Rubella virus, a member of the *Togaviridae* family, is spread by respiratory droplets and causes a mild infection with viremia. Rubella is harmful only to fetuses, and the effects can be devastating. A rubella infection during pregnancy can cause miscarriage, preterm birth, stillbirth, or various birth defects. The risks decrease as pregnancy progresses. The main goal of rubella immunization is to prevent congenital rubella syndrome. The live attenuated rubella virus vaccine is given subcutaneously, now usually as a component of MMR or MMRV vaccine, beginning between 12 and 15 months of age. The live rubella virus vaccine strain RA 27/3 is grown in human diploid cell culture. In the U.S., universal immunization (both boys and girls) is used to reduce infection of pregnant women. As a result, rubella and congenital rubella syndrome have been eliminated in the U.S. Rubella vaccine is part of MMR or MMRV combination vaccines for universal immunization starting at 12 to 15 months, followed by a booster dose at school entry (~5 to 6 years).

Varicella Zoster Virus Vaccine

Varicella zoster virus is one of the most infectious among agents that affect humans. It is spread by the respiratory route by small aerosol particles (cough, sneeze, etc.). Infection causes a febrile syndrome with vesicular rash, sometimes complicated by pneumonia or invasive bacterial skin disease. Congenital varicella syndrome can occur if varicella infection occurs during pregnancy. The vaccine used is the Oka strain of live attenuated VZV attenuated by sequential passage in cell monolayer cultures; it was licensed for universal immunization in the U.S. in 1995. The virus in the Oka/Merck vaccine in current use in the U.S. was further passaged in MRC-5 human diploid-cell cultures. The vaccine is often given as a part of the combination MMRV vaccine.

Hepatitis A Virus Vaccines

Hepatitis A virus infection causes acute liver disease after transmission by the fecal-oral route. An inactivated vaccine is recommended for all children, starting at 1 year of age. Two hepatitis A vaccines and one hepatitis A vaccine/hepatitis B combo vaccine are licensed in the U.S. The vaccine is given as a two-dose series.

Hepatitis B Virus Vaccines

Hepatitis B virus is transmitted between people by contact with blood or other bodily fluids, including by sexual contact and maternal transfer to fetus or infant. Hepatitis B virus can cause a life-threatening and sometimes chronic liver disease. All infants receive the hepatitis B vaccine. When the mother has active infection, the neonate is treated with both the vaccine and hepatitis B immune globulin. The vaccine is a recombinant protein produced in yeast that is the protective antigen, hepatitis B surface antigen (see also Chapter 63).

Rotavirus Vaccines

Throughout the world, rotavirus is the most common cause of dehydrating diarrhea in infants. Four or five types (based on the surface proteins) cause severe disease. An early live attenuated vaccine (Rotashield) was withdrawn after association with intussusception (a segmental, telescoping collapse of the intestine). Two similar vaccines are now used that are safe and immunogenic. One is an oral pentavalent human-bovine reassortant rotavirus vaccine (containing five reassortant rotaviruses developed from human and the Wistar Calf 3 bovine parent rotaviral strains) first licensed in the U.S. in 2006 (RotaTeq). This vaccine is administered in a three-dose schedule, at 2, 4, and 6 months of age. Another oral live attenuated rotavirus vaccine licensed in the U.S. is based on a single attenuated human strain (Rotarix) using a two-dose schedule, beginning at 2 months of age. Rotavirus vaccines are used for universal immunization during infancy, with care to keep the initiation of the two- or three-dose series at a young age, as the rare rotavirus-associated intussusception risk with infection appears slightly higher at older ages.

Influenza Virus Vaccines

The orthomyxovirus influenza virus is a respiratory virus spread person-to-person by large-particle aerosols and fomites. The virus circulates in humans in two major serotypes (types A and B); two distinct A subtypes, designated H1N1 and H3N2, currently cause disease (“the flu”) in humans. Current seasonal influenza vaccines are trivalent, including A/H1N1, A/H3N2, and B antigens, or quadrivalent with a second type B antigen. Experimental vaccines are being tested for some avian influenza viruses (such as A/H5N1 and A/H7N9) that have infected humans and have pandemic potential. During each annual seasonal epidemic, point mutations occur in genes encoding the hemagglutinin and neuraminidase proteins, which are the principal targets for protective antibodies. This antigenic drift in circulating influenza strains has led to a process in which regulatory officials and manufacturers adjust the virus antigens in influenza vaccines every year. Occasionally, the segmented virus genome reassorts during coinfection of an animal with a human and an avian virus, a new virus arises (antigenic shift), and a pandemic occurs. Major worldwide pandemics occurred in 1918 (H1N1), 1957 (H2N2), 1968 (H3N2), and 2009 (a novel H1N1). Major adjustments of vaccines must be made in such instances.

Two principal types of influenza vaccines are licensed at present, inactivated vaccine and live attenuated virus vaccine. The inactivated vaccine is prepared by treating wild-type viruses prepared in eggs or cell culture with an inactivating agent. Inactivated vaccine often prevents more than half of serious influenza-related disease when the viruses chosen for the seasonal vaccine antigenically match the eventual epidemic virus well. The vaccine is most effective at preventing severe respiratory disease and influenza-related hospitalizations.

All persons aged 6 months and above should be vaccinated. Those at most risk of severe disease and in most need of vaccine are infants, young children, people older than 65 years, pregnant women, and those with chronic health conditions or immunodeficiency. This vaccine is contraindicated in those who have had a life-threatening allergic reaction after a

dose of influenza vaccine or have a severe allergy to any component of the vaccine, some of which contain a small amount of egg protein. Some people with a history of Guillain-Barré syndrome should not receive this vaccine. The vaccine is usually given as a single dose each year, although children 6 months through 8 years of age may need two doses during a single influenza season. Some IIVs contain a small amount of the preservative thimerosal (see Preservatives, Including Thimerosal). Although any association with developmental disorders has been disproven, public concern about this topic has led to the development of thimerosal-free IIVs.

The second principal type of influenza vaccine is a trivalent or quadrivalent live attenuated virus vaccine that is administered topically by nasal spray. New vaccines are prepared each year to address antigenic drift by reasserting genes encoding the current HA and NA antigens with a virus genetic background containing internal viral genes with well-defined attenuating mutations. The vaccine is licensed in the U.S. for persons 2 to 49 years of age. In some pediatric studies, the live attenuated vaccine appeared to provide a higher level of protection than inactivated vaccine; however, CDC vaccine effectiveness data from the influenza seasons in 2013–2016 in the U.S. indicated that the quadrivalent live attenuated vaccine did not demonstrate statistically significant effectiveness in children 2–17 years of age. Therefore, the CDC provided an interim recommendation that the vaccine should not be used in any setting in the U.S. for the 2016–2017 influenza season. Practitioners should check regularly for updated guidelines from the CDC on this point.

Human Papillomavirus Vaccines

Human papillomaviruses cause nearly all cases of cervical and anal cancer and a majority of oropharyngeal cancers. Most such cancers are caused by just two of the many HPV serotypes, types 16 and 18. Remarkably, even though the virus cannot be grown efficiently in culture, effective HPV vaccines were developed using VLPs that are formed by HPV surface components. All licensed HPV vaccines protect against at least these two types and some protect against four or nine types of HPV, with effectiveness against vaginal and vulvar cancers in women, as well as most cases of anal cancer and genital warts in both females and males. HPV vaccines

are recommended for all 11- and 12-year-olds to protect against HPV infection and for women 13 to 26 years old and men 13 to 21 years old not previously vaccinated. HPV vaccination is also recommended for any man who has sex with a man. The vaccines are given in a three-dose regimen on a schedule of 0, 1-2, and 6 months.

Maternal Immunization

Maternal immunization during pregnancy can enhance newborn protection after birth by providing passive immunity to the neonate. Immunizing pregnant mothers is safe and protects the child from deadly infectious pathogens early in life when the immune system is not fully developed. One of the most successful maternal immunization protocols involves injection of tetanus toxoid to stimulate the production of IgG antibodies that have high neutralizing capacity and can cross the placenta. Vaccines for group B *Streptococcus*, Hib, RSV, *Streptococcus pneumoniae*, *Bordetella pertussis*, and trivalent IIVs have been tested in pregnant women. For a complete list of maternal vaccines, see Table 36–7.

Vaccines for Travel

International travelers should ensure that their vaccination status is current for conventional vaccines, including diphtheria, tetanus, pertussis, hepatitis A and B, and poliovirus; exposures to these agents may be more common in some international settings. There are additional vaccines that may be of benefit as preventive vaccines; these are listed next.

Japanese Encephalitis Virus Vaccine

Japanese encephalitis is a serious mosquito-borne flavivirus infection (not spread person to person) that can cause mild infections with fever and headache, serious neurological sequelae, and even death. Travelers who spend a month or longer in some rural parts of Korea, Japan, China, and eastern areas of Russia should consider vaccination. Two JE vaccines

TABLE 36–7 ■ VACCINES THAT MAY BE USED IN MOTHERS BEFORE, DURING, OR AFTER PREGNANCY^a

VACCINE	BEFORE PREGNANCY	DURING PREGNANCY	AFTER PREGNANCY	TYPE OF VACCINE
Influenza	Yes	Yes, during season	Yes	Inactivated
Tdap	May be recommended; better to vaccinate during pregnancy when possible	Yes, during each pregnancy	Yes, immediately postpartum, if Tdap never received in lifetime; it is better to vaccinate during pregnancy	Toxoid/inactivated
Td	May be recommended	May be recommended, but Tdap is preferred	May be recommended	Toxoid
Hepatitis A	May be recommended	May be recommended	May be recommended	Inactivated
Hepatitis B	May be recommended	May be recommended	May be recommended	Inactivated
Meningococcal	May be recommended	Base decision on risk vs. benefit; inadequate data for specific recommendation	May be recommended	Inactivated
Pneumococcal	May be recommended	Base decision on risk vs. benefit; inadequate data for specific recommendation	May be recommended	Inactivated
HPV	May be recommended (through 26 years of age)	No	May be recommended (through 26 years of age)	Inactivated
MMR	May be recommended; once received, avoid conception for 4 weeks	No	May be recommended	Live
Varicella	May be recommended; once received, avoid conception for 4 weeks	No	May be recommended	Live

^aAdapted from CDC guidance: <http://www.cdc.gov/vaccines/pregnancy/downloads/immunizations-preg-chart.pdf>.

are licensed in the U.S.: an inactivated mouse brain–derived JE vaccine (JE-MB) for use in travelers aged 1 year or older and an inactivated Vero cell culture–derived JE vaccine (JE-VC) for persons aged 17 years or older.

Yellow Fever Virus Vaccine

Yellow fever is a mosquito-borne flaviviral disease with a wide range of systemic symptoms. In severe cases, the disease causes hepatitis, hemorrhagic fever, and death. The CDC recommends this vaccine for children older than 9 months and adults who will be traveling to high-risk areas. There is generally a requirement for documentation of vaccination for travel to and from infected areas. The vaccine is a live attenuated virus vaccine that has been used successfully for many decades. For international travel, yellow fever virus vaccine must be approved by WHO and must be administered by an approved yellow fever vaccination center that can provide both vaccination and a validated International Certificate of Vaccination. The vaccine should be given at least 10 days before travel to an endemic area. Generally, a single dose suffices.

Typhoid Vaccine

Typhoid fever is an acute illness caused by the bacterium *S. typhi*, which is transmitted by ingestion of contaminated water or food. Typhoid vaccination is recommended for international travelers who will visit rural areas or villages that have inadequate sanitation. Symptoms include fever, headache, anorexia, and abdominal discomfort; the disease can be fatal. Treatment is challenging, and there has been an increase in the number of drug-resistant strains of *S. typhi* over the last several decades. There are two vaccines available to prevent infection: a single-dose, injectable, inactivated typhoid vaccine and an oral live typhoid vaccine that is taken in a four-dose course.

Rabies Virus Vaccine

Rabies is caused by a lyssavirus transmitted to humans from the bite of infected mammals; the untreated infection is nearly always fatal in humans. Rabies vaccination is used in two ways, first as a preventive vaccine prior to exposure and second as a postexposure intervention to prevent progression to fatal disease. Candidates for preexposure vaccination are people at high risk of exposure to natural rabies (veterinarians, animal handlers, spelunkers, et al.) or to laboratory strains or tissues (such as those involved in production of rabies biologicals). Preventive vaccination should be offered to international travelers who are likely to come in contact with animals in parts of the world where rabies is common (see CDC website). The vaccine is given in a three-dose series on days 0, 7, and 28. For those who may be repeatedly exposed to rabies virus, periodic testing for immunity is recommended, and booster doses can be administered as needed to maintain immunity. Postexposure vaccination is used in emergency settings following a bite or close exposure to an animal that may be rabid. In this setting, the vaccine is given in a four-dose series on days 0, 3, 7, and 14, concomitant with two injections of rabies immune globulin on day 0, one locally into the bite site and a second in an intramuscular injection for systemic administration of antibodies. A bite victim who has been previously vaccinated should receive two doses of rabies vaccine on days 0 and 3 but does not need rabies immune globulin.

Specialty Vaccines

There are limited-use vaccines that are offered in special circumstances to at-risk persons.

Anthrax Vaccine

Anthrax vaccine is offered to certain at-risk adults 18 to 65 years of age, including some members of the U.S. military, laboratory workers who work with anthrax, and some veterinarians or other individuals who handle animals or animal products. Anthrax is a serious disease in animals and human caused by *Bacillus anthracis*. People can contract anthrax from contact with

infected animals or animal products. Usually, the cutaneous infection causes ulcers on the skin and systemic symptoms, including fever and malaise; up to 20% of untreated cases are fatal. Inhaled spores of *B. anthracis* usually cause fatal infection. AVA, given as multiple booster injections, protects against cutaneous and inhalation anthrax acquired by exposure on skin or by inhalation. The CDC recommends anthrax intramuscular booster shots 4 weeks, 6 months, 12 months, 18 months, and then annually.

Vaccinia Virus (Smallpox Vaccine)

Vaccinia vaccine is a live attenuated orthopoxvirus vaccine developed by multiple passages in cell culture to isolate viral variants that cause only limited infection in humans. The virus is produced as purified calf lymph and given percutaneously with a bifurcated needle. This vaccine was used in the first successful worldwide efforts to eradicate a human virus, variola or smallpox. Routine universal vaccinia immunization was discontinued around 1980, following the declaration by WHO that variola (smallpox) was eradicated, but the vaccine is still available. The nonemergency use of vaccinia vaccine includes vaccination of laboratory and healthcare workers exposed occupationally to vaccinia virus, to recombinant vaccinia viruses, or other orthopoxviruses that can infect humans, such as monkeypox virus and cowpox virus. Because there are still laboratory stocks of variola in research use in several countries, including the U.S., the U.S. ACIP has developed recommendations for the use of vaccinia vaccine if variola virus were used as an agent of biological terrorism or if a smallpox outbreak occurred accidentally. Large-scale use in the military and consideration of use in medical first responders in the U.S. has been implemented in recent decades. A derivative of conventional vaccinia virus vaccine has been developed that has desirable properties. MVA virus is a highly attenuated strain of vaccinia virus isolated after more than 500 passages in chicken embryo fibroblasts, during which the virus lost about 10% of the vaccinia genome and the ability to replicate productively in human and other primate cells.

Other Vaccines for Biodefense and Special Pathogens

There are a number of limited-use vaccines, such as those for workers in high-containment facilities conducting research on highly pathogenic agents that are emerging infectious diseases or potential agents for use in bioterrorism or biowarfare. Typically, these vaccines are used only under Investigational New Drug status. Examples include vaccines for Eastern equine encephalitis (EEE) virus, Venezuelan equine encephalitis (VEE) virus, Rift Valley fever virus, botulinum toxin, and others.

International Vaccines

There are additional vaccines pertinent to exposures in other countries that are licensed in some areas, but not yet in the U.S.

Dengue Virus Vaccine

Dengue fever is another mosquito-borne flaviviral disease caused by four different viral serotypes and annually affecting about 400 million people worldwide. The disease can be a mild systemic febrile illness during primary infection but can cause severe dengue disease and death during a second infection with virus of a different serotype. It is thought that cross-reactive nonneutralizing antibodies induced by one infection enhance the disease caused by subsequent infection with a heterologous serotype virus. This antibody-dependent enhancement concern has been a significant barrier to vaccine development efforts. Nevertheless, much progress has been made recently in dengue vaccine development.

There is currently no dengue vaccine approved for use in the U.S.; however, CYD-TDV developed by Sanofi Pasteur is a recombinant tetravalent (four-serotype) live attenuated virus vaccine that was first licensed in Mexico in December 2015 for use in individuals 9–45 years of age living in endemic areas. It is given as a three-dose series on a 0-, 6-, 12-month schedule. Additional dengue vaccine candidates are in clinical development.

Malaria Vaccine

The RTS,S vaccine is a recombinant protein-based malaria vaccine with AS01 adjuvant against *Plasmodium falciparum* that was developed by a large international public-private consortium and is the first malaria vaccine to complete efficacy trial testing with a positive review of the outcome. It is relevant for *P. falciparum*, which is common in sub-Saharan Africa, but does not protect against *Plasmodium vivax* malaria, which is more common in many countries outside Africa. The EMA issued a “European scientific opinion” on the vaccine, and WHO and its SAGE have advocated its use in large-scale implementation pilot tests in Africa.

BCG Vaccine

BCG vaccine is used to prevent severe disease due to *Mycobacterium tuberculosis* (TB). BCG vaccine is produced using a live attenuated bovine bacillus strain, *Mycobacterium bovis*, that has lost its ability to cause severe disease in humans. The vaccine typically is given as a single intradermal dose, often to infants near the time of birth. The efficacy of BCG vaccine against TB is uncertain in many settings, but the consensus is that the vaccine does protect against the most severe forms of disseminated TB, such as miliary disease and TB meningitis. The vaccine is a WHO essential medicine for endemic areas but is not used for universal vaccination in the U.S.

The Future of Vaccine Technology

Vaccination technology and improved methods to generate vaccines have led to the prevention of many infectious diseases. People no longer die at the high rates that prevailed before vaccines were developed. In the developing world, however, according to WHO reports, over 40% of deaths are due to infectious diseases, highlighting a continued need to improve existing vaccines, develop new vaccines, and improve delivery methods to increase efficacy. Viruses, bacteria, parasites, and antigens on cancerous cells are all future vaccine targets. New vaccines for pregnant mothers will be available to prevent diseases that can become chronic if the fetus becomes infected in utero, as is the case with malaria. Furthermore, an increasing elderly population will need access to better vaccines that can stimulate their aging immune systems, which are susceptible to infections like influenza and varicella viruses. Delivery methods are being explored to utilize nanoparticles and alternative adjuvants to improve vaccine immunogenicity so people will only need one vaccine dose rather than several. Needle-less delivery is already possible, as in the case of oral polio vaccine or via nasal sprays for influenza. Investigation continues on developing new edible vaccines using plants, microneedles, and needle-free dermal patches.

Most vaccines work through preventing disease due to acute infections; the challenge remains to develop vaccines against chronic viral infections where the host is immunosuppressed. These pathogens evade the immune system and persist in the host's own cells. To overcome these chronic pathogens, vaccines need to elicit both antibody and T cell responses, where B cells can neutralize the pathogen and T cells can actively kill and destroy infected cells. Vaccines against HPV and hepatitis B viruses protect not only from viral infection but also from developing infection-associated cancers.

New vaccines for other viral pathogens that can cause further complications are needed. For example, infection with group A streptococcus can lead to rheumatic fever, *Helicobacter pylori* may result in stomach cancer, and chlamydia infection can cause blindness and infertility. Vaccines provide effective prophylaxis; however, the frontier in vaccine technology will involve vaccines as therapies for already-established disease. Vaccines can be utilized against pathogens that become chronic, as in shingles, and also in conditions of autoimmunity and cancer, where the immune response is dysregulated. In the case of cancer, vaccines can be utilized to augment immunity to tumors to prevent their growth and metastasis. In the case of autoimmunity, the goal of this “negative vaccination” is to use vaccines to dampen immune function to prevent self-tissue destruction (Nossal, 2011).

Vaccine Safety: Myths, Truths, and Consequences

Vaccine Adjuvants and Safety

Adjuvants are substances added to vaccines to enhance the magnitude, quality, and duration of the protective immune response. Adjuvants are useful in vaccines because they stimulate the innate immune system that subsequently activates a strong adaptive immune response to ensure immune protection. Because many modern vaccines do not contain live pathogens, they must include adjuvants to ensure vaccine efficacy. Adjuvants are particularly useful in subunit protein vaccines, which often are inadequately immunogenic without enhancement.

There is extensive experience in human vaccines with two adjuvants, aluminum and monophosphoryl lipid A. Aluminum, in the form of alum, has been used for nearly 90 years in vaccines; aluminum hydroxide [$\text{Al}(\text{OH})_3$] and aluminum phosphate (AlPO_4) are currently used. Aluminum is used in many childhood vaccines in the U.S. targeted to diphtheria-tetanus-pertussis, Hib and pneumococcus, hepatitis A and B, and HPV. Monophosphoryl lipid A (isolated from bacteria) has been used in the HPV vaccine Cervarix since 2009. A new influenza vaccine licensed for the 2016–2017 season included the adjuvant MF59, an oil-in-water emulsion of squalene oil. Another new influenza vaccine that is targeted to influenza H5N1 contains a new adjuvant termed AS03 (an “adjuvant system” containing α -tocopherol and squalene in an oil-in-water emulsion) and was licensed for inclusion in the U.S. pandemic influenza vaccine stockpile. Live attenuated virus vaccines do not contain adjuvants; thus, adjuvant-free vaccines include those directed against measles, mumps, rubella, chickenpox, rotavirus, polio, and live attenuated seasonal influenza virus.

Vaccines Do Not Cause Autism

Autism spectrum disorder rates have increased in the U.S. and other parts of the world in parallel with expansion in the diagnostic criteria of autism that now include spectrum disorders with a broader array of symptoms (Hansen et al., 2015). The CDC found that 1 of 68 children in the U.S. has ASD. Patients with this disorder have development impairments that affect their communication, behavior, and social interactions. Even though some people have been concerned with a causal link between vaccines and autism, many large scientific studies have failed to detect any such link (Hviid et al., 2003; Madsen et al., 2002; Schechter and Grether, 2008; Taylor et al., 2014). The IOM (now termed the National Academy of Medicine) conducted thorough reviews and concluded that current childhood and adult vaccines are very safe. In 2014, a CDC study added to reports around the world that vaccines do not cause ASD. They concluded that the total amount of antigen received from vaccines did not differ between children with ASD and those without the disorder. Vaccination with the MMR vaccine also is not associated with development of ASD in children.

Preservatives, Including Thimerosal

Preservatives added to vaccine preparations are designed to kill or inhibit the growth of bacteria and fungi that could contaminate a vaccine vial. There are historical reports of severe adverse events or death due to bacterial contamination of multidose vials lacking preservative. The highest risk of contamination is probably due to repetitive puncture of a multidose vaccine vial that is stored over time. Therefore, The U.S. *Code of Federal Regulations* requires the addition of a preservative to multidose vials of vaccines. Preservatives eliminate or reduce contamination in this setting. Several preservatives have been incorporated into licensed vaccines, including 2-phenoxyethanol, benzethonium chloride, phenol, and thimerosal.

Thimerosal, known to many by the trade name Merthiolate, has been one of the most commonly used preservatives; it is an organomercurial, an organic compound containing mercury. Thimerosal has been used safely since the early 20th century as a preservative in biologics, including many vaccines, and has a long history of use. Over time, concerns were raised about its safety because some organomercurials were increasingly associated with neurotoxicity, and children began receiving increasing numbers of licensed vaccines. The FDA chose to work with manufacturers toward reduction or elimination of thimerosal from childhood vaccines because of these *theoretical concerns*. As a result, thimerosal has been eliminated or reduced to trace amounts in nearly all childhood vaccines except some IIVs.

In terms of toxicity from mercury, most of the data in the field pertains to methylmercury, whereas thimerosal is a derivative of ethylmercury, which is cleared more rapidly. Thimerosal does not have significant toxic effects at the concentrations used in vaccine formulations. However, questions were raised about the potential association of thimerosal-containing vaccines in children and the occurrence of neurodevelopmental disorders, especially autism. A rather sordid history of fraud, conflict of interest, and other irregularities has been revealed pertaining to the now-debunked association studies of thimerosal and autism; decades of studies have been conducted in safety reviews around this matter.

The National Vaccine Advisory Committee, ACIP of the CDC, and the IOM's Immunization Safety Review Committee have all conducted extensive reviews of association studies, and the conclusion is that autism is not associated with the amount of thimerosal in childhood vaccines. In any event, recognizing public concern, between 2001 and 2003, thimerosal was eliminated from or reduced in childhood vaccines (except for flu) for children under 6 years old in hopes of encouraging childhood vaccination. The CDC has compiled a thorough review and list of articles relating to this issue (CDC, 2015).

Adverse Events With Vaccines

For injectable vaccines, common adverse effects include minor *local reactions* to vaccines at the injection site (pain, swelling, and redness). More widespread effects, termed *systemic reactions*, may include fever, rash, irritability, drowsiness, and other symptoms, depending on the vaccine. The profile of reactions seen in large-scale trials is carefully documented in package inserts. During vaccine candidate testing, any occurrence of serious adverse events (SAEs) are examined carefully. SAEs are events following vaccination that involve hospitalization, life-threatening events, death, disability, permanent damage, congenital anomaly/birth defect, or other conditions requiring medical intervention. Vaccines with clear association with SAEs are typically not licensed. In some cases, to increase the likelihood of detecting of rare SAEs, the FDA requires phase 4 studies (postmarketing surveillance) to follow the performance of vaccines as use expands beyond the size of the trials leading to licensure. The government also collects data after licensure through the vaccine adverse event reporting system (VAERS). Vaccines can be withdrawn from market if concerns arise. For example, licensure for use of the live oral rotavirus vaccine Rotashield, which was recommended for routine immunization of the U.S. infants in 1998, was withdrawn in 1999 when reports in VAERS suggested an association between the vaccine and intussusception, a form of bowel obstruction.

Allergic Reactions

Allergy to components of vaccine formulations also can cause reactions. Trace amounts of antibiotics like neomycin, used to ensure sterility in some vaccines (e.g., MMR, trivalent IPV, and varicella vaccine), may cause adverse reactions. A history of anaphylactic reaction (but not local reaction) to neomycin is a contraindication to future immunization with those vaccines. Persons with a history of egg allergy should not be given an influenza vaccine prepared in eggs. Gelatin, which is used as a stabilizer in some virus vaccines like varicella and MMR vaccines, may cause allergic reaction in some.

Fainting

Fainting, or syncope, also has been reported in people after vaccination. Fainting is more common in adolescents than in children or adults and thus is more common after vaccination with HPV, MCV4, and Tdap. Immediate fainting episodes following vaccination procedures is triggered by pain or anxiety, rather than the contents of the vaccines. While fainting is not serious, falling while fainting can cause injury, with head injuries the most serious. Clinicians can give patients drinks and snacks to prevent some fainting and can prevent falls by having patients lie down or sit during the procedure. Patients who faint after vaccination will recover after a few minutes, and clinicians should observe patients for at least 15 min after vaccination (a recommendation of the CDC).

Febrile Seizure

Fevers of 102°F (38.9°C) or higher can cause children to experience febrile seizures, which are characterized by body spasms and jerky movements that may last for up to 2 min. About 5% of children will experience a febrile seizure in their lifetime, with most occurring at 14–18 months of age. Children experiencing simple febrile seizures recover quickly without long-term harm. These common seizures also are caused by febrile illnesses associated with viral infections, especially roseola, ear infections, and other common childhood illnesses. Current vaccines sometimes induce fevers, usually low grade in nature, but rarely result in febrile seizures. Although fever following vaccination with most vaccines rarely causes febrile seizure, there is a small increase in risk after MMR and MMRV vaccines. The CDC also has reported a small increase in febrile seizures after a child receives the IIV together with PCV13 vaccine or in combination with diphtheria, tetanus, or DTaP vaccines. The increase of febrile seizures when combining these vaccines is small, and the CDC does not recommend delivering them on separate days. Importantly, vaccine usage can help prevent febrile seizures by providing vaccinated children protection against measles, mumps, rubella, chickenpox, influenza, and pneumococcal infectious pathogens that may result in febrile seizures.

Guillain-Barré Syndrome

Guillain-Barré syndrome is a rare disease that affects the nervous system. Patients with GBS display muscle weakness and sometimes paralysis that results when their own immune system injures their neurons. GBS often occurs after an infection with bacteria or virus; most patients with GBS recover fully. However, some subjects can have permanent nerve damage. The incidence of GBS in the U.S. currently is about 3000–6000 cases per year; thus, it is rare in a population of about 350 million. GBS is more common in older adults, with people older than 50 years at greater risk. GBS may have several underlying causes, but scientists report that two-thirds of GBS cases occurred after patients were ill with gastroenteritis or respiratory tract infections. Infection with *Campylobacter jejuni* is the most common risk factor for the disease, but GBS also has been reported commonly after influenza virus, cytomegalovirus, or Epstein-Barr viral infection. GBS after vaccination is reported but rare.

An IOM study reported that widespread use of the 1976 swine influenza virus vaccine was associated with a small increase in risk for GBS, with an additional case of GBS per 100,000 people who were vaccinated, although later statistical review called this association into question. Current assessments are that there is no significant risk of GBS after obtaining a seasonal influenza vaccine, or if there is an association, the risk is approximately one case per million vaccinated individuals, a low rate that is difficult to detect with certainty. Studies have shown that a person is more likely to get GBS after influenza infection than vaccination. Importantly, severe morbidity and mortality are a significant risk after influenza infection, and preventing complications and death can be achieved by getting vaccinated.

Sudden Infant Death Syndrome

Sudden infant death syndrome peaks when babies are between 2 and 4 months old, and infants are also given many vaccines during this period. The temporal overlap of peak SIDS incidence and the period of initiation of childhood vaccination series led to questions about any causal relationship between vaccines and SIDS. Numerous studies have failed to detect a

causative association for vaccines and SIDS (Silvers et al., 2001). The IOM 2003 report reviewed the relationship of SIDS and vaccines and concluded that vaccines do not cause SIDS. Infant death by SIDS has decreased dramatically due to the 1992 American Academy of Pediatrics recommendations to place infants on their backs to sleep and the 1994 National Institute of Child Health and Human Development campaign efforts.

