Waxman, 2013). CYP3A inhibitors (e.g., protease inhibitors used in HIV therapy, erythromycin, and cimetidine) inhibit sildenafil metabolism, thereby prolonging the $t_{1/2}$ and elevating blood levels of sildenafil. Consistent with its mechanism of action, potentiation of cGMP signaling, sildenafil and other PDE5 inhibitors potentiate the hypotensive effects of nitrate vasodilators, producing dangerously low blood pressure. Thus, the administration of PDE5 inhibitors to patients receiving organic nitrates is contraindicated. In any event, the patient's underlying cardiovascular status and concurrent use of hypotensive agents (e.g., nitrate vasodilators, α adrenergic antagonists) must be considered prior to use of this class of drugs.

Headache (16%) and flushing (10%) are the most frequently reported side effects. Patients taking sildenafil or vardenafil may notice a transient blue-green tinting of vision due to inhibition of retinal PDE6, which is involved in phototransduction (see Figure 69-9).

Other PDE5 Inhibitors. Vardenafil is structurally similar to sildenafil and a potent inhibitor of PDE5. Although not FDA-approved for PAH in the U.S., its clinical efficacy in PAH appears similar to that of sildenafil (Cockrill and Waxman, 2013). Tadalafil, another PDE5 inhibitor used for the treatment of PAH, differs structurally from sildenafil and has a longer half-life (Cockrill and Waxman, 2013). See Table 45-2 for comparative pharmacokinetic data of PDE5 inhibitors.

Prostacyclin Receptor Agonists

Prostacyclin is mainly synthesized in and released from vascular ECs and exerts relaxant and antiproliferative effects on vascular smooth muscle cells. Similar to NO, endogenous PGI₂ is considered an endothelium-derived relaxing factor. Decreased PGI₂ synthesis occurs in patients

with idiopathic PAH, a finding that provided the rationale for using PGI₂ and its analogues for treatment of PAH (Christman et al., 1992).

Mechanism of Action. Prostacyclin binds to the IPR in the plasma membrane of PASMCs and activates the G_s-AC-cAMP-PKA pathway (Figure 31-4). PKA continues the signaling cascade by (1) decreasing $[Ca^{2+}]_{cyt}$ via activating K⁺ channels (which causes membrane hyperpolarization and repolarization, leading to closure of VDCCs) and (2) inhibiting myosin light chain kinase, thereby causing smooth muscle relaxation and vasodilation (Olschewski et al., 2004). Activated PKA can also exert an antiproliferative effect on PASMCs by inhibiting the signaling cascades of hedgehog, ERK/p21, and Akt/mTOR. Inhibition of cyclic nucleotide PDEs, mainly PDE3 and PDE4, enhances the cAMP-PKA-mediated relaxant and antiproliferative effects on vascular smooth muscle cells.

Epoprostenol (Prostacyclin)

Clinical Use, Adverse Effects and Precautions. The first synthetic PGI₂, epoprostenol, has dose-dependent inhibitory effects on both SVR and PVR, paired with increases in cardiac output, for patients with PAH (Rubin et al., 1982). Epoprostenol's short half-life (3–5 min) requires the use of a drug delivery pump system for continuous intravenous infusion to achieve long-term efficacy in the treatment of PAH. In a clinical trial, epoprostenol treatment caused significant improvements in pulmonary hemodynamics, patient symptoms, and survival over a 12-week period (Barst et al., 1996).

Epoprostenol is light and temperature sensitive, although a more recent thermostable formulation is now available that permits its use at room temperature (20°C–25°C). This agent remains a mainstay of PAH treatment, particularly in advanced stages of the disease. Adverse effects of epoprostenol are similar for the entire class of PGI₂ analogues and include myalgias and pain in the extremities, jaw pain, nausea, headaches, abdominal discomfort, diarrhea, flushing, dizziness, and systemic hypotension. Side effects are generally dose dependent, and slow titration is required for the drug to be sufficiently tolerated.

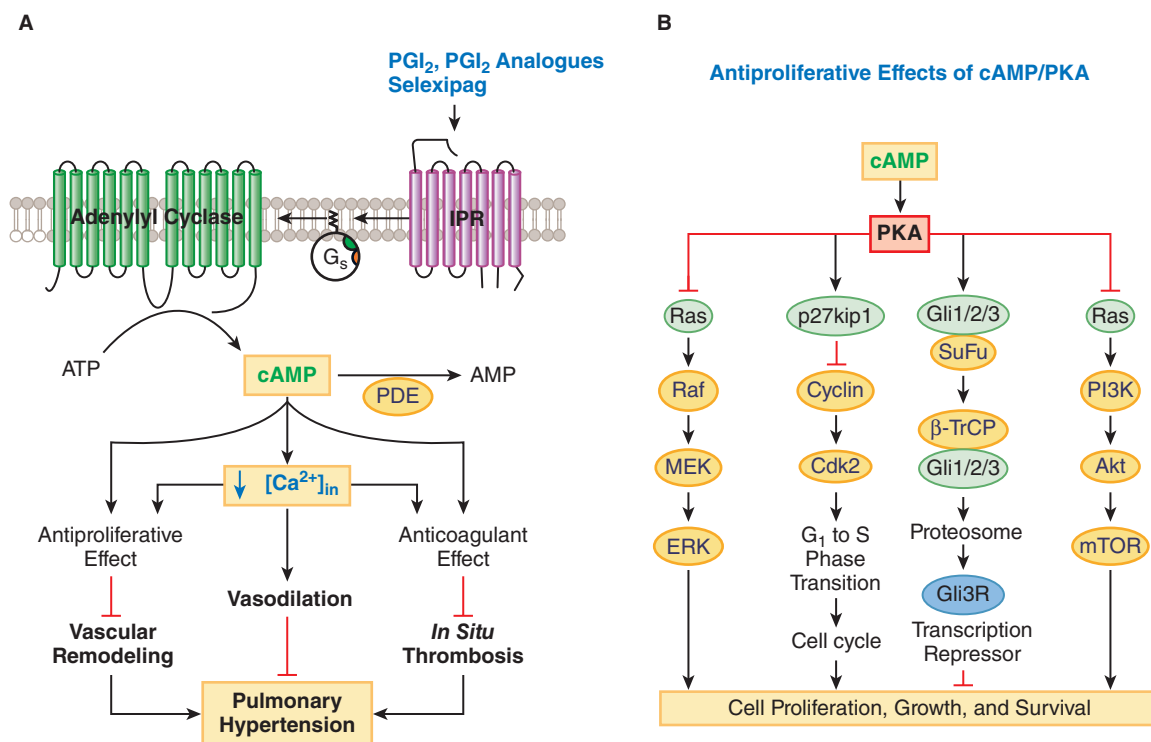

Figure 31-4 Membrane receptor agonists that increase cAMP. Therapies targeting the IPR, including PGI₂, PGI₂ analogues, and selexipag, increase cAMP through stimulation of its production by AC. The vasodilating properties of cAMP are produced through decreased $[Ca^{2+}]_{cyt}$ as well as anticoagulant and antiproliferative effects that are both dependent and independent of $[Ca^{2+}]_{cyt}$. The antiproliferative effects of cAMP (panel B) are shown through numerous distinct pathways, many of which are currently under investigation as novel therapies.

Treprostinil

Clinical Use. Treprostinil, a PGI₂ analogue with longer half-life than that of epoprostenol, is available for continuous intravenous infusion, subcutaneous infusion, inhalation, and oral delivery. The risk of bacteremia or other catheter-related complications can be reduced by subcutaneous delivery. Subcutaneous treprostinil has similar efficacy to intravenous formulations of epoprostenol and treprostinil (Simonneau et al., 2002). Adverse effects related to delivery into the subcutaneous tissue of the lower abdomen are common, including pain and erythema in a majority of patients; these effects subside over time.

Compared to intravenous treprostinil, the inhaled formulation has more potent pulmonary vasodilating effects, but patients find the dosing scheme complex: Multiple breaths are taken through a nebulizer or inhaler four times a day and slowly titrated up to a maximum of nine breaths four times a day. Inhaled treprostinil has comparable hemodynamic effects to inhaled iloprost with a longer duration of effect in patients with PAH. The most common adverse effect related to inhalation is transient coughing.

Monotherapy with extended-release oral formulations of treprostinil are effective in patients with PAH with moderate functional impairments (Jing et al., 2013). The dose is given twice a day, starting at 0.25 mg and titrating up every 3 days to a maximum of 21 mg twice a day. Serum concentrations at a steady dose of 3.5 mg twice daily are thought to approximate therapeutic levels of intravenous treprostinil. Oral treprostinil fails to show any significant improvement in 6-min walk distance for patients on baseline treatment with either an ERA or PDE5 inhibitor and is therefore not recommended in patients already treated (Tapson et al., 2012).

Iloprost

Clinical Use, Adverse Effects and Precautions. The first PGI₂ analogue available in an inhaled formulation, iloprost was designed to target the pulmonary vasculature with minimal systemic side effects. Inhalation has potent vasodilative effects on the pulmonary circulation, with less systemic vasodilation than intravenous PGI₂ (Olschewski et al., 1996). The effects of a single inhalation decline to baseline over 60–120 min, and current dosing strategies suggest 6–9 inhalations daily. The dose is generally titrated from 2.5 mg/inhalation to 5 mg after the first 2–4 weeks. Minor side effects common to the PGI₂ class include headache and jaw pain. Side effects specific to the inhaled formulation are cough, although this appears to resolve over time.

Beraprost

The first orally available PGI₂ analogue, beraprost, showed promise in early trials, but long-term trials showed no benefit over 12 months of therapy (Barst et al., 2003). As a result, beraprost is not approved for use in the U.S. or E.U.

Selexipag

Selexipag is an orally active, selective IPR agonist that is chemically distinct and has different kinetic properties compared to other PGI₂ analogues.

ADME. Selexipag is rapidly absorbed and hydrolyzed in the liver ($t_{1/2} = 1\text{--}2$ h) to an active metabolite, ACT-333679 (Kaufmann et al., 2015). The active metabolite has a longer half-life, 10–14 h, allowing twice-daily dosing.

Clinical Use, Adverse Effects, and Precautions. The drug is taken at a starting dose of 200 µg and titrated upward weekly to a maximum dose of 1600 µg twice daily. In phase 3 clinical trials, selexipag reduced the risk of morbidity and mortality in patients with PAH (Simonneau et al., 2012; Sitbon et al., 2015). Selexipag was added to existing pulmonary vasodilator therapy in a majority of patients in the clinical trials for this agent. Adverse effects of selexipag are similar to those of PGI₂ analogues and include headache, jaw pain, nausea, dizziness, flushing, nasopharyngitis, and vomiting. Adverse effects appear to be more common when the drug is taken while fasting and wane over time.

Endothelin and Endothelin Receptor Antagonists

Endothelin 1

Amino Acid Sequence of Human Endothelin 1

Biosynthesis. Endothelins are a trio of 21 amino acid peptides, each the product of a different gene, produced through a pre-pro and pro-peptide sequence by ECE activities (ECE-1, ECE-2). ECE-1 is the rate-limiting step in ET-1 synthesis. Each mature ET peptide contains two disulfide bridges. ET-1, the predominant form, is encoded by the *EDN1* gene and produced in vascular ECs, although other cell types can also produce endothelin. A variety of cytokines, angiotensin II, and mechanical stress enhance ET-1 production. NO and PGI₂ reduce *EDN1* gene expression. ETs interact with two GPCRs, the ET_A and ET_B receptors, as described in the material that follows. ET-1 is cleared by interaction with the ET_B receptor and via proteolytic degradation by neutral endopeptidase NEP24.11. Davenport and colleagues (2016) have reviewed key concepts of the biosynthesis, signaling, and pharmacology of ETs.

Endothelin Signaling. Endothelin 1 was discovered as a potent, endothelium-derived, constricting factor (Yanagisawa et al., 1988). The constrictor response is mediated by the ET_A receptor, which is localized on PSMCs. The ET_B receptor is present on both PSMCs and PAEC. Binding of ET-1 to ET_A receptor on PSMCs activates the G_q-PLC-IP₃-Ca²⁺ and DAG-Ca²⁺-PKC pathways (Figure 31–5 and Chapter 3). IP₃ activates the Ca²⁺ release channel on intracellular Ca²⁺ storage organelles, thereby

Figure 31–5 Agents that inhibit receptor-mediated activation of phospholipase C. The potent vasoconstricting agent ET-1 exerts effect on PSMCs primarily through the endothelin receptor ET_A, a GPCR. Stimulation of the receptor leads to activation of PLC and production of IP₃ and DAG, both of which lead to increased [Ca²⁺]_{cyt}. Similarly, distinct receptor tyrosine kinases, such as PDGF, VEGF, and EGF, can lead to increased IP₃ and DAG and subsequent increases in [Ca²⁺]_{cyt} through a similar, yet distinct, pathway.

mobilizing Ca^{2+} and increasing $[\text{Ca}^{2+}]_{\text{cyt}}$. DAG can reportedly activate ROCs on the plasma membrane, enhance Ca^{2+} influx, and contribute to the increased $[\text{Ca}^{2+}]_{\text{cyt}}$. The elevated cytosolic Ca^{2+} produces vasoconstriction (Figure 3–14). ET-1 is also a mitogenic factor that exerts proliferative effects on many types of cells, including vascular smooth muscle cells and myofibroblasts via intracellular signaling cascades (e.g., PI3K/Akt/mTOR and Ras/ERK/p21 pathways) (Davenport et al., 2016). The activation of ET_B receptors on ECs mediates vasodilation by increasing production of NO and PGI_2 and can inhibit ET-1 production.

Rationale for Antagonizing ET's Effects in PAH. Endothelin 1 is implicated as a contributory factor in idiopathic PAH (Giaid et al., 1993): Plasma ET-1 levels are increased up to 10-fold in patients with PAH and correlate well with severity of disease and the elevation of right atrial pressure. There are no clinically available specific inhibitors of ECE-1, the rate-limiting step in ET-1 synthesis, but a number of orally effective small molecule antagonists of ET receptors have been developed. Despite the opposing effects of ET_A and ET_B receptor activation, pharmacological targeting of specific ET_A receptors has not led to significantly altered clinical responses compared to dual antagonism (e.g., antagonism of ET-1 binding to both ET_A and ET_B receptors) in treating PAH.

Endothelin Receptor Antagonists

Available ET receptor antagonists (ERAs) are bosentan, macitentan, and ambrisentan.

Commonalities. Endothelin antagonists generally share adverse effects. Common side effects of the class include headache, pulmonary edema, and nasal congestion/pharyngitis, with a risk of testicular atrophy and infertility. Bosentan and ambrisentan may increase liver transaminases, which should be monitored closely, and the drugs are contraindicated in patients with moderate-to-severe liver disease; the elevation of liver enzymes generally resolves after discontinuation of treatment.

The three available ET antagonists are metabolized by CYP3A4 and to some extent by CYPs 2C9 and 2C19. Repeated bosentan dosing elicits induction of CYPs 3A4 and 2C9, reducing exposure to drugs that are also metabolized by these CYPs (contraceptives, warfarin, some statins; coadministration with cyclosporine and glyburide is contraindicated); likewise, coadministration of bosentan or macitentan with a CYP inducer such as rifampin should be avoided. Inhibitors of these CYPs (e.g., ketoconazole and ritonavir) can increase bosentan and macitentan exposure (O'Callaghan et al., 2011).

The ERAs are potent teratogens and should be used with caution in women of childbearing age. These agents must not be used in pregnant patients. Documentation of a negative pregnancy test prior to initiation of therapy and a clear contraceptive plan are recommended, and fertile women must use two acceptable methods of birth control while taking ET antagonists.

Bosentan. Bosentan is a nonpeptide, orally effective, competitive antagonist of ET_A and ET_B receptors. In patients with PAH with mild-to-severe functional impairment (functional classes II–IV), bosentan improves symptoms, functional capacity, and pulmonary hemodynamic parameters (Rubin et al., 2002). Bosentan is usually started at 62.5 mg twice daily, increasing to 125 mg twice daily after 4 weeks. Bosentan is metabolized by hepatic CYPs 2C9 and 3A4 with a $t_{1/2}$ of about 5 h, with excretion of metabolites in the bile.

Macitentan. Macitentan is an orally active, competitive ET_A and ET_B receptor antagonist. At a dose of 10 mg daily, macitentan improves the time to disease progression or death in PAH and improves symptoms, functional capacity, and pulmonary hemodynamic measurements (Pulido et al., 2013). The drug is relatively well tolerated and has thus far not been associated with elevation of liver-associated enzymes, but caution is recommended. Macitentan is metabolized by CYPs to an active metabolite; the $t_{1/2}$ of the parent compound is about 16 h, that of the active metabolite about 48 h, such that the metabolite contributes about 40% of the total pharmacologic activity over time.

Ambrisentan. Unlike bosentan and macitentan, ambrisentan is a relatively selective ET_A antagonist (approximately 4000 times greater affinity

for ET_A than ET_B). Ambrisentan is initiated at a dose of 5 mg daily and increased to a maximum of 10 mg daily. The $t_{1/2}$ is 9 h at steady state. Liver-associated enzyme abnormalities are much less common than with bosentan, yet monitoring of liver function tests is still recommended. Elimination is largely via nonrenal pathways that have not been extensively characterized. There is some metabolism by CYPs 3A4 and 2C19, followed by glucuronidation; thus, drug interactions might be expected, although clinically relevant interactions have not been reported.

Receptor Tyrosine Kinase Inhibitors

Many growth factors and mitogenic factors are reportedly upregulated in tissues of patients with PAH. Elevations of ET-1, ATP, VIP, PDGF, VEGFs, EGF, fibroblast growth factor, and insulin-like growth factor in lung tissue, vascular smooth muscle cells, and peripheral blood have been assessed in PAH (Budhiraja et al., 2004; Du et al., 2003; Schermuly et al., 2005). These myriad mitogenic factors can activate TKRs, such as PDGF and EGF receptors. Activation of these receptors induces cell proliferation, growth, migration, and contraction in PSMCs, PAECs, and pulmonary vascular fibroblasts. With these actions as a rationale, antagonists of TKRs have been tried as therapeutics for PAH (Moreno-Vinasco et al., 2008; Gombert-Maitland et al., 2010).

Imatinib

Imatinib was initially developed as targeted treatment of chronic myelogenous leukemia by targeting the ABL TKR; the compound is now known to have many other targets, one of which is the PDGF receptor that has been linked to vascular smooth muscle hypertrophy in the development of PAH (Humbert et al., 1998). Imatinib as add-on therapy for refractory PAH has shown efficacy in both case reports and a clinical trial, although serious adverse reactions, particularly subdural hematoma, are of concern (Hoepfer et al., 2013). Larger clinical trials are needed before imatinib can be used in PAH treatment regimens.

Calcium Channels and Their Blockers

An increase in $[\text{Ca}^{2+}]_{\text{cyt}}$ in PSMCs causes pulmonary vasoconstriction and is an important stimulant of proliferation, migration, and vascular remodeling. $[\text{Ca}^{2+}]_{\text{cyt}}$ in PSMCs can be increased by Ca^{2+} influx through membrane Ca^{2+} channels and Ca^{2+} mobilization through the Ca^{2+} release channels/ IP_3 receptors in the SR membrane. $[\text{Ca}^{2+}]_{\text{cyt}}$ can be decreased in three ways: by Ca^{2+} extrusion via the $\text{Ca}^{2+}/\text{Mg}^{2+}$ ATPase (the Ca^{2+} pump

Figure 31–6 Treatment algorithm for use of CCBs in PAH. Vasoreactivity testing is used to identify the minority of patients who may have a substantial benefit from high-dose CCB therapy. These individuals must be monitored closely to ensure a sustained response. Patients without a positive vasodilator response should potentially be started on therapies approved for PAH based on symptoms at presentation. The patients with the most severe disease who fail to respond to therapy may need referral for surgical intervention to treat their disease.

Figure 31-7 Interactions between endothelium and vascular smooth muscle in PAH. **A. Balance.** In normal pulmonary artery, there is a balance between constrictor and relaxant influences that may be viewed as competition between Ca²⁺ signaling pathways and cyclic nucleotide signaling pathways in VSM. ET-1 binds to the ET_A receptor on VSM cells and activates the G_q-PLC-IP₃ pathway to increase cytosolic Ca²⁺; ET-1 may also couple to G_i to inhibit cAMP production. As VSM cells depolarize, Ca²⁺ may enter via the L-type Ca²⁺ channel (Ca_v1.2) or transient receptor potential cation channel (TRPC6). ECs also produce relaxant factors, PGI₂, and NO. NO stimulates the sGC, causing accumulation of cGMP in VSM cells; PGI₂ binds to the IP₂ and stimulates cAMP production; elevation of these cyclic nucleotides promotes VSM relaxation (see Figures 31-3, 40-4 and 45-6). **B. Imbalance.** In PAH, ET-1 production is enhanced, production of PGI₂ and NO is reduced, and the balance is shifted toward constriction and proliferation of VSM. **C. Restored balance.** In treating PAH, ET_A receptor antagonists can reduce the constrictor effects of ET-1, and Ca²⁺ channel antagonists can further reduce Ca²⁺-dependent contraction. Exogenous PGI₂ and NO can be supplied to promote vasodilation (relaxation of VSM); the sGC can be activated pharmacologically (riociguat); inhibition of PDE5 can enhance the relaxant effect of elevated cGMP by inhibiting the degradation of cGMP. Thus, these drugs can reduce Ca²⁺ signaling and enhance cyclic nucleotide signaling, restoring the balance between the forces of contraction/proliferation and relaxation/antiproliferation. Remodeling and deposition of extracellular matrix by adjacent fibroblasts is influenced positively and negatively by the same contractile and relaxant signaling pathways, respectively. Effects of pharmacological agonists are noted by green arrows, effects of antagonists by red T-bars.

in the plasma membrane), export of Ca^{2+} by the $\text{Na}^+/\text{Ca}^{2+}$ exchanger, and by sequestration of cytosolic Ca^{2+} into the SR by SR Ca^{2+} -ATPase. There are three classes of Ca^{2+} -permeable channels functionally expressed in the plasma membrane of PAMCs: (1) VDCCs, (2) ROCs, and (3) store-operated Ca^{2+} channels. These are targets in the current therapy of PAH and putative targets for therapeutics of the future.

Voltage-Gated Ca^{2+} Channel Blockers

A rare subset of patients (typically less than 5%–15% of all group I PAH confirmed by right heart catheterization) is considered vasoreactive, which is defined as a significant decrease in mean PAP (>10 mm Hg drop to absolute mean PAP < 40 mm Hg) while preserving cardiac output during the administration of inhaled NO or intravenous injection of PGI_2 or adenosine (Rich and Brundage, 1987). Vasoreactive patients can achieve prolonged survival, sustained functional improvement, and hemodynamic improvement with CCB therapy (Hemnes et al., 2015; Rich and Brundage, 1987). The utility of CCB therapy in patients with vasoreactive PAH was supported by a series of well-designed observational studies (Hemnes et al., 2015; Rich and Brundage, 1987; Sitbon et al., 2005).

Clinical Use. Therapy with CCB can be initiated with a low dose of long-acting nifedipine, amlodipine, diltiazem, or verapamil. The dose is then increased to the maximal tolerated dose. Systemic blood pressure, heart rate, and oxygen saturation should be carefully monitored during titration. Sustained-release preparations of nifedipine, verapamil, and diltiazem are available that minimize the adverse effects of therapy, especially systemic hypotension. Patients who respond (defined as asymptomatic or minimal symptoms) to CCB therapy with a dihydropyridine or diltiazem are typically reassessed for sustaining the response (Figure 31–6).

Adverse Effects and Precautions. Adverse effects are common with CCB therapy. Systemic vasodilation may cause hypotension, while pulmonary vasodilation may reduce HPV. Loss or inhibition of HPV can worsen V/Q mismatch and cause hypoxemia. CCBs may also be associated with deterioration of RV function because of their inhibitory effect on VDCC in cardiomyocytes. The pharmacology of CCBs is discussed in detail in Chapter 27.

PAH Drugs in Development

In addition to the PAH drugs in clinical use, there are many repurposed drugs and newly developed drugs that have therapeutic benefits in experimental models of PH. These agents have potential as future therapies for PAH:

- antagonists of 5HT_{2B} receptors and transporters (e.g., LY393558);
- allosteric antagonists of Ca^{2+} -sensing receptors (e.g., NPS2143 and calhex 231);
- openers or activators of Ca^{2+} -activated and voltage-gated K^+ channels and ATP-sensitive K^+ channels (e.g., cromakalim);
- inhibitors of the PI3K/Akt1/mTOR signaling cascades (e.g., perifosine, ipatasertib, and rapamycin derivatives sirolimus, temsirolimus, everolimus, deforolimus);
- inhibitors of the Notch signaling pathway (e.g., DAPT and MK-0752);
- VIP;
- blockers of transient receptor potential cation channels (e.g., 2-APB, ML204, aniline-thiazoles);
- extracellular elastase inhibitors (e.g., elafin and sivelestat);
- Rho kinase inhibitors (e.g., fasudil); and
- angiopoietin 1 inhibitors (e.g., trebananib).

Some of these drugs are already in phase 3 clinical trials; others are still in preclinical development.

A Pharmacologist’s View of Signal Integration in PAH

As noted, an imbalance of vasoactive mediators, mitogenic and angiogenic factors, and pro- and antiapoptotic proteins plays an important role in PAH development. The pharmacological agents employed in PAH are focused on restoring the balance between contraction and proliferation on the one hand and relaxation and antiproliferation on the other, as summarized in Figure 31–7.

Drug Facts for Your Personal Formulary: Pulmonary Hypertension Therapeutics

Drug	Indication	Clinical Pharmacology and Tips
cGMP Signaling Modulators: PDE5 Inhibitors		
Sildenafil Tadalafil Vardenafil	• First-line therapy for moderate PAH (functional class II–III)	• Oral administration • Avoid nitrates and α adrenergic antagonists due to hypotension • Major side effects: epistaxis, headache, dyspepsia, vision or hearing loss (not sildenafil), flushing, insomnia, dyspnea, priapism • Vardenafil, currently not recommended due to limited evidence for efficacy in PAH
cGMP Signaling Modulators: sGC Stimulator		
Riociguat	• First-line therapy for moderate PAH (functional class II–III)	• Oral administration • Efficacy confirmed in PAH patients and CTEPH patients • Side effects: headache, dyspepsia, edema, nausea, dizziness, syncope
IP Receptor Agonists: Prostacyclin and Prostacyclin Analogs		
Epoprostenol	• First-line therapy for severe PAH (functional class IV)	• Administration by continuous IV infusion • Major side effects: jaw pain, hypotension, myalgia, flushing, nausea, vomiting, dizziness • Short half-life requires immediate medical attention to pump failure
Treprostinil	• Same as epoprostenol	• Available as IV, SC, inhaled and oral preps • Longer half-life than epoprostenol with similar side effects • Local adverse effects of SC dose may improve over time • Oral administration to be used as monotherapy only

IP Receptor Agonists: Prostacyclin and Prostacyclin Analogs (continued)		
Iloprost	<ul style="list-style-type: none"> Alternative for epoprostenol in combination therapy for severe PAH (functional class IV) 	<ul style="list-style-type: none"> Inhaled administration, at least 2 h apart Side effects include flushing, hypotension, headache, nausea, throat irritation, cough, insomnia
Selexipag	<ul style="list-style-type: none"> Alternative for eprostenol in combination therapy for severe PAH (functional class IV) 	<ul style="list-style-type: none"> Oral administration Selective PGI₂ receptor agonist Side effects include headache, jaw pain, nausea, diarrhea
Endothelin Receptor Antagonists: Oral administration, teratogenic		
Bosentan	<ul style="list-style-type: none"> First-line therapy for moderate PAH (functional class II-III) 	<ul style="list-style-type: none"> Monitor liver function and hemoglobin levels Metabolized by CYP2C9 and CYP3A4 Side effects: liver impairment, palpitations, itching, edema, anemia, respiratory infections
Ambrisentan	<ul style="list-style-type: none"> First-line therapy for moderate PAH (functional class II-III) 	<ul style="list-style-type: none"> Side effects: edema, nasal congestion, constipation, flushing, palpitations, abdominal pain Cyclosporin coadministration increases drug levels Low risk for liver toxicity
Macitentan	<ul style="list-style-type: none"> First-line therapy for moderate PAH (functional class II-III) 	<ul style="list-style-type: none"> Metabolized by CYP3A4 Side effects include nasopharyngitis, headache, anemia Liver function and hemoglobin testing recommended prior to therapy
L-type Ca ²⁺ Channel Blockers		
Nifedipine (long acting) Amlodipine Diltiazem	<ul style="list-style-type: none"> Use only in PAH patients with positive vasodilator testing 	<ul style="list-style-type: none"> Oral administration Side effects include edema, fatigue, hypotension Diltiazem: significant negative chronotropic and inotropic effects; avoid in bradycardia

Chapter 32

Blood Coagulation and Anticoagulant, Fibrinolytic, and Antiplatelet Drugs

Kerstin Hogg and Jeffrey I. Weitz

OVERVIEW OF HEMOSTASIS: PLATELET FUNCTION, BLOOD COAGULATION, AND FIBRINOLYSIS

- Conversion of Fibrinogen to Fibrin

STRUCTURE OF COAGULATION FACTORS

NONENZYMATIC PROTEIN COFACTORS

- Factor VIII and Factor V Are Procofactors

ACTIVATION OF PROTHROMBIN

- Initiation of Coagulation
- Fibrinolysis
- Coagulation In Vitro
- Natural Anticoagulant Mechanisms
- Parenteral Anticoagulants: Heparin, LMWHs, Fondaparinux
- Other Parenteral Anticoagulants

VITAMIN K ANTAGONIST

- Warfarin

DIRECT ORAL ANTICOAGULANTS

- Direct Oral Thrombin Inhibitor

- Direct Oral Factor Xa Inhibitors
- Reversal Agents for Direct Oral Anticoagulants

FIBRINOLYTIC DRUGS

- Tissue Plasminogen Activator

INHIBITORS OF FIBRINOLYSIS

- ϵ -Aminocaproic Acid and Tranexamic Acid

ANTIPLATELET DRUGS

- Aspirin
- Dipyridamole
- P2Y₁₂ Receptor Antagonists
- Thrombin Receptor Inhibitor
- Glycoprotein IIb/IIIa Inhibitors

THE ROLE OF VITAMIN K

- Physiological Functions and Pharmacological Actions
- Inadequate Intake
- Inadequate Absorption
- Inadequate Utilization

Blood must remain fluid within the vasculature and yet clot quickly when exposed to subendothelial surfaces at sites of vascular injury. Under normal circumstances, a delicate balance between coagulation and fibrinolysis prevents both thrombosis and hemorrhage. Alteration of this balance in favor of coagulation results in thrombosis. Thrombi, composed of platelet aggregates, fibrin, and trapped red blood cells, can form in arteries or veins. Antithrombotic drugs used to treat thrombosis include antiplatelet drugs, which inhibit platelet activation or aggregation; anticoagulants, which attenuate fibrin formation; and fibrinolytic agents, which degrade fibrin. All antithrombotic drugs increase the risk of bleeding.

This chapter reviews the agents commonly used for controlling blood fluidity, including

- the parenteral anticoagulant heparin and its derivatives, which activate antithrombin, a natural inhibitor of coagulant proteases;
- the coumarin anticoagulants, which block multiple steps in the coagulation cascade;
- the direct oral anticoagulants, which inhibit factor Xa or thrombin;
- fibrinolytic agents, which degrade fibrin;
- antiplatelet agents, which attenuate platelet activation (aspirin, clopidogrel, prasugrel, ticagrelor, and vorapaxar) or aggregation (glycoprotein IIb/IIIa inhibitors); and
- vitamin K, which is required for the biosynthesis of key coagulation factors.

release substances that activate nearby platelets, thereby recruiting them to the site of injury. Activated platelets then aggregate to form the primary hemostatic plug.

Vessel wall injury also exposes tissue factor (TF), which initiates the coagulation system. Activated platelets enhance activation of the coagulation system by providing a surface onto which clotting factors assemble and by releasing stored clotting factors. This results in a burst of *thrombin* (*factor IIa*) generation. Thrombin converts soluble fibrinogen to fibrin, activates platelets, and feeds back to promote additional thrombin generation. The fibrin strands tie the platelet aggregates together to form a stable clot.

The processes of platelet activation and aggregation and blood coagulation are summarized in Figures 32–1 and 32–2 (see also the animation on the Goodman & Gilman site on *AccessMedicine.com*). Coagulation involves a series of zymogen activation reactions, as shown in Figure 32–2. At each stage, a precursor protein, or *zymogen*, is converted to an active protease by cleavage of one or more peptide bonds in the precursor molecule. The final protease generated is thrombin. Later, as wound healing occurs, the fibrin clot is degraded. The pathway of clot removal, fibrinolysis, is shown in Figure 32–3, along with sites of action of fibrinolytic agents.

Conversion of Fibrinogen to Fibrin

Fibrinogen, a 340,000-Da protein, is a dimer, each half of which consists of three pairs of polypeptide chains (designated α , β , and γ). Disulfide bonds covalently link the chains and the two halves of the molecule. Thrombin converts fibrinogen to fibrin monomers by releasing fibrinopeptide A (a 16-amino acid fragment) and fibrinopeptide B (a 14-amino acid fragment) from the amino termini of the α and β chains, respectively.

Overview of Hemostasis: Platelet Function, Blood Coagulation, and Fibrinolysis

Hemostasis is the cessation of blood loss from a damaged vessel. Platelets first adhere to macromolecules in the subendothelial regions of the injured blood vessel, where they become activated. Adherent platelets

Abbreviations

ACT: activated clotting time
ADP: adenosine diphosphate
 α_2 -AP: α_2 -antiplasmin
aPTT: activated partial thromboplastin time
CNS: central nervous system
COX: cyclooxygenase
CPR: cardiopulmonary resuscitation
CrCL: creatinine clearance
CYP: cytochrome P450
EDTA: ethylenediaminetetraacetic acid
EPCR: endothelial protein C receptor
GI: gastrointestinal
Gla: γ -carboxyglutamic acid
Glu: glutamic acid
GP: glycoprotein
INR: international normalized ratio
IP₃: inositol 1,4,5-trisphosphate
KGD: lysine-glycine-aspartate
LMWH: low-molecular-weight heparin
NO: nitric oxide
PAI: plasminogen activator inhibitor
PAR: protease-activated receptor
PGI₂: prostaglandin I₂ or prostacyclin
PLC: phospholipase C
PT: prothrombin time
RGD: arginine-glycine-aspartate
TF: tissue factor
TFPI: tissue factor pathway inhibitor
t-PA: tissue plasminogen activator
TxA₂: thromboxane A₂
u-PA: urokinase plasminogen activator
USP: U.S. Pharmacopeia
VKOR: vitamin K epoxide reductase
VKORC1: C1 subunit of vitamin K epoxide reductase
vWF: von Willebrand factor

Removal of the fibrinopeptides creates new amino termini, which form knobs that fit into preformed holes on other fibrin monomers to form a fibrin gel, which is the end point of in vitro tests of coagulation (see Coagulation In Vitro). Initially, the fibrin monomers are bound to each other noncovalently. Subsequently, factor XIII, a transglutaminase that is activated by thrombin, catalyzes interchain covalent cross-links between adjacent fibrin monomers, which strengthen the clot.

Structure of Coagulation Factors

In addition to factor XIII, the coagulation factors include factors II (prothrombin), VII, IX, X, XI, XII, high-molecular-weight kininogen and prekallikrein. A stretch of about 200 amino acid residues at the carboxyl termini of each of these zymogens exhibits homology to trypsin and contains the active site of the proteases. In addition, 9–12 Glu residues near the amino termini of factors II, VII, IX, and X are converted to Gla residues in a vitamin K–dependent posttranslational step. The Gla residues bind Ca²⁺ and are essential for the coagulant activities of these proteins by enabling their interaction with the anionic phospholipid membrane of activated platelets.

Nonenzymatic Protein Cofactors

TF, factor V, and factor VIII are critical cofactors in coagulation. A nonenzymatic lipoprotein cofactor, TF is not normally present on

blood-contacting cells. TF is constitutively expressed on the surface of subendothelial smooth muscle cells and fibroblasts, which are exposed when the vessel wall is damaged. TF binds factor VIIa and enhances its catalytic efficiency. The TF/factor VIIa complex initiates coagulation by activating factors IX and X.

Factor VIII and Factor V Are Procofactors

Factor VIII circulates in plasma bound to *von Willebrand factor*, which serves to stabilize it. Factor V circulates in plasma, is stored in platelets in a partially activated form, and is released when platelets are activated. Thrombin releases von Willebrand factor from factor VIII and activates factors V and VIII to yield factor Va and VIIIa, respectively. Once activated, the cofactors bind to the surface of activated platelets and serve as receptors; factor VIIIa serves as the receptor for factor IXa, while factor Va serves as the receptor for factor Xa. In addition to binding factors IXa and Xa, factors VIIIa and Va bind their substrates, factors X and prothrombin (factor II), respectively.

Activation of Prothrombin

By cleaving two peptide bonds on prothrombin, factor Xa converts it to thrombin. In the presence of factor Va, a negatively charged phospholipid surface, and Ca²⁺ (the so-called prothrombinase complex), factor Xa activates prothrombin with 10⁹-fold greater efficiency. This maximal rate of activation only occurs when prothrombin and factor Xa contain Gla residues at their amino terminals, which endows them with the capacity to bind calcium and interact with the anionic phospholipid surface.

Initiation of Coagulation

TF exposed at sites of vessel wall injury initiates coagulation via the *extrinsic pathway*. The small amount of factor VIIa circulating in plasma binds subendothelial TF and the TF–factor VIIa complex, then activates factors X and IX (see Figure 32–2). When bound to TF in the presence of anionic phospholipids and Ca²⁺ (extrinsic tenase), factor VIIa activity is increased 30,000-fold over that of factor VIIa alone.

The *intrinsic pathway* is initiated in vitro when factor XII, prekallikrein, and high-molecular-weight kininogen interact with kaolin, glass, or another negatively charged surface to generate small amounts of factor XIIa. Factor XII can be activated in vivo by contact of the blood with medical devices, such as mechanical heart valves or extracorporeal circuits, or by cell-free DNA, neutrophil extracellular traps, which are web-like structures composed of DNA and histones extruded from activated neutrophils, or inorganic polyphosphates released from activated platelets. Factor XIIa activates factor XI and the resultant factor XIa, then activates factor IX. Factor IXa activates factor X in a reaction accelerated by factor VIIIa, anionic phospholipids, and Ca²⁺. Optimal thrombin generation depends on the formation of this factor IXa complex (intrinsic tenase) because it activates factor X more efficiently than the TF–factor VIIa complex.

Activation of factor XII is not essential for hemostasis, as evidenced by the fact that patients deficient in factor XII, prekallikrein, or high-molecular-weight kininogen do not have excessive bleeding. Factor XI deficiency is associated with a variable and usually mild bleeding disorder. In contrast, congenital deficiency of factor VIII or IX results in hemophilia A or B, respectively, and is associated with spontaneous bleeding, which can be fatal.

Fibrinolysis

The fibrinolysis pathway is summarized in Figure 32–3. The fibrinolytic system dissolves intravascular *fibrin* through the action of *plasmin*. To initiate fibrinolysis, plasminogen activators convert single-chain plasminogen, an inactive precursor, into two-chain *plasmin* by cleavage of a specific peptide bond. There are two distinct plasminogen activators: *t-PA* and *u-PA*, which is also known as urokinase. Although both activators are synthesized by endothelial cells, *t-PA* predominates under most conditions and drives intravascular fibrinolysis, while synthesis of *u-PA* mainly

Figure 32–1 Platelet adhesion and aggregation. GPVI and GPIb are platelet receptors that bind to collagen and vWF, causing platelets to adhere to the subendothelium of a damaged blood vessel. PAR-1 and PAR-4 are PARs that respond to thrombin (IIa); P2Y₁ and P2Y₁₂ are receptors for ADP; when stimulated by agonists, these receptors activate the fibrinogen-binding protein GPIIb/IIIa and COX-1 to promote platelet aggregation and secretion. TxA₂ is the major product of COX-1 involved in platelet activation. Prostacyclin (PGI₂), synthesized by endothelial cells, inhibits platelet activation.

occurs in response to inflammatory stimuli and promotes extravascular fibrinolysis.

The fibrinolytic system is regulated such that unwanted fibrin thrombi are removed, while fibrin in wounds is preserved to maintain hemostasis. t-PA is released from endothelial cells in response to various stimuli. Released t-PA is rapidly cleared from blood or inhibited by PAI-1 and, to a lesser extent, by PAI-2. Therefore, t-PA exerts little effect on circulating plasminogen in the absence of fibrin, and circulating α_2 -antiplasmin rapidly inhibits any plasmin that is generated. The catalytic efficiency of t-PA activation of plasminogen increases more than 300-fold in the presence of fibrin, which promotes plasmin generation on its surface.

Plasminogen and plasmin bind to lysine residues on fibrin via five loop-like regions near their amino termini, which are known as *kringle domains*. To inactivate plasmin, α_2 -antiplasmin binds to the first of these kringle domains and then blocks the active site of plasmin. Because the kringle

domains are occupied when plasmin binds to fibrin, plasmin on the fibrin surface is protected from inhibition by α_2 -antiplasmin and can digest the fibrin. Once the fibrin clot undergoes degradation, α_2 -antiplasmin rapidly inhibits any plasmin that escapes from this local milieu. To prevent premature clot lysis, factor XIIIa mediates covalent cross-linking of small amounts of α_2 -antiplasmin onto fibrin.

When thrombi occlude major arteries or veins, therapeutic doses of plasminogen activators are sometimes administered to rapidly degrade the fibrin and restore blood flow. In high doses, these plasminogen activators promote the generation of so much plasmin that the inhibitory controls are overwhelmed. Plasmin is a relatively nonspecific protease; in addition to degrading fibrin, it degrades several coagulation factors. Reduction in the levels of these coagulation proteins impairs the capacity for thrombin generation, which can contribute to bleeding. In addition, unopposed plasmin tends to dissolve fibrin in hemostatic plugs as well as

Figure 32–2 Major reactions of blood coagulation. Shown are interactions among proteins of the “extrinsic” (TF and factor VII), “intrinsic” (factors IX and VIII), and “common” (factors X, V, and II) coagulation pathways that are important in vivo. Boxes enclose the coagulation factor zymogens (indicated by Roman numerals); the rounded boxes represent the active proteases. Activated coagulation factors are followed by the letter *a*: II, prothrombin; IIa, thrombin.

Figure 32-3 Fibrinolysis. Endothelial cells secrete t-PA at sites of injury. t-PA binds to fibrin and converts plasminogen to plasmin, which digests fibrin. PAI-1 and PAI-2 inactivate t-PA; α_2 -AP inactivates plasmin.

that in pathological thrombi, a phenomenon that also increases the risk of bleeding. Therefore, fibrinolytic drugs can produce hemorrhage as their major side effect.

Coagulation In Vitro

Whole blood normally clots in 4–8 min when placed in a glass tube. Under these conditions, contact of the blood with glass activates factor XII, thereby initiating coagulation via the *intrinsic pathway*. Clotting is prevented if a chelating agent such as EDTA or citrate is added to bind Ca^{2+} . Recalcified plasma normally clots in 2–4 min. The clotting time after recalcification is shortened to 26–33 sec by the addition of negatively charged phospholipids and particulate substances, such as kaolin (aluminum silicate) or celite (diatomaceous earth), which activate factor XII; the measurement of this is termed the *aPTT*. Alternatively, recalcified plasma clots in 12–14 sec after addition of “thromboplastin” (a mixture of TF and phospholipid) and calcium; the measurement of this is termed the *PT*.

Natural Anticoagulant Mechanisms

Platelet activation and coagulation do not normally occur within an intact blood vessel. Thrombosis is prevented by several regulatory mechanisms that require healthy vascular endothelium. Nitric oxide and prostacyclin synthesized by endothelial cells inhibit platelet activation (see Chapter 37).

Antithrombin is a plasma protein that inhibits coagulation enzymes of the extrinsic, intrinsic, and common pathways. Heparan sulfate proteoglycans synthesized by endothelial cells enhance the activity of antithrombin by about 1000-fold. Another regulatory system involves protein C, a plasma zymogen that is homologous to factors II, VII, IX, and X; its activity depends on the binding of Ca^{2+} to Gla residues within its amino terminal domain. Protein C binds to EPCR, which presents it to the thrombin-thrombomodulin complex for activation. Activated protein C then dissociates from EPCR, and, in combination with protein S, its non-enzymatic Gla-containing cofactor, activated protein C degrades factors Va and VIIIa. Without these activated cofactors, the rates of activation of prothrombin and factor X are greatly diminished, and thrombin generation is attenuated. Congenital or acquired deficiency of protein C or protein S is associated with an increased risk of venous thrombosis.

Tissue factor pathway inhibitor is a natural anticoagulant found in the lipoprotein fraction of plasma or bound to endothelial cell surface. TFPI first binds and inhibits factor Xa, and this binary complex then inhibits factor VIIa bound to TF. By this mechanism, factor Xa regulates its own generation.

Parenteral Anticoagulants: Heparin, LMWHs, Fondaparinux

Heparin and Its Standardization

Heparin, a glycosaminoglycan found in the secretory granules of mast cells, is synthesized from UDP-sugar precursors as a polymer of alternating D-glucuronic acid and N-acetyl-D-glucosamine residues. Heparin is commonly extracted from porcine intestinal mucosa, which is rich in mast cells, and preparations may contain small amounts of other glycosaminoglycans. Various commercial heparin preparations have similar biological activity (~150 USP units/mg). A USP unit reflects the quantity of heparin that prevents 1 mL of citrated sheep plasma from clotting for 1 h after calcium addition. European manufacturers measure potency with an anti-factor Xa assay. To determine heparin potency, residual factor Xa activity in the sample is compared with that detected in controls containing known concentrations of an international heparin standard. When assessed this way, heparin potency is expressed in international units per milligram. Effective October 1, 2009, the new USP unit dose was harmonized with the international unit dose. As a result, the new USP unit dose is about 10% less potent than the old one, which results in a requirement for somewhat higher heparin doses to achieve the same level of anticoagulation.

Heparin Derivatives

Derivatives of heparin in current use include LMWH and fondaparinux (see their comparison in Table 32-1).

Mechanism of Action. Heparin, LMWHs, and fondaparinux have no intrinsic anticoagulant activity; rather, these agents bind to antithrombin and accelerate the rate at which it inhibits various coagulation proteases. Synthesized in the liver, antithrombin circulates in plasma at an approximate concentration of 2.5 μM . Antithrombin inhibits activated coagulation factors, particularly thrombin and factor Xa, by serving as a “suicide substrate.” Thus, inhibition occurs when the protease attacks a specific Arg-Ser peptide bond in the reactive center loop of antithrombin and becomes trapped as a stable 1:1 complex. Heparin binds to antithrombin via a specific pentasaccharide sequence that contains a 3-O-sulfated glucosamine residue (Figure 32-4).

Pentasaccharide binding to antithrombin induces a conformational change in antithrombin that renders its reactive site more accessible to the target protease (Figure 32-5). This conformational change accelerates the rate of factor Xa inhibition by at least two orders of magnitude but has no effect on the rate of thrombin inhibition. To enhance the rate of thrombin

TABLE 32-1 ■ COMPARISON OF THE FEATURES OF SUBCUTANEOUS HEPARIN, LOW-MOLECULAR-WEIGHT HEPARIN, AND FONDAPARINUX

FEATURES	HEPARIN	LMWH	FONDAPARINUX
Source	Biological	Biological	Synthetic
Mean molecular weight (Da)	15,000	5000	1500
Target	Xa and IIa	Xa and IIa	Xa
Subcutaneous			
Bioavailability (%)	30 (at low doses)	90	100
$t_{1/2}$ (h)	1–8 ^a	4	17
Renal excretion	No	Yes	Yes
Antidote effect	Complete	Partial	None
Thrombocytopenia	<5%	<1%	<0.1%

^aHalf-life $t_{1/2}$ is dose dependent; half-life is 1 h with 5000 units given subcutaneously and can extend to 8 h with higher doses.

inhibition by antithrombin, heparin serves as a catalytic template to which both the inhibitor and the protease bind. Only heparin molecules composed of 18 or more saccharide units (molecular weight > 5400) are of sufficient length to bridge antithrombin and thrombin together. Consequently, by definition, heparin catalyzes the rates of factor Xa and thrombin inhibition to a similar extent, as expressed by an anti-factor Xa to anti-factor IIa (thrombin) ratio of 1:1 (Figure 32-5A). In contrast, at least half of LMWH molecules (mean molecular weight of 5000, which corresponds with about 17 saccharide units) are too short to provide this bridging function and have no effect on the rate of thrombin inhibition by antithrombin (Figure 32-5B). Because these shorter molecules still induce the conformational change in antithrombin that accelerates inhibition of factor Xa, LMWH has greater anti-factor Xa activity than anti-factor IIa activity, and the ratio ranges from 3:1 to 2:1 depending on the preparation. Fondaparinux, a synthetic analogue of the pentasaccharide sequence in heparin or LMWH that mediates their interaction with antithrombin, has only anti-factor Xa activity because it is too short to bridge antithrombin to thrombin (Figure 32-5C).

Heparin, LMWH, and fondaparinux act in a catalytic fashion. After binding to antithrombin and promoting the formation of covalent complexes between antithrombin and target proteases, the heparin, LMWH, or fondaparinux dissociates from the complex and can then catalyze other antithrombin molecules.