Safety of Multiple Vaccinations

Children are exposed to a large number of bacteria and viruses in their environment through food, teething of objects, and exposure to pets and to other humans. The typical viral infection results in exposure of the immune system to a dozen or more antigens; some bacteria express hundreds of antigens during infection. Each recommended childhood vaccine protects against 1 to 69 antigens. When a child is given the full recommended vaccines on the 2014 schedule, they are exposed to up to 315 antigens by age 2, which provides them critical protection against pathogens in the environment (CDC, 2016). Vaccinating patients against multiple antigens has been shown to be safe when they are delivered in combination at the same time. This strategy is advantageous for patients, especially children, because they lack immunity to most vaccine preventable diseases, so receiving this protection during the relatively vulnerable period of early development is important. The patient also has fewer doctor visits with combination or multiple vaccinations, reducing cost in terms of money and time for parents and disruption for children. Numerous studies have shown that giving various vaccine combinations does not cause chronic disease. Furthermore, each time a combination vaccine or multiple vaccination schedule is licensed, that intervention already has been tested for safety and efficacy in combination with the vaccines previously recommended for that age group. The ACIP and the Academy of Pediatrics recommend receiving multiple vaccines at the same time (CDC, 2016).

Vaccine Myths and Their Public Health Consequences

The public health success of vaccines is demonstrated by the decreased rates of mortality and morbidity due to infectious diseases contracted in childhood and adulthood. A dramatic example of success is the worldwide eradication of smallpox, a pathogen responsible for epidemics that killed 300–500 million people in the 20th century and disfigured many survivors. In the 20th century, poliovirus and MeV also incapacitated and killed infected individuals, especially young children. New generations have never seen the debilitating effects of these infectious diseases, thanks to decades of successful public health vaccination strategies. Infectious diseases, however, continue to affect the lives of many people in the developing world who have less access to healthcare or are affected by wars or famine. Recently, preventable diseases are arising again in the developed world because of vaccine myths that have reduced vaccination rates in these countries.

One of these myths concerns autism. A study that has been retracted and discredited claimed there was a link between vaccination in children and autism (Wakefield et al., 1998). Despite major shortcomings and incorrect interpretations, this study changed public perceptions regarding vaccine safety, and its influence persists. Experimental studies in different parts of the world with large cohorts, statistical power, and rigor have found no evidence that vaccines cause autism (American Academy of Pediatrics, 2017; Madsen et al., 2002). Researchers have found that autism occurs in families, may have a genetic component, and may be affected by environmental triggers such as insecticides, certain drugs, and rubella virus. The exact causes of ASDs are unknown and continue to be investigated (Landrigan, 2010).

Nonetheless, the antivaccination movement has gained momentum, with celebrities, politicians, and social media continuing to propagate erroneous vaccine information and conspiracy theories. According to the CDC, vaccination rates have fallen in many parts of the U.S. In nine U.S. states, fewer than two-thirds of children ages 19 to 35 months have been vaccinated with the recommended seven-vaccination regimen. This dismissal of scientific evidence on vaccines can have deadly consequences. Infectious epidemics due to preventable agents like poliovirus and MeV can reemerge. Unvaccinated children will be more susceptible to infection,

and many of them will not survive. Furthermore, unvaccinated subjects contribute to reducing the benefits of herd immunity that protects people who cannot be vaccinated for medical reasons, such as cancer, HIV infection, and other types of immunodeficiency.

Diseases due to pertussis, polio, measles, *H. influenzae*, and rubella virus once affected hundreds of thousands of people and killed thousands. Following the introduction of universal vaccinations, the rates of these diseases decreased to near-zero levels in the U.S. Some believe that because these diseases have been nearly eliminated in the U.S., vaccination is no longer needed. This thinking is incorrect. Vaccine-preventable diseases are communicable diseases, spreading from person to person, and the causative viruses and bacteria survive in nature. People, especially the unvaccinated, can be infected, and infected individuals will spread the disease to unvaccinated individuals. A greater fraction of vaccinated individuals in a population leads to fewer opportunities for the disease to spread (herd immunity).

Parental vaccine concerns should be taken seriously, and misconceptions should be thoroughly discussed by providers to ensure that patients have scientific information and are informed about the risks associated with failure to vaccinate. By providing parental education, pediatricians and other primary care medical providers can help reduce vaccine hesitancy.

Licensure and Monitoring of Vaccines

Immune Correlates and Mechanisms

During the process of vaccine development and testing, manufacturers seek to define laboratory tests and parameters that are associated with efficacy, which have been designated immune CoPs. First, it is important theoretically to understand some features of the biological mechanism of protection to optimize development and use of vaccines. At a practical level, identification of a correlate allows monitoring of the reproducibility of vaccines during repetitive manufacture, monitoring the expected impact of new combinations of vaccine antigens on immunogenicity of existing vaccines, and other critical issues.

Plotkin and others have developed terminology for principal types of correlates (Plotkin and Gilbert, 2012). A CoP is a marker of immune function that statistically correlates with protection. Such markers can be simply associated with protection (termed nCoP) or alternatively may be known to measure directly the immune effectors that mediate protection (mCoP). From a practical standpoint, either an nCoP or an mCoP can enable monitoring and prediction of effective vaccination.

The ideal CoP is one that is quantitative and derives from a reproducible laboratory test that has been validated under good laboratory practice conditions. The type of protection suggested for a particular correlate may vary because vaccines may be designed to prevent differing classes of infection, such as local versus systemic infection or severe disease versus any disease. Examples of quantitative CoPs in use include a threshold of 10 mIU/mL in serum of hepatitis B antibodies detected in a standardized ELISA (enzyme-linked immunosorbent assay), serum diphtheria toxin neutralization concentration of 0.01 to 0.1 IU/mL, a serum virus neutralization dilution titer of 1/5 for yellow fever virus, or a 1/40 dilution of serum in influenza hemagglutination inhibition titer.

Regulatory and Advisory Bodies

The Center for Biologics Evaluation and Research (CBER) of the FDA regulates vaccine products in the U.S., with recommendations from its Vaccines and Related Biological Products Advisory Committee. The EMA regulates in Europe. Manufacturers conduct phase 1 (safety and immunogenicity studies) in a small number of closely monitored subjects; phase 2 studies (dose-ranging studies) typically in several hundred subjects; and then phase 3 trials (efficacy studies) typically in thousands of subjects. If successful, the sponsor submits a Biologics License Application (BLA) to the FDA, which may lead to licensure. Licensure allows use, but decisions on whether vaccines are recommended for specific populations

or for universal use are made by additional advisory bodies. The CDC hosts the ACIP, a committee of public health and medical experts, which makes recommendations for use of vaccines in the U.S. Various professional medical societies also publish recommendations, for instance, the American Academy of Pediatrics publishes the *AAP Red Book*, or “Report of the Committee on Infectious Diseases of the American Academy of Pediatrics,” which contains vaccine recommendations. Finally, third-party payers, such as insurance companies, affect usage through reimbursement policies; thus, issues of cost, benefit, and profitability become considerations, as examined in Chapter 1.

Platelet-Activating Factor

- Chemistry and Biosynthesis
- Sites of PAF Synthesis
- Mechanism of Action of PAF
- Physiological and Pathological Functions of PAF
- PAF Receptor Antagonists

Membrane lipids supply the substrate for the synthesis of *eicosanoids* and *platelet-activating factor* (PAF). Arachidonic acid (AA) metabolites, including PGs, PGI₂, TxA₂, LTs, and *epoxygenase products* of CYPs, collectively the eicosanoids, are not stored but are produced by most cells when a variety of physical, chemical, and hormonal stimuli activate acyl hydrolases that make arachidonate available. *Membrane glycerophosphocholine* derivatives can be modified enzymatically to produce PAF. PAF is formed by a smaller number of cell types, principally leukocytes, platelets, and endothelial cells. Eicosanoids and PAF lipids function as signaling molecules in many biological processes, including the regulation of vascular tone, renal function, hemostasis, parturition, GI mucosal integrity, and stem cell function. They are also important mediators of innate immunity and inflammation. Several classes of drugs, most notably NSAIDs (see Chapter 38), including aspirin, owe their principal therapeutic effects—relief of inflammatory pain and antipyresis—to blockade of PG formation.

Eicosanoids

Eicosanoids, from the Greek *eikosi* (“twenty”) are formed from precursor essential fatty acids that contain 20 carbons and 3, 4, or 5 double bonds: 8,11,14-eicosatrienoic acid (dihomo- γ -linolenic acid), 5,8,11,14-eicosatetraenoic acid (AA; Figure 37–1), and EPA. AA is the most abundant precursor, derived from the dietary omega-6 fatty acid, linoleic acid (9,12-octadecadienoic acid), or ingested directly as a dietary constituent. EPA is a major constituent of oils from fatty fish such as salmon.

History

In 1930, American gynecologists Kurzrok and Lieb observed that strips of uterine myometrium relax or contract when exposed to semen. Subsequently, Goldblatt in England and von Euler in Sweden reported independently on smooth muscle contracting and vasodepressor activities in seminal fluid and accessory reproductive glands. In 1935, von Euler identified the active material as a lipid-soluble acid, which he named *prostaglandin*. Samuelsson, Bergström, and their colleagues elucidated the structures of PGE₁ and PGF_{1 α} in 1962. In 1964, Bergström and coworkers and van Dorp and associates independently achieved biosynthesis of PGE₂ from AA. Discovery of TxA₂, PGI₂, and the LTs followed. Vane, Smith, and Willis in 1971 reported that aspirin and NSAIDs act by inhibiting PG biosynthesis. This remarkable period of discovery linked the Nobel Prize of von Euler in 1970 to that of Bergström, Samuelsson, and Vane in 1982.

Biosynthesis

Biosynthesis of eicosanoids is limited by the availability of AA and depends primarily on the release of esterified AA from membrane phospholipids or other complex lipids by acyl hydrolases, notably PLA₂. Once liberated, AA is metabolized rapidly to oxygenated products by COXs, LOXs, and CYPs (Figure 37–1).

Chemical and physical stimuli activate the Ca²⁺-dependent translocation of group IV_A cytosolic phospholipase A₂ (cPLA₂) to the membrane, where it hydrolyzes the *sn*-2 ester bond of membrane phosphatidylcholine and phosphatidylethanolamine, releasing AA. Multiple additional PLA₂ isoforms (secretory [s] and Ca²⁺-independent [i] forms) have been characterized. Under basal conditions, AA liberated by iPLA₂ is reincorporated into cell membranes. During stimulation, cPLA₂ dominates the acute release of AA, while an inducible sPLA₂ contributes to AA release under conditions of sustained or intense stimulation. sPLA₂ contributes to platelet microparticle generation of eicosanoids that then direct microparticle internalization by neutrophils driving inflammation (Duchez et al., 2015).

Products of Cyclooxygenases (Prostaglandin G/H Synthases)

Prostaglandin endoperoxide G/H synthase is called *cyclooxygenase* or COX colloquially. Products of this pathway are PGs, PGI₂, and TxA₂, collectively termed *prostanoids*. The pathway is described by Figure 37–1 and its legend.

Prostanoids are distinguished by substitutions on their cyclopentane rings the number of double bonds in their side chains, as indicated by numerical subscripts (dihomo- γ -linolenic acid is the precursor of *series*₁, AA for *series*₂, and EPA for *series*₃). Prostanoids derived from AA carry the subscript 2 and are the major series in mammals.

There are two distinct COX isoforms, COX-1 and COX-2 (Rouzer and Marnett, 2009; Smith et al., 2011). COX-1, expressed constitutively in most cells, is the dominant source of prostanoids for housekeeping functions, such as cytoprotection of the gastric epithelium (see Chapter 49). COX-2, in contrast, is upregulated by cytokines, shear stress, and growth factors and is the principal source of prostanoid formation in inflammation and cancer. However, this distinction is not absolute; both enzymes may contribute to the generation of autoregulatory and homeostatic prostanoids during physiologic and pathophysiologic processes.

With 61% amino acid identity, COX-1 and COX-2 have remarkably similar crystal structures. Both isoforms are expressed as dimers homotypically inserted into the endoplasmic reticular membrane. Through sequential COX and POX activity, both COXs convert AA to two unstable intermediates that are then converted to the prostanoids

Abbreviations

AA:	arachidonic acid
ACTH:	corticotropin (formerly adrenocorticotrophic hormone)
BLT1/2:	LTB ₄ receptors
cAMP:	cyclic adenosine monophosphate
COX:	cyclooxygenase
CYP:	cytochrome P450
CysLT:	cysteinyl leukotriene
CysLT1/2:	CysLT receptors
DP₂:	a member of the fMLP-receptor superfamily, CRTH2
DP:	PGD ₂ receptor
EDHF:	endothelium-derived hyperpolarizing factor
EET:	epoxyeicosatrienoic acid
EP:	PGE ₂ receptor
EPA:	5,8,11,14,17-eicosapentaenoic acid
FLAP:	5-LOX-activating protein
FP:	PGF ₂ α receptor
fMLP:	formyl-methionyl-leucyl-phenylalanine
GPCR:	G protein-coupled receptor
HETE:	hydroxyeicosatetraenoic acid
HPETE:	hydroxyperoxyeicosatetraenoic acid
IL:	interleukin
IP₃:	inositol 1,4,5-trisphosphate
IP:	PGI ₂ receptor
iPLA₂:	independent PLA ₂
IsoP:	isoprostane
LOX:	lipoxygenase
LT:	leukotriene
LX*:	lipoxin*, e.g., LXA, LXB
NSAID:	nonsteroidal anti-inflammatory drug
PAF:	platelet-activating factor
PAF-AH:	PAF acetylhydrolase
PG:	prostaglandin
PGDH:	PG 15-OH dehydrogenase
PGI₂:	prostacyclin
PL*:	phospholipase*, e.g., PLA, PLC
PMN:	polymorphonuclear leukocyte
POX:	peroxidase
TNF:	tumor necrosis factor
TP:	TxA ₂ receptor
TxA:	thromboxane A

by synthases, expressed in a relatively cell-specific fashion. For example, COX-1-derived TxA₂ is the dominant product in platelets, whereas COX-2-derived PGE₂ and TxA₂ dominate in activated macrophages. Prostanoids are released from cells by diffusion, although transport may be facilitated through the multidrug resistance-associated protein (MRP) transporter (Schuster, 2002).

Lipoxygenase Products

Major products of the LOX pathways are hydroxy fatty acid derivatives known as HETEs, LTs, and LXs (Figure 37-2) (Haeggström and Funk, 2011; Powell and Rokach, 2015). LTs play a major role in the development and persistence of the inflammatory response.

The LOXs are a family of enzymes containing nonheme iron; LOXs catalyze the oxygenation of polyenic fatty acids to corresponding lipid hydroperoxides. The enzymes require a fatty acid substrate with two cis double bonds separated by a methylene group. AA, which contains several double bonds in this configuration, is metabolized to HPETEs, which vary in the site of insertion of the hydroperoxy group. HPETEs are converted to their corresponding HETEs either nonenzymatically or by a POX.

There are five active human LOXs—5(S)-LOX, 12(S)-LOX, 12(R)-LOX, 15(S)-LOX-1, and 15(S)-LOX-2—classified according to the site of hydroperoxy group insertion. Their expression is frequently cell specific; platelets have only 12(S)-LOX, whereas leukocytes contain both 5(S)- and 12(S)-LOX (Figure 37-2). 12(R)-LOX is restricted in expression mostly to the skin. The epidermal LOXs, which constitute a distinct LOX subgroup, also include 15-LOX-2 and eLOX-3, the most recently identified family member. eLOX-3 has been reported to metabolize further 12(R)-HETE, the product of 12(R)-LOX, to a specific epoxyalcohol product.

The 5-LOX pathway leads to the synthesis of the LTs. When eosinophils, mast cells, PMNs, or monocytes are activated, 5-LOX translocates to the nuclear membrane and associates with FLAP, an integral membrane protein that facilitates AA to 5-LOX interaction (Evans et al., 2008). Drugs that inhibit FLAP block LT production. A two-step reaction is catalyzed by 5-LOX: oxygenation of AA to form 5-HPETE followed by dehydration to an unstable epoxide, LTA₄. LTA₄ is transformed by distinct enzymes to LTB₄ or LTC₄. Extracellular metabolism of the peptide moiety of LTC₄ generates LTD₄ and LTE₄ (Peters-Golden and Henderson, 2007). Collectively, LTC₄, LTD₄, and LTE₄ are the CysLTs. LTB₄ and LTC₄ are actively transported out of the cell. LTA₄, the primary product of the 5-LOX pathway, is metabolized by 12-LOX to form LXA₄ and LXB₄. These mediators also can arise through 5-LOX metabolism of 15-HETE.

Products of CYPs

The CYP epoxygenases, primarily CYP2C and CYP2J, metabolize AA to EETs (Fleming, 2014). In endothelial cells, EETs function as EDHFs, particularly in the coronary circulation. EET biosynthesis can be altered by pharmacological, nutritional, and genetic factors that affect CYP expression.

Other Pathways

The isoeicosanoids, a family of eicosanoid isomers, are generated by non-enzymatic free radical catalyzed oxidation of AA. Unlike PGs, these compounds are initially formed esterified in phospholipids and released by PLs; the isoeicosanoids then circulate and are metabolized and excreted into urine. Their production is not inhibited *in vivo* by inhibitors of COX-1 or COX-2, but their formation is suppressed by antioxidants. Isoprostanes correlate with cardiovascular risk factors, and increased levels are found in a large number of clinical conditions (Milne et al., 2015). Their relevance as biologically active mediators remains unclear. A series of compounds, LXs, maresins, resolvins, when synthesized and administered to certain models of inflammation, hasten its resolution. It remains to be established whether the endogenous compounds are formed in quantities sufficient to exert this effect *in vivo* (Skarke et al., 2015).

Inhibitors of Eicosanoid Biosynthesis

Inhibition of PLA₂ decreases the release of the precursor fatty acid and the synthesis of all its metabolites. PLA₂ may be inhibited by drugs that reduce the availability of Ca²⁺. Glucocorticoids inhibit PLA₂ indirectly by inducing the synthesis of a group of proteins termed *annexins* that modulate PLA₂ activity. Glucocorticoids also downregulate induced expression of COX-2 but not of COX-1 (see Chapter 46). Aspirin and NSAIDs inhibit the COX, but not the POX, moiety of both COX enzymes and thus the formation of downstream prostanoids. These drugs do not inhibit LOXs and may cause increased formation of LTs by shunting of substrate to the LOX pathway. Dual inhibitors of COX and 5-LOX have proven effective in some models of inflammation and tissue injury (Minutoli et al., 2015; Oak et al., 2014). LTs may contribute to the GI side effects associated with NSAIDs (Janusz et al., 1998; Xu et al., 2009).

Differences in the sensitivity of COX-1 and COX-2 to inhibition by certain anti-inflammatory drugs led to the development of selective inhibitors of COX-2, including the coxibs (Grosser et al., 2010) (see Chapter 38). These drugs were hypothesized to offer therapeutic advantages over older NSAIDs (many of which are nonselective COX inhibitors) because COX-2 was thought to be the predominant source of PGs in inflammation, whereas COX-1 is the major source

Figure 37-1 Metabolism of AA. Cyclic endoperoxides (PGG₂ and PGH₂) arise from the sequential COX and hydroperoxidase actions of COX-1 or COX-2 on AA released from membrane phospholipids. Subsequent products are generated by tissue-specific synthases and transduce their effects via membrane-bound receptors (blue boxes). EETs and isoprostanes are generated via CYP activity and nonenzymatic free radical attack, respectively. Aspirin and nonselective NSAIDs are nonselective inhibitors of COX-1 and COX-2 but do not affect LOX activity. See the text and the Abbreviations list for further definitions.

of cytoprotective PGs in the GI tract. Randomized trials of selective COX-2 inhibitors reported their superiority in GI safety over nonselective NSAID comparators.

However, there now is compelling evidence that COX-2 inhibitors confer a spectrum of cardiovascular hazards (myocardial infarction, stroke, systemic and pulmonary hypertension, congestive heart failure, and sudden cardiac death) (Grosser et al., 2010). The hazards can be explained sufficiently by suppression of cardioprotective COX-2-derived PGs, especially PGI₂, and the unrestrained effects of endogenous stimuli, such as platelet COX-1-derived TxA₂, on platelet activation, vascular proliferation and remodeling, hypertension, and atherogenesis.

Because LTs mediate inflammation, efforts have focused on development of LT receptor antagonists and selective inhibitors of the LOXs. Zileuton, an inhibitor of 5-LOX, and selective CysLT₁ receptor antagonists (zafirlukast, pranlukast, and montelukast) have established efficacy in the treatment of mild-to-moderate asthma (see Chapter 40). These treatments remain, however, less effective than inhaled corticosteroids. A common polymorphism in the gene for LTC₄ synthase that correlates with increased LTC₄ generation may be associated with higher asthma risk in some populations and with the efficacy of anti-LT therapy. Interestingly, although polymorphisms in the genes encoding 5-LOX or FLAP have yet to be linked to asthma, studies have demonstrated an association of these genes with myocardial infarction, stroke, and atherosclerosis (Peters-Golden and Henderson, 2007); thus, inhibition of LT biosynthesis may eventually prove to be useful in the prevention of cardiovascular disease.

Eicosanoid Degradation

Most eicosanoids are efficiently and rapidly inactivated (Figure 37-3). The enzymatic catabolic reactions are of two types:

- a rapid initial step, catalyzed by widely distributed PG-specific enzymes, wherein PGs lose most of their biological activity; and
- a second step in which these metabolites are oxidized, probably by enzymes identical to those responsible for the β and ω oxidation of fatty acids.

The lung, kidney, and liver play prominent roles in the enzymatically catalyzed reactions. Metabolic clearance requires an energy-dependent cellular uptake PG transporter and possibly other transporters (Schuster et al., 2002). The initial step is the oxidation of the 15-OH group to the corresponding ketone by PGDH. PGI₂ and TxA₂, however, undergo spontaneous hydrolysis as a first degradative step. LTC₄ degradation also occurs in the lungs, kidney, and liver but may also occur in LTC₄ via CYP4F enzymes. Inactivation of 15-hydroxyprostaglandin dehydrogenase, which elevates the capacity of tissues to form PGE₂, enhances tissue regeneration after hematopoietic stem cell transplantation and after hemihepatectomy (Zhang et al., 2015).

Pharmacological Properties

The eicosanoids function through activation of specific GPCRs (Table 37-1) that couple to intracellular second-messenger systems to modulate cellular activity (Figure 37-4).

Figure 37-2 Lipooxygenase pathways of AA metabolism. FLAP presents AA to 5-LOX, leading to the generation of the LTs and CysLTs. LXs (boxed) are products of cellular interaction via a 5-LOX–12-LOX pathway or via a 15-LOX–5-LOX pathway. Biological effects are transduced via membrane-bound receptors (blue boxes). While its biological relevance remains controversial, LXA₄ can activate a GPCR also activated by Annexin A1 and by the formyl peptide. This GPCR is termed the AnxA1-Formyl peptide receptor 2/ALX receptor (AnxA1-FPR2/ALX) to reflect the range of its putative ligands. Zileuton inhibits 5-LOX but not the COX pathways (expanded in Figure 37-1). CysLT antagonists prevent activation of the CysLT₁ receptor. See the text and the Abbreviations list for further definitions.

Figure 37-3 Major pathways of prostanoid degradation. Active metabolites are boxed. *Major urinary metabolites (M). See the text and the Abbreviations list for further definitions.

TABLE 37-1 ■ HUMAN EICOSANOID RECEPTORS

RECEPTOR	LIGANDS 1° (2°)	PRIMARY COUPLING	MAJOR PHENOTYPE IN KNOCKOUT MICE
DP ₁	PGD ₂	G _s	↓ Allergic asthma
DP ₂ /CHRT ₂	PGD ₂ (15d-PGJ ₂)	G _i	↑ or ↓ Allergic airway inflammation
EP ₁	PGE ₂ (PGI ₂)	G _q	↓ Response of colon to carcinogens
EP ₂	PGE ₂	G _s	Impaired ovulation and fertilization Salt-sensitive hypertension
EP ₃ I–VI, e, f	PGE ₂	G _p ; G _s ; G _q	Resistance to pyrogens ↓ Acute cutaneous inflammation
EP ₄	PGE ₂	G _s	Patent ductus arteriosus ↓ Bone mass/density in aged mice ↑ Bowel inflammatory response ↓ Colon carcinogenesis
FP _{A,B}	PGF _{2α} (IsoPs)	G _q	Failure of parturition
IP	PGI ₂ (PGE ₂)	G _s	↑ Thrombotic response ↓ Response to vascular injury ↑ Atherosclerosis ↑ Cardiac fibrosis Salt-sensitive hypertension ↓ Joint inflammation
TP _{αβ}	TxA ₂ (IsoPs)	G _q , G _p , G _{12/13} , G ₁₆	↑ Bleeding time ↓ Response to vascular injury ↓ Atherosclerosis ↑ Survival after cardiac allograft
BLT ₁	LTB ₄	G ₁₆ , G _i	Some suppression of inflammatory response
BLT ₂	LTB ₄ [12(S)-HETE, 12(R)-HETE]	G _q -like, G _i -like, G _z -like	? (Reports of altered inflammatory processes)
CysLT ₁	LTD ₄ (LTC ₄ /LTE ₄)	G _q	↓ Innate and adaptive immune vascular permeability response ↑ Pulmonary inflammatory and fibrotic response
CysLT ₂	LTC ₄ /LTD ₄ (LTE ₄)	G _q	↓ Pulmonary inflammatory and fibrotic response

This table lists the major classes of eicosanoid receptors and their signaling characteristics. Splice variants for EP₃, TP, and FP are indicated.

Prostaglandin Receptors

The PGs activate membrane receptors locally near their sites of formation. Eicosanoid receptors interact with G_s, G_p, and G_q to modulate the activities of adenylyl cyclase and PLC (see Chapter 3). Single-gene products have been identified for the receptors for PGI₂ (the IP), PGF_{2α} (the FP), and TxA₂ (the TP). Four distinct PGE₂ receptors (EP_{1–4}) and two PGD₂ receptors (DP₁ and DP₂—also known as CRTH₂) have been cloned. Additional isoforms of the TP (α and β), FP (A and B), and EP₃ (I–VI, e, f) receptors can arise through differential messenger RNA splicing (Smyth et al., 2009; Woodward et al., 2011). The prostanoid receptors appear to derive from an ancestral EP receptor and share high homology. Phylogenetic comparison of this receptor family reveals three subclusters (Figure 37-4):

- the relaxant receptors EP₂, EP₄, IP, and DP₁, which increase cellular cyclic AMP generation;
- the contractile receptors EP₁, FP, and TP, which increase cytosolic levels of Ca²⁺; and
- EP₃, which can couple to both elevation of cytosolic [Ca²⁺] and inhibition of adenylyl cyclase.

The DP₂ receptor is an exception and is unrelated to the other prostanoid receptors; rather, it is a member of the fMLP receptor superfamily.

Leukotriene Receptors

Two receptors exist for both LTB₄ (BLT₁ and BLT₂) and CysLT₁ and CysLT₂ (Bäck et al., 2011, 2014). The fMLP-2 receptor also binds LXA₄, but the functional importance of this ligand in vivo remains controversial. All

are GPCRs and couple with G_q and other G proteins, depending on the cellular context. BLT₁ is expressed predominantly in leukocytes, thymus, and spleen, whereas BLT₂, the low-affinity receptor for LTB₄, is found in spleen, leukocytes, ovary, liver, and intestine.

CysLT₁ binds LTD₄ with higher affinity than LTC₄, while CysLT₂ shows equal affinity for both LTs. Both receptors bind LTE₄ with low affinity. Activation of G_q, leading to mobilization of intracellular Ca²⁺, is the primary signaling pathway reported. Studies also have placed G_i downstream of CysLT₂. CysLT₁ is expressed in lung and intestinal smooth muscle, spleen, and peripheral blood leukocytes, whereas CysLT₂ is found in heart, spleen, peripheral blood leukocytes, adrenal medulla, and brain.

Other Agents

Other AA-derived products (e.g., isoprostanes, EETs) have potent biological activities, and there is evidence for distinct receptors for some of these substances. An orphan receptor, GPR31, has been identified as a receptor for 12(S)-HETE (Powell and Rokach, 2015). Specific receptors for the HETEs and EETs have been proposed, and evidence that the orphan receptor GPR75 functions as a receptor for 20-HETE has recently been provided (Garcia et al 2017).

Physiological Actions and Pharmacological Effects

The widespread biosynthesis and myriad pharmacological actions of eicosanoids are reflected in their complex physiology and pathophysiology. Knowledge of the distribution of the major eicosanoid receptors helps to put the complexity into perspective (Figure 37-1). The development of mice with targeted disruptions of genes regulating eicosanoid biosynthesis

Figure 37-4 Prostanoid receptors and their primary signaling pathways. Prostanoid receptors are heptaspanning GPCRs. The terms *relaxant*, *contractile*, and *inhibitory* refer to the phylogenetic characterization of their primary effects. All EP₃ isoforms couple through G_i; some can also activate G_s or G_{12/13} pathways. RhoGEF, Rho Guanine nucleotide Exchange Factor.

and eicosanoid receptors has revealed unexpected roles for these autacoids and has clarified hypotheses about their function (see Table 37-1). These topics, summarized here, were well reviewed by Smyth et al. (2011).

Cardiovascular System

Because of their short $t_{1/2}$, prostanoids act locally and generally are considered not to affect systemic vascular tone directly. They may modulate vascular tone locally at their sites of biosynthesis or through renal or other indirect effects. PGI₂, the major arachidonate metabolite released from the vascular endothelium, is derived primarily from COX-2 in humans. PGI₂ generation and release is regulated by shear stress and by both vasoconstrictor and vasodilator autacoids. In most vascular beds, PGE₂, PGI₂, and PGD₂ elicit vasodilation and a drop in blood pressure; physiologically, these responses are quite local because endogenous prostanoids are paracrine mediators that do not circulate (Smyth et al., 2009). Responses to PGF_{2α} is a potent constrictor of both pulmonary arteries and veins. TxA₂ is a potent vasoconstrictor and a mitogen in smooth muscle cells.

Prostaglandin E₂ can also cause vasoconstriction through activation of EP₁ and EP₃. Infusion of PGD₂ in humans results in flushing, nasal stuffiness, and hypotension. Local subcutaneous release of PGD₂ contributes to dilation of the vasculature in the skin, which causes facial flushing associated with niacin treatment in humans. Subsequent formation of F-ring metabolites from PGD₂ may result in hypertension. PGI₂, the major prostanoid released from the vascular endothelium, relaxes vascular smooth muscle, causing hypotension and reflex tachycardia on intravenous administration. PGI₂ limits pulmonary hypertension induced by hypoxia and systemic hypertension induced by AngII and lowers pulmonary resistance in patients with pulmonary hypertension.

Cyclooxygenase 2-derived PGE₂, acting via the EP₄ maintains the ductus arteriosus patent until birth, when reduced PGE₂ levels (a consequence

of increased PGE₂ metabolism) permit closure. The traditional NSAIDs induce closure of a patent ductus in neonates (see Chapter 38). Contrary to expectation, animals lacking the EP₄ die with a patent ductus during the perinatal period (Table 37-1) because the mechanism for control of the ductus in utero, and its remodeling at birth, is absent.

Infusion of PGs of the E and F series generally increases cardiac output. Weak, direct inotropic effects have been noted in various isolated preparations. In the intact animal, however, increased force of contraction and increased heart rate are, in large measure, a reflex consequence of a fall in total peripheral resistance. PGI₂ and PGE₂, acting on the IP or the EP₃, respectively, protect against oxidative injury in cardiac tissue.

Studies suggest a role for COX-2 in cardiac function. PGI₂ and PGE₂, acting on the IP or the EP₃, respectively, protect against oxidative injury in cardiac tissue. IP deletion augments myocardial ischemia/reperfusion injury, and both mPGE synthase-1 (mPGES-1) deletion and cardiomyocyte-specific deletion of the EP₄ exacerbate the decline in cardiac function after experimental myocardial infarction. COX-2-derived TxA₂ contributed to oxidant stress, isoprostane generation, and activation of the TP, and also possibly the FP, to increase cardiomyocyte apoptosis and fibrosis in a model of heart failure. Selective deletion of COX-2 in cardiomyocytes results in mild heart failure and a predisposition to arrhythmogenesis (Wang et al., 2009).

Leukotriene C₄ and LTD₄ can constrict or relax isolated vascular smooth muscle preparations, depending on the concentrations used and the vascular bed (Bäck et al., 2011). Although LTC₄ and LTD₄ have little effect on most large arteries or veins, nanomolar concentrations of these agents contract coronary arteries and distal segments of the pulmonary artery. The renal vasculature is resistant to this constrictor action, but the mesenteric vasculature is not. LTC₄ and LTD₄ act in the microvasculature to increase permeability of postcapillary venules; they are about 1000-fold

more potent than histamine in this regard. At higher concentrations, LTC_4 and LTD_4 can constrict arterioles and reduce exudation of plasma. There is evidence for a role of the LTs in cardiovascular disease (Peters-Golden and Henderson, 2007). Human genetic studies have demonstrated a link between cardiovascular disease and polymorphisms in the LT biosynthetic enzymes and FLAP.

The EETs cause vasodilation in a number of vascular beds by activating the large conductance Ca^{2+} -activated K^+ channels of smooth muscle cells, thereby hyperpolarizing the smooth muscle and causing relaxation. EETs likely also function as EDHFs, particularly in the coronary circulation. Endogenous biosynthesis of EETs is increased in human syndromes of hypertension.

Platelets

Platelet aggregation leads to activation of membrane phospholipases, with the release of AA and consequent eicosanoid biosynthesis. In human platelets, TxA_2 and 12-HETE are the two major eicosanoids formed, although eicosanoids from other sources (e.g., PGI_2 derived from vascular endothelium) also affect platelet function. Mature platelets express only COX-1. TxA_2 , the major product of COX-1 in platelets, induces platelet aggregation and amplifies the signal for other, more potent platelet agonists, such as thrombin and ADP. The importance of the TxA_2 pathway is evident from the efficacy of platelet COX-1 inhibition with low-dose aspirin in the secondary prevention of myocardial infarction and ischemic stroke. The total biosynthesis of TxA_2 , as determined by excretion of its urinary metabolites, is augmented in clinical syndromes of platelet activation, including unstable angina, myocardial infarction, and stroke. Deletion of the TP in the mouse prolongs bleeding time, renders platelets unresponsive to TP agonists, and blunts the response to vasopressors and the proliferative response to vascular injury (Smyth et al., 2009). TxA_2 induces platelet shape change, through $\text{G}_{12}/\text{G}_{13}$ -mediated Rho/Rho kinase-dependent regulation of myosin light-chain phosphorylation, and aggregation through G_q -dependent activation of PKC. The actions of TxA_2 on platelets are restrained by its short $t_{1/2}$ (~30 sec), by rapid TP desensitization, and by endogenous inhibitors of platelet function, including NO and PGI_2 .

Low concentrations of PGE_2 , via the EP_3 , enhance platelet aggregation. In contrast, higher concentrations of PGE_2 , acting via the IP or possibly EP_2 or EP_4 inhibit platelet aggregation. Both PGI_2 and PGD_2 inhibit the aggregation of platelets. PGI_2 limits platelet activation by TxA_2 , and disaggregates preformed platelet clumps. The increased incidence of myocardial infarction and stroke in patients receiving selective inhibitors of COX-2, explained by inhibition of COX-2-dependent PGI_2 formation, supports this concept (Grosser et al., 2010).

Inflammation and Immunity

Eicosanoids play a major role in inflammatory and immune responses. LTs generally are pro-inflammatory and interact with PGs to promote and sustain inflammation (Ricciotti and FitzGerald, 2011), although there are some exceptions, such as the inhibitory actions of PGE_2 on mast cell activation. PGs and LXs and related compounds may also contribute to the resolution of inflammation (Buckley et al., 2014). COX-2 is the major source of prostanoids formed during and after an inflammatory response.

Prostaglandin E_2 and PGI_2 are the predominant pro-inflammatory prostanoids as a result of increased vascular permeability and blood flow in the inflamed region. TxA_2 can increase platelet-leukocyte interaction. PGD_2 may contribute to the resolution of inflammation. Lymphocytes have a minimal capacity to form PGs, yet they are a primary target of their action. PGs generally inhibit lymphocyte function and proliferation, suppressing the immune response. PGE_2 depresses the humoral antibody response by inhibiting the differentiation of B lymphocytes into antibody-secreting plasma cells. PGE_2 acts on T lymphocytes to inhibit mitogen-stimulated proliferation and lymphokine release by sensitized cells. PGE_2 and TxA_2 also may play a role in T-lymphocyte development by regulating apoptosis of immature thymocytes. PGE_2 , acting via EP_2 and EP_4 , has been shown to interact with the programmed cell death ligand to restrain cytotoxic T-cell function and survival during chronic infection

in mice (Chen et al., 2015). The COX-2/ $\text{mPGES-1}/\text{PGE}_2$ pathway can regulate PD-L1 expression in tumor infiltrating myeloid cells (Prima et al 2017). Given the efficacy of blockade of this pathway in a range of cancers, the possibility that blockade of PGE_2 synthesis or action might augment this effect has been suggested. PGD_2 is a potent leukocyte chemoattractant, primarily through the DP_2 .

The LTs are potent mediators of inflammation. Deletion of either 5-LOX or FLAP reduces inflammatory responses in model systems. LTB_4 is a potent chemotactic agent for neutrophils, T lymphocytes, eosinophils, monocytes, dendritic cells, and possibly also mast cells (Bäck et al., 2011). LTB_4 stimulates the aggregation of eosinophils and promotes degranulation and the generation of superoxide. LTB_4 promotes adhesion of neutrophils to vascular endothelial cells and their transendothelial migration and stimulates synthesis of pro-inflammatory cytokines from macrophages and lymphocytes.

The CysLTs are chemotaxins for eosinophils and monocytes. They also induce cytokine generation in eosinophils, mast cells, and dendritic cells. At higher concentrations, these LTs also promote eosinophil adherence, degranulation, cytokine or chemokine release, and oxygen radical formation. In addition, CysLTs contribute to inflammation by increasing endothelial permeability, thus promoting migration of inflammatory cells to the site of inflammation.

Bronchial and Tracheal Muscle

A complex mixture of autacoids is released when sensitized lung tissue is challenged by the appropriate antigen, including COX-derived bronchodilator and bronchoconstrictor substances. Amongst these, TxA_2 , $\text{PGF}_{2\alpha}$, and PGD_2 contract, and PGE_2 and PGI_2 relax, bronchial and tracheal muscle. PGI_2 causes bronchodilation in most species; human bronchial tissue is particularly sensitive. PGI_2 antagonizes bronchoconstriction induced by other agents. PGD_2 appears to be the primary bronchoconstrictor prostanoid of relevance in humans. Polymorphisms in the genes for PGD_2 synthase and the TP have been associated with asthma in humans.

Roughly 10% of people given aspirin or NSAIDs develop bronchospasm. This appears attributable to a shift in AA metabolism to LT formation. This substrate diversion appears to involve COX-1, not COX-2. CysLTs are bronchoconstrictors that act principally on smooth muscle in the airways and are a thousand times more potent than histamine. They also stimulate bronchial mucus secretion and cause mucosal edema.

The CysLTs probably dominate during allergic constriction of the airway. Deficiency of 5-LOX leads to reduced influx of eosinophils in airways and attenuates bronchoconstriction. Furthermore, unlike COX inhibitors and histaminergic antagonists, CysLT receptor antagonists and 5-LOX inhibitors are effective in the treatment of human asthma (see Inhibitors of Eicosanoid Biosynthesis). The relatively slow LT metabolism in lung contributes to the long-lasting bronchoconstriction that follows challenge with antigen and may be a factor in the high bronchial tone that is observed in asthmatic patients in periods between acute attacks (see Chapter 40).

GI Smooth Muscle

Prostaglandin E_2 and PGF_2 stimulate contraction of the main longitudinal muscle from stomach to colon. PG endoperoxides, TxA_2 , and PGI_2 also produce contraction but are less active. Circular muscle generally relaxes in response to PGE_2 and contracts in response to $\text{PGF}_{2\alpha}$. The LTs have potent contractile effects. PGs reduce transit time in the small intestine and colon. Diarrhea, cramps, and reflux of bile have been noted in response to oral PGE. PGEs and PGFs stimulate the movement of water and electrolytes into the intestinal lumen. Such effects may underlie the watery diarrhea that follows their oral or parenteral administration. PGE_2 appears to contribute to the water and electrolyte loss in cholera, a disease that is somewhat responsive to therapy with NSAIDs.

GI Secretion

In the stomach, PGE_2 and PGI_2 contribute to increased mucus secretion (cytoprotection), reduced acid secretion, and reduced pepsin content. PGE_2 and its analogues also inhibit gastric damage caused by a variety of ulcerogenic agents and promote healing of duodenal and gastric ulcers (see Chapter 49). Although COX-1 may be the dominant source of such

cytoprotective PGs under physiological conditions, COX-2 predominates during ulcer healing. Selective inhibitors of COX-2 and deletion of the enzyme delay ulcer healing in rodents, but the impact of COX-2 inhibitors in humans is unclear. CysLTs, by constricting gastric blood vessels and enhancing production of pro-inflammatory cytokines, may contribute to the gastric damage.

Uterus

Strips of nonpregnant human uterus are contracted by $\text{PGF}_{2\alpha}$ and TxA_2 but are relaxed by PGEs. Sensitivity to the contractile response is most prominent before menstruation, whereas relaxation is greatest at midcycle. PGE_2 , together with oxytocin, is essential for the onset of parturition. PGI_2 and high concentrations of PGE_2 produce relaxation. The intravenous infusion of low concentrations of PGE_2 or $\text{PGF}_{2\alpha}$ to pregnant women produces a dose-dependent increase in uterine tone and in the frequency and intensity of rhythmic uterine contractions. PGEs and PGFs are used to terminate pregnancy. Uterine responsiveness to PGs increases as pregnancy progresses but remains smaller than the response to oxytocin.

Kidney

Cyclooxygenase-2-derived PGE_2 and PGI_2 increase medullary blood flow, resulting in pressure diuresis, and inhibit tubular sodium reabsorption (Hao and Breyer, 2007). Expression of medullary COX-2 is increased during high salt intake. COX-1-derived products promote salt excretion in the collecting ducts. Cortical COX-2-derived PGE_2 and PGI_2 increase renal blood flow and glomerular filtration through their local vasodilating effects and as part of the tubuloglomerular feedback mechanism that controls renin release. Expression of COX-2 in macula densa cells increases in conditions of low distal tubular flow during low dietary salt intake or volume depletion. COX-2-derived PGE_2 , and also possibly PGI_2 , results in increased renin release, leading to sodium retention and elevated blood pressure.

TxA_2 , generated at low levels in the normal kidney, has potent vasoconstrictor effects that reduce renal blood flow and glomerular filtration rate. Infusion of $\text{PGF}_{2\alpha}$ causes both natriuresis and diuresis. Conversely, $\text{PGF}_{2\alpha}$ may activate the renin-angiotensin system, contributing to elevated blood pressure. CYP epoxygenase products may regulate renal function. Both 20-HETE and the EETs are generated in renal tissue; 20-HETE constricts the renal arteries, while EETs mediate vasodilation and natriuresis.

Bartter syndrome is an autosomal recessive trait that manifests as hypokalemic metabolic alkalosis. The antenatal variant of Bartter syndrome is due to dysfunctional ROMK2 (Kir1.1), the K^+ channel that recycles K^+ into the tubular fluid. This syndrome also is known as *hyperPGE syndrome*. The relationship between dysfunctional ROMK2 and elevated PGE_2 synthesis is not clear; however, in patients with antenatal Bartter syndrome, inhibition of COX-2 ameliorates many of the clinical symptoms.

Eye

Prostaglandin $\text{F}_{2\alpha}$ induces constriction of the iris sphincter muscle, but its overall effect in the eye is to decrease intraocular pressure by increasing the aqueous humor outflow. A variety of FP agonists have proven effective in the treatment of open-angle glaucoma, a condition associated with the loss of COX-2 expression in the pigmented epithelium of the ciliary body (see Chapter 69).

Central Nervous System

Prostaglandin E_2 induces fever. The hypothalamus regulates the body temperature set point, which is elevated by endogenous pyrogens such as IL-1 β , IL-6, TNF- α , and interferons (Morrison and Nakamura, 2011). The response is mediated by coordinate induction of COX-2 and mPGES-1 in the endothelium of blood vessels in the preoptic hypothalamic area to form PGE_2 . PGE_2 can cross the blood-brain barrier and act on the EP_3 (and perhaps EP_1) on thermosensitive neurons, triggering the hypothalamus to elevate body temperature. Exogenous $\text{PGF}_{2\alpha}$ and PGI_2 induce fever but do not contribute to the endogenous pyretic response. PGD_2 appears to act on arachnoid trabecular cells in the basal forebrain to mediate an increase in extracellular adenosine that, in turn, facilitates induction of sleep. COX-2-derived prostanoids also have been implicated in the pathogenesis of several CNS degenerative disorders (e.g., Alzheimer disease, Parkinson disease; see Chapter 18).

Pain

Inflammatory mediators, including LTs and PGs, increase the sensitivity of nociceptors and potentiate pain perception. Centrally, both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli. Both PGE_2 , through the EP_1 and EP_4 and PGI_2 , via the IP, reduce the threshold to stimulation of nociceptors, causing “peripheral sensitization.” PGE_2 , and perhaps PGD_2 , PGI_2 , and $\text{PGF}_{2\alpha}$, can increase excitability in pain transmission neuronal pathways in the spinal cord, causing hyperalgesia and allodynia. LTB_4 also produces hyperalgesia. The release of these eicosanoids during the inflammatory process thus serves as an amplification system for the pain mechanism. The role of PGE_2 and PGI_2 in inflammatory pain is discussed in more detail in Chapter 38.

Endocrine System

The systemic administration of PGE_2 increases circulating concentrations of ACTH, growth hormone, prolactin, and gonadotropins. Other effects include stimulation of steroid production by the adrenals, stimulation of insulin release, and thyrotropin-like effects on the thyroid. PGE_2 works as part of a positive-feedback loop to induce oocyte maturation required for fertilization during and after ovulation. The critical role of $\text{PGF}_{2\alpha}$ in parturition relies on its ability to induce an oxytocin-dependent decline in progesterone levels. LOX metabolites also have endocrine effects. 12-HETE stimulates the release of aldosterone from the adrenal cortex and mediates a portion of the aldosterone release stimulated by AngII, but not that which occurs in response to ACTH.

Bone

Prostaglandins are strong modulators of bone metabolism. COX-1 is expressed in normal bone, while COX-2 is upregulated in settings such as inflammation and during mechanical stress. PGE_2 stimulates bone formation by increasing osteoblastogenesis and bone resorption via activation of osteoclasts.

Cancer

Pharmacological inhibition or genetic deletion of COX-2 restrains tumor formation in models of colon, breast, lung, and other cancers. Large human epidemiological studies reported that the incidental use of NSAIDs is associated with significant reductions in relative risk for developing these and other cancers. PGE_2 has been implicated as the primary pro-oncogenic prostanoid in multiple studies.

Therapeutic Uses

Inhibitors and Antagonists

The NSAIDs are used widely as anti-inflammatory drugs, whereas low-dose aspirin is employed frequently for cardioprotection (see Chapter 38). LT antagonists are useful clinically in the treatment of asthma, and FP agonists are used in the treatment of open-angle glaucoma (see Chapter 69). EP agonists are used to induce labor and to ameliorate gastric irritation owing to NSAIDs. DP_1 antagonists may be useful in offsetting the facial flushing associated with niacin. Orally active antagonists of LTC_4 and D_4 , which block the CysLT_1 are used in the treatment of asthma that is mild to moderately severe (see Chapter 40). Their effectiveness in patients with aspirin-induced asthma also has been shown.

Prostanoids and Their Analogues

Prostanoids have a short $t_{1/2}$ in the circulation, and their systemic administration produces significant adverse effects. Nonetheless, several prostanoids are of clinical utility in the following situations.

Labor and Therapeutic Abortion. Prostaglandin E_2 , $\text{PGF}_{2\alpha}$, and their analogues are used to induce labor at term and terminate pregnancy at any stage by promoting uterine contractions. These agents facilitate labor by promoting ripening and dilation of the cervix. Dinoprostone or misoprostol, synthetic analogues of PGE_2 and PGE_1 , are used for cervical ripening and induction of labor and as abortifacients in the second trimester of pregnancy. Misoprostol, in combination with the antiprogesterone mifepristone (RU486), is highly effective in the termination of pregnancy.

An analogue of $\text{PGF}_{2\alpha}$, carboprost tromethamine, is used to induce second-trimester abortions and to control postpartum hemorrhage that does not respond to conventional methods.

Maintenance of Patent Ductus Arteriosus. The ductus arteriosus in neonates is highly sensitive to vasodilation by PGE_1 . Maintenance of a patent ductus may be important hemodynamically in some neonates with congenital heart disease. PGE_1 (alprostadil) is highly effective for palliative therapy to maintain temporary patency until surgery can be performed. Apnea is observed in about 10% of neonates treated, particularly those who weigh less than 2 kg at birth.

Gastric Cytoprotection. Several PG analogues are used to suppress gastric ulceration. Misoprostol, a PGE_1 analogue, is approved for prevention of NSAID-induced gastric ulcers and is about as effective as the proton pump inhibitor omeprazole (Chapter 49).

Impotence. Prostaglandin E_1 (alprostadil), given as an intracavernous injection or urethral suppository, is a second-line treatment of erectile dysfunction. Phosphodiesterase 5 inhibitors (e.g., sildenafil, tadalafil, vardenafil, and avanafil; see Chapter 45) have superseded PGE_1 as the preferred treatment of this condition.

Pulmonary Hypertension. Long-term therapy with PGI_2 (epoprostenol), via continuous intravenous infusion, improves symptoms and can delay or preclude the need for lung or heart-lung transplantation in a number of patients. Several orally available PGI_2 analogues with longer $t_{1/2}$ have been used clinically. Iloprost can be inhaled or delivered by intravenous administration (injectable form is not available in the U.S.). Treprostinil ($t_{1/2} \sim 4$ h) may be delivered by continuous subcutaneous or intravenous infusion. Chapter 31 presents a comprehensive picture of the treatment of pulmonary artery hypertension.

Glaucoma. Latanoprost, a stable, long-acting $\text{PGF}_{2\alpha}$ derivative, was the first prostanoid used for glaucoma. Similar prostanoids with ocular hypotensive effects include bimatoprost, tafluprost, and travoprost. These drugs act as agonists at the FP and are administered as ophthalmic drops (see Chapter 69).

Platelet-Activating Factor

In 1971, Henson demonstrated that a soluble factor released from leukocytes caused platelets to aggregate. Benveniste and his coworkers characterized the factor as a polar lipid and named it *platelet-activating factor*. During this period, Muirhead described an antihypertensive polar renal lipid (APRL) produced by interstitial cells of the renal medulla that proved to be identical to PAF. Hanahan and coworkers then synthesized acetyl glyceryl ether phosphorylcholine (AGEPC) and determined that this phospholipid had chemical and biological properties identical to those of platelet activating factor (PAF). Independent determination of the structures of PAF and APRL showed them to be structurally identical to AGEPC. The commonly accepted name for this substance is PAF; however, its actions extend far beyond platelets.

Chemistry and Biosynthesis

Platelet-activating factor (1-*O*-alkyl-2-acetyl-*sn*-glycero-3-phosphocholine) represents a family of phospholipids because the alkyl group at position 1 can vary in length from 12 to 18 carbon atoms (Prescott et al., 2000). In human neutrophils, PAF consists predominantly of a mixture of the 16- and 18-carbon ethers, but its composition may change when cells are stimulated.

Synthesis of eicosanoids and PAF depends on PLA_2 activity. The major biosynthetic pathway for PAF, the remodeling pathway, involves the precursor 1-*O*-alkyl-2-acyl-glycerophosphocholine, a membrane lipid; the 2-acyl substituents include AA. PAF is synthesized from this substrate in two steps (Figure 37-5). The rate-limiting step is the second one, acetyl-coenzyme-A-lyso-PAF acetyltransferase. The synthesis of PAF may be stimulated during antigen-antibody reactions or by a variety of agents, including chemotactic peptides, thrombin, collagen, and other autacoids; PAF also can stimulate its own formation. Both the PL and acetyltransferase are Ca^{2+} -dependent enzymes; thus, PAF synthesis is regulated by the availability of Ca^{2+} . The inactivation of PAF is catalyzed by PAF-AHs. PAF is inactivated by PAF-AH-catalyzed hydrolysis of the acetyl group, generating Lyso-PAF, which is then converted to a 1-*O*-alkyl-2-acyl-glycerophosphocholine by an acyltransferase (McIntyre et al., 2009; Stafforini et al., 2003).

Synthesis of PAF also can occur *de novo* by transfer of a phosphocholine substituent to alkyl acetyl glycerol by a lyso-glycerophosphate acetyl-coenzyme A transferase. This pathway may contribute to physiological levels of PAF for normal cellular functions. PAF-like molecules can be formed from oxidized phospholipids (oxPLs) (Stafforini et al., 2003). These compounds are increased in settings of oxidant stress, such as cigarette smoking, and differ structurally from PAF in that they contain a fatty acid at the *sn*-1 position of glycerol joined through an ester bond and various short-chain acyl groups at the *sn*-2 position. oxPLs mimic the structure of PAF, bind to its receptor, and elicit the same responses. Unlike the synthesis of PAF, which is highly controlled, oxPL production is unregulated. Degradation of oxPLs by PAF-AH is therefore necessary to suppress toxicity. Increased levels of plasma PAF-AH have been reported in colon cancer, cardiovascular disease, and stroke.

Sites of PAF Synthesis

Platelet-activating factor is not stored in cells but is synthesized in response to stimulation. PAF is synthesized by platelets, neutrophils, monocytes, mast cells, eosinophils, renal mesangial cells, renal medullary cells, and vascular endothelial cells. Depending on cell type, PAF can either remain cell associated or be secreted. For example, PAF is released from monocytes but retained by leukocytes and endothelial cells. In endothelial cells,

Figure 37-5 Synthesis and degradation of PAF. RCOO^- is a mixture of fatty acids but is enriched in AA that may be metabolized to eicosanoids.

Mechanism of Action of PAF

Extracellular PAF exerts its actions by stimulating a specific GPCR (Honda et al., 2002). The PAF receptor couples to Gq (to activate the PLC-IP₃-Ca²⁺ pathway) and to Gi (to inhibit adenylyl cyclase). Consequent activation of PLs A₂, C, and D gives rise to second messengers, including AA-derived PGs, TxA₂, or LTs, which may function as mediators of the effects of PAF.

In addition, p38 mitogen-activated protein kinase is activated downstream of the PAF-receptor-Gq interaction, while extracellular signal-regulated kinase activation can occur via interaction of activated PAF receptor with Gq, Go, or their $\beta\gamma$ subunits, or via transactivation of the EGF receptor, leading to nuclear factor kappa B activation. PAF exerts many of its important pro-inflammatory actions without leaving its cell of origin. For example, PAF is synthesized in a regulated fashion by endothelial cells stimulated by inflammatory mediators. This PAF is presented on the surface of the endothelium, where it activates the PAF receptor on juxtaposed cells, including platelets, PMNs, and monocytes, and acts cooperatively with P selectin to promote adhesion. This function of PAF is important for orchestrating the interaction of platelets and circulating inflammatory cells with the inflamed endothelium.

Physiological and Pathological Functions of PAF

Platelet-activating factor generally is viewed as a mediator of pathological events and has been implicated in allergic asthma, endotoxic shock, acute pancreatitis, certain cancers, dermal inflammation, and inflammatory cardiovascular diseases such as atherosclerosis.

Inflammatory and Allergic Responses

Experimental administration of PAF reproduces many of the signs and symptoms in anaphylactic shock. However, the effects of PAF antagonists in the treatment of inflammatory and allergic disorders have been disappointing. In patients with asthma, PAF antagonists partially inhibit the bronchoconstriction induced by antigen challenge but not by challenges by methacholine, exercise, or inhalation of cold air. These results may reflect the complexity of these pathological conditions and the likelihood that other mediators contribute to the inflammation associated with these disorders.

Cardiovascular System

Platelet-activating factor is a potent vasodilator in most vascular beds; when administered intravenously, it causes hypotension. PAF-induced vasodilation is independent of effects on sympathetic innervation, the renin-angiotensin system, or AA metabolism and likely results from a combination of direct and indirect actions. PAF may, alternatively, induce vasoconstriction depending on the concentration, vascular bed, and involvement of platelets or leukocytes. For example, the intracoronary administration of very low concentrations of PAF increases coronary blood flow by a mechanism that involves the release of a platelet-derived vasodilator. Coronary blood flow is decreased at higher doses by the formation of intravascular aggregates of platelets or the formation of TxA₂. The pulmonary vasculature also is constricted by PAF, and a similar mechanism is thought to be involved.

Intradermal injection of PAF causes an initial vasoconstriction followed by a typical wheal and flare. PAF increases vascular permeability and edema in the same manner as histamine and bradykinin. The increase in permeability is due to contraction of venular endothelial cells, but PAF is more potent than histamine or bradykinin by three orders of magnitude.

Platelets

The PAF receptor is constitutively expressed on the surface of platelets. PAF potently stimulates platelet aggregation. The intravenous injection of PAF causes formation of intravascular platelet aggregates and

thrombocytopenia. Although this is accompanied by the release of TxA₂ and the granular contents of the platelet, PAF does not require the presence of TxA₂ or other aggregating agents to produce this effect. PAF antagonists fail to block thrombin-induced aggregation, even though they prolong bleeding time and prevent thrombus formation in some experimental models. Thus, PAF may contribute to thrombus formation, but it does not function as an independent mediator of platelet aggregation.

Leukocytes

Platelet-activating factor is a potent and common activator of inflammatory cells. PAF stimulates a variety of responses in PMNs (eosinophils, neutrophils, and basophils). PAF stimulates PMNs to aggregate, degranulate, and generate free radicals and LTs. PAF is a potent chemotactic for eosinophils, neutrophils, and monocytes and promotes PMN-endothelial adhesion contributing, along with other adhesion molecular systems, to leukocyte rolling, tight adhesion, and migration through the endothelial monolayer. PAF also stimulates basophils to release histamine, activates mast cells, and induces cytokine release from monocytes. In addition, PAF promotes aggregation of monocytes and degranulation of eosinophils.

Smooth Muscle

Platelet-activating factor contracts GI, uterine, and pulmonary smooth muscle. PAF enhances the amplitude of spontaneous uterine contractions; these contractions are inhibited by inhibitors of PG synthesis. PAF does not affect tracheal smooth muscle but contracts airway smooth muscle. When given by aerosol, PAF increases airway resistance as well as the responsiveness to other bronchoconstrictors. PAF also increases mucus secretion and the permeability of pulmonary microvessels.

Stomach

In addition to contracting the fundus of the stomach, PAF is the most potent known ulcerogen. When given intravenously, it causes hemorrhagic erosions of the gastric mucosa that extend into the submucosa.

Kidney

Platelet-activating factor decreases renal blood flow, glomerular filtration rate, urine volume, and excretion of Na⁺ without changes in systemic hemodynamics. PAF exerts a receptor-mediated biphasic effect on afferent arterioles, dilating them at low concentrations and constricting them at higher concentrations. The vasoconstrictor effect appears to be mediated, at least in part, by COX products, whereas vasodilation is a consequence of the stimulation of NO production by endothelium.

Other

Platelet-activating factor, a potent mediator of angiogenesis, has been implicated in breast and prostate cancer. PAF-AH deficiency has been associated with small increases in a range of cardiovascular and thrombotic diseases in some human populations.