Platelet factor 4, a cationic protein released from α -granules during platelet activation, binds heparin and prevents it from interacting with antithrombin. This phenomenon may limit the activity of heparin in the vicinity of platelet-rich thrombi. Because LMWH and fondaparinux have a lower affinity for platelet factor 4, these agents may retain their activity in the vicinity of such thrombi to a greater extent than heparin.

Miscellaneous Pharmacological Effects. High doses of heparin can interfere with platelet aggregation and prolong the bleeding time. In contrast, LMWH and fondaparinux have little effect on platelets. Heparin “clears” lipemic plasma in vivo by causing the release of lipoprotein lipase

into the circulation. Lipoprotein lipase hydrolyzes triglycerides to glycerol and free fatty acids. The clearing of lipemic plasma may occur at concentrations of heparin below those necessary to produce an anticoagulant effect.

Clinical Use. Heparin, LMWH, or fondaparinux can be used to initiate treatment of deep vein thrombosis and pulmonary embolism. They also can be used for the initial management of patients with unstable angina or acute myocardial infarction (Gara et al., 2013; Roffi et al., 2015). For most of these indications, LMWH or fondaparinux has replaced continuous heparin infusions because of their pharmacokinetic advantages, which permit subcutaneous administration once or twice daily in fixed or weight-adjusted doses without coagulation monitoring. Thus, LMWH or fondaparinux can be used for out-of-hospital management of patients with deep vein thrombosis or pulmonary embolism.

Heparin or LMWH is used during coronary balloon angioplasty with or without stent placement to prevent thrombosis. Fondaparinux is not used in this setting because of the risk of catheter thrombosis, a complication caused by catheter-induced activation of factor XII; longer heparin molecules are better than shorter ones for blocking this process. Cardiopulmonary bypass circuits also activate factor XII, which can cause clotting of the oxygenator. Heparin remains the agent of choice for surgery requiring cardiopulmonary bypass. Heparin or LMWH also is used to treat selected patients with disseminated intravascular coagulation. Subcutaneous administration of low-dose heparin or LMWH is often used for thromboprophylaxis in immobilized medically ill patients (Kahn et al., 2012) or in those who have undergone major surgery (Falck-Ytter et al., 2012; Gould et al., 2012).

Unlike the oral anticoagulants, heparin, LMWH, and fondaparinux do not cross the placenta and have not been associated with fetal malformations, making them the drugs of choice for anticoagulation during pregnancy. Heparin, LMWH, and fondaparinux do not appear to increase fetal mortality or prematurity. If possible, the drugs should be discontinued 24 h before delivery to minimize the risk of postpartum bleeding.

Figure 32-4 The antithrombin-binding pentasaccharide structure of heparin. Sulfate groups required for binding to antithrombin are indicated in red.

Figure 32-5 Mechanism of action of heparin, LMWH, and fondaparinux, a synthetic pentasaccharide. **A.** Heparin binds to antithrombin via its pentasaccharide sequence. This induces a conformational change in the reactive center loop of antithrombin that accelerates its interaction with factor Xa. To potentiate thrombin inhibition, heparin must simultaneously bind to antithrombin and thrombin. Only heparin chains composed of at least 18 saccharide units (MW ~ 5400 Da) are of sufficient length to perform this bridging function. With a mean MW of approximately 15,000 Da, virtually all of the heparin chains are long enough to do this. **B.** LMWH has greater capacity to potentiate factor Xa inhibition by antithrombin than thrombin because at least half of the LMWH chains (mean MW ~ 4500–5000 Da) are too short to bridge antithrombin to thrombin. **C.** The pentasaccharide accelerates only factor Xa inhibition by antithrombin; the pentasaccharide is too short to bridge antithrombin to thrombin.

ADME. Heparin, LMWH, and fondaparinux are not absorbed through the GI mucosa and must be given parenterally. Heparin is given by continuous intravenous infusion, intermittent infusion every 4–6 h, or subcutaneous injection every 8–12 h. Heparin has an immediate onset of action when given intravenously. In contrast, there is considerable variation in the bioavailability of heparin given subcutaneously, and the onset of action is delayed by 1–2 h. LMWH and fondaparinux are absorbed more uniformly after subcutaneous injection. The $t_{1/2}$ of heparin in plasma depends on the dose administered. When doses of 100, 400, or 800 units/kg of heparin are injected intravenously, the half-lives are about 1, 2.5, and 5 h, respectively. Heparin appears to be cleared and degraded primarily by the reticuloendothelial system; a small amount of intact heparin appears in the urine.

Both LMWH and fondaparinux have longer biological half-lives than heparin, 4–6 and 17 h, respectively. Because these smaller heparin

fragments are cleared almost exclusively by the kidneys, the drugs can accumulate in patients with renal impairment and lead to bleeding. Both LMWH and fondaparinux are contraindicated in patients with a creatinine clearance below 30 mL/min. In addition, thromboprophylaxis with fondaparinux is contraindicated in patients undergoing hip fracture, hip replacement, knee replacement, or abdominal surgery who have a body weight less than 50 kg.

Administration and Monitoring. Full-dose heparin usually is administered by continuous intravenous infusion. Treatment of venous thromboembolism is initiated with a fixed-dose bolus injection of 5000 units or with a weight-adjusted bolus, followed by 800–1600 units/h delivered by an infusion pump. Therapy is monitored by measuring the aPTT. The therapeutic range for heparin is considered to be that which is equivalent to a plasma heparin level of 0.3–0.7 units/mL, as determined with an

anti-factor Xa assay. An aPTT that is two or three times the normal mean aPTT value generally is assumed to be therapeutic. The aPTT should be measured initially and the infusion rate adjusted every 6 h. Once a steady dosage schedule has been established, daily aPTT monitoring usually is sufficient. Very high doses of heparin are required to prevent clotting in patients undergoing percutaneous coronary intervention or cardiac surgery with cardiopulmonary bypass. The aPTT is infinitely prolonged with these high doses of heparin, so a less-sensitive coagulation test, the ACT, is employed to monitor therapy in this situation.

For therapeutic purposes, heparin also can be administered subcutaneously on a twice-daily basis. A total daily dose of about 35,000 units administered as divided doses every 8–12 h usually is sufficient to achieve an aPTT of twice the control value (measured midway between doses). For low-dose heparin therapy (to prevent venous thromboembolism in hospitalized medical or surgical patients), a subcutaneous dose of 5000 units is given two or three times daily.

Heparin Resistance. Patients who fail to achieve a therapeutic aPTT with daily doses of heparin of 35,000 units or more are considered to have heparin resistance, which may reflect pseudo- or true resistance. Concomitant measurement of the aPTT and the anti-factor Xa level distinguishes between these two possibilities. With heparin pseudoresistance, the anti-factor Xa level is therapeutic despite the subtherapeutic aPTT, whereas with true heparin resistance both the anti-factor Xa level and the aPTT are subtherapeutic. Pseudoresistance to heparin occurs if the aPTT is shorter than the control value prior to initiating heparin treatment because of high concentrations of factor VIII and fibrinogen. True heparin resistance occurs because of high plasma levels of proteins that compete with antithrombin for heparin binding or because of antithrombin deficiency. Heparin does not require dose adjustment in patients with pseudoresistance because the anti-factor Xa level is therapeutic. In contrast, with true resistance, heparin doses need to be increased until a therapeutic aPTT or anti-factor Xa level is achieved. Patients with severe antithrombin deficiency may require antithrombin concentrate to achieve therapeutic anticoagulation with heparin.

LMWH Preparations

Enoxaparin and dalteparin are the LMWH preparations marketed in the U.S.; tinzaparin is available in other countries. The composition of these agents differs, as do their dosing regimens. Because LMWH produces a relatively predictable anticoagulant response, monitoring is not done routinely. Patients with renal impairment may require monitoring with an anti-factor Xa assay because this condition can prolong the $t_{1/2}$ and slow the elimination of LMWH. Obese patients, pregnant women, and children given LMWH also may require monitoring.

Fondaparinux

Fondaparinux, a synthetic pentasaccharide, is administered by subcutaneous injection, reaches peak plasma levels in 2 h, has a $t_{1/2}$ of 17 h, and is excreted in the urine. Because of the risk of accumulation and subsequent bleeding, fondaparinux should not be used in patients with a creatinine clearance less than 30 mL/min. Fondaparinux can be given subcutaneously once a day at a fixed or weight-adjusted dose without coagulation monitoring. Fondaparinux is much less likely than heparin or LMWH to trigger heparin-induced thrombocytopenia, and the drug has been used successfully to treat patients with this condition. Fondaparinux is approved for thromboprophylaxis in patients undergoing hip or knee surgery or surgery for hip fracture and for initial therapy of patients with deep vein thrombosis or pulmonary embolism. In some countries, but not the U.S., fondaparinux also is licensed as an alternative to heparin or LMWH in patients with acute coronary syndrome. For this indication and for thromboprophylaxis, fondaparinux is administered subcutaneously once daily at a dose of 2.5 mg.

Bleeding. The major untoward effect of heparin, LMWH, and fondaparinux is bleeding. Major bleeding occurs in 1%–5% of patients treated with intravenous heparin for venous thromboembolism. The incidence of bleeding is somewhat less in patients treated with LMWH for this

indication. Often, an underlying cause for bleeding is present, such as recent surgery, trauma, peptic ulcer disease, or platelet dysfunction due to concomitant administration of aspirin or other antiplatelet drugs.

The anticoagulant effect of heparin disappears within hours of discontinuation of the drug. Mild bleeding due to heparin usually can be controlled without administration of an antagonist. If life-threatening hemorrhage occurs, heparin can rapidly be reversed by the intravenous infusion of *protamine sulfate* (a mixture of basic polypeptides isolated from salmon sperm), which binds tightly to heparin and neutralizes its anticoagulant effect. Protamine also interacts with platelets, fibrinogen, and other plasma proteins and may cause an anticoagulant effect of its own. Therefore, one should give the minimal amount of protamine required to neutralize the heparin present in the plasma. This amount is 1 mg of protamine for every 100 units of heparin remaining in the patient; protamine is given intravenously at a slow rate (up to a maximum of 50 mg over 10 min). Protamine binds only long heparin molecules. Therefore, protamine only partially reverses the anticoagulant activity of LMWH and has no effect on that of fondaparinux.

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (platelet count < 150,000/mL or a 50% decrease from the pretreatment value) occurs in about 0.5% of medical patients 5–10 days after initiation of therapy with heparin. Although the incidence is lower, thrombocytopenia also occurs with LMWH and rarely with fondaparinux. Life-threatening thrombotic complications that can lead to limb amputation, which occurs in up to one-half of the affected heparin-treated patients and may precede the onset of thrombocytopenia. Women are twice as likely as men to develop this condition, and heparin-induced thrombocytopenia is more common in surgical patients than medical patients.

Venous thromboembolism occurs most commonly, but arterial thrombosis causing limb ischemia, myocardial infarction, or stroke also occurs. Bilateral adrenal hemorrhage, skin lesions at the site of subcutaneous heparin injection, and a variety of systemic reactions may accompany heparin-induced thrombocytopenia. The development of immunoglobulin G antibodies against complexes of heparin with platelet factor 4 (or, rarely, other chemokines) causes most of these reactions.

Heparin or LMWH should be discontinued immediately if unexplained thrombocytopenia or any of the clinical manifestations mentioned occur 5 or more days after beginning therapy, regardless of the dose or route of administration. The diagnosis of heparin-induced thrombocytopenia can be confirmed with a heparin-dependent platelet activation assay or an immunoassay for antibodies that react with heparin–platelet factor 4 complexes. Because thrombotic complications may occur after cessation of therapy, an alternative anticoagulant such as bivalirudin or argatroban (see the next section) or fondaparinux should be administered to patients with heparin-induced thrombocytopenia. LMWH should be avoided because it cross-reacts with heparin antibodies. *Warfarin may precipitate venous limb gangrene or skin necrosis in patients with heparin-induced thrombocytopenia and should not be used until the platelet count returns to normal.*

Other Toxicities. Abnormalities of hepatic function tests occur frequently in patients who are receiving heparin or LMWH. Osteoporosis occurs occasionally in patients who have received therapeutic doses of heparin (>20,000 units/d) for extended periods (e.g., 3–6 months). The risk of osteoporosis is lower with LMWH or fondaparinux than it is with heparin. Heparin can inhibit the synthesis of aldosterone by the adrenal glands and occasionally causes hyperkalemia.

Other Parenteral Anticoagulants

Desirudin and Lepirudin

Desirudin and lepirudin (not available in the U.S.) are recombinant forms of hirudin. Desirudin is indicated for thromboprophylaxis in patients undergoing elective hip replacement surgery. Both desirudin and lepirudin are also used for treating thrombosis in the setting of heparin-induced thrombocytopenia (Kelton et al., 2013). Desirudin and lepirudin are eliminated by the kidneys; the $t_{1/2}$ is about 2 h after subcutaneous

administration and about 10 min after intravenous infusion. Both drugs should be used cautiously in patients with decreased renal function, and serum creatinine and aPTT should be monitored daily.

Bivalirudin

Bivalirudin is a synthetic 20-amino acid polypeptide that directly inhibits thrombin. Bivalirudin is administered intravenously and is used as an alternative to heparin in patients undergoing coronary angioplasty or cardiopulmonary bypass surgery (Barria Perez et al. 2016). Patients with heparin-induced thrombocytopenia or a history of this disorder also can be given bivalirudin instead of heparin during coronary angioplasty. The $t_{1/2}$ of bivalirudin is 25 min; dosage reductions are recommended for patients with renal impairment.

Argatroban

Argatroban, a synthetic compound based on the structure of L-arginine, binds reversibly to the active site of thrombin. Argatroban is administered intravenously and has a $t_{1/2}$ of 40–50 min. It is metabolized in the liver and excreted in the bile. Therefore, argatroban can be used in patients with renal impairment, but dose reduction is required for patients with hepatic insufficiency. Argatroban is licensed for the prophylaxis or treatment of patients with, or at risk of developing, heparin-induced thrombocytopenia (Grouzi, 2014). In addition to prolonging the aPTT, argatroban prolongs the PT, which can complicate the transitioning of patients from argatroban to warfarin. A factor X assay can be used instead of the PT to monitor warfarin in these patients.

Vitamin K Antagonist

Warfarin

Warfarin or other vitamin K antagonists are commonly used oral anticoagulants.

Mechanism of Action

Coagulation factors II, VII, IX, and X and proteins C and S are synthesized in the liver and are biologically inactive unless 9–13 of the amino-terminal Glu residues are γ -carboxylated to form the Ca^{2+} -binding Gla domain. This carboxylation reaction requires CO_2 , O_2 , and reduced vitamin K and is catalyzed by γ -glutamyl carboxylase (Figure 32–6). Carboxylation is coupled to the oxidation of vitamin K to its corresponding epoxide form. Reduced vitamin K must be regenerated from the epoxide form for sustained carboxylation and synthesis of functional proteins. The enzyme that catalyzes this reaction, VKOR is inhibited by therapeutic doses of warfarin.

At therapeutic doses, warfarin decreases the functional amount of each vitamin K-dependent coagulation factor made by the liver by 30%–70%. Warfarin has no effect on the activity of fully γ -carboxylated factors already in the circulation, and these must be cleared before it can produce an anticoagulant effect. The approximate $t_{1/2}$ values of factors VII, IX, X, and II are 6, 24, 36, and 50 h, respectively, while the $t_{1/2}$ values of protein C and protein S are 8 and 24 h, respectively. Because of the long $t_{1/2}$ of some of the coagulation factors, in particular factor II, the full antithrombotic effect of warfarin is not achieved for 4 to 5 days. For this reason, warfarin must be overlapped with a rapidly acting parenteral anticoagulant, such as heparin, LMWH, or fondaparinux, in patients with thrombosis or at high risk for thrombosis.

ADME

The bioavailability of warfarin is nearly complete when the drug is administered orally, intravenously, or rectally. Generic warfarin tablets may vary in their rate of dissolution, and this may cause some variation in the rate and extent of absorption. Food in the GI tract also can decrease the rate of absorption. Plasma warfarin concentrations peak in 2–8 h. Warfarin is administered as a racemic mixture of *S*- and *R*-warfarin. *S*-Warfarin is 3- to 5-fold more potent than *R*-warfarin and is mainly metabolized by CYP2C9. Inactive metabolites of warfarin are excreted

Figure 32–6 The vitamin K cycle and mechanism of action of warfarin. In the racemic mixture of *S*- and *R*-enantiomers, *S*-warfarin is more active. By blocking VKOR encoded by the *VKORC1* gene, warfarin inhibits the conversion of oxidized vitamin K epoxide into its reduced form, vitamin K hydroquinone. This inhibits vitamin K-dependent γ -carboxylation of factors II, VII, IX, and X because reduced vitamin K serves as a cofactor for a γ -glutamyl carboxylase that catalyzes the γ -carboxylation process whereby prozymogens are converted to zymogens capable of binding Ca^{2+} and interacting with anionic phospholipids. *S*-Warfarin is metabolized by CYP2C9; common genetic polymorphisms in this enzyme increase warfarin metabolism. Polymorphisms in the VKORC1 increase the susceptibility of the enzyme to warfarin-induced inhibition. Thus, patients expressing polymorphisms in these two enzymes require reduction of warfarin dosage (see Table 32–2).

TABLE 32-2 ■ EFFECT OF *CYP2C9* GENOTYPES AND *VKORC1* HAPLOTYPES ON WARFARIN DOSING

GENOTYPE/HAPLOTYPE	FREQUENCY (%)			DOSE REDUCTION COMPARED WITH WILD TYPE (%)
	CAUCASIANS	AFRICAN AMERICANS	ASIANS	
CYP2C9				
*1/*1	70	90	95	—
*1/*2	17	2	0	22
*1/*3	9	3	4	34
*2/*2	2	0	0	43
*2/*3	1	0	0	53
*3/*3	0	0	1	76
VKORC1				
Non-A/non-A	37	82	7	—
Non-A/A	45	12	30	26
A/A	18	6	63	50

Polymorphisms in two genes, *CYP2C9* and *VKORC1*, largely account for the genetic contribution to the variability in warfarin response. *CYP2C9* variants affect warfarin pharmacokinetics. *CYP2C9* metabolizes warfarin, and the non-*1/*1 variants are less active than *CYP2C9**1/*1, necessitating a reduction in dose. *VKORC1* variants affect warfarin pharmacodynamics. *VKORC1* is the target of coumarin anticoagulants such as warfarin. The non-A/A and A/A forms have decreased requirements for warfarin.

Source: Ghimire LV, Stein CM. Warfarin pharmacogenetics. Goodman and Gilman Online.

in urine and stool. The $t_{1/2}$ varies (25–60 h), but the duration of action of warfarin is 2–5 days.

Table 32-2 summarizes the effects of known genetic factors on warfarin dose requirements. Polymorphisms in two genes, *CYP2C9* and *VKORC1* account for most of the genetic contribution to variability in warfarin response (International Warfarin Pharmacogenetics Consortium, 2009; McClain et al., 2008). *CYP2C9* variants affect warfarin pharmacokinetics, whereas *VKORC1* variants affect warfarin pharmacodynamics. Common variations in the *CYP2C9* gene (designated *CYP2C9**2 and *3), encode an enzyme with decreased activity and thus are associated with higher drug concentrations and reduced warfarin dose requirements. *VKORC1* variants are more prevalent than those of *CYP2C9*, particularly in Asians, followed by European Americans and African Americans (Limdi et al., 2015). The warfarin dose requirement is decreased in patients with these variants (Shi et al., 2015). Point-of-care methods for *CYP2C9* and *VKORC1* genotyping and algorithms that incorporate genotype information have been developed to facilitate precision dosing of warfarin. It remains uncertain, however, whether precision dosing improves clinical outcome compared with usual warfarin management.

Clinical Use

Vitamin K antagonists are used to prevent the progression or recurrence of acute deep vein thrombosis or pulmonary embolism following an initial course of heparin, LMWH, or fondaparinux (Kearon et al., 2016). They also are effective in preventing stroke or systemic embolization in patients with atrial fibrillation, mechanical heart valves, or ventricular assist devices.

Prior to initiation of therapy, laboratory tests are used in conjunction with the history and physical examination to uncover hemostatic defects that might make the use of warfarin more dangerous (e.g., congenital coagulation factor deficiency, thrombocytopenia, hepatic or renal insufficiency, vascular abnormalities). Thereafter, the INR calculated from the patient's PT is used to monitor the extent of anticoagulation and compliance. Therapeutic INR ranges for various clinical indications have been established and reflect the extent of anticoagulation that reduces the morbidity from thromboembolic disease while minimally increasing the risk of serious hemorrhage. For most indications, an INR range of 2–3 is used. A higher INR range (2.5–3.5) is recommended for patients with mechanical heart valves in the mitral position or for patients with mechanical valves in another position who have concomitant atrial fibrillation or a prior history of stroke.

For treatment of acute venous thromboembolism, heparin, LMWH, or fondaparinux usually is continued for at least 5 days after warfarin therapy is begun. The parenteral agent is stopped when the INR is in the therapeutic range on 2 consecutive days. This overlap allows for adequate depletion of vitamin K–dependent coagulation factors with long half-lives, especially factor II. Frequent INR measurements are indicated at the onset of therapy to ensure that a therapeutic effect is obtained. Once a stable dose of warfarin has been identified, the INR can be monitored every 3 to 4 weeks.

Dosage

The usual adult dosage of warfarin is 2–5 mg/d for 2–4 days, followed by 1–10 mg/d as indicated by measurements of the INR (see the functional definition of INR in the section on clinical use). A lower initial dose should be given to patients with an increased risk of bleeding, including the elderly.

Interactions

Warfarin interactions can be caused by drugs, foods, or genetic factors that alter (1) uptake or metabolism of warfarin or vitamin K; (2) synthesis, function, or clearance of clotting factors; or (3), the integrity of any epithelial surface. Reduced warfarin efficacy can occur because of reduced absorption (e.g., binding to cholestyramine in the GI tract) or increased hepatic clearance from induction of hepatic enzymes (e.g., *CYP2C9* induction by barbiturates, carbamazepine, or rifampin). Warfarin has a decreased volume of distribution and a short $t_{1/2}$ with hypoproteinemia, such as occurs with nephrotic syndrome. Relative warfarin resistance can also be caused by ingestion of large amounts of vitamin K–rich foods or supplements or by increased levels of coagulation factors during pregnancy.

Drug interactions that enhance the risk of hemorrhage in patients taking warfarin include decreased metabolism due to *CYP2C9* inhibition by amiodarone, azole antifungals, cimetidine, clopidogrel, cotrimoxazole, disulfiram, fluoxetine, isoniazid, metronidazole, sulfapyrazole, tolcapone, or zafirlukast. Relative deficiency of vitamin K may result from inadequate diet (e.g., postoperative patients on parenteral fluids), especially when coupled with the elimination of intestinal flora by antimicrobial agents. Gut bacteria synthesize vitamin K and are an important source of this vitamin. Consequently, antibiotics can cause an increase in the INR in patients on warfarin. Low concentrations of coagulation factors may result from impaired hepatic function, congestive heart failure, or hypermetabolic states, such as hyperthyroidism; generally, these conditions enhance the effect of warfarin on the INR. Serious interactions that do not alter the

INR include inhibition of platelet function by agents such as *aspirin* and gastritis or frank ulceration induced by anti-inflammatory drugs. Agents may have more than one effect (e.g., clofibrate increases the rate of turnover of coagulation factors and inhibits platelet function).

Hypersensitivity to Warfarin

About 10% of patients require less than 1.5 mg/d of warfarin to achieve an INR of 2–3. These patients often possess variants of *CYP2C9* or *VKORC1*; these affect the pharmacokinetics or pharmacodynamics of warfarin, respectively. Supplementation with low daily doses of vitamin K renders these patients less sensitive to warfarin and may result in more stable dosing.

Adverse Effects

Bleeding. The most common side effect of warfarin is bleeding. The risk of bleeding increases with the intensity and duration of anticoagulant therapy, the use of other medications that interfere with hemostasis, and the presence of an anatomical source of bleeding. The incidence of major bleeding episodes is generally less than 3% per year in patients treated to a target INR of 2–3. The risk of intracranial hemorrhage increases dramatically with an INR greater than 4, although up to two-thirds of intracranial bleeds on warfarin occur when the INR is therapeutic.

If the INR is above the therapeutic range and the patient is not bleeding or in need of a surgical procedure, warfarin can be held temporarily and restarted at a lower dose once the INR is within the therapeutic range. If the INR is 10 or greater, vitamin K₁ can be given orally at a dose of 2.5 to 5 mg. These doses of oral vitamin K₁ generally cause the INR to decrease substantially within 24–48 h without rendering the patient resistant to further warfarin therapy. Higher doses or parenteral administration may be required if more rapid correction of the INR is necessary. The effect of vitamin K₁ is delayed for at least several hours because reversal of anticoagulation requires synthesis of fully carboxylated coagulation factors. If immediate hemostatic competence is necessary because of serious bleeding or profound warfarin overdosage, adequate concentrations of vitamin K–dependent coagulation factors can be restored by transfusion of four-factor prothrombin complex concentrate, supplemented with 10 mg of vitamin K₁, given by slow intravenous infusion. Vitamin K₁ administered intravenously carries the risk of anaphylactoid reactions. Patients who receive high doses of vitamin K₁ may become unresponsive to warfarin for several days, but heparin or LMWH can be given if continued anticoagulation is required.

Birth Defects. Administration of warfarin during pregnancy causes birth defects and abortion. CNS abnormalities have been reported following exposure during the second and third trimesters. Fetal or neonatal hemorrhage and intrauterine death may occur, even when maternal INR values are within the therapeutic range. Vitamin K antagonists should not be used during pregnancy, but heparin or LMWH can be used safely.

Skin Necrosis. Warfarin-induced skin necrosis is a rare complication characterized by the appearance of skin lesions 3–10 days after treatment is initiated. The lesions typically are on the extremities, but adipose tissue, the penis, and the female breast also may be involved. Skin necrosis occurs in patients with protein C or S deficiency or in those with heparin-induced thrombocytopenia.

Other Toxicities. A reversible, sometimes painful, blue-tinged discoloration of the plantar surfaces and sides of the toes that blanches with pressure and fades with elevation of the legs (purple toe syndrome) may develop 3–8 weeks after initiation of therapy with warfarin; cholesterol emboli released from atheromatous plaques have been implicated as the cause. Other infrequent reactions include alopecia, urticaria, dermatitis, fever, nausea, diarrhea, abdominal cramps, and anorexia.

Direct Oral Anticoagulants

Direct Oral Thrombin Inhibitor

Dabigatran

Dabigatran etexilate is a synthetic prodrug with a molecular weight of 628 Da.

Mechanism of Action. Dabigatran etexilate is rapidly converted to dabigatran by plasma esterases. Dabigatran competitively and reversibly blocks the active site of free and clot-bound thrombin. In turn, this blocks thrombin-mediated conversion of fibrinogen to fibrin, feedback activation of coagulation, and platelet activation.

ADME. Dabigatran has oral bioavailability of about 6%, a peak onset of action in 2 h, and a plasma $t_{1/2}$ of 12–14 h. Dabigatran is given twice a day in capsule form. The bioavailability of the drug is altered if capsules are chewed or broken prior to ingestion. Therefore, the capsules should be swallowed whole. Circulating dabigatran is 35% bound to plasma proteins. Around 80% of absorbed dabigatran is excreted unchanged by the kidneys. A dosage reduction is required when dabigatran is administered to patients with severe renal impairment (creatinine clearance 15 to 30 mL/min). Dosage recommendations are not available for patients with a creatinine clearance below 15 mL/min.

When given in fixed doses, dabigatran etexilate produces such a predictable anticoagulant response that routine coagulation monitoring is unnecessary. Although dabigatran prolongs the aPTT, the values plateau with higher drug levels. Dabigatran has an unreliable effect on the INR. The thrombin time is too sensitive to use to monitor dabigatran therapy because the test is markedly prolonged with even low levels of drug. To circumvent this problem, a diluted thrombin time assay has been developed. By comparing the results with those obtained with dabigatran calibrators, this test can be used to quantify plasma dabigatran concentrations.

Therapeutic Uses. Dabigatran is licensed for treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation with heparin, LMWH, or fondaparinux (Schulman et al., 2009) and for secondary prevention of venous thromboembolism (Beyer-Westendorf and Agno, 2015; Gomez-Outes et al., 2015). Dabigatran also is licensed for stroke prevention in patients with nonvalvular atrial fibrillation (Connolly et al., 2009). It is contraindicated in patients with mechanical heart valves (Eikelboom et al., 2013). In some countries, lower-dose regimens of once-daily dabigatran are licensed for thromboprophylaxis after knee or hip arthroplasty. Dabigatran is contraindicated for stroke prevention in patients with mechanical heart valves.

Adverse Effects. Bleeding is the major side effect of dabigatran. In elderly patients with atrial fibrillation, the annual risk of major bleeding with dabigatran 150 mg twice daily is similar to that with warfarin, about 3.0%. However, the risk of intracranial bleeding is reduced by 70% with dabigatran compared with warfarin. In contrast, the risk of GI bleeding is higher with dabigatran, particularly in those over 75 years of age. Additional risks for bleeding with dabigatran include renal impairment and concurrent use of antiplatelet agents or nonsteroidal anti-inflammatory drugs.

Drug Interactions. Dabigatran is a substrate for P-glycoprotein, so drugs that inhibit or induce P-glycoprotein have the potential to increase or decrease plasma dabigatran concentrations, respectively. Verapamil, dronedarone, quinidine, ketoconazole, and clarithromycin can increase dabigatran concentrations, while rifampicin may decrease the concentration.

Direct Oral Factor Xa Inhibitors

Rivaroxaban, Apixaban, and Edoxaban

Mechanism of Action. Rivaroxaban, apixaban, and edoxaban inhibit free and clot-associated factor Xa, which results in reduced thrombin generation. In turn, platelet aggregation and fibrin formation are suppressed.

ADME. Rivaroxaban has 80% oral bioavailability, a peak onset of action in 3 h, and a plasma $t_{1/2}$ of 7–11 h. Maximum absorption of rivaroxaban occurs in the stomach, and when given in therapeutic doses, the drug should be administered with a meal to enhance absorption. Rivaroxaban is provided in tablet form; the tablet can be crushed and delivered via nasogastric tube. Rivaroxaban is 95% plasma protein bound. About one-third of the drug is excreted unchanged in the urine; the remainder is

metabolized by the hepatic CYP3A4 system, and inactive metabolites are excreted equally in the urine and feces. Rivaroxaban exposure is increased in patients with renal impairment or severe hepatic dysfunction. The therapeutic dose of rivaroxaban is reduced from 20 mg once daily to 15 mg once daily if the creatinine clearance is 15–50 mL/min. The drug should not be used in those with a lower creatinine clearance.

The bioavailability of apixaban is around 50%, and peak concentrations are achieved 1 to 3 h after ingestion. Food does not affect absorption, and the drug can be administered as a whole tablet or the tablet can be crushed in water and delivered via a nasogastric tube. Apixaban is 87% plasma protein bound, and about 27% of the drug is cleared unchanged via the kidneys. Apixaban is metabolized by the hepatic CYP3A4 system, and metabolites are excreted in the bile, intestines, and urine. The usual dose of apixaban is 5 mg twice daily. The dose is reduced to 2.5 mg twice daily in patients who have two of the following three characteristics: age over 80 years, body weight of 60 kg or less, or serum creatinine concentration of 1.5 mg/dL or higher. In patients with acute venous thromboembolism, patients start apixaban at a dose of 10 mg twice daily for 7 days, and the dose is then decreased to 5 mg twice daily thereafter. For those requiring treatment beyond 6 to 12 months, the apixaban dose can be decreased to 2.5 mg twice daily.

The bioavailability of edoxaban is 62%, and peak drug concentrations are achieved 1 to 2 h after ingestion. Food does not affect absorption. Edoxaban is 55% protein bound. Of the absorbed edoxaban, about 50% is eliminated as unchanged drug in the urine. There is minimal hepatic metabolism, and liver disease does not affect drug pharmacodynamics. Drug exposure is increased by renal impairment, low body weight, and concomitant intake of potent P-glycoprotein inhibitors. Therefore, the dose of edoxaban should be reduced from 60 to 30 mg once daily in patients with a creatinine clearance between 15 and 50 mL/min, in those with a body weight of 60 kg or less, or in those taking quinidine, dronedarone, rifampin, erythromycin, ketoconazole, or cyclosporine. Edoxaban is contraindicated in those with a creatinine clearance below 15 mL/min. Edoxaban is also not recommended in patients with a high creatinine clearance over 95 mL/min because of increased risk of ischemic stroke compared with warfarin.

Rivaroxaban, apixaban, and edoxaban are given in fixed doses and do not require routine coagulation monitoring. The drugs affect the PT more than the aPTT, but they prolong the PT to a variable extent, and this test does not provide a reliable measure of their anticoagulant activity. Anti-factor Xa assays using specific drug calibrators can be used to measure drug levels. Renal function should be assessed at least yearly in patients taking oral factor Xa inhibitors or more frequently in patients with renal dysfunction.

Therapeutic Uses. Rivaroxaban, apixaban, and edoxaban are licensed for stroke prevention in patients with atrial fibrillation (Giugliano et al., 2013; Granger et al., 2011; Patel et al., 2011) and for treatment of acute deep vein thrombosis or pulmonary embolism (Beyer-Westendorf and Agno, 2015; Gomez-Outes et al., 2015). For the last indication, edoxaban is only started after a minimum 5-day course of treatment with heparin, LMWH, or fondaparinux (Hokusai VTE Investigators, 2013). In contrast, rivaroxaban and apixaban can be started immediately without the need for heparin bridging (EINSTEIN investigators, 2010, 2012; Granziera et al., 2016). Rivaroxaban and apixaban are also licensed for postoperative thromboprophylaxis in patients undergoing hip or knee arthroplasty (Falck-Ytter et al., 2012); for this indication, the drugs are given at doses of 10 mg once daily and 2.5 mg twice daily, respectively. All three drugs are contraindicated for stroke prevention in patients with mechanical heart valves.

Adverse Effects. As with all anticoagulants, the major adverse effect is bleeding. Rates of intracranial bleeding with rivaroxaban, apixaban, and edoxaban are at least 50% lower than that with warfarin. Rates of bleeding in other sites are similar or lower than those with warfarin. The sole exception is the GI tract; rates of GI bleeding with rivaroxaban and edoxaban, but not apixaban, are higher than that with warfarin. The explanation for this difference is uncertain, but it may reflect the

capacity of unabsorbed anticoagulant in the gut to promote bleeding from preexisting lesions. Despite the increased risk of GI bleeding, rates of life-threatening and fatal bleeding are lower with all of the oral factor Xa inhibitors than with warfarin. Like with other anticoagulants, the risk of bleeding with rivaroxaban, apixaban, or edoxaban is increased in patients taking concomitant antiplatelet agents or nonsteroidal anti-inflammatory agents.

Drug Interactions. All of the oral factor Xa inhibitors are substrates for P-glycoprotein. Consequently, potent inhibitors or inducers of P-glycoprotein will increase or decrease drug concentrations, respectively. Rivaroxaban and apixaban are metabolized by CYP3A4, whereas edoxaban undergoes only minimal CYP3A4-mediated metabolism. Plasma levels of rivaroxaban and apixaban are reduced by potent inducers of both P-glycoprotein and CYP3A4, such as carbamazepine, phenytoin, rifampin, and St. John's wort and increased by potent inhibitors, such as dronedarone, ketoconazole, itraconazole, ritonavir, clarithromycin, erythromycin, and cyclosporine.

Reversal Agents for Direct Oral Anticoagulants

Life-threatening bleeding can occur with the direct oral anticoagulants, and patients taking these drugs may require urgent surgery or interventions. Therefore, the availability of specific reversal agents streamlines the management of such patients. Idarucizumab, the reversal agent for dabigatran, is licensed. Andexanet alfa, a reversal agent for rivaroxaban, apixaban, and edoxaban, is in advanced phase 3 evaluation, while ciraparantag, a potential reversal agent for all of the direct anticoagulants, is at an earlier stage of development.

If specific reversal agents are not available, prothrombin complex concentrate, activated prothrombin complex concentrate, or recombinant factor VIIa have been recommended to manage patients taking dabigatran, rivaroxaban, apixaban, or edoxaban who present with life-threatening bleeding, such as intracranial or pericardial bleeding. In patients taking dabigatran who present with serious bleeding in the setting of acute renal failure, hemodialysis can be used to remove dabigatran from the circulation. Dialysis is of no value for removal of rivaroxaban, apixaban or edoxaban because of their higher protein binding.

Idarucizumab

A specific reversal agent for dabigatran, idarucizumab is a humanized mouse monoclonal antibody fragment directed against dabigatran. The antibody binds dabigatran with an affinity 350-fold higher than that of dabigatran for thrombin, and the essentially irreversible idarucizumab-dabigatran complex is cleared by the kidneys. Idarucizumab is infused as two intravenous boluses, each of 2.5 g. It rapidly reverses the anticoagulant effects of dabigatran, and patients have then safely undergone major surgery (Pollack et al., 2015).

Andexanet Alfa

Designed as a decoy for the oral factor Xa inhibitors, andexanet alfa is a recombinant analogue of factor Xa that has the active site serine residue replaced with an alanine residue to eliminate catalytic activity and the Gla domain removed to preclude its incorporation in the prothrombinase complex. Andexanet is administered as an intravenous bolus followed by a 2-h infusion. By sequestering circulating factor Xa inhibitors, andexanet rapidly reverses the anti-factor Xa activity produced by these agents and restores thrombin generation (Siegal et al., 2015). Higher doses of andexanet are needed to reverse rivaroxaban or edoxaban than apixaban. An ongoing phase 3 study is evaluating the effect of andexanet in patients taking these agents who present with serious bleeding.

Ciraparantag

Ciraparantag is a synthetic, small cationic molecule that is reported to bind dabigatran, rivaroxaban, apixaban, and edoxaban, as well as heparin and LMWH. In healthy volunteers given edoxaban, an intravenous bolus of ciraparantag restored the whole-blood clotting time to normal. Ciraparantag has yet to be evaluated in patients.

Fibrinolytic Drugs

Fibrinolytic drugs initiate the fibrinolytic pathway, which is summarized in Figure 32–3. These agents include recombinant t-PA and its variants, urokinase and streptokinase, although the latter are rarely used.

Tissue Plasminogen Activator

Tissue plasminogen activator is a serine protease and a poor plasminogen activator in the absence of fibrin. When bound to fibrin, t-PA activates fibrin-bound plasminogen several 100-fold more rapidly than it activates plasminogen in the circulation. Because it has little activity except in the presence of fibrin, physiological t-PA concentrations of 5–10 ng/mL do not induce systemic plasmin generation. With therapeutic infusion of recombinant t-PA, the concentrations rise to 300–3000 ng/mL, which can induce systemic fibrinogen degradation. Clearance of t-PA primarily occurs via hepatic metabolism, and its $t_{1/2}$ is about 5 min. t-PA is effective for treatment of acute myocardial infarction (Gara et al., 2013), acute ischemic stroke, and life-threatening pulmonary embolism (Meyer et al., 2014).

For coronary thrombolysis, t-PA is given as a 15-mg intravenous bolus, followed by 0.75 mg/kg over 30 min (not to exceed 50 mg) and 0.5 mg/kg (up to 35 mg accumulated dose) over the following hour. Recombinant variants of t-PA include *reteplase* and *tenecteplase*. They differ from native t-PA by having longer plasma half-lives that allow convenient bolus dosing. In addition, in contrast to t-PA, tenecteplase is relatively resistant to inhibition by PAI-1. Despite these apparent advantages, these agents are similar to t-PA in efficacy and toxicity.

Hemorrhagic Toxicity of Thrombolytic Therapy

The major toxicity of all thrombolytic agents is hemorrhage. It is due to (1) degradation of fibrin in hemostatic plugs at sites of vascular injury or (2) the systemic lytic state that results from the systemic generation of plasmin, which degrades fibrinogen and other coagulation factors, especially factors V and VIII. Contraindications to fibrinolytic therapy are listed in Table 32–3.

If heparin is used concurrently with t-PA, serious hemorrhage will occur in 2%–4% of patients. Intracranial hemorrhage is the most serious problem and can occur in up to 1% of patients. For this reason, mechanical reperfusion is preferred over systemic thrombolysis in patients with acute myocardial infarction with ST-segment elevation. In patients with acute ischemic stroke, the current standard of care is mechanical thrombus extraction, which can be done with or without adjunctive t-PA or tenecteplase.

TABLE 32–3 ■ ABSOLUTE AND RELATIVE CONTRAINDICATIONS TO FIBRINOLYTIC THERAPY

Absolute Contraindications

- Prior intracranial hemorrhage
- Known structural cerebral vascular lesion
- Known malignant intracranial neoplasm
- Ischemic stroke within 3 months
- Suspected aortic dissection
- Active bleeding or bleeding diathesis (excluding menses)
- Significant closed-head trauma or facial trauma within 3 months

Relative Contraindications

- Uncontrolled hypertension (systolic blood pressure > 180 mm Hg or diastolic blood pressure > 110 mm Hg)
- Traumatic or prolonged CPR or major surgery within 3 weeks
- Recent (within 2–4 weeks) internal bleeding
- Noncompressible vascular punctures
- For streptokinase: prior exposure (more than 5 days ago) or prior allergic reaction to streptokinase
- Pregnancy
- Active peptic ulcer
- Current use of warfarin and INR > 1.7

Inhibitors of Fibrinolysis

ε-Aminocaproic Acid and Tranexamic Acid

ε-Aminocaproic acid and tranexamic acid are lysine analogues that compete for lysine binding sites on plasminogen and plasmin, thereby blocking their interaction with fibrin. Therefore, these agents inhibit fibrinolysis and can reverse states that are associated with excessive fibrinolysis.

The main problem with their use is that thrombi that form during treatment are not degraded. For example, in patients with hematuria, ureteral obstruction by clots may lead to renal failure after treatment with ε-aminocaproic acid or tranexamic acid. ε-Aminocaproic acid has been used intravenously to reduce bleeding after prostatic surgery and orally to reduce bleeding after tooth extractions in hemophiliacs. ε-Aminocaproic acid is absorbed rapidly after oral administration, and 50% is excreted unchanged in the urine within 12 h. For intravenous use, a loading dose of 4–5 g is given over 1 h, followed by an infusion of 1–1.25 g/h until bleeding is controlled. No more than 30 g should be given in a 24-h period. Rarely, the drug causes myopathy and muscle necrosis.

Tranexamic acid is given intravenously in trauma resuscitation and in patients with massive hemorrhage (CRASH2 trial investigators, 2010). It is also used to reduce operative bleeding in patients undergoing hip or knee arthroplasty or cardiac surgery. There appears to be little or no increased risk of thrombosis. Tranexamic acid is excreted in the urine; therefore, dose reduction is necessary in patients with renal impairment. Oral tranexamic acid is approved for treatment of heavy menstrual bleeding, usually given at a dose of 1 g four times daily for 4 days.

Antiplatelet Drugs

Platelet aggregates form the initial hemostatic plug at sites of vascular injury. Platelets also contribute to the pathological thrombi that lead to myocardial infarction, stroke, and peripheral arterial thrombosis. Potent inhibitors of platelet function have been developed in recent years. These drugs act by discrete mechanisms (Figure 32–7); thus, in combination, their effects are additive or even synergistic.

Aspirin

In platelets, the major COX-1 product is TxA_2 , a labile inducer of platelet aggregation and a potent vasoconstrictor. Aspirin blocks production of TxA_2 by acetylating a serine residue near the active site of platelet COX-1. Because platelets do not synthesize new proteins, the action of aspirin on platelet COX-1 is permanent, lasting for the lifetime of the platelet (7–10 days). Thus, repeated doses of aspirin produce a cumulative effect on platelet function.

Complete inactivation of platelet COX-1 is achieved with a daily aspirin dose of 75 mg. Therefore, aspirin is maximally effective as an antithrombotic agent at doses much lower than those required for other actions of the drug. Numerous trials indicated that aspirin, when used as an antithrombotic drug, is maximally effective at doses of 50–325 mg/d. Higher doses do not improve efficacy and potentially are less efficacious because of inhibition of prostacyclin production, which can be largely spared by using lower doses of aspirin. Higher doses also increase toxicity, especially bleeding. Therefore, daily aspirin doses of 100 mg or less are used for most indications (Cohen et al., 2015; Ittaman et al., 2014). Nonsteroidal anti-inflammatory drugs that are reversible inhibitors of COX-1 have not been shown to have antithrombotic efficacy and in fact may even interfere with low-dose aspirin regimens (see Chapters 37 and 38).

Dipyridamole

Dipyridamole interferes with platelet function by increasing the intracellular concentration of cyclic AMP. This effect is mediated by inhibition of phosphodiesterase or by blockade of uptake of adenosine, thereby increasing the dwell time of adenosine at cell surface adenosine A_2 receptors that link to the stimulation of platelet adenylyl cyclase. Dipyridamole is a vasodilator that, in combination with warfarin, inhibits embolization

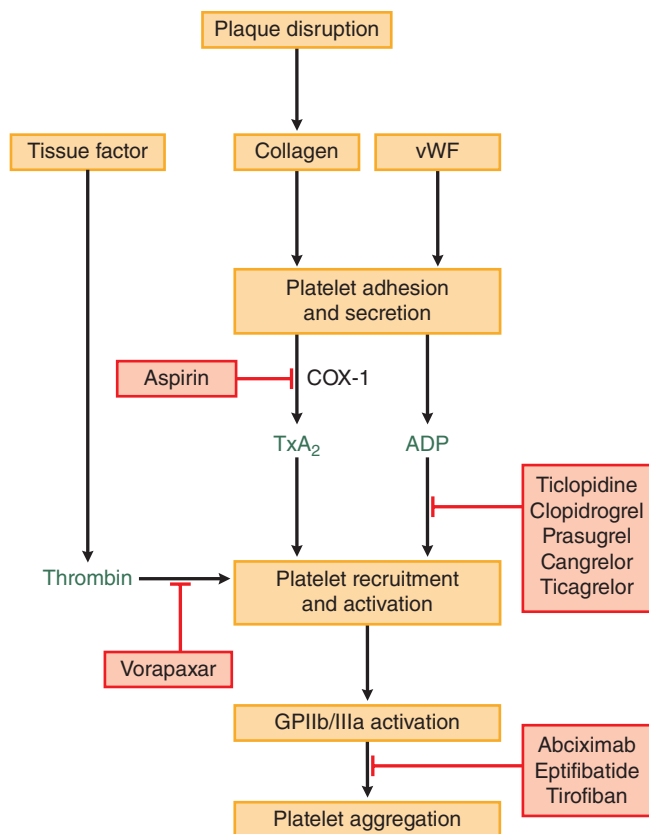

Figure 32-7 Sites of action of antiplatelet drugs. Aspirin inhibits TxA_2 synthesis by irreversibly acetylating COX-1. Reduced TxA_2 release attenuates platelet activation and recruitment to the site of vascular injury. Ticlopidine, clopidogrel, and prasugrel irreversibly block P2Y_{12} , a key ADP receptor on the platelet surface; cangrelor and ticagrelor are reversible inhibitors of P2Y_{12} . Abciximab, eptifibatide, and tirofiban inhibit the final common pathway of platelet aggregation by blocking fibrinogen and vWF from binding to activated GPIIb/IIIa. Vorapaxar inhibits thrombin-mediated platelet activation by targeting PAR-1, the major thrombin receptor on platelets.

from prosthetic heart valves. Dipyridamole is approved for secondary prevention of stroke when it is combined with low-dose aspirin.

P2Y₁₂ Receptor Antagonists

Clopidogrel

Clopidogrel is a thienopyridine prodrug that inhibits the P2Y_{12} receptor. Platelets contain two purinergic receptors, P2Y_1 and P2Y_{12} ; both are G protein-coupled receptors for ADP. The ADP-activated platelet P2Y_1 receptor couples to the G_q -PLC-IP₃-Ca²⁺ pathway and induces a shape change and aggregation. The P2Y_{12} receptor couples to G_i and, when activated by ADP, inhibits adenylyl cyclase, resulting in lower levels of intracellular cyclic AMP and thereby less cyclic AMP-dependent inhibition of platelet activation. Both receptors must be stimulated to result in maximal platelet activation.

Clopidogrel is an irreversible inhibitor of P2Y_{12} . It has largely replaced ticlopidine because clopidogrel is more potent and less toxic, with thrombocytopenia and leukopenia occurring only rarely. Clopidogrel is a pro-drug that requires metabolic activation in the liver. Therefore, it has a slow onset of action. It also has a slow offset of action because of its irreversible effect on P2Y_{12} . Metabolic activation of clopidogrel can be affected by polymorphisms in *CYP2C19* that result in reduced or absent *CYP2C19* activity. These polymorphisms contribute to the variable effect of clopidogrel on ADP-induced platelet aggregation. Inhibition of platelet activation is seen 2 h postingestion of a loading dose of clopidogrel, and platelets are affected for the remainder of their life span.

Therapeutic Uses. Clopidogrel is somewhat better than aspirin for secondary prevention of stroke, and the combination of clopidogrel plus aspirin is superior to aspirin alone for prevention of recurrent ischemia in patients with unstable angina. The FDA-approved indications for clopidogrel are to reduce the rate of stroke, myocardial infarction, and death in patients with recent myocardial infarction or stroke, established peripheral artery disease, or acute coronary syndrome (Amsterdam et al., 2014; Gara et al., 2013; Park et al., 2016; Roffi et al., 2015; Zhang et al., 2015). Clopidogrel is often used in combination with aspirin after coronary stent implantation.

Adverse Effects. Clopidogrel increases the risk of bleeding, particularly when combined with aspirin or an anticoagulant. Thrombotic thrombocytopenic purpura can occur but is rare.

Drug Interactions. CYP219 inhibition by proton pump inhibitors (e.g., omeprazole, lansoprazole, deslansprazole, and pantoprazole) may reduce conversion to the active metabolite of clopidogrel, which may contribute to the lower efficacy of clopidogrel when coadministered with proton pump inhibitors.

Prasugrel

The newest member of the thienopyridine class, prasugrel is a prodrug that requires metabolic activation in the liver. However, because the activation of prasugrel is more efficient than that of clopidogrel, prasugrel has a more rapid onset of action, and it produces greater and more predictable inhibition of ADP-induced platelet aggregation.

Prasugrel is rapidly and completely absorbed from the gut. It is hydrolyzed in the intestine to a thiolactone, which is then converted to the active metabolite in the liver. Virtually all of the absorbed prasugrel undergoes activation; by comparison, only 15% of absorbed clopidogrel undergoes metabolic activation. Because the active metabolites of prasugrel bind irreversibly to the P2Y_{12} receptor, its effect lasts the lifetime of the platelets. This slow offset of action can be problematic if patients require urgent surgery. Prasugrel is inactivated by methylation or conjugation with cysteine. Moderate renal or hepatic impairment does not appear to change the drug pharmacodynamics.

Therapeutic Uses. Prasugrel is indicated to reduce the rate of thrombotic cardiovascular events (including stent thrombosis) in patients with acute coronary syndrome who are managed with percutaneous coronary intervention (Gara et al., 2013; Guimaraes and Tricoci, 2015; Lhermusier and Waksman, 2015). The incidence of cardiovascular death, myocardial infarction, and stroke is significantly lower with prasugrel than with clopidogrel, mainly reflecting a reduction in the incidence of nonfatal myocardial infarction. The incidence of stent thrombosis is also lower with prasugrel than with clopidogrel.

Adverse Effects. Prasugrel is associated with higher rates of fatal and life-threatening bleeding than clopidogrel. Because patients with a history of a prior stroke or transient ischemic attack are at particularly high risk of intracranial bleeding, the drug is contraindicated in such patients. Patients over 75 years of age should not be prescribed prasugrel because of the increased bleeding risk. After a loading dose of 60 mg, prasugrel is given once daily at a dose of 10 mg. The daily dose should be reduced to 5 mg in patients weighing less than 60 kg. No dose adjustment is required in patients with hepatic or renal impairment. If patients present with serious bleeding, platelet transfusion may be beneficial. Prasugrel has been reported to cause thrombotic thrombocytopenic purpura.

Drug Interactions. Concomitant administration of prasugrel with an anticoagulant or nonsteroidal anti-inflammatory drugs increases the risk of bleeding.

Ticagrelor

Ticagrelor is an orally active, reversible inhibitor of P2Y_{12} . The drug is given twice daily and not only has a more rapid onset and offset of action than clopidogrel, but also produces greater and more predictable inhibition of ADP-induced platelet aggregation. The bioavailability of ticagrelor is about 36%. It can be given as a whole tablet or crushed in water and administered via a nasogastric tube. Ticagrelor is metabolized by hepatic CYP3A4.

Therapeutic Uses. Ticagrelor is FDA-approved for reduction in the risk of cardiovascular death, myocardial infarction, and stroke in patients with acute coronary syndrome (Gara et al., 2013) or a history of myocardial infarction (Dobesh and Oestreich, 2014). In contrast to prasugrel in patients with acute coronary syndrome, which is only indicated in those undergoing percutaneous intervention, ticagrelor is indicated in those undergoing intervention and in those managed medically.

Adverse Effects. Dyspnea is reported in 17% of patients. This is often transient and not associated with pulmonary disease. Ticagrelor is associated with a higher risk of intracranial bleeding than clopidogrel and is contraindicated in patients with a history of prior intracranial bleeding. Platelet transfusion is ineffective in patients taking ticagrelor who present with serious bleeding, and a neutralizing antibody is under investigation for urgent reversal.

Drug Interactions. Concomitant aspirin at a dose greater than 100 mg daily may reduce the effectiveness of ticagrelor. Potent inhibitors of CYP3A (such as ketoconazole, itraconazole, voriconazole, clarithromycin, nefazodone, ritonavir, saquinavir, nelfinavir, indinavir, atazanavir, and telithromycin) and strong inducers of CYP3A (such as rifampin, phenytoin, carbamazepine, and phenobarbital) should be avoided. Ticagrelor increases serum concentrations of simvastatin and lovastatin and may affect digoxin metabolism.

Cangrelor

Cangrelor is a parenteral reversible inhibitor of P2Y₁₂. When administered intravenously as a bolus followed by an infusion, cangrelor inhibits ADP-induced platelet aggregation within minutes, and its effect on platelet aggregation disappears within 1 h of discontinuation of the drug. Cangrelor has a short half-life because it is rapidly dephosphorylated in the circulation to an inactive metabolite.

Therapeutic Use. Cangrelor is indicated for reduction in the risk of periprocedural myocardial infarction, repeat coronary revascularization, and stent thrombosis in patients undergoing percutaneous coronary intervention who have not been treated with an oral P2Y₁₂ inhibitor and are not given a glycoprotein IIb/IIIa antagonist (Keating et al., 2015).

Adverse Effects. The risk of bleeding with cangrelor is greater than that with clopidogrel during the coronary intervention.

Drug Interactions. Coadministered clopidogrel or prasugrel will have no antiplatelet effect. Administration of ticagrelor, prasugrel, or clopidogrel should be delayed until the cangrelor infusion is stopped.

Thrombin Receptor Inhibitor

There are two major thrombin receptors on the platelet surface, PAR-1 and PAR-4, respectively. Thrombin binds to these G protein-coupled receptors and cleaves them at their amino terminals. The newly created amino terminals then serve as tethered ligands to activate the receptors. PAR-1 is activated by lower concentrations of thrombin than are required to activate PAR-4.

Vorapaxar

Vorapaxar is a competitive antagonist of PAR-1 and inhibits thrombin-induced platelet aggregation. The drug is 90% bioavailable and has a rapid onset of action and a circulating half-life of 3 or 4 days. However, because vorapaxar remains tightly bound to PAR-1 on platelets,

its effect on thrombin-induced platelet aggregation can persist for up to 4 weeks after the drug is stopped. Vorapaxar is metabolized in the liver by CYP3A4.

Therapeutic Uses. Vorapaxar is given orally in combination with either aspirin or clopidogrel. It is indicated for the reduction of thrombotic cardiovascular events in patients with a history of myocardial infarction or peripheral artery disease (Arif et al., 2015; Moschonas et al., 2015).

Adverse Effects. Vorapaxar increases the risk of bleeding and is contraindicated in patients with a history of intracranial bleeding, stroke, or transient ischemic attack.

Drug Interactions. Potent CYP3A4 inducers, such as rifampin, reduce drug exposure, while strong CYP3A4 inhibitors, such as ketoconazole, increase drug exposure. Antacids and pantoprazole reduce drug exposure.

Glycoprotein IIb/IIIa Inhibitors

Glycoprotein IIb/IIIa is a platelet-surface integrin, designated $\alpha_{IIb}\beta_3$ by the integrin nomenclature. This dimeric glycoprotein undergoes a conformational transformation when platelets are activated to serve as a receptor for fibrinogen and von Willebrand factor, which anchor platelets to each other, thereby mediating aggregation (Figure 32-1). Thus, inhibitors of this receptor are potent antiplatelet agents that act by a mechanism distinct from that of aspirin or P2Y₁₂ or PAR-1 inhibitors. Three agents are approved for use at present; their features are highlighted in Table 32-4. The use of these agents has decreased with the availability of potent P2Y₁₂ inhibitors such as prasugrel and ticagrelor.

Abciximab

Abciximab is the Fab fragment of a humanized monoclonal antibody directed against the $\alpha_{IIb}\beta_3$ receptor. It also binds to the vitronectin receptor on platelets, vascular endothelial cells, and smooth muscle cells.

The antibody is administered to patients undergoing percutaneous coronary intervention and, when used in conjunction with aspirin and heparin, has been shown to prevent recurrent myocardial infarction and death (Gara et al., 2013; Roffi et al., 2015). The $t_{1/2}$ of the circulating antibody is about 30 min, but antibody remains bound to the $\alpha_{IIb}\beta_3$ receptor and inhibits platelet aggregation as measured in vitro for 18–24 h after infusion. It is given as a 0.25-mg/kg bolus followed by an infusion of 0.125 μ g/kg/min (maximum 10 μ g/kg/min) for 12 to 24 h.

Adverse Effects. The major side effect of abciximab is bleeding, and the contraindications to its use are similar to those for the fibrinolytic agents listed in Table 32-4. The frequency of major hemorrhage in clinical trials varies from 1% to 10%, depending on the intensity of concomitant anticoagulation with heparin. Thrombocytopenia with a platelet count below 50,000 occurs in about 2% of patients and may be due the formation of antibodies directed against neopeptides induced by bound antibody. Because the duration of action is long, if major bleeding occurs, platelet transfusion may reverse the aggregation defect because free antibody concentrations fall rapidly after cessation of infusion.

Eptifibatide

Eptifibatide is a cyclic peptide inhibitor of the fibrinogen binding site on $\alpha_{IIb}\beta_3$. It is administered intravenously and blocks platelet aggregation. In patients undergoing percutaneous coronary intervention,

TABLE 32-4 ■ FEATURES OF GPIIb/IIIa ANTAGONISTS

FEATURE	ABCIXIMAB	EPTIFIBATIDE	TIROFIBAN
Description	Fab fragment of humanized mouse monoclonal antibody	Cyclical KGD-containing heptapeptide	Nonpeptidic RGD-mimetic
Specific for GPIIb/IIIa	No	Yes	Yes
Plasma $t_{1/2}$	Short (minutes)	Long (2.5 h)	Long (2.0 h)
Platelet-bound $t_{1/2}$	Long (days)	Short (seconds)	Short (seconds)
Renal clearance	No	Yes	Yes

eptifibatide is typically given as a double intravenous bolus of 180 µg/kg (spaced 10 min apart), followed by an infusion of 2 µg/kg/min for 18 to 24 h. The drug is cleared by the kidneys and has a short plasma half-life of 10 to 15 min. Like abciximab, eptifibatide is mainly used in patients undergoing primary percutaneous coronary intervention for acute ST-segment elevation myocardial infarction, although it also can be used in patients with unstable angina.

Adverse Effects. The major side effect is bleeding. Thrombocytopenia occurs in 0.5%–1% of patients and is less frequent than with abciximab.

Tirofiban

Tirofiban is an intravenously administered nonpeptide, small-molecule inhibitor of $\alpha_{\text{IIb}}\beta_3$. It has a short duration of action and is used for management of patients with non-ST-segment elevation acute coronary syndrome. Tirofiban is administered as an intravenously bolus of 25 µg/kg followed by an infusion of 0.15 µg/kg/min for up to 18 h. The infusion dose is reduced by half in patients with a creatinine clearance below 60 mL/min. Like the other agents in this class, the major side effect of tirofiban is bleeding, and it may induce thrombocytopenia.

The Role of Vitamin K

Green plants are a nutritional source of vitamin K for humans, in whom vitamin K is an essential cofactor in the γ -carboxylation of multiple glutamate residues of several clotting factors and anticoagulant proteins. The vitamin K-dependent formation of Gla residues permits the appropriate interactions of clotting factors, Ca^{2+} , and membrane phospholipids and modulator proteins (see Figures 32–1, 32–2, and 32–3). Vitamin K antagonists (coumarin derivatives) block Gla formation and thereby inhibit clotting; excess vitamin K_1 can reverse the effects.

Vitamin K activity is associated with at least two distinct natural substances, designated as vitamin K_1 and vitamin K_2 . Vitamin K_1 , or *phytonadione* (also referred to as *phylloquinone*), is 2-methyl-3-phytyl-1,4-naphthoquinone; it is found in plants and is the only natural vitamin K available for therapeutic use. Vitamin K_2 actually is a series of compounds (the *menaquinones*) in which the phytyl side chain of phytonadione has been replaced by a side chain built up of 2–13 prenyl units. Considerable synthesis of menaquinones occurs in gram-positive bacteria; indeed, intestinal flora synthesizes the large amounts of vitamin K contained in human and animal feces. Menadione is at least as active on a molar basis as phytonadione.

PHYTONADIONE (vitamin K_1 , phylloquinone)

Physiological Functions and Pharmacological Actions

Phytonadione and menaquinones promote the biosynthesis of the clotting factors II (prothrombin), VII, IX, and X as well as the anticoagulant proteins C and S and protein Z (a cofactor to the inhibitor of Xa).

Figure 32–6 summarizes the coupling of the vitamin K cycle with glutamate carboxylation. The γ -glutamyl carboxylase and epoxide reductase are integral membrane proteins of the endoplasmic reticulum and function as a multicomponent complex. With respect to proteins affecting blood coagulation, these reactions occur in the liver, but γ -carboxylation of glutamate also occurs in lung, bone, and other cell types. Mutations in γ -glutamyl carboxylase lead to bleeding disorders.

Human Requirements

In patients rendered vitamin K deficient by a starvation diet and antibiotic therapy for 3–4 weeks, the minimum daily requirement is estimated to

be 0.03 µg/kg of body weight and possibly as high as 1 µg/kg, which is approximately the recommended intake for adults (70 µg/d).

Symptoms of Deficiency

The major clinical manifestation of vitamin K deficiency is bleeding. Ecchymoses, epistaxis, hematuria, GI bleeding, and postoperative hemorrhage are common; intracranial hemorrhage may occur. Hemoptysis is uncommon. The presence of vitamin K-dependent proteins in bone such as osteocalcin and matrix Gla protein may explain why fetal bone abnormalities can occur with maternal warfarin administration in the first trimester of pregnancy. Vitamin K plays a role in adult skeletal maintenance and the prevention of osteoporosis. Low concentrations of the vitamin are associated with decreased bone mineral density and subsequent fractures; vitamin K supplementation increases the carboxylation state of osteocalcin and improves bone mineral density, but the relationship between these effects is unclear. Bone mineral density in adults does not appear to be changed with long-term warfarin therapy, but new bone formation may be affected.

Toxicity

Phytonadione and the menaquinones are nontoxic. Menadione and its derivatives (synthetic forms of vitamin K) may produce hemolytic anemia and kernicterus in neonates and should not be used as therapeutic forms of vitamin K.

ADME

The mechanism of intestinal absorption of compounds with vitamin K activity varies depending on their solubility. In the presence of bile salts, phytonadione and the menaquinones are adequately absorbed from the intestine, phytonadione by an energy-dependent, saturable process in proximal portions of the small intestine and menaquinones by diffusion in the distal small intestine and the colon. After absorption, phytonadione is incorporated into chylomicrons in close association with triglycerides and lipoproteins. The low phytonadione levels in newborns may partly reflect the low plasma lipoprotein concentrations at birth and may lead to an underestimation of vitamin K tissue stores. After absorption, phytonadione and menaquinones are concentrated in the liver, but the concentration of phytonadione declines rapidly. Menaquinones, produced in the distal bowel, are less biologically active because of their long side chain. Very little vitamin K accumulates in other tissues. There is only modest storage of vitamin K in the body. Consequently, when lack of bile interferes with absorption of vitamin K, there is progressive reduction in the levels of the vitamin K-dependent clotting factors over the course of several weeks.

Therapeutic Uses

Vitamin K is used therapeutically to correct the bleeding tendency or hemorrhage associated with its deficiency. Vitamin K deficiency can result from inadequate intake, absorption, or utilization of the vitamin or as a consequence of the action of warfarin.

Phytonadione is available in tablet form and in a dispersion with buffered polysorbate and propylene glycol or polyoxyethylated fatty acid derivatives and dextrose. Phytonadione may be given by any route; however, the subcutaneous route should be avoided in patients with a coagulopathy because of the risk of bleeding. The oral route is preferred, but if more rapid reversal is required, phytonadione can be given by slow intravenous infusion; it should not be given rapidly because severe reactions resembling anaphylaxis can occur.

Inadequate Intake

After infancy, hypoprothrombinemia due to dietary deficiency of vitamin K is extremely rare. The vitamin is present in many foods and is synthesized by intestinal bacteria. Occasionally, the use of a broad-spectrum antibiotic may itself produce hypoprothrombinemia that responds readily to small doses of vitamin K and reestablishment of normal bowel flora. Hypoprothrombinemia can occur in patients receiving prolonged intravenous alimentation; to prevent this, it is recommended that such patients receive 1 mg of phytonadione per week (the equivalent of about 150 µg/day).

Hypoprothrombinemia of the Newborn

Healthy newborn infants have decreased plasma concentrations of vitamin K–dependent clotting factors for a few days after birth, the time required for adequate dietary intake of the vitamin and for establishment of normal intestinal flora. Measurements of non- γ -carboxylated prothrombin suggest that vitamin K deficiency occurs in about 3% of live births.

Hemorrhagic disease of the newborn has been associated with breastfeeding; human milk has low concentrations of vitamin K. In addition, the microbiome of breast-fed infants may lack microorganisms that synthesize the vitamin. Commercial infant formulas are supplemented with vitamin K. In the neonate with hemorrhagic disease of the newborn, administration of vitamin K raises the concentration of these clotting factors to levels normal for newborns and controls the bleeding tendency within about 6 h. Routine administration of 1 mg phytonadione intramuscularly at birth is required by law in the U.S. The dose may have to be increased or repeated if the mother has received warfarin or anticonvulsant drug therapy or if the infant develops a bleeding diathesis. Alternatively, some clinicians treat mothers who are receiving anticonvulsants with oral vitamin K prior to delivery (20 mg/d for 2 weeks).

Inadequate Absorption

Vitamin K is poorly absorbed in the absence of bile. Thus, hypoprothrombinemia may be associated with intrahepatic or extrahepatic biliary obstruction or with defective intestinal absorption of fat from other causes.

Biliary Obstruction or Fistula

Bleeding that accompanies obstructive jaundice or a biliary fistula responds promptly to the administration of vitamin K. Oral phytonadione administered with bile salts is both safe and effective and should be used in the care of the jaundiced patient, both preoperatively and postoperatively. In the

absence of significant hepatocellular disease, the prothrombin level rapidly returns to normal. If oral administration is not feasible, a parenteral preparation should be used. The usual daily dose of vitamin K is 10 mg.

Malabsorption Syndromes

Among the disorders that result in inadequate absorption of vitamin K from the intestinal tract are cystic fibrosis, celiac disease, Crohn disease, ulcerative colitis, dysentery, and extensive resection of bowel. Because drugs that reduce the bacterial population of the bowel are used frequently in many of these disorders, the availability of the vitamin may be further reduced. For immediate correction of the deficiency, parenteral vitamin K should be given.

Inadequate Utilization

Hepatocellular disease or long-standing biliary obstruction may be accompanied or followed by hypoprothrombinemia. If inadequate secretion of bile salts is contributing to the syndrome, some benefit may be obtained from the parenteral administration of 10 mg of phytonadione daily. Paradoxically, administration of large doses of vitamin K or its analogues in an attempt to correct the hypoprothrombinemia can be associated with severe hepatitis or cirrhosis, which may contribute to a further reduction in the level of prothrombin.

Drug- and Venom-Induced Hypoprothrombinemia

Warfarin and its congeners act as competitive antagonists of vitamin K and interfere with the hepatic biosynthesis of Gla-containing clotting factors. The treatment of bleeding caused by oral anticoagulants was described previously. Vitamin K may be of help in combating the bleeding and hypoprothrombinemia that follow the bite of the tropical American pit viper or other species whose venom degrades or inactivates prothrombin.

Drug Facts for Your Personal Formulary: Agents That Modify Blood Coagulation

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Unfractionated Heparin		
Heparin	<ul style="list-style-type: none"> • Prophylaxis/treatment of venous thromboembolism • Acute coronary syndrome • Percutaneous coronary intervention • Cardiopulmonary bypass surgery • Disseminated intravascular coagulation 	<ul style="list-style-type: none"> • Administered SC 2–3 times daily for thromboprophylaxis • Administered IV for immediate onset of action with aPTT monitoring • Can be used in renal impairment • Can be used in pregnancy
Low-Molecular-Weight Heparin		
Enoxaparin Dalteparin Tinzaparin (not in the U.S.)	<ul style="list-style-type: none"> • Prophylaxis against venous thrombosis • Initial treatment of venous thromboembolism • Maintenance treatment in patients with cancer-associated venous thromboembolism • Acute coronary syndrome 	<ul style="list-style-type: none"> • Administered SC once or twice daily • Routine anti-factor Xa monitoring not required • Dosage adjustment required when CrCL < 30 mL/min • Can be used in pregnancy
Fondaparinux		
Fondaparinux	<ul style="list-style-type: none"> • Prophylaxis against venous thromboembolism • Initial treatment of venous thromboembolism • Heparin-induced thrombocytopenia • Acute coronary syndrome in some countries 	<ul style="list-style-type: none"> • Once-daily SC injection • Lower dose used for thromboprophylaxis and in acute coronary syndrome • Contraindicated if CrCL < 30 mL/min • Use in pregnancy less established than for low-molecular-weight heparin • Routine anti-factor Xa monitoring not required
Other Anticoagulants		
Desirudin	<ul style="list-style-type: none"> • Thromboprophylaxis after hip arthroplasty 	<ul style="list-style-type: none"> • Twice-daily SC injection • Dosage adjustment required with renal impairment
Bivalirudin	<ul style="list-style-type: none"> • Percutaneous coronary intervention • Heparin-induced thrombocytopenia 	<ul style="list-style-type: none"> • Administered IV • ACT or aPTT monitoring • Requires dose reduction with renal impairment
Argatroban	<ul style="list-style-type: none"> • Heparin-induced thrombocytopenia 	<ul style="list-style-type: none"> • Hepatic metabolism • Can be used in renal impairment • Increases INR, which can complicate transition to warfarin

Vitamin K Antagonist		
Warfarin	<ul style="list-style-type: none"> • Treatment of venous thromboembolism in tandem with parenteral anticoagulation • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Prevention of stroke in patient with mechanical heart valves or ventricular assist devices 	<ul style="list-style-type: none"> • Oral vitamin K antagonist • Narrow therapeutic index • Requires regular INR monitoring • Multiple drug interactions • Dietary vitamin K interactions • Can be used in renal failure • Contraindicated in pregnancy
Direct Oral Thrombin Inhibitor		
Dabigatran etexilate	<ul style="list-style-type: none"> • Treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Thromboprophylaxis after hip or knee arthroplasty 	<ul style="list-style-type: none"> • Fixed twice-daily oral dosing (once daily if used for thromboprophylaxis) • Reduce the dose with CrCL 15–30 mL/min • Contraindicated if CrCL < 15 mL/min • Use with caution in patients with recent bleeding, especially GI bleeding • Can be reversed with idarucizumab
Direct Oral Factor Xa Inhibitors		
Rivaroxaban	<ul style="list-style-type: none"> • Treatment of acute venous thromboembolism • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Thromboprophylaxis after hip or knee arthroplasty • Prevention of recurrent ischemia in stabilized acute coronary syndrome patients (not in North America) 	<ul style="list-style-type: none"> • Fixed oral dosing (once daily with the exception of initial treatment of venous thromboembolism, which starts with twice-daily dosing for 21 days and once daily thereafter, or secondary prevention after acute coronary syndrome where the drug is given twice daily) • Avoid in patients with renal/hepatic dysfunction • Use with caution in patients with recent bleeding, especially GI bleeding
Apixaban	<ul style="list-style-type: none"> • Treatment of acute venous thromboembolism • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation • Thromboprophylaxis after hip or knee arthroplasty 	<ul style="list-style-type: none"> • Fixed oral dosing (twice daily, higher dose for the first 7 days for acute venous thromboembolism) • Reduce dose for stroke prophylaxis if any two of age > 80 years, body weight < 60 kg, or serum creatinine \geq 1.5 mg/dL • Use with caution in patients with recent bleeding, especially GI bleeding
Edoxaban	<ul style="list-style-type: none"> • Treatment of acute venous thromboembolism after at least 5 days of parenteral anticoagulation • Secondary prevention of venous thromboembolism • Prevention of stroke in atrial fibrillation 	<ul style="list-style-type: none"> • Fixed once-daily dosing • Reduce the dose if any of CrCL 15–50 mL/min, body weight < 60 kg, or concomitant potent P-glycoprotein inhibitor • Not recommended for patients with CrCL < 15 mL/min • Contraindicated if CrCL > 95 mL/min • Use with caution in patients with recent bleeding, especially GI bleeding
Reversal Agents for Direct Oral Anticoagulants		
Idarucizumab	<ul style="list-style-type: none"> • Reversal of dabigatran 	<ul style="list-style-type: none"> • Humanized Fab fragment against dabigatran • Bolus IV administration • Rapid and complete reversal
Andexanet alfa	<ul style="list-style-type: none"> • Reversal of rivaroxaban, apixaban, or edoxaban 	<ul style="list-style-type: none"> • Recombinant analogue of factor Xa • Acts as a decoy for oral factor Xa inhibitors • Given as IV bolus followed by 2-h IV infusion • In phase 3 evaluation
Ciraparantag	<ul style="list-style-type: none"> • Reversal of dabigatran, rivaroxaban, apixaban, or edoxaban 	<ul style="list-style-type: none"> • Synthetic small molecule • Binds target drugs • In phase 2 evaluation
Fibrinolytic Drugs		
Alteplase	<ul style="list-style-type: none"> • Thrombolysis in acute ischemic stroke, massive pulmonary embolism, or myocardial infarction 	<ul style="list-style-type: none"> • IV bolus followed by an infusion • Risk of major bleeding, including intracranial bleeding

ATHEROSCLEROTIC CARDIOVASCULAR DISEASE RISK ASSESSMENT

STATIN DRUG THERAPY

NONSTATIN DRUG THERAPIES

- Bile Acid Sequestrants
- Niacin (Nicotinic Acid)
- Fibrin Acid Derivatives
- Inhibitor of Cholesterol Absorption
- Omega-3 Fatty Acid Ethyl Esters
- PCSK9 Inhibitors
- Inhibitor of Microsomal Triglyceride Transfer
- Inhibitor of Apolipoprotein B-100 Synthesis

Dyslipidemia is a major cause of ASCVDs, such as CHD, ischemic cerebrovascular disease, and peripheral vascular disease. Cardiovascular disease represents the number one cause of death among adults in many developed nations (Mozaffarian et al., 2015). Both genetic disorders and lifestyle contribute to the dyslipidemias, including hypercholesterolemia and low levels of HDL-C.

Classes of drugs that modify cholesterol levels include the following:

- Inhibitors of HMG-CoA reductase (*statins*)
- Bile acid-binding resins
- Nicotinic acid (*niacin*)
- Fibrin acid derivatives (*fibrates*)
- Inhibitor of cholesterol absorption (*ezetimibe*)
- Omega-3 fatty acid ethyl esters (fish oil)
- PCSK9 inhibitors
- MTP inhibitor (*lomitapide*)
- Inhibitor of apolipoprotein B-100 synthesis (*mipomersen*)

The 2014 ACC/AHA Guideline on the Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults (Stone et al., 2014) recommends a substantial shift in approach to cholesterol management compared to the ATPIII (Grundy et al., 2004; NCEP, 2002). Whereas ATPIII advocated treating to specific lipoprotein targets, the 2014 ACC/AHA guideline focuses on offering fixed doses of statins to patients in four statin benefit groups to reduce morbidity and mortality. Since the 2014 release of the ACC/AHA guideline, several additional expert consensus recommendations have been published, providing alternative opinions on cholesterol management (Jacobson et al., 2015) and recommendations regarding the role of nonstatin cholesterol treatments (Lloyd-Jones et al., 2016) in reduction of ASCVD risk (see Table 33-1).

Plasma Lipoprotein Metabolism

Lipoproteins are macromolecular assemblies that contain lipids and proteins. The lipid constituents include free and esterified cholesterol, triglycerides, and phospholipids. The protein components, known as *apolipoproteins* or *apoproteins*, provide structural stability to the lipoproteins and also may function as ligands in lipoprotein-receptor interactions or as cofactors in enzymatic processes that regulate lipoprotein

metabolism. The major classes of lipoproteins and their properties are summarized in Table 33-2. Apoproteins have well-defined roles in plasma lipoprotein metabolism (Table 33-3). Mutations in lipoproteins or their receptors can lead to familial dyslipidemias and premature death due to accelerated atherosclerosis.

In all spherical lipoproteins, the most water-insoluble lipids (cholesteryl esters and triglycerides) are core components, and the more polar, water-soluble components (apoproteins, phospholipids, and unesterified cholesterol) are located on the surface. Except for apo(a), the lipid-binding regions of all apoproteins contain amphipathic helices that interact with the polar, hydrophilic lipids (such as surface phospholipids) and with the aqueous plasma environment in which the lipoproteins circulate. Differences in the non-lipid-binding regions determine the functional specificities of the apolipoproteins.

Figure 33-1 summarizes the pathways involved in the uptake and transport of dietary fat and cholesterol, pathways that involve the lipoprotein structures described next.

Chylomicrons

Chylomicrons are synthesized from the fatty acids of dietary triglycerides and cholesterol absorbed by epithelial cells in the small intestine. Chylomicrons are the largest and lowest-density plasma lipoproteins. In normolipidemic individuals, chylomicrons are present in plasma for 3–6 h after a fat-containing meal has been ingested. Intestinal cholesterol absorption is mediated by *NPC1L1*, which appears to be the target of *ezetimibe*, a cholesterol absorption inhibitor.

After their synthesis in the endoplasmic reticulum, triglycerides are transferred by *MTP* to the site where newly synthesized apo B-48 is available to form chylomicrons. Apo B-48, synthesized only by intestinal epithelial cells, is unique to chylomicrons and functions primarily as a structural component of chylomicrons. Dietary cholesterol is esterified by the ACAT-2. ACAT-2 is found in the intestine and in the liver, where cellular free cholesterol is esterified before triglyceride-rich lipoproteins (chylomicrons and *VLDLs*) are assembled.

After entering the circulation via the thoracic duct, chylomicrons are metabolized initially at the capillary luminal surface of tissues that synthesize LPL (see Figure 33-1), including adipose tissue, skeletal and cardiac muscle, and breast tissue of lactating women. The resulting free fatty acids are taken up and used by the adjacent tissues. The interaction of chylomicrons and LPL requires apo C-II as a cofactor.

Abbreviations

ACAT-2: type 2 isozyme of acyl coenzyme A:cholesterol acyltransferase
ACC: American College of Cardiology
AHA: American Heart Association
ALT: alanine aminotransferase
apo(a): apolipoprotein (a)
ASCVD: atherosclerotic cardiovascular disease
AST: aspartate aminotransferase
ATPIII: 2002 Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults
CETP: cholesteryl ester transfer protein
CHD: coronary heart disease
DHA: docosahexaenoic acid
DM: diabetes mellitus
EPA: eicosapentaenoic acid
ER: extended release
FH: familial hypercholesterolemia
FRS: Hard CHD Framingham Risk Score
HDL: high-density lipoprotein
HDL-C: high-density lipoprotein cholesterol
heFH: heterozygous familial hypercholesterolemia
HL: hepatic lipase
HMG-CoA: 3-hydroxy-3-methylglutaryl coenzyme A
hoFH: homozygous familial hypercholesterolemia
HSL: hormone-sensitive lipase
IDL: intermediate-density lipoprotein
LCAT: lecithin:cholesterol acyltransferase
LDL: low-density lipoprotein
LDL-C: low-density lipoprotein cholesterol
LDLR: LDL receptor
LP(a): lipoprotein (a)
LPL: lipoprotein lipase
LRP: LDL receptor-related protein
MTP: microsomal triglyceride transfer protein
NCEP: National Cholesterol Education Program
NHLBI: National Heart, Lung, and Blood Institute
NLA: National Lipid Association
NPC1L1: Niemann-Pick C1-like 1 protein
OTC: over the counter
PCE: pooled cohort equation
PCSK9: proprotein convertase subtilisin/kexin type 9
PPAR: peroxisome proliferator-activated receptor
SR: scavenger receptor
SREBP: sterol regulatory element-binding protein
USPSTF: U.S. Preventive Services Task Force
VLDL: very low-density lipoprotein

Chylomicron Remnants

After LPL-mediated removal of much of the dietary triglycerides, the *chylomicron remnants*, with all of the dietary cholesterol, detach from the capillary surface and within minutes are removed from the circulation by the liver (see Figure 33-1). First, the remnants are sequestered by the interaction of apo E with heparan sulfate proteoglycans on the surface of hepatocytes and are processed by *HL*, further reducing the remnant triglyceride content. Next, apo E mediates remnant uptake by interacting with the hepatic *LDL* receptor or the *LRP*.

During the initial hydrolysis of chylomicron triglycerides by LPL, apo A-I and phospholipids are shed from the surface of chylomicrons and remain in the plasma. This is one mechanism by which nascent

(precursor) HDL are generated. Chylomicron remnants are not precursors of LDL, but the dietary cholesterol delivered to the liver by remnants increases plasma LDL levels by reducing LDL receptor-mediated catabolism of LDL by the liver.

Very Low-Density Lipoproteins

The VLDLs are produced in the liver when triglyceride production is stimulated by an increased flux of free fatty acids or by increased *de novo* synthesis of fatty acids by the liver. Apo B-100, apo E, and apo C-I, C-II, and C-III are synthesized constitutively by the liver and incorporated into VLDLs (see Table 33-3). Triglycerides are synthesized in the endoplasmic reticulum, and along with other lipid constituents, are transferred by MTP to the site in the endoplasmic reticulum where newly synthesized apo B-100 is available to form nascent (precursor) VLDL. Small amounts of apo E and the C apoproteins are incorporated into nascent particles within the liver before secretion, but most of these apoproteins are acquired from plasma HDL after the VLDLs are secreted by the liver. Mutations of MTP that result in the inability of triglycerides to be transferred to either apo B-100 in the liver or apo B-48 in the intestine prevent VLDL and chylomicron production and cause the genetic disorder *abetalipoproteinemia*.

Plasma VLDL is catabolized by LPL in the capillary beds in a process similar to the lipolytic processing of chylomicrons (see Figure 33-1). When triglyceride hydrolysis is nearly complete, the VLDL remnants, usually termed *IDLs*, are released from the capillary endothelium and reenter the circulation. Apo B-100-containing small VLDLs and IDLs, which have a $t_{1/2}$ of less than 30 min, have two potential fates. About 40%–60% are cleared from the plasma by the liver via apo B-100- and apo E-mediated interaction with LDL receptors and LRP. LPL and HL convert the remainder of the IDLs to LDLs by removal of additional triglycerides. The C apoproteins, apo E, and apo A-V redistribute to HDL.

Apolipoprotein E plays a major role in the metabolism of triglyceride-rich lipoproteins (chylomicrons, chylomicron remnants, VLDLs, and IDLs). About half of the apo E in the plasma of fasting subjects is associated with triglyceride-rich lipoproteins, and the other half is a constituent of HDL.

Low-Density Lipoproteins

Virtually all of the LDL particles in the circulation are derived from VLDL. The LDL particles have a $t_{1/2}$ of 1.5–2 days. In subjects without

Figure 33-1 The major pathways involved in the metabolism of chylomicrons synthesized by the intestine and VLDL synthesized by the liver. Chylomicrons are converted to chylomicron remnants by the hydrolysis of their triglycerides by LPL. Chylomicron remnants are rapidly cleared from the plasma by the liver. “Remnant receptors” include the LRP, LDL receptors, and perhaps other receptors. FFA released by LPL is used by muscle tissue as an energy source or taken up and stored by adipose tissue.

TABLE 33-1 ■ COMPARISON OF KEY CLINICAL GUIDELINES FOR THE MANAGEMENT OF CHOLESTEROL IN ADULTS

	ATPIII 2004	ACC/AHA 2014	NLA 2015	USPSTF 2016
Risk assessment strategy	10-year FRS; CHD risk factors	10-year PCE	ASCVD risk factors used; FRS, PCE, or other	10-year PCE
Candidates for treatment	Patients above LDL goal	Patients in four statin benefit groups	Patients above LDL goal	Primary prevention in patients with risk
Recommended statin intensity	Titrated to achieve LDL goal	Moderate-to-high intensity	Titrated to achieve LDL goal	Low-to-moderate intensity
Recommendations	<p><i>Risk groups and LDL goals:</i></p> <ul style="list-style-type: none"> High risk (LDL goal < 100, < 70 optional) if CHD, risk equivalent, or FRS ≥ 20% Moderate-high risk (LDL goal < 130, < 100 optional) if ≥ 2 risk factors or FRS 10% to < 20% Moderate risk (LDL goal < 130, therapy started if LDL > 160) if ≥ 2 risk factors or FRS < 10% Lower risk (LDL goal < 160, therapy started if LDL > 190) if 0 or 1 risk factor 	<p><i>Four statin benefit groups:</i></p> <ul style="list-style-type: none"> If ≥ 21 years old, clinical ASCVD, high-intensity statin (or moderate if > 75 years old) If ≥ 21 years old and LDL ≥ 190, high-intensity statin 40–75 years old with DM and LDL 70–189, moderate intensity (or high intensity if ASCVD ≥ 7.5%) 40–75 years old with LDL 70–189, moderate-to-high intensity if ASCVD ≥ 7.5% 	<p><i>Risk groups and LDL goals:</i></p> <ul style="list-style-type: none"> Very high risk (LDL goal < 70) if ASCVD or DM + multiple risk factors or end-organ damage High risk (LDL goal < 100) if 3 or more risk factors, DM + 0–1 risk factors, chronic kidney disease, LDL > 190, or high risk per calculator Moderate risk (LDL goal < 100) if ≥ 2 risk factors or high risk per calculator Low risk (LDL goal < 100) if 0–1 risk factors 	<ul style="list-style-type: none"> Statins recommended if 10-year risk ≥ 10% and 40 to 75 years old Patient-specific approach if 10-year risk 7.5% to < 10% and with 1 or more cardiovascular risk factors Statins not recommended if ≥ 75 years old

Refer to Table 33-4 for discussion of ASCVD risk factors.

Source: Data from ATPIII (Grundey et al., 2004; NCEP, 2002), ACC/AHA (Stone et al., 2014), NLA (Jacobson et al., 2015), USPSTF (2016).

hypertriglyceridemia, two-thirds of plasma cholesterol is found in the LDL. Plasma clearance of LDL is mediated primarily by LDL receptors (apo B-100 binds LDL to its receptor); a small component is mediated by non-receptor clearance mechanisms.

The most common cause of autosomal dominant hypercholesterolemia involves mutations of the LDL receptor gene. Defective or absent LDL receptors cause high levels of plasma LDL and *FH*. Treatment of *hoFH*, which is associated with accelerated ASCVD and premature death at the age of 30 or before, is treated by inhibiting apo B-100 synthesis with *mipomersen*, as well as by inhibiting cholesterol synthesis with statins. LDL becomes atherogenic when modified by oxidation, a required step for LDL

uptake by the SRs of macrophages. This process leads to foam cell formation in arterial lesions. At least two SRs are involved (SR-AI/II and CD36). SR-AI/II appears to be expressed more in early atherogenesis, and CD36 expression is greater as foam cells form during lesion progression. The liver expresses a large complement of LDL receptors and removes about 75% of all LDL from the plasma. Consequently, manipulation of hepatic LDL receptor gene expression is a most effective way to modulate plasma LDL-C levels. *The most effective dietary alteration (decreased consumption of saturated fat and cholesterol) and pharmacological treatment (statins) for hypercholesterolemia act by enhancing hepatic LDL receptor expression.*

TABLE 33-2 ■ CHARACTERISTICS OF PLASMA LIPOPROTEINS

LIPOPROTEIN CLASS	DENSITY (g/mL)	MAJOR LIPID CONSTITUENT	TG:CHOL	SIGNIFICANT APOPROTEINS	SITE OF SYNTHESIS	CATABOLIC PATHWAY
Chylomicrons and remnants	<1.006	Dietary triglycerides and cholesterol	10:1	B-48, E, A-I, A-IV, C-I, C-II, C-III	Intestine	Triglyceride hydrolysis by LPL; apo E-mediated remnant uptake by liver
VLDL	<1.006	"Endogenous" or hepatic triglycerides	5:1	B-100, E, C-I, C-II, C-III	Liver	Triglyceride hydrolysis by LPL
IDL	1.006–1.019	Cholesteryl esters and "endogenous" triglycerides	1:1	B-100, E, C-II, C-III	Product of VLDL catabolism	50% converted to LDL mediated by HL; 50% apo E-mediated uptake by liver
LDL	1.019–1.063	Cholesteryl esters	NS	B-100	Product of VLDL catabolism	Apo B-100-mediated uptake by LDL receptor (~75% in liver)
HDL	1.063–1.21	Phospholipids, cholesteryl esters	NS	A-I, A-II, E, C-I, C-II, C-III	Intestine, liver, plasma	Complex: transfer of cholesteryl ester to VLDL and LDL; uptake of HDL cholesterol by hepatocytes
Lp(a)	1.05–1.09	Cholesteryl esters	NS	B-100, apo(a)	Liver	Unknown

CHOL, cholesterol; NS, not significant (triglyceride is < 5% of LDL and HDL); TG, triglyceride.

TABLE 33-3 ■ APOLIPOPROTEINS

APOLIPOPROTEIN (MW in kDa)	AVERAGE CONCENTRATION (mg/dL)	SITES OF SYNTHESIS	FUNCTIONS
apo A-I (~29)	130	Liver, intestine	Structural in HDL; LCAT cofactor; ligand of ABCA1 receptor; reverse cholesterol transport
apo A-II (~17)	40	Liver	Forms -S-S- complex with apo E-2 and E-3, which inhibits E-2 and E-3 binding to lipoprotein receptors
apo A-V (~40)	<1	Liver	Modulates triglyceride incorporation into hepatic VLDL; activates LPL
apo B-100 (~513)	85	Liver	Structural protein of VLDL, IDL, LDL; LDL receptor ligand
apo B-48 (~241)	Fluctuates according to dietary fat intake	Intestine	Structural protein of chylomicrons
apo C-I (~6.6)	6	Liver	LCAT activator; modulates receptor binding of remnants
apo C-II (8.9)	3	Liver	Lipoprotein lipase cofactor
apo C-III (8.8)	12	Liver	Modulates receptor binding of remnants
apo E (34)	5	Liver, brain, skin, gonads, spleen	Ligand for LDL receptor and receptors binding remnants; reverse cholesterol transport (HDL with apo E)
apo (a) (Variable)	Variable (under genetic control)	Liver	Modulator of fibrinolysis

High-Density Lipoproteins

The HDLs are protective lipoproteins that decrease the risk of CHD; thus, high levels of HDL are desirable. This protective effect may result from the participation of HDL in reverse cholesterol transport, the process by which excess cholesterol is acquired from cells and transferred to the liver for excretion. HDL effects also include putative anti-inflammatory, antioxidant, platelet antiaggregatory, anticoagulant, and profibrinolytic activities. Apo A-I is the major HDL apoprotein and its plasma concentration is a more powerful inverse predictor of CHD risk than is the HDL-C level. Apo A-I synthesis is required for normal production of HDL.

Mutations in the apo A-I gene that cause HDL deficiency often are associated with accelerated atherogenesis. In addition, two major subclasses of mature HDL particles in the plasma can be differentiated by their content of the major HDL apoproteins, apo A-I and apo A-II. Epidemiologic evidence in humans suggests that apo A-II may be atheroprotective.

The membrane transporter ABCA1 facilitates the transfer of free cholesterol from cells to HDL. After free cholesterol is acquired by the pre- β 1 HDL, it is esterified by LCAT. The newly esterified and nonpolar cholesterol moves into the core of the particle, which becomes progressively more spherical, larger, and less dense with continued cholesterol acquisition and esterification. As the cholesteryl ester content of the particle (now called HDL₂) increases, the cholesteryl esters of these particles begin to be exchanged for triglycerides derived from any of the triglyceride-containing lipoproteins (chylomicrons, VLDLs, remnant lipoproteins, and LDLs). This exchange, mediated by the CETP, accounts for the removal of about two-thirds of the cholesterol associated with HDL in humans. The transferred cholesterol subsequently is metabolized as part of the lipoprotein into which it was transferred. Treatments that target CETP and the ABC transporters have yielded equivocal results in humans. While CETP inhibitors effectively reduce LDL, they also paradoxically increase the frequency of adverse cardiovascular events (angina, revascularization, myocardial infarction, heart failure, and death).

The triglyceride that is transferred into HDL₂ is hydrolyzed in the liver by HL, a process that regenerates smaller, spherical HDL₃ particles that recirculate and acquire additional free cholesterol from tissues containing excess free cholesterol. HL activity is regulated and modulates HDL-C levels. Androgens increase HL gene expression/activity, which accounts for the lower HDL-C values observed in men than in women. Estrogens reduce HL activity, but their impact on HDL-C levels in women is substantially less than that of androgens on HDL-C levels in men. HL

appears to have a pivotal role in regulating HDL-C levels, as HL activity is increased in many patients with low HDL-C levels.

Lipoprotein (a)

Lipoprotein (a) [Lp(a)] is composed of an LDL particle that has a second apoprotein, apo(a), in addition to apo B-100. Apo(a) of Lp(a) is structurally related to plasminogen and appears to be atherogenic.

Atherosclerotic Cardiovascular Disease Risk Assessment

Therapy for dyslipidemias is based on reducing the risk of fatal and nonfatal atherosclerotic cardiovascular events, including myocardial infarction and stroke. A flowchart that illustrates the assessment and management of ASCVD risk is shown in Figure 33-2.

The major conventional risk factors for ASCVD are elevated LDL-C, reduced HDL-C, cigarette smoking, hypertension, type 2 diabetes mellitus, advancing age, and a family history of premature CHD events (men < 55 years; women < 65 years) in a first-degree relative (Table 33-4).

Primary prevention involves management of risk factors to prevent a first-ever ASCVD event. Secondary prevention is aimed at patients who have had a prior ASCVD event (myocardial infarction, stroke, or revascularization) and whose risk factors must be treated aggressively. In addition to cholesterol management, a comprehensive approach to ASCVD risk reduction includes smoking cessation, weight management, physical activity, healthy eating habits, antiplatelet use, and glucose and blood pressure management. All treatment plans to reduce ASCVD risk must include patient counseling to effect lifestyle changes. Secondary causes of dyslipidemias (Table 33-5), including medications that affect cholesterol, should also be considered prior to initiating treatment. Patients should also be evaluated for metabolic syndrome, which affects more than one in three adults and includes insulin resistance, obesity, hypertension, low HDL-C levels, a procoagulant state, vascular inflammation, and substantially increased risk of cardiovascular disease.

The PCE, published as part of the 2014 ACC/AHA guideline on the assessment of cardiovascular risk, was developed based on data from nine NHLBI-funded cohort studies and included data from geographically and racially diverse patient populations. The PCE estimates an individual patient's 10-year risk of ASCVD (defined as nonfatal myocardial infarction,

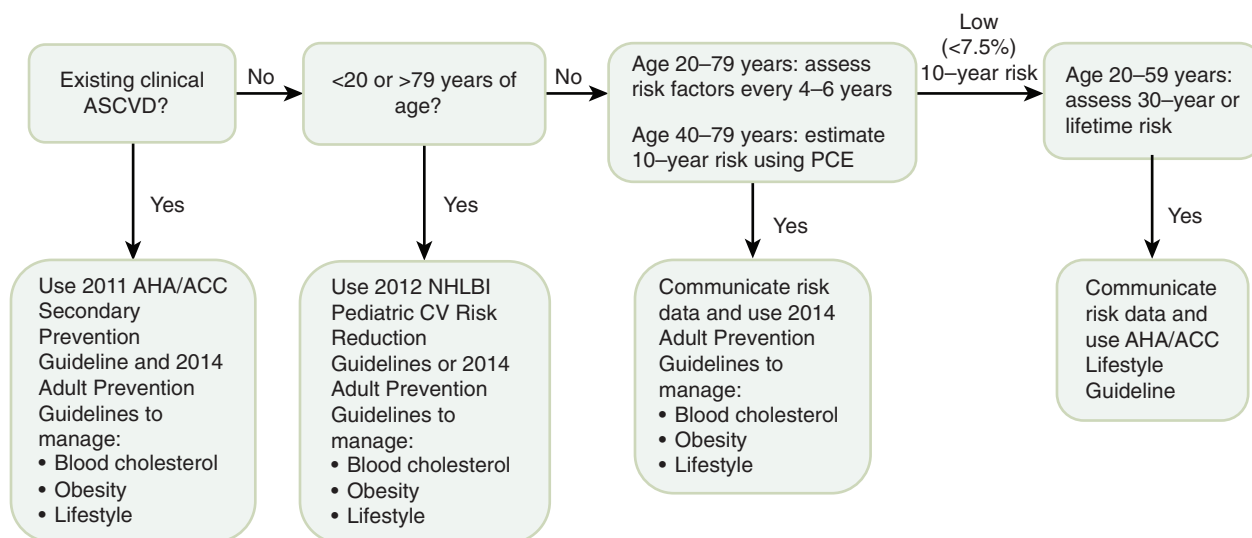

Figure 33–2 Flowchart for assessing and managing ASCVD risk. This chart is based on the 2014 ACC/AHA guideline on the assessment of cardiovascular risk. Refer to Table 33–1 and the ACC/AHA guidelines (Stone et al., 2014) for additional details.