PAF Receptor Antagonists

Several experimental PAF receptor antagonists exist that selectively inhibit the actions of PAF in vivo and in vitro. None has proven clinically useful. Thus, synthetic PAF, when administered in sufficient quantities, exerts a broad spectrum of effects. However, the evidence of its importance as an endogenous mediator remains to be established. Interestingly, inhibition of PAF-AH, which would be expected to elevate endogenous levels of PAF, was pursued as the protein also functions as a lipoprotein-associated PLA₂. Trials of an inhibitor, darapladib, failed to establish either clinical efficacy attributable to eicosanoid suppression or an adverse effect profile potentially attributable to increased levels of PAF (O'Donoghue et al., 2014).

- Uricosuric Agents

This chapter describes the non-steroidal anti-inflammatory drugs (NSAIDs) used to treat inflammation, pain, and fever and the drugs used for hyperuricemia and gout. The NSAIDs are first considered by class, then by groups of chemically similar agents described in more detail. Many of the basic properties of these drugs are summarized in Tables 38–1, 38–2, and 38–3.

The NSAIDs act by inhibiting the prostaglandin (PG) G/H synthase enzymes, colloquially known as the cyclooxygenases (COXs) (see Chapter 37). There are two forms, COX-1 and COX-2. The inhibition of COX-2 is thought to mediate, in large part, the antipyretic, analgesic, and anti-inflammatory actions of NSAIDs. Adverse reactions are largely caused by the inhibition of COX-1 and COX-2 in tissues in which they fulfill physiological functions, such as the GI tract, the kidney, and the cardiovascular system. Aspirin is the only irreversible inhibitor of the COX enzymes in clinical use. All other NSAIDs bind the COXs reversibly and act either by competing directly with arachidonic acid (AA) at the active site of COX-1 and COX-2 or by changing their steric confirmation in a way that alters their ability to bind arachidonic acid. Acetaminophen (paracetamol) is effective as an antipyretic and analgesic agent at typical doses that partly inhibit COXs and has only weak anti-inflammatory activity. Purposefully designed selective inhibitors of COX-2 (celecoxib, etoricoxib) are a subclass of NSAIDs; several of the older traditional NSAIDs, such as diclofenac and meloxicam (see Figure 38–1) also selectively inhibit COX-2 at therapeutic doses.

Inflammation, Pain, and Fever

Inflammation

The inflammatory process is the immune system's protective response to an injurious stimulus. It can be evoked by noxious agents, infections, and physical injuries, which release damage- and pathogen-associated molecules that are recognized by cells charged with immune surveillance (Tang et al., 2012). The ability to mount an inflammatory response is essential for survival in the face of environmental pathogens and injury. In some situations and diseases, inflammation may be exaggerated and sustained

HISTORICAL PERSPECTIVE

The history of aspirin provides an interesting example of the translation of a compound from the realm of herbal folklore to contemporary therapeutics. The use of willow bark and leaves to relieve fever has been attributed to Hippocrates but was most clearly documented by Edmund Stone in a 1763 letter to the president of the Royal Society. Similar properties were attributed to potions from meadowsweet (*Spiraea ulmaria*), from which the name aspirin is derived. Salicin was crystallized in 1829 by Leroux, and Pina isolated salicylic acid in 1836. In 1859, Kolbe synthesized salicylic acid, and by 1874, it was being produced industrially. It soon was being used for rheumatic fever and gout and as a general antipyretic. However, its unpleasant taste and adverse GI effects made it difficult to tolerate for more than short periods. In 1899, Hoffmann, a chemist at Bayer Laboratories, sought to improve the adverse effect profile of salicylic acid (which his father was taking with difficulty for arthritis). Hoffmann came across the earlier work of the French chemist Gerhardt, who had acetylated salicylic acid in 1853, apparently ameliorating its adverse effect profile, but without improving its efficacy, and therefore abandoned the project. Hoffmann resumed the quest, and Bayer began testing acetylsalicylic acid (ASA) in animals by 1899 and proceeded soon thereafter to human studies and the marketing of aspirin.

Acetaminophen was first used in medicine by von Mering in 1893. However, it gained popularity only after 1949, when it was recognized as the major active metabolite of both acetanilide and phenacetin. Acetanilide is the parent member of this group of drugs. It was introduced into medicine in 1886 under the name antifebrin by Cahn and Hepp, who had discovered its antipyretic action accidentally. However, acetanilide proved to be excessively toxic. A number of chemical derivatives were developed and tested. One of the more satisfactory of these was phenacetin. It was introduced into therapy in 1887 and was extensively employed in analgesic mixtures until it was implicated in analgesic abuse nephropathy, hemolytic anemia, and bladder cancer; it was withdrawn in the 1980s.

Abbreviations

AA: arachidonic acid
ACE: angiotensin-converting enzyme
ASA: acetylsalicylic acid/aspirin
AUC: area under the curve
COX: cyclooxygenase
CSF: cerebrospinal fluid
G6PD: glucose-6-phosphate dehydrogenase
GSH: glutathione
15(R)-HETE: 15(R)-hydroxyeicosatetraenoic acid
5-HIAA: 5-hydroxyindoleacetic acid
5HT: 5-hydroxytryptamine/serotonin
Ig: immunoglobulin
IL: interleukin
IM: intramuscular
IV: intravenous
LOX: lipoxygenase
LT: leukotriene
MI: myocardial infarction
NAC: N-acetylcysteine
NAPQI: N-acetyl-p-benzoquinone imine
NSAID: nonsteroidal anti-inflammatory drug
OAT: organic anion transporter
OTC: over the counter
PAF: platelet-activating factor
PG: prostaglandin
PGI₂: prostacyclin
PPI: proton pump inhibitor
TNF: tumor necrosis factor
Tx: thromboxane
UGT: uridine diphosphate glucuronosyltransferase
URAT: urate transporter
XO: xanthine oxidase

without apparent benefit and even with severe adverse consequences (e.g., hypersensitivity, autoimmune diseases, chronic inflammation). The inflammatory response is characterized mechanistically by

- transient local vasodilation and increased capillary permeability;
- infiltration of leukocytes and phagocytic cells; and
- resolution with or without tissue degeneration and fibrosis.

Many molecules are involved in the promotion and resolution of the inflammatory process. Histamine, bradykinin, 5HT, prostanoids, LTs, PAF, and an array of cytokines are important mediators (see Chapters 34, 37, and 39). Prostanoid biosynthesis is significantly increased in inflamed tissue. PGE₂ and prostacyclin (PGI₂) are the primary prostanoids that mediate inflammation. They increase local blood flow, vascular permeability, and leukocyte infiltration through activation of their respective receptors, EP₂ and IP. PGD₂, a major product of mast cells, contributes to inflammation in allergic responses, particularly in the lung.

Activation of endothelial cells plays a key role in recruiting circulating cells to inflammatory sites (Muller, 2011). Endothelial activation results in leukocyte rolling and adhesion as the leukocytes recognize newly expressed selectins, integrins, and adhesion molecules. PGE₂ and TxA₂ enhance leukocyte chemoattraction and endothelial adhesion.

The recruitment of inflammatory cells to sites of injury also involves the concerted interactions of the complement factors PAF, and eicosanoids such as LTB₄ (see Chapter 37). All can act as chemotactic agonists. Cytokines play essential roles in orchestrating the inflammatory process, especially TNF and IL-1. Several biological anti-inflammatory therapeutics target these cytokines or their signaling pathways (see Chapter 35). Other cytokines and growth factors (e.g., IL-2, IL-6, IL-8, granulocyte-macrophage colony-stimulating factor) contribute to manifestations of the inflammatory response. The concentrations of many of these factors are increased in the synovia of patients with inflammatory arthritis. Glucocorticoids interfere with the synthesis and actions of cytokines, such as IL-1 or TNF-α (see Chapter 35). Although some of the actions of these cytokines are accompanied by the release of PGs and TxA₂, COX inhibitors appear to block primarily their pyrogenic effects.

Figure 38-1 Classification of NSAIDs by chemical similarity (A), COX isoform selectivity (B), and plasma t_{1/2} (C). The COX selectivity chart is plotted from data published in Warner T, et al. Nonsteroid drug selectivities for cyclooxygenase-1 rather than cyclooxygenase-2 are associated with human gastrointestinal toxicity: a full in vitro analysis. *Proc Natl Acad Sci U S A*, 1999, 96:7563–7568; and FitzGerald GA, Patrono C. The coxibs, selective inhibitors of cyclooxygenase-2. *N Engl J Med*, 2001, 345:433–442.

Pain

Nociceptors, peripheral terminals of primary afferent fibers that sense pain, can be activated by various stimuli, such as heat, acids, or pressure. Inflammatory mediators released from nonneuronal cells during tissue injury increase the sensitivity of nociceptors and potentiate pain perception. Among these mediators are bradykinin, H^+ , 5HT, ATP, neurotrophins (nerve growth factor), LTs, and PGs. PGE_2 and PGI_2 reduce the threshold to stimulation of nociceptors, causing *peripheral sensitization*. Reversal of peripheral sensitization is thought to represent the mechanistic basis for the peripheral component of the analgesic activity of NSAIDs. NSAIDs may also have important central actions in the spinal cord and brain. Both COX-1 and COX-2 are expressed in the spinal cord under basal conditions and release PGs in response to peripheral pain stimuli.

Centrally active PGE_2 and perhaps also PGD_2 , PGI_2 , and $PGF_{2\alpha}$ contribute to *central sensitization*, an increase in excitability of spinal dorsal horn neurons that causes hyperalgesia and allodynia in part by disinhibition of glycinergic pathways (Chen et al., 2013). Central sensitization reflects the plasticity of the nociceptive system that is invoked by injury. This usually is reversible within hours to days following adequate responses of the nociceptive system (e.g., in postoperative pain). However, chronic inflammatory diseases may cause persistent modification of the architecture of the nociceptive system, which may lead to long-lasting changes in its responsiveness. These mechanisms contribute to chronic pain.

Fever

The hypothalamus regulates the set point at which body temperature is maintained. This set point is elevated in fever, reflecting an infection, or resulting from tissue damage, inflammation, graft rejection, or malignancy. These conditions all enhance formation of cytokines such as IL- 1β , IL-6, TNF- α , and interferons, which act as endogenous pyrogens. The initial phase of the thermoregulatory response to such pyrogens may be mediated by ceramide release in neurons of the preoptic area in the anterior hypothalamus (Sanchez-Alavez et al., 2006). The second phase is mediated by coordinate induction of COX-2 and formation of PGE_2 (Engblom et al., 2003). PGE_2 can cross the blood-brain barrier and acts on EP_3 and perhaps EP_1 receptors on thermosensitive neurons. This triggers the hypothalamus to elevate body temperature by promoting an increase in heat generation and a decrease in heat loss. NSAIDs suppress this response by inhibiting COX-2-dependent PGE_2 synthesis.

Nonsteroidal Anti-inflammatory Drugs

The NSAIDs are mechanistically classified as *isoform nonselective NSAIDs*, which inhibit both COX-1 and COX-2, and *COX-2-selective NSAIDs* (FitzGerald and Patrono, 2001). Most NSAIDs are competitive, noncompetitive, or mixed reversible inhibitors of the COX enzymes. Aspirin (ASA) is a noncompetitive, irreversible inhibitor because it acetylates the isozymes in the AA-binding channel. Acetaminophen, which is antipyretic and analgesic but largely devoid of anti-inflammatory activity, acts as a noncompetitive reversible inhibitor by reducing the peroxide site of the enzymes.

The majority of NSAIDs are organic acids with relatively low pK_a values. As organic acids, the compounds generally are well absorbed orally, highly bound to plasma proteins, and excreted either by glomerular filtration or by tubular secretion. They also accumulate in sites of inflammation, where the pH is lower, potentially confounding the relationship between plasma concentrations and duration of drug effect. Most COX-2-selective NSAIDs have a relatively bulky side group, which aligns with a large side pocket in the AA-binding channel of COX-2 but hinders its optimal orientation in the smaller binding channel of COX-1 (Smith et al., 2011). Both isoform nonselective NSAIDs and the COX-2-selective NSAIDs generally are hydrophobic drugs, a feature that allows them to access the hydrophobic AA-binding channel and results in shared pharmacokinetic characteristics. Again, aspirin and acetaminophen are exceptions to this rule.

Mechanism of Action

Cyclooxygenase Inhibition

The principal therapeutic effects of NSAIDs derive from their ability to inhibit PG production. The first enzyme in the PG synthetic pathway is COX, also known as PG G/H synthase. This enzyme converts AA to the unstable intermediates PGG_2 and PGH_2 and leads to the production of the prostanoids, TxA_2 , and a variety of PGs (see Chapter 37). COX-1, expressed constitutively in most cells, is the dominant source of prostanoids for housekeeping functions, such as hemostasis. Conversely, COX-2, induced by cytokines, shear stress, and tumor promoters, is the more important source of prostanoid formation in inflammation and perhaps in cancer (see Chapter 37). However, both enzymes contribute to the generation of autoregulatory and homeostatic prostanoids with important functions in normal physiology (see Chapter 37). The indiscriminate inhibition of both inflammatory and homeostatic prostanoids by NSAIDs explains mechanistically most adverse reactions to this drug class. For example, inhibition of COX-1 accounts largely for the gastric adverse events and bleeding that complicate therapy because COX-1 is the dominant cytoprotective isoform in gastric epithelial cells and forms TxA_2 in platelets, which amplifies platelet activation and constricts blood vessels at the site of injury. Similarly, COX-2-derived products play important roles in blood pressure regulation and act as endogenous inhibitors of hemostasis. Inhibition of COX-2 can cause or exacerbate hypertension and increases the likelihood of thrombotic events.

While the functional COX enzymes are sequence homodimers, they are configured as conformational heterodimers in which one of the monomers functions as the catalytic subunit with heme bound and the other, without heme, serves as the allosteric subunit. Most NSAIDs inhibit the catalytic subunits of COX-1 and COX-2. However, COX-2 inhibition by naproxen, and flurbiprofen occurs primarily on the allosteric subunit (Dong et al., 2011; Zou et al., 2012).

Irreversible Cyclooxygenase Inhibition by Aspirin

Aspirin covalently acetylates the catalytic subunits of the COX-1 and COX-2 dimers, irreversibly inhibiting COX activity. This is an important distinction from all the other NSAIDs because the duration of aspirin's effects is related to the turnover rate of the COXs in different target tissues.

The importance of enzyme turnover in recovery from aspirin action is most notable in platelets, which, being anucleate, have a markedly limited capacity for protein synthesis. Thus, the consequences of inhibition of platelet COX-1 last for the lifetime of the platelet. Inhibition of platelet COX-1-dependent TxA_2 formation therefore is cumulative with repeated doses of aspirin (at least as low as 30 mg/d) and takes 8–12 days (the platelet turnover time) to recover fully once therapy has been stopped. Importantly, even a partially recovered platelet pool—just a few days after the last aspirin dose—may afford recovery of sufficient hemostatic integrity for some types of elective surgery to be performed. However, such a partial platelet function also may predispose noncompliant patients on low-dose aspirin for antiplatelet therapy to thrombotic events. The unique sensitivity of platelets to inhibition by low doses of aspirin is related to their presystemic inhibition in the portal circulation before aspirin is deacetylated to salicylate on first pass through the liver (Pedersen and FitzGerald, 1984). In contrast to aspirin, salicylic acid has no acetylating capacity. It is a relatively weak, reversible inhibitor of COX. Salicylic acid derivatives, rather than the acid, are available for clinical use.

The COXs are configured such that the active site is accessed by the AA substrate via a hydrophobic channel. Aspirin acetylates serine 529 of COX-1, located high up in the hydrophobic channel. Interposition of the bulky acetyl residue prevents the binding of AA to the active site of the enzyme and thus impedes the ability of the enzyme to make PGs. Aspirin acetylates a homologous serine at position 516 in COX-2. Although covalent modification of COX-2 by aspirin also blocks the COX activity of this isoform, an interesting property not shared by COX-1 is that acetylated COX-2 synthesizes 15(R)-HETE. This may be metabolized, at least in vitro, by 5-LOX to yield 15-epi-lipoxin A_4 , which has anti-inflammatory properties in model systems (see Chapter 37).

Selective Inhibition of Cyclooxygenase 2

The chronic use of the NSAIDs is limited by their poor GI tolerability. Selective inhibitors of COX-2 were developed to afford efficacy similar to traditional NSAIDs with better GI tolerability (FitzGerald and Patrono, 2001). Six such COX-2 inhibitors, the coxibs, were initially approved for clinical use: celecoxib, rofecoxib, valdecoxib (approved in the U.S.) and its prodrug parecoxib, etoricoxib, and lumiracoxib. Most coxibs have been either restricted in their use or withdrawn from the market in view of their adverse cardiovascular risk profile (Grosser et al., 2010). Celecoxib currently is the only COX-2 inhibitor licensed for use in the U.S. Some older NSAID compounds—diclofenac, etodolac, meloxicam, and nimesulide (the last not available in the U.S.)—exhibit selectivity for COX-2 that is close to that of celecoxib (Figure 38–1).

ADME

Absorption. The NSAIDs are rapidly absorbed following oral ingestion, and peak plasma concentrations are reached within 2–3 h. The poor aqueous solubility of most NSAIDs often is reflected by a less-than-proportional increase in the AUC of plasma concentration–time curves, due to incomplete dissolution, when the dose is increased. Food intake may delay absorption and systemic availability (i.e., fenoprofen, sulindac). Antacids, commonly prescribed to patients on NSAID therapy, variably delay absorption. Some compounds (e.g., diclofenac, nabumetone) undergo first-pass or presystemic elimination. Aspirin begins to acetylate platelets within minutes of reaching the presystemic circulation (Pedersen and FitzGerald, 1984).

Distribution. Most NSAIDs are extensively bound (95%–99%) to plasma proteins, usually albumin. Conditions that alter plasma protein concentration may result in an increased free drug fraction with potential toxic effects. Highly protein bound NSAIDs have the potential to displace other drugs if they compete for the same binding sites. Most NSAIDs are distributed widely throughout the body and readily penetrate arthritic joints, yielding synovial fluid concentrations in the range of half the plasma concentration (i.e., ibuprofen, naproxen, piroxicam) (Day et al., 1999). Most NSAIDs achieve sufficient concentrations in the CNS to have a central analgesic effect. Celecoxib is particularly lipophilic and moves readily into the CNS. Multiple NSAIDs are marketed in formulations for topical application on inflamed or injured joints. However, direct transport of topically applied NSAIDs into inflamed tissues and joints appears to be minimal, and detectable concentrations in synovial fluid of some agents (i.e., diclofenac) following topical use are primarily attained via dermal absorption and systemic circulation. Methods designed to enhance transdermal delivery, such as iontophoresis or chemical penetration enhancers, are under investigation. Topical application is also being explored as a delivery route for drug combinations containing narcotics and NSAIDs.

Metabolism and Excretion. Hepatic biotransformation and renal excretion are the principal routes of metabolism and elimination of the majority of NSAIDs. Plasma $t_{1/2}$ varies considerably among NSAIDs. Ibuprofen, diclofenac, and acetaminophen have a $t_{1/2}$ of 1–4 h, while piroxicam has a $t_{1/2}$ of about 50 h at steady state. Naproxen has a comparatively long but highly variable $t_{1/2}$ ranging from 9 to 25 h. Genetic variation in the major metabolizing enzymes and variation in the composition of intestinal microbiota may contribute to variability in metabolism and elimination. Elimination pathways frequently involve oxidation or hydroxylation. Acetaminophen, at therapeutic doses, is oxidized only to a small degree to form traces of the highly reactive metabolite NAPQI. Following overdose, however, the principal metabolic pathways are saturated, and hepatotoxic NAPQI concentrations can be formed (see Figure 4–5). Several NSAIDs or their metabolites are glucuronidated or otherwise conjugated. In some cases, such as the propionic acid derivatives naproxen and ketoprofen, the glucuronide metabolites can hydrolyze back to form the active parent drug when the metabolite is not removed efficiently due to renal insufficiency or competition for renal excretion with other drugs. This may prolong elimination of the NSAID significantly. In general, NSAIDs are not recommended in the setting of advanced hepatic or renal disease due to their adverse pharmacodynamic effects. NSAIDs usually are not removed by

hemodialysis due to their extensive plasma protein binding; salicylic acid is an exception to this rule.

Therapeutic Uses

The NSAIDs are antipyretic, analgesic, and anti-inflammatory, with the exception of acetaminophen, which is antipyretic and analgesic but is largely devoid of anti-inflammatory activity.

Inflammation

The NSAIDs provide mostly symptomatic relief from pain and inflammation associated with musculoskeletal disorders, such as rheumatoid arthritis and osteoarthritis. Some NSAIDs are approved for the treatment of ankylosing spondylitis and gout. Patients with more debilitating disease may not respond adequately to full therapeutic doses of NSAIDs and may require aggressive therapy with second-line agents.

Pain

The NSAIDs are effective against inflammatory pain of low-to-moderate intensity. Although their maximal efficacy is generally less than the opioids, NSAIDs lack the unwanted adverse effects of opiates in the CNS, including respiratory depression and the potential for development of physical dependence. Coadministration of NSAIDs can reduce the opioid dose needed for sufficient pain control and reduce the likelihood of adverse opioid effects. For example, acetaminophen can be prescribed in combination with hydrocodone. NSAIDs do not change the perception of sensory modalities other than pain. NSAIDs are particularly effective when inflammation has caused sensitization of pain perception (see other discussion in this section on inflammation, pain, and fever). Thus, post-operative pain or pain arising from inflammation, such as arthritic pain, is controlled well by NSAIDs, whereas pain arising from the hollow viscera usually is not relieved. An exception to this is menstrual pain. Treatment of menstrual pain with NSAIDs has met with considerable success because cramps and other symptoms of primary dysmenorrhea are caused by the release of PGs by the endometrium during menstruation. NSAIDs are commonly used to treat migraine attacks and can be combined with drugs such as the triptans or with antiemetics to aid relief of the associated nausea. NSAIDs generally lack efficacy in neuropathic pain.

Fever

Antipyretic therapy is reserved for patients in whom fever in itself may be deleterious and for those who experience considerable relief when fever is lowered. NSAIDs reduce fever in most situations, but not the circadian variation in temperature or the rise in response to exercise or increased ambient temperature.

Fetal Circulatory System

The PGs are implicated in the maintenance of patency of the ductus arteriosus, and indomethacin, ibuprofen, and other NSAIDs have been used in neonates to close the inappropriately patent ductus. Conversely, infusion of prostaglandin analogues maintains ductal patency after birth (see Chapter 37).

Cardioprotection

Ingestion of aspirin prolongs bleeding time. This effect is due to irreversible acetylation of platelet COX and the consequent inhibition of platelet function. It is the permanent suppression of platelet TxA_2 formation that is thought to underlie the cardioprotective effect of aspirin.

Aspirin reduces the risk of serious vascular events in high-risk patients (e.g., those with previous myocardial infarction) by 20%–25%. The reduction of subsequent thrombotic strokes is somewhat less, roughly 10%–15% (Antithrombotic Trialists' Collaboration et al., 2009). Low-dose aspirin (≤ 100 mg/d) is associated with a lower risk for GI adverse events than higher doses (e.g., 325 mg/d) and is often used following percutaneous coronary intervention (Xian et al., 2015). Low doses of aspirin are associated with a small (roughly 2-fold) but detectable increase in the incidence of serious GI bleeds and intracranial bleeds in placebo-controlled trials. The benefit from aspirin, however, outweighs these risks in the case of secondary prevention of cardiovascular disease. The issue is much more nuanced in patients who have never had a serious atherothrombotic

event (primary prevention); here, prevention of myocardial infarction by aspirin is numerically balanced by the serious GI bleeds it precipitates (Patrono, 2015). Given their relatively short $t_{1/2}$ and reversible COX inhibition, most other NSAIDs are not thought to afford cardioprotection. Data suggest that cardioprotection is lost when combining low-dose aspirin with NSAIDs through a drug-drug interaction at the aspirin target site in platelet COX-1 (Catella-Lawson et al., 2001; Farkouh et al., 2004; Li et al., 2014). COX-2-selective NSAIDs are devoid of antiplatelet activity, as mature platelets do not express COX-2.

Other Clinical Uses

Systemic Mastocytosis. Systemic mastocytosis is a condition in which there are excessive mast cells in the bone marrow, reticuloendothelial system, GI system, bones, and skin (Theoharides et al., 2015). In patients with systemic mastocytosis, PGD_2 , released from mast cells is the major mediator of severe episodes of flushing, vasodilation, and hypotension; this PGD_2 effect is resistant to antihistamines. The addition of aspirin or ketoprofen (off-label use) may be beneficial in patients with high levels of urinary PGD metabolites who have flushing and angioedema. However, NSAIDs can cause degranulation of mast cells, so blockade with histamine receptor antagonists should be established before NSAIDs are initiated.

Niacin Tolerability. Large doses of niacin (nicotinic acid) effectively lower serum cholesterol levels, reduce low-density lipoprotein, and raise high-density lipoprotein (see Chapter 33). However, niacin induces intense facial flushing mediated largely by release of PGD_2 from the skin, which can be inhibited by treatment with aspirin (Song et al., 2012).

Bartter Syndrome. Bartter syndrome includes a series of rare disorders (frequency $\leq 1/100,000$ persons) characterized by hypokalemic, hypochloremic metabolic alkalosis with normal blood pressure and hyperplasia of the juxtaglomerular apparatus. Fatigue, muscle weakness, diarrhea, and dehydration are the main symptoms. Distinct variants are caused by mutations in a $Na^+-K^+-2Cl^-$ cotransporter, an apical ATP-regulated K^+

channel, a basolateral Cl^- channel, a protein (barttin) involved in cotransporter trafficking, and the extracellular Ca^{2+} -sensing receptor. Renal COX-2 is induced, and biosynthesis of PGE_2 is increased. Treatment with indomethacin, combined with potassium repletion and spironolactone, is associated with improvement in the biochemical derangements and symptoms. Selective COX-2 inhibitors also have been used (Nusing et al., 2001).

Cancer Chemoprevention. Epidemiological studies suggested that daily use of aspirin is associated with a 24% decrease in the incidence of colon cancer (Rothwell et al., 2010). Similar observations have been made with NSAID use in this and other cancers. NSAIDs have been used in patients with familial adenomatous polyposis, an inherited disorder characterized by multiple adenomatous colon polyps developing during adolescence and the inevitable occurrence of colon cancer by the sixth decade.

Adverse Effects of NSAID Therapy

Adverse events common to aspirin and NSAIDs are outlined in Table 38–1. To minimize potential adverse events of NSAIDs, the lowest effective dose should be used for the shortest feasible length of time. Age generally is correlated with an increased probability of developing serious adverse reactions to NSAIDs, and caution is warranted in choosing a lower starting dose for elderly patients. NSAIDs are labeled with a black-box warning related to cardiovascular risks and are specifically contraindicated following coronary artery bypass graft (CABG) surgery.

Gastrointestinal

The most common symptoms associated with these drugs are GI (~40% of patients), including dyspepsia, abdominal pain, anorexia, nausea, and diarrhea. However, these symptoms are not predictive of gastric or intestinal lesions such as subepithelial hemorrhages, erosions, and ulcers, which can be endoscopically detected in about 30%–50% of NSAID users, but are often asymptomatic and tend to heal spontaneously. Serious complications—bleeding, perforation, or obstruction—occur at an annual

TABLE 38–1 ■ SOME SHARED ADVERSE EFFECTS OF NSAIDS^a

SYSTEM	MANIFESTATIONS
Gastrointestinal	Abdominal pain, bleeding, constipation, diarrhea, dyspepsia, dysphagia, eructation, ^b esophageal stricture/ulceration, esophagitis, flatulence, gastritis, hematemesis, ^b melena, ^b nausea, odynophagia, perforation, pyrosis, stomatitis, ulcers, vomiting, xerostomia ^b
Platelets	Inhibited platelet activation, ^b propensity for bruising, ^b increased risk of hemorrhage, ^b platelet dysfunction, ^b thrombocytopenia ^b
Renal	Azotemia, ^b cystitis, ^b dysuria, ^b hematuria, hyponatremia, interstitial nephritis, nephrotic syndrome, ^b oliguria, ^b polyuria, ^b renal failure, renal papillary necrosis, proteinuria, salt and water retention, hypertension, worsening of renal function in renal/cardiac/cirrhotic patients, ↓ effectiveness of antihypertensives and diuretics, hyperkalemia, ^b ↓ urate excretion (especially with aspirin)
Cardiovascular	Edema, ^b heart failure, ^c hypertension, MI, ^c palpitations, ^b premature closure of ductus arteriosus, sinus tachycardia, ^b stroke, ^c thrombosis, ^c vasculitis ^b
Neurologic	Anorexia, ^b anxiety, ^b aseptic meningitis, confusion, ^b depression, dizziness, drowsiness, ^b headache, insomnia, ^b malaise, ^b paresthesias, tinnitus, seizures, ^b syncope, ^b vertigo ^b
Reproductive	Prolongation of gestation, inhibition of labor, delayed ovulation
Hypersensitivity	Anaphylactoid reactions, angioedema, severe bronchospasm, urticaria, flushing, hypotension, shock
Hematologic	Anemia, agranulocytosis, aplastic anemia, ^b hemolytic anemia, ^b leukopenia ^b
Hepatic	Elevated enzymes, hepatitis, hepatic failure, ^b jaundice
Dermatologic	Diaphoresis, ^b exfoliative dermatitis, photosensitivity, ^b pruritus, purpura, ^b rash, Stevens-Johnson syndrome, toxic epidermal necrolysis, urticaria
Respiratory	Dyspnea, ^b hyperventilation (salicylates)
Other	Alopecia, ^b blurred vision, ^b conjunctivitis, ^b epistaxis, ^b fever, ^b hearing loss, ^b pancreatitis, ^b paresthesias, visual disturbance, ^b weight gain ^b

^bReported for most, but not all, NSAIDs.