CHD death, or fatal or nonfatal stroke) based on age, gender, total cholesterol, HDL-C, race, systolic blood pressure, smoking status, and history of diabetes, and hypertension. The ASCVD risk assessment calculator using the PCE is available online (<https://tools.acc.org/ASCVD-Risk-Estimator/>) and as a mobile app. Cardiovascular risk assessment calculators have also been developed for lifetime risk of cardiovascular disease.

Statin Drug Therapy

Although an understanding of optimal lipoprotein levels is helpful (see ranges in Table 33–6), the 2014 ACC/AHA guideline recommends the use of fixed statin doses for at-risk patients, instead of titration to specific lipoprotein goals. The ACC/AHA guidelines identify four statin benefit groups or patient populations most likely to benefit from statin therapy.

TABLE 33–4 ■ RISK FACTORS FOR ATHEROSCLEROTIC CARDIOVASCULAR DISEASE

Age

Male > 45 years of age or female > 55 years of age

Family history of premature CHD^a

A first-degree relative (male < 55 years of age or female < 65 years of age when the first CHD clinical event occurs)

Current cigarette smoking

Defined as smoking within the preceding 30 days

Hypertension

Systolic blood pressure ≥ 140, diastolic pressure ≥ 90 or use of antihypertensive medication, irrespective of blood pressure

Low HDL-C

< 40 mg/dL (consider < 50 mg/dL as “low” for women)

Obesity

Body mass index > 25 kg/m² and waist circumference > 40 inches (men) or > 35 inches (women)

Type 2 diabetes mellitus^b

^aCHD defined as myocardial infarction, coronary death, or a coronary revascularization procedure.

^bDiabetes mellitus is considered a high or very high risk condition for ASCVD.

Source: Data from 2015 NLA recommendations, part 1 (Jacobson et al, 2015).

Patients with known history of clinical ASCVD and those with elevated LDL-C greater than or equal to 190 mg/dL should be offered statins.

For primary prevention in patients 40 through 79 years of age with LDL 70 to 189 mg/dL, use of the PCE is recommended to identify patients more likely to benefit from treatment. Table 33–1 summarizes ACC/AHA recommendations for use of statins in adults. In November 2016, the USPSTF released recommendations for the use of statins in primary prevention populations (USPSTF, 2016). These recommendations build on those in the ACC/AHA guideline in helping to further identify higher-risk primary prevention patients. USPSTF also questions the use of higher-intensity statins in the 2014 ACC/AHA guideline and instead recommends low- to moderate-intensity statins for primary prevention patients.

Because the overwhelming body of evidence for ASCVD risk reduction with lipid-lowering therapies is from statin trials, evidence-based statin therapy of appropriate intensity is the hallmark of drug therapy of dyslipidemias. These drugs are competitive inhibitors of HMG-CoA reductase, which catalyzes an early, rate-limiting step in cholesterol biosynthesis. Higher doses of the more potent statins (e.g., atorvastatin, simvastatin, and rosuvastatin) also can reduce triglyceride levels caused by elevated VLDL levels. Figure 33–3 shows a representative statin structure and the reaction catalyzed by HMG-CoA reductase.

Mechanism of Action

Statins exert their major effect—reduction of LDL levels—through a mevalonic acid–like moiety that competitively inhibits HMG-CoA reductase. By reducing the conversion of HMG-CoA to mevalonate, statins inhibit an early and rate-limiting step in cholesterol biosynthesis. Statins affect blood cholesterol levels by inhibiting hepatic cholesterol synthesis, which results in increased expression of the LDL receptor gene. Some studies suggested that statins also can reduce LDL levels by enhancing the removal of LDL precursors (VLDL and IDL) and by decreasing hepatic VLDL production. The reduction in hepatic VLDL production induced by statins is thought to be mediated by reduced synthesis of cholesterol, a required component of VLDLs.

ADME

After oral administration, intestinal absorption of the statins is variable (30%–85%). All the statins, except simvastatin and lovastatin, are administered in the β-hydroxy acid form, which is the form that inhibits HMG-CoA reductase. Simvastatin and lovastatin are administered as inactive lactones that must be transformed in the liver to their respective β-hydroxy acids, simvastatin acid, and lovastatin acid. There is extensive first-pass hepatic uptake of all statins, mediated primarily by the organic

anion transporter OATP1B1 (see Chapter 5). *Hepatic cholesterol synthesis is maximal between midnight and 2:00 AM. Thus, statins with $t_{1/2}$ of 4 h or less (all but atorvastatin and rosuvastatin) should be taken in the evening.* Atorvastatin and rosuvastatin both have longer half-lives and may be taken at other times of day to optimize adherence.

TABLE 33-6 ■ CLASSIFICATION OF PLASMA LIPID LEVELS (mg/dL)

Non-HDL-C	
<130	Desirable
130–159	Above desirable
160–189	Borderline high
190–219	High
≥220	Very high
HDL-C	
<40	Low (consider < 50 mg/dL as low for women)
>60	High (desirable because of negative risk)
LDL-C	
<70	Optimal for very high risk ^a
<100	Desirable
100–129	Above desirable
130–159	Borderline high
160–189	High
≥190	Very high
Triglycerides	
<150	Normal
150–199	Borderline high
200–499	High
≥500	Very high

^aSome consider LDL < 70 the optimal goal for patients with CHD or risk equivalents.

Due to extensive first-pass hepatic uptake, systemic bioavailability of the statins and their hepatic metabolites varies between 5% and 30% of administered doses. The metabolites of all statins, except fluvastatin and pravastatin, have some HMG-CoA reductase inhibitory activity. Under steady-state conditions, small amounts of the parent drug and its metabolites produced in the liver can be found in the systemic circulation. In the plasma, more than 95% of statins and their metabolites are protein bound, with the exception of pravastatin and its metabolites, which are only 50% bound. Peak plasma concentrations of statins are achieved in 1–4 h. The $t_{1/2}$ of the parent compounds are 1–4 h, except in the case of atorvastatin and rosuvastatin, which have half-lives of about 20 h, and simvastatin with a $t_{1/2}$ of about 12 h. The longer $t_{1/2}$ of atorvastatin and rosuvastatin may contribute to their greater cholesterol-lowering efficacy. The liver biotransforms all statins, and more than 70% of statin metabolites are excreted by the liver, with subsequent elimination in the feces.

Therapeutic Effects

Triglyceride Reduction by Statins

Triglyceride levels greater than 250 mg/dL are reduced substantially by statins, and the percentage reduction achieved is similar to the percentage reduction in LDL-C.

Effect of Statins on HDL-C Levels

Most studies of patients treated with statins have systematically excluded patients with low HDL-C levels. In studies of patients with elevated LDL-C levels and gender-appropriate HDL-C levels (40–50 mg/dL for men; 50–60 mg/dL for women), an increase in HDL-C of 5%–10% was observed, irrespective of the dose or statin employed. However, in patients with reduced HDL-C levels (<35 mg/dL), statins may differ in their effects on HDL-C levels. More studies are needed to ascertain

Figure 33–3 Lovastatin and the HMG-CoA reductase reaction.

whether the effects of statins on HDL-C in patients with low HDL-C levels are clinically significant.

Effects of Statins on LDL-C Levels

Dose-response relationships for all statins demonstrate that the efficacy of LDL-C lowering is log linear; LDL-C is reduced by about 6% (from baseline) with each doubling of the dose. Maximal effects on plasma cholesterol levels are achieved within 7–10 days. The statins are effective in almost all patients with high LDL-C levels. The exception is patients with *hoFH*, who have very attenuated responses to the usual doses of statins because both alleles of the LDL receptor gene code for dysfunctional LDL receptors.

Adverse Effects and Drug Interactions

Hepatotoxicity

Serious hepatotoxicity is rare and unpredictable, with a rate of about 1 case per million person-years of use. ACC/AHA guidelines recommend measuring ALT at baseline prior to initiation of statins. However since 2012, the FDA has no longer recommended routine monitoring of ALT or other liver enzymes following the initiation of statin therapy because routine periodic monitoring does not appear to be effective in detecting or preventing serious liver injury. Liver enzymes should be evaluated in patients with clinical symptoms suggestive of liver injury following initiation or changes in statin treatment (FDA, 2012).

Myopathy

The major adverse effect associated with statin use is myopathy. Myopathy refers to a broad spectrum of muscle complaints, ranging from mild muscle soreness or weakness (myalgia) to life-threatening rhabdomyolysis. The risk of muscle adverse effects increases in proportion to statin dose and plasma concentrations. Consequently, factors inhibiting statin catabolism are associated with increased myopathy risk, including advanced age (especially > 80 years of age), hepatic or renal dysfunction, perioperative periods, small body size, and untreated hypothyroidism. Measurements of creatinine kinase are not routinely necessary unless the patient also is taking a drug that enhances the risk of myopathy. Concomitant use of drugs that diminish statin catabolism or interfere with hepatic uptake is associated with increased risk of myopathy and rhabdomyolysis. The most common statin interactions occur with fibrates, especially *gemfibrozil* (38%), and with *cyclosporine* (4%), *digoxin* (5%), *warfarin* (4%), macrolide antibiotics (3%), and azole antifungals (1%). Other drugs that increase the risk of statin-induced myopathy include niacin (rare), HIV protease inhibitors, *amiodarone*, and *nefazodone*.

Gemfibrozil, the drug most commonly associated with statin-induced myopathy, both inhibits uptake of the active hydroxy acid forms of statins

into hepatocytes by OATP1B1 and interferes with the transformation of most statins by glucuronidases. Coadministration of gemfibrozil nearly doubles the plasma concentration of the statin hydroxy acids. When statins are administered with niacin, the myopathy probably is caused by an enhanced inhibition of skeletal muscle cholesterol synthesis (a pharmacodynamic interaction). In 2016, the FDA withdrew approval for statin drug combinations containing fibrates or niacin (FDA, 2016).

Drugs that interfere with statin oxidation are those metabolized primarily by CYP3A4 and include certain macrolide antibiotics (e.g., *erythromycin*); azole antifungals (e.g., *itraconazole*); cyclosporine; *nefazodone*, a phenylpiperazine antidepressant; HIV protease inhibitors; and *amiodarone*. These pharmacokinetic interactions are associated with increased plasma concentrations of statins and their active metabolites. Atorvastatin, lovastatin, and simvastatin are primarily metabolized by CYPs 3A4 and 3A5. Fluvastatin is mostly (50%–80%) metabolized by CYP2C9 to inactive metabolites, but CYP3A4 and CYP2C8 also contribute to its metabolism. Pravastatin, however, is not metabolized to any appreciable extent by the CYP system and is excreted unchanged in the urine. Because pravastatin, fluvastatin, and rosuvastatin are not extensively metabolized by CYP3A4, these statins may be less likely to cause myopathy when used with one of the predisposing drugs. However, the benefits of combined therapy with any statin should be carefully weighed against the risk of myopathy.

Other Considerations

The choice of statins should be patient specific and based on factors such as cost, drug interactions, possible adverse effects, and desired intensity. Statin doses are characterized as low, moderate, or high intensity (Table 33–7), based on the degree of LDL-C lowering expected (range 30%–60%).

Rosuvastatin and pravastatin may be better tolerated than other statins and should be considered in patients with a history of myalgias with other statins. Lovastatin absorption is increased when taken with food, and patients should be encouraged to take with their evening meal. According to a 2012 FDA warning, simvastatin should not be used in combination with cyclosporine, HIV protease inhibitors, erythromycin, or gemfibrozil. In patients taking amlodipine or amiodarone, the daily dose of simvastatin should not exceed 20 mg. No more than 10 mg of simvastatin should be used in combination with diltiazem or verapamil. Concerns have been raised about possible cognitive impairment with statins, although review of the published data do not suggest that statins harm cognition. In contrast, other studies suggested statins may have a role in the prevention of dementias. Statins, especially at higher doses, likely confer a small increased risk of developing diabetes. However, the beneficial effects of

TABLE 33-7 ■ INTENSITY OF STATINS BY APPROXIMATE REDUCTIONS IN LDL-C WITH DAILY DOSING

Source: Data from Table 5 in 2014 ACC/AHA guidelines (Stone et al., 2014) and Table 2 in “2016 ACC Expert Consensus Decision Pathway on the Role of Non-Statins Therapies” (Lloyd-Jones et al., 2016).

statins on ASCVD events and mortality outweigh any increased risk conferred by promoting the development of diabetes. Atorvastatin is often the statin of choice for patients with severe renal dysfunction as it does not require dose adjustment.

Some statins have been approved for use in children with heFH. Atorvastatin, lovastatin, and simvastatin are indicated for children 11 years and older. Pravastatin is approved for children 8 years and older. *Statins are contraindicated during pregnancy and should be discontinued prior to conception if possible.* Data regarding statin use while breastfeeding are limited, and use should be discouraged.

Nonstatin Drug Therapies

The 2014 ACC/AHA guideline focuses on the use of statins to reduce ASCVD risk. However, several important clinical trials have evaluated whether fibrates, niacin, ezetimibe, and fish oil result in further reductions in ASCVD risk when used in addition to statins (ACCORD, 2010; AIM-HIGH, 2011; Cannon et al., 2015; HPS2-THRIVE, 2014; ORIGIN, 2012). The National Lipid Association released recommendations in 2015 that continued to emphasize specific LDL goals and encouraged the use of nonstatin therapies in addition to statins in high-risk individuals (Jacobson et al., 2015). In April 2016, the FDA withdrew approval for niacin ER or fenofibrate when used in addition to statins, citing studies that demonstrated no additional reduction in ASCVD events versus monotherapy with a statin (FDA, 2016). In July 2016, the ACC also released an expert consensus decision pathway to aid clinicians in the use of nonstatins (bile acid sequestrants, PCSK9 inhibitors, or ezetimibe) in addition to statins for the management of ASCVD risk (Lloyd-Jones et al., 2016). The use of nonstatins in high-risk patient populations requires careful shared decision-making.

Elevated triglycerides are an important risk factor for pancreatitis. Treatment with agents most effective at reducing levels of triglycerides (fibrate or fish oil) are recommended in patients with very elevated triglycerides (>1000 mg/dL) to reduce the risk of pancreatitis. These therapies may be used in addition to statin treatment if the patient otherwise has risk factors for ASCVD that make the patient an appropriate candidate for statin therapy.

Bile Acid Sequestrants

Cholestyramine, Colestipol, Colesevelam

The bile acid sequestrants cholestyramine and colestipol are among the oldest of the hypolipidemic drugs and are probably the safest because

they are not absorbed from the intestine. These resins also are recommended for patients 11–20 years of age. Although statins are remarkably effective as monotherapy, the resins could be utilized as a second agent if statin therapy does not lower LDL-C levels sufficiently or in cases of statin intolerance.

Mechanism of Action. The bile acid sequestrants are highly positively charged and bind negatively charged bile acids. Because of their large size, the resins are not absorbed, and the bound bile acids are excreted in the stool. Because more than 95% of bile acids are normally reabsorbed, interruption of this process depletes the pool of bile acids, and hepatic bile acid synthesis increases. As a result, hepatic cholesterol content declines, stimulating the production of LDL receptors, an effect similar to that of statins. The increase in hepatic LDL receptors increases LDL clearance and lowers LDL-C levels, but this effect is partially offset by the enhanced cholesterol synthesis caused by upregulation of HMG-CoA reductase. Inhibition of reductase activity by a statin substantially increases the effectiveness of the resins. The resin-induced increase in bile acid production is accompanied by an increase in hepatic triglyceride synthesis, which is of consequence in patients with significant hypertriglyceridemia (baseline triglyceride level > 250 mg/dL). Use of colestipol to lower LDL-C levels in hypertriglyceridemic patients should be accompanied by frequent (every 1–2 weeks) monitoring of fasting triglyceride levels.

Effects on Lipoprotein Levels. The reduction in LDL-C by resins is dose dependent. Doses of 8–12 g of cholestyramine or 10–15 g of colestipol are associated with 12%–18% reductions in LDL-C. Colesevelam lowers LDL-C by 18% at its maximum dose. Maximal doses (24 g of cholestyramine, 30 g of colestipol) may reduce LDL-C by as much as 25% but will cause GI side effects, which are often unacceptable. One to 2 weeks is sufficient to attain maximal LDL-C reduction by a given resin dose. In patients with normal triglyceride levels, triglycerides may increase transiently and then return to baseline. When used with a statin, resins are usually prescribed at submaximal doses due to poor tolerability.

Preparations and Use. The powdered forms of cholestyramine (4 g/dose) and colestipol (5 g/dose) are either mixed with a fluid (water or juice) and drunk as a slurry or mixed with crushed ice in a blender. Ideally, patients should take the resins before breakfast and before supper, starting with 1 scoop or packet twice daily and increasing the dosage after several weeks or longer as needed and as tolerated. Patients generally will not take more than 2 doses (scoops or packets) twice daily. Colesevelam hydrochloride is available as a solid tablet containing 0.625 g of colestipol and as a powder in packets of 3.75 g or 1.875 g. The starting dose is either 3 tablets taken twice daily with meals or all 6 tablets taken with a meal. The tablets should be taken with a liquid. The maximum daily dose is 7 tablets (4.375 g).

Adverse Effects and Drug Interactions. The resins are generally safe, as they are not systemically absorbed. Because they are administered as chloride salts, rare instances of hyperchloremic acidosis have been reported. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol because these resins increase triglyceride levels. At present, there are insufficient data on the effect of colestipol on triglyceride levels.

Drinking a slurry of powdered cholestyramine or colestipol produces a gritty sensation that is unpleasant but generally tolerated. Colestipol is available in a tablet form. Colesevelam is available as a hard capsule that absorbs water and creates a soft, gelatinous material that allegedly minimizes the potential for GI irritation. Patients taking cholestyramine and colestipol complain of bloating and dyspepsia. These symptoms can be substantially reduced if the drug is completely suspended in liquid several hours before ingestion. Constipation may occur but sometimes can be prevented by adequate daily water intake and psyllium. Colesevelam may be less likely than colestipol to cause the dyspepsia, bloating, and constipation.

The effect of cholestyramine and colestipol on the absorption of most drugs has not been studied. Cholestyramine and colestipol bind and interfere with the absorption of many drugs, including some thiazides, *furosemide*, *propranolol*, *L-thyroxine*, *digoxin*, *warfarin*, and some of the statins.

Colesevelam does not appear to interfere with the absorption of fat-soluble vitamins or of drugs such as digoxin, lovastatin, warfarin, *metoprolol*, *quinidine*, and *valproic acid*. Colesevelam reduces the maximum concentration and the area under the curve of sustained-release *verapamil* by 31% and 11%, respectively. In the absence of information to the contrary, prudence suggests that patients take other medications 1 h before or 3–4 h after a dose of colesevelam or colestipol. The safety and efficacy of colesevelam have not been studied in pediatric patients or pregnant women.

Niacin (Nicotinic Acid)

Niacin is a water-soluble B-complex vitamin that functions as a vitamin only after conversion to NAD or NADP, in which it occurs as an amide. Both niacin and its amide may be given orally as a source of niacin for its functions as a vitamin, but only niacin affects lipid levels. The hypolipidemic effects of niacin require larger doses than are required for its vitamin effects.

Mechanism of Action

In adipose tissue, niacin inhibits the lipolysis of triglycerides by HSL, thereby reducing transport of free fatty acids to the liver and decreasing hepatic triglyceride synthesis. Niacin may exert its effects on lipolysis by stimulating a G protein-coupled receptor (GPR109A) that couples to G_i and inhibits cyclic AMP production in adipocytes. In the liver, niacin reduces triglyceride synthesis by inhibiting both the synthesis and the esterification of fatty acids, effects that increase apo B degradation. Reduction of triglyceride synthesis reduces hepatic VLDL production, which accounts for the reduced LDL levels. Niacin also enhances LPL activity, an action that promotes the clearance of chylomicrons and VLDL triglycerides. Niacin raises HDL-C levels by decreasing the fractional clearance of apo A-I in HDL rather than by enhancing HDL synthesis.

ADME

The doses of regular (crystalline) niacin used to treat dyslipidemia are almost completely absorbed, and peak plasma concentrations (up to 0.24 mmol) are achieved within 30–60 min. The $t_{1/2}$ is about 60 min, which necessitates dosing two to three times daily. At lower doses, most niacin is taken up by the liver; only the major metabolite, nicotinuric acid, is found in the urine. At higher doses, a greater proportion of the drug is excreted in the urine as unchanged nicotinic acid.

Effects on Plasma Lipoprotein Levels

Regular or crystalline niacin in doses of 2–6 g/d reduces triglycerides by 35%–50% (as effectively as fibrates and statins); the maximal effect occurs within 4–7 days. Reductions of 25% in LDL-C levels are possible with doses of 4.5–6 g/d; 3–6 weeks are required for maximal effect. Niacin is the most effective agent available for increasing HDL-C (30%–40%), but the effect is less in patients with HDL-C levels less than 35 mg/dL. Niacin also is the only lipid-lowering drug that reduces Lp(a) levels significantly. Despite salutary effect on lipids, niacin's side effects limit its use (see Adverse Effects).

Therapeutic Use

Niacin is indicated for hypertriglyceridemia and elevated LDL-C. There are two commonly available forms of niacin. Crystalline niacin (immediate release or regular) refers to niacin tablets that dissolve quickly after ingestion. Sustained-release niacin refers to preparations that continuously release niacin for 6–8 h after ingestion. Niacin ER is the only preparation of niacin that is FDA-approved for treating dyslipidemia and that requires a prescription.

Crystalline niacin tablets are available OTC in a variety of strengths, from 50- to 500-mg tablets. The dose may be increased stepwise every 7 days

to a total daily dose of 1.5–2 g. After 2–4 weeks at this dose, transaminases, serum albumin, fasting glucose, and uric acid levels should be measured. After a stable dose is attained, blood should be drawn every 3–6 months to monitor for the various toxicities. OTC, sustained-release niacin preparations, and niacin ER are effective up to a total daily dose of 2 g. All doses of sustained-release niacin, but particularly doses above 2 g/d, have been reported to cause hepatotoxicity, which may occur soon after beginning therapy or after several years of use. The potential for severe liver damage should preclude use of OTC preparations in most patients. Niacin ER may be less likely to cause hepatotoxicity.

Concurrent use of niacin and a statin can cause myopathy. Two randomized trials evaluating niacin as add-on therapy to a statin versus statin monotherapy demonstrated no further reduction in ASCVD risk, despite improved lipoprotein parameters. Given this evidence, the FDA removed the indication for niacin use in addition to statin therapy and withdrew approval for statin combination formulations containing niacin (FDA, 2016). Niacin could still be considered as monotherapy in a statin-intolerant patient.

Adverse Effects

Two of niacin's side effects, flushing and dyspepsia, limit patient compliance. The cutaneous effects include flushing and pruritus of the face and upper trunk, skin rashes, and acanthosis nigricans. Flushing and associated pruritus are prostaglandin-mediated, thus taking an aspirin each day can alleviate the flushing in many patients. Flushing is worse when therapy is initiated or the dosage is increased but ceases in most patients after 1–2 weeks of a stable dose. Flushing is more likely to occur when niacin is consumed with hot beverages or with alcohol. Flushing is minimized if therapy is initiated with low doses (100–250 mg twice daily) and if the drug is taken after a meal. Dry skin, a frequent complaint, can be dealt with by using skin moisturizers, and acanthosis nigricans can be dealt with by using lotions containing *salicylic acid*. Dyspepsia and rarer episodes of nausea, vomiting, and diarrhea are less likely to occur if the drug is taken after a meal. Patients with any history of peptic ulcer disease should not take niacin.

The most common, medically serious side effects are hepatotoxicity, manifested as elevated serum transaminases, and hyperglycemia. Both regular (crystalline) niacin and sustained-release niacin, which was developed to reduce flushing and itching, have been reported to cause severe liver toxicity. Niacin ER appears to be less likely to cause severe hepatotoxicity, perhaps simply because it is administered once daily. The incidence of flushing and pruritus with this preparation is not substantially different from that with regular niacin. Severe hepatotoxicity is more likely to occur when patients take more than 2 g of sustained-release OTC preparations. Affected patients experience flu-like fatigue and weakness; usually, aspartate transaminase and ALT are elevated, serum albumin levels decline, and total cholesterol and LDL-C levels decline substantially.

In patients with diabetes mellitus, niacin should be used cautiously because niacin-induced insulin resistance can cause severe hyperglycemia. If niacin is prescribed for patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until proven to be stable. Niacin also elevates uric acid levels and may reactivate gout. A history of gout is a relative contraindication for niacin use. Rarer reversible side effects include toxic amblyopia and toxic maculopathy. Atrial tachyarrhythmias and atrial fibrillation have been reported, more commonly in elderly patients. *Niacin, at doses used in humans, has been associated with birth defects in experimental animals and should not be taken by pregnant women.*

Fibric Acid Derivatives

Clofibrate is a halogenated fibric acid derivative. Gemfibrozil is a nonhalogenated acid that is distinct from the halogenated fibrates. A number of fibric acid analogues (e.g., fenofibrate, *bezafibrate*, *ciprofibrate*) have been developed and are used in Europe and elsewhere.

Mechanism of Action

The mechanisms by which fibrates lower lipoprotein levels, or raise HDL levels, remain unclear. Many of the effects of these compounds on blood

lipids are mediated by their interaction with PPARs, which regulate gene transcription. Fibrates bind to PPAR α and reduce triglycerides through PPAR α -mediated stimulation of fatty acid oxidation, increased LPL synthesis, and reduced expression of apo C-III. Increased LPL synthesis would enhance the clearance of triglyceride-rich lipoproteins. Reduced hepatic production of apo C-III, which serves as an inhibitor of lipolysis and receptor-mediated clearance, would enhance the clearance of VLDLs. Fibrate-mediated increases in HDL-C are due to PPAR α stimulation of apo A-I and apo A-II expression, which increases HDL levels. Fenofibrate is more effective than gemfibrozil at increasing HDL levels. Most fibrates have potential antithrombotic effects, including inhibition of coagulation and enhancement of fibrinolysis.

ADME

Fibrates are absorbed rapidly and efficiently (>90%) when given with a meal but less efficiently when taken on an empty stomach. Peak plasma concentrations are attained within 1–4 h. More than 95% of these drugs in plasma are bound to protein, nearly exclusively to albumin. The $t_{1/2}$ of fibrates range from 1.1 (gemfibrozil) to 20 h (fenofibrate). The drugs are widely distributed throughout the body, and concentrations in liver, kidney, and intestine exceed the plasma level. Gemfibrozil is transferred across the placenta. The fibrate drugs are excreted predominantly as glucuronide conjugates (60%–90%) in the urine, with smaller amounts appearing in the feces. Excretion of these drugs is impaired in renal failure.

Effects on Lipoprotein Levels

Effects of fibric acid agents on lipoprotein levels differ widely, depending on the starting lipoprotein profile, the presence or absence of a genetic hyperlipoproteinemia, the associated environmental influences, and the specific fibrate used. Patients with type III hyperlipoproteinemia (*dysbetalipoproteinemia*) are among the most sensitive responders to fibrates. Elevated triglyceride and cholesterol levels are dramatically lowered, and tuberoeruptive and palmar xanthomas may regress completely. Angina and intermittent claudication also improve.

In patients with mild hypertriglyceridemia (e.g., triglycerides < 400 mg/dL), fibrate treatment decreases triglyceride levels by up to 50% and increases HDL-C concentrations by about 15%; LDL-C levels may be unchanged or increase. Normotriglyceridemic patients with heFH usually experience little change in LDL levels with gemfibrozil; with the other fibric acid agents, reductions as great as 20% may occur in some patients. Fibrates usually are the drugs of choice for treating severe hypertriglyceridemia and the chylomicronemia syndrome. While the primary therapy is to remove alcohol and lower dietary fat intake as much as possible, fibrates assist by increasing triglyceride clearance and decreasing hepatic triglyceride synthesis. In patients with chylomicronemia syndrome, fibrate maintenance therapy and a low-fat diet keep triglyceride levels well below 1000 mg/dL and thus prevent episodes of pancreatitis.

Therapeutic Use

Gemfibrozil usually is administered as a 600-mg dose taken twice daily, 30 min before the morning and evening meals. Fenofibrate is available in tablets of 48 and 145 mg or capsules containing 67, 134, and 200 mg. The choline salt of fenofibric acid is available in capsules of 135 and 45 mg. Equivalent doses of fenofibrate formulations are 135 mg of choline salt, 145-mg tablets, and 200-mg capsules. Fibrates are the drugs of choice for treating hyperlipidemic subjects with type III hyperlipoproteinemia, as well as subjects with severe hypertriglyceridemia (triglycerides > 1000 mg/dL) who are at risk for pancreatitis. A randomized clinical trial of fenofibrate added on to background statin therapy resulted in no further reduction of ASCVD risk (ACCORD, 2010). In 2016, the FDA withdrew approval for use of fenofibrate in addition to statin therapy for ASCVD risk reduction.

Adverse Effects and Drug Interactions

Fibric acid compounds usually are well tolerated. GI side effects occur in up to 5% of patients. Infrequent side effects include rash, urticaria, hair loss, myalgias, fatigue, headache, impotence, and anemia. Minor increases in liver transaminases and alkaline phosphatase have been reported. Clofibrate, bezafibrate, and fenofibrate reportedly potentiate the action of

warfarin. Careful monitoring of the prothrombin time and reduction in dosage of warfarin may be appropriate.

A myopathy syndrome occasionally occurs in subjects taking clofibrate, gemfibrozil, or fenofibrate and may occur in up to 5% of patients treated with a combination of gemfibrozil and higher doses of statins. Gemfibrozil inhibits hepatic uptake of statins by OATP1B1 and competes for the same glucuronosyl transferases that metabolize most statins. Thus, levels of both drugs may be elevated when they are coadministered. Patients taking this combination should be followed at 3-month intervals with careful history and determination of creatine kinase values until a stable pattern is established. Patients taking fibrates with rosuvastatin should be followed especially closely even if low doses (5–10 mg) of rosuvastatin are employed. Fenofibrate is glucuronidated by enzymes that are not involved in statin glucuronidation; thus, fenofibrate-statin combinations are less likely to cause myopathy than combination therapy with gemfibrozil and statins.

All of the fibrates increase the lithogenicity of bile. Clofibrate use has been associated with increased risk of gallstone formation. Renal failure is a relative contraindication to the use of fibric acid agents, as is hepatic dysfunction. *Fibrates should not be used by children or pregnant women.*

Inhibitor of Cholesterol Absorption

Ezetimibe is the first compound approved for lowering total and LDL-C levels that inhibits cholesterol absorption by enterocytes in the small intestine. It lowers LDL-C levels by about 20% and may be used as adjunctive therapy with statins.

Mechanism of Action

Ezetimibe inhibits luminal cholesterol uptake by jejunal enterocytes, by inhibiting the transport protein NPC1L1. In human subjects, ezetimibe reduces cholesterol absorption by 54%, precipitating a compensatory increase in cholesterol synthesis that can be inhibited with a cholesterol synthesis inhibitor (e.g., a statin). The consequence of inhibiting intestinal cholesterol absorption is a reduction in the incorporation of cholesterol into chylomicrons; this diminishes the delivery of cholesterol to the liver by chylomicron remnants. The diminished remnant cholesterol content may decrease atherogenesis directly, as chylomicron remnants are very atherogenic lipoproteins. Reduced delivery of intestinal cholesterol to the liver by chylomicron remnants stimulates expression of the hepatic genes regulating LDL receptor expression and cholesterol biosynthesis. The greater expression of hepatic LDL receptors enhances LDL-C clearance from the plasma. Ezetimibe reduces LDL-C levels by 15%–20%.

ADME

Ezetimibe is highly water insoluble, precluding studies of its bioavailability. After ingestion, it is glucuronidated in the intestinal epithelium and absorbed and then enters an enterohepatic recirculation. Pharmacokinetic studies indicated that about 70% is excreted in the feces and about 10% in the urine (as a glucuronide conjugate). Bile acid sequestrants inhibit absorption of ezetimibe, and the two agents should not be administered together.

Therapeutic Use

Ezetimibe is available as a 10-mg tablet that may be taken at any time during the day, with or without food. Ezetimibe may be taken in combination with other dyslipidemia medications except bile acid sequestrants, which inhibit its absorption.

The role of ezetimibe as monotherapy of patients with elevated LDL-C levels is generally limited to the small group of statin-intolerant patients. The actions of ezetimibe are complementary to those of statins. Dual therapy with these two classes of drugs prevents both the enhanced cholesterol synthesis induced by ezetimibe and the increase in cholesterol absorption induced by statins, providing additive reductions in LDL-C levels. A combination tablet containing ezetimibe, 10 mg, and various doses of simvastatin (10, 20, 40, and 80 mg) has been approved. LDL reduction at the highest simvastatin dose plus ezetimibe is similar to that of high-intensity statins.

Adverse Effects and Drug Interactions

Other than rare allergic reactions, specific adverse effects have not been observed in patients taking ezetimibe. *Because all statins are*

contraindicated in pregnant and nursing women, combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.

Omega-3 Fatty Acid Ethyl Esters

Mechanism of Action

Omega-3 fatty acids, commonly EPA and DHA ethyl esters, reduce VLDL triglycerides and are used as an adjunct to diet for treatment of adult patients with severe hypertriglyceridemia. The recommended daily oral dose for patients with severe hypertriglyceridemia is 3–4 g/d administered with food.

ADME

The small intestine absorbs EPA and DHA, which are mainly oxidized in the liver, similar to fatty acids derived from dietary sources. The $t_{1/2}$ of elimination is approximately 50 to 80 h.

Therapeutic Use

Fish oil or other products containing omega-3 fatty acids are among the most common OTC herbal, vitamin, or nutritional supplements purchased by consumers each year. Doses and formulations of OTC items vary considerably. The AHA recommends that consumers eat a variety of fish at least twice a week and that fish oil supplements should only be considered for individuals with heart disease or high triglyceride levels in consultation with a medical professional. In addition to OTC fish oil products, several prescription-only products are available, generally at higher doses than those used OTC (1–1.2 g) and containing a combination of EPA and DHA. Icosapent ethyl, an ethyl ester derivative of EPA, does not contain DHA. Mixtures containing both EPA and DHA have increased LDL-C in patients with severe hypertriglyceridemia, whereas studies of EPA-only products suggest they may not significantly increase LDL-C while still reducing triglycerides. Controversy exists about when to treat hypertriglyceridemia. Modifiable secondary causes of high triglycerides such as uncontrolled diabetes and excessive alcohol intake should always be addressed prior to initiating therapy. While prescription omega-3 products generally have FDA indications for triglycerides 500 mg/dL or greater, many professional organizations advocate that such products be limited to patients with levels of 1000 mg/dL or greater who are at greatest risk for pancreatitis. The ORIGIN trial found no additional reduction in ASCVD risk associated with the use of omega-3 fatty acids versus background therapy with statins alone, calling into question the common use of fish oil supplements for “heart protection” by consumers.

Adverse Effects and Drug Interactions

Adverse effects may include arthralgia, nausea, fishy burps, dyspepsia, and increased LDL. Because omega-3 fatty acids may prolong bleeding time, patients taking anticoagulants should be monitored.

PCSK9 Inhibitors

Mechanism of Action

Proprotein convertase subtilisin/kexin type 9 is a protease that binds to the LDL receptor on the surface of hepatocytes and enhances lysosomal degradation of the LDL receptor, resulting in higher plasma LDL concentrations. Loss-of-function mutations of PCSK9 are associated with reduced LDL and lowered risk of ASCVD. Conversely, mutations leading to increased PCSK9 expression result in increased LDL levels and higher risk of ASCVD events. Two PCSK9 inhibitors, *alirocumab* and *evolocumab*, antibodies to PCSK9, are FDA-approved as adjunctive therapy to diet and maximally tolerated statin therapy in adult patients with hoFH and heFH or established ASCVD requiring additional LDL lowering. Evolocumab and alirocumab are fully humanized monoclonal antibodies that bind free PCSK9, thereby interfering with its binding to the LDL receptor, leading to increased liver clearance of LDL from the circulation and lower serum LDL levels (see Figure 33–4).

Although studies are ongoing, ORION-1 describes a novel RNA interference therapeutic, inclisiran, that targets PCSK9 mRNA and thus blocks PCSK9 protein synthesis (Ray et al., 2017). Early clinical trials showed

promise for an RNA interference therapeutic (ALN-PCS) that targets PCSK9 mRNA and thus blocks PCSK9 protein synthesis. Low-volume subcutaneous injections of inclisiran resulted in persistent reductions in LDL-C and other atherogenic lipids for 180 days, suggesting that a biannual subcutaneous dosing regimen might be possible.

ADME

The PCSK9 inhibitors are administered as subcutaneous injections either every 2 weeks or once monthly, depending on the dose and indication. Evolocumab is administered as a 140-mg injection every 2 weeks or 420 mg once monthly. For hoFH, evolocumab 420 mg is administered once monthly or every 2 weeks, and alirocumab (75 mg or 150 mg) is administered once every 2 weeks. Administration requirements and storage of these medications are barriers when compared with the ease of oral dosage forms of other medications.

The LDL-C plasma levels may be measured 4 to 8 weeks after initiating therapy or changing doses. These medications inhibit PCSK9 availability for 2 to 3 weeks after administration (half-life of elimination is 11 to 20 days), after which LDL levels begin to rise. Limited data are available in individuals with renal or hepatic impairment, although dose adjustments are not expected to be necessary. *PCSK9 inhibitors should not be used in pregnancy because transmission across the placenta is expected. It is not known to what degree the medications will be present in breast milk, so use during lactation is not recommended.*

Therapeutic Use

The effects of PCSK9 inhibitors are complementary to those of statins. While statins interfere with cholesterol production and stimulate the production of LDL receptors, PCSK9 inhibitors enable more LDL receptors to be available on the surface of liver cells. PCSK9 inhibitors reduce LDL-C in a dose-dependent manner by as much as 70% when used as monotherapy or by as much as 60% in patients already on statin therapy. Indications and approvals of these agents vary between countries. Currently, PCSK9 inhibitors are not FDA-approved for treatment of dyslipidemias in statin-intolerant patients without known ASCVD, although they are being used in this population elsewhere. Among patients with known ASCVD and LDL >70 despite treatment with moderate-high intensity statins, the addition of evolocumab further reduced the risk of ASCVD events, but not death, in the FOURIER trial (Sabatine et al., 2017). Given the high cost of treatment with PCSK9 inhibitors versus relatively inexpensive statin treatment, cost-effectiveness studies will also need to be conducted in a variety of patient populations to provide further recommendations on the patients most likely to benefit from these therapies. Currently, and because of cost-effectiveness, treatment with maximally tolerated doses of statins and ezetimibe is recommended prior to initiation of PCSK9 inhibitors.

Adverse Effects and Drug Interactions

Several clinical trials have identified a small (<1%) risk of neurocognitive effects in patients treated with PCSK9 inhibitors compared to placebo. Additional studies are under way to better understand the long-term neurocognitive effects of these medications, if any. Unlike other medications used to treat dyslipidemias, PCSK9 inhibitors do not appear to substantially increase the risk of myopathies when used as monotherapy or in combination with statins. Similar to other monoclonal antibodies, risk of infections, including nasopharyngitis, urinary tract infections, or upper respiratory infections, is slightly increased. Injection site reactions are the most frequent adverse effect, although these occur in less than 10% of patients. There are no expected drug interactions with PCSK9 inhibitors.

Inhibitor of Microsomal Triglyceride Transfer

Lomitapide

Mechanism of Action. Lomitapide mesylate is the first drug that acts by inhibiting MTP, which is essential for the formation of VLDLs.

ADME. Lomitapide is administered with water and without food (or at least 2 h after the evening meal) because administration with food may

Figure 33-4 LDL catabolism: effects of PCSK9, antibody to PCSK9, and statins. Hepatic LDL uptake varies with the density of LDLRs in the hepatocyte membrane. The extent of LDLR synthesis and recycling affect the availability of LDLRs, variables that PCSK9, antibody to PCSK9, and statins can influence. **A.** In the absence of PCSK9, the LDLR is synthesized and inserted into the plasma membrane, where it binds LDL. The LDLR-LDL complex enters the hepatocyte by endocytosis. The complex dissociates within the endosome, the LDL entering the lysosomal pathway (degradation), and the LDLR being recycled to the membrane. **B.** In the presence of PCSK9 biosynthesis, however, PCSK9 is exported into the circulation. At the surface of the hepatocyte, PCSK9 interacts with the LDLR-LDL complex, entering the endosome and preventing the dissociation of LDLRs from LDL. As a consequence, the entire LDLR-LDL-PCSK9 complex enters the lysosomal pathway for degradation. Little or no LDLR is recycled, and future LDL uptake is reduced. There are gain-of-function mutations that enhance PCSK9 activity (see text). **C.** In the presence of PCSK9 and antibody to PCSK9, antibody to PCSK9 (Ab^{PCSK9}) prevents the binding of PCSK9 to the LDLR-LDL complex, returning the fate of the LDLR-LDL complex to that described in **A**, lysosomal degradation of LDL and recycling of LDLR to the membrane. **D.** In the presence of PCSK9, antibody to PCSK9, and a statin, levels of LDLR are increased by two different mechanisms. Statins, by inhibiting HMG-CoA reductase, reduce cell cholesterol, thereby activating SREBP and upregulating transcription of genes under its control; those include genes for LDLR and PCSK9. Expression of LDLR and PCSK9 increases. The newly synthesized LDLR molecules are inserted into the plasma membrane; the newly synthesized PCSK9 is exported. In the absence of Ab^{PCSK9} , the increased extracellular PCSK9 will bind to LDLR-LDL complexes, cause their lysosomal destruction, and thereby counteract some the statin's effect on circulating LDL and its uptake by hepatic LDLRs. In the presence of antibody to PCSK9, however, PCSK9 is complexed by Ab^{PCSK9} and rendered inactive, permitting an increase in LDLR presence on the hepatocyte membrane and an increase in recycling of used LDLR to the membrane. Thus, by protecting LDLRs from degradation and enhancing synthesis of new LDLRs, the combination of a statin and Ab^{PCSK9} can have a greater LDL-lowering effect than would the statin alone.

increase risk of GI adverse effects. The drug is metabolized by CYP3A4 and is contraindicated with inhibitors of CYP3A4.

Therapeutic Use. Lomitapide is FDA-approved as an adjunct to diet for lowering LDL-C, total cholesterol, apo B, and non-HDL-C lipoproteins in patients with hoFH. Lomitapide reduces LDL by up to 50% and should be used in combination with maximally tolerated statin therapy. The recommended starting oral dose (5 mg/d) is titrated upward at 4-week intervals to a maximum dose of 60 mg daily. The long-term cardiovascular effects of lomitapide are currently unknown.

Adverse Effects and Drug Interactions. Reported adverse effects commonly include significant diarrhea, vomiting, and abdominal pain in most patients. A strict low-fat diet may improve tolerability. Serious concerns also exist regarding hepatotoxicity and liver steatosis. In clinical trials, a third of patients experienced elevations in ALT or AST greater than three times the upper limit of normal. Lomitapide also increases hepatic fat, with or without concomitant increases in transaminases. The agent is used under an FDA risk evaluation and mitigation strategy due to its concerning side-effect profile. Lomitapide may be embryotoxic, and women of childbearing potential should have a negative pregnancy test before starting treatment and use effective contraception during treatment.

Inhibitor of Apolipoprotein B-100 Synthesis

Mipomersen

Mechanism of Action. Mipomersen is the first antisense oligonucleotide inhibitor of apo B-100 synthesis. Mipomersen binds to the mRNA

of apo B-100 in a sequence-specific manner, which results in degradation or disruption of the apo B-100 mRNA, thereby reducing expression of apo B-100 protein.

ADME. The recommended dose is 1 mL of a 200-mg/mL solution, injected subcutaneously, once a week. It is metabolized in tissues by endonucleases to form shorter oligonucleotides available for further metabolism by exonucleases. The $t_{1/2}$ is 1 to 2 months. Maximal LDL reduction occurs after 6 months of treatment. Use is contraindicated in individuals with liver disease.

Therapeutic Use. In 2013, mipomersen was approved by the FDA as an addition to lipid-lowering medications and diet for patients with hoFH. However, given the side-effect profile of the medication, it was not approved elsewhere, including in Europe. LDL levels are reduced 30% to 50% with this treatment, although the discontinuation rates were high in clinical trials with this drug.

Adverse Effects and Drug Interactions. Injection site reactions are common (80%) and include erythema, pain, itching, and hematoma. Other common adverse effects include flu-like symptoms (30%), fatigue, and headache (15%). The agent is used under an FDA risk evaluation and mitigation strategy due to concerns about hepatotoxicity. Elevations in liver enzymes greater than three times the upper limit of normal occurred in approximately 10%–15% of patients in clinical trials.

Drug Facts for Your Personal Formulary: Therapy for Dyslipidemias

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
HMG-CoA Reductase Inhibitors (Statins)		
Atorvastatin Simvastatin Rosuvastatin Lovastatin Pravastatin Fluvastatin Pitavastatin	<ul style="list-style-type: none"> The most effective and best-tolerated agents to treat dyslipidemias, especially elevated LDL-C 	<ul style="list-style-type: none"> <i>Safety of statins during pregnancy has not been established.</i> Women wishing to conceive and nursing mothers should not take statins. During their childbearing years, women taking statins should use highly effective contraception. Hepatotoxicity (one case per million person-years of use); measure liver enzymes (ALT) at baseline and thereafter only when clinically indicated. Myopathy and rhabdomyolysis (one death per million prescriptions (30-day supply); risk ↑ with dose and concomitant administration of drugs that interfere with statin catabolism or hepatic uptake.
Bile Acid–Binding Resins (Bile Acid Sequestrants)		
Cholestyramine Colestipol Colesevelam	<ul style="list-style-type: none"> Probably safest lipid-lowering drugs (not absorbed systemically) Recommended for patients 11–20 years of age 	<ul style="list-style-type: none"> Common GI side effects: bloating, dyspepsia, constipation. Cholestyramine and colestipol bind and interfere with absorption of many drugs; administer all other drugs either 1 h before or 3–4 h after dose of a bile acid resin. Severe hypertriglyceridemia is a contraindication to the use of cholestyramine and colestipol; they ↑ triglyceride levels.
Nicotinic Acid		
Niacin	<ul style="list-style-type: none"> Favorably affects all lipid parameters; most effective agent for increasing HDL-C; also lowers triglycerides and reduces LDL-C 	<ul style="list-style-type: none"> <i>Should not be taken by pregnant women.</i> Flushing, pruritus, and dyspepsia limit patient compliance. Rarer episodes of nausea, vomiting, and diarrhea. Hepatotoxicity, manifested as ↑ serum transaminases. Hyperglycemia and niacin-induced insulin resistance; in patients with known or suspected diabetes, blood glucose levels should be monitored at least weekly until stable. Concurrent use of niacin and a statin can cause myopathy and is contraindicated. Contraindicated if any history of peptic ulcer disease. Gout is a relative contraindication.
Fibric Acid (Fibrates)		
Gemfibrozil Fenofibrate <i>Not in the U.S.:</i> Ciprofibrate Bezafibrate	<ul style="list-style-type: none"> Usual drugs of choice for treating chylomicronemia, hyperlipidemia with type III hyperlipoproteinemia, severe hypertriglyceridemia (triglycerides > 1000 mg/dL) 	<ul style="list-style-type: none"> GI side effects occur in up to 5% of patients. <i>Fibrates should not be used by children or pregnant women.</i> A myopathy syndrome may occur in subjects taking clofibrate, gemfibrozil, or fenofibrate. The FDA has withdrawn approval for coadministration of fibrates with statins. Renal failure and hepatic dysfunction are relative contraindications to the use of fibrates.

Drug Facts for Your Personal Formulary: *Therapy for Dyslipidemias (continued)*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Cholesterol Absorption Inhibitor		
Ezetimibe	<ul style="list-style-type: none"> • Monotherapy in patients with ↑ LDL-C who are statin intolerant • Combination with statin ⇒ additive reductions in LDL-C 	<ul style="list-style-type: none"> • Bile-acid sequestrants inhibit absorption of ezetimibe; avoid concurrent use. • <i>Combination products containing ezetimibe and a statin should not be used by women in childbearing years in the absence of contraception.</i> • Generally well tolerated agent.
PCSK9 Inhibitors (Monoclonal Antibodies)		
Alirocumab Evolocumab	<ul style="list-style-type: none"> • Adjunct to diet and maximally tolerated statin therapy for adults with hoFH, heFH or clinical ASCVD who require additional lowering of LDL-C 	<ul style="list-style-type: none"> • Hypersensitivity or injection site reactions are possible. • Most effective agents at reducing LDL-C. • Like other monoclonal antibodies, influenza-like symptoms, nasopharyngitis, upper respiratory infections may occur. • Used in addition to maximally tolerated statin doses (complementary mechanism; see Figure 33–4).
Omega-3 Fatty Acid Ethyl Esters		
Omega-3 fatty acids (EPA and DHA)	<ul style="list-style-type: none"> • Adjunct for treating severe hypertriglyceridemia (triglycerides > 1000 mg/dL) 	<ul style="list-style-type: none"> • Adverse effects may include arthralgia, nausea, fishy burps, dyspepsia, and increased LDL. • Since omega-3-fatty acids may prolong bleeding time, patients taking anticoagulants should be monitored.
Inhibitor of Apo B-100 Synthesis (Antisense Oligonucleotide)		
Mipomersen	<ul style="list-style-type: none"> • Used as an adjunct to lipid-lowering agents and diet in patients with hoFH 	<ul style="list-style-type: none"> • Common adverse effects include injection site reactions, flu-like symptoms, headache, and elevation of liver enzymes. • The agent is used under an FDA risk evaluation and mitigation strategy.
Inhibitor of Liver Microsomal Triglyceride Transfer Protein		
Lomitapide	<ul style="list-style-type: none"> • Used as an adjunct to diet for lowering LDL-C, total cholesterol, apo B, and non-HDL-C in patients with hoFH 	<ul style="list-style-type: none"> • In patients with hoFH, treatment can reduce LDL-C by 40%–50%. • Adverse effects include GI symptoms, elevation of serum liver enzymes, and increased liver fat in most patients. • The agent is used under an FDA risk evaluation and mitigation strategy.