^cWith the exception of low-dose aspirin.

rate of 1%–2% in regular NSAID users. Many patients who develop a serious upper GI adverse event while receiving NSAID therapy are asymptomatic prior to diagnosis. The risk is particularly high in those with *Helicobacter pylori* infection, heavy alcohol consumption, or other risk factors for mucosal injury, including the concurrent use of glucocorticoids. All selective COX-2 inhibitors are less prone to induce gastric ulcers than equally efficacious doses of isoform nonselective NSAIDs (Sostres et al., 2013).

Several mechanisms contribute to NSAID-induced GI complications (see Chapter 37). Inhibition of COX-1 in gastric epithelial cells depresses mucosal cytoprotective PGs, especially PGI₂ and PGE₂. These eicosanoids inhibit acid secretion by the stomach, enhance mucosal blood flow, and promote the secretion of cytoprotective mucus in the intestine. COX-2 also contributes to constitutive formation of these PGs by human gastric epithelium, and products of COX-2 may contribute to ulcer healing. Another factor that may play a part in the formation of ulcers is the local irritation from contact of orally administered NSAIDs—most of which are organic acids—with the gastric mucosa. However, the incidence of serious GI adverse events is not significantly reduced by formulations devised to limit drug contact with the gastric mucosa, such as enteric coating or effervescent solutions, suggesting that the contribution of direct irritation to the overall risk is minor. Platelet inhibition by NSAIDs increases the likelihood of bleeds when mucosal damage has occurred. Coadministration of proton pump inhibitors or H₂ antagonists in conjunction with NSAIDs reduces the rate of duodenal and gastric ulceration (see Chapter 49, Figure 49-1).

Cardiovascular

The COX-2-selective NSAIDs were developed to improve GI safety. However, COX-2 inhibitors depress formation of PGI₂ but do not inhibit the COX-1-catalyzed formation of platelet TxA₂. PGI₂ inhibits platelet aggregation and constrains the effect of prothrombotic and atherogenic stimuli by TxA₂ (Grosser et al., 2006, 2010, 2017), and renal PGI₂ and PGE₂ formed by COX-2 contribute to arterial pressure homeostasis (see Chapter 37). Genetic deletion of the PGI₂ receptor, IP, in mice augments the thrombotic response to endothelial injury, accelerates experimental atherogenesis, increases vascular proliferation, and adds to the effect of hypertensive stimuli (Cheng et al., 2002, 2006; Egan et al., 2004; Kobayashi et al., 2004). Tissue-specific genetic deletion of COX-2 in the vasculature accelerates the response to thrombotic stimuli and raises blood pressure (Yu et al., 2012). Together, these mechanisms would be expected to alter the cardiovascular risk of humans, as COX-2 inhibition in humans depresses PGI₂ synthesis (Catella-Lawson et al., 1999; McAdam et al., 1999). Indeed, a human mutation of the IP, which disrupts its signaling, is associated with increased cardiovascular risk (Arehart et al., 2008).

Clinical trials—with celecoxib, valdecoxib (withdrawn), and rofecoxib (withdrawn)—revealed an increase in the incidence of myocardial infarction, stroke, and vascular death by approximately 1.4-fold (Coxib and Traditional NSAID Trialists' Collaboration et al., 2013). The risk extends to diclofenac, which is almost as COX-2 selective as celecoxib, and to some of the other older NSAIDs. An exception in some individuals may be naproxen. There is considerable between-person variation in the $t_{1/2}$ of naproxen, and platelet inhibition might be anticipated throughout the dosing interval in some, but not all, individuals on naproxen (Capone et al., 2005). While this is supported by randomized controlled trials (Coxib and Traditional NSAID Trialists' Collaboration et al., 2013), identifying individuals who fall into the long-acting group is currently not practical in clinical routine. The FDA has determined that the data differentiating the risk between distinct NSAIDs is not sufficient to distinguish between drugs on the regulatory level; thus, a cardiovascular risk warning is included on the label of all NSAIDs (U.S. Food and Drug Administration, 2015). Similarly, all NSAIDs share a class black-box warning contraindicating their use for the treatment of perioperative pain in the setting of CABG surgery.

The NSAIDs with selectivity for COX-2 should be reserved for patients at high risk for GI complications. The cardiovascular risk appears to be conditioned by factors influencing drug exposure, such as dose, $t_{1/2}$, degree of COX-2 selectivity, potency, and treatment duration. Thus, the lowest possible dose should be prescribed for the shortest possible period.

Blood Pressure and Renal Adverse Events

All NSAIDs have been associated with renal and renovascular adverse events. Up to 5% of regular NSAID users can be expected to develop hypertension. Clinical studies suggest that hypertensive complications occur more commonly in patients treated with COX-2-selective than with nonselective NSAIDs. Heart failure risk is roughly doubled.

The NSAIDs have little effect on renal function or blood pressure in healthy human subjects because of the redundancy of systems that regulate renal function. In situations that challenge the regulatory systems, such as dehydration, hypovolemia, congestive heart failure, hepatic cirrhosis, chronic kidney disease, and other states of activation of the sympathoadrenal or renin-angiotensin systems, regulation of renal function by PG formation becomes crucial (see Chapter 37). NSAIDs impair the PG-induced inhibition of both the reabsorption of Cl[−] and the action of antidiuretic hormone, which may result in the retention of salt and water. Inhibition of COX-2-derived PGs that contribute to the regulation of renal medullary blood flow may lead to a rise in blood pressure, increasing the risk of cardiovascular thrombotic events and heart failure. NSAIDs promote reabsorption of K⁺ as a result of decreased availability of Na⁺ at distal tubular sites and suppression of the PG-induced secretion of renin. The last effect may account in part for the usefulness of NSAIDs in the treatment of Bartter syndrome (see Bartter Syndrome section).

Analgesic Nephropathy. Analgesic nephropathy is a condition of slowly progressive renal failure, decreased concentrating capacity of the renal tubule, and sterile pyuria. Risk factors are the chronic use of high doses of combinations of NSAIDs and frequent urinary tract infections. If recognized early, discontinuation of NSAIDs may permit recovery of renal function.

Pregnancy

Myometrial COX-2 expression and levels of PGE₂ and PGF_{2α} increase markedly in the myometrium during labor. Prolongation of gestation by NSAIDs has been demonstrated in humans. Some NSAIDs, particularly indomethacin, have been used off label to stop preterm labor. However, this use is associated with closure of the ductus arteriosus and impaired fetal circulation in utero, particularly in fetuses older than 32 weeks of gestation. COX-2-selective inhibitors have been used off label as tocolytic agents; this use has been associated with stenosis of the ductus arteriosus and oligohydramnios. Low-dose aspirin (81 mg/d) reduces the risk of preeclampsia by 24% when used as (off-label) preventive medication after 12 weeks of gestation in women who are at high risk (LeFevre and Force, 2014).

Hypersensitivity

Hypersensitivity symptoms to aspirin and NSAIDs range from vasomotor rhinitis, generalized urticaria, and bronchial asthma to laryngeal edema, bronchoconstriction, flushing, hypotension, and shock. Aspirin intolerance (including aspirin-associated asthma) is a contraindication to therapy with any other NSAID because of cross sensitivity. Although less common in children, this cross sensitivity may occur in 10%–25% of patients with asthma, nasal polyps, or chronic urticaria and in 1% of apparently healthy individuals. It is provoked by even low doses (<80 mg) of aspirin and apparently involves COX inhibition. Treatment of aspirin hypersensitivity is similar to that of other severe hypersensitivity reactions, with support of vital organ function and administration of epinephrine.

Aspirin Resistance

All forms of treatment failure with aspirin have been collectively called *aspirin resistance*, but pharmacological resistance to aspirin is rare. Pseudoresistance, reflecting delayed and reduced drug absorption, complicates enteric-coated, but not immediate-release aspirin administration (Grosser et al., 2013).

Hepatotoxicity

Liver injury occurs in 17% of adults with unintentional acetaminophen overdose (Blieden et al., 2014). Liver toxicity from therapeutic doses of acetaminophen is extremely rare (see Acetaminophen section). By contrast, therapeutic dosing of diclofenac may be complicated by hepatotoxicity.

While the entire class of NSAIDs has a rate of less than 1 liver injury per 100,000 patients on average, chronic consumption of diclofenac is associated with a risk of 6–11 liver injuries per 100,000 users (Bjornsson et al., 2013; de Abajo et al., 2004) (see Diclofenac section). NSAIDs are not recommended in advanced hepatic or renal disease.

Reye Syndrome

Due to the possible association with Reye syndrome, aspirin and other salicylates are contraindicated in children and young adults less than 20 years of age with viral illness–associated fever (Schrör, 2007). Reye syndrome, a severe and often fatal disease, is characterized by the acute onset of encephalopathy, liver dysfunction, and fatty infiltration of the liver and other viscera. Although a mechanistic understanding is lacking, the epidemiologic association between aspirin use and Reye syndrome is sufficiently strong that aspirin and bismuth subsalicylate labels must indicate the risk. As the use of aspirin in children has declined dramatically, so has the incidence of Reye syndrome. Acetaminophen and ibuprofen have not been implicated in Reye syndrome and are the agents of choice for antipyresis in children and youths.

Drug Interactions

Refer to the individual product labels for a comprehensive listing of NSAID drug-drug interactions.

Concomitant NSAIDs and Low-Dose Aspirin

Many patients consume both an NSAID for chronic pain and low-dose aspirin for cardioprotection. Epidemiological studies suggest that this combination therapy increases significantly the likelihood of GI adverse events over either class of NSAID alone. In addition, prior occupancy of platelet COX-1 by the NSAID can impede access of aspirin to its acetylation target Ser 529 and prevents irreversible inhibition of platelet function (Catella-Lawson et al., 2001). This has been unequivocally shown to occur with ibuprofen and naproxen and may also affect other isoform nonselective NSAIDs (Li et al., 2014). This drug-drug interaction may undermine the cardioprotective effect of aspirin. Celecoxib is unlikely to cause this drug-drug interaction *in vivo*, but confers a direct cardiovascular hazard (Grosser et al., 2017). Thus, pain management in patients with preexisting cardiovascular disease remains a particular challenge because of the cardiovascular adverse effects of NSAIDs and the risk of drug-drug interactions that might undermine the antiplatelet effects of aspirin.

Other Drug-Drug Interactions

The ACE inhibitors act, at least partly, by preventing the breakdown of kinins that stimulate PG production (see Figure 39–4). Thus, NSAIDs may attenuate the effectiveness of ACE inhibitors by blocking the production of vasodilator and natriuretic PGs. The combination of NSAIDs and ACE inhibitors also can produce marked hyperkalemia, leading to cardiac arrhythmia, especially in the elderly and in patients with hypertension, diabetes mellitus, or ischemic heart disease. Corticosteroids and selective serotonin reuptake inhibitors may increase the frequency or severity of GI complications when combined with NSAIDs.

The NSAIDs may augment the risk of bleeding in patients receiving warfarin both because almost all NSAIDs suppress normal platelet function temporarily during the dosing interval and because some NSAIDs also increase warfarin levels by interfering with its metabolism. Thus, concurrent administration should be avoided.

Many NSAIDs are highly bound to plasma proteins, so they may displace other drugs from their binding sites. Such interactions can occur in patients given salicylates or other NSAIDs together with warfarin, sulfonylurea hypoglycemic agents, or methotrexate; the dosage of such agents may require adjustment to prevent toxicity. Patients taking lithium should be monitored because NSAIDs, including aspirin, reduce the renal excretion of this drug and can lead to toxicity.

Pediatric and Geriatric Use

Therapeutic Uses in Children

Therapeutic uses for NSAIDs in children include fever (acetaminophen, ibuprofen); pain (acetaminophen, ibuprofen); postoperative pain

(ketorolac injection [single-dose only]); inflammatory disorders, such as juvenile arthritis (celecoxib, etodolac, meloxicam, naproxen, oxaprozin, tolmetin) and Kawasaki disease (off-label high-dose aspirin); and relief of ocular itching due to seasonal allergic rhinitis and postoperative inflammation after cataract extraction (ketorolac ophthalmic solution).

Kawasaki Disease. Aspirin generally is avoided in pediatric populations due to its potential association with Reye syndrome (see Reye Syndrome). However, high doses of aspirin (30–100 mg/kg/d) are used to treat children during the acute phase of Kawasaki disease, followed by low-dose antiplatelet therapy in the subacute phase.

Pharmacokinetics in Children

The NSAID dosing recommendations frequently are based on extrapolation of pharmacokinetic data from adults or children older than 2 years, and there are often insufficient data for dose selection in younger infants. For example, the pharmacokinetics of the most commonly used NSAID in children, acetaminophen, differ substantially between the neonatal period and older children or adults. The systemic bioavailability of rectal acetaminophen formulations in neonates and preterm babies is higher than in older patients. Acetaminophen clearance is reduced in preterm neonates, probably due to their immature glucuronide conjugation system (sulfation is the principal route of biotransformation at this age). Therefore, acetaminophen dosing intervals need to be extended (8–12 h) or daily doses reduced to avoid accumulation and liver toxicity.

Aspirin elimination also is delayed in neonates and young infants compared to adults, raising the risk of accumulation. Disease also may affect NSAID disposition in children. For example, ibuprofen plasma concentrations are reduced and clearance increased (~80%) in children with cystic fibrosis. This is probably related to the GI and hepatic pathologies associated with this disease. Aspirin's kinetics are markedly altered during the febrile phase of rheumatic fever or Kawasaki vasculitis. The reduction in serum albumin associated with these conditions causes an elevation of the free salicylate concentration, which may saturate renal excretion and result in salicylate accumulation to toxic levels. In addition to dose reduction, monitoring of the free drug may be warranted in these situations.

Pharmacokinetics in the Elderly

The clearance of many NSAIDs is reduced in the elderly due to changes in hepatic metabolism and creatine clearance. NSAIDs with a long $t_{1/2}$ and primarily oxidative metabolism (i.e., piroxicam, tenoxicam, celecoxib) have elevated plasma concentrations in elderly patients. For example, plasma concentrations after the same dose of celecoxib may rise up to 2-fold higher in patients older than 65 years than in patients younger than 50 years of age, warranting dose adjustment. The capacity of plasma albumin to bind drugs is diminished in older patients and may result in higher concentrations of unbound NSAIDs. For example, free naproxen concentrations are markedly increased in older patients, although total plasma concentrations essentially are unchanged, and the higher susceptibility of older patients to GI complications may be due in part to elevated total or free NSAID concentrations. Generally, it is advisable to start most NSAIDs at a low dosage in the elderly and increase the dosage only if the therapeutic efficacy is insufficient.

Specific Properties of Individual NSAIDs

General properties shared by NSAIDs were considered in the section, Nonsteroidal Anti-inflammatory Drugs. In this section, important characteristics of individual substances are discussed. NSAIDs are grouped by their chemical similarity, as in Figure 38–1.

Aspirin and Other Salicylates

The salicylates include aspirin, salicylic acid, methyl salicylate, diflunisal, salsalate (an unapproved marketed drug in the U.S.), olsalazine, sulfasalazine, balsalazide, choline magnesium trisalicylate (an unapproved marketed drug in the U.S.), magnesium salicylate, mesalamine, and salicylamide (a carboxamide derivative of salicylic acid contained as an ingredient in some OTC combination pain relievers). Salicylic acid is so irritating

that it can only be used externally; therefore, the various derivatives of this acid have been synthesized for systemic use. For example, aspirin is the acetate ester of salicylic acid (ASA). Aspirin is a widely consumed analgesic, antipyretic, and anti-inflammatory agent. Because aspirin is so available, the possibility of misuse and serious toxicity is underappreciated, and it remains a cause of fatal poisoning in children.

Table 38–2 summarizes the clinical pharmacokinetic properties of two salicylates, aspirin and diflunisal.

Mechanism of Action

The effects of aspirin are largely caused by its capacity to acetylate proteins, as described in Irreversible Cyclooxygenase Inhibition by Aspirin. Other salicylates generally act by virtue of their content of salicylic acid, which is a relatively weak inhibitor of the purified COX enzymes. Salicylic acid may also suppress inflammatory upregulation of COX-2 by interfering with transcription factor binding to the COX-2 promoter.

ADME

Absorption. Orally ingested salicylates are absorbed rapidly, partly from the stomach, but mostly from the upper small intestine. The peak plasma level is reached in about 1 h. The rate of absorption is determined by disintegration and dissolution rates of the tablets administered, the pH at the mucosal surface, and gastric emptying time. Even though salicylate is more ionized as the pH is increased, a rise in pH also increases the solubility of salicylate and thus dissolution of the tablets. The overall effect is to enhance absorption. The presence of food delays absorption of salicylates. Rectal absorption of salicylate usually is slower than oral absorption and is incomplete and inconsistent.

Salicylic acid is absorbed rapidly from the intact skin, especially when applied in oily liniments or ointments, and systemic poisoning has occurred from its application to large areas of skin. Methyl salicylate likewise is speedily absorbed when applied cutaneously; however, its GI absorption may be delayed many hours, making gastric lavage effective for removal even in poisonings that present late after oral ingestion.

Enteric coating delays and reduces the bioavailability of aspirin by roughly half and renders absorption more variable in the presence of food (Bogentoft et al., 1978), which is likely the cause of “pseudoresistance” to aspirin (see Aspirin Resistance).

Distribution. After absorption, salicylates are distributed throughout most body tissues and transcellular fluids, primarily by pH-dependent processes. Salicylates are transported actively out of the CSF across the choroid plexus. The drugs readily cross the placental barrier. Ingested aspirin mainly is absorbed as such, but some enters the systemic circulation as salicylic acid after hydrolysis by esterases in the GI mucosa and liver. Roughly 80%–90% of the salicylate in plasma is bound to proteins, especially albumin; the proportion of the total that is bound declines as plasma concentrations increase. Hypoalbuminemia, as may occur in rheumatoid arthritis, is associated with a proportionately higher level of free salicylate in the plasma. Salicylate competes with a variety of compounds for plasma protein-binding sites; these include thyroxine, triiodothyronine, penicillin, phenytoin, sulfapyrazone, bilirubin, uric acid, and other NSAIDs, such as naproxen. Aspirin is bound to a more limited extent; however, it acetylates human plasma albumin in vivo by reaction with the ϵ -amino group of lysine and may change the binding of other drugs to albumin. Aspirin also acetylates other plasma and tissue proteins, but there is no evidence that this contributes to clinical efficacy or adverse events.

Metabolism and Excretion. Aspirin is rapidly deacetylated to form salicylic acid by spontaneous hydrolysis or esterases located in the intestinal

wall, red blood cells, and the liver. The three chief metabolic products are salicyluric acid (the glycine conjugate), the ether or phenolic glucuronide, and the ester or acyl glucuronide. Salicylates and their metabolites are excreted in the urine. The excretion of free salicylates is variable and depends on the dose and the urinary pH. For example, the clearance of salicylate is about four times as great at pH 8 as at pH 6, and it is well above the glomerular filtration rate at pH 8. High rates of urine flow decrease tubular reabsorption, whereas the opposite is true in oliguria. The plasma $t_{1/2}$ for aspirin is about 20 min, and for salicylate is 2–3 h at antiplatelet doses, rising to 12 h at usual anti-inflammatory doses. The $t_{1/2}$ of salicylate may rise to 15–30 h at high therapeutic doses or when there is intoxication. This dose-dependent elimination is the result of the limited capacity of the liver to form salicyluric acid and the phenolic glucuronide, resulting in a larger proportion of unchanged drug being excreted in the urine at higher doses. Salicylate metabolism shows high intersubject variability due to the variable contribution of different metabolic pathways. Women frequently exhibit higher plasma concentrations, perhaps due to lower intrinsic esterase activity and gender differences in hepatic metabolism. Salicylate clearance is reduced and salicylate exposure is significantly increased in the elderly. The plasma concentration of salicylate is increased by conditions that decrease the glomerular filtration rate or reduce proximal tubule secretion, such as renal disease, or the presence of inhibitors that compete for the transport system (e.g., probenecid). In case of an overdose, hemodialysis and hemofiltration techniques remove salicylic acid effectively from the circulation.

Monitoring of Plasma Salicylate Concentrations. Aspirin is one of the NSAIDs for which plasma salicylate can provide a means to monitor therapy and toxicity. Intermittent analgesic-antipyretic doses of aspirin typically produce plasma aspirin levels of less than 20 $\mu\text{g/mL}$ and plasma salicylate levels of less than 60 $\mu\text{g/mL}$. The daily ingestion of anti-inflammatory doses of 4–5 g of aspirin produces plasma salicylate levels in the range of 120–350 $\mu\text{g/mL}$. Optimal anti-inflammatory effects for patients with rheumatic diseases require plasma salicylate concentrations of 150–300 $\mu\text{g/mL}$. Significant adverse effects can be seen at levels greater than 300 $\mu\text{g/mL}$. At lower concentrations, the drug clearance is nearly constant (despite the fact that saturation of metabolic capacity is approached) because the fraction of drug that is free, and thus available for metabolism or excretion, increases as binding sites on plasma proteins are saturated. The total concentration of salicylate in plasma is therefore a relatively linear function of dose at lower concentrations. At higher concentrations, however, as metabolic pathways of disposition become saturated, small increments in dose can disproportionately increase plasma salicylate concentration. Failure to anticipate this phenomenon can lead to toxicity.

Therapeutic Uses

Systemic Uses. The analgesic-antipyretic dose of aspirin for adults is 325–1000 mg orally every 4–6 h. It is only rarely used for inflammatory diseases such as arthritis, spondyloarthropathies, and systemic lupus erythematosus; NSAIDs with a better GI safety profile are preferred. The anti-inflammatory doses of aspirin, as might be given in rheumatic fever, range from 4 to 8 g/d in divided doses. The maximum recommended daily dose of aspirin for adults and children 12 years or older is 4 g. The rectal administration of aspirin suppositories may be preferred in infants or when the oral route is unavailable. Aspirin suppresses clinical signs and improves tissue inflammation in acute rheumatic fever. Other salicylates available for systemic use include salsalate (salicylsalicylic acid), magnesium salicylate, diflunisal, and a combination of choline salicylate and magnesium salicylate (choline magnesium trisalicylate).

Diflunisal is a difluorophenyl derivative of salicylic acid that is not converted to salicylic acid in vivo. It is a competitive inhibitor of COX and a potent anti-inflammatory drug but is largely devoid of antipyretic effects, perhaps because of poor penetration into the CNS. The drug has been used primarily as an analgesic in the treatment of osteoarthritis and musculoskeletal strains or sprains; in these circumstances, it is about three to four times more potent than aspirin. For rheumatoid arthritis or osteoarthritis, 250–1000 mg/d is administered in two divided doses; maintenance dosage should not exceed 1.5 g/d. Diflunisal may produce

TABLE 38-2 ■ NSAIDS: SALICYLATES, ACETAMINOPHEN, AND ACETIC ACID DERIVATIVES

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Salicylates				
Aspirin	Peak C_p , 1 h Protein binding, 80–90% Metabolite, Salicylic acid $t_{1/2}$, therapeutic, 2–3 h $t_{1/2}$, toxic dose, 15–30 h	Antiplatelet, 40–80 mg/day Pain/fever, 325–650 mg 4–6 h Rheumatic fever, Children 1 g/ 4–6 h or 10 mg/kg 4–6 h	Permanent platelet COX-1 inhibition Adverse effects: GL, ↑ clotting time hypersensitivity Avoid in children with acute febrile illness (Reye syndrome)	
Diflunisal	Peak C_p , 2–3 h Protein binding, 99% Metabolite, Glucuronide $t_{1/2}$, 8–12 h	250–500 mg every 8–12 h (maximum = 1 g/dose and 4 g/d); children <12 y: 10–15 mg/kg every 4 h (maximum 5 doses/24 h) IV (>50 kg): 1000 mg every 6 h or 650 mg every 4 h; (<50 kg): 15 mg/kg every 6 h or 12.5 mg/kg 4h	Not metabolized to salicylic, competitive COX inhibitor, excreted into breast milk.	Analgesic and anti-inflammatory, 4–5 × more potent Antipyretic, weaker Fewer platelet and GI side effects.
Para-aminophenol derivative				
Acetaminophen	Peak C_p , 30–60 min Protein binding, 20–50% Metabolites, Glucuronides (60%); sulfates (35%) $t_{1/2}$, 2 h	650 mg or less every 4 h (maximum of 4000 mg/24 h)	Weak nonspecific COX inhibitor at common doses Potency may be modulated by peroxidase Overdose ⇒ toxic metabolite, (NAPQI) liver necrosis	Analgesic/antipyretic, equivalent Anti-inflammatory, GI, and platelet effects < aspirin at 1000 mg/day
Acetic acid derivatives				
Indomethacin	Peak C_p , 1–2 h Protein binding, 99% Metabolites, O-demethyl (50%); unchanged (20%) $t_{1/2}$, 2 h	25 mg 2–3 times/day; 75–100 mg at night	Side effects (3–50%); frontal headache, neutropenia, thrombocytopenia; 20% discontinue	10–40 × more potent; intolerance typically limits dose
Sulindac (sulfoxide prodrug)	Peak C_p , 1–2 h; active metabolite 8 h, extensive enterohepatic circulation Metabolites, sulfone/conjugates (30%); sulindac/conjugate (25%) $t_{1/2}$, 7 h; 18 h for active sulfone metabolite	150–200 mg twice/day	20% GI side effects; 10% CNS side effects (headache, dizziness rash)	Efficacy comparable
Etodolac	Peak C_p , 1 h Protein binding, 99% Metabolism, Hepatic $t_{1/2}$, 7 h	200–400 mg 3–4 times/day, max: 1200 mg/d or 1000 mg/d (extended release) > 6 years (extended release): 400 mg/d (20–30 kg); add 200 mg/15 kg more wgt.	Some COX-2 selectivity in vitro Adverse effects similar to sulindac, but ~ half as frequent	100 mg etodolac efficacy ≈ 650 mg of aspirin, may be better tolerated
Tolmetin	Peak C_p , 20–60 min Protein binding, 99% Metabolites, Carboxylate conjugates $t_{1/2}$, 5 h	Adults: 400–600 mg 3 times/d Children > 2 y: 20 mg/kg/d in 3–4 divided doses	Food delays anti decreases peak absorption. May persist in synovial fluid ⇒ biological efficacy > plasma $t_{1/2}$	Efficacy similar; 25–40% develop side effects; 5–10% discontinue drug
Ketorolac	Peak C_p , 30–60 min Protein binding, 99% Metabolite, Glucuronide (90%) $t_{1/2}$, 4–6 h	See FDA Package insert	Parenterally (60 mg IM, then 30 mg every 6 h, or 30 mg IV every 6 h) Available as ocular prep	Potent analgesic, poor anti-inflammatory

(Continued)

TABLE 38-2 ■ NSAIDS: SALICYLATES, ACETAMINOPHEN, AND ACETIC ACID DERIVATIVES (CONTINUED)

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Diclofenac	Peak C_p , 1 h; extended release, 5 h Protein binding, 99% Metabolites, Glucuronide and sulfide (renal 65%, bile 35%) $t_{1/2}$ 1.2–2 h (immediate-release tabs); 12 h (topical epolamine patch)	50 mg 3 times/day or 75 mg twice/day	As topical gel, ocular solution, oral tablets combined with misoprostol First-pass effect; oral bioavailability, 50%	More potent; 20%, side effects; 2% discontinue; 15%, elevated liver enzymes Substrate for CYPs 2C9 and 3A4
Nabumetone (6-methoxy-2-naphthylacetic acid prodrug)	Peak C_p , ~3 h Protein binding, 99% Metabolites, conjugates $t_{1/2}$, 19–26 h; 22–38 h (elderly)	500–1000 mg 1–2 times/d (maximum 2000 mg/d); Patients < 50 kg less likely to require more than 1000 mg/d	First-pass effects, 35% conversion of prodrug to active metabolite; preferential COX-2 inhibition at low doses; Adverse effects (13%): GI upset, abdominal pain	Less fecal blood loss during short-term therapy

Time to peak plasma drug concentration C_p is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical $t_{1/2}$ is listed for therapeutic doses; if $t_{1/2}$ is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications

fewer auditory side effects (see Ototoxic Effects) and appears to cause fewer and less-intense GI and antiplatelet effects than does aspirin.

Local Uses. Mesalamine (5-aminosalicylic acid) is a salicylate that is used for its local effects in the treatment of *inflammatory bowel disease* (see Figure 51-4). Oral formulations that deliver drug to the lower intestine are efficacious in the treatment of inflammatory bowel disease (in particular, ulcerative colitis). These preparations rely on pH-sensitive coatings and other delayed-release mechanisms such as linkage to another moiety to create a poorly absorbed parent compound that must be cleaved by bacteria in the colon to form the active drug. Mesalamine is available as a rectal enema for treatment of mild-to-moderate ulcerative colitis, proctitis, and proctosigmoiditis and as a rectal suppository for the treatment of active ulcerative proctitis. Mesalamine derivatives in clinical use include *balsalazide*, *sulfasalazine*, and *olsalazine*. Sulfasalazine (salicylazosulfapyridine) contains mesalamine linked covalently to sulfapyridine, and balsalazide contains mesalamine linked to the inert carrier molecule 4-aminobenzoyl- β -alanine. Sulfasalazine and olsalazine have been used in the treatment of rheumatoid arthritis and ankylosing spondylitis. Some OTC medications to relieve indigestion and diarrhea agents contain bismuth subsalicylate and have the potential to cause salicylate intoxication, particularly in children.

The keratolytic action of free salicylic acid is employed for the local treatment of warts, corns, fungal infections, and certain types of eczematous dermatitis. After treatment with salicylic acid, tissue cells swell, soften, and desquamate. Methyl salicylate (oil of wintergreen) is a common ingredient of ointments and deep-heating liniments used in the management of musculoskeletal pain; it also is available in herbal medicines and as a flavoring agent. The cutaneous application of methyl salicylate can result in pharmacologically active, and even toxic, systemic salicylate concentrations and has been reported to increase prothrombin time in patients receiving warfarin.

Adverse Effects and Toxicity

Respiration. Salicylates increase O_2 consumption and CO_2 production (especially in skeletal muscle) at anti-inflammatory doses, a result of uncoupling oxidative phosphorylation. The increased production of CO_2 stimulates respiration. Salicylates also stimulate the respiratory center directly in the medulla. Respiratory rate and depth increases, the PCO_2 falls, and respiratory alkalosis ensues.

Acid-Base and Electrolyte Balance and Renal Effects. Therapeutic doses of salicylate produce definite changes in the acid-base balance and electrolyte pattern. Compensation for the initial event, respiratory alkalosis, is achieved by increased renal excretion of bicarbonate, which is

accompanied by increased Na^+ and K^+ excretion; plasma bicarbonate is thus lowered, and blood pH returns toward normal. This stage of compensatory renal acidosis was often seen in adults given intensive salicylate therapy before the development of safer alternatives. Today, it is an indicator of ensuing intoxication (see Salicylate Intoxication). Salicylates can cause retention of salt and water, as well as acute reduction of renal function in patients with congestive heart failure, renal disease, or hypovolemia. Although long-term use of salicylates alone rarely is associated with nephrotoxicity, the prolonged and excessive ingestion of analgesic mixtures containing salicylates in combination with other NSAIDs can produce papillary necrosis and interstitial nephritis (see Analgesic Nephropathy).

Cardiovascular Effects. Low-dose aspirin (≤ 100 mg daily) lowers cardiovascular risk and is recommended for the prevention of myocardial infarction and stroke in patients at elevated risk (see Cardioprotection section) (Patrono, 2015). At high therapeutic doses (≥ 3 g daily), salt and water retention can lead to an increase ($\leq 20\%$) in circulating plasma volume and decreased hematocrit (via a dilutional effect). There is a tendency for the peripheral vessels to dilate because of a direct effect on vascular smooth muscle. Cardiac output and work are increased. Those with carditis or compromised cardiac function may not have sufficient cardiac reserve to meet the increased demands, and congestive cardiac failure and pulmonary edema can occur. High doses of salicylates can produce non-cardiogenic pulmonary edema, particularly in older patients who ingest salicylates regularly over a prolonged period.

GI Effects. Ingestion of salicylates may result in epigastric distress, heartburn, dyspepsia, nausea, and vomiting. Salicylates also may cause erosive gastritis and GI ulceration and hemorrhage. These effects occur primarily with acetylated salicylates (i.e., aspirin). Because nonacetylated salicylates lack the ability to acetylate COX and thereby irreversibly inhibit its activity, they are weaker inhibitors than aspirin.

Aspirin-induced gastric bleeding sometimes is painless and, if unrecognized, may lead to iron-deficiency anemia. The daily ingestion of anti-inflammatory doses of aspirin (3–4 g) results in an average fecal blood loss of between 3 and 8 mL/d, as compared with about 0.6 mL/d in untreated subjects. Gastroscopic examination of aspirin-treated subjects often reveals discrete ulcerative and hemorrhagic lesions of the gastric mucosa; in many cases, multiple hemorrhagic lesions with sharply demarcated areas of focal necrosis are observed.

Hepatic Effects. Salicylates can cause hepatic injury, usually after high doses that result in plasma salicylate concentrations greater than 150 μ g/mL. The injury is not an acute effect; rather, the onset

characteristically occurs after several months of high-dose treatment. The majority of cases occur in patients with connective tissue disorders. There usually are no symptoms, simply an increase in serum levels of hepatic transaminases, but some patients note right upper quadrant abdominal discomfort and tenderness. Overt jaundice is uncommon. The injury usually is reversible on discontinuation of salicylates. However, the use of salicylates is contraindicated in patients with chronic liver disease. Considerable evidence implicates the use of salicylates as an important factor in the severe hepatic injury and encephalopathy observed in Reye syndrome. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen.

Uricosuric Effects. The effects of salicylates on uric acid excretion are markedly dependent on dose. Low doses (1 or 2 g/d) may decrease urate excretion and elevate plasma urate concentrations; intermediate doses (2 or 3 g/d) usually do not alter urate excretion. Larger-than-recommended doses (>5 g/d) induce uricosuria and lower plasma urate levels; however, such large doses are tolerated poorly. Even small doses of salicylate can block the effects of probenecid and other uricosuric agents that decrease tubular reabsorption of uric acid.

Hematologic Effects. Irreversible inhibition of platelet function underlies the cardioprotective effect of aspirin. If possible, aspirin therapy should be stopped at least 1 week before surgery; however, preoperative aspirin often is recommended prior to cardiovascular surgery and percutaneous interventions. Patients with severe hepatic damage, hypoprothrombinemia, vitamin K deficiency, or hemophilia should avoid aspirin because the inhibition of platelet hemostasis can result in hemorrhage. Salicylates ordinarily do not alter the leukocyte or platelet count, the hematocrit, or the hemoglobin content. However, doses of 3–4 g/d markedly decrease plasma iron concentration and shorten erythrocyte survival time. Aspirin can cause a mild degree of hemolysis in individuals with a deficiency of G6PD.

Endocrine Effects. Long-term administration of salicylates decreases thyroidal uptake and clearance of iodine, but increases O_2 consumption and the rate of disappearance of thyroxine and triiodothyronine from the circulation. These effects probably are caused by the competitive displacement by salicylate of thyroxine and triiodothyronine from transthyretin and the thyroxine-binding globulin in plasma (see Chapter 43).

Ototoxic Effects. Hearing impairment, alterations of perceived sounds, and tinnitus commonly occur during high-dose salicylate therapy and are sometimes observed at low doses. Ototoxic symptoms are caused by increased labyrinthine pressure or an effect on the hair cells of the cochlea, perhaps secondary to vasoconstriction in the auditory microvasculature. Symptoms usually resolve within 2 or 3 days after withdrawal of the drug. As most competitive COX inhibitors are not associated with hearing loss or tinnitus, a direct effect of salicylic acid rather than suppression of PG synthesis is likely.

Salicylates and Pregnancy. Infants born to women who ingest salicylates for long periods may have significantly reduced birth weights. When administered during the third trimester, there also is an increase in perinatal mortality, anemia, antepartum and postpartum hemorrhage, prolonged gestation, and complicated deliveries; thus, its use during this period should be avoided. NSAIDs during the third trimester of pregnancy also can cause premature closure of the ductus arteriosus and should be avoided.

Local Irritant Effects. Salicylic acid is irritating to skin and mucosa and destroys epithelial cells.

Salicylate Intoxication. Salicylate poisoning or serious intoxication most often occurs in children and sometimes is fatal. CNS effects, intense hyperpnea, and hyperpyrexia are prominent symptoms. Death has followed use of 10–30 g of sodium salicylate or aspirin in adults, but much larger amounts (130 g of aspirin in one case) have been ingested without a fatal outcome. The lethal dose of methyl salicylate (also known as oil of wintergreen, sweet birch oil, gaultheria oil, betula oil) is considerably less than that of sodium salicylate. As little as a 4 mL (4.7 g) of methyl salicylate may cause severe systemic toxicity in children. Mild chronic salicylate intoxication is called *salicylism*. When fully developed, the

syndrome includes headache, dizziness, tinnitus, difficulty hearing, dimness of vision, mental confusion, lassitude, drowsiness, sweating, thirst, hyperventilation, nausea, vomiting, and occasionally diarrhea.

Neurological Effects. In high doses, salicylates have toxic effects on the CNS, consisting of stimulation (including convulsions) followed by depression. Confusion, dizziness, tinnitus, high-tone deafness, delirium, psychosis, stupor, and coma may occur. Salicylates induce nausea and vomiting, which result from stimulation of sites that are accessible from the CSF, probably in the medullary chemoreceptor trigger zone.

Respiration. The respiratory effects of salicylates contribute to the serious acid-base balance disturbances that characterize poisoning by this class of compounds. Salicylates stimulate respiration indirectly by uncoupling of oxidative phosphorylation and directly by stimulation of the respiratory center in the medulla (described previously). Uncoupling of oxidative phosphorylation also leads to excessive heat production, and salicylate toxicity is associated with hyperthermia, particularly in children. Prolonged exposure to high doses of salicylates leads to depression of the medulla, with central respiratory depression and circulatory collapse, secondary to vasomotor depression. Because enhanced CO_2 production continues, respiratory acidosis ensues. Respiratory failure is the usual cause of death in fatal cases of salicylate poisoning. Elderly patients with chronic salicylate intoxication often develop noncardiogenic pulmonary edema, which is considered an indication for hemodialysis.

Acid-Base Balance and Electrolytes. High therapeutic doses of salicylate are associated with a primary respiratory alkalosis and compensatory metabolic acidosis. The phase of primary respiratory alkalosis rarely is recognized in children with salicylate toxicity. They usually present in a state of mixed respiratory and metabolic acidosis, characterized by a decrease in blood pH, a low plasma bicarbonate concentration, and normal or nearly normal plasma PCO_2 . Direct salicylate-induced depression of respiration prevents adequate respiratory hyperventilation to match the increased peripheral production of CO_2 . Consequently, plasma PCO_2 increases and blood pH decreases. Because the concentration of bicarbonate in plasma already is low due to increased renal bicarbonate excretion, the acid-base status at this stage essentially is an uncompensated respiratory acidosis.

Superimposed, however, is a true metabolic acidosis caused by accumulation of acids as a result of three processes. First, toxic concentrations of salicylates displace plasma bicarbonate. Second, vasomotor depression caused by toxic doses of salicylates impairs renal function, with consequent accumulation of sulfuric and phosphoric acids; renal failure can ensue. Third, salicylates in toxic doses may decrease aerobic metabolism as a result of inhibition of various enzymes. This derangement of carbohydrate metabolism leads to the accumulation of organic acids, especially pyruvic, lactic, and acetoacetic acids.

The same series of events also causes alterations of water and electrolyte balance. The low plasma PCO_2 leads to decreased renal tubular reabsorption of bicarbonate and increased renal excretion of Na^+ , K^+ , and water. Water also is lost by salicylate-induced sweating (especially in the presence of hyperthermia) and hyperventilation. Dehydration, which can be profound, particularly in children, rapidly occurs. Because more water than electrolyte is lost through the lungs and by sweating, the dehydration is associated with hyponatremia.

Cardiovascular Effects. Toxic doses of salicylates lead to an exaggeration of the unfavorable cardiovascular responses seen at high therapeutic doses, and central vasomotor paralysis occurs. Petechiae may be seen due to defective platelet function.

Metabolic Effects. Large doses of salicylates may cause hyperglycemia and glycosuria and deplete liver and muscle glycogen; these effects are partly explained by the release of epinephrine. Such doses also reduce aerobic metabolism of glucose, increase glucose-6-phosphatase activity, and promote the secretion of glucocorticoids. There is a greater risk of hypoglycemia and subsequent permanent brain injury in children. Salicylates in toxic doses cause a significant negative nitrogen balance, characterized by an aminoaciduria. Adrenocortical activation may contribute to the negative nitrogen balance by enhancing protein catabolism. Salicylates reduce lipogenesis by partially blocking incorporation of acetate into fatty acids; they also inhibit epinephrine-stimulated lipolysis in fat cells

and displace long-chain fatty acids from binding sites on human plasma proteins. The combination of these effects leads to increased entry and enhanced oxidation of fatty acids in muscle, liver, and other tissues and to decreased plasma concentrations of free fatty acids, phospholipid, and cholesterol; the oxidation of ketone bodies also is increased.

Management of Salicylate Overdose. Salicylate poisoning represents an acute medical emergency, and death may result despite maximal therapy. Monitoring of salicylate levels is a useful guide to therapy but must be used in conjunction with an assessment of the patient's overall clinical condition, acid-base balance, formulation of salicylate ingested, timing, and dose. There is no specific antidote for salicylate poisoning.

Drug Interactions

The plasma concentration of salicylates generally is little affected by other drugs, but concurrent administration of aspirin lowers the concentrations of indomethacin, naproxen, ketoprofen, and fenoprofen, at least in part by displacement from plasma proteins. Important adverse interactions of aspirin with warfarin, sulfonylureas, and methotrexate were mentioned previously (in Drug Interactions). Other interactions of aspirin include the antagonism of spironolactone-induced natriuresis and the blockade of the active transport of penicillin from CSF to blood. Magnesium-aluminum hydroxide antacids can alkalinize the urine enough to increase salicylic acid clearance significantly and reduce steady-state concentrations. Conversely, discontinuation of antacid therapy can increase plasma concentrations to toxic levels.

Acetaminophen

Acetaminophen (paracetamol; *N*-acetyl-*p*-aminophenol) is the active metabolite of phenacetin.

Acetaminophen raises the threshold to painful stimuli, thus exerting an analgesic effect against pain due to a variety of etiologies. Acetaminophen is available without a prescription and is used as a common household analgesic by children and adults. It also is available in fixed-dose combinations containing narcotic and nonnarcotic analgesics (including aspirin and other salicylates), barbiturates, caffeine, vascular headache remedies, sleep aids, toothache remedies, antihistamines, antitussives, decongestants, expectorants, cold and flu preparations, and sore throat treatments. Acetaminophen is well tolerated; however, overdose—two-thirds of which are intentionally induced—can cause severe hepatic damage (see Figure 4-4); it leads to nearly 80,000 emergency department visits and 30,000 hospitalizations annually in the U.S. (Bliden et al., 2014). The maximum FDA-recommended dose of acetaminophen is 4 g/d.

Mechanism of Action

Acetaminophen has analgesic and antipyretic effects similar to those of aspirin, but only weak anti-inflammatory effects. It is a nonselective COX inhibitor, which acts at the peroxide site of the enzyme and is thus distinct among NSAIDs. The presence of high concentrations of peroxides, as occur at sites of inflammation, reduces its COX-inhibitory activity.

ADME

Oral acetaminophen has excellent bioavailability. Peak plasma concentrations occur within 30–60 min, and the $t_{1/2}$ in plasma is about 2 h. Acetaminophen is relatively uniformly distributed throughout most body fluids. Binding of the drug to plasma proteins is variable, but less than with other NSAIDs. Some 90%–100% of drug may be recovered in the urine within the first day at therapeutic dosing, primarily after hepatic conjugation with glucuronic acid (~60%), sulfuric acid (~35%), or cysteine (~3%); small amounts of hydroxylated and deacetylated metabolites also have been detected (see Table 38-2). Children have less capacity for glucuronidation of the drug than do adults. A small proportion of acetaminophen

undergoes CYP-mediated *N*-hydroxylation to form NAPQI, a highly reactive intermediate. This metabolite normally reacts with sulfhydryl groups in GSH and thereby is rendered harmless. However, after ingestion of large doses of acetaminophen, the metabolite is formed in amounts sufficient to deplete hepatic GSH and contributes significantly to the toxic effects of overdose (see Acetaminophen Intoxication).

Therapeutic Uses

Acetaminophen is suitable for analgesic or antipyretic uses; it is particularly valuable for patients in whom aspirin is contraindicated (e.g., those with aspirin hypersensitivity, children with a febrile illness, patients with bleeding disorders). The conventional oral dose of acetaminophen is 325–650 mg every 4–6 h; total daily doses should not exceed 4 g (2 g/d for chronic alcoholics). Single doses for children 2–11 years old depend on age and weight (~10–15 mg/kg); no more than five doses should be administered in 24 h. An injectable preparation is available. Particular attention is warranted due to the availability of a wide variety of prescription and nonprescription multi-ingredient medications that represent potentially toxic overlapping sources of acetaminophen.

Adverse Effects and Toxicity

Acetaminophen usually is well tolerated. Therapeutic doses of acetaminophen have no clinically relevant effects on the cardiovascular and respiratory systems, platelets, or coagulation. The GI adverse effects are less common than with therapeutic doses of NSAIDs. Rash and other allergic reactions occur occasionally, but sometimes these are more serious and may be accompanied by drug fever and mucosal lesions. Patients who show hypersensitivity reactions to the salicylates only rarely exhibit sensitivity to acetaminophen. The most serious acute adverse effect of overdosage of acetaminophen is a potentially fatal hepatic necrosis (Graham et al., 2005). Hepatic injury with acetaminophen involves its conversion to the toxic metabolite NAPQI. The glucuronide and sulfate conjugation pathways become saturated, and increasing amounts undergo CYP-mediated *N*-hydroxylation to form NAPQI. This is eliminated rapidly by conjugation with GSH and then further metabolized to a mercapturic acid and excreted into the urine. In the setting of acetaminophen overdose, hepatocellular levels of GSH become depleted. The highly reactive NAPQI metabolite binds covalently to cell macromolecules, leading to dysfunction of enzymatic systems and structural and metabolic disarray. Furthermore, depletion of intracellular GSH renders the hepatocytes highly susceptible to oxidative stress and apoptosis. Renal tubular necrosis and hypoglycemic coma also may occur.

In adults, hepatotoxicity may occur after ingestion of a single dose of 10–15 g (150–250 mg/kg) of acetaminophen; doses of 20–25 g or more are potentially fatal. Conditions of CYP induction (e.g., heavy alcohol consumption) or GSH depletion (e.g., fasting or malnutrition) increase the susceptibility to hepatic injury, which has been documented, albeit uncommonly, with doses in the therapeutic range. Plasma transaminases become elevated, sometimes markedly so, beginning about 12–36 h after ingestion. Symptoms that occur during the first 2 days of acute poisoning by acetaminophen reflect gastric distress (e.g., nausea, abdominal pain, anorexia) and belie the potential seriousness of the intoxication. Clinical indications of hepatic damage manifest within 2–4 days of ingestion of toxic doses, with right subcostal pain, tender hepatomegaly, jaundice, and coagulopathy. Renal impairment or frank renal failure may occur. Liver enzyme abnormalities typically peak 72–96 h after ingestion. Biopsy of the liver reveals centrilobular necrosis with sparing of the periportal area. In nonfatal cases, the hepatic lesions are reversible over a period of weeks or months.

Management of Acetaminophen Intoxication. Severe liver damage occurs in 90% of patients with plasma concentrations of acetaminophen greater than 300 µg/mL at 4 h or 45 µg/mL at 15 h after the ingestion of the drug. Activated charcoal, if given within 4 h of ingestion, decreases acetaminophen absorption by 50%–90% and should be administered if the ingested dose is suspected to exceed 7.5 g. NAC is indicated for those at risk of hepatic injury. NAC functions by detoxifying NAPQI. It both repletes GSH stores and may conjugate directly with NAPQI by serving as a GSH substitute. In addition to NAC therapy, aggressive supportive

care is warranted. This includes management of hepatic and renal failure, if they occur, and intubation if the patient becomes obtunded. Hypoglycemia can result from liver failure, and plasma glucose should be monitored closely. Fulminant hepatic failure is an indication for liver transplantation.

Acetic Acid Derivatives

Diclofenac

Diclofenac, a phenylacetic acid derivative, is among the most commonly used NSAIDs in Europe. Diclofenac has analgesic, antipyretic, and anti-inflammatory activities. Its potency is substantially greater than that of other NSAIDs. Although it was not developed to be a COX-2 selective drug, the selectivity of diclofenac for COX-2 resembles that of celecoxib (see Figure 38–1).

ADME. Diclofenac displays rapid absorption, extensive protein binding, and a $t_{1/2}$ of 1–2 h (see Table 38–2). The short $t_{1/2}$ makes it necessary to give doses of diclofenac considerably higher than would be required to inhibit COX-2 fully at peak plasma concentrations to afford sustained COX inhibition throughout the dosing interval. Thus, both COX isoforms are inhibited for the first phase of the dosing interval. However, as plasma levels decrease, diclofenac behaves like a COX-2 inhibitor in the later phase of the dosing interval. There is a substantial first-pass effect, such that only about 50% of diclofenac is available systemically. The drug accumulates in synovial fluid after oral administration, which may explain why its duration of therapeutic effect is considerably longer than its plasma $t_{1/2}$. Diclofenac is metabolized in the liver by a member of the CYP2C subfamily to 4-hydroxydiclofenac, the principal metabolite, and other hydroxylated forms; after glucuronidation and sulfation, the metabolites are excreted in the urine (65%) and bile (35%).

Therapeutic Uses. Diclofenac is approved in the U.S. for the long-term symptomatic treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, and acute migraine. Multiple oral formulations are available, providing a range of release times; the usual daily oral dosage is 50–150 mg, given in several divided doses. For acute pain such as migraine, a powdered form for dissolution in water and a solution for intravenous injection are available. Diclofenac also is available in combination with misoprostol, a PGE₁ analogue; this combination retains the efficacy of diclofenac while reducing the frequency of GI ulcers and erosions. A 1% topical gel, a topical solution, and a transdermal patch are available for short-term treatment of pain due to minor strains, sprains, and bruises. A 3% gel formulation is indicated for topical treatment of actinic keratosis. In addition, an ophthalmic solution of diclofenac is available for treatment of postoperative inflammation following cataract extraction and for the temporary relief of pain and photophobia in patients undergoing corneal refractive surgery.

Adverse Effects. Diclofenac produces side effects (particularly GI) in about 20% of patients. The incidence of serious GI adverse effects, hypertension, and myocardial infarction are similar to the COX-2-selective inhibitors (Cannon et al., 2006). Hypersensitivity reactions have occurred following topical application and systemic administration. Severe liver injury occurs in 6–11 per 100,000 regular users annually (Bjornsson et al., 2013; de Abajo et al., 2004). Elevation of hepatic transaminases in plasma by more than three times the upper normal limit, indicating significant liver damage, occurs in about 4% of patients (Rostom et al., 2005). Transaminases should be monitored during the first 8 weeks of therapy with diclofenac. Other untoward responses to diclofenac include CNS effects, rashes, fluid retention, edema, and renal function impairment. The drug is not recommended for children, nursing mothers, or pregnant women.

Diclofenac is extensively metabolized. One metabolite, 4'-hydroxy diclofenac, can form reactive benzoquinone imines (similar to acetaminophen's metabolite NAPQI) that deplete hepatic GSH. Another highly reactive metabolite, diclofenac acyl glucuronide, is primarily catalyzed by UGT2B7 (King et al., 2001). Genetic variation that causes higher catalytic activity of UGT2B7 is associated with an increased risk of hepatotoxicity among patients taking diclofenac (Daly et al., 2007).

Indomethacin

Indomethacin is a methylated indole derivative indicated for the treatment of moderate-to-severe rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis; acute gouty arthritis; and acute painful shoulder. Although indomethacin is still used clinically, mainly as a steroid-sparing agent, toxicity and the availability of safer alternatives have limited its use.

Indomethacin is a potent nonselective inhibitor of the COXs. It also inhibits the motility of polymorphonuclear leukocytes, depresses the biosynthesis of mucopolysaccharides, and may have a direct, COX-independent vasoconstrictor effect. Indomethacin has prominent anti-inflammatory and analgesic-antipyretic properties similar to those of the salicylates.

ADME. Oral indomethacin has excellent bioavailability. Peak concentrations occur 1–2 h after dosing (Table 38–2). The concentration of the drug in the CSF is low, but its concentration in synovial fluid is equal to that in plasma within 5 h of administration. There is enterohepatic cycling of the indomethacin metabolites and probably of indomethacin itself. The $t_{1/2}$ in plasma is variable, perhaps because of enterohepatic cycling, but averages about 2.5 h.

Therapeutic Uses. While indomethacin is estimated to be about 20 times more potent than aspirin, a high rate of intolerance limits its use. An intravenous formulation of indomethacin is approved for closure of persistent patent ductus arteriosus in premature infants. The regimen involves intravenous administration of 0.1–0.25 mg/kg every 12 h for three doses, with the course repeated one time if necessary. Successful closure can be expected in more than 70% of neonates treated. The principal limitation of treating neonates is renal toxicity, and therapy is interrupted if the output of urine falls significantly (<0.6 mL/kg/h). An injectable formulation of ibuprofen is an alternative for the treatment of patent ductus arteriosus.

Adverse Effects. A very high percentage (35%–50%) of patients receiving indomethacin experience adverse drug reactions. GI adverse events are common and can be fatal; elderly patients are at significantly greater risk. Diarrhea may occur and sometimes is associated with ulcerative lesions of the bowel. Acute pancreatitis has been reported, as have rare, but potentially fatal, cases of hepatitis. The most frequent CNS effect is severe frontal headache. Dizziness, vertigo, light-headedness, and mental confusion may occur. Seizures have been reported, as have severe depression, psychosis, hallucinations, and suicide. Caution is advised when administering indomethacin to elderly patients or to those with underlying epilepsy, psychiatric disorders, or Parkinson disease because they are at greater risk for the development of serious CNS adverse effects. Hematopoietic reactions include neutropenia, thrombocytopenia, and rarely aplastic anemia.

The total plasma concentration of indomethacin plus its inactive metabolites is increased by concurrent administration of probenecid. Indomethacin antagonizes the natriuretic and antihypertensive effects of furosemide and thiazide diuretics and blunts the antihypertensive effect of β receptor antagonists, AT₁-receptor antagonists, and ACE inhibitors.

Sulindac

Sulindac is a congener of indomethacin. Sulindac is a prodrug whose anti-inflammatory activity resides in its sulfide metabolite, which is more than 500 times more potent than sulindac as an inhibitor of COX but less than half as potent as indomethacin (see Figure 38–1). ADME data are summarized in Table 38–2. Sulindac is used for the treatment of rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, painful shoulder, and gouty arthritis. Its analgesic and anti-inflammatory effects are comparable to those achieved with aspirin. The most common dosage for adults is 150–200 mg twice a day. Although the incidence of toxicity is lower than with indomethacin, adverse reactions to sulindac are common. The typical NSAID GI side effects are seen in nearly 20% of patients. CNS side effects as described for indomethacin are seen in 10% or fewer of patients. Rash occurs in (3%–9%) of patients, and pruritus occurs in 1%–3% of patients. Transient elevations of hepatic transaminases in plasma are less common. The same precautions that apply to other NSAIDs regarding patients at risk for GI toxicity, cardiovascular risk, and renal impairment also apply to sulindac.

Etodolac

Etodolac is an acetic acid derivative with some degree of COX-2 selectivity (see Table 38–2, Figure 38–1). A single oral dose (200–400 mg) of etodolac provides postoperative analgesia that lasts for 6–8 h. Etodolac also is effective in the treatment of osteoarthritis, rheumatoid arthritis, and mild-to-moderate pain, and the drug appears to be uricosuric. Sustained-release preparations are available. Etodolac is relatively well tolerated. About 5% of patients who have taken the drug for 1 year or less discontinue treatment because of GI side effects, rashes, and CNS effects.

Tolmetin

Tolmetin is approved for the treatment of osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis and has been used in the treatment of ankylosing spondylitis. ADME and comparison to aspirin are in Table 38–2. Tolmetin recommended doses for adults (200–600 mg three times/d) are typically given with meals, milk, or antacids to lessen abdominal discomfort. However, peak plasma concentrations and bioavailability are reduced when the drug is taken with food. Side effects occur in 25%–40% of patients who take tolmetin. GI side effects are the most common (~15%), and gastric ulceration has been observed. CNS side effects similar to those seen with indomethacin and aspirin occur, but they are less common and less severe.

Ketorolac

Ketorolac is a potent analgesic but only a moderately effective anti-inflammatory drug. The use of ketorolac is limited to 5 days or less for acute pain and can be administered orally, intravenously, intramuscularly, or intranasally. Typical doses are 30–60 mg (intramuscular), 15–30 mg (intravenous), 10–20 mg (oral), and 31.5 mg (intranasal). Pediatric patients aged between 2 and 16 years may receive a single intramuscular (1 mg/kg up to 30 mg) or intravenous (0.5 mg/kg up to 15 mg) dose of ketorolac for severe acute pain. Ketorolac has a rapid onset of action and a short duration of action (see Table 38–2). It is widely used in postoperative patients, but it should not be used for routine obstetric analgesia. Topical (ophthalmic) ketorolac is approved for the treatment of seasonal allergic conjunctivitis and postoperative ocular inflammation. Ketorolac in a fixed-dose combination with phenylephrine is indicated as an irrigation during cataract or intraocular lens replacement surgery to maintain pupil size, prevent miosis, and reduce postoperative pain. Side effects of systemic ketorolac include somnolence (6%), dizziness (7%), headache (17%), GI pain (13%), dyspepsia (12%), nausea (12%), and pain at the site of injection (2%). Serious adverse GI, renal, bleeding, and hypersensitivity reactions to ketorolac may occur. Patients receiving greater than recommended doses or concomitant NSAID therapy, and the elderly, appear to be particularly at risk.

Nabumetone

Nabumetone is the prodrug of 6-methoxy-2-naphthylacetic acid. Nabumetone is approved for the treatment of rheumatoid arthritis and osteoarthritis. Its comparative pharmacokinetic properties are summarized in Table 38–2. Nabumetone is associated with crampy lower abdominal pain (12%) and diarrhea (14%). Other side effects include rash (3%–9%); headache (3%–9%); dizziness (3%–9%); heartburn, tinnitus, and pruritus (3%–9%).

Propionic Acid Derivatives

The propionic acid derivatives *ibuprofen*, *naproxen*, *flurbiprofen*, *fenoprofen*, *ketoprofen*, and *oxaprozin* are available in the U.S. (see Table 38–3). Ibuprofen is the most commonly used NSAID in the U.S. and is available with or without a prescription. Naproxen, also available with or without a prescription, has a longer but variable $t_{1/2}$. Oxaprozin also has a long $t_{1/2}$ and may be given once daily.

Mechanism of Action

Propionic acid derivatives are nonselective COX inhibitors with the effects and side effects common to other NSAIDs. Some of the propionic acid derivatives, particularly naproxen, have inhibitory effects on leukocyte function, and some evidence suggests that naproxen may have slightly better efficacy with regard to analgesia and relief of morning stiffness.

This suggestion of benefit accords with the longer $t_{1/2}$ of naproxen in comparison to other propionic acid derivatives.

Therapeutic Uses

Propionic acid derivatives are approved for use in the symptomatic treatment of rheumatoid arthritis, juvenile arthritis, and osteoarthritis. Some also are approved for pain, ankylosing spondylitis, acute gouty arthritis, tendinitis, bursitis, headache, postoperative dental pain and swelling, and primary dysmenorrhea. These agents may be comparable in efficacy to aspirin for the control of the signs and symptoms of rheumatoid arthritis and osteoarthritis.

Drug Interactions

Ibuprofen and naproxen have been shown to interfere with the antiplatelet effects of aspirin (Catella-Lawson et al., 2001; Li et al., 2014). Propionic acid derivatives have not been shown to alter the pharmacokinetics of the oral hypoglycemic drugs or warfarin. Refer to the full product labeling for a comprehensive listing of other drug interactions.