- Chronic Inflammation

IMMUNE SYSTEM-RELATED CONDITIONS

- Hypersensitivity Reactions
- Autoimmunity, Immune Deficiency, and Transplant Rejection
- Cancer Immunotherapy

The introduction of pathogens and foreign proteins into the human body can stimulate immune recognition, leading to inflammatory and allergic responses. Aspects of these responses are subject to pharmacological modulation. Before describing the actions of pharmacological agents affecting allergy and immunity, this chapter describes the cellular and molecular basis of immune and allergic responses and the points of pharmacological intervention. Subsequent chapters in this section cover in detail the classes of agents that can alter allergic and immune responses, as well as the biology and pharmacology of inflammation.

Cells and Organs of the Immune System

Hematopoiesis

All blood cells, including immune cells, originate from pluripotent hematopoietic stem cells (HSCs) of the bone marrow. HSCs are a population of undifferentiated progenitor cells that are capable of self-renewal. On exposure to cytokines and contact with the surrounding stromal cells, HSCs can differentiate into megakaryocytes (the source of platelets), erythrocytes (red blood cells), and leukocytes (white blood cells). This process is known as hematopoiesis (Figure 34-1).

The HSC pool can be divided in two populations: long-term (LT) and short-term (ST) HSCs. LT-HSCs are capable of lifelong self-renewal, allowing for continuous hematopoiesis throughout life. ST-HSCs have limited self-renewing capability, and differentiate into multipotent progenitors—the common myeloid progenitor (CMP) and the common lymphoid progenitor (CLP). The CMP gives rise to the myeloid lineage of cells that includes megakaryocytes; erythrocytes; granulocytes (neutrophils, eosinophils, basophils, mast cells); monocytes; macrophages; and dendritic cells (DCs). In contrast, the CLP gives rise to the lymphoid lineage of cells that includes natural killer (NK) cells, B lymphocytes (B cells), and T lymphocytes (T cells) (Doulatov et al., 2012; Eaves, 2015).

Cells of the Innate Immune System

Innate immunity refers to the host defense mechanisms that are immediately available on exposure to pathogens.

Granulocytes

Granulocytes have characteristic cytoplasmic granules containing substances that, in addition to killing invading pathogens, enhance inflammation at the site of infection or injury. Neutrophils are the most abundant of the granulocytes and are generally the first cells to arrive at the site of injury. They are specialized at engulfing and killing pathogens—a process known as phagocytosis. Like neutrophils, eosinophils are also motile phagocytic cells. These cells defend against parasitic organisms such as helminths by releasing the contents of their granules, which are thought to damage the parasite membrane. Basophils and mast cells have granules that contain histamine and other pharmacologically active substances. In addition to their protective function, these cells can become dysregulated during the generation of allergic responses, in which they play an important role (see Hypersensitivity Reactions).

Mononuclear Phagocytes

Mononuclear phagocytes consist of monocytes and macrophages. Monocytes circulate in the blood and then migrate into tissues where they differentiate into macrophages, increase 5- to 10-fold in size, and acquire enhanced phagocytic and microbicidal activity. Macrophages engulf and eliminate pathogens, dead cells, and cellular debris. Macrophages can remain motile and travel throughout the tissues by amoeboid movements, and they can also take up residence in specific tissues, becoming tissue-resident macrophages. In addition to their role as phagocytes, macrophages release pro-inflammatory molecules, such as cytokines and eicosanoids, that recruit other immune cells to the site of infection (see Inflammation).

Natural Killer Cells

Natural killer cells are cytotoxic, granular lymphocytes that target tumor and virus-infected cells. NK cell receptors selectively target damaged or infected host cells by recognizing abnormal expression of surface molecules seen on damaged, but not healthy, cells.

Dendritic Cells

Dendritic cells are specialized cells that reside in tissues and stimulate adaptive immune responses. Immature DCs patrol peripheral tissues and sample their environment for infection by capturing pathogens through

Abbreviations

Ag: antigen
APC: antigen presenting cell
BCR: B-cell receptor
C#: complement component # (e.g. C3, C5)
CD: cluster of differentiation
CLL: chronic lymphocytic leukemia
CR#: complement receptor #
CTL: cytotoxic T lymphocyte
CTLA-4: cytotoxic T-lymphocyte-associated protein 4
DC: dendritic cell
HLA: human leukocyte antigen
HSC: hematopoietic stem cell
IFN: interferon
Ig: immunoglobulin
IL: interleukin
iNOS: inducible nitric oxide synthase: NOS2
IRF#: interferon regulatory factor #
ISG: interferon-stimulated gene
ISRE: interferon-stimulated response element
LTB₄: Leukotriene B ₄
MADCAM-1: mucosal vascular addressin cell adhesion molecule 1
MALT: mucosa-associated lymphoid tissue
MHC: major histocompatibility complex
NK cell: natural killer cell
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
PAMP: pathogen-associated molecular pattern
PD1: programmed cell death protein 1
PRR: pattern recognition receptor
Rh: rhesus
ROS: reactive oxygen species
ST: short term
TAP: transporter associated with antigen processing
T_C: cytotoxic T cell
TCR: T-cell receptor
T_{FH}: follicular helper T cells
T_H: helper T cell
TLR: toll-like receptor
TNF-α: tumor necrosis factor alpha
T_{Reg}: T-regulatory cells

phagocytosis, receptor-mediated endocytosis, and pinocytosis. After maturation, DCs shift from a phenotype that promotes antigen capture, to one that supports antigen presentation. Mature DCs migrate from the peripheral tissues to lymphoid organs and present antigens to activate helper and cytotoxic T cells (see Antigen Processing and Presentation).

Cells of the Adaptive Immune System

Adaptive immunity (also known as the acquired immune system) represents a branch of the immune system that is characterized by antigen specificity and immunological memory. It is mediated by B and T lymphocytes following exposure to specific antigens and is more complex than innate immunity in that it requires prior antigen processing and recognition to launch lymphocyte responses. Furthermore, in contrast to innate immune responses, which occur within hours after infection, B- and T-lymphocyte responses take days to develop.

B Cells

The B lymphocytes, also known as B cells, express cell surface pathogen receptors called immunoglobulins. When a naïve B cell (one that has not previously encountered antigen) detects a pathogen through

binding of its immunoglobulin, it begins to proliferate. Its progeny can differentiate into plasma cells or memory B cells. Plasma cells are short-lived effector cells that specialize in secreting antibodies—the soluble form of immunoglobulins. Memory B cells are long-lived and persist for years following an infection. Because memory B cells express the same immunoglobulin as their parent B cell, they mount an enhanced secondary response to a pathogen on reinfection and are the basis for B cell-mediated immunity.

T Cells

The T lymphocytes, also known as T cells, express cell surface pathogen receptors called TCRs. Unlike immunoglobulins, which independently recognize antigens, TCRs only recognize antigens presented on MHC molecules on the surface of DCs or other APCs. T cells are divided into two subpopulations—T_C cells and T_H cells. T_C cells or killer T cells destroy host cells that are infected with intracellular pathogens, whereas T_H cells secrete cytokines that help enhance the function of other immune cells to mediate pathogen clearance. Activated T cells can differentiate into effector cells—cells that carry out immediate functions to help clear the infection—or memory cells. Memory T cells, like memory B cells, persist for years following an infection and mount an enhanced response on reexposure to the same pathogen (see Immunological Memory).

Organs of the Immune System

The organs of the immune system are divided into two categories based on their function: *primary lymphoid organs* and *secondary lymphoid organs*. Lymphocyte maturation and development take place in the primary lymphoid organs, whereas secondary lymphoid organs provide sites for mature lymphocytes to interact with APCs. These lymphoid organs are interconnected by blood and lymphatic vessels.

Primary Lymphoid Organs

The bone marrow and thymus make up the primary lymphoid organs. Both B-cell and T-cell precursors originate in the bone marrow from HSCs. B cells complete their maturation in the bone marrow, whereas T-cell precursors migrate to the thymus to complete their development.

The bone marrow tissue is composed of a meshwork of stromal cells (e.g., endothelial cells, adipocytes, fibroblasts, osteoclasts, osteoblasts, and macrophages). Immature B cells proliferate and differentiate within the bone marrow with direct (cell-cell contact) and indirect (cytokine release) help from stromal cells. IL-1, IL-6, and IL-7 are the most important cytokines guiding the B-cell differentiation process (Hoggatt et al., 2016).

The thymus is a bilobe organ that sits above the heart. Each lobe is divided into smaller lobules that consist of an outer compartment (cortex) and an inner compartment (medulla). Both the cortex and the medulla contain a stromal cell network comprising epithelial cells, DCs, and macrophages that present self-antigens to maturing T cells. This stromal cell network is responsible for the maturation process, and the cytokines IL-1, IL-2, IL-6, and IL-7 also play an important role in this process. The thymus begins to atrophy after puberty (as the thymic stroma is eventually replaced with adipose tissue), causing a decline in T-cell output. By age 35, T-cell production drops to 20% compared to that of newborn levels, and by age 65 this number further decreases to 2% (Palmer, 2013). Importantly, once the periphery is seeded with mature T cells, the host is equipped with a diversity of naïve T cells that will respond to any pathogen encounter, irrespective of diminished thymic output.

Secondary Lymphoid Organs

The secondary lymphoid organs, including the spleen, lymph nodes, and mucosa-associated lymphoid tissue MALT, are the sites where adaptive immune responses are initiated. The spleen is the largest lymphoid organ, consisting of red pulp and white pulp. The red pulp is a sponge-like tissue where old or damaged erythrocytes are recycled, whereas the white pulp region consists of lymphocytes. The spleen is the only lymphoid organ that is not connected to the lymphatic vessels. Instead, immune cells enter and exit the spleen through blood vessels.

Figure 34–1 Development of myeloid and lymphoid lineage cells from HSCs in the bone marrow. HSCs give rise to lineage-specific precursors, which differentiate into all myeloid and lymphoid cells.

Lymph nodes are round, specialized structures that are positioned along the lymphatic vessels like beads on a chain. They collect the lymph (containing immune cells and antigens) that drains from the skin and internal organs and provide the physical location where antigen presentation and lymphocyte activation occur. The MALTs are loosely organized lymphoid tissues located in the submucosal surfaces of the gastrointestinal (GI) tract, respiratory system, and urinary tract (Neely and Flajnik, 2016).

The Lymphatic System

The “lymphatic system” or “lymphatics” represent a network of lymphatic vessels (similar to the circulatory system’s veins and capillaries) that are connected to lymph nodes. Similar to their circulatory counterparts, small lymph capillaries are made up of single endothelial cell layers, whereas in larger lymph vessels the endothelial cells are surrounded by layers of smooth muscle cells. Additional parts of the lymphatic system are the tonsils, adenoids, spleen, and thymus. The lymphatics collect plasma continuously leaking out from blood vessels into the interstitial spaces and return this fluid, now called lymph, to the blood (after filtration in the lymph nodes) into the subclavian veins located on either side of the neck near the clavicles. Unlike blood movement, which is driven by a pump and flows throughout the body in a continuous loop, lymph flows in only one direction—upward toward the neck—and movement originates from rhythmic contractions of the smooth muscle cells, with directionality achieved via semilunar valves inside the vessels. The lymphatics therefore have an important function in regulating both immune and fluid homeostasis.

The B and T cells, unlike other blood cells, traffic through the body via both blood and lymph (hence the term *lymphocyte*). After completing their development in the primary lymphoid organs, B and T cells enter the bloodstream. When lymphocytes reach blood capillaries that empty into secondary lymphoid tissues, they enter these tissues. If a naïve lymphocyte encounters antigen, it will remain in the secondary lymphoid tissue and become activated. Otherwise, if no antigen is detected, the lymphocyte

then exits through the efferent lymph and reenters the bloodstream. This pattern of movement between the blood and lymph is referred to as lymphocyte recirculation, and it allows the lymphocyte population to continuously monitor the secondary lymphoid organs for signs of infection (Masopust and Schenkel, 2013; Thomas et al., 2016).

Innate Immunity

Innate immunity refers to the defense mechanisms that are immediately available on exposure to pathogens. These mechanisms consist of anatomical barriers, soluble mediators, and cellular responses. To establish an infection, a pathogen must first penetrate a host’s anatomical barriers, including the skin and mucous membranes. If a pathogen manages to breach these anatomical barriers, the cellular innate immune response initiates rapidly, within a matter of minutes, to activate further mechanisms of the immune response.

Anatomical Barriers

The skin and mucosal surfaces form the first line of defense against pathogens. The skin is made up of a thin outer layer (epidermis) of tightly packed epithelial cells and an inner layer (dermis) of connective tissue containing blood vessels, sebaceous glands, and sweat glands. The respiratory, GI, and urogenital tracts are lined by mucous membranes. Like skin, mucous membranes consist of an outer layer of epithelial cells and an underlying layer of connective tissue. These anatomical surfaces act as more than just passive barriers against pathogens. All epithelial surfaces secrete antimicrobial peptides called host defense peptides (HDPs). HDPs kill bacteria, fungi, and viruses by disrupting their membranes (Hancock et al., 2016). The sebum secreted by the sebaceous glands contains fatty acids and lactic acids that inhibit bacterial growth on the skin. Mucosal surfaces are continuously covered in mucus (a viscous fluid secreted by epithelial cells of mucous membranes) containing

antimicrobial substances that trap foreign microorganisms and help limit the spread of infection. In the respiratory tract, this mucous is continually removed by the action of cilia on epithelial cells. In addition, all these anatomical surfaces harbor commensal microorganisms. These commensals help protect against disease by preventing colonization by harmful microorganisms. These physical, mechanical, chemical, and microbiological barriers prevent a majority of pathogens from gaining access to the cells and tissues of the body (Belkaid and Tamoutounour, 2016).

However, some pathogens manage to breach these barriers. Microbes can enter the skin through scratches, wounds, or insect bites, such as those from mosquitoes (e.g., *Plasmodium falciparum*, the protozoan species predominantly responsible for malaria); ticks (e.g., *Borrelia burgdorferi*, the bacterium responsible for Lyme disease); and fleas (e.g., *Yersinia pestis*, the bacterium responsible for bubonic plague). Many pathogens enter the body by penetrating mucous membranes. One example is the influenza virus, which expresses a surface molecule that allows it to attach to and invade cells in the mucous membranes of the respiratory tract.

Once a pathogen breaches these anatomical barriers, the innate immune system first responds by detecting the pathogen. This initiates an inflammatory response—mediated by soluble effectors such as complement, eicosanoids, and cytokines—that results in the recruitment of immune cells to the site of infection, direct lysis or phagocytosis of pathogens, and eventual activation of the adaptive immune response.

Pathogen Recognition

The first phase of an innate immune response involves pathogen detection, which is mediated by secreted and cell surface pathogen receptors. Innate immune cells recognize broad structural patterns that are conserved within microbial species but are absent from host tissues. These broad structural patterns are referred to as *PAMPs* and the receptors that recognize them are called *PRRs*. PRRs can be broadly divided into three classes: secreted, endocytic, and signaling PRRs.

Secreted PRRs and the Complement System

Secreted PRRs are opsonins (molecules that enhance phagocytosis) that bind to microbial cell walls and tag them for destruction by the complement system or by phagocytes. C-reactive protein and mannose-binding lectin are two examples of secreted PRRs; both are components of the acute-phase response (see Inflammation).

The plasma proteins known as the complement system are some of the first to act following pathogen entry into host tissues. Over 30 proteins make up the complement system. These proteins circulate in blood and interstitial fluid in inactive forms that become activated in sequential cascades in response to interaction with molecular components of pathogens, leading to the activation of C3, which plays the most important role in pathogen detection and clearance. Complement activation leads to the cleavage of C3 into C3b and C3a fragments. The large C3b fragment (an opsonin) attaches to pathogen surfaces in a process called complement fixation and can activate C5 and a lytic pathway that can damage the plasma membrane of adjacent cells and microorganisms. The C5a fragment attracts macrophages and neutrophils and can activate mast cells. The small C3a fragment (anaphylatoxin) also promotes inflammation. Thus, complement fixation has two functions: the formation of protein complexes that damage the pathogen's membrane and marking the pathogen for destruction by phagocytes (Morgan and Harris, 2015).

Endocytic PRRs

Endocytic PRRs are expressed on the surface of phagocytic cells. These receptors mediate the uptake and transport of microbes into lysosomes, where they are degraded. The degraded microbial peptides are processed and presented to T cells by members of the MHC family of cell surface proteins. (In humans, the MHC is also called *human leukocyte antigen* or *HLA*). The mannose, glucan, and scavenger receptors are part of this class of receptors.

Signaling PRRs

On PAMP detection, signaling PRRs trigger intracellular signaling cascades that eventually result in the production of cytokines that orchestrate the early immune response. The most-studied group of signaling PRRs are the TLRs. TLRs are a family of PRRs that recognize a variety of microbial products. These transmembrane proteins are composed of an extracellular domain that detects pathogens and a cytoplasmic signaling domain that relays information to the nucleus. TLRs are expressed on the plasma membranes and endosomes of immune cells.

Signaling through TLRs leads to activation of two distinct signal transduction pathways (see PAMPs, PRRs, and the Induction of Interferons on next page). Most TLRs signal through a pathway that promotes the activation of the transcription factor NF- κ B and the production of pro-inflammatory cytokines such as IL-1, IL-6, IL-12, and TNF- α . The exception is TLR3, which signals through a pathway that leads to the activation of the transcription factor IRF3, and the production of interferon (IFN) types I and III. TLR4 is unique in that it signals through both pathways (Cao, 2016).

Type I (IFN- α and IFN- β) and type III (IFN- λ) IFNs promote the production of ISGs in infected and neighboring cells, the products of which induce an intracellular antimicrobial program that limits the spread of infectious pathogens, particularly viruses. Type I IFNs also augment antigen presentation and cytokine production by innate immune cells, leading to enhanced adaptive immune responses (Gonzalez-Navajas et al., 2012).

Pathogen Clearance

Pathogens vary in the manner by which they live and replicate within their hosts. Extracellular pathogens replicate on epithelial surfaces, or within the interstitial spaces, blood, and lymph of their host. Intracellular pathogens establish infections within host cells, either in the cytoplasm or in cellular vesicles. Depending on the nature of the infection, different immune cells and effector mechanisms are involved in the control and elimination of the pathogen.

Extracellular Pathogens

Unlike pathogens that replicate within host cells, extracellular pathogens are accessible to soluble effector proteins. Pathogens that replicate within interstitial spaces, blood, and lymph are detected by secreted PRRs and complement proteins. Complement fixation triggers direct lysis of the pathogen and enhances pathogen uptake by phagocytic cells. The phagocytic cells involved in the clearance of extracellular pathogens are macrophages and neutrophils. Tissue-resident macrophages are long-lived cells that are present from the start of an infection. They engulf pathogens and release inflammatory mediators to alert host cells of an attack. Neutrophils, in contrast, are short-lived, circulating phagocytes. Inflammatory cues, such as those released by macrophages, recruit neutrophils to the site of infection, where they soon become the dominant phagocyte.

On entry into host tissues, the first immune cells a pathogen encounters are the tissue-resident macrophages. Macrophages phagocytize microorganisms in a nonspecific fashion through their phagocytic receptors. Proteins of the complement system enhance this process by binding to receptors expressed by macrophages. One such receptor is complement receptor 1 (CR1). CR1 molecules interact with C3b fragments that have been deposited on the pathogen's surface, facilitating the engulfment and destruction of the pathogen.

In addition to engulfing invading pathogens, macrophages alert host cells of an infection. TLR4 engagement on macrophages leads to the production of pro-inflammatory cytokines such as IL-1, IL-6, IL-12, TNF- α , and CXCL8 (see Inflammation). These cytokines recruit immune cells, the most prominent of which are neutrophils, to the infected tissue (Lavin et al., 2015).

Circulating neutrophils have an average life span of less than 2 days. Mature neutrophils are kept in the bone marrow for up to 5 days before being released into circulation, ensuring a large reserve that can be summoned during an infection. When neutrophils sense inflammatory signals such as cytokines, chemokines, eicosanoids, ROS, or NO, they migrate to the site of infection, where they engulf and kill the invading pathogen.

PAMPs, PRRs, and the Induction of Interferons

Cells of the innate immune system—predominantly dendritic cells and macrophages—recognize broad structural patterns that are conserved within microbial species but are absent from host tissues. These patterns are called *pathogen-associated molecular patterns* (PAMPs); *Pattern recognition receptors* (PRRs) recognize PAMPs. There are three broad classes of PRRs: secreted, endocytic, and signaling PRRs.

Activation of signaling PRRs results in the production of cytokines that orchestrate the early immune response. The most well-studied group of signaling PRRs are the 11 Toll-like receptors (TLRs), each of which displays specificity for a distinct PAMP (e.g., TLR4 recognizes lipopolysaccharide (LPS); TLR3 binds double-stranded RNA [dsRNA]; TLR9 interacts with foreign DNA, etc.). Another receptor group, C-type lectin-like receptors, recognizes unique carbohydrate structures on invading microorganisms. Other signaling PRRs are cytosolic, such as retinoic acid-inducible gene (RIG)-I-like receptors (RLRs) that are activated by cytoplasmic double-stranded and 5'-triphosphorylated RNA species, and the nucleotide-binding oligomerization domain (NOD)-like receptor (NLRs) that detect cytosolic endotoxins. Signaling through most PRRs leads to broad cytokine responses, mediated by nuclear factor kappa B (NF- κ B) and resulting in the production of pro-inflammatory cytokines such as interleukin (IL) 1, IL-6, IL-12, and tumor necrosis factor alpha (TNF- α).

In response to attack by viruses, bacteria, parasites, and tumor cells, membrane-bound and cytosolic (endosomal) signaling PRRs, including TLRs, work via several convergent pathways to stimulate the production of yet another class of cytokines, the interferons (IFNs). There are three types of IFNs: type I IFN (mainly IFN- α and IFN- β , plus other minor forms such as IFN- ϵ or IFN- ω); type II IFN (IFN- γ); and type III IFN (IFN- λ). IFNs are about 145 amino acid glycoproteins, with molecular masses of approximately 19–24 kDa, depending on the extent of glycosylation. Viral infections are the major inducers of the transcription of genes encoding type I IFNs. Pathways leading to IFN production are complex. The contemporary model now encompasses the concept that PRRs trigger intracellular signaling cascades that involve receptor-associated adapters (e.g., TRIM, TIRAP, MyD88, etc.) and the assembly of a signalosome containing various kinases (e.g., TBK1, IKK ϵ , TAK, ASK1, etc.). Activation of these kinases in response to pathogen recognition leads to the phosphorylation and activation of the latent cytoplasmic transcription factors termed interferon regulatory factors (IRFs). Activation of IRF3 and IRF7, sometimes in combination with other transcription factors, activates transcription of the genes encoding type I IFNs.

Actions of IFNs

The IFNs are unique among the cytokine superfamily in that they produce an array of pleiotropic effects when they bind to their specific receptor. IFNs convey antiviral, antiproliferative, and immunomodulatory functions onto their target cells.

The IFNs are the most crucial cytokines in the defense against invading microorganisms, particularly viruses. IFN- α , IFN- β , and the more recently discovered IFN- λ , are vital elements in these defense mechanisms. Type I IFNs promote the production of interferon-stimulated genes (ISGs) in infected and neighboring cells, the products of which induce an intracellular antimicrobial program that limits the spread of infectious pathogens. Type I IFNs also augment antigen presentation, costimulation, and cytokine production by innate immune cells, leading to enhanced adaptive immune responses.

Produced by activated helper T (T_H) and natural killer (NK) cells, IFN- γ enhances the microbicidal activity of macrophages by inducing mammalian inducible nitric oxide synthase (iNOS, also called NOS2), thereby increasing their production of nitric oxide (NO) and their capacity to kill intracellular pathogens. Furthermore, CD8 $^+$ T cells

utilize IFN- γ to directly kill infected cells and tumors. Indeed, IFN- γ contributes significantly to the adaptive immune system, where it also influences developmental processes such as immunoglobulin (Ig) isotype switching in B cells and T_H1 cell differentiation.

Cellular Signaling in Responses to IFNs

Interferon signaling is a complex mechanism that elicits the appropriate antimicrobial program in target cells. IFNs bind to distinct heteromeric membrane receptors. Binding of the type I IFNs to their specific cell surface receptors leads to cross tyrosine phosphorylation, recruitment and activation of the STAT (Janus kinase/signal transducer and activator of transcription) pathway. Several members of the STAT family of transcription factors and IRF9 cooperatively form the DNA binding protein complex ISGF3, which is required for expression of ISGs through activation of the interferon-stimulated response element (ISRE) in their promoters. Transcriptional induction of these immediate early response genes facilitates the establishment of an antiviral state, achieves antiproliferation in normal and tumor cells, and influences adaptive immune responses (e.g., via modulation of IL-2 production and expression of the α chain [CD25] of the IL-2R complex; see Figure 35–2).

Numerous genes contain an ISRE. Their gene products are components of the antiviral defense: 2'-5' poly-A-synthase, dsRNA activated protein kinase (PKR), cell surface proteins such as ICAM and the major histocompatibility complex (MHC) I and II classes, chemokines (e.g., ISG15 and the IP10), and myriad genes of unknown function. More recently, numerous micro-RNAs have been added to the repertoire of IFN-induced response genes that contribute to control of pathogens.

In addition, neutrophils can release extracellular DNA nets that trap bacterial pathogens (von Kockritz-Blickwede and Nizet, 2009). Neutrophils die within 2 h of entry into infected tissues, forming the characteristic pus that develops at sites of infection (Kruger et al., 2015).

Intracellular Pathogens

The NK cells provide an early defense against intracellular pathogens. Like neutrophils, these circulating leukocytes migrate from the blood to the site of infection in response to inflammatory cues. Once at the site of infection, NK cells target and kill infected host cells.

The NK cells express receptors that deliver either activating or inhibitory signals. The ligands for the activating NK cell receptors are typically cell surface proteins whose expression is altered during infection or trauma. Healthy cells are protected from attack by NK cells because the signals generated from the inhibitory NK cell receptors dominate those generated from the activating receptors. In contrast, interaction between NK cells and infected or damaged cells shifts the balance of inhibitory and activating signals to favor an attack. This system allows NK cells to discriminate between healthy cells that should be protected and infected cells that should be destroyed.

The NK cells are stimulated by cytokines, including type I IFNs, IL-12, and TNF- α . IFN- α and IFN- β enhance NK cell cytotoxicity and induce NK cell proliferation, whereas IL-12 enhances cytokine production. The key cytokine produced by NK cells is IFN- γ , also called type II IFN. One function of IFN- γ is to activate macrophages. Activated macrophages exhibit enhanced microbicidal activity. One mechanism of their microbicidal activity is the induction of iNOS and the production of prodigious amounts of NO (Bjorkstrom et al., 2016).

Adaptive Immunity

Adaptive immunity refers to the arm of the immune response that changes (adapts) with each new infection. The cells responsible for adaptive immunity are B cells and T cells. The effector mechanisms used by B and T cells

Figure 34–2 Antigen processing and presentation via the MHC class I and II pathways. Endogenous peptides from a variety of sources are processed by proteasomes; the resulting peptides are transported via the TAP complex into the ER, where they encounter MHC class I– β_2m (β_2 -microglobulin) heterodimers. After the peptide loading of the MHC class I complex, the final peptide–MHC class I complexes migrate through the Golgi and are delivered to the cell surface to engage CD8⁺ T cells. Exogenous antigens are endocytosed and processed by a lysosome/proteasome. The MHC class II complex is assembled in the ER, migrates through the Golgi, and subsequently fuses with the vesicle containing processed antigen fragments. These peptide cleavage products are loaded into the peptide-binding groove of the MHC class II, and the peptide–MHC class II complexes are transported to the cell surface and presented to CD4⁺ T cells.

are similar to those used by innate immune cells; however, the important distinction between innate and adaptive immunity lies in their mode of pathogen recognition. Whereas the PRRs of the innate immune response recognize broad microbial patterns, B cells and T cells express receptors that recognize highly specific molecular structures. Following pathogen exposure, B and T cells with receptors that recognize the invading pathogen proliferate robustly and differentiate into effector lymphocytes. Soon after pathogen clearance, a large number of effector B and T cells die, but a small population of memory cells survives. Those cells have the ability to mount a rapid and specific response on reexposure to the same pathogen. This memory response, unique to adaptive immunity, is the basis for vaccination (see Chapter 36).

Initiation of the Adaptive Immune Response

The skin and mucosal surfaces prevent the majority of pathogens from entering host tissues and causing infections. Innate immune responses generally eliminate microorganisms that breach these barriers, typically within a few days. However, some pathogens establish an infection that cannot be controlled entirely by the innate immune response. In these cases, pathogen clearance requires the adaptive immune response.

Dendritic cells provide an essential link between innate and adaptive immunity. DCs engulf pathogens at the site of infection and travel to the lymphoid organs. Once there, they activate T cells by presenting them with fragments of the engulfed pathogen loaded on MHC molecules (see section on Antigen Processing and Presentation).

Pathogen Recognition

The innate immune system detects pathogens by a fixed repertoire of soluble and cell-surface receptors that recognize broad structures shared by different pathogens. The genes encoding these pathogen receptors are inherited from one generation to the next in a stable form.

The adaptive immune system uses a more focused strategy of pathogen recognition. B and T cells recognize pathogens by using cell surface receptors of one molecular type: BCRs and TCRs. In contrast to the stably inherited genes encoding innate immune pathogen receptors, the genes encoding BCRs and TCRs rearrange during the course of lymphocyte development. This gene rearrangement enables the development of millions of pathogen receptors with unique binding sites, each expressed by a small subset of lymphocytes. On pathogen exposure, only those lymphocytes with receptors that recognize specific components of the invading pathogen (referred to as the receptor's *cognate antigen*) are selected to proliferate and differentiate into effector cells.

Pathogen Receptors: BCRs and TCRs

The BCRs and TCRs are structurally related molecules. The BCR, also called immunoglobulin, is composed of two identical heavy chains and two identical light chains. Each polypeptide chain expresses an amino-terminal variable region, which contains the antigen-binding site, and a carboxy-terminal constant region. Immunoglobulins are anchored in the B-cell membrane by two transmembrane regions at the end of each heavy chain. Immunoglobulins are initially surface bound but become soluble when a B cell differentiates into a plasma cell. The soluble forms of immunoglobulins are called antibodies.

The TCR is composed of an α chain (TCR α) and a β chain (TCR β), both anchored in the T-cell membrane by a transmembrane region. The α and β chains consist of a variable region that contains the antigen-binding site and a constant region. In contrast to immunoglobulins, TCRs remain membrane bound and are not secreted.

Both BCRs and TCRs develop through gene rearrangement. This genetic recombination process (which B cells complete in the bone marrow and T cells in the thymus) is a defining feature of the adaptive immune system. The human BCR and its soluble derivative, the antibody, are composed from genes of three loci, the *IG heavy chain*, the *IG κ light*

chain, and the $IG\lambda$ light chain, yielding a repertoire of more than 10^{11} possible combinations. In close resemblance, the TCR comprises either an α and a β chain (most common) or a γ and a δ chain. Two of the key enzymes involved are RAG1 and RAG2 (RAG, recombination-activating gene; deficiencies in these enzymes result in a complete absence of mature lymphocytes) and the terminal deoxynucleotidyl transferase, albeit the full complexity of the DNA repair machinery is required to accomplish a productive rearrangement. Failure to do so will lead to the elimination of the unsuccessful B or T cells by programmed cell death (Nemazee, 2006). These recombination and subsequent somatic hypermutation events are vital for an optimally performing adaptive immune system. They remain unutilized as pharmacological targets.

Antigen Processing and Presentation

Immunoglobulins are capable of recognizing antigens in their native form. TCRs, in contrast, only recognize processed antigen fragments presented by specialized molecules encoded by the MHC (Figure 34-2). The MHC was first identified as a genetic complex that determines an organism's ability to accept or reject transplanted tissue. Further studies highlighted the importance of MHC molecules in generating T_H - and T_C -cell responses.

There are two types of MHC molecules involved in antigen presentation: MHC class I and MHC class II. These structurally related molecules are expressed on different cell types but perform parallel functions in priming T-cell responses.

MHC Class I

MHC class I molecules consist of a transmembrane glycoprotein α chain noncovalently associated with a β_2m molecule. MHC class I molecules are expressed on the surface of nearly all nucleated cells and present peptides from endogenous antigens to CD8 T_C cells.

MHC Class II

MHC class II molecules consist of two noncovalently associated transmembrane glycoproteins, an α chain and a β chain. MHC class II molecules are primarily expressed on the surface of professional APCs (DCs, macrophages, B cells) and present peptides from exogenous antigens to CD4 T_H cells.

Antigen Processing for Presentation by MHC

Unlike immunoglobulins, which recognize a wide range of molecular structures in their native form, TCRs can only recognize antigens in the form of a peptide bound to an MHC molecule. For a pathogen to be recognized by a T cell, pathogen-derived proteins need to be degraded into peptides—an event referred to as antigen processing (Figure 34-2). Endogenous antigens, those derived from intracellular pathogens, are processed by the cytosolic pathway for presentation by MHC class I molecules. Proteins in the cytosol are degraded into peptides by the proteasome. The resultant peptides are then transported out of the cytosol and into the ER by a protein called the *TAP*, which is embedded in the ER membrane. Once newly synthesized MHC class I α chains and β_2m molecules are translocated into the ER membrane, the α chains and β_2m molecules associate and bind peptide, forming a peptide-MHC complex. These peptide-MHC complexes make their way to the plasma membrane in membrane-enclosed vesicles of the Golgi apparatus.

Exogenous antigens, those derived from extracellular pathogens, are processed by the endocytic pathway for presentation by MHC class II molecules. In this pathway, extracellular pathogens are internalized by host cells through endocytosis or phagocytosis and are degraded by proteolytic enzymes within endocytic vesicles. Newly synthesized MHC class II α and β chains are translocated into the ER membrane, where they associate with a third chain, called the invariant chain. The invariant chain prevents MHC class II molecules from binding peptides in the ER and delivers MHC class II molecules to endocytic vesicles. Once in the endocytic vesicles, MHC class II molecules bind peptide and are carried to the cell surface by outgoing vesicles.

All T cells require peptide-MHC presentation by professional APCs for activation (see Primary Responses). If an intracellular pathogen does not infect a professional APC, CD8 T_C -cell responses can be generated

through a third pathway of antigen presentation called *cross-presentation*. Cross-presentation involves the uptake of extracellular material by professional APCs and its delivery to the MHC class I presentation pathway instead of the MHC class II presentation pathway via a mechanism that remains incompletely understood (Blum et al., 2013).

Note that protein degradation occurs continuously, even in the absence of infection. In uninfected cells, MHC molecules carry self-peptides—derived from normal cellular protein turnover—to the cell surface. While these peptide-MHC complexes do not normally provoke an immune response, recognition of these self-peptides by autoreactive T cells can result in the development of *autoimmunity* (see *Autoimmunity: A Breach of Tolerance*).

Lymphocyte Development and Tolerance

Innate immune PRRs are fixed receptors that recognize broad microbial structures or structures associated with damaged host cells. These receptors rarely, if ever, recognize self-antigens expressed by healthy cells. In contrast, because BCRs and TCRs develop from gene rearrangement, receptors that recognize self-antigens expressed by healthy host cells can arise. The goal of lymphocyte development is to produce cells with functional pathogen receptors but eliminate cells whose receptors recognize self-antigens. Next, we describe the processes of B-cell and T-cell development and highlight the mechanisms that maintain self-tolerance.

B-Cell Development

B-cell development takes place in the bone marrow and is driven by interaction with bone marrow stromal cells and the local cytokine environment. B-cell development can be broadly divided into pro-B-, pre-B-, immature B-, and mature B-cell stages. BCR gene rearrangement starts at the early pro-B stage and continues throughout the pre-B stage. By the immature B-cell stage, B cells express fully rearranged IgM immunoglobulins on their cell surface. At this stage, immature B cells leave the bone marrow and complete their maturation in the periphery. Mature B cells express both IgM and IgD immunoglobulins on their cell surfaces (LeBien and Tedder, 2008).

Because B-cell activation depends on help from CD4 T_H cells, negative selection of T cells whose receptors recognize self-antigens also ensures that B cells whose receptors bind to the same self-antigen will not be activated. Consequently, B cells do not undergo as rigorous of a selection process as T cells. However, B cells whose receptors recognize components of the bone marrow are negatively selected and die by apoptosis.

T-Cell Development

Unlike B cells, which develop in the bone marrow, T-cell precursors complete their development in the thymus. T-cell precursors enter the thymus as CD4⁺CD8[−] DN (double negative) cells, not yet committed to the T-cell lineage.

The DN T cells can be divided into four subsets—DN1 to DN4—based on the expression of certain cell surface molecules. Gene rearrangement of the TCRB chain begins during the DN2 stage and continues through the DN3 stage. After β -chain rearrangement is complete, the newly synthesized β -chain combines with a protein known as the pre-T α chain, forming the pre-TCR. DN3 cells then progress to the DN4 stage and express both the CD4 and CD8 coreceptors. These cells are now referred to as CD4⁺CD8⁺ DP (double positive) cells. DP T cells proliferate rapidly, generating clones of cells expressing the same β chain. After this period of rapid proliferation, T cells begin to rearrange their α -chain genes. Because cells within each clone can rearrange a different α chain, they generate a more diverse population than if the original cell had rearranged both the β chain and α chain before proliferating. Once a DP T cell expresses a fully rearranged TCR, it undergoes the processes of positive and negative selection.

The T cells migrate into the thymic cortex to undergo positive selection. The purpose of positive selection is to select for T cells whose TCRs can interact with an individual's own MHC molecules. In the cortex, T cells interact with cortical thymic epithelial cells, which express both MHC class I and MHC class II molecules. T cells with TCRs that do not recognize self-MHC molecules die by apoptosis. T cells with TCRs that can successfully bind to self-MHC molecules are signaled to survive and proceed

to the thymic medulla. As a result of positive selection, DP thymocytes mature into single-positive T cells that express just one coreceptor (CD4 or CD8). T cells that successfully interact with MHC class I molecules develop into CD8 T cells, whereas T cells that interact with MHC class II molecules become CD4 cells.

After positive selection, T cells migrate to the thymic medulla to undergo negative selection. The purpose of negative selection is to eliminate T cells whose TCRs recognize self-antigens. This is accomplished by medullary thymic epithelial cells, which promiscuously express self-peptides on their MHC molecules. If T cells interact with self-peptides with high affinity, they are deleted by apoptosis (Shah and Zuniga-Pflucker, 2014).

The positive and negative selection processes responsible for generating self-MHC restricted and self-tolerant T cells are rigorous. It is estimated that over 98% of thymocytes die by apoptosis within the thymus, with the majority failing at the positive selection stage. The T cells that manage to successfully complete both positive and negative selection leave the thymus and take up residence in the secondary lymphoid structures.

Primary Responses

The processes of lymphocyte development and gene rearrangement generate millions of unique lymphocytes that each express pathogen receptors of a single specificity. During an infection, only a small portion of these B and T cells express receptors that can recognize the invading pathogen. To increase their numbers, each lymphocyte that recognizes the invading pathogen becomes activated and proliferates, giving rise to clones expressing identical immunoglobulins or TCRs. These processes, referred to as *clonal selection* and *clonal expansion*, are essential features of lymphocyte activation and differentiation, and facilitate the effector mechanisms that B and T cells use to combat infection.

B-Cell Activation and Antibody Production

In the majority of primary immune responses, B-cell activation and subsequent antibody production are dependent on help from CD4 T_H cells. When circulating B cells home to secondary lymphoid tissues, they first enter at the T-cell zone. If a B cell encounters its specific antigen, cross-linking of the BCR and coreceptor induces a signal transduction cascade that mediates changes in cell surface expression of adhesion molecules and chemokine receptors, preventing the B cells from leaving the T-cell zone.

After immunoglobulins bind their cognate antigen, they internalize the antigen by receptor-mediated endocytosis and process the antigen for display by MHC class II molecules. If a CD4 T_H cell recognizes its antigen, the B and T cell form a conjugate pair. This cognate interaction facilitates the delivery of T cell–derived cytokines to B cells. The most important of these cytokines is IL-4, which is essential for B-cell proliferation and differentiation into antibody-secreting plasma cells.

The initial antibodies produced by plasma cells are of generally low affinity. They help to keep the infection under control until a stronger antibody response is generated. Antibody quality improves over the course of the infection due to two processes: somatic hypermutation and isotype switching. Somatic hypermutation introduces random single-nucleotide substitutions throughout the immunoglobulin variable regions. These changes can result in immunoglobulin molecules with increased affinity for the pathogen. B cells producing these improved immunoglobulin molecules outcompete for binding to the invading pathogen and are preferentially selected to become plasma cells. As an infection proceeds, antibodies of higher affinity are produced—a process referred to as *affinity maturation* (Di Noia and Neuberger, 2007).

Isotype Switching. Immunoglobulins can be divided into five classes (isotypes) called IgA, IgD, IgE, IgG, and IgM. These isotypes differ in their heavy-chain constant regions and have specialized effector functions. IgM is the first antibody secreted following B-cell activation and marks pathogens for destruction by the complement system. As an infection proceeds, antibodies with additional effector functions are generated by isotype switching. Isotype switching is a process by which proliferating B cells

rearrange their DNA to change their immunoglobulin constant regions. This process is strongly influenced by cytokines secreted by the B cell's cognate T cell (Xu et al., 2012).

Role of Antibodies in Pathogen Clearance. Antibodies can aid in pathogen clearance in a number of ways. They can bind to a pathogen (or toxin) and prevent it from interacting with host cells. These antibodies are called neutralizing antibodies. Antibodies can also function as opsonins—coating of pathogens with antibodies can facilitate their engulfment by phagocytic cells, which often express receptors for the constant regions of antibodies. In addition, antibody deposition can activate the complement system, leading to the direct lysis of pathogens.

T-Cell Activation

Naïve T cells first encounter antigen presented by DCs in the secondary lymphoid tissues. For T cells to become fully activated, they need to receive two signals (Figure 34–3):

- a primary signal generated through ligation of the TCR
- a costimulatory signal generated through ligation of a T-cell surface protein called CD28

Both of these signals must be delivered by ligands on the same APC.

The primary signal is generated when the TCR engages a peptide-MHC complex. The TCR associates with an accessory molecule called CD3, forming the TCR-CD3 complex. CD3 does not influence the interaction of the TCR with its antigen but participates in the signal transduction that occurs after antigen engagement. The T-cell coreceptors CD4 and CD8 bind to the conserved regions of MHC molecules, strengthening and stabilizing the interaction between the TCR and the peptide-MHC complex. CD4 and CD8 also participate in signal transduction.

The costimulatory signal is generated when CD28 binds to its ligands, called B7-1 (CD80) and B7-2 (CD86). These costimulatory B7 molecules are only expressed on activated professional APCs, highlighting their importance in T-cell activation.

Engagement of the TCR complex activates signal transduction cascades that induce the expression of multiple genes, including NFAT, AP-1, and NF- κ B. One of the most important downstream targets of these genes is IL-2, a cytokine that is essential for T-cell proliferation and survival. The IL-2 receptor, CD25, is expressed on activated T cells. When T cells become activated, they begin to express a cell surface protein called CTLA-4. This protein resembles CD28 and binds to the costimulatory B7 molecules with higher affinity than does CD28. Whereas CD28 ligation promotes T-cell activation, CTLA-4 ligation dampens T-cell activation. This inhibitory molecule serves to keep T-cell responses in check (Brownlie and Zamoyska, 2013). In addition to CTLA-4, T cells upregulate expression of other inhibitory coreceptors such as PD1 and PSGL-1 that help to fine-tune the ensuing T-cell response (Attanasio et al., 2016; Tinoco et al., 2016).

T-Cell Anergy. For a naïve T cell to become fully activated, it must receive a signal through the TCR and CD28. If a T cell engages a peptide-MHC complex in the absence of a sufficient costimulatory signal, it enters a state of nonresponsiveness referred to as clonal anergy. Anergy is defined by the inability of T cells to proliferate after engaging a peptide-MHC complex due to a lack of IL-2 production and signaling (see Figure 35–2).

CD4 T_H -Cell Differentiation and Effector Functions. Following activation, naïve CD4 T_H cells can differentiate into specialized T_H -cell subsets. These T_H -cell subsets display unique patterns of cytokine production and perform distinct effector functions. The initial studies on T_H -cell differentiation generated a biphasic model in which activated T_H cells differentiate into either T_H1 cells, which defend mainly against intracellular pathogens, or T_H2 cells, which aid in the clearance of extracellular pathogens. More recent models of T_H -cell differentiation have been expanded to include T_H9 , T_H17 , T_H22 , T_{FH} , and T_{reg} cells (DuPage and Bluestone, 2016).

As their name implies, CD4 T_H cells help activate other immune cells. T_H1 cells secrete IFN- γ and TNF- α , which activate macrophages to kill pathogens located within their phagosomes. These cytokines also activate CD8 T_c cells to kill infected host cells. T_H2 cells, which produce IL-4 and

Figure 34-3 *T-cell receptor signaling.* TCR signaling on CD4⁺ cells after engagement with an MHC class II–peptide complex is enhanced by activating coreceptors (green-shaded area) or attenuated by inhibitory coreceptors (red-shaded area) after these bind their respective ligands on APCs or tumor cells. Numerous activating (→) or blocking (—) monoclonal antibodies interfere with this fine-tuning of TCR signaling, thus allowing for the pharmacological modulation of the resulting immune response.

IL-5, defend against extracellular pathogens by enhancing humoral immunity. IL-4 activates B cells to differentiate into antibody-secreting plasma cells. T_H2-derived cytokines also induce class switching to IgA and IgE. Another subset of CD4 T_H cell, the T_{Reg} cell, is responsible for maintaining peripheral tolerance. Through various mechanisms, these cells suppress the proliferation of effector T cells, keeping the T-cell response under control.

CD8 T_C-Cell Effector Functions. The main role of CD8 T_C cells is to induce cytolysis of infected host cells expressing peptide-MHC class I complexes. Activated CD8 T_C cells kill their target cells by two distinct pathways: the granule exocytosis pathway and the Fas-FasL pathway. The granule exocytosis pathway involves the release of perforin and granule enzymes (granzymes A and B). Perforin molecules form pores in the target cell membrane, allowing the granzyme molecules to enter the cell. Upregulation of FasL (CD95L) on activated T_C cells induces the aggregation of Fas (CD95) on target cells. Both of these pathways activate the caspase cascade in the target cell, resulting in programmed cell death.

In addition to their cytolytic activity, activated CD8 T_C cells release pro-inflammatory cytokines, including IFN- γ and TNF- α . These cytokines further aid in pathogen clearance by enhancing the activity of macrophages and neutrophils (Harty et al., 2000).

Leukocyte Extravasation: Diapedesis

Leukocytes fulfill most of their immunological functions outside the bloodstream in the surrounding tissues. Consequently, traversing the blood endothelial cell layer barrier is a crucial step in this process. Extravasation (diapedesis) refers to the movement of leukocytes out of the blood into the site of infection or physical tissue damage (Figure 34-4). In the case of blood monocytes, extravasation also occurs in the absence of pathophysiological events and facilitates their conversion into tissue macrophages. On a molecular level, diapedesis can be dissected into four

mechanistic steps: *chemoattraction*, *rolling adhesion*, *tight adhesion*, and *transmigration* (Vestweber, 2015).

While initially believed to play its most important role in innate immunity, diapedesis has garnered more attention in recent years as a pharmacological target in the treatment of chronic (inflammatory) autoimmune diseases such as *multiple sclerosis* or *Crohn disease* (see Autoimmunity). The leukocyte cell surface adhesion molecule $\alpha_4\beta_1$ integrin (VLA-4) that facilitates extravasation of CD4⁺ T cells interacts with VCAM-1 on vascular endothelial cells. Natalizumab is a humanized monoclonal antibody directed against α_4 integrin whose interference with the $\alpha_4\beta_1$ integrin–VCAM-1 interaction leads to a blockade of autoreactive T-cell diapedesis into the brain and thus prevents attack on the myelin composing the nerve shielding. Similarly, natalizumab-mediated prevention of $\alpha_4\beta_1$ integrin binding to the adhesion molecule MADCAM-1 found on endothelial cells of venules is responsible for the efficacy of the drug against Crohn disease. Another monoclonal antibody recently approved for the treatment of Crohn disease and ulcerative colitis is vedolizumab, which produces fewer side effects due to its $\alpha_4\beta_7$ -restricted binding specificity. Preventing entry of effector cells to inflammatory sites through the use of neutralizing antibodies has shown high therapeutic potential in multiple disease settings.