Ibuprofen

ADME. Table 38–3 summarizes the comparative pharmacokinetics of ibuprofen. Ibuprofen is absorbed rapidly, bound avidly to protein, and undergoes hepatic metabolism (90% is metabolized to hydroxylate or carboxylate derivatives) and renal excretion of metabolites. The $t_{1/2}$ is about 2 h. Slow equilibration with the synovial space means that its antiarthritic effects may persist after plasma levels decline. In experimental animals, ibuprofen and its metabolites readily cross the placenta.

Therapeutic Uses. Ibuprofen is supplied as tablets, chewable tablets, capsules, caplets, and gelcaps containing 50–600 mg; as oral drops; and as an oral suspension. An injectable formulation of ibuprofen is approved to close patent ductus arteriosus in premature infants. Solid oral dosage forms containing 200 mg or less are available without a prescription. Ibuprofen is licensed for marketing alone and in fixed-dose combinations with antihistamines, decongestants, famotidine, oxycodone, and hydrocodone. It is short acting, with a $t_{1/2}$ of about 2 h. The usual dose for mild-to-moderate pain is 400 mg every 4–6 h as needed.

Adverse Effects. Ibuprofen is better tolerated than aspirin and indomethacin and has been used in patients with a history of GI intolerance to other NSAIDs. Nevertheless, 5%–15% of patients experience GI side effects. Less-frequent adverse effects of ibuprofen include rashes (3%–9%), thrombocytopenia (<1%), headache (1%–3%), dizziness (3%–9%), blurred vision (<1%), and, in a few cases, toxic amblyopia (<1%), fluid retention (1%–3%), and edema (1%–3%). Patients who develop ocular disturbances should discontinue the use of ibuprofen and have an ophthalmic evaluation. Ibuprofen can be used occasionally by pregnant women; however, the concerns apply regarding third-trimester effects, including delay of parturition. Excretion into breast milk is thought to be minimal, so ibuprofen also can be used with caution by women who are breastfeeding.

Naproxen

Naproxen is supplied as tablets, delayed-release tablets, extended-release tablets, gelcaps, and caplets containing 200–500 mg of naproxen or naproxen sodium and as an oral suspension and suppositories. Solid oral dosage forms containing 200 mg or less are available without a prescription. Naproxen is licensed for marketing alone and in fixed-dose combinations with pseudoephedrine, diphenhydramine, esomeprazole, and sumatriptan; it is copackaged with lansoprazole. Naproxen is indicated for juvenile and rheumatoid arthritis, osteoarthritis, ankylosing spondylitis, pain, primary dysmenorrhea, tendonitis, bursitis, and acute gout.

ADME. Naproxen is absorbed fully after oral administration. Naproxen also is absorbed rectally but more slowly than after oral administration. Naproxen is almost completely (99%) bound to plasma proteins after normal therapeutic doses. The $t_{1/2}$ of naproxen in plasma is variable, 9 to 25 h. Age plays a role in the variability of the $t_{1/2}$ because of the age-related decline in renal function (and consequently longer $t_{1/2}$) (see Table 38–3). Low doses should be prescribed in the elderly. Naproxen is extensively metabolized in the liver. About 30% of the drug undergoes 6-desmethylation, and most of this metabolite, as well as naproxen

TABLE 38-3 ■ COMPARISON OF REPRESENTATIVE NSAIDS: FENAMATES AND PROPIONIC ACID DERIVATIVES

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Fenamates				
Mefenamic acid	Peak C_p , 2–4 h Protein binding, >90% Metabolism, CYP2C9 oxidation; glucuronidation of parent drug and metabolites $t_{1/2}$, 2–4 h	500 mg load, then 250 mg every 6 h	Therapy usually should not exceed 7 days or 2–3 days (dysmenorrhea); 15% elevated liver enzymes; excreted in breast milk	Efficacy similar
Meclofenamate	Peak C_p , 0.5–2 h; 3–4 h (with food) Protein binding, 99% Metabolism, Oxidation to 3-OH (~20% activity of parent) $t_{1/2}$, 0.8–2.1 h (parent); 0.5–4 h (active metabolite)	50–100 mg 4–6 times/d (maximum 400 mg/d)	Side effects: CNS, GI, and rash (all > 10%); administration with food ↓ rate/extent of absorption	Efficacy similar
Propionic acid derivatives				
Ibuprofen	Peak C_p , 2 h (tablets), 1 h (chewable tablets), 0.75 h (liquid) Protein binding, 99% Metabolites, CYP2C9 oxidation to 2- and 3-hydroxylates; conjugation to acyl glucuronides $t_{1/2}$, 2–4 h (adults); 23–75 h (premature infants); 0.9–2.3 h (children)	200–800 mg 3–6 times/d with food (maximum 3.2 g/d); Canadian and U.S. pediatric max 2.4 g/d Children: 4–10 mg/kg/dose, 3–4 times/d	10%–15% discontinue; may increase risk of aseptic meningitis; excreted in breast milk Racemate: 60% of R-enantiomer converts to S-ibuprofen	Equipotent
Naproxen	Peak C_p , 2–4 h (base tabs); 1–4 h (liquid); 1–2 h (sodium salt); 4–12 h (delayed-release tabs) Protein binding, 99% (↑ free fraction in elderly) Metabolism, CYPs 2C9, 1A2, 2C8 oxidation to 6-O-desmethyl and other metabolites $t_{1/2}$, 9–25 h	250 mg 3–4 times/d; 250–550 mg 2 times/d; 750–1000 mg daily (extended release) Children: 5 mg/kg 2 times/d (max 15 mg/kg/d)	Peak anti-inflammatory effects after 2–4 weeks; ↑ free fraction and ↓ excretion ⇒ ↑ risk of toxicity in elderly; may increase risk of aseptic meningitis; excreted in breast milk; variably prolonged $t_{1/2}$ may afford cardioprotection in some individuals	Usually better tolerated
Fenoprofen	Peak C_p , 2 h Protein binding, 99% Metabolites, 4-OH metabolite; glucuronide conjugates $t_{1/2}$, 2.5–3 h	200 mg 4–6 times/d or 300–600 mg 3–4 times/d (max 3.2 g/d)	Peak anti-inflammatory effects after 2–3 weeks; 15% experience side effects; few discontinue use; excreted in breast milk	Generally better tolerated
Ketoprofen	Peak C_p , 1.2 h; 6.8 h (extended-release) Protein binding, 99% Metabolites, Glucuronide conjugates; enterohepatic recirculation? $t_{1/2}$, 0.9–3.3 h	25–50 mg 3–4 times/d; 75 mg 3 times/d; 200 mg daily (extended release); max 300 mg/d Anti-inflammatory, 50–75 mg, 3–4/d	30% develop side effects (usually GI, usually mild); ~13% liver function abnormalities; unbound fraction, systemic exposure, and $t_{1/2}$ ↑ with age in elderly; excreted in breast milk	Generally better tolerated; biological efficacy > plasma $t_{1/2}$
Flurbiprofen	Peak C_p , ~2 h Protein binding, 99% Metabolism, CYP2C9 oxidation, UGTB7 glucuronidation of parent and 4'-OH metabolite $t_{1/2}$, 7.5 h	200–300 mg/d in 2–4 divided doses (maximum 100 mg/dose)	Racemate; excreted in breast milk; available for ophthalmic use	Generally better tolerated

(Continued)

TABLE 38-3 ■ COMPARISON OF REPRESENTATIVE NSAIDS: FENAMATES AND PROPIONIC ACID DERIVATIVES (CONTINUED)

CLASS/DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Oxaprozin	Peak C_p , 2.4–3 h Protein binding, 99% Metabolism, 65% oxidates, 35% glucuronides $t_{1/2}$, 41–55 h	600–1200 mg daily (maximum 1800 mg); children > 21 kg: 600–1200 mg daily based on weight (maximum 1200 mg)	Slow onset, not indicated for fever or acute pain; dose in elderly adjusted on the basis of weight; expected to be excreted in breast milk	Generally better tolerated

Time to peak plasma drug concentration C_p is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical $t_{1/2}$ is listed for therapeutic doses; if $t_{1/2}$ is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications.

itself, is excreted as the glucuronide or other conjugates. Metabolites of naproxen are excreted almost entirely in the urine. Naproxen crosses the placenta and appears in the milk of lactating women at about 1% of the maternal plasma concentration.

Adverse Effects. Although the best available data were consistent with the suggestion that naproxen is an NSAID that is not associated with an increase in myocardial infarction rate (Coxib and Traditional NSAID Trialists' Collaboration et al., 2013), the FDA in 2015, based on the advisory committee recommendations, has issued a warning that NSAIDs can cause heart attacks and strokes, and that there is inconclusive evidence regarding whether the particular risk of any NSAID is definitively higher or lower than another NSAID (<https://www.fda.gov/Drugs/DrugSafety/ucm451800.htm>).

About 1%–10% of patients taking naproxen experience GI adverse effects that include heartburn, abdominal pain, constipation, diarrhea, nausea, dyspepsia, and stomatitis. Adverse effects with naproxen occur at approximately the same frequency as with indomethacin and other NSAIDs (see Table 38-1). CNS side effects include drowsiness (3%–9%), headache (3%–9%), dizziness ($\leq 9\%$), vertigo ($< 3\%$), and depression ($< 1\%$). Other common reactions include pruritus (3%–9%) and diaphoresis ($< 3\%$). Rare instances of jaundice, impairment of renal function, angioedema, thrombocytopenia, and agranulocytosis have been reported.

Fenamates

The fenamates (anthranilic acids) include *mefenamic acid*, *meclofenamate*, and *flufenamic acid*. The pharmacological properties of the fenamates are those of typical NSAIDs, and therapeutically, they have no advantages over others in the class (see Table 38-3). Mefenamic acid and meclofenamate sodium are used in the short-term treatment of pain in soft-tissue injuries, dysmenorrhea, and rheumatoid and osteoarthritis. These drugs are not recommended for use in children or pregnant women. Roughly 5% of patients develop a reversible elevation of hepatic transaminases. Diarrhea, which may be severe and associated with steatorrhea and inflammation of the bowel, also is relatively common. Autoimmune hemolytic anemia is a potentially serious but rare side effect.

Enolic Acids (Oxicams)

The oxamic derivative *piroxicam* is the nonselective COX inhibitor with the longest $t_{1/2}$. *Meloxicam* shows modest COX-2 selectivity comparable to celecoxib (see Figure 38-1) and was approved as a COX-2-selective NSAID in some countries. These agents are similar in efficacy to aspirin, indomethacin, or naproxen for the long-term treatment of rheumatoid arthritis or osteoarthritis. The main advantage suggested for these compounds is their long $t_{1/2}$, which permits once-a-day dosing (see comparative pharmacokinetic and dosing data in Table 38-4).

Piroxicam

Piroxicam may inhibit activation of neutrophils, apparently independently of its ability to inhibit COX; hence, additional modes of anti-inflammatory action have been proposed, including inhibition of proteoglycanase and collagenase in cartilage.

Piroxicam is approved for the treatment of rheumatoid arthritis and osteoarthritis. Due to its slow onset of action and delayed attainment of steady state, it is less suited for acute analgesia but has been used to treat acute gout.

ADME. The pharmacokinetics of piroxicam are described in Table 38-4. The usual daily dose is 20 mg. Piroxicam is absorbed completely after oral administration and undergoes enterohepatic recirculation. Estimates of the $t_{1/2}$ in plasma have been variable; the average is about 50 h. Steady-state blood levels are reached in 7–12 days. Less than 5% of the drug is excreted into the urine unchanged. The major metabolic transformation in humans is hydroxylation of the pyridyl ring (predominantly by an isozyme of the CYP2C subfamily), and this inactive metabolite and its glucuronide conjugate account for about 60% of the drug excreted in the urine and feces.

Adverse Effects. Approximately 20% of patients experience side effects with piroxicam, and about 5% of patients discontinue use because of these effects. Piroxicam may be associated with more GI and serious skin reactions than other nonselective NSAIDs. In 2007, the European Medicines Agency reviewed the safety of orally administered piroxicam and concluded that its benefits outweigh its risks, but advised it should no longer considered a first-line agent or be used for the treatment of acute (short-term) pain and inflammation.

Meloxicam

Meloxicam is approved for use in osteoarthritis, rheumatoid arthritis, and juvenile rheumatoid arthritis. The recommended adult dose of meloxicam is 7.5–15 mg once daily. Meloxicam demonstrates some COX-2 selectivity (see Figure 38-1). There is significantly less gastric injury compared to piroxicam (20 mg/d) in subjects treated with 7.5 mg/d of meloxicam, but the advantage is lost with a dosage of 15 mg/d (Patoia et al., 1996).

Purpose-Developed COX-2 Selective NSAIDs

Selective inhibitors of COX-2 are molecules with side chains that fit within its hydrophobic pocket but are too large to block COX-1 with equally high affinity. Celecoxib is the only purposefully developed COX-2 inhibitor still approved in the U.S. (see its clinical pharmacokinetic properties and precautions in Table 38-4). As mentioned, other, older compounds (diclofenac, etodolac, meloxicam, nimesulide) have been retrospectively found to have a certain degree of selectivity for COX-2 (see Figure 38-1). Etoricoxib is approved in several countries, but restricted in its indications; rofecoxib, valdecoxib, and lumiracoxib were withdrawn worldwide because of the cardiovascular complications caused by suppression of cardioprotective COX-2-derived PGs, especially PGI_2 , and the unrestrained effects of endogenous stimuli, such as platelet COX-1-derived TxA_2 , on platelet activation, vascular proliferation and remodeling, hypertension, and atherogenesis. COX-2-selective NSAIDs should be avoided in patients prone to cardiovascular or cerebrovascular disease. While the purposefully developed COX-2 inhibitors have generally been shown to reduce severe GI complications when compared to isoform nonselective compounds, none of the COX-2-selective NSAIDs has established superior efficacy.

TABLE 38-4 ■ REPRESENTATIVE NSAIDS: ENOLIC ACID DERIVATIVES AND COXIBS

CLASS/ DRUG	PHARMACOKINETICS	DOSING	COMMENTS	COMPARED TO ASPIRIN
Enolic acid derivatives				
Piroxicam	Peak C_p , 3–5 h Protein binding, 99% Metabolites, CYP2C9 hydroxylation, conjugation, <i>N</i> -demethylation $t_{1/2}$, ~50 h	20 mg daily	20% side effects; 5% discontinue; slow onset, not indicated for fever or acute pain; excreted in breast milk	Equipotent with lower incidence of minor GI effects
Meloxicam	Peak C_p , 4–5 h (and 12–14 h due to biliary recycling) Protein binding, 99% Metabolism, Hydroxylation $t_{1/2}$, 15–20 h	7.5 mg daily (maximum 15 mg/d); Children ≥ 2 : lowest effective dose, 0.125 mg/kg daily (maximum 7.5 mg daily)	Some COX-2 selectivity, especially at lower doses; elderly females have higher systemic exposure and peak plasma concentrations than men and young women; excretion in breast milk unknown	—
Diaryl heterocyclic nsoids (COX-2 selective)				
			Evidence for cardiovascular adverse events	Decrease in GI side effects and in platelet effects
Celecoxib	Peak C_p , ~3 h Protein binding, 97% Metabolism, CYPs 2C9 (major) and 3A4 (minor), glucuronide $t_{1/2}$, 11.2 h	100–200 mg 1–2 times/d; 400 mg followed by 200 mg if needed on first day (acute pain); maximum, 800 mg/d. Children > 2 y: 50 mg (10–25 kg) or 100 mg (>25 kg) 2 times/d	CYP2D6 and CYP2D8 inhibitor; Adverse effects: GI complaints (5%); aseptic meningitis and methemoglobinemia have been reported; disseminated intravascular coagulation risk in pediatric patients; 40% higher systemic exposure in blacks and elderly females; excreted in breast milk	Usually better tolerated; does not usually prolong bleeding time

Time to peak plasma drug concentration C_p is after a single dose. In general, food delays absorption but does not decrease peak concentration. The majority of NSAIDs undergo hepatic metabolism, and the metabolites are excreted in the urine. Major metabolites or disposal pathways are listed. Typical $t_{1/2}$ is listed for therapeutic doses; if $t_{1/2}$ is much different with the toxic dose, this is also given. Typical adult oral doses are listed unless otherwise noted. Refer to the current product labeling for complete prescribing information, including current labeled pediatric indications.

Celecoxib

ADME. The bioavailability of oral celecoxib is not known; peak plasma levels occur at 2–4 h after administration. The elderly (≥ 65 years of age) may have up to 2-fold higher peak concentrations and AUC values than younger patients (≤ 55 years of age). Celecoxib is bound extensively to plasma proteins. Most is excreted as carboxylic acid and glucuronide metabolites in the urine and feces. The elimination $t_{1/2}$ is about 11 h. The drug commonly is given once or twice daily during chronic treatment. Plasma concentrations are increased in patients with mild and moderate hepatic impairment, requiring reduction in dose. Celecoxib is metabolized predominantly by CYP2C9 and inhibits CYP2D6. Clinical vigilance is necessary during coadministration of drugs that are known to inhibit CYP2C9 and drugs that are metabolized by CYP2D6.

Therapeutic Uses. Celecoxib is used for the management of acute pain for the treatment of osteoarthritis, rheumatoid arthritis, juvenile rheumatoid arthritis, ankylosing spondylitis, and primary dysmenorrhea. The recommended dose for treating osteoarthritis is 200 mg/d as a single dose or divided as two doses. In the treatment of rheumatoid arthritis, the recommended dose is 100–200 mg twice daily. Due to cardiovascular hazard, physicians are advised to use the lowest possible dose for the shortest possible duration.

Adverse Effects. Celecoxib confers a risk of myocardial infarction and stroke, and this appears to relate to dose and the underlying risk of cardiovascular disease. Effects attributed to inhibition of PG production in the kidney—hypertension and edema—occur with nonselective COX inhibitors and also with celecoxib. Selective COX-2 inhibitors lose their GI advantage over other NSAIDs alone when used in conjunction with aspirin. Chronic use of celecoxib may decrease bone mineral density, particularly in older male patients. There is some suggestion that celecoxib may slow fracture healing and tendon-to-bone healing.

Etoricoxib

Etoricoxib is a COX-2-selective inhibitor with selectivity second only to that of lumiracoxib (see Figure 38–1). Etoricoxib is incompletely (~80%) absorbed and has a long $t_{1/2}$ of 20–26 h. It is extensively metabolized before excretion. Patients with hepatic impairment are prone to drug accumulation. Renal insufficiency does not affect drug clearance. Etoricoxib is used for symptomatic relief in the treatment of osteoarthritis, rheumatoid arthritis, and acute gouty arthritis, as well as for the short-term treatment of musculoskeletal pain, postoperative pain, and primary dysmenorrhea. The drug is associated with the increased risk of heart attack and stroke. Etoricoxib is not available in the U.S.

Disease-Modifying Antirheumatic Drugs

Rheumatoid arthritis is an autoimmune disease that affects about 1% of the population. The pharmacological management of rheumatoid arthritis includes symptomatic relief through the use of NSAIDs. However, although they have anti-inflammatory effects, NSAIDs have minimal, if any, effect on progression of joint deformity. Disease-modifying antirheumatic drugs (DMARDs), on the other hand, reduce the disease activity of rheumatoid arthritis and retard the progression of arthritic tissue destruction. DMARDs include a diverse group of small-molecule nonbiological and biological agents (mainly antibodies or binding proteins), as summarized in Table 38–5.

Biological DMARDs remain reserved for patients with persistent moderate or high disease activity and indicators of poor prognosis. Therapy is tailored to the individual patient, and the use of these agents must be weighed against their potentially serious adverse effects. The combination of NSAIDs with these agents is common.

TABLE 38-5 ■ DISEASE-MODIFYING ANTIRHEUMATIC DRUGS

DRUG	CLASS OR ACTION	CHAPTER NUMBER
Small molecules		
Methotrexate	Antifolate	66
Leflunomide	Pyrimidine synthase inhibitor	66
Hydroxychloroquine	Antimalarial	53
Minocycline	5-Lipoxygenase inhibitor, tetracycline antibiotic	37, 59
Sulfasalazine	Salicylate	38, 51
Azathioprine	Purine synthase inhibitor	66
Cyclosporine	Calcineurin inhibitor	35
Cyclophosphamide	Alkylating agent	66
Penicillamine	Chelating agent	71
Auranofin	Gold compound	71
Biologicals		
Adalimumab	Ab, TNF- α antagonist	34, 35
Golimumab	Ab, TNF- α antagonist	
Etanercept	Ab, TNF- α antagonist	
Infliximab	IgG-TNF receptor fusion protein (anti-TNF)	
Certolizumab	Fab fragment toward TNF- α	
Abatacept	T-cell costimulation inhibitor (binds B7 protein on antigen-presenting cell)	34, 35
Rituximab	Ab toward CD20 (cytotoxic toward B cells)	67
Anakinra	IL-1 receptor antagonist	35, 67
Tocilizumab	IL-6 receptor antagonist	35, 67
Tofacitinib	Janus kinase inhibitor	67

Pharmacotherapy of Gout

Gout results from the precipitation of urate crystals in the tissues and the subsequent inflammatory response. Acute gout usually causes painful distal monoarthritis and can cause joint destruction, subcutaneous deposits (tophi), and renal calculi and damage. Gout affects 3% of the adult population of Western countries.

The pathophysiology of gout is incompletely understood. Hyperuricemia, while a prerequisite, does not inevitably lead to gout. Uric acid, the end product of purine metabolism, is relatively insoluble compared to its hypoxanthine and xanthine precursors, and normal serum urate levels (~5 mg/dL, or 0.3 mM) approach the limit of solubility. In most patients with gout, hyperuricemia arises from underexcretion rather than overproduction of urate. Mutations of one of the renal URATs, URAT-1, are associated with hypouricemia. Urate tends to crystallize as monosodium urate in colder or more acidic conditions. Monosodium urate crystals activate monocytes/macrophages via the toll-like receptor pathway mounting an innate immune response. This results in the activation of the cryopyrin inflammasome, the secretion of cytokines, including IL-1 β and TNF- α , endothelial activation, and attraction of neutrophils to the site of inflammation. Neutrophils secrete inflammatory mediators that lower the local pH and lead to further urate precipitation. The aims of treatment are to:

- decrease the symptoms of an acute attack;
- decrease the risk of recurrent attacks; and
- lower serum urate levels.

The following substances are available for these purposes:

- Drugs that relieve inflammation and pain (NSAIDs, colchicine, glucocorticoids)

- Drugs that prevent inflammatory responses to crystals (colchicine and NSAIDs)
- Drugs that act by inhibition of urate formation (e.g., allopurinol, febuxostat) or to augment urate excretion (probenecid)

The NSAIDs have been discussed previously. Glucocorticoids are discussed in Chapter 46. This section focuses on *colchicine*, *allopurinol*, *febuxostat*, *pegloticase*, *rasburicase*, and the uricosuric agents *probenecid* and *benzbromarone*. Some other drugs used off label to reduce uric acid levels or treat gout include losartan, fenofibrate, and canakinumab; in 2011, the FDA denied a license application for canakinumab, citing an unfavorable risk-versus-benefit safety profile.

Colchicine

Colchicine is one of the oldest available therapies for acute gout. Plant extracts containing colchicine were used for joint pain in the 6th century. Colchicine is considered second-line therapy because it has a narrow therapeutic window and a high rate of side effects, particularly at higher doses.

Mechanism of Action

Colchicine exerts a variety of pharmacological effects, but how these relate to its activity in gout is partially understood (Leung et al., 2015). It has antimitotic effects, arresting cell division in G₁ by interfering with microtubule and spindle formation (an effect shared with vinca alkaloids). This effect is greatest on cells with rapid turnover (e.g., neutrophils, GI epithelium). Depolymerization of microtubules by colchicine reduces neutrophil recruitment to inflamed tissue and neutrophil adhesion. Colchicine may alter neutrophil motility and decreases the secretion of chemotactic factors and superoxide anions by activated neutrophils. Colchicine limits monosodium urate crystal-induced NALP3

inflammasome activation and subsequent formation of IL-1 β and IL-18. This mechanism may explain its therapeutic activity in familial Mediterranean fever and other inflammatory diseases. Colchicine inhibits the release of histamine-containing granules from mast cells, the secretion of insulin from pancreatic β cells, and the movement of melanin granules in melanophores.

Colchicine also exhibits a variety of other pharmacological effects. It lowers body temperature, increases the sensitivity to central depressants, depresses the respiratory center, enhances the response to sympathomimetic agents, constricts blood vessels, and induces hypertension by central vasomotor stimulation. It enhances GI activity by neurogenic stimulation, but depresses it by a direct effect, and alters neuromuscular function.

ADME

Absorption of oral colchicine is rapid but variable. Peak plasma concentrations occur 0.5–2 h after dosing. Food does not affect the rate or extent of colchicine absorption. In plasma, 39% of colchicine is protein bound, primarily to albumin. The formation of colchicine-tubulin complexes in many tissues contributes to its large volume of distribution. There is significant enterohepatic circulation. The exact metabolism of colchicine in humans is unknown, but in vitro studies indicated that it may undergo oxidative demethylation by CYP3A4; glucuronidation may also be involved. In healthy volunteers, 40%–65% of the total absorbed oral dose of colchicine is recovered unchanged in the urine. The kidney, liver, and spleen also contain high concentrations of colchicine, but it apparently is largely excluded from heart, skeletal muscle, and brain. Colchicine is a substrate of P-glycoprotein efflux. The plasma $t_{1/2}$ of colchicine is about 31 h. The drug is contraindicated in patients with hepatic or renal impairment requiring concomitant therapy with CYP3A4 or P-glycoprotein inhibitors. Colchicine is not removed by hemodialysis.

Therapeutic Uses

The dosing regimen for colchicine must be individualized on the basis of age, renal and hepatic function, concomitant use of other medications, and disease severity. A minimum of 3 days, but preferably 7–14 days, should elapse between courses of gout treatment with colchicine to avoid cumulative toxicity. Patients with hepatic or renal disease and dialysis patients should receive reduced doses or less-frequent therapy. For elderly patients, adjust the dose for renal function. For those with cardiac, renal, hepatic, or GI disease, NSAIDs or glucocorticoids may be preferred.

Acute Gout. Colchicine dramatically relieves acute attacks of gout. It is effective in roughly two-thirds of patients if given within 24 h of attack onset. Pain, swelling, and redness abate within 12 h and are completely gone within 48–72 h. The regimen approved for adults recommends a total of two doses taken 1 h apart: 1.2 mg (2 tablets) at the first sign of a gout flare followed by 0.6 mg (1 tablet) 1 h later. Patients with severe renal or hepatic dysfunction and patients receiving dialysis should not receive repeat courses of therapy more frequently than every 2 weeks.

Prevention of Acute Gout. Colchicine is used in the prevention of recurrent gout, particularly in the early stages of antihyperuricemic therapy. The typical dose for prophylaxis in patients with normal renal and hepatic function is 0.6 mg taken orally 3 or 4 days/week for patients who have less than 1 attack per year, 0.6 mg daily for patients who have more than 1 attack per year, and 0.6 mg up to two times daily for patients who have severe attacks.

Adverse Effects

Exposure of the GI tract to large amounts of colchicine and its metabolites via enterohepatic circulation and the rapid rate of turnover of the GI mucosa may explain why the GI tract is particularly susceptible to colchicine toxicity. Nausea, vomiting, diarrhea, and abdominal pain are the most common untoward effects and the earliest signs of impending colchicine toxicity. Drug administration should be discontinued as soon as these symptoms occur. There is a latent period, which is not altered by dose, of several hours or more between the administration of the drug and the onset of symptoms. A dosing study demonstrated that one dose initially and a single additional dose after 1 h was much less toxic than the

traditional hourly dosing regimen for acute gout flares. Acute intoxication causes hemorrhagic gastropathy.

Other serious side effects of colchicine therapy include myelosuppression, leukopenia, granulocytopenia, thrombopenia, aplastic anemia, and rhabdomyolysis. Life-threatening toxicities are associated with administration of concomitant therapy with P-glycoprotein or CYP3A4 inhibitors. The FDA suspended the U.S. marketing of all injectable dosage forms of colchicine in 2008. Colchicine is marketed in a fixed-dose combination with probenecid for the management of frequent recurrent gout attacks.

Allopurinol

History

Allopurinol initially was synthesized as a candidate antineoplastic agent but was found to lack antineoplastic activity. Subsequent testing showed it to be an inhibitor of XO that was useful clinically for the treatment of gout.

Allopurinol inhibits XO and prevents the synthesis of urate from hypoxanthine and xanthine. Allopurinol is used to treat hyperuricemia in patients with gout and to prevent it in those with hematological malignancies about to undergo chemotherapy (acute tumor lysis syndrome). Even though underexcretion rather than overproduction is the underlying defect in most gout patients, allopurinol remains effective therapy.

Allopurinol is an analogue of hypoxanthine. Its active metabolite, oxypurinol, is an analogue of xanthine.

Mechanism of Action

Both allopurinol and its primary metabolite, oxypurinol (alloxanthine), reduce urate production by inhibiting XO, which converts xanthine to uric acid. Allopurinol competitively inhibits XO at low concentrations and is a noncompetitive inhibitor at high concentrations. Allopurinol also is a substrate for XO; the product of this reaction, oxypurinol, also is a noncompetitive inhibitor of the enzyme. The formation of oxypurinol, together with its long persistence in tissues, is responsible for much of the pharmacological activity of allopurinol.

In the absence of allopurinol, the dominant urinary purine is uric acid. During allopurinol treatment, the urinary purines include hypoxanthine, xanthine, and uric acid. Because each has its independent solubility, the concentration of uric acid in plasma is reduced and purine excretion is increased, without exposing the urinary tract to an excessive load of uric acid. Despite their increased concentrations during allopurinol therapy, hypoxanthine and xanthine are efficiently excreted, and tissue deposition does not occur. There is a small risk of xanthine stones in patients with a very high urate load before allopurinol therapy, which can be minimized by liberal fluid intake and urinary alkalization.