Immunological Memory

The B- and T-cell numbers decline after pathogen clearance, leaving behind a small population of memory cells. These memory cells have the ability to mount an enhanced secondary immune response on reexposure to the same pathogen.

Due to their expression of certain cell surface molecules, memory T cells are more sensitive to TCR-mediated activation by peptide-MHC complexes than naïve T cells. In addition, memory T cells have less-stringent requirements for costimulatory signals, allowing them to respond to

Figure 34–4 Leukocyte diapedesis. Leukocytes are recruited to the site of injury or infection by various chemoattractants. The expression of specific, complementary adhesion molecules on the surfaces of both the endothelial cells and the leukocytes facilitates the initial capture and subsequently the “rolling” binding of the leukocyte. After engagement of additional adhesion molecules, the leukocyte enters the subendothelial space, either by squeezing between endothelial cells (paracellular migration) or via movement through individual endothelial cells (transcellular migration). CAM, cellular adhesion molecule; ESAM, endothelial CAM; VCAM-1, vascular CAM 1; MADCAM-1, mucosal vascular addressin CAM 1; ICAM, inter-CAM; PSGL-1, P-selectin glycoprotein ligand 1; CD99, cluster of differentiation 99 antigen; MAC-1, macrophage-1 antigen.

peptide-MHC complexes displayed on cells that lack the costimulatory B7 molecules (Farber et al., 2014). Memory B cells produce better antibodies than naïve B cells because they express immunoglobulins that underwent somatic hypermutation and isotype switching during the first antigen encounter (Kurosaki et al., 2015). Combined, these properties allow for a faster and stronger secondary immune response, features that form the foundation of vaccination and subsequent “booster” or “refresher” inoculations (see Chapter 36).

Summary: Innate and Adaptive Immunity in Infectious Diseases

As described, the innate and adaptive immune systems work together to keep the host healthy. The innate immune response is the body’s first line of defense and eliminates the majority of pathogens on its own. In the case that the innate immune system is insufficient to eliminate the pathogen, it keeps the infection in check until the adaptive immune system is able to mount a response. Pathogens will be cleared (acute infections), or they may evade the immune response and persist (chronic infections). Chronic infections such as HIV/AIDS and hepatitis B and C lead to immune system suppression that results in susceptibility to secondary infections or cancers associated with infection.

Inflammation

What Is Inflammation, and What Purpose Does It Serve?

The inflammatory response, or inflammation, is a physiologic response to tissue injury and infection, although it should be clear that *inflammation*

is not a synonym for *infection*. The Romans described the characteristics of this response almost 2000 years ago: pain (*dolor*), heat (*calor*), redness (*rubor*), and swelling (*tumor*). Within minutes of tissue injury and infection, plasma proteins mediate an increase in vascular diameter (vasodilation) and vascular permeability. Vasodilation increases blood flow to the area of injury, resulting in the heating and reddening of the tissue. Increased vascular permeability allows leakage of fluid from the blood vessels into the damaged tissue, resulting in swelling (edema). Within a few hours of these vascular changes, leukocytes arrive at the site of injury. They adhere to activated endothelial cells in the inflamed region and pass through the capillary walls into the tissue (extravasation). These leukocytes phagocytize the invading pathogens and release soluble mediators—cytokines, prostaglandins, leukotrienes—that further contribute to the inflammatory response and the recruitment and activation of effector cells.

Inflammation can be acute, as in response to tissue injury, or it may be chronic, leading to progressive tissue destruction, as seen in chronic infections, autoimmunity, and certain cancers. Next, we discuss both forms of inflammation, including their triggers, the soluble mediators and cell types involved, and the resulting tissue pathology.

Acute Inflammatory Response

The acute inflammatory response provides protection following tissue injury and infection by restricting damage to the localized site, recruiting immune cells to eliminate the invading pathogen, and initiating the process of wound repair.

Following tissue damage, a number of plasma proteins are activated, including those of the clotting and kinin systems. The enzymatic cascade of the clotting system produces fibrin strands that accumulate to form clots, limiting the spread of infection into the blood. The enzymatic

cascade of the kinin system results in the production of bradykinin—a peptide that induces vasodilation and enhanced vascular permeability (see Chapter 39). In addition, the complement products C3a and C5a bind to receptors on local mast cells, facilitating their degranulation. The resulting release of histamine, prostaglandins, and leukotrienes contributes to vascular changes by inducing vasodilation and enhancing vascular permeability. Prostaglandins and leukotrienes also serve as chemoattractants for neutrophils (see Chapter 37).

Within a few hours of these vascular changes, neutrophils bind to the endothelial cells of the inflamed region and extravasate into the tissue (see previous section, Diapedesis). They phagocytize the invading pathogens and release soluble inflammatory mediators, including macrophage inflammatory proteins (MIPs) 1 α and 1 β , which are chemokines that attract macrophages to the site of inflammation. Macrophages arrive at the damaged tissue 5 to 6 h after the onset of the inflammatory response. Activated macrophages secrete three major pro-inflammatory cytokines: IL-1, IL-6, and TNF- α . These cytokines induce coagulation, increase vascular permeability, and promote the acute-phase response. IL-1 and TNF- α also induce increased expression of adhesion molecules on endothelial cells, allowing for circulating leukocytes (neutrophils, macrophages, granulocytes, and lymphocytes) to interact with the endothelium and extravasate into the inflamed tissues. Acute inflammation displays a rapid onset following tissue injury and resolves relatively quickly. The resulting tissue pathology is typically mild and localized.

Chronic Inflammation

Chronic inflammation results from continuous exposure to the offending element. This can be due to pathogen persistence, autoimmune diseases in which self-antigens continuously activate T cells, and cancers. The hallmark of chronic inflammation is the accumulation and activation of macrophages and lymphocytes, as well as fibroblasts that replace the original, damaged, or necrotic tissue. Soluble factors released by macrophages and lymphocytes play an important role in the development of chronic inflammation. While during acute inflammation non-protein-based soluble factors (e.g., eicosanoids, bioamines, etc.) dominate the landscape, chronic inflammation is largely caused not only by cytokines, chemokines, growth factors, and secreted/released enzymes, but also by ROS. For instance, cytotoxic T cells and Th1 cells release IFN- γ , which activates macrophages and DCs. These, in turn, release a variety of soluble factors, such as IL-6 and TNF- α , that ultimately result in tissue injury and cell death. Replacement of tissue lost this way by fibroblasts leads to fibrosis—an excessive deposition of fibrous tissue that can interfere with normal tissue function—due to excessive amounts of growth factors (platelet-derived growth factor, transforming growth factor- β), fibrogenic cytokines (IL-1 and TNF- α), and angiogenic factors (fibroblast growth factor, vascular endothelial growth factor). Chronic inflammation can also lead to the formation of granulomas—a mass of cells consisting of activated macrophages surrounded by activated lymphocytes.

Many mediators of acute and chronic inflammation have been identified, and there are myriad anti-inflammatory drugs available. The oldest class, NSAIDs, includes aspirin, which entered the market over a century ago, and the more recently introduced agents acetaminophen (1956) and ibuprofen (1969). NSAIDs target cyclooxygenase (COX), the rate-limiting enzyme in the production of prostaglandins, but can lead to an increase in leukotriene production. In contrast, glucocorticoids prevent the liberation of arachidonic acid from plasma-membrane phospholipids and thus reduce the synthesis of both classes of eicosanoids. The newest group of anti-inflammatory agents, whose use is limited to chronic inflammatory conditions, aims to eliminate pro-inflammatory cytokines through the use of monoclonal antibodies, or soluble receptors (typically a truncated receptor encompassing only the ligand-binding, extracellular domain). Infliximab, adalimumab, certolizumab, and golimumab are monoclonal antibodies that bind and neutralize TNF- α ; etanercept is a TNF- α receptor fusion protein with the same goal.

Immune System–Related Conditions

There are pathologic conditions to which the immune system contributes, such as overreactions (allergy, autoimmunity, transplant rejection) or insufficient responses (immune deficiencies, cancer).

Hypersensitivity Reactions

The immune system mobilizes a number of effector mechanisms to eliminate pathogens from the body. These effector mechanisms typically generate a localized inflammatory response that effectively eliminates the pathogen, with minimal collateral damage to the surrounding tissue. Besides pathogens, humans come into contact with numerous foreign antigens, such as plant pollen and food. Contact with these environmental antigens does not elicit an immune response in the majority of individuals. However, in certain predisposed individuals, the immune system can mount a response to these generally innocuous antigens, resulting in tissue damage that ranges from mild irritation to life-threatening anaphylactic shock. These immune responses are referred to as allergic reactions or hypersensitivity reactions. Hypersensitivity reactions can be divided into four categories, type I to type IV, distinguished by the cell types and effector molecules involved (Burmester et al., 2003).

Type I Hypersensitivity: Immediate Hypersensitivity Reactions

Type I hypersensitivity reactions require that an individual first produces IgE antibodies on initial encounter with an antigen, also referred to as an allergen. After the antigen is cleared, the remaining antigen-specific IgE molecules will be bound by mast cells, basophils, and eosinophils that express receptors for the IgE constant region (Fc ϵ R1). This process is referred to as sensitization. On subsequent exposure to antigen, cross-linking of the IgE molecules on sensitized cells induces their immediate degranulation. The release of inflammatory mediators such as histamine, leukotrienes, and prostaglandins causes vasodilation, bronchial smooth muscle contraction, and mucus production similar to that seen during inflammatory responses to tissue injury and infection. Type I hypersensitivity reactions can be local or systemic. Systemic reactions against peanut or bee venom antigens can result in anaphylaxis, a potentially life-threatening condition.

Allergic asthma is an example of type I hypersensitivity. On exposure to certain allergens (typically inhaled), individuals with allergic asthma experience inflammation of the airways, characterized by tissue swelling and excessive mucus production. This narrowing of the airways makes it difficult to breathe (see Chapter 40).

Type II Hypersensitivity: Antibody-Mediated Cytotoxic Reactions

Type II hypersensitivities are antibody-mediated cytotoxic reactions. One example is the immunization to erythrocyte antigens during pregnancy. In an Rh-negative mother with an Rh-positive fetus (Rh inherited from the father), the mother forms antibodies against the Rh antigen when fetal blood cells come into contact with the maternal immune system, typically during delivery. If a subsequent pregnancy with an Rh-positive fetus occurs, maternal IgG antibodies can cross the placenta and cause hemolysis of fetal Rh-positive erythrocytes. Close monitoring and adequate symptomatic treatments (e.g., plasma exchange, intrauterine infusion, Rh immunoglobulin) are prescribed, as fetal symptoms can range from mild to potential fetal death from heart failure.

Type III Hypersensitivity: Immune Complex–Mediated Reactions

Type III hypersensitivity reactions are mediated by antibody-antigen complexes that form during an immune response (Figures 34–3 and 34–5). When not properly cleared, these immune complexes can settle into various tissues, where they induce complement activation. These immune complexes are of particular concern in the kidney, where they can lead to glomerulonephritis and kidney failure. While in the past

Figure 34–5 Professional APCs. APCs such as DCs display peptide-loaded MHC class I and class II complexes on their cell surface. CD8⁺ or CD4⁺ T cells, respectively, engage these MHC-antigen complexes, leading to signaling via the TCR. Simultaneous occupation of activating or inhibitory coreceptors, as well as various cytokine receptors, determines the ultimate T-cell response.

type III hypersensitivity reactions fell largely in the realm of autoimmune diseases (e.g., systemic lupus erythematosus), their incidence rate has significantly risen with the introduction of nonhuman or nonhumanized monoclonal antibodies as pharmacological agents (human antimouse antibodies). Murine or murine-human chimeric therapeutic monoclonal antibodies are “mistaken” by the patient’s immune system as potentially dangerous, foreign antigens. The resulting immune response not only “defuses” the therapeutic antibody, but also promotes the formation of antibody(mu)-antibody(hu) or antibody(chim)-antibody(hu) complexes that trigger type III hypersensitivity reactions.

Type IV Hypersensitivity: Delayed Hypersensitivity Reactions

Unlike type I–III hypersensitivity reactions, which are antibody mediated, type IV reactions are mediated by T cells. However, all these hypersensitivity reactions are memory responses. Haptens are molecules that are too small to function as antigens on their own. These molecules penetrate the epidermis and bind to carrier proteins in the skin. Hapten-carrier complexes are detected by APCs in the skin (Langerhans cells), which then migrate to the lymph nodes and prime T-cell responses. When an individual is reexposed to the hapten, antigen-specific T cells migrate to the skin, causing local inflammation and edema. Nickel in clothing and jewelry is a common trigger of type IV hypersensitivity reactions.

Autoimmunity, Immune Deficiency, and Transplant Rejection

Just as for a regular and, appropriate immune response, autoimmunity is founded in either humoral (autoantibody) or cellular (T-cell) responses. As described in the section on lymphocyte development, the process of central tolerance limits the development of autoreactive B and T cells. This process is imperfect, and mechanisms of peripheral tolerance are in place to limit the activity of self-reactive lymphocytes that manage to escape thymic deletion. Peripheral tolerance is primarily mediated by two mechanisms: the action of T_{Reg} cells (see section on CD4 T_H-cell effector functions), and the induction of T-cell anergy. Naïve T cells require costimulatory signals to become activated. Consequently,

autoreactive T cells typically will not become activated if they interact with an MHC molecule expressing self-antigen because most tissues do not express costimulatory molecules. Induction of anergy leaves T cells unresponsive, even on subsequent exposure to antigen with sufficient costimulation.

Autoimmunity: A Breach of Tolerance

Several theories exist that aim to explain the origins of individual autoimmune disorders:

- **Molecular Mimicry.** The hypothesis of “molecular mimicry” reasons that unique pathogen-derived antigens resemble endogenous host antigens. If an infection occurs, the immune system’s defensive arsenal (antibodies, CTLs, and NK cells) not only attack the pathogen-derived antigen but also assault the host’s structurally similar antigen, thus causing autoimmunity in the form of “collateral damage.”
- **Relationship Between Autoimmunity and the HLA System.** Individuals with specific HLA types are more likely to develop certain autoimmune diseases (e.g., type I diabetes, ankylosing spondylitis, celiac disease, systemic lupus erythematosus). A reasonable explanation for this observation might be found in the fact that particular HLA proteins are more “efficient” than others in presenting antigens and consequently might erroneously activate T cells.
- **Altered Thymic Function.** Thymic T-cell selection is crucial to central tolerance, and type I IFNs, which are highly induced during infectious events, also govern several steps in T-cell selection. Therefore, pathogen-induced disturbances to thymic events might negatively affect elimination of autoreactive T cells. Regardless of the mechanism, central tolerance has thus far not been exploited for pharmacological intervention.

Immune Deficiencies

Primary immunodeficiency encompasses genetic or developmental defects in the immune system that leave the individual susceptible to infections to various degrees. Severe forms (severe combined immunodeficiency) are typically diagnosed in early childhood and are associated with significantly reduced life expectancy. Presently, nine classes of primary immunodeficiency are recognized, totaling over 120 unique conditions. Unfortunately, current treatment options are limited to supportive therapy in the form of antiviral, antifungal, and antibacterial drugs.

Figure 34-7 Former nomenclature of therapeutic monoclonal antibodies. This older nomenclature, still in use by some workers, focused primarily on the source of the antibody (murine, human, chimeric, or humanized). Current nomenclature (Figure 34-6) incorporates information on the target tissue as well. Fab, antigen-binding fragment; Fc, crystallizable fragment; CDR, complementarity-determining regions of the variable domains, also called hypervariable regions.

antitumor T cells and reinvigorating them to kill tumors. It is important to be aware that whereas some monoclonal antibodies block their respective target (PD1), others block the respective ligand (PD-L1). The therapeutic goal is to interfere with this inhibitory interaction that is actively suppressing T cells in the tumor microenvironment.

The two immune checkpoint receptors that have been the most extensively characterized in the context of cancer immunotherapy are CTLA-4 and PD1. These inhibitory molecules are highly expressed on antitumor T cells. When bound by their respective ligands (CD80/86 and PD-L1/PD-L2) on APCs or tumor cells, these inhibitory receptors dampen the T-cell response, albeit by different intracellular pathways. As antitumor T cells express PD1, tumor cells engage it through their expression of PD-L1. The tumor effectively inactivates the T cells and the tumor continues to grow (Pardoll, 2012; Tang et al., 2016). These pathways are further discussed in the cancer therapy chapters (Chapters 65–68).

Immunotherapy to cancers holds great promise for treating patients with advanced disease, as evidenced by the success of clinical trials using this technology. Biologics to stimulate antitumor T cells have been rapidly approved by the FDA and have become the first line of treatment of cancers such as metastatic melanoma, non-small cell lung cancer, and renal cell carcinoma. In addition, anti-PD1, anti-PD-L1, and anti-CTLA-4 therapies are currently in clinical trials to assess their efficacy in head and neck cancers, breast cancer, small cell lung cancer, Hodgkin lymphoma, gastric cancer, hepatocellular carcinoma, bladder cancer, ovarian cancer, colon cancer, and Merkel cell carcinoma. It is important to note that only a small fraction of patients respond to checkpoint monotherapy, and this frequency can increase when patients are given combination therapy, such as administering both anti-PD1 and anti-CTLA-4 antibodies. Furthermore, combination strategies that include checkpoint blockade paired with radiation or chemotherapy may further increase responsiveness in cancer patients.

One consequence of checkpoint blockade is that autoreactive T cells are also unleashed after therapy. Patients can develop toxicities that include hepatic, pneumonitis, colitis, rash, vitiligo, and endocrine pathology. Greater immunotherapy efficacy will likely be achieved when drugs are developed to target other inhibitory pathways and are used in combination, but caution must be evaluated to ensure patient safety (Callahan et al., 2016).

In addition to solid tumors, liquid tumors like CLL are also being targeted by immunotherapeutic approaches. Patient T cells are engineered to express chimeric antigen receptors (CARs) comprising antibody-binding domains connected to domains that activate T cells. In the case of CLL, CAR T cells recognize CD19 on B cells, and their chimeric receptor sustains T activation. CAR T cells are engineered from patient blood, expanded in vitro; then, millions are infused into the same patient. These cells then circulate in the patient and recognize all B cells expressing CD19 and destroy them. This cellular therapy has shown

promise in patients with CLL with high durable objective responses (Kalos et al., 2011).

IMMUNOTHERAPY FOR MULTIPLE SCLEROSIS

- Clinical Features and Pathology

This chapter reviews the components of the immune response and drugs that modulate immunity via immunosuppression or tolerance. Four major classes of immunosuppressive drugs are discussed: glucocorticoids (see Chapter 46), calcineurin inhibitors, antiproliferative and antimetabolic agents (see Chapter 66), and antibodies. While there are similarities, the approach to the use of immunosuppressant drugs in transplant rejection has evolved separately from the approaches used to treat autoimmune disease and thus is presented separately. Finally, the chapter ends with a brief case study of immunotherapy for the autoimmune disease MS.

The Immune Response

The immune system evolved to discriminate self from nonself. *Innate immunity* (natural immunity) is primitive, does not require priming, and is of relatively low affinity, but it is broadly reactive. *Adaptive immunity* (learned immunity) is antigen specific, depends on antigen exposure or priming, and can be of very high affinity. The two arms of immunity work closely together, with the innate immune system most active early in an immune response and adaptive immunity becoming progressively dominant over time.

The major effectors of *innate immunity* are complement, granulocytes, monocytes/macrophages, NK cells, mast cells, and basophils. The major effectors of *adaptive immunity* are B and T lymphocytes. B lymphocytes make antibodies; T lymphocytes function as helper, cytolytic, and regulatory (suppressor) cells. These cells not only are important in the normal immune response to infection and tumors but also mediate transplant rejection and autoimmunity.

Immunoglobulins (antibodies) on the B-lymphocyte surface are receptors for a large variety of specific structural conformations. In contrast, T lymphocytes recognize antigens as peptide fragments in the context of self MHC antigens (called HLAs in humans) on the surface of APCs, such as dendritic cells, macrophages, and other cell types expressing MHC class I and class II antigens. Once activated by specific antigen recognition, both B and T lymphocytes are triggered to differentiate and divide, leading to release of soluble mediators (cytokines, lymphokines) that perform as effectors and regulators of the immune response. Chapter 34 presents a more detailed view of the immune system at the levels of the molecules, cells, and organs involved in immunity.

Immunosuppression

Immunosuppressive drugs are used to dampen the immune response in organ transplantation and autoimmune disease. In transplantation, the major classes of immunosuppressive drugs used today are the following:

- Glucocorticoids
- Calcineurin inhibitors
- Antiproliferative/antimetabolic agents
- Biologicals (antibodies)

Table 35–1 summarizes the sites of action of representative immunosuppressants on T-cell activation. These drugs are successful in treating conditions such as acute immune rejection of organ transplants and autoimmune diseases. However, such therapies often require lifelong use and nonspecifically suppress the entire immune system, exposing patients in some instances to higher risks of infection and cancer. The calcineurin inhibitors and daily glucocorticoids, in particular, are nephrotoxic and diabetogenic, respectively, thus restricting their usefulness in a variety of clinical settings.

Monoclonal and polyclonal antibody preparations directed at both T cells and B cells or against cytokines such as TNF- α are important therapies providing an opportunity to more specifically target immune pathways. Finally, newer small molecules and antibodies have expanded the arsenal of immunosuppressives. In particular, mTOR inhibitors (*sirolimus*, *everolimus*, *temsirolimus*) (Budde et al., 2011; Euvrard et al., 2012), and anti-CD25 (IL-2R) antibodies (*basiliximab*, *daclizumab*) (Nashan, 2005) target growth factor pathways. *Belatacept* (Satyananda and Shapiro, 2014) inhibits T-cell costimulation. Thus, there are useful pharmacological tools that can substantially limit clonal expansion and potentially promote tolerance (Goldfarb-Rumyantzev et al., 2006; Krensky et al., 1990).

General Approach to Organ Transplantation Therapy

Organ transplantation therapy is organized around five general principles.

1. Carefully prepare the patient and select the best available ABO blood type-compatible HLA match for organ donation.
2. Employ multitier immunosuppressive therapy; simultaneously use several agents, each of which is directed at a different molecular target within the allograft response. Synergistic effects permit use of the

Abbreviations

ALG: antilymphocyte globulin
APC: antigen-presenting cell
ATG: antithymocyte globulin
AUC: area under the curve
CD: cluster of differentiation
CLL: chronic lymphocytic leukemia
CNS: central nervous system
CTL: cytotoxic T lymphocyte
CTLA4: cytotoxic T-lymphocyte-associated antigen 4
FKBP-12: FK506-binding protein 12
CYP: cytochrome P450
GVHD: graft-versus-host disease
HLA: human leukocyte antigen
HRPT: hypoxanthine-guanine phosphoribosyl transferase
IFN- β : interferon type I beta
Ig: immunoglobulin
IL: interleukin
IL-1RA: IL-1 receptor antagonist
IL-2R: interleukin 2 receptor
JCV: polyomavirus JC
LDL: low-density lipoprotein
LFA: lymphocyte function-associated antigen
mAb: monoclonal antibody
MHC: histocompatibility complex
MMF: mycophenolate mofetil
6-MP: 6-mercaptopurine
MPA: mycophenolic acid
MPAG: MPA glucuronide
MS: multiple sclerosis
mTOR: mammalian target of rapamycin
NFAT: nuclear factor of activated T lymphocytes
NHP: nonhuman primate
NK: natural killer
NSAID: nonsteroidal anti-inflammatory drug
PD1: programmed cell death protein 1
PD-L1: programmed death ligand 1
PML: progressive multifocal leukoencephalopathy
RA: rheumatoid arthritis
S1P-R: sphingosine-1-phosphate receptor
TCR: T-cell receptor
VZV: varicella zoster virus
WBC: white blood cell

various agents at relatively low doses, thereby limiting specific toxicities while maximizing the immunosuppressive effect.

- Employ intensive induction and lower-dose maintenance drug protocols; greater immunosuppression is required to gain early engraftment or to treat established rejection than to maintain long-term immunosuppression. The early high risk of acute rejection is replaced over time by the increased risk of the medications' side effects, necessitating a slow reduction of maintenance immunosuppressive drugs.
- Investigation of each episode of transplant dysfunction is required, including evaluation for recurrence of the disease, rejection, drug toxicity, and infection (keeping in mind that these various problems can and often do coexist).
- Reduce dosage or withdraw a drug if its toxicity exceeds its benefit (Danovitch et al., 2007).

Biological Induction Therapy

In many transplant centers, induction therapy with biological agents is used to delay the use of the nephrotoxic calcineurin inhibitors or to

TABLE 35-1 ■ SITES OF ACTION OF SELECTED IMMUNOSUPPRESSIVE AGENTS ON T-CELL ACTIVATION

DRUG	SITE (AND MECHANISM) OF ACTION
Glucocorticoids	Glucocorticoid response elements in DNA (regulate gene transcription)
Cyclosporine	Calcineurin (inhibits phosphatase activity)
Tacrolimus	Calcineurin (inhibits phosphatase activity)
Azathioprine	DNA (false nucleotide incorporation)
Mycophenolate mofetil	Inosine monophosphate dehydrogenase (inhibits activity)
Sirolimus	mTOR, protein kinase involved in cell-cycle progression (inhibits activity)
Everolimus	mTOR, protein kinase involved in cell-cycle progression (inhibits activity)
Belatacept	Costimulatory ligands (CD80 and CD86) present on antigen presenting cells (inhibits activity)
Alemtuzumab	CD52 protein, widely expressed on B cells, T cells, macrophages, NK cells (induces lysis)
Muromonab-CD3	T-cell receptor complex (blocks antigen recognition)
Daclizumab, basiliximab	IL-2R (block IL-2-mediated T-cell activation)

intensify the initial immunosuppressive therapy in patients at high risk of rejection (i.e., repeat transplants, broadly presensitized patients, African American patients, or pediatric patients). This strategy has been an important component of immunosuppression since the 1960s, when Starzl and colleagues demonstrated the beneficial effect of antilymphocyte globulin (ALC) in the prophylaxis of rejection. Two preparations are FDA-approved for use in transplantation: lymphocyte immune globulin (Atgam) and antithymocyte globulin (ATG; Thymoglobulin) (Brennan et al., 2006; Nashan, 2005). ATG is the most frequently used depleting agent. Alemtuzumab, a humanized anti-CD52 mAb that produces prolonged lymphocyte depletion, is approved for use in CLL and MS but is increasingly used off label as induction therapy in transplantation (Jones and Coles, 2014).

Most limitations of murine-based mAbs generally were overcome by the introduction of chimeric or humanized mAbs that lack antigenicity and have a prolonged serum $t_{1/2}$. Antibodies derived from transgenic mice carrying human antibody genes are labeled "humanized" (90%–95% human) or "fully human" (100% human); antibodies derived from human cells are labeled "human." However, all three types of antibodies are of equal efficacy and safety. Chimeric antibodies generally contain about 33% mouse protein and 67% human protein and can still produce an antibody response that results in reduced efficacy and shorter $t_{1/2}$ compared to humanized antibodies.

Biological agents for induction therapy in the prophylaxis of rejection currently are used in about 70% of de novo transplant patients. Biological agents for induction can be divided into two groups: the *depleting agents* and the *immune modulators*. The depleting agents consist of lymphocyte immune globulin, ATG, and muromonab-CD3 mAb; their efficacy derives from their ability to deplete the recipient's CD3-positive cells at the time of transplantation and antigen presentation. The second group of biological agents, the anti-IL-2R mAbs, do not deplete T lymphocytes, but rather block IL-2-mediated T-cell activation by binding to the α chain of IL-2R (CD25). For patients with high levels of anti-HLA antibodies and humoral rejection, more aggressive therapies include plasmapheresis, intravenous immunoglobulin, and rituximab, a chimeric anti-CD20 mAb (Brennan et al., 2006; Chan et al., 2011; Guerra et al., 2011; Nashan, 2005; Sureshkumar et al., 2012).

Maintenance Immunotherapy

Basic immunosuppressive therapy uses multiple drugs simultaneously, typically a calcineurin inhibitor, glucocorticoids, and mycophenolate (a purine metabolism inhibitor), each directed at a discrete step in T-cell activation (Vincenti et al., 2008). Glucocorticoids, azathioprine, cyclosporine, tacrolimus, mycophenolate, sirolimus, belatacept, and various mAbs and polyclonal antibodies all are approved for use in transplantation.

Therapy for Established Rejection

Low doses of prednisone, calcineurin inhibitors, purine metabolism inhibitors, sirolimus, or belatacept are effective in preventing acute cellular rejection; they are less effective in blocking activated T lymphocytes and thus are not very effective against established, acute rejection or for the total prevention of chronic rejection. Therefore, treatment of established rejection requires the use of agents directed against activated T cells. These include glucocorticoids in high doses (pulse therapy), polyclonal antilymphocyte antibodies, or muromonab-CD3 (licensed by the FDA but not currently marketed in the U.S. due to decreased use).

Glucocorticoids

The introduction of glucocorticoids as immunosuppressive drugs in the 1960s played a key role in making organ transplantation possible. Prednisone, prednisolone, and other glucocorticoids are used alone and in combination with other immunosuppressive agents for treatment of transplant rejection and autoimmune disorders. The pharmacological properties of glucocorticoids are described in Chapter 46.

Mechanism of Action

Glucocorticoids have broad anti-inflammatory effects on multiple components of cellular immunity, but relatively little effect on humoral immunity. Glucocorticoids bind to receptors inside cells and regulate the transcription of numerous other genes (see Chapter 46). Glucocorticoids also curtail activation of NF- κ B, suppress formation of pro-inflammatory cytokines such as IL-1 and IL-6, inhibit T cells from making IL-2 and proliferating, and inhibit the activation of CTLs. In addition, glucocorticoid-treated neutrophils and monocytes display poor chemotaxis and decreased lysosomal enzyme release.

Therapeutic Uses

There are numerous therapeutic indications for glucocorticoids. They commonly are combined with other immunosuppressive agents to prevent and treat transplant rejection. Glucocorticoids also are efficacious for treatment of GVHD in bone marrow transplantation. Glucocorticoids are routinely used to treat autoimmune disorders such as rheumatoid and other arthritides, systemic lupus erythematosus, systemic dermatomyositis, psoriasis and other skin conditions, asthma and other allergic disorders, inflammatory bowel disease, inflammatory ophthalmic diseases, autoimmune hematological disorders, and acute exacerbations of MS (see multiple sclerosis section). Lower-dose oral glucocorticoids, however, appear to have different biologic effects; low-dose oral prednisone made optic neuritis worse compared to high-dose intravenous solumedrol (Beck et al., 1992). In addition, glucocorticoids limit allergic reactions that occur with other immunosuppressive agents and are used in transplant recipients to block first-dose cytokine storm caused by treatment with muromonab-CD3 and to a lesser extent ATG (see Antithymocyte Globulin). Most transplant centers use an initial high dose of intravenous solumedrol with tapering to a maintenance dose of 5–10 mg/d in the long term. Currently, more than one-third of kidney transplant centers in the U.S. aim to withdraw steroids within the first 3 months after transplantation (Bergmann et al., 2012).

Toxicity

Extensive glucocorticoid use often results in disabling and life-threatening adverse effects. These effects include growth retardation in children, avascular necrosis of bone, osteopenia, increased risk of infection, poor wound healing, cataracts, hyperglycemia, and hypertension (see Chapter 46). The advent of combined glucocorticoid/calcineurin inhibitor regimens has

allowed reduced doses or rapid withdrawal of steroids, resulting in lower steroid-induced morbidities (Vincenti et al., 2008).

Calcineurin Inhibitors

The most effective immunosuppressive drugs in routine use are the calcineurin inhibitors *cyclosporine* and *tacrolimus* (Figure 35–1), which target intracellular signaling pathways induced as a consequence of TCR activation (Figure 35–2). Cyclosporine and tacrolimus bind to an immunophilin (cyclophilin for cyclosporine or FKBP-12 for tacrolimus), resulting in subsequent interaction with calcineurin to block its phosphatase activity. Calcineurin-catalyzed dephosphorylation is required for movement of a component of the NFAT into the nucleus. NFAT, in turn, is required to induce a number of cytokine genes, including IL-2, a prototypic T-cell growth and differentiation factor (Verghese et al., 2014).

Tacrolimus

Tacrolimus is a macrolide antibiotic produced by *Streptomyces tsukubaensis*. Because of perceived slightly greater efficacy and ease of blood level monitoring, tacrolimus has become the preferred calcineurin inhibitor in most transplant centers (Ekberg et al., 2007).

Mechanism of Action. Like cyclosporine, tacrolimus inhibits T-cell activation by inhibiting calcineurin. Tacrolimus binds to an intracellular protein, FKBP-12, an immunophilin structurally related to cyclophilin. A complex of tacrolimus–FKBP-12, Ca^{2+} , calmodulin, and calcineurin then forms, and calcineurin phosphatase activity is inhibited (see Figure 35–2). Inhibition of phosphatase activity prevents dephosphorylation and nuclear translocation of NFAT and inhibits T-cell activation. Thus, although the intracellular receptors differ, cyclosporine and tacrolimus target the same pathway for immunosuppression.

ADME. Tacrolimus is available for oral administration as capsules and extended-release capsules (0.5, 1, and 5 mg); extended-release tablets (0.75, 1, and 4 mg); and a solution for injection (5 mg/mL). Sublingual tacrolimus has been used off label for the short term in patients who are unable to receive medications orally. Because of intersubject variability in pharmacokinetics, individualized dosing is required for optimal therapy. For tacrolimus, whole blood is the preferred sampling compartment; the trough drug level in whole blood seems to correlate better with clinical events for tacrolimus than for cyclosporine. Target concentrations are 10–15 ng/mL in the early preoperative period and 6–8 ng/mL at 3 months posttransplantation. Gastrointestinal absorption is incomplete and variable. Target concentrations are dependent on sampling technique and on product-release characteristics, immediate- versus extended-release forms. Food decreases the rate and extent of absorption. Plasma protein binding of tacrolimus is 75%–99%, involving primarily albumin and α_1 -acid glycoprotein. The $t_{1/2}$ of tacrolimus is about 12 h. Tacrolimus is extensively metabolized in the liver by CYP3A; some of the metabolites are active. The bulk of excretion of the parent drug and metabolites is in the feces.

Therapeutic Uses. Tacrolimus is indicated for the prophylaxis of solid-organ allograft rejection in a manner similar to cyclosporine (see Cyclosporine) and is used off label as rescue therapy in patients with rejection episodes despite “therapeutic” levels of cyclosporine. Recommended initial oral doses are 0.2 mg/kg/d for adult kidney transplant patients, 0.1–0.15 mg/kg/d for adult liver transplant patients, 0.075 mg/kg/d for adult heart transplant patients, and 0.15–0.2 mg/kg/d for pediatric liver transplant patients in two divided doses 12 h apart. These dosages are intended to achieve typical blood trough levels in the 5- to 20-ng/mL range (Goring et al., 2014). Note that the oral dose of tacrolimus depends on product release characteristics (immediate- vs. extended-release formulation) and the specific cocktail of medications selected for prophylaxis.

Toxicity. Nephrotoxicity; neurotoxicity (e.g., tremor, headache, motor disturbances, seizures); GI complaints; hypertension; hyperkalemia; hyperglycemia; and diabetes all are associated with tacrolimus use. Tacrolimus has a negative effect on pancreatic islet β cells, and glucose intolerance and diabetes mellitus are well-recognized complications of

Figure 35-1 Structures of selected immunosuppressive drugs.

tacrolimus-based immunosuppression. While combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, new-onset diabetes after transplantation (NODAT) incidence was significantly higher with tacrolimus compared to cyclosporine, the other calcineurin inhibitor. Obese patients, African American or Hispanic transplant recipients, or those with a family history of type 2 diabetes or obesity are especially at risk. As with other immunosuppressive agents, there is an increased risk of secondary tumors and opportunistic infections. Notably, tacrolimus does not adversely affect uric acid or LDL cholesterol. Diarrhea and alopecia are common in patients on concomitant mycophenolate therapy.

Drug Interactions. Because of its potential for nephrotoxicity, tacrolimus blood levels and renal function should be monitored closely. Coadministration with cyclosporine results in additive or synergistic nephrotoxicity; therefore, a delay of at least 24 h is required when switching a patient from cyclosporine to tacrolimus. Because tacrolimus is metabolized mainly by CYP3A, the potential interactions described in the following section for cyclosporine also apply for tacrolimus. Per the label, concomitant use of tacrolimus with cyclosporine or sirolimus is not recommended for prophylaxis against renal transplant rejection.

Cyclosporine

Cyclosporine (cyclosporin A) is a cyclic polypeptide of 11 amino acids, produced by the fungus *Beauveria nivea*, that inhibits calcineurin activity (Azzi et al., 2013).

Mechanism of Action. Cyclosporine forms a complex with cyclophilin, a cytoplasmic-receptor protein present in target cells (Figure 35-2). This complex binds to calcineurin, inhibiting Ca^{2+} -stimulated dephosphorylation of the cytosolic component of NFAT. When cytoplasmic NFAT is dephosphorylated, it translocates to the nucleus and complexes with nuclear components required for complete T-cell activation, including transactivation of IL-2 and other lymphokine genes. Calcineurin phosphatase activity is inhibited after physical interaction with the cyclosporine/cyclophilin complex.

At the level of immune system function, cyclosporine suppresses some humoral immunity but is more effective against T-cell-dependent immune mechanisms such as those underlying transplant rejection and some forms of autoimmunity. It preferentially inhibits antigen-triggered signal transduction in T lymphocytes, blunting expression of many lymphokines, including IL-2, and the expression of antiapoptotic proteins.

Figure 35-2 T-cell activation and sites of action of immunosuppressive agents. The TCR recognizes antigens bound to the MHC. A costimulatory signal is required for T-cell activation: The CD80/CD86-CD28 interaction from the APC to the T cell. Activation leads to IL-2 production (in a positive-feedback loop) and a host of other events, some of which are bracketed in the lower right-hand corner. Numerous agents are available to suppress T-cell activation. Cyclosporine and tacrolimus bind to immunophilins (cyclophilin and FKBP, respectively), forming a complex that inhibits the phosphatase calcineurin and the calcineurin-catalyzed dephosphorylation that permits translocation of NFAT into the nucleus. NFAT is required for transcription of IL-2 and other growth and differentiation-associated cytokines (lymphokines). Sirolimus (rapamycin) works downstream of the IL-2R, binding to FKBP; the FKBP-sirolimus complex binds to and inhibits the mTOR, a kinase involved in cell cycle progression (proliferation). MMF and azathioprine inhibit nucleic acid synthesis, thereby inhibiting T-cell proliferation. The antibody muromonab (OKT3) inhibits TCR function via interaction with its CD3 component. Daclizumab and basiliximab block IL-2 signaling by interacting with the alpha subunit of the IL-2R complex (CD25). Several antibodies can block the systemic effects of released TNF. Alemtuzumab, by binding to CD52, marks the cell for destruction, thereby depleting CD52 $^{+}$ cells.

Cyclosporine also increases expression of TGF- β , a potent inhibitor of IL-2-stimulated T-cell proliferation and generation of CTLs (Colombo and Ammirati, 2011; Molnar et al., 2015).

ADME. Because cyclosporine is lipophilic and highly hydrophobic, it is formulated for clinical administration using castor oil or other strategies to ensure solubilization. Cyclosporine can be administered intravenously or orally. The intravenous preparation is provided as a solution in an ethanol-polyoxyethylated castor oil vehicle that must be further diluted in 0.9% sodium chloride solution or 5% dextrose solution before injection. The oral dosage forms include soft gelatin capsules and oral solutions. Cyclosporine supplied in the original soft gelatin capsule is absorbed slowly, with 20%–50% bioavailability. A modified microemulsion formulation, NEORAL, has become the most widely used preparation. It has more uniform and slightly increased bioavailability compared to the original formulation. It is provided as 25- and 100-mg soft gelatin capsules and

a 100-mg/mL oral solution. The original and microemulsion formulations are *not bioequivalent* and cannot be used interchangeably without heightened monitoring of drug concentrations and assessment of graft function. A second modified formulation, GENGRAF, is also marketed, and like NEORAL, is *not interchangeable* with nonmodified cyclosporine formulations. Transplant units need to educate patients that the cyclosporine preparation known as SANDIMMUNE and its generics are not the same as NEORAL and its generics, such that one preparation cannot be substituted for another without risk of inadequate immunosuppression or increased toxicity. The danger of unauthorized, inadvertent, unmonitored, or inappropriate substitution of nonequivalent formulations can result in graft loss and other adverse patient outcomes.

Blood levels taken 2 h after a dose administration (so-called C $_2$ levels) may correlate better with the AUC than other single points, but no single time point can simulate the exposure better than more frequent drug

sampling. In practice, if a patient has clinical signs or symptoms of toxicity or if there is unexplained rejection or renal dysfunction, a pharmacokinetic profile can be used to estimate that person's systemic exposure to the drug.

Cyclosporine absorption is incomplete following oral administration and varies with the individual patient and the formulation used. Cyclosporine is distributed extensively outside the vascular compartment. After intravenous dosing, the steady-state volume of distribution reportedly is as high as 3–5 L/kg in solid-organ transplant recipients. The elimination of cyclosporine from the blood generally is biphasic, with a terminal $t_{1/2}$ of 5–18 h. After intravenous infusion, clearance is about 5–7 mL/min/kg in adult recipients of renal transplants, but results differ by age and between different patient populations. For example, clearance is slower in cardiac transplant patients and more rapid in children. Thus, the intersubject variability is so large that individual monitoring is required.

After oral administration of cyclosporine (as NEORAL), the time to peak blood concentrations is 1.5–2 h. Administration with food delays and decreases absorption. High- and low-fat meals consumed within 30 min of administration decrease the AUC by about 13% and the maximum concentration by 33%. This makes it imperative to individualize dosage regimens for outpatients. Cyclosporine is extensively metabolized in the liver by hepatic CYP3A and to a lesser degree in the GI tract and kidneys. At least 25 metabolites have been identified in human bile, feces, blood, and urine. All of the metabolites have reduced biological activity and toxicity compared to the parent drug. Cyclosporine and its metabolites are excreted principally through the bile into the feces, with about 6% excreted in the urine. Cyclosporine also is excreted in human milk. In the presence of hepatic dysfunction, dosage adjustments are required. No adjustments generally are necessary for patients on dialysis or with renal failure.

Therapeutic Uses. Clinical indications for cyclosporine are kidney, liver, heart, and other organ transplantation; rheumatoid arthritis; psoriasis; and xerophthalmia. Its use in dermatology is discussed in Chapter 70. Cyclosporine usually is combined with other agents, especially glucocorticoids and either azathioprine or mycophenolate, and, most recently, sirolimus. The dose of cyclosporine varies, depending on the organ transplanted and the other drugs used in the specific treatment protocol(s). The initial dose generally is not given before the transplant because of the concern about nephrotoxicity. For renal transplant patients, therapeutic algorithms have been developed to delay cyclosporine or tacrolimus introduction until a threshold renal function has been attained. Dosing is guided by signs of rejection (too low a dose), renal or other toxicity (too high a dose), and close monitoring of blood levels. Great care must be taken to differentiate renal toxicity from rejection in kidney transplant patients. Ultrasound-guided allograft biopsy is the best way to assess the basis for renal dysfunction. Because adverse reactions have been ascribed more frequently to the intravenous formulation, this route of administration is discontinued as soon as the patient can take the drug orally.

In rheumatoid arthritis, cyclosporine is used in severe cases that have not responded to methotrexate. Cyclosporine can be combined with methotrexate, but the levels of both drugs must be monitored closely. In psoriasis, cyclosporine is indicated for treatment of adult immunocompetent patients with severe and disabling disease for whom other systemic therapies are contraindicated or have failed. Because of its mechanism of action, there is a theoretical basis for the use of cyclosporine in a variety of other T-cell-mediated diseases. Cyclosporine reportedly is effective in Behçet's, acute ocular syndrome, endogenous uveitis, atopic dermatitis, inflammatory bowel disease, and nephrotic syndrome, even when standard therapies have failed.

Toxicity. The principal adverse reactions to cyclosporine therapy are renal dysfunction and hypertension; tremor, hirsutism, hyperlipidemia, and gum hyperplasia also are frequently encountered. Hypertension occurs in about 50% of renal transplant and almost all cardiac transplant patients. Hyperuricemia may lead to worsening of gout, increased P-glycoprotein activity, and hypercholesterolemia (see Chapters 5, 33, and 38). Nephrotoxicity occurs in the majority of patients and is the

major reason for cessation or modification of therapy. Combined use of calcineurin inhibitors and glucocorticoids is particularly diabetogenic, although this seems more problematic in patients treated with tacrolimus (see previous Tacrolimus section). Cyclosporine, as opposed to tacrolimus, is more likely to produce elevations in LDL cholesterol.

Drug Interactions. Cyclosporine interacts with a wide variety of commonly used drugs, and close attention must be paid to drug interactions. Any drug that affects CYPs, especially CYP3A, may affect cyclosporine blood concentrations. Substances that inhibit this enzyme can decrease cyclosporine metabolism and increase blood concentrations. These include Ca^{2+} channel blockers (e.g., *verapamil*, *nicardipine*); antifungal agents (e.g., *fluconazole*, *ketoconazole*); antibiotics (e.g., *erythromycin*); glucocorticoids (e.g., *methylprednisolone*); HIV-protease inhibitors (e.g., *indinavir*); and other drugs (e.g., *allopurinol*, *metoclopramide*). Grapefruit juice inhibits CYP3A and the P-glycoprotein multidrug efflux pump and thereby can increase cyclosporine blood concentrations. In contrast, drugs that induce CYP3A activity can increase cyclosporine metabolism and decrease blood concentrations. Such drugs include antibiotics (e.g., *nafticillin*, *rifampin*); anticonvulsants (e.g., *phenobarbital*, *phenytoin*); and others (e.g., *octreotide*, *ticlopidine*).

Interactions between cyclosporine and sirolimus require that administration of the two drugs be separated by time. Sirolimus aggravates cyclosporine-induced renal dysfunction, while cyclosporine increases sirolimus-induced hyperlipidemia and myelosuppression. Additive nephrotoxicity may occur when cyclosporine is coadministered with NSAIDs and other drugs that cause renal dysfunction; elevation of methotrexate levels may occur when the two drugs are coadministered, as can reduced clearance of other drugs, including prednisolone, digoxin, and statins (Azzi et al., 2013; Ekberg et al., 2007).

Antiproliferative and Antimetabolic Drugs

Sirolimus

Sirolimus (rapamycin) is a macrocyclic lactone produced by *Streptomyces hygroscopicus*.

Mechanism of Action. Sirolimus inhibits T-lymphocyte activation and proliferation downstream of the IL-2 and other T-cell growth factor receptors (see Figure 35–2). Like cyclosporine and tacrolimus, therapeutic action of sirolimus requires formation of a complex with an immunophilin, in this case FKBP-12. The *sirolimus*-FKBP-12 complex does not affect calcineurin activity; rather, it binds to and inhibits the protein kinase mTOR, which is a key enzyme in cell cycle progression. Inhibition of mTOR blocks cell cycle progression at the $G_1 \rightarrow S$ phase transition.

In animal models, sirolimus not only inhibits transplant rejection, GVHD, and a variety of autoimmune diseases, but also has effects for several months after discontinuation, suggesting a tolerizing effect (see Tolerance). A newer indication for sirolimus is the avoidance of calcineurin inhibitors, even when patients are stable, to protect kidney function (Schna et al., 2009).

ADME. After oral administration, sirolimus is absorbed rapidly and reaches a peak blood concentration within about 1 h after a single dose in healthy subjects and within about 2 h after multiple oral doses in renal transplant patients. Systemic availability is about 15%, and blood concentrations are proportional to dose between 3 and 12 mg/m². A high-fat meal decreases peak blood concentration by 34%; sirolimus therefore should be taken consistently either with or without food, and blood levels should be monitored closely. About 40% of sirolimus in plasma is protein bound, especially to albumin. The drug partitions into formed elements of blood (blood-to-plasma ratio = 38 in renal transplant patients). Sirolimus is extensively metabolized by CYP3A4 and is transported by P-glycoprotein. The bulk of total excretion is via the feces. Although some of its metabolites are active, sirolimus itself is the major active component in whole blood and contributes more than 90% of the immunosuppressive effect. The blood $t_{1/2}$ after multiple doses in stable renal transplant patients is 62 h. A loading dose of three times the maintenance dose will provide nearly steady-state concentrations within 1 day in most patients.

Therapeutic Uses. Sirolimus is indicated for prophylaxis of organ transplant rejection, usually in combination with a reduced dose of calcineurin inhibitor and glucocorticoids. Sirolimus has been used with glucocorticoids and mycophenolate to avoid permanent renal damage. Sirolimus dosing regimens are relatively complex, with blood levels generally targeted between 5 and 15 ng/mL. It is recommended that the daily maintenance dose be reduced by approximately one-third in patients with hepatic impairment. Sirolimus also has been incorporated into stents to inhibit local cell proliferation and blood vessel occlusion (Moes et al., 2015).

Toxicity. The use of sirolimus in renal transplant patients is associated with a dose-dependent increase in serum cholesterol and triglycerides that may require treatment. Although immunotherapy with sirolimus per se is not considered nephrotoxic, patients treated with cyclosporine plus sirolimus have impaired renal function compared to patients treated with cyclosporine alone. Sirolimus can worsen proteinuria and should be used with caution in patients with GFR below 30% or proteinuria; these conditions can worsen renal failure. Renal function and proteinuria therefore must be monitored closely in such patients. Lymphocele, a known surgical complication associated with renal transplantation, is increased in a dose-dependent fashion by sirolimus, requiring close postoperative follow-up.

Other adverse effects include anemia, leukopenia, thrombocytopenia, mouth ulcer, hypokalemia, and GI effects. Delayed wound healing may occur with sirolimus use. This mTOR inhibitor has been shown to have anticancer effect, especially on skin cancer; it is considered the immunosuppressant of choice in patients with a history of malignancy. Temsirolimus is specifically approved for kidney (but not skin) cancer, while everolimus is approved for a variety of cancers (but not skin cancer). As with other immunosuppressive agents, there is an increased risk of infections.

Drug Interactions. Because sirolimus is a substrate for CYP3A4 and is transported by P-glycoprotein, close attention to interactions with other drugs that are metabolized or transported by these proteins is required (see Chapters 5 and 6). Dose adjustment may be required when sirolimus is coadministered with CYP3A4 and P-glycoprotein inhibitors (such as diltiazem) or strong inducers (such as rifampin) (Alberú et al., 2011; Euvrard et al., 2012).

Everolimus

Everolimus [40-O-(2-hydroxyethyl)-rapamycin] is FDA-approved for treatment of astrocytoma, breast cancer, kidney and liver transplant rejection prophylaxis, pancreatic neuroendocrine tumor, renal angiomyolipoma, and renal cell cancer. It is chemically closely related to sirolimus but has distinct pharmacokinetics. The main difference is a shorter $t_{1/2}$ and thus a shorter time to achieve steady-state concentrations of the drug. Dosage on a milligram per kilogram basis is similar to (but not the same as) that of sirolimus. In kidney transplant rejection prophylaxis, the initial dose of everolimus is 0.75 mg twice daily, with later adjustment based on serum concentrations. As with sirolimus, the combination of a calcineurin inhibitor and an mTOR inhibitor produces worse renal function at 1 year than does calcineurin inhibitor therapy alone, suggesting a drug interaction between the mTOR inhibitors and the calcineurin inhibitors that reduces rejection but enhances toxicity. The toxicity of everolimus and the potential for drug interactions seem to be the same as with sirolimus (Budde et al., 2011; Moes et al., 2015). Like sirolimus, individualization of drug dose through therapeutic drug monitoring is required.

Azathioprine

Azathioprine is a purine antimetabolite. It is an imidazolyl derivative of 6-mercaptopurine, metabolites of which can inhibit purine synthesis.

Mechanism of Action. Following exposure to nucleophiles such as glutathione, azathioprine is cleaved to 6-MP, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Chapter 66). A fraudulent nucleotide, 6-thio-IMP, is converted to 6-thio-GMP and finally to 6-thio-GTP, which is incorporated into DNA. Cell proliferation thereby is inhibited, impairing a variety of lymphocyte functions. Azathioprine appears to be a more potent immunosuppressive agent than 6-MP (Hardinger et al., 2013).

ADME. Azathioprine is well absorbed orally and reaches maximum blood levels within 1–2 h after administration. The $t_{1/2}$ of azathioprine is about 10 min, and the $t_{1/2}$ of 6-MP is about 1 h. Other metabolites have a $t_{1/2}$ of up to 5 h. Blood levels have limited predictive value because of extensive metabolism, significant activity of many different metabolites, and high tissue levels attained. Azathioprine and mercaptopurine are moderately bound to plasma proteins and are partially dialyzable. Both are rapidly removed from the blood by oxidation or methylation in the liver or erythrocytes. Renal clearance has little impact on the biological effectiveness or toxicity.

Therapeutic Uses. Azathioprine is indicated as an adjunct for prevention of organ transplant rejection and in severe rheumatoid arthritis. The usual starting dose of azathioprine is 3–5 mg/kg/d. Lower initial doses (1 mg/kg/d) are used in treating rheumatoid arthritis. Complete blood count and liver function tests should be monitored.

Toxicity. The major side effect of azathioprine is bone marrow suppression, including leukopenia (common), thrombocytopenia (less common), or anemia (uncommon). Other important adverse effects include increased susceptibility to infections (especially varicella and herpes simplex viruses), hepatotoxicity, alopecia, GI toxicity, pancreatitis, and increased risk of neoplasia.

Drug Interactions. Xanthine oxidase, an enzyme of major importance in the catabolism of azathioprine metabolites, is blocked by allopurinol. Hence, the combination of azathioprine with allopurinol should be avoided. Adverse effects resulting from coadministration of azathioprine with other myelosuppressive agents or angiotensin-converting enzyme inhibitors include leukopenia, thrombocytopenia, and anemia as a result of myelosuppression.

Mycophenolate Mofetil

Mycophenolate mofetil is the 2-morpholinoethyl ester of MPA (Darji et al., 2008; Molnar et al., 2015).

Mechanism of Action. Mycophenolate mofetil is a prodrug that is rapidly hydrolyzed to the active drug MPA, a selective, noncompetitive, reversible inhibitor of inosine monophosphate dehydrogenase (IMPDH), an enzyme in the de novo pathway of guanine nucleotide synthesis. B and T lymphocytes are highly dependent on this pathway for cell proliferation; MPA thus selectively inhibits lymphocyte proliferation and functions, including antibody formation, cellular adhesion, and migration.

ADME. Mycophenolate mofetil undergoes rapid and complete metabolism to MPA after oral or intravenous administration. MPA is then metabolized to the inactive glucuronide MPAG. The parent drug is cleared from the blood within a few minutes. The $t_{1/2}$ of MPA is ~16 h. Most (87%) is excreted in the urine as MPAG. Plasma concentrations of MPA and MPAG are increased in patients with renal insufficiency.

Therapeutic Uses. Mycophenolate mofetil is indicated for prophylaxis of transplant rejection, and it typically is used in combination with glucocorticoids and a calcineurin inhibitor but not with azathioprine. Combined treatment with sirolimus is possible, although potential drug interactions necessitate careful monitoring of drug levels. The approved dose for liver transplantation rejection prophylaxis is 1 g twice daily. For renal transplants, 1 g is administered orally or intravenously (over 2 h) twice daily (2 g/d). A higher dose, 1.5 g twice daily (3 g/d), may be recommended for African American renal transplant patients and all liver and cardiac transplant patients. MMF is increasingly used off label in systemic lupus. MMF has been used to treat a number of different inflammatory disorders, including MS and sarcoidosis. A delayed-release formulation of MPA is available; it does not release MPA under acidic conditions (pH < 5), as in the stomach, but is soluble in neutral pH, as in the intestine. The enteric coating results in a delay in the time to reach maximum MPA concentrations (Darji et al., 2008).

Toxicity. The principal toxicities of MMF are GI and hematologic: leukopenia, pure red cell aplasia, diarrhea, and vomiting. The MPA formulation has been introduced to reduce the frequent GI upset and has had variable results. There also is an increased incidence of some infections, especially sepsis associated with cytomegalovirus. Tacrolimus in combination with

MMF has been associated with activation of polyoma viruses such as BK virus, which can cause interstitial nephritis. The use of mycophenolate in pregnancy is associated with congenital anomalies and increased risk of pregnancy loss.

Drug Interactions. Tacrolimus delays elimination of MMF by impairing the conversion of MPA to MPAG. This may enhance GI toxicity. Coadministration with antacids containing aluminum or magnesium hydroxide leads to decreased absorption of MMF; thus, these drugs should not be administered simultaneously. MMF should not be administered with cholestyramine or other drugs that affect enterohepatic circulation. Such agents decrease plasma MPA concentrations, probably by binding free MPA in the intestines. Acyclovir and ganciclovir may compete with MPAG for tubular secretion, possibly resulting in increased concentrations of both MPAG and the antiviral agents in the blood, an effect that may be compounded in patients with renal insufficiency. Mycophenolate serum level monitoring is not performed routinely (Darji et al., 2008; Goldfarb-Rumyantsev et al., 2006).

Other Antiproliferative and Cytotoxic Agents

Many of the cytotoxic and antimetabolic agents used in cancer chemotherapy (see Chapter 66) are immunosuppressive due to their action on lymphocytes and other cells of the immune system. Other cytotoxic drugs that have been used both on and off label as immunosuppressive agents include methotrexate, cyclophosphamide, thalidomide, and chlorambucil. *Methotrexate* is used for prophylaxis against GVHD and treatment of rheumatoid arthritis, psoriasis, bullous pemphigoid, and some cancers. *Cyclophosphamide* and *chlorambucil* are used in leukemia and lymphomas and a variety of other malignancies. Cyclophosphamide also is FDA-approved for childhood nephrotic syndrome and is used widely off label for treatment of severe systemic lupus erythematosus, MS, and vasculitides such as Wegener granulomatosis. *Leflunomide* is a pyrimidine synthesis inhibitor indicated for the treatment of adults with rheumatoid arthritis. This drug has found increasing empirical use in the treatment of polyomavirus nephropathy seen in immunosuppressed renal transplant recipients. There are no controlled studies showing efficacy compared with control patients treated with only withdrawal or reduction of immunosuppression alone in BK virus nephropathy. The drug inhibits dihydroorotate dehydrogenase in the de novo pathway of pyrimidine synthesis. It is hepatotoxic and can cause fetal injury when administered to pregnant women.

Fingolimod

Fingolimod is the first agent in a new class of small molecules, S1P-R agonists. This S1P-R prodrug reduces recirculation of lymphocytes from the lymphatic system to the blood and peripheral tissues, thereby shunting lymphocytes away from inflammatory lesions and organ grafts.

Mechanism of Action. *Fingolimod* specifically and reversibly causes sequestration of host lymphocytes into the lymph nodes and Peyer patches and thus away from the circulation, thereby protecting lesions and grafts from T-cell-mediated attack. Fingolimod does not impair T- and B-cell functions. Sphingosine kinase 2 phosphorylates fingolimod; the fingolimod-phosphate product is a potent agonist at S1P-Rs, producing the altered lymphocyte traffic.

Therapeutic Uses. Fingolimod is not useful for treatment of transplant rejection but is effective and FDA-approved as a first-line therapy in the MS (see section on MS; Pelletier and Hafler, 2012).

Toxicity. Lymphopenia, the predictable and most common side effect of fingolimod, reverses on discontinuation of the drug. Of greater concern is the negative chronotropic effect on the heart, which has been observed with the first dose in up to 30% of patients (Vincenti and Kirk, 2008). In most patients, the heart rate returns to baseline within 48 h, with the remainder returning to baseline thereafter.

Immunosuppression Antibodies and Fusion Receptor Protein

Polyclonal and mAbs against lymphocyte cell surface antigens are widely used for prevention and treatment of organ transplant rejection.

Polyclonal antisera are generated by repeated injections of human thymocytes (ATG) or lymphocytes (ALG) into animals and then purifying the serum immunoglobulin fraction. These preparations vary in efficacy and toxicity from batch to batch.

The capacity to produce mAbs (Figure 35–3) has overcome the problems of variability in efficacy and toxicity seen with the polyclonal products, but mAbs are more limited in their target specificity. The first-generation murine mAbs have been replaced by newer humanized or fully human mAbs that lack antigenicity, have a prolonged $t_{1/2}$, and can be mutagenized to alter their affinity to Fc receptors.

Another class of biological agents being developed for both autoimmunity and transplantation are fusion receptor proteins. These agents consist of the ligand-binding domains of receptors bound to the Fc region of an immunoglobulin (usually IgG1) to provide a longer $t_{1/2}$ (Baldo, 2015). Examples of such agents include *abatacept* (CTLA4-Ig) and *belatacept* (a second-generation CTLA4-Ig), discussed in the Costimulatory Blockade section.

Antithymocyte Globulin

Antithymocyte globulin is a purified gamma globulin from the serum of rabbits immunized with human thymocytes (Thiyagarajan et al., 2013). It is provided as a sterile, freeze-dried product for intravenous administration after reconstitution with sterile water. ATG is one of many immune globulin preparations used therapeutically, generally for passive immunization (see Table 35–2 and Chapter 36).

Mechanism of Action. Antithymocyte globulin contains cytotoxic antibodies that bind to CD2, CD3, CD4, CD8, CD11a, CD18, CD25, CD44, CD45, and HLA class I and II molecules on the surface of human T lymphocytes. The antibodies deplete circulating lymphocytes by direct cytotoxicity (both complement and cell mediated) and block lymphocyte function by binding to cell surface molecules involved in the regulation of cell function.

Therapeutic Uses. Antithymocyte globulin is used for induction immunosuppression, although the approved indications are for the treatment and prophylaxis of acute renal transplant rejection in combination with other immunosuppressive agents and for the treatment of aplastic anemia. Antilymphocyte-depleting agents (Thymoglobulin, Atgam, and OKT3) are not registered for use as induction immunosuppression. A course of antithymocyte-globulin often is given to renal transplant patients with delayed graft function to avoid early treatment with the nephrotoxic calcineurin inhibitors, thereby aiding in recovery from ischemic reperfusion injury. The recommended dose of Thymoglobulin for acute rejection of renal grafts is 1.5 mg/kg/d (over 4–6 h) for 7–14 days. Mean T-cell counts fall by day 2 of therapy. The recommended dose of Atgam for acute rejection of renal grafts is 10–15 mg/kg/d for 14 days. ATG also is used for acute rejection of other types of organ transplants and for prophylaxis of rejection.

Toxicity. Polyclonal antibodies are xenogeneic proteins that can elicit major side effects, including fever and chills with the potential for hypotension. Premedication with corticosteroids, acetaminophen, or an antihistamine and administration of the antiserum by slow infusion (over 4–6 h) into a large-diameter vessel minimize such reactions. Serum sickness and glomerulonephritis can occur; anaphylaxis is rare. Hematologic complications include leukopenia and thrombocytopenia. As with other immunosuppressive agents, there is an increased risk of infection and malignancy, especially when multiple immunosuppressive agents are combined. No drug interactions have been described; anti-ATG antibodies develop but do not limit repeated use.

Monoclonal Antibodies

Immunotherapy and the Nature of Costimulation and Inhibition

Multiple costimulatory and inhibitory molecules interact to regulate T-cell responses. Immune activation requires two signals that emanate from the interaction of membrane proteins on APCs and T cells

Figure 35–3 *Generation of mAbs.* Mice are immunized with the selected antigen, and the spleen or lymph node is harvested and B cells separated. These B cells are fused to a suitable B-cell myeloma selected for its ability to grow in medium supplemented with HAT (hypoxanthine, aminopterin, and thymidine). Only myeloma cells that fuse with B cells can survive in HAT-supplemented medium. The hybridomas expand in culture. Hybridomas of interest are selected based on a specific screening technique and then cloned by limiting dilution. The mAbs can be used directly as supernatants or ascites fluid for experimental use but are purified for clinical use.

TABLE 35–2 ■ SELECTED IMMUNE GLOBULIN PREPARATIONS

GENERIC NAME	COMMON SYNONYMS	ORIGIN
Antithymocyte globulin	ATG	Rabbit
Botulism immune globulin intravenous	BIG-IV	Human
Cytomegalovirus immune globulin intravenous	CMV-IGIV	Human
Hepatitis B immune globulin	HBIG	Human
Immune globulin intramuscular	Gamma globulin, IgG, IGIM	Human
Immune globulin intravenous	IVIG	Human
Immune globulin subcutaneous	IGSC	Human
Lymphocyte immune globulin	ALG, antithymocyte globulin (equine), ATG (equine)	Equine
Rabies immune globulin	RIG	Human
Rho(D) immune globulin intramuscular	Rho[D] IGIM	Human
Rho(D) immune globulin intravenous	Rho[D] IGIV	Human
Rho(D) immune globulin microdose	Rho[D] IG microdose	Human
Tetanus immune globulin	TIG	Human
Vaccinia immune globulin intravenous	VIGIV	Human

(Figures 34–5A and 34–5B). A growing number of antibodies directed at these interacting proteins permits interruption of immune activation to produce a state of immune suppression. Figures 35–2 and 35–4 point out some of these antibodies, which are especially useful in preventing rejection after organ transplantation, as summarized in the material that follows.

In what might be considered an antiparallel system to activation, inhibitory regulation of T-cell activity can also result from the interaction of paired membrane ligands of APCs and T cells (Figure 35–4C). These points of negative regulation are called *immune checkpoints*. By targeting and blocking these immune checkpoints, antibodies can permit T-cell activation to proceed, unfettered by downregulation (Figure 35–4C and 35–4D). Activating immune attacks of tumor cells by blockade of immune checkpoints is producing new therapeutic options for cancer therapy (Callahan et al., 2016; Topalian et al., 2015). Chapter 67 presents the use of immunotherapy in cancer treatment.

Anti-CD3 Monoclonal Antibodies

CD3 is a component of the TCR complex on the surface of human T lymphocytes (Figure 35–2). Antibodies directed at the ϵ chain of CD3 have been used with considerable efficacy in human transplantation. The anti-CD3 antibody is monoclonal and targets the CD3 chain of the TCR, inducing its endocytosis and T-cell inactivation and removal through phagocytosis. The original mouse IgG2a antihuman CD3 mAb, *muromonab-CD3* (OKT3), is no longer marketed due to its side effects: It frequently causes cytokine release syndrome and severe pulmonary edema. Nevertheless, muromonab remains FDA-registered and could be reintroduced to the market at any time.

Recently, genetically altered anti-CD3 mAbs have been developed that are “humanized” to minimize the occurrence of anti-antibody responses and mutated to prevent binding to Fc receptors. In initial clinical trials, a humanized anti-CD3 mAb that does not bind to Fc receptors reversed acute renal allograft rejection without causing the first-dose

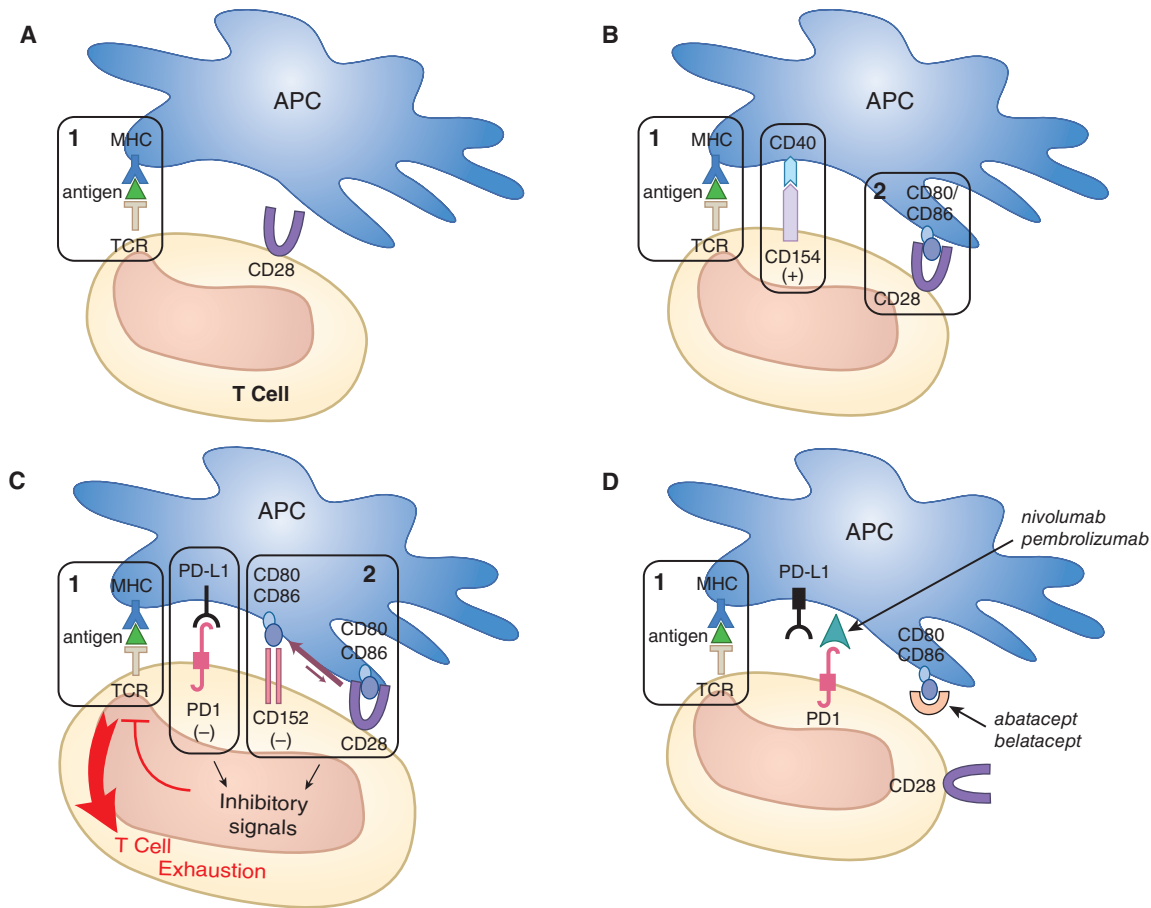

Figure 35-4 *T-cell activation: costimulation and coinhibitory checkpoints.* Numerous membrane CD proteins may be expressed on the APC and the T cell that lead to signaling interactions between ligands and receptors. These interactions can enhance or reduce the activation state of the T cell. Two signals are required for T-cell activation: presentation of an antigen ligand to the TCR and signaling by an additional “costimulatory” pair. **A.** The primary signal, *signal 1*, is the interaction of the TCR with the MHC-antigen complex on the APC. Activation requires a second, costimulatory interaction. **B.** *Signal 2*, the costimulatory interaction between CD28 on the T cell (the costimulatory receptor) and the costimulatory ligand on the APC, CD80/CD86, leads to T-cell activation. Additional costimulatory signals, such as the interaction of CD154 with CD40 on the APC, can further enhance T-cell activation (+). In the absence of costimulation, a T cell can become anergic or unresponsive. **C.** Additional APC–T-cell interactions can occur after T-cell activation, and some can be inhibitory, providing *immune checkpoints* that are important for reducing autoimmunity and for regulating the size and extent of immune responses. For example, the interaction of CD152 (CTLA4) with CD80/86 produces inhibitory signals that attenuate T-cell activation and proliferation (–). CD28 and CD152 compete for binding to CD80/CD86. As the figure suggests, the affinity of CD152 for CD80/CD86 exceeds that of CD28, and the equilibrium lies toward the formation of the inhibitory signaling complex, CD152–CD80/CD86. T cells may express varying amounts of another important modifier, PD1 (CD279). When liganded by PD–L1, PD1 produces inhibitory signals (↑ protein phosphatase activity, ↓ signaling by TCR, ↓ MAPK activity; see Figure 35–2) and reduces T-cell proliferation, leading to T-cell exhaustion, a state of hyporesponsiveness. When PD1 is highly expressed, as during conditions of chronic viral infection and cancer, suppression of T-cell activity via this pathway can be very effective; this pathway can facilitate continued viral replication and tumor progression. **D.** These immune checkpoints are useful sites for pharmacological regulation of T-cell activation. For instance, the agents abatacept and belatacept are fusion proteins that contain the CTLA4 domain of CD154 and act as decoys. These agents block costimulation of T cells by binding CD80/CD86 (see additional examples in Figure 35–2). Nivolumab and pembrolizumab are antibodies to PD1 and block interaction of PD1 with PD–L1, thereby blocking the immune suppression that would normally ensue and producing a state of immune hyperactivity. Checkpoint inhibitors that enhance immune responses are being used in cancer therapy (see Chapter 67). Antibodies can also be designed to be stimulatory ligands at checkpoints, to aid in generating a state of immune suppression that would be useful in treating autoimmune diseases.

cytokine release syndrome. Humanized anti-CD3 mAbs are also in phase 3 trials in patients with type 1 autoimmune diabetes.

Anti-CD52 Monoclonal Antibody (Alemtuzumab)

Alemtuzumab is a depleting humanized anti-CD52 mAb.

Mechanism of Action. Alemtuzumab binds the CD52 protein that is widely expressed on B cells and T-cells, as well as macrophages, NK cells, and some granulocytes. Alemtuzumab binding to CD52 induces an antibody-dependent lysis of cells and a profound leukopenia that may last for more than a year (Jones and Coles, 2014).

Therapeutic Uses. Alemtuzumab is used mainly for induction of immunosuppressive therapy and allows the avoidance of the early high dose of steroids. For transplants, the most common regimen is a single

intraoperative dose of 30 mg. Alemtuzumab is also used for the treatment of refractory acute cellular- and antibody-mediated rejections with the same dose used during induction. The drug is licensed for the management of CLL and MS (CAMMS223 Investigators et al., 2008).

Toxicity. Neutropenia remains the most common adverse effect seen with alemtuzumab. Almost half of the patients will also experience thrombocytopenia and anemia. Another major side effect is autoimmune hemolytic anemia and other autoimmune diseases thought to be due to immune reconstitution after the profound lymphocyte depletion.

Anti-IL-2 Receptor (Anti-CD25) Antibodies

Daclizumab is a humanized murine complementarity-determining region/human IgG1 chimeric mAb. Basiliximab is a murine-human chimeric mAb. Both are licensed for use in conjunction with cyclosporine

and corticosteroids for the prophylaxis of acute organ rejection in patients receiving renal transplants.

Mechanism of Action. The anti-CD25 mAbs bind with high affinity to the α subunit of the IL-2 receptor (Figure 35–2) and act as a receptor antagonist, inhibiting T-cell activation and proliferation without inducing cell lysis (Table 35–1). *Daclizumab* has a somewhat lower affinity but a longer $t_{1/2}$ (20 days) than *basiliximab* (Brennan et al., 2006). In addition, the induction of CD56⁺ CD4⁺ T cells is associated with response to therapy in patients with MS (D’Amico et al., 2015).

Therapeutic Uses. Anti-CD25 mAbs are used for induction therapy in solid-organ transplantation. They are also in phase 3 clinical trials in patients with MS. The long $t_{1/2}$ of daclizumab (20 days) results in saturation of the IL-2R α on circulating lymphocytes for up to 120 days after transplantation. Daclizumab is administered in five doses (1 mg/kg given intravenously over 15 min in 50–100 mL of normal saline) starting immediately preoperatively and subsequently at biweekly intervals.

The $t_{1/2}$ of basiliximab is 7 days. In trials, basiliximab was administered in a fixed dose of 20 mg preoperatively and on days 0 and 4 after transplantation. This regimen of basiliximab saturated IL-2R on circulating lymphocytes for 25–35 days after transplantation. Basiliximab was used with a maintenance regimen consisting of cyclosporine and prednisone and was found to be safe and effective when used in a maintenance regimen consisting of cyclosporine, MMF, and prednisone.

While daclizumab and basiliximab are comparable in effectiveness, daclizumab has a more costly dosing regimen. The higher cost has reduced demand, and daclizumab is now produced only for use in treating MS.

Toxicity. *Basiliximab* and *daclizumab* seem to be relatively safe as induction agents, with most of the clinical trials reporting adverse reactions rates comparable to placebo. No cytokine-release syndrome has been noted, but anaphylactic reactions and rare lymphoproliferative disorders and opportunistic infections may occur. No drug interactions have been described.

Belatacept, a Fusion Protein

Belatacept is a fusion protein composed of a modified Fc fragment of a human immunoglobulin linked to the extracellular domain of the CTLA4 (CD152) that is present on T cells (Figure 35–5). This second-generation CTLA4-Ig has two amino acid substitutions, increasing its affinity for CD80 (2-fold) and CD86 (4-fold), yielding a 10-fold increase in potency in vitro compared to CTLA4-Ig (Chinen et al., 2015).

Mechanism of Action. Induction of specific immune responses by T lymphocytes requires two signals: an antigen-specific signal via the TCR and a costimulatory signal provided by the interaction of molecules such as CD28 on CD4 lymphocyte with CD80 and CD86 on APCs and CD2 engagement by LFA-3 (CD58) on CD8 cells (Figure 35–4) (Riella and Sayegh, 2013). *Belatacept* is a selective T-cell costimulation blocker that potently binds the cell surface costimulatory ligands (CD80 and CD86) present on APCs, interrupting their interaction with CD28 on T cells (signal 2). The inhibition of signal 2 inhibits T-cell activation, promoting anergy and apoptosis.

Disposition and Pharmacokinetics. *Belatacept* is the first intravenous maintenance therapy in solid-organ transplantation. *Belatacept*’s pharmacokinetics were determined to be linear, with zero-order intravenous infusion and first-order elimination within the standard dose range of 5–10 mg/kg. The $t_{1/2}$ of *belatacept* is about 11 days.

Therapeutic Uses. Preclinical renal transplant studies showed that *belatacept* did not induce tolerance but did prolong graft survival. *Belatacept* is FDA approved as an alternative to calcineurin inhibitors as a strategy to prevent long-term calcineurin inhibitor toxicity (Satyananda and Shapiro, 2014; Talawila and Pengel, 2015). *Belatacept* has been approved specifically for prophylaxis of organ rejection in adult patients receiving a kidney transplant in combination with basiliximab induction, MMF, and corticosteroids.

The BENEFIT trial compared two *belatacept*-based regimens to cyclosporine and showed better kidney function and metabolic profile with

Figure 35–5 Structure of *belatacept*, a CTLA4-Ig congener. For details, see the text and Figure 35–4.

belatacept-treated patients compared to cyclosporine. Patients were induced with basiliximab and maintained on MMF and a prednisone taper. While infusions of *belatacept* are required relatively frequently early after transplantation, it becomes once/month by the end of the first or third month, depending on the dosage regimen chosen (Masson et al., 2014).

Toxicity. An increased risk of posttransplant lymphoproliferative disorder in Epstein-Barr virus seronegative patients has been observed with *belatacept* treatment. Hence, its use is restricted to Epstein-Barr virus seropositive patients. Infusion-related reactions occur infrequently, and the drug is generally well tolerated (Masson et al., 2014).

Drug Interactions. No specific pharmacokinetic drug-drug interactions have been reported with *belatacept* (Pestana et al., 2012).

General Approach to Treatment of Autoimmune Diseases

Genome-wide association scans have clearly clustered genetic variants around a group of diseases that appear to be mediated by autoimmune responses (Farh et al., 2015). Therapeutically, these diseases respond well to immunosuppression and the use of mAbs directed against cytokine pathways. However, these genetic investigations have revealed that a risk variant in one disease may be protective in another (Maier et al., 2009), consistent with the observation that inhibiting cytokine responses in one disease state, such as anti-TNF- α in rheumatoid arthritis, may lead to flare-ups in another disease (MS).

Anti-IL-2 Receptor (Anti-CD25) Antibodies

Anti-IL-2R mAbs discussed previously have been FDA-approved as a second line drug for patients with MS.

Anti-CD52

Mature lymphocytes express CD52 (CAMPATH-1 antigen), a negatively charged membrane dodecapeptide. *Alemtuzumab*, discussed previously, is a humanized mAb that binds to CD52 and targets the lymphocyte for destruction. In addition to the uses mentioned, *alemtuzumab* is approved for use in CLL and MS.

Tumor necrosis factor alpha is a pro-inflammatory cytokine that has been implicated in the pathogenesis of several immune-mediated intestinal, skin, and joint diseases. Several diseases (rheumatoid arthritis, Crohn disease) are associated with elevated levels of TNF- α . As a result, a number of anti-TNF agents have been developed as treatments.

Infliximab is a chimeric IgG1 mAb containing a human constant (Fc) region and a murine variable region. It binds with high affinity to TNF- α and prevents the cytokine from binding to its receptors. Infliximab is approved in the U.S. for treating the symptoms of rheumatoid arthritis and is typically used in combination with methotrexate in patients who do not respond to methotrexate alone. Infliximab also is approved for treatment of symptoms of moderate-to-severe Crohn disease in patients who have failed to respond to conventional therapy (see Chapter 51). Other FDA-approved indications include ankylosing spondylitis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis. About 1 in 6 patients receiving infliximab experiences an infusion reaction characterized by fever, urticaria, hypotension, and dyspnea within 1–2 h after antibody administration. The development of antinuclear antibodies, and rarely a lupus-like syndrome, has been reported after treatment with infliximab (Meroni et al., 2015).

Etanercept is a fusion protein that targets TNF- α . Etanercept contains the ligand-binding portion of a human TNF- α receptor fused to the Fc portion of human IgG1 and binds to TNF- α and prevents it from interacting with its receptors. It is approved for treatment of the symptoms of rheumatoid arthritis, ankylosing spondylitis, plaque psoriasis, polyarticular juvenile idiopathic arthritis, and psoriatic arthritis. Etanercept can be used in combination with methotrexate in patients who have not responded adequately to methotrexate alone. Injection-site reactions (i.e., erythema, itching, pain, or swelling) have occurred in more than one-third of etanercept-treated patients.

Adalimumab is another anti-TNF product for intravenous use. This recombinant human IgG1 mAb is approved for use in rheumatoid arthritis, ankylosing spondylitis, Crohn disease, juvenile idiopathic arthritis, plaque psoriasis, psoriatic arthritis, and ulcerative colitis.

Golimumab is a human IgG1 (anti-TNF- α) monoclonal antibody. Golimumab alone or in combination with methotrexate is approved for treatment of moderately to severely active rheumatoid arthritis and active psoriatic arthritis. It is also approved for treatment of patients with ankylosing spondylitis and moderately to severely active ulcerative colitis. Golimumab is administered by subcutaneous injections and is available in 50- and 100-mg doses.

Certolizumab pegol is a humanized pegylated antibody specific to TNF- α . Pegylation of the Fab' fragment provides sustained activity. This agent is approved for the treatment of adults with Crohn disease and rheumatoid arthritis, active psoriatic arthritis, and active ankylosing spondylitis. It is available as 200 mg lyophilized powder or 200-mg/mL prefilled sterile injections for subcutaneous administration.

Toxicity. All anti-TNF agents (i.e., *infliximab*, *etanercept*, *adalimumab*, *golimumab*, *certolizumab*) increase the risk of serious infections, lymphomas, and other malignancies. For example, fatal hepatosplenic T-cell lymphomas have been reported in adolescent and young adult patients with Crohn disease treated with infliximab in conjunction with azathioprine or 6-MP.

IL-1 Inhibition

Plasma IL-1 levels are increased in patients with active inflammation (see Chapter 34). In addition to the naturally occurring IL-1RA, several IL-1RAs are in development, and a few have been approved for clinical use.

Anakinra is an FDA-approved recombinant, nonglycosylated form of human IL-1RA for the management of joint disease in rheumatoid arthritis. *Anakinra* is also approved for cryopyrin-associated periodic syndromes (CAPS), a group of rare inherited inflammatory diseases associated with overproduction of IL-1 that includes familial cold autoinflammatory and Muckle-Wells syndromes and for treatment of neonatal-onset multisystem inflammatory disease. It can be used alone or in combination with anti-TNF agents such as etanercept, infliximab, or adalimumab.

Canakinumab is an IL-1 β mAb that is FDA approved for CAPS and active systemic juvenile idiopathic arthritis. *Canakinumab* is being evaluated for use in chronic obstructive pulmonary disease.

Rilonacept, a fusion protein that binds IL-1, is being evaluated for gout. IL-1 is an inflammatory mediator of joint pain associated with elevated uric acid crystals.

Other Interleukin Antagonists

Tocilizumab, an IL-6R, is FDA-approved for treatment of rheumatoid arthritis and systemic juvenile idiopathic arthritis; *siltuximab*, another IL-6 antagonist, is FDA approved for treatment of multicentric Castleman disease if the patient is HIV and human herpesvirus 8 negative. *Ustekinumab* is a human IL-12 and IL-23 antagonist indicated for the treatment of plaque psoriasis and psoriatic arthritis.

Secukinumab is a human anti-IL-17A antagonist indicated for treatment of plaque psoriasis.

Inhibition of Lymphocyte Function–Associated Antigen

Efalizumab is a humanized IgG1 mAb targeting the CD11a chain of LFA-1. Efalizumab binds to LFA-1 on lymphocytes and prevents LFA-1 interaction with intercellular adhesion molecule (ICAM), thereby inhibiting T-cell adhesion, trafficking, and activation. Efalizumab was approved for use in patients with psoriasis but has been withdrawn from the market because of excessive progressive multifocal leukoencephalopathy (Prater et al., 2014).

Alefacept is a human LFA-3–IgG1 fusion protein. The LFA-3 portion of alefacept binds to CD2 on T lymphocytes, blocking the interaction between LFA-3 and CD2 and interfering with T-cell activation. Alefacept is approved for use in psoriasis. Treatment with alefacept has been shown to produce a dose-dependent reduction in T-effector memory cells (CD45, RO⁺) but not in naïve cells (CD45, RA⁺) (Vincenti and Kirk, 2008). This effect has been related to its efficacy in psoriatic disease and is of significant interest in transplantation because T-effector memory cells are associated with costimulation blockade-resistant and depletion induction-resistant rejection. Alefacept delays rejection in NHP cardiac transplantation and has synergistic potential when used with costimulation blockade or sirolimus-based regimens in NHPs (Vincenti and Kirk, 2008). A phase II multicenter study to assess the safety and efficacy of maintenance therapy with alefacept in kidney transplant recipients showed no difference from placebo controls (Rostaing et al., 2013).

Cytokine Therapy: Interferon

For a description of IFN induction and signaling and the major actions of IFN, see Chapter 34. Interferon- β (IFN- β) was among the first cytokines used for the treatment of autoimmune diseases, particularly MS. IFNs are endogenous regulatory cytokines that increase or decrease transcriptional initiation of hundreds of genes in a cell-dependent fashion with multiple mechanisms of action, including induction of IL-10. The different IFN- β formulations have modest therapeutic efficacy, decreasing the exacerbation rate in MS by approximately 30%. They are relatively safe; fatigue is the major side effect. There are multiple preparations of IFN- β in the market that are administered either by the intramuscular or subcutaneous routes. IFN- β preparations are usually used for MS and IFN- α/γ preparations are used for infections. Three IFN- β preparations are currently on the market: AVONEX and REBIF are 1 α formulations for MS; BETASERON, EXTAVIA (1 β preparations) and *peginterferon* (1 α) are indicated for relapsing MS. There are no significant differences between these IFN preparations, and as more efficacious drugs are now available, they should no longer be considered first-line drugs for the treatment of MS.

Targeting B Cells

Most of the advances in transplantation can be attributed to drugs designed to inhibit T-cell responses. As a result, T-cell-mediated acute rejection has become much less of a problem, while B-cell-mediated responses such as antibody-mediated rejection and other effects of donor-specific

antibodies have become more evident. Both biologicals and small molecules with B-cell-specific effects now are in development for transplantation, including humanized mAbs to CD20 and inhibitors of the two B-cell-activation factors, BLYS and APRIL, and their respective receptors. *Belimumab*, a mAb that targets BLYS, was recently approved for use in patients with systemic lupus erythematosus.

The CD20 antibodies *rituximab* and *ocrelizumab* deplete circulating mature B lymphocytes (though they may remain to some degree in lymph nodes), and positive results from clinical trials in patients with rheumatoid arthritis and MS strongly suggest that B cells play a critical part in disease pathogenesis. Genetic fine mapping studies demonstrated a potentially pathogenic role of B cells in MS and rheumatoid arthritis that were not limited to antibody production. In particular, a definitive genetic modeling study pointed to the crucial role of B cells as APCs (Farh et al., 2015).

Tolerance

Immunosuppression has concomitant risks of opportunistic infections and secondary tumors. Therefore, the ultimate goal of research on organ transplantation and autoimmune diseases is to induce and maintain immunological tolerance, the active state of antigen-specific nonresponsiveness (Krensky and Clayberger, 1994). Tolerance, if attainable, would represent a true cure for conditions discussed previously in this section without the side effects of the various immunosuppressive therapies. The calcineurin inhibitors prevent tolerance induction in some, but not all, preclinical models. In these same model systems, *sirolimus* does not prevent tolerance and may even promote tolerance (Kawai et al., 2014; Krensky and Clayberger, 1994). In experimental animals, *sirolimus* promotes regulatory T cells, a subtype of T cells shown to suppress all immunity, and promotes tolerance. Studies in kidney transplant recipients showed that *sirolimus* spared regulatory T cells in the periphery, unlike calcineurin inhibitors, which reduced their percentage (Segundo et al., 2006).

Costimulatory Blockade

Inhibition of the costimulatory signal has been shown to induce tolerance (Figure 35–4).

Abatacept is a fusion protein (see previous discussion) that contains the binding region of CTLA4 (CD152), which is a CD28 homolog, and the Fc region of the human IgG1. CTLA4-Ig competitively inhibits CD28 binding to CD80 and CD86 and thus activation of T cells. CTLA4-Ig is effective in the treatment of rheumatoid arthritis in patients resistant to other drugs.

A second costimulatory pathway involves the interaction of CD40 on activated T cells with CD40 ligand (CD154) on B cells, endothelium, or APCs (see Figure 35–4). Among the purported activities of anti-CD154 antibody treatment is the blockade of B7 expression induced by immune activation. Two humanized anti-CD154 mAbs have been used in clinical trials in renal transplantation and autoimmune diseases. The development of these antibodies, however, is on hold because of associated thromboembolic events. An alternative approach to block the CD154-CD40 pathway is to target CD40 with mAbs. These antibodies are undergoing trials in non-Hodgkin lymphoma but are also likely to be developed for autoimmunity and transplantation.

Donor Cell Chimerism

A promising approach is induction of chimerism (coexistence of cells from two genetic lineages in a single individual) by first dampening or eliminating immune function in the recipient with ionizing radiation, drugs such as cyclophosphamide, or antibody treatment and then providing a new source of immune function by adoptive transfer (transfusion) of bone marrow or hematopoietic stem cells. On reconstitution of immune function, the recipient no longer recognizes new antigens provided during a critical period as “nonself.” Such tolerance is long lived and less likely to be complicated by the use of calcineurin inhibitors.

Antigens

Specific antigens induce immunological tolerance in preclinical models of diabetes mellitus, arthritis, and MS. In vitro and preclinical in vivo studies demonstrated that one can selectively inhibit immune responses to specific antigens without the associated toxicity of immunosuppressive therapies. With these insights comes the promise of specific immune therapies to treat an array of immune disorders from autoimmunity to transplant rejection (Riedhammer and Weissert, 2015). To date, this approach has only worked in animal models of autoimmune disease.

Soluble HLA

In the precyclosporine era, blood transfusions were shown to be associated with improved outcomes in renal transplant patients. These findings gave rise to donor-specific transfusion protocols that improved outcomes. After the introduction of cyclosporine, however, these effects of blood transfusions disappeared, presumably due to the efficacy of this drug in blocking T-cell activation. Nevertheless, the existence of tolerance-promoting effects of transfusions is irrefutable. It is possible that this effect is due to HLA molecules on the surface of cells or in soluble forms. Soluble HLA and peptides corresponding to linear sequences of HLA molecules can induce immunological tolerance in animal models via a variety of mechanisms (Murphy and Krensky, 1999).

Immunotherapy for Multiple Sclerosis

Clinical Features and Pathology

Multiple sclerosis is a genetically mediated demyelinating inflammatory disease of the CNS white matter, characterized by mononuclear cell infiltration into the white matter with relative demyelination to axonal loss. Dense meningeal infiltrates are found in the subarachnoid spaces of patients, and these infiltrates are intimately associated with subpial demyelination, neuronal and neuritic damage, oligodendrocyte loss, cortical atrophy, and parenchymal microglial activation in the outer cortical layers. Inflammatory cortical demyelination occurs early in MS, preceding the appearance of classic white matter plaques with neurodegenerative changes, including oligodendrocyte loss, reactive astrocytosis, and axonal and neuronal injury within these cortical plaques on a background of inflammation. MS may be episodic or progressive and occurs with prevalence increasing from late adolescence to 35 years of age and then declining. MS is 3-fold more common in females than in males and occurs mainly in higher latitudes of the temperate climates. Epidemiologic studies suggest a role for environmental factors in the pathogenesis of MS, including low vitamin D, smoking, increases in body mass index, and high salt intake (Ransohoff et al., 2015).

Genome-wide association studies have identified genetic variants associated with MS susceptibility (International Multiple Sclerosis Genetics Consortium, et al., 2007), now with 200 variants identified. Although each of these contributes only a small increase in the complex phenotype of disease risk, the biological functions associated with individual allelic variants have been striking. Many of these variants fall within specific signaling cascades, which suggests that alterations in pathways—rather than individual genes—may be useful in predicting response to therapy. Over half of genetic variants associated with MS risk are also found in other putative autoimmune diseases, and risk alleles are primarily associated with genes that regulate immune function. Approximately 60% of probable causal variants mapped to enhancer-like elements, with preferential correspondence to stimulus-dependent CD4⁺ T-cell enhancers. By overlapping causal single-nucleotide variants with transcription factor-binding maps generated by ENCODE, single-nucleotide variants were strongly enriched within binding sites for immune-related transcription factors (Farh et al., 2015). In patients with MS, there are activated T cells that are reactive to different myelin antigens, including myelin basic protein, and these T cells secrete pro-inflammatory cytokines, whereas in healthy controls, T cells secrete the anti-inflammatory IL-10 cytokine (Cao et al., 2015). It is difficult to

vigorously find autoantibodies to myelin antigens in patients with MS, distinguishing MS from other autoimmune diseases.

Attacks are classified by type and severity and likely correspond to specific degrees of CNS damage and pathological processes. Thus, physicians refer to relapsing-remitting MS (the form in 85% of younger patients), secondary progressive MS (progressive neurological deterioration following a long period of relapsing-remitting disease), and primary progressive MS (~15% of patients, wherein deterioration with relatively little inflammation is apparent at onset).

Pharmacotherapy

There have been major advances in the treatment of MS. Table 35–3 summarizes current immunomodulatory therapies for MS. Specific therapies are aimed at resolving acute attacks, reducing recurrences and exacerbations, and slowing the progression of disability. MS exacerbations are treated with 3 to 5 days of 1000 mg of intravenous methylprednisolone, as oral prednisone alone is an ineffective treatment that increases the risk of new attacks. The so-called first-generation (but not necessarily “first-line”) drugs include a variety of IFN- β (discussed previously in Cytokine Therapy) and random polymers that contain amino acids commonly used as MHC anchors, and TCR contact residues have been proposed as possible “universal altered peptide ligands.” Glatiramer acetate (GA), a random-sequence polypeptide consisting of four amino acids (alanine [A], lysine [K], glutamate [E], and tyrosine [Y]) with an average length of 40–100 amino acids, binds efficiently to MHC class II DR molecules *in vitro*. In clinical trials, GA, administered subcutaneously to patients with relapsing-remitting MS, decreased the rate of exacerbations by about 30%, similar to the efficacy of IFN- β . *In vivo* administration of GA induces highly cross-reactive CD4⁺ T cells that are immune deviated to secrete anti-inflammatory Th2 cytokines such as IL-4 and IL-13. Administration of GA also prevents the appearance of new lesions detectable by MRI (Duda et al., 2000). This represents one of the first successful uses of an agent that ameliorates autoimmune disease by altering signals through the TCR complex.

The long-term treatment of patients with MS is in transition, having moved from the use of first-era therapies of IFN- β and GA to more

effective treatments. The anti-CD20 B cell depletion therapy with *ocrelizumab* is currently the most efficacious treatment (Hauser et al., 2017) and should in most instances be considered as a first line therapy. There is no rationale for the use of step therapy with IFN- β and GA before using the more effective drugs such as *ocrelizumab* and *natalizumab*.

The mAb *natalizumab*, directed against the adhesion molecule α_4 integrin, antagonizes interactions with integrin heterodimers containing α_4 integrin, such as $\alpha_4\beta_1$ integrin that is expressed on the surface of activated lymphocytes and monocytes. An interaction of $\alpha_4\beta_1$ integrin with vascular cell adhesion molecule 1 is critical for T-cell trafficking from the periphery into the CNS; blocking this interaction has been highly effective in inhibiting disease exacerbations.

Similarly, the S1P agonist *fingolimod* (mechanism discussed previously) is FDA-approved as a first-line therapy in MS, decreasing the exacerbation rate by about 50%. Use of *natalizumab* is associated with the development of progressive multifocal leukoencephalopathy, and availability is limited to a special distribution program (Touch) administered by the manufacturer that dictates measurement of JCV antibodies. Patients negative for JCV are often recommended to begin *natalizumab*, while JCV-positive persons are tested for VZV to evaluate *fingolimod* treatment. If the result is positive, indicating VZV immunity, *fingolimod* can be begun. If not, *fingolimod* treatment should follow VZV immunization. Regarding safety, *natalizumab* seems to be safe in patients negative for JCV antibody. In patients with cardiac issues—particularly with bundle branch blocks—*fingolimod* should be avoided.

Dimethyl fumarate appears to have multiple immunomodulatory effects and is an activator of *nrf2* that mediates antioxidative response. In two pivotal phase 3 trials, *dimethyl fumarate* reduced relapse rates by about 50% as compared with placebo, with a significant reduction of gadolinium-enhanced lesions as well as T2 lesions on MRI. The drug seems to be safe, although gastrointestinal side effects can occasionally cause difficulties.

Monoclonal antibodies directed against CD52 (*alemtuzumab*) were recently approved for relapsing-remitting MS (discussed previously). While it appears to be highly effective and long lived in terms of response, secondary autoimmune responses that emerge in patients with MS but

TABLE 35–3 ■ EFFICACY RANKING OF APPROVED THERAPIES FOR MULTIPLE SCLEROSIS^a

DRUG	ERA OF DEVELOPMENT	MECHANISM OF ACTION	KEY CONSIDERATIONS
Most effective			
Natalizumab	Second	Monoclonal antibody against integrin α_4	Risk of PML must be assessed via presence of JCV antibodies.
Ocrelizumab	Third	mAB against CD20 (B cells)	Low risk PML, slight increase in infections
Alemtuzumab	Third	mAB against CD52	High risk of 2° thyroiditis & other autoimmune disease
Highly effective			
Fingolimod	Second	Sphingosine S1P-R modulator	Cardiac complications preclude use in individuals over the age of 50 and those with history of cardiac disease. VZV antibody testing must be conducted to mitigate risk of disseminated herpes zoster.
Dimethyl fumarate	Third	Immunomodulator	Necessary to monitor lymphocyte count as risk mitigation against PML. GI complications may limit use.
Moderately effective			
IFN- β	First	Immunomodulator	Well-characterized long-term safety and efficacy profiles. Patients should not be required to “fail” before receiving alternative treatments.
Glatiramer acetate	First	Immunomodulator	Best safety profile for pregnant women with mild disease. Patients should not be required to “fail” before receiving alternative treatments.
Teriflunomide	Third	Pyrimidine-synthesis inhibitor	Risk of teratogenicity precludes use in women who are, or intend to become, pregnant.

^aRankings are estimated on the basis of clinical trials, postapproval studies, and few head-to-head comparisons. The factors that determine drug efficacy in any individual patient are largely undefined, and good clinical judgment is essential for treatment selection. For details, see Ransohoff et al., 2015.

not in those with CLL are thyroiditis and, more rarely, idiopathic thrombocytopenic purpura. The anti-CD20 antibody *ocrelizumab* has recently completed a phase 3 trial and has the most dramatic efficacy in treating MS, leading to FDA approval. It is now considered a first line drug in the treatment of relapsing remitting MS.

With all of these agents, the earlier in the course of MS that they are used, the more effective they are in preventing disease relapses. What is not clear is whether any of these agents will prevent or diminish the later onset of secondary progressive disease, which causes more severe disability.

Historical Perspective

The historical impact of infectious diseases is evident in the high mortality rates in young children and adults and the disruption that these diseases have caused in emerging societies. The rise of civilization in conjunction with the domestication of plants and animals permitted people to live in denser communities with each other and with their animals. Such proximity provided ideal breeding grounds for infectious pathogens, and their spread resulted in epidemics throughout the world. As people began to question the underlying causes of disease and the apparent protection to reinfection afforded to some survivors of a disease, ideas of immunity and disease prevention were born, apparently as early as the 5th century.

The concept of immunity goes back at least to the 17th century when emperor K'ang of China documented his practice of variolation, or inoculation, of his troops and his own children with smallpox to confer protection from the disease (Hopkins, 2002). Variolation involved taking liquid from a smallpox pustule of an infected patient, cutting the skin of an uninfected person, and then introducing the inoculum. Records from the 18th century note that Africans brought to the U.S. as slaves bore scars from smallpox variolation and were under the belief that they were immune to the disease. Variolation against smallpox was also reported by Lady Mary Montagu during her time in Constantinople (1716–1718). Lady Montagu, herself a survivor of smallpox, reported that certain Turkish women

would open a wound in healthy individuals and introduce the contents of a smallpox vesicle with a large needle, thereby providing a level of protection against smallpox. About 2%–3% died after variolation, whereas 20%–30% died from natural infection. Lady Montagu had herself and a son variolated and later had a daughter successfully variolated in London under the auspices of physicians of the Royal Society. Positive outcomes notwithstanding, fear of the procedure persisted.

Around the same time, in Boston, Cotton Mather and Dr. Zabdiel Boylston began a program of variolation against smallpox. The program met with general success but was opposed by many physicians, fearful that inoculation spread the disease and worried by deaths after inoculation (~2% of those inoculated). One Puritan religious leader, Edmund Massey, preached against inoculation, quoting from the book of Job (Job 2:7: “So Satan went forth from the presence of the Lord and smote Job with sore boils.”) and arguing that Satan was the prime practitioner of inoculation and that such diseases as smallpox were a necessary trial of faith or punishment for sins, the fear of which “is a happy restraint upon many people” (Gross and Sepkowitz, 1998). Medical practice in Boston has come a long way since that time.

In 1796, Edward Jenner, who coined the term *vaccination*, from *vacca*, Latin for “cow,” helped to advance vaccine safety. He tested the hypothesis that smallpox protection could be achieved by using cowpox, a nonfatal, self-limited disease in humans caused by a virus of the Poxviridae family that includes monkeypox and smallpox and that can spread from cows to

RSV: respiratory syncytial virus
SAE: serious adverse event
SAGE: Strategic Advisory Group of Experts
SIDS: sudden infant death syndrome
TB: *Mycobacterium tuberculosis*
Td: tetanus toxoid and reduced diphtheria toxoid
Tdap: tetanus toxoid, reduced diphtheria toxoid, acellular pertussis
VDJ: variable, diversity, joining
VLP: virus-like particle
VZV: varicella zoster virus
WHO: World Health Organization

humans. Jenner infected a boy with cowpox pus from an infected milkmaid; the boy got mildly ill from cowpox, recovered, and when challenged with smallpox collected from scabs of a smallpox patient, was unaffected, showed no symptoms, and was fully protected against the disease. Thus, it was possible to inoculate against a disease using material from a related but less-harmful disease.

By the early to mid-19th century, vaccination was accepted widely, and governments in the U.S. and Europe began to require vaccination of children. As in our own era, there was organized resistance from antivaccination groups. There was also a sense that immunity waned with time, and revaccinations were introduced, producing a sustained diminution of smallpox.

The work of Pasteur and Koch established a link between microorganisms and disease and provided the scientific understanding to develop more specific vaccines. Preservatives (glycerol was an early additive) and refrigeration increased shelf life of vaccines and permitted their wider distribution. The cells of the immune system began to be identified around 1890, followed by the discovery of antibodies and hyperimmune serum and demonstration of the efficacy of adjuvants (aluminum was the first) to increase immunogenicity (Marrack et al., 2009). In the 1950s, freeze-drying became standard, permitting worldwide distribution of purified vaccines. Through the coordinating efforts of the WHO, smallpox was declared “eliminated” in 1979.

Other scourges were attacked by vaccination in the mid-20th century. One was polio, an incurable neurological disease causing muscle wasting, paralysis, and death if the diaphragm is affected. In 1955, Jonas Salk released a vaccine against poliovirus. The Salk vaccine, an inactivated virus preparation administered by injection, was followed in 1961 by the Sabin oral vaccine, which employs an attenuated poliovirus that provides immunity to all three types of poliovirus. As a result of the polio vaccines, the annual number of cases in the U.S. fell to 161 in 1961 from 35,000 in 1955 (Hinman, 1984). Eradication of polio depends on interruption of person-to-person transmission, which requires that a high percentage of the susceptible population be inoculated. Most adults in developed countries are immune, but when a significant fraction of children is unvaccinated, there is the potential for an outbreak because wild polioviruses circulate.

These fundamental observations and experiments paved the way for the modern vaccines that have reduced mortality and morbidity rates from infectious pathogens across the globe. Modern laboratory technologies have rendered vaccines safe and highly effective against infectious pathogens and virus-transforming cancers and against neoantigens on cancerous cells. Vaccination strategies are a public health success, as shown by the complete worldwide eradication of smallpox and the elimination of polio in the Americas in 1994, Europe in 2002, and South-East Asia in 2014, with remaining endemic cases only in Pakistan, Afghanistan, and Nigeria in 2016 according to WHO. In 2016, WHO and the Pan American Health Organization declared the Americas free of endemic measles, credited to immunization campaigns. The current recommendations for childhood vaccinations are summarized in Table 36–1. The issue of non-vaccinators is presented further in the chapter.

Vaccination Induces Development of Immunological Memory

The hallmarks of an immune response to pathogens are the recognition and activation of the innate immune response that limits pathogen spread when microbes breach the host's natural protective barriers, such as the skin, the respiratory epithelium, or the GI epithelium. If the pathogen is not controlled, the innate immune system then recruits the humoral (antibody-secreting B cell) and cellular (T cell) arms of the adaptive immune response to specifically target and destroy the invading pathogen. Once the microbe is eliminated during this primary response, small numbers of pathogen-specific B and T cells survive long term, sometimes

TABLE 36-1 ■ RECOMMENDED IMMUNIZATION SCHEDULE FOR CHILDREN AND ADOLESCENTS AGED 18 YEARS OR YOUNGER, U.S., 2017.

Vaccine	Birth	1 mo	2 mos	4 mos	6 mos	9 mos	12 mos	15 mos	18 mos	19-23 mos	2-3 yrs	4-6 yrs	7-10 yrs	11-12 yrs	13-15 yrs	16 yrs	17-18 yrs

Range of recommended ages for all children

Range of recommended ages for catch-up immunization

Range of recommended ages for certain high-risk groups

Range of recommended ages for non-high-risk groups that may receive vaccine, subject to individual clinical decision making

No recommendation

These recommendations are reprinted from the website of the Centers for Disease Control and Prevention (CDC) and should be read with the footnotes provided on the CDC website: <https://www.cdc.gov/vaccines/schedules/>. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars. To determine minimum intervals between doses, see the catch-up schedule on the CDC website. School entry and adolescent vaccine age groups are shaded in gray.

for the entire life of the host, as *memory B and T cells*. These memory cells confer host protection against reinfection with the same pathogen. During a second response, memory cells use their specific antigen receptors to recognize the invading pathogen. This results in their activation and expansion to directly kill infected cells (via T cells) or generate antibodies (via B cells) that will neutralize the pathogen.

Vaccination technology takes advantage of this paradigm. As a means of generating immunological memory, uninfected individuals are given a controlled infection or exposed to antigen that elicits an immune response. When these vaccinated individuals are subsequently infected with these pathogens in their environment, the responses of their memory T and B cells outpace the invading microbes to neutralize and prevent their spread in a much more rapid and greater magnitude secondary response.

B cell clonal expansion results in the differentiation of long-lived memory B cells and emergence of shorter-lived plasma cells that produce antibodies. During the primary response, following the vaccination, B cells will undergo this differentiation process and will initially secrete IgM antibodies. IgM antibodies are large and provide some protection. Days after the response is initiated, B cells will undergo clonal selection and will produce IgG, which is a higher-affinity antibody with enhanced pathogen neutralization capacity.

Differentiated plasma cells can also produce other antibody classes, such as IgA, IgD, and IgE, that have unique functions. IgD can be expressed on the surface of B cells; its function continues to be investigated. IgA antibodies are concentrated in mucous secretions, breast milk, and tears. IgE antibodies are important in the elimination of parasitic infections. *Because IgG antibodies have undergone a selection process that increases their affinity, these antibody types are the targets of vaccine design.* Secondary responses after vaccination therefore elicit a faster and larger B-cell response, and these B cells primarily make IgG antibodies (Clem, 2011).

Cellular immunity involving both CD4⁺ and CD8⁺ T cells is also a target of vaccine design. Unlike B cells, T cells target intracellular pathogens that have infected host cells. CD4⁺ T cells or helper T cells, stimulate B cells to produce antibody. CD8⁺ T cells kill infected cells. Like B cells, antigen-memory T cells survive long term and provide protection for future encounters with their specific antigen.

Immunization Strategies

Immunity can be achieved from either passive or active methods involving exposure to natural infection or through artificial human-made antigens. Individuals can develop antibodies from natural infection or after vaccination.

Passive

Passive immunity involves the transfer of preformed antibodies from an immune individual to a nonimmune individual to confer temporary immunity. An example of passive natural immunity is the transfer of antibodies from mother to fetus during pregnancy and through breast milk and colostrum consumed by an infant. These antibodies enter the body and provide a first line of defense to the fetus or infant, which otherwise has no immunity to any pathogen.

An example of *artificial passive immunization* is the injection of antivenom antibodies. Animals are immunized with venom antigen and their hyperimmunized serum is transfused into the patient. Antivenom can be monovalent, effective against one type of venom, or polyvalent and effective against venom from multiple species. An antivenom binds and neutralizes a toxin. Early administration after injury is critical because antivenom can halt but not reverse venom damage. Even though antivenom is purified, trace proteins remain, and these can trigger anaphylaxis or serum sickness in patients. Most antivenoms are administered intravenously but can also be injected intramuscularly against stonefish and redback spider venom. Antivenoms have been developed against venomous spiders, acarids, insects, scorpions, marine animals, and snakes. Passive immunization is used for a variety

Antithymocyte globulin

of toxins and infections; a list of available immunoglobulins is shown in Table 36-2.

Active

A natural infection that stimulates the immune response in uninfected individuals may lead to development of immunological memory and protection from reinfection, as in the case of infection with the MeV. This only occurs if the individual survives the primary infection, which is not always the case for viruses like measles, influenza, or ebola. Active immunization through injection of artificial antigens elicits a controlled immune response leading to the generation of immunological memory. This type of immunization, compared to natural infection, does not cause infectious disease or compromise the life of the individual. Thus, vaccine technologies through active stimulation of the immune system ensure that the individual survives and has protection against the pathogen in the natural environment.

Vaccine Types

Advanced technologies are currently used to generate vaccines to prevent many infectious diseases and to deter infectious pathogens that cause cancer such as hepatitis viruses that can lead to hepatocellular carcinoma and HPVs, which can cause cervical, anal, vaginal, and penile cancers. Effective vaccines activate both the innate and the adaptive immune systems. There are many different types of vaccines, each with advantages and disadvantages. Vaccine design involves an understanding of the nature of the microbe, the tropism of the pathogen, and the practical need in certain regions of the world. The following section summarizes current methods used in vaccine design. For a list of vaccines approved by the U.S. Food and Drug Administration, see Table 36-3.

Live Attenuated

Live attenuated vaccines use a weakened form of a virus that contains antigens that appropriately stimulate an immune response. Such viruses have been passaged to reduce their virulence but retain immunogenic antigens that elicit strong humoral and cellular responses and the development of memory cells after one or two doses. A virus, for example, can be isolated

TABLE 36-3 ■ APPROVED VACCINES IN THE U.S.**Toxoids**

Tetanus and diphtheria toxoids adsorbed for adult use
 Tetanus toxoid adsorbed
 Tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccine, adsorbed

Bacterial polysaccharide

Meningococcal polysaccharide vaccine, groups A, C, Y, and W-135 combined
 Pneumococcal vaccine, polyvalent
 Typhoid Vi polysaccharide vaccine

Bacterial conjugate vaccines

Haemophilus b conjugate vaccine (meningococcal protein conjugate)
Haemophilus b conjugate vaccine (tetanus toxoid conjugate)
 Pneumococcal 7-valent conjugate vaccine (diphtheria CRM₁₉₇ protein)
 Pneumococcal 13-valent conjugate vaccine (diphtheria CRM₁₉₇ protein)
 Meningococcal (groups A, C, Y, and W-135) oligosaccharide diphtheria CRM₁₉₇ conjugate vaccine
 Meningococcal groups C and Y and *Haemophilus* b tetanus toxoid conjugate vaccine
 Meningococcal (groups A, C, Y, and W-135) polysaccharide diphtheria toxoid conjugate vaccine
 Meningococcal group B vaccine

Live bacterial

BCG live
 Typhoid vaccine live oral Ty21a
 Cholera vaccine live oral

Inactivated bacterial

Plague vaccine

Live Viral

Measles and mumps virus vaccine, live
 Measles, mumps, and rubella virus vaccine, live
 Measles, mumps, rubella and varicella virus vaccine, live
 Varicella virus vaccine, live
 Zoster vaccine, live
 Rotavirus vaccine, live, oral
 Rotavirus vaccine, live, oral, pentavalent
 Influenza vaccine, live, intranasal (quadrivalent, types A and types B)
 Adenovirus type 4 and type 7 vaccine, live, oral
 Yellow fever vaccine
 Smallpox (vaccinia) vaccine, live

Inactivated or subunit viral

Poliovirus vaccine inactivated (human diploid cell)
 Poliovirus vaccine inactivated (monkey kidney cell)
 Hepatitis A vaccine, inactivated
 Hepatitis B (recombinant) vaccine
 Hepatitis A vaccine, inactivated, and Hepatitis B (recombinant) vaccine
 Influenza A (H1N1) 2009 monovalent vaccine
 Influenza virus vaccine, H5N1 (for national stockpile)
 Influenza A (H5N1) virus monovalent vaccine, adjuvanted
 Influenza virus vaccine (trivalent, types A and B)
 Influenza virus vaccine (quadrivalent, types A and B)
 Human papillomavirus bivalent (types 16, 18) vaccine, recombinant
 Human papillomavirus quadrivalent (types 6, 11, 16, 18) vaccine, recombinant
 Human papillomavirus 9-valent vaccine, recombinant
 Japanese encephalitis virus vaccine, inactivated
 Japanese encephalitis virus vaccine, inactivated, adsorbed
 Rabies vaccine
 Rabies vaccine adsorbed

from humans and then used to infect monkey cells. After several passages, the virus can no longer infect human cells but retains immunogenic capacity. These attenuated viruses can elicit a robust immune response because they are similar to the natural pathogen.

Several drawbacks exist with these vaccines. Because these are live viruses, they generally must be refrigerated to retain their activity. In remote areas of the world where refrigeration is not available, obtaining and storing this type of vaccine can be limiting. Because viruses can mutate and change in the host, it may be possible that viruses can become virulent again and cause disease, although the frequency of adverse reactions using these vaccines is very low. Furthermore, attenuated vaccines cannot be utilized in immune-compromised individuals (e.g., patients with HIV or cancer). In addition, these vaccines are usually not given during pregnancy. Measles, polio, rotavirus, yellow fever, and chickenpox viruses are examples of pathogens for which live attenuated vaccines have been generated. Attenuated vaccines for bacteria are more challenging to generate than for viruses because bacteria have more complex genomes; however, recombinant DNA technology can be utilized to remove virulence but retain immunogenicity. A vaccine against *Vibrio cholera* has been generated this way (currently not approved in the U.S.). A live attenuated vaccine for tuberculosis also has been developed.

Inactivated

Polio, influenza, and rabies viruses and typhoid and plague bacteria have been utilized to generate inactivated vaccines. Killing pathogens through the use of heat, radiation, or chemicals to inactivate them generates the antigenic starting materials. The dead pathogens can no longer replicate or mutate to their disease-causing state and thus are safe. These types of vaccines are useful because they can be freeze-dried and transported without refrigeration, an important consideration in reaching developing countries. A drawback with inactivated vaccines is that they induce an immune response that is much weaker than that induced by the natural infection; thus, patients require multiple doses to sustain immunity to the pathogen. In areas where people have limited access to healthcare, ensuring that these multiple doses are delivered on time can be problematic and may result in reduced immunity to the pathogen, as in the case of poliovirus endemic disease.

Subunit Vaccines

As with inactivated vaccines, subunit vaccines do not contain live pathogens; rather, subunit vaccines use a component of the microorganism as a vaccine antigen to mimic exposure to the organism itself. Subunit vaccines typically contain *polysaccharides* or proteins (*surface proteins* or *toxoids*). Compared to live attenuated vaccines, subunit vaccines induce a less-robust immune response. The selection of antigenic subunit and the design and development of the vaccine can be lengthy and costly because the pathogen's subunit antigens and their combination must be thoroughly tested to ensure they elicit an effective immune response. Scientists can identify the more immunogenic antigens in the laboratory and manufacture these antigen molecules via recombinant DNA technology, producing *recombinant subunit vaccines*. For example, the hepatitis B vaccine is generated by the insertion into baker's yeast of hepatitis B genes coding for selected antigens. The yeast cells express these antigens, which are then purified and used in making a vaccine. A drawback to these vaccines is that even though they elicit an immune response, immunity is not guaranteed. Subunit vaccines usually are considered safe because they have no live replicating pathogen present.

Polysaccharides. Polysaccharide subunit vaccines utilize polysaccharide (sugar) antigens to induce an immune response. Bacterial cell walls are composed of peptidoglycan polysaccharides that help pathogens evade the immune system. This evasion mechanism is highly effective in infants and young children, making them more susceptible to infection. Unfortunately, these polysaccharides are not very immunogenic. Furthermore, the vaccines produced to sugar antigens cause suboptimal immune responses that result in only short-term immunity. Meningococcal

infection caused by *Neisseria meningitidis* (groups A, C, W-135, and Y) and *pneumococcal* disease are polysaccharide subunit vaccines against bacterial pathogens. Conjugate subunit vaccines use a technology to bind polysaccharide from the bacterial capsule to a carrier protein, often diphtheria or tetanus toxoid. This sort of antigen combination can induce long-term protection in infants and adults. These vaccines provide protection against pathogens where plain polysaccharide vaccines fail to work in infants and also provide more long-term protection in young children and adults. The *Haemophilus influenzae* type b (Hib) and *Pneumococcal* (PCV7 valent, PCV10 valent, PCV13 valent) are conjugate subunit vaccines recommended for children (see Table 36–1). The *meningococcal* A vaccine used in Africa is also an example of a conjugate subunit vaccine.

Surface Protein Subunit Vaccines. T protein–based subunit vaccines utilize purified proteins from the pathogen to induce an immune response. Because these proteins may not be presented in native form (i.e., as in the live pathogen), antibodies generated against these antigens may not bind efficiently to the live pathogen. Acellular pertussis (aP) and hepatitis B vaccines are examples of protein-based subunit vaccines. The hepatitis B vaccine contains the hepatitis B virus envelope protein made as an antigen produced in yeast cell culture.

Toxoids. Pathogenic bacteria such as *Clostridium tetani* and *Corynebacterium diphtheria* induce disease (tetanus or diphtheria, respectively) through production of their toxins. Vaccines against these toxins, known as toxoid vaccines, are effective because they elicit an immune response that results in the production of antibodies that can bind and neutralize these toxins, preventing cell damage in the patient. Inactivated or killed toxins are used as the immunogen; however, because they are not highly immunogenic, they must be adsorbed to adjuvants (aluminum or calcium salts) to increase their capacity to stimulate the immune response. Toxoid vaccines are safe because they do not contain live pathogens. In addition, they are stable over a wide range of temperatures and humidities (Baxter, 2007).

DNA Vaccines

Sequencing the genome of a pathogen provides information that enables the production of a DNA vaccine against selected genetic material. A microbe's antigenic genes are selected and incorporated in synthetic DNA. Intramuscular or intradermal injection delivers this engineered DNA to APCs, which uptake the DNA and transcribe and translate it to produce antigenic proteins. These APCs present these antigens to both humoral and cellular immune system components to generate immunity. This type of vaccine poses no risk of infection, can easily be developed and produced, is cost-effective, is stable, and provides long-term protection (Robinson et al., 2000). Disadvantages include its limit to protein antigens and the possibility of generating tolerance to that antigen because of low immunogenicity, thereby rendering ineffective immunity.

Many of these vaccines are currently in experimental phases, but none has been licensed in the U.S. DNA vaccines for influenza virus, herpesvirus, flaviviruses like Zika virus, and others are in the early stages of development. A DNA vaccine against West Nile virus has been approved for veterinary use. Delivery platforms for enhancing efficacy of DNA vaccines (such as electroporation) are being developed. There is also an emerging research field to use RNA as a vaccine delivery platform.

Recombinant Vectors

A vector is a virus or bacterium that is used to deliver heterologous microbial genes to cells for expression in the vaccinee to elicit an immune response. Once the vector infects or transduces host cells, the selected antigens will be presented during the immune response to generate immunity. Both viruses and bacteria are being investigated as recombinant vectors for candidate vaccines. Virus vectors that have been used in candidate vaccines include many poxviruses (vaccinia virus, modified vaccinia Ankara, avian poxviruses, and others), a large number of adenoviruses (of both human and primate origin), and other families of viruses.

Immunoglobulins

Structure

Vaccination results in the expansion and differentiation of B cells into long-lived memory cells that provide long-term protection to secondary challenge, and plasma cells, which are immunoglobulin (antibody)–generating cells that produce large quantities of these proteins. Antibodies in the body are found in two forms, either membrane bound on B cells as BCRs that can deliver signals to activate and induce B-cell differentiation after antigen ligation or as soluble effector molecules that neutralize antigens throughout the body. Antibodies are heterodimeric proteins composed of two chains, the light and heavy chains. Both light and heavy chains contain variable regions in the N-terminal region of the protein that engage antigens. Naïve B cells express BCRs with low affinity to antigen. These BCRs can be selected through VDJ recombination via the activity of RAG enzymes. Antibody diversity is achieved through antigen-binding site region variation, combinatorial diversity of gene segments, and combination of light and heavy regions, an overall diversity program that can result in an antibody repertoire of potentially 10^{16} to 10^{18} different molecules, ensuring that a unique B cell in the body will exist to recognize any foreign antigen. In addition to this diversity, antibodies also can undergo class-switch recombination in which the constant region of the heavy chain can be switched, based on cytokine signals by T cells, to tailor antibody specificity and function. It is this portion of the antibody that determines the five main isotypes: IgM, IgD, IgG, IgA, and IgE. These isotypes differ in size, Fc receptor binding, ability to fix complement, and appropriate isotypes for specific pathogens (Schroeder and Cavacini, 2010).

Antibody diversity can be further enhanced on antigen recognition by B cells and help from CD4⁺ T cells. B cells can further strengthen their antibody affinity by mutating their variable regions, and with repetitive antigen stimulation, the affinity of binding to antigen can increase further. This mechanism explains why some vaccines, like the one for hepatitis B, are most immunogenic when delivered in three doses. This repeated antigen stimulation induces somatic hypermutation of antibody variable genes to increase antibody efficacy. AID is a key enzyme in mediating class-switch recombination and somatic hypermutation. Human patients with defective AID suffer from hyper-IgM syndrome and are unable to class switch their antibodies, which makes them more susceptible to certain infections.

Manufactured antibodies can be used for passive immunization; for a list of available antibodies, see Table 36–4. Such monoclonal antibodies are biologicals that have become some of the most important drugs of our era. To date, monoclonal antibodies have been implemented most effectively for use in cancer immunotherapy and management of autoimmune diseases. Palivizumab is a humanized murine monoclonal antibody that is licensed for use in high-risk infants to prevent hospitalization due to RSV. As the cost of production of monoclonal antibodies continues to fall, more of these biologicals will likely be used for prophylaxis or treatment of infectious diseases.

Antibody Classes and Functions

Immunoglobulin M

The first antibody class expressed by B cells is IgM. IgM molecules are membrane-bound monomers found on circulating mature B cells. When mature B cells are antigen stimulated, they generate IgM pentamers that are secreted. IgM antibodies, also called natural antibodies, have low affinity as monomers, but their avidity can increase in their pentameric structure, which improves epitope binding to repeating antigens on pathogens. These antibodies are found at mucosal surfaces and constitute 10% of the antibody content of serum. These antibodies are associated with a primary immune response. IgM molecules function by coating their specific antigen to target the pathogen for destruction via phagocytosis or to induce complement fixation to kill the pathogen (Schroeder and Cavacini, 2010).

TABLE 36-4 ■ THERAPEUTIC MONOCLONAL ANTIBODIES APPROVED IN THE E.U. AND THE U.S.

ANTIBODY	TARGET; Ab Type	THERAPEUTIC USE
Abciximab	GPIIb/IIIa; <i>chimeric IgG1 Fab</i>	Prevention of blood clots in angioplasty
Adalimumab	TNF; <i>human IgG1</i>	Rheumatoid arthritis
Ado-trastuzumab emtansine	HER2; <i>humanized IgG1; immunoconjugate</i>	Breast cancer
Alemtuzumab	CD52; <i>humanized IgG1</i>	Multiple sclerosis
Alirocumab	PCSK9; <i>human IgG1</i>	Lowering cholesterol
Atezolizumab ^a	PD-L1; <i>humanized IgG1</i>	Bladder cancer
Avelumab	PD-L1/ <i>human IgG1</i>	Merkel cell carcinoma
Basiliximab	IL-2R; <i>chimeric IgG1</i>	Prevention of kidney transplant rejection
Belimumab	BLyS; <i>human IgG1</i>	Systemic lupus erythematosus
Bevacizumab	VEGF; <i>humanized IgG1</i>	Colorectal cancer
Bezlotoxumab	<i>Clostridium difficile</i> toxin B/ <i>human IgG1</i>	<i>Clostridium difficile</i> infections
Blinatumomab	CD19, CD3; <i>murine bispecific tandem scFv</i>	Acute lymphoblastic leukemia
Brentuximab vedotin	CD30; <i>chimeric IgG1; immunoconjugate</i>	Hodgkin lymphoma, systemic anaplastic large cell lymphoma
Brodalumab	IL-17RA/ <i>human IgG2</i>	Plaque psoriasis
Canakinumab	IL-1 β ; <i>human IgG1</i>	Muckle-Wells syndrome
Catumaxomab ^b	EPCAM/CD3; <i>rat/mouse bispecific mAb</i>	Malignant ascites
Certolizumab pegol	TNF; <i>humanized Fab, pegylated</i>	Crohn disease
Cetuximab	EGFR; <i>chimeric IgG1</i>	Colorectal cancer
Daclizumab	IL-2R; <i>humanized IgG1</i>	Multiple sclerosis
Daratumumab	CD38; <i>human IgG1</i>	Multiple myeloma
Denosumab	RANK-L; <i>human IgG2</i>	Bone loss
Dinutuximab	GD2; <i>chimeric IgG1</i>	Neuroblastoma
Dupilumab	IL-4R α / <i>human IgG4</i>	Eczema
Durvalumab	PD-L1/ <i>human IgG1</i>	Urothelial carcinoma
Eculizumab	C5; <i>humanized IgG2/4</i>	Paroxysmal nocturnal hemoglobinuria
Efalizumab	CD11a; <i>humanized IgG1</i>	Psoriasis
Elotuzumab	SLAMF7; <i>humanized IgG1</i>	Multiple myeloma
Evolocumab	PCSK9; <i>human IgG2</i>	Lowering cholesterol
Gemtuzumab ozogamicin ^a	CD33; <i>humanized IgG4</i>	Acute myeloid leukemia
Golimumab	TNF; <i>human IgG1</i>	Rheumatoid and psoriatic arthritis, ankylosing spondylitis
Ibritumomab tiuxetan	CD20; <i>murine IgG1</i>	Non-Hodgkin lymphoma
Idarucizumab	Dabigatran; <i>humanized Fab</i>	Dabigatran excess (reversing anticoagulation)
Infliximab	TNF; <i>chimeric IgG1</i>	Crohn disease
Ipilimumab	CTLA-4; <i>human IgG1</i>	Metastatic melanoma
Ixekizumab	IL-17a; <i>humanized IgG4</i>	Psoriasis
Mepolizumab	IL-5; <i>hIgG1</i>	Severe eosinophilic asthma
Muromonab-CD3	CD3; <i>murine IgG2a</i>	Reversal of kidney transplant rejection
Natalizumab	α 4 integrin; <i>humanized IgG4</i>	Multiple sclerosis
Necitumumab	EGFR; <i>human IgG1</i>	Non-small cell lung cancer
Nivolumab	PD1; <i>human IgG4</i>	Melanoma, non-small cell lung cancer, renal cell carcinoma, non small cell carcinoma
Obiltoxaximab ^a	Protective antigen of <i>B. anthracis</i> exotoxin ^c ; <i>chimeric IgG1</i>	Prevention of inhalational anthrax
Obinutuzumab	CD20; <i>humanized IgG1; glycoengineered</i>	Chronic lymphocytic leukemia
Ocrelizumab	CD20/ <i>human IgG1</i>	Multiple Sclerosis
Ofatumumab	CD20; <i>human IgG1</i>	Chronic lymphocytic leukemia

(Continued)

TABLE 36-4 ■ THERAPEUTIC MONOCLONAL ANTIBODIES APPROVED IN THE E.U. AND THE U.S.(CONTINUED)

ANTIBODY	TARGET; Ab Type	THERAPEUTIC USE
Olaratumab	PDGFR/human IgG1	Soft tissue sarcoma
Omalizumab	IgE; humanized IgG1	Asthma
Palivizumab	RSV; humanized IgG1	Prevention of respiratory syncytial virus infection
Panitumumab	EGFR; human IgG2	Colorectal cancer
Pembrolizumab	PD1; humanized IgG4	Melanoma, non-small cell carcinoma
Pertuzumab	HER2; humanized IgG1	Breast cancer
Ramucirumab	VEGFR2; human IgG1	Gastric cancer
Ranibizumab	VEGF; humanized IgG1 Fab	Macular degeneration
Raxibacumab ^a	<i>B. anthracis</i> protective antigen ^c ; human IgG1	Prevention of inhalational anthrax
Reslizumab	IL-5; humanized IgG4	Asthma
Rituximab	CD20; chimeric IgG1	Non-Hodgkin lymphoma
Sarilumab	IL-6R/human IgG1	Rheumatoid arthritis
Secukinumab	IL-17a; human IgG1	Psoriasis
Siltuximab	IL-6; chimeric IgG1	Castleman disease
Tocilizumab	IL-6R; humanized IgG1	Rheumatoid arthritis
Tositumomab-I ¹³¹ ^a	CD20; murine IgG2a	Non-Hodgkin lymphoma
Trastuzumab	HER2; hIgG1	Breast cancer
Ustekinumab	IL-12/23; human IgG1	Psoriasis
Vedolizumab	$\alpha 4\beta 7$ integrin; humanized IgG1	Ulcerative colitis, Crohn disease

^aNot approved in the E.U.^bNot approved in the U.S.^cInhibits the binding of the protective antigen to its membrane receptors, thereby preventing the intracellular entry of the anthrax lethal factor and edema factor, the enzymatic toxin components responsible for the pathogenic effects of anthrax toxin.

Immunoglobulin D

Like IgM molecules, IgD molecules are also expressed on naïve B cells that have not been activated by their specific antigen and thus have not undergone somatic hypermutation. They are expressed as monomers on the surface of B cells and can also be secreted; they represent less than 0.5% of the antibody in the serum (Schroeder and Cavacini, 2010). The exact function of this antibody is not fully known, but it can bind bacterial proteins through the constant region (Riesbeck and Nordstrom, 2006).

Immunoglobulin G

The IgG antibodies exist as monomers, represent about 70% of the antibody in circulation, and have been the most studied. They have the longest $t_{1/2}$ in serum and are generated with high affinity after affinity maturation. The constant region of the heavy chain can further lead to diversity in the structure of these antibodies to generate four subclasses: IgG1, IgG2, IgG3, and IgG4. These subclasses are named based on their concentrations in serum, with IgG1 the most abundant and IgG4 the least. IgG1, IgG2, and IgG3 subclasses can activate complement to opsonize pathogens, but IgG4 cannot. These antibodies can also differ in their ability and affinity to engage Fc receptors, which further enhances their effector functions. All IgG subclasses cross the placenta to provide passive immunity to the fetus.

Vaccines predominantly induce these antibody types, which become important during the secondary immune response to inactivate pathogens. Different subclasses are selected during the secondary antibody response. In designing vaccines, scientists must determine which antibody subclass will provide the optimal response. In addition to complement and opsonization, IgG antibodies can directly neutralize toxins and viruses (Schroeder and Cavacini, 2010).

Immunoglobulin A

The IgA antibody class is expressed as monomers or dimers and represents about 15% of the antibodies in serum, slightly higher than IgM antibodies.

At mucosal surfaces, saliva, and breast milk, however, IgA antibodies are found at the highest concentrations (Woof and Mestecky, 2005). In late pregnancy and the early post-natal period, female mammary glands produce colostrum; more than half of the protein content of colostrum that breast-feeding neonates consume is IgA antibodies. IgA is primarily a monomer in the serum but a dimer at mucosal sites.

IgA antibodies have two subclasses, IgA1 and IgA2, that differ only slightly in their structures. IgA1 antibodies are longer than IgA2 antibodies and are therefore more sensitive to degradation. IgA2 is more stable and is found primarily in mucosal secretions, in contrast to IgA1, which predominates in serum. IgA antibodies work via direct neutralization of viruses, bacteria, and toxins to protect mucosal tissues. They prevent antigen binding to host cells that damage or infect them. IgA antibodies within cells may also prevent pathogen tropism. Even though IgA antibodies do not lead to complement fixation, neutrophils can uptake them to mediate ADCC (Schroeder and Cavacini, 2010).

Immunoglobulin E

The IgE antibody class is present at the lowest serum concentration, less than 0.01% of circulating antibodies, and has the shortest $t_{1/2}$. IgE binds to Fc γ receptors with very high affinity. Langerhans and mast cells, basophils, and eosinophils express Fc γ receptors that bind IgE antibodies. Fc receptor engagement also results in Fc γ R upregulation on bound cells. These antibodies recognize antigens on parasitic worms when they are cross-linked on granulocytes; the cells degranulate to release inflammatory mediators to destroy the parasite. IgE antibodies are also relevant in mediating allergic reactions by recognizing innocuous antigens, such as bee venom and peanut antigen.

Patients who develop allergic reactions generate memory B cells that produce IgE antibodies to specific antigens. The granulocytes become coated with IgE antibodies and on antigen reexposure such as a bee's sting or peanuts, the antigen cross-links IgEs, leading to granulocyte

degranulation, which can result in anaphylactic shock. Therapies are in development to generate and use antibodies against soluble IgE molecules to prevent their uptake by granulocytes. For a list of approved monoclonal antibodies, see Table 36–4.

Specific Conventional Vaccines Recommended in the U.S.

The CDC maintains tables listing currently recommended vaccinations for various susceptibilities throughout life. Next is a discussion of the properties and schedule of administration for the vaccinations recommended from birth to elder adulthood. The vaccines are grouped by the target type (bacterium, virus, etc.) and then by vaccine type, as discussed in the previous section. See Table 36–1 for infant and childhood vaccination schedules. For a complete list of the adult recommended immunization schedule, see Tables 36–5 and 36–6.

Vaccines for Bacteria

Bacterial Toxoid Vaccines: Diphtheria and Tetanus

Tetanus Toxoid Vaccine. Tetanus is a disease characterized by prolonged spasms and tetany caused by the toxin secreted by the bacterium *C. tetani*, which enters from environmental sources through wounds. Tetanus toxin enters the nervous system and by retrograde transport reaches the inhibitory interneurons of the spinal cord, where the active fragment cleaves synaptobrevin (see Figures 8–3 to 8–6), thereby inhibiting exocytosis of neurotransmitter from these nerve cells and resulting in uninhibited skeletal muscle contraction. The toxoid is produced by deactivating toxin isolated from the bacterium using formaldehyde. Immunization usually begins at about age 2 months, as a component of the combination vaccine DTaP that is given to infants. Tetanus toxoid is included in several combination vaccine formulations. DTaP is the vaccine used in children younger than age 7; Tdap and Td, given at later ages, are booster immunizations that offer continued protection from those diseases for adolescents and adults. In these designations, upper- and lowercase letters represent the comparative quantity of antigen present. Thus, the shared uppercase *T* indicates there is about the same amount of tetanus toxoid in DTaP, Tdap, and Td. The uppercase *D* and *P* in the childhood formulation indicate that there is more diphtheria and pertussis antigen in DTaP than in Tdap or Td.

Diphtheria Toxoid Vaccines. Diphtheria is a disease caused by a secreted toxin of the aerobic gram-positive bacterium *C. diphtheria*; toxin production is under control of the bacterial systems, but the structural gene for toxin production is contributed by a β phage that infects all pathogenic strains of *C. diphtheria*. The A subunit of the toxin is an ADP-ribosylase; following its entry into a cell, it ADP-ribosylates eukaryotic elongation factor 2 (eEF-2) and thereby inhibits protein translation in human cells (Gill et al., 1973). The throat of the victim becomes swollen and sore during infection, and the toxin causes damage to myelin sheaths in the nervous system, leading to loss of sensation or motor control. The vaccine, which has been used for nearly 80 years, is a toxoid that is produced by treating toxin with formalin. The toxoid is used to immunize infants beginning at about 2 months, typically as part of the combination DTaP vaccine. The diphtheria toxin also has been detoxified genetically by introduction of point mutations that abrogate enzymatic activity but allow retention of binding activity; for instance, the mutant diphtheria toxin protein CRM₁₉₇ is the protein carrier for a licensed Hib vaccine.

Pertussis Vaccines. Pertussis, or whooping cough, is a respiratory tract disease characterized by prolonged paroxysmal coughing and sometimes respiratory failure; it is caused by the gram-negative coccobacillus *Bordetella pertussis*. The secreted pertussis toxin has an A subunit that, once in the cell cytosol, ADP-ribosylates the α subunit of the G_i protein that couples inhibitory GPCR signaling to adenylyl cyclase to reduce cyclic AMP production. After ADP-ribosylation, G_i_α becomes inactive, and GPCR-mediated reduction of cyclic AMP production is abolished. The physiological sequelae of this action of pertussis toxin are thought to contribute

to the constellation of symptoms of whooping cough. Routine vaccination typically begins as part of the childhood combination DTaP vaccine series. It is also appropriate to immunize healthy adults, adolescents, and pregnant mothers as pertussis does occur throughout life due to waning immunity. There are two licensed pertussis vaccines, the historical inactivated organism “whole-cell” vaccine used in the past in the U.S. and still in many other countries and a second “acellular” formulation that incorporates antigen fragments derived from the organism. Both vaccines are immunogenic and protective. The whole-cell vaccine appears to induce more durable immunity, but the acellular vaccine causes about a 10-fold lower rate of side effects such as fever or injection site pain and erythema. Most developed countries now use acellular pertussis vaccine to reduce the reactivity profile, but many other countries continue to use the whole-cell vaccine successfully because the response is equally efficacious and more durable and the vaccine is economical.

Conjugated Bacterial Polysaccharide Vaccines

Haemophilus influenzae Type B Vaccine. *Haemophilus influenzae* is a major cause of life-threatening childhood bacterial diseases, including buccal, preseptal and orbital cellulitis, epiglottitis, bacteremia with sepsis, and meningitis. Universal vaccination with the Hib vaccine has nearly eliminated these diseases in the U.S. The Hib vaccine is a polysaccharide-protein conjugate that confers immunity to the disease by inducing antibodies to the capsular polysaccharide PRP. The Hib polysaccharide has been conjugated to diverse proteins, including the mutant diphtheria protein CRM₁₉₇ (a vaccine termed HbOC); the meningococcal group B outer membrane protein C (a vaccine termed PRP-OMP); and tetanospasmin, which is a toxoid of the *C. tetani* neurotoxin (a vaccine termed PRP-T). The vaccines all exhibit a high level of safety and immunogenicity. Interestingly, widespread immunization not only reduces disease in those vaccinated, but also reduces nasal carriage of the bacterium, resulting in reduced transmission to even those not vaccinated and providing evidence of herd immunity.

Streptococcus pneumoniae Vaccines. The gram-positive encapsulated bacterium *S. pneumoniae* causes invasive diseases in infants and young children, including meningitis, bacteremia and sepsis, and pneumonia. There are myriad *S. pneumoniae* types, based on the capsular polysaccharide; thus, polyvalent vaccines are needed. Vaccines confer immunity by inducing type-specific antipolysaccharide antibodies. Two types of vaccines are available, *polysaccharide* and *conjugate* vaccines. The 23-valent polysaccharide vaccine contains long chains of capsular polysaccharides that are collected from inactivated bacteria. Polysaccharide vaccine is used in children older than 2 years and in at-risk adults. PCVs have been developed, and increasing numbers of serotypes have been incorporated over time. The combined 13 serotypes in PCV13 protect against most invasive disease in the U.S. Infants are given a primary series of PCV13 at ages 2, 4, and 6 months, with a booster at 12 to 15 months.

Neisseria meningitidis Vaccines. *Neisseria meningitidis* is a significant cause of invasive bacterial disease in childhood, causing sepsis and meningitis. As with *S. pneumoniae*, there are diverse types of polysaccharide; thus, type-specific anticapsular polysaccharide antibodies mediate protection against invasive disease. Therefore, multivalent vaccines are required. A licensed quadrivalent polysaccharide vaccine protects against four subtypes of meningococcus—designated A, C, Y, and W-135. The polysaccharide vaccine works only in children older than 2 years. A tetavalent meningococcal conjugate vaccine, also containing the A, C, Y, and W-135 subtypes, is used in persons 9 months to 55 years of age. In 2013, the European Commission licensed a four-component, protein-based meningococcal B vaccine (incorporating fHbp, NadA, NHBA, and PorA P1.4 proteins) to prevent septicemia and meningitis.

Vaccines for Viruses

Poliovirus Vaccines

Polio is characterized by acute flaccid paralysis, against which the WHO and others are conducting a worldwide eradication campaign. There are two types of poliovirus vaccines in use. The first is a *live attenuated oral*

TABLE 36-5 ■ RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER BY AGE GROUP, U.S., 2017.

Vaccine	19–21 years	22–26 years	27–59 years	60–64 years	≥ 65 years
Influenza*	1 dose annually				
Td/Tdap*	Substitute Tdap for Td once, then Td booster every 10 yrs				
MMR*	1 or 2 doses depending on indication				
VAR*	2 doses				
HZV*				1 dose	
HPV-Female*	3 doses				
HPV-Male*	3 doses				
PCV13*					1 dose
PPSV23*	1 or 2 doses depending on indication				1 dose
HepA*	2 or 3 doses depending on vaccine				
HepB*	3 doses				
MenACWY or MPSV*	1 or more doses depending on indication				
MenB*	2 or 3 doses depending on vaccine				
Hib*	1 or 3 doses depending on indication				

Recommended for adults who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended for adults with additional medical conditions or other indications

No recommendation

***NOTE:** The above recommendations are reprinted from the website of the Centers for Disease Control and Prevention (CDC) and should be read along with the footnotes of this schedule available on the CDC website: <https://www.cdc.gov/vaccines/schedules/>.

TABLE 36-6 ■ RECOMMENDED IMMUNIZATION SCHEDULE FOR ADULTS AGED 19 YEARS OR OLDER BY MEDICAL CONDITION AND OTHER INDICATIONS, UNITED STATES, 2017.

Vaccine	Pregnancy	Immuno-compromised (excluding HIV infection)	HIV infection CD4+ count (cells/μL)		Asplenia, persistent complement deficiencies	Kidney failure, end-stage renal disease, on hemodialysis	Heart or lung disease, chronic alcoholism	Chronic liver disease	Diabetes	Healthcare personnel	Men who have sex with men
			< 200	≥ 200							
Influenza	1 dose annually										
Td/Tdap	1 dose Tdap each pregnancy	Substitute Tdap for Td once, then Td booster every 10 yrs									
MMR	contraindicated			1 or 2 doses depending on indication							
VAR	contraindicated			2 doses							
HZV	contraindicated				1 dose						
HPV–Female		3 doses through age 26 yrs									
HPV–Male		3 doses through age 26 yrs			3 doses through age 21 yrs						3 doses through age 26 yrs
PCV13		1 dose									
PPSV23		1, 2, or 3 doses depending on indication									
HepA	2 or 3 doses depending on vaccine										
HepB						3 doses					
MenACWY or MPSV4			1 or more doses depending on indication								
MenB					2 or 3 doses depending on vaccine						
Hib		3 doses post-HSCT recipients only		1 dose							

Recommended for adults who meet the age requirement, lack documentation of vaccination, or lack evidence of past infection
 Recommended for adults with additional medical conditions or other indications
 Contraindicated
 No recommendation

*NOTE: The above recommendations are reprinted from the website of the Centers for Disease Control and Prevention (CDC) and should be read along with the footnotes of this schedule available on the CDC website: <https://www.cdc.gov/vaccines/schedules/>.

vaccine in use since the early 1960s (the “Sabin vaccine”), containing attenuated poliovirus types I, II, and III, produced in monkey kidney cell tissue culture. The vaccine replicates in the intestine and induces systemic and mucosal immunity, but also is shed in the stool, sometimes transmitting to close contacts. Infection of most close contacts contributes to herd immunity in the human population. Rarely (about one case per million doses), partial revertant viruses occur that cause vaccine-associated paralytic poliomyelitis in contacts. In many parts of the world, live poliovirus vaccine is still used. The last known case of naturally acquired poliovirus disease acquired in the U.S. occurred in 1979; the U.S. discontinued use of the live vaccine in 2000. Live poliovirus vaccine is contraindicated in subjects with primary immunodeficiency. Pregnant women and children with symptomatic HIV infection should receive IPV vaccine.

The second type of vaccine is a *killed virus* preparation called *IPV* (the “Salk vaccine”). Killed vaccine induces mainly humoral immunity but still exhibits excellent efficacy against disease. IPV does not transmit virus to contacts and does not cause vaccine-associated paralysis. An enhanced-potency IPV vaccine has been available since 1998, and this IPV preparation is now a component of some combination vaccines.

Measles Virus Vaccines

The current measles vaccine is a live attenuated strain given subcutaneously. A live, “more attenuated” preparation of the Enders-Edmonston virus strain (designated the “Moraten” strain) is the MeV vaccine currently used in the U.S. Vaccination is initiated at 12 to 15 months of age in the U.S. because transplacentally acquired maternal antibodies inhibit immunogenicity of vaccine in the first year of life.

Mumps Virus Vaccine

Mumps virus causes a febrile illness most commonly associated with inflammation of the parotids and sometimes with more severe conditions, including aseptic meningitis. A live attenuated virus vaccine has been used exclusively since the 1970s. The Jeryl-Lynn vaccine (from a mixture of two strains) was isolated from the throat of the daughter of Maurice Hilleman, a noted vaccine developer. The vaccine is typically given as a component of the combination MMR or MMRV vaccine at 12 to 15 months of age.

Rubella Virus Vaccine