Allopurinol facilitates the dissolution of tophi and prevents the development or progression of chronic gouty arthritis by lowering the uric acid concentration in plasma below the limit of its solubility. The formation of uric acid stones virtually disappears with therapy, which prevents the development of nephropathy. Once significant renal injury has occurred, allopurinol cannot restore renal function but may delay disease progression. The incidence of acute attacks of gouty arthritis may increase during the early months of allopurinol therapy as a consequence of mobilization of tissue stores of uric acid. Coadministration of colchicine helps suppress such acute attacks. In some patients, the allopurinol-induced increase in excretion of oxypurines is less than the reduction in uric acid excretion; this disparity primarily is a result of reutilization of oxypurines and feedback inhibition of de novo purine biosynthesis.

Allopurinol is absorbed relatively rapidly after oral ingestion, and peak plasma concentrations are reached within 60–90 min. About 20% is excreted in the feces in 48–72 h, presumably as unabsorbed drug, and 10%–30% is excreted unchanged in the urine. The remainder undergoes metabolism, mostly to oxypurinol. Oxypurinol is excreted slowly in the urine by glomerular filtration, counterbalanced by some tubular reabsorption. The plasma $t_{1/2}$ of allopurinol and oxypurinol is about 1–2 h and about 18–30 h (longer in those individuals with renal impairment), respectively. This allows for once-daily dosing and makes allopurinol the most commonly used antihyperuricemic agent. Allopurinol and its active metabolite oxypurinol are distributed in total tissue water, with the exception of brain, where their concentrations are about one-third of those in other tissues. Neither compound is bound to plasma proteins. The plasma concentrations of the two compounds do not correlate well with therapeutic or toxic effects.

Therapeutic Uses

Allopurinol is available for oral and intravenous use. Oral therapy provides effective therapy for primary and secondary gout, hyperuricemia secondary to malignancies, and calcium oxalate calculi. The goal of therapy is to reduce the plasma uric acid concentration to less than 6 mg/dL (<360 $\mu\text{mol/L}$) and typically less than 5 mg/dL (<297 $\mu\text{mol/L}$) in patients with tophi to accelerate the clearance of monosodium urate. In the management of gout, it is customary to antecede allopurinol therapy with colchicine and to avoid starting allopurinol during an acute attack. Fluid intake should be sufficient to maintain daily urinary volume greater than 2 L; slightly alkaline urine is preferred. An initial daily dose of 100 mg in patients with estimated glomerular filtration rates greater than 40 mg/min is increased by 100-mg increments at weekly intervals. Most patients can be maintained on 300 mg/d. Patients with reduced glomerular filtration require a lower dose to achieve the targeted uric acid concentration, and their clinical and pharmacological response needs be monitored frequently. Those with hematological malignancies may need up to 800 mg/d beginning 2–3 days before the start of chemotherapy. Daily doses greater than 300 mg should be divided.

The usual daily dose in children with secondary hyperuricemia associated with malignancies is 150–300 mg, depending on age. Allopurinol also is useful in lowering the high plasma concentrations of uric acid in patients with Lesch-Nyhan syndrome (orphan designation) and thereby prevents the complications resulting from hyperuricemia; there is no evidence that it alters the progressive neurological and behavioral abnormalities that are characteristic of the disease. Other orphan uses for allopurinol include Chagas disease and the ex vivo preservation of cadaveric kidneys prior to transplantation.

Adverse Effects

Allopurinol generally is well tolerated. The most common adverse effects are hypersensitivity reactions that may manifest after months or years of therapy. Serious hypersensitivity reactions preclude further use of the drug. The cutaneous reaction caused by allopurinol is predominantly a pruritic, erythematous, or maculopapular eruption, but occasionally the lesion is urticarial or purpuric.

Rarely, toxic epidermal necrolysis or Stevens-Johnson syndrome occurs, which can be fatal. The risk for Stevens-Johnson syndrome is limited primarily to the first 2 months of treatment. Because the rash may precede severe hypersensitivity reactions, patients who develop a rash should discontinue allopurinol. If indicated, desensitization to allopurinol can be carried out starting at 10–25 $\mu\text{g/d}$, with the drug diluted in oral suspension and doubled every 3–14 days until the desired dose is reached. This is successful in approximately half of patients.

Oxypurinol has orphan drug status and is available for compassionate use in the U.S. for patients intolerant of allopurinol. Fever, malaise, and myalgias also may occur in about 3% of patients, more frequently in those with renal impairment. Transient leukopenia or leukocytosis and eosinophilia are rare reactions that may require cessation of therapy. Hepatomegaly and elevated levels of transaminases in plasma and progressive renal insufficiency also may occur.

Allopurinol is contraindicated in patients who have exhibited serious adverse effects or hypersensitivity reactions to the medication and in nursing mothers and children, except those with malignancy or certain inborn errors of purine metabolism (e.g., Lesch-Nyhan syndrome). Allopurinol generally is used in patients with hyperuricemia posttransplantation. It can be used in conjunction with a uricosuric agent.

Drug Interactions

Allopurinol increases the $t_{1/2}$ of probenecid and enhances its uricosuric effect, while probenecid increases the clearance of oxypurinol, thereby increasing dose requirements of allopurinol. Allopurinol inhibits the enzymatic inactivation of mercaptopurine and its derivative azathioprine by XO. Thus, when allopurinol is used concomitantly with oral mercaptopurine or azathioprine, dosage of the antineoplastic agent must be reduced to 25%–33% of the usual dose (see Chapters 35 and 66). This is of importance when treating gout in the transplant recipient. The risk of bone marrow suppression also is increased when allopurinol is administered with cytotoxic agents that are not metabolized by XO, particularly cyclophosphamide. Allopurinol also may interfere with the hepatic inactivation of other drugs, including warfarin. Although the effect is variable, increased monitoring of prothrombin activity is recommended in patients receiving both medications.

It remains to be established whether the increased incidence of rash in patients receiving concurrent allopurinol and ampicillin should be ascribed to allopurinol or to hyperuricemia. Hypersensitivity reactions have been reported in patients with compromised renal function, especially those who are receiving a combination of allopurinol and a thiazide diuretic. The concomitant administration of allopurinol and theophylline leads to increased accumulation of an active metabolite of theophylline, 1-methylxanthine; the concentration of theophylline in plasma also may be increased (see Chapter 40).

Febuxostat

Febuxostat is an XO inhibitor approved for treatment of hyperuricemia in patients with gout.

Mechanism of Action

Febuxostat is a nonpurine inhibitor of XO. Unlike oxypurinol, the active metabolite of allopurinol, which inhibits the reduced form of XO, febuxostat forms a stable complex with both the reduced and oxidized enzymes and inhibits catalytic function in both states.

ADME

Febuxostat is rapidly absorbed with maximum plasma concentrations at 1–1.5 h postdose. The absolute bioavailability is unknown. Magnesium hydroxide and aluminum hydroxide delay absorption by about 1 h. Food reduces absorption slightly. Febuxostat, $t_{1/2}$ of 5–8 h, is extensively metabolized by both conjugation via UGT enzymes, including UGT1A1, UGT1A3, UGT1A9, and UGT2B7, and oxidation by CYPs 1A2, 2C8, and 2C9 and non-CYP enzymes and has elimination by both hepatic and renal pathways. Mild-to-moderate renal or hepatic impairment does not affect its elimination kinetics relevantly.

Therapeutic Use

Febuxostat is approved for hyperuric patients with gout attacks but is not recommended for treatment of asymptomatic hyperuricemia. It is available in 40- and 80-mg oral tablets. A dose of 40-mg/d febuxostat lowered serum uric acid to similar levels as 300-mg/d allopurinol. More patients reached the target concentration of 6.0 mg/dL (360 $\mu\text{mol/L}$) on 80-mg/d febuxostat than on 300-mg/d allopurinol. Thus, therapy should be initiated with 40 mg/d and the dose increased if the target serum uric acid concentration is not reached within 2 weeks.

Adverse Events

The most common adverse reactions in clinical studies were liver function abnormalities, nausea, joint pain, and rash. Liver function should be monitored periodically. An increase in gout flares was frequently observed after initiation of therapy, due to reduction in serum uric acid levels resulting

in mobilization of urate from tissue deposits. Concurrent prophylactic treatment with an NSAID or colchicine is usually required. There was a higher rate of myocardial infarction and stroke in patients on febuxostat than on allopurinol. Whether there is a causal relationship between the cardiovascular events and febuxostat therapy or whether these were due to chance is not clear. Meanwhile patients should be monitored for cardiovascular complications.

Drug Interactions

Plasma levels of drugs metabolized by XO (e.g., theophylline, mercaptopurine, azathioprine) will increase when administered concurrently with febuxostat. Thus, febuxostat is contraindicated in patients on azathioprine or mercaptopurine; care should be exercised with concomitant administration of theophylline due to a 400-fold increase in the urinary excretion of the 1-methylxanthine metabolite.

Uricase

Pegloticase is a pegylated uricase (urate oxidase) that catalyzes the enzymatic oxidation of uric acid into allantoin, a more soluble and inactive metabolite. The recombinant enzyme, based on the porcine uricase, is administered by infusion. Pegloticase is used for the treatment of severe, treatment-refractory, chronic gout or when use of other urate-lowering therapies is contraindicated.

The drug's efficacy may be hampered by the production of antibodies against the drug. Pegloticase antibodies develop in nearly 90% of people, and high titers are associated with loss of the urate-lowering effect and with an elevated risk for infusion reactions. Anaphylactic reactions, and hemolysis in G6PD-deficient patients, have been associated with the use of pegloticase. Other frequently observed adverse reactions include vomiting, nausea, chest pain, constipation, diarrhea, and erythema, pruritus, and urticaria.

Rasburicase is a recombinant uricase that has been shown to lower urate levels more effectively than allopurinol. It is indicated for the initial management of elevated plasma uric acid levels in pediatric and adult patients with leukemia, lymphoma, and solid tumor malignancies who are receiving anticancer therapy expected to result in tumor lysis and significant hyperuricemia. The experience with rasburicase for treatment of gout is limited because of the formation of activity-limiting antibodies against the drug. Hemolysis in G6PD-deficient patients, methemoglobinemia, acute renal failure, and anaphylaxis have been associated with the use of rasburicase. Other frequently observed adverse reactions include vomiting, fever, nausea, headache, abdominal pain, constipation, diarrhea, and mucositis. Rasburicase causes enzymatic degradation of the uric acid in blood samples, and special handling is required to prevent spuriously low values for plasma uric acid in patients receiving the drug.

Uricosuric Agents

Uricosuric agents increase the excretion of uric acid. These agents are typically reserved for patients who underexcrete uric acid relative to their plasma levels. In humans, urate is filtered, secreted, and reabsorbed by the kidneys. Reabsorption is robust, such that the net amount excreted usually is about 10% of that filtered. Reabsorption is mediated by an OAT family member, URAT-1, which can be inhibited.

Urate is exchanged by URAT-1 for either an organic anion such as lactate or nicotinate or less potently for an inorganic anion such as chloride. Uricosuric drugs such as probenecid, benzbromarone (not available in the U.S.), and losartan compete with urate for the transporter, thereby inhibiting its reabsorption via the urate-anion exchanger system. However, transport is bidirectional, and depending on dosage, a drug may either decrease or increase the excretion of uric acid.

There are two mechanisms by which a drug may nullify the uricosuric action of another. First, the drug may inhibit the secretion of the uricosuric agent, thereby denying it access to its site of action, the luminal aspect of the brush border. Second, the inhibition of urate secretion by one drug may counterbalance the inhibition of urate reabsorption by the other.

Probenecid

Probenecid is a highly lipid-soluble benzoic acid derivative (pK_a 3.4).

Mechanism of Action. Inhibition of Organic Acid Transport. The actions of probenecid are confined largely to inhibition of the transport of organic acids across epithelial barriers. Probenecid inhibits the reabsorption of uric acid by OATs, principally URAT-1. Uric acid is the only important endogenous compound whose excretion is known to be increased by probenecid. The uricosuric action of probenecid is blunted by the coadministration of salicylates.

Inhibition of Transport of Miscellaneous Substances. Probenecid inhibits the tubular secretion of a number of drugs, such as methotrexate and the active metabolite of clofibrate. It inhibits renal secretion of the inactive glucuronide metabolites of NSAIDs such as naproxen, ketoprofen, and indomethacin and thereby can increase their plasma concentrations. Probenecid inhibits the transport of 5-HIAA and other acidic metabolites of cerebral monoamines from the CSF to the plasma. The transport of drugs such as penicillin G also may be affected, and probenecid is used therapeutically to elevate and prolong plasma β -lactam levels. Probenecid depresses the biliary secretion of certain compounds, including the diagnostic agents indocyanine green and bromosulphophthalein. It also decreases the biliary secretion of rifampin, leading to higher plasma concentrations.

ADME. Probenecid is absorbed completely after oral administration. Peak plasma concentrations are reached in 2–4 h. The $t_{1/2}$ of the drug in plasma is dose dependent and varies from less than 5 to more than 8 h. Between 85% and 95% of the drug is bound to plasma albumin; the 5%–15% of unbound drug is cleared by glomerular filtration and active secretion by the proximal tubule. A small amount of probenecid glucuronide appears in the urine. It also is hydroxylated to metabolites that retain their carboxyl function and have uricosuric activity.

Therapeutic Uses. Probenecid is marketed for oral administration, alone and in combination with colchicine. The starting dose is 250 mg twice daily, increasing over 1–2 weeks to 500–1000 mg twice daily. Probenecid increases urinary urate levels. Liberal fluid intake therefore should be maintained throughout therapy to minimize the risk of renal stones. Probenecid should not be used in gouty patients with nephrolithiasis or with overproduction of uric acid. Concomitant colchicine or NSAIDs are indicated early in the course of therapy to avoid precipitating an attack of gout, which may occur in 20% or fewer of gouty patients treated with probenecid alone. After 6 months, if serum uric acid levels are within normal limits and there have been no gout attacks, the dose of probenecid may be tapered off by 500 mg every 6 months.

Combination With Penicillin. Higher doses of probenecid (1–2 g/d) are used as an adjuvant to prolong the dwell time of penicillin and other β -lactam antibiotics in the body (see Chapter 57).

Adverse Effects. Probenecid is well tolerated. Approximately 2% of patients develop mild GI irritation. The risk is increased at higher doses. It is ineffective in patients with renal insufficiency and should be avoided in those with creatinine clearance of less than 50 mL/min. Hypersensitivity reactions usually are mild and occur in 2%–4% of patients. Substantial overdosage with probenecid results in CNS stimulation, convulsions, and death from respiratory failure.

Benzbromarone

Benzbromarone is a potent uricosuric agent that has been marketed in several countries since 1970. It is a reversible inhibitor of the urate-anion exchanger in the proximal tubule. Hepatotoxicity reported in conjunction with its use has limited its availability. The drug is absorbed readily after oral ingestion; peak plasma levels are achieved in about 4 h. It is

metabolized to monobrominated and dehalogenated derivatives, both of which have uricosuric activity, and is excreted primarily in the bile.

As the micronized powder, it is effective in a single daily dose ranging from 25 to 100 mg. It is effective in patients with renal insufficiency and may be prescribed to patients who are either allergic or refractory to other drugs used for the treatment of gout. Preparations that combine allopurinol and benzbromarone are more effective than either drug alone in lowering serum uric acid levels, in spite of the fact that benzbromarone lowers plasma levels of oxypurinol, the active metabolite of allopurinol. The uricosuric action is blunted by aspirin or sulfinpyrazone.

Lesinurad

Lesinurad is FDA approved for combination therapy with an XO inhibitor in treating hyperuricemia.

Mechanism of Action. Lesinurad inhibits the URAT-1 and OAT-4 transporters, thereby reducing renal uric acid reabsorption.

ADME. Lesinurad is rapidly absorbed after oral administration and has bioavailability of about 100%. Lesinurad is largely bound to plasma albumin and other plasma proteins (<98%). The elimination $t_{1/2}$ is about 5 h (clearance ~ 6 L/h). CYP2C9 is the major metabolizing enzyme. Lesinurad (30% unchanged) and its metabolites are excreted in the urine (>60% of dose) and feces. Renal impairment increases exposure, and lesinurid

should not be used when the renal function is severely reduced (estimated creatinine clearance < 45 mL/min).

Therapeutic Uses. Lesinurad (200 mg/d) is marketed for the treatment of gout in patients who have not achieved the target serum uric acid levels with an XO inhibitor alone. It should not be used for the treatment of asymptomatic hyperuricemia or as monotherapy.

Adverse Effects. Lesinurad has been labeled with a black-box warning because of a risk of acute renal failure that is more common when it is used without an XO inhibitor. Increases in blood creatinine levels (1.5- to 2-fold) were observed with a frequency of approximately 4% during combination therapy and 8% during monotherapy. Renal failure occurred in less than 1% of patients during combination therapy and approximately 9% during monotherapy. Similarly, the risk of nephrolithiasis is increased when lesinurad is given alone. Thus, if treatment with the XO inhibitor is interrupted, lesinurid dosing should also be interrupted. Other adverse reactions reported by patients during clinical trials include headache (~5%), influenza-like symptoms (~5%), and gastroesophageal reflux (~3%).

Drug Facts For Your Personal Formulary: *Gout*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Drugs that relieve inflammation and pain		
NSAIDs	• See NSAIDs, above	• See NSAIDs, above
Glucocorticoids	• See Chapter 46	• See Chapter 46
Colchicine	• Prophylaxis and the treatment of acute gout flares	<ul style="list-style-type: none"> • Depolymerizes microtubules \Rightarrow \downarrow neutrophil migration into inflamed area • Narrow therapeutic index; toxic effects related to antimitotic activity • $t_{1/2}$: 31 h (21–50 h) • Individualize dose on the basis of age, hepatic and renal function • Contraindicated in patients with GI, renal, hepatic or cardiac disorders • Adverse effects: primarily GI • Drug interactions with P-gp and CYP3A4 inhibitors
Xanthine oxidase (XO) inhibitors • Inhibit urate synthesis		
Allopurinol	<ul style="list-style-type: none"> • Hyperuricemia in patients with gout • Calcium oxalate calculi • Hyperuricemia associated with cancer treatment 	<ul style="list-style-type: none"> • active metabolite: oxypurinol • $t_{1/2}$: allopurinol 1–2 h, oxypurinol 18–30h; adjust dose in renal impairment • Rash, diarrhea, nausea frequent • Risk of gout attacks during the early months of therapy (tissue urate mobilization) • Serum [urate] usually \downarrow in 24–48 h, normal 1–3 weeks
Febuxostat	• Hyperuricemia	<ul style="list-style-type: none"> • non-purine • more selective for XO than allopurinol • $t_{1/2}$: 5 to 8 h • Liver function abnormalities (5–7%)
Uricase • Oxidizes uric acid to allantoin (more soluble and inactive metabolite)		
Pegloticase	• Chronic gout refractory to conventional therapy	<ul style="list-style-type: none"> • $t_{1/2}$: 14 days • \downarrow Blood urate within hours of initial administration • Antibody development against drug may limit efficacy, cause hypersensitivity reactions • Adverse effects: bruising (11%), urticaria (11%), nausea (11%), gout flare during early therapy (74%), chest pain (6%)
Rasburicase	• Hyperuricemia associated with malignancy (pediatric and adult patients)	<ul style="list-style-type: none"> • $t_{1/2}$: 16 to 23 h • \downarrow Uric acid levels within hours of initial administration • Not suitable for chronic gout; activity-limiting antibodies form against the drug.
Uricosuric drugs—Inhibit of reabsorption of uric acid by organic anion transporters, thereby increasing excretion of uric acid		
Probenecid	<ul style="list-style-type: none"> • Hyperuricemia associated with gout (but not for acute attacks) • Prolongation and elevation of beta-lactam plasma levels 	<ul style="list-style-type: none"> • Interferes with renal tubular handling of organic acids • $t_{1/2}$: 6–12 h (dose-dependent) • Risk of gout attacks during the early months of therapy (tissue urate mobilization) • ineffective in patients with renal insufficiency
Lesinurad	• Gout in patients who have not achieved the target serum uric acid levels with XO inhibitor alone	<ul style="list-style-type: none"> • $t_{1/2}$: 5 h • CYP2C9 substrate, so caution is recommended in patients who are CYP2C9 poor metabolizers • Must be used together with XO inhibitor due to renal failure risk

BRADYKININ, KALLIDIN, AND THEIR ANTAGONISTS

- The Endogenous Kallikrein-Kininogen-Kinin System
- Kallikrein Inhibitors
- Bradykinin and the Effects of ACE Inhibitors
- Kinin Receptor Antagonists

Endogenous histamine plays a role in the immediate allergic response and is an important regulator of gastric acid secretion. More recently, a role for histamine as a modulator of neurotransmitter release in the central and peripheral nervous systems has emerged. The cloning of four receptors for histamine and the development of subtype-specific receptor antagonists have enhanced our understanding of the physiological and pathophysiological roles of histamine. Competitive antagonists of H₁ receptors are used therapeutically in treating allergies, urticaria, anaphylactic reactions, nausea, motion sickness, and insomnia. Antagonists of the H₂ receptor are effective in reducing gastric acid secretion.

The peptides bradykinin and kallidin, released after activation of the kallikrein-kinin system, have cardiovascular effects similar to those of histamine and play prominent roles in inflammation and nociception. Icatibant, a competitive antagonist of the bradykinin B₂ receptor, and ecallantide, a specific plasma kallikrein inhibitor, are approved for the treatment of acute episodes of edema in patients with hereditary angioedema.

Histamine

Histamine is a hydrophilic molecule consisting of an imidazole ring and an amino group connected by an ethylene group; histamine is biosynthesized from histidine by decarboxylation (Figure 39–1). Histamine acts through four classes of receptors, designated H₁ through H₄. The four histamine receptors, all GPCRs, can be differentially activated by analogues of histamine (Figure 39–2) and inhibited by specific antagonists (Table 39–1).

Distribution and Biosynthesis

Distribution

Almost all mammalian tissues contain histamine in amounts ranging from less than 1 to more than 100 µg/g. Concentrations in plasma and other body fluids are generally very low, but they are significant in human CSF.

HISTORY

Histamine was first prepared synthetically in 1907 and isolated from ergot extracts in 1910 (Emanuel, 1999). It was identified as a natural constituent of mammalian tissues in 1927 by Best and colleagues and named *histamine* after the Greek word for tissue, *histos*. Dale and Laidlaw made the crucial observation that histamine injection into mammals caused a shock-like reaction and proposed its role in mediating symptoms of anaphylaxis (Emanuel, 1999).

The concentration of histamine is particularly high in tissues that contain large numbers of mast cells, such as skin, bronchial mucosa, and intestinal mucosa.

Synthesis, Storage, and Metabolism

Histamine is formed by the decarboxylation of histidine by the enzyme *L-histidine decarboxylase* (Figure 39–1). Mast cells and basophils synthesize histamine and store it in secretory granules. At the secretory granule pH of about 5.5, histamine is positively charged and ionically complexed with negatively charged acidic groups on other granule constituents, primarily proteases and heparin or chondroitin sulfate proteoglycans. The turnover rate of histamine in secretory granules is slow (days to weeks). Non-mast cell sites of histamine formation include the epidermis, enterochromaffin-like cells of the gastric mucosa, neurons within the CNS, and cells in regenerating or rapidly growing tissues. Turnover is rapid at these non-mast cell sites because the histamine is released continuously rather than stored. Non-mast cell sites of histamine production contribute significantly to the daily excretion of histamine metabolites in the urine. Because *L-histidine decarboxylase* is an inducible enzyme, the histamine-forming capacity at such sites is subject to regulation. Histamine that is released or ingested is rapidly metabolized by either ring methylation catalyzed by *histamine-N-methyltransferase* or oxidative deamination catalyzed by *diamine oxidase* (Figure 39–1), and the metabolites are eliminated in the urine.

Release and Functions of Endogenous Histamine

Histamine is released from storage granules as a result of the interaction of antigen with IgE antibodies on the mast cell surface. Histamine plays a central role in immediate hypersensitivity and allergic responses. The actions of histamine on bronchial smooth muscle and blood vessels account for many of the symptoms of the allergic response. Histamine is a leukocyte chemoattractant, plays a major role in regulating gastric acid secretion, and modulates neurotransmitter release. In addition, some drugs act directly on mast cells to release histamine, causing untoward effects.

Role in Allergic Responses

The principal target cells of immediate hypersensitivity reactions are mast cells and basophils (Schwartz, 1994). As part of the allergic response to an antigen, IgE antibodies are generated and bind to the surfaces of mast cells and basophils via specific high-affinity F_c receptors. This receptor, FcεRI, consists of α, β, and two γ chains (see Chapter 34). Antigen bridges the IgE molecules and via FcεRI activates signaling pathways in mast cells or

Abbreviations

EDHF: endothelial-derived hyperpolarizing factor
EET: epoxyeicosatrienoic acid
eNOS: endothelial nitric oxide synthase
GABA: gamma-aminobutyric acid
GPCR: G protein-coupled receptor
HMW: high molecular weight
5HT: serotonin
IgE: immunoglobulin E
IL-1: interleukin 1
iNOS: inducible nitric oxide synthase
IP₃: inositol triphosphate
JNK1/2: c-Jun N-terminal kinase1/2
LMW: low molecular weight
MAO: monoamine oxidase
PAF: platelet-activating factor
PG: prostaglandin
TNF- α : tumor necrosis factor alpha

basophils involving tyrosine kinases and subsequent phosphorylation of multiple protein substrates within 5–15 sec of contact with antigen. These events trigger the exocytosis of the contents of secretory granules that, in addition to histamine, includes serotonin, proteases, lysosomal enzymes, cytokines, and proteoglycans (Schwartz, 1994).

Release of Other Autacoids

Stimulation of IgE receptors also activates PLA₂, leading to the production of a host of mediators, including PAF and metabolites of arachidonic acid such as leukotrienes C₄ and D₄, which contract bronchial smooth muscle (Chapters 37 and 40). Kinins also are generated during some allergic responses. Thus, the mast cell secretes a variety of inflammatory mediators in addition to histamine, each contributing to aspects of the allergic response (see discussion that follows).

Histamine Release by Drugs, Peptides, Venoms, and Other Agents

Mechanical injury and many compounds, including a large number of therapeutic agents, stimulate the release of histamine from mast cells directly and without prior sensitization. Responses of this sort are most likely to occur following intravenous injections of certain categories of substances, particularly organic bases. Tubocurarine, succinylcholine, morphine, some antibiotics, radiocontrast media, and certain carbohydrate plasma expanders also may elicit the response. The phenomenon is one of clinical concern and may account for unexpected anaphylactoid reactions. Basic polypeptides often are effective histamine releasers, and over a limited range, their potency generally increases with the number of basic groups. For example, bradykinin is a poor histamine releaser, whereas kallidin (Lys-bradykinin) and substance P, with more positively charged amino acids, are more active (Johnson and Erdos, 1973). Some venoms, such as that of the wasp, contain potent histamine-releasing peptides. Basic polypeptides released on tissue injury constitute pathophysiological stimuli for secretion from mast cells and basophils.

Figure 39–1 Pathways of histamine synthesis and metabolism in humans. Histamine is synthesized from histidine by decarboxylation. Histamine is metabolized via two pathways, predominantly by methylation of the ring followed by oxidative deamination (left side of figure) and secondarily by oxidative deamination and then conjugation with ribose.

Within seconds of the intravenous injection of a histamine liberator, human subjects experience a burning, itching sensation. This effect, most marked in the palms of the hand and in the face, scalp, and ears, is soon followed by a feeling of intense warmth. The skin reddens, and the color rapidly spreads over the trunk. Blood pressure falls, the heart rate accelerates, and the subject usually complains of headache. After a few minutes, blood pressure recovers, and crops of hives usually appear on the skin. Colic, nausea, hypersecretion of acid, and moderate bronchospasm also frequently occur. The effect becomes less intense with successive administration of the secretagogue as mast cell stores of histamine are depleted. Histamine liberators do not deplete histamine from non-mast cell sites. The mechanism by which basic secretagogues release histamine likely involves their direct interaction with G proteins or activation of a mast cell-specific cell surface GPCR named MRGRX2 (Seifert, 2015).

Increased Proliferation of Mast Cells and Basophils; Gastric Carcinoid Tumors

In urticaria pigmentosa (cutaneous mastocytosis), mast cells aggregate in the upper corium and give rise to pigmented cutaneous lesions that sting when stroked. In systemic mastocytosis, overproliferation of mast cells is also found in other organs. Patients with these syndromes suffer a constellation of signs and symptoms attributable to excessive histamine release, including urticaria, dermatographism, pruritus, headache, weakness, hypotension, flushing of the face, and a variety of GI effects, such as diarrhea or peptic ulceration. A variety of stimuli, including exertion, insect stings, exposure to heat, allergens (including drugs to which a patient is allergic), can activate mast cells and cause histamine release, as can organic bases (many drugs) that cause histamine release directly. In

Figure 39–2 Structure of histamine and some H₁, H₂, H₃, and H₄ agonists. Dimaprit and 4-methylhistamine, originally identified as specific H₂ agonists, have a much higher affinity for the H₄ receptor; 4-methylhistamine is the most specific available H₄ agonist, with about 10-fold higher affinity than dimaprit, a partial H₄ agonist. Impromidine not only is among the most potent H₂ agonists but also is an antagonist at H₁ and H₃ receptors and a partial agonist at H₄ receptors. (R)-α-Methylhistamine and imetit are high-affinity agonists of H₃ receptors and lower-affinity full agonists at H₄ receptors.

myelogenous leukemia, elevation of blood basophils can result in histamine content high enough to cause flushing, pruritus, and hypotension. Management of these patients can be complicated by a large release of histamine after cytotoxicity, causing shock. Gastric carcinoid tumors secrete histamine, which is responsible for episodes of vasodilation as part of the patchy “geographical” flush.

Gastric Acid Secretion

Histamine acting at H₂ receptors is a powerful gastric secretagogue, evoking copious secretion of acid from parietal cells (see Figure 49–1); it also increases the output of pepsin and intrinsic factor. The secretion of gastric acid from parietal cells also is caused by stimulation of the vagus nerve and by the enteric hormone gastrin. However, histamine is the dominant physiological mediator of acid secretion; blockade of H₂ receptors not only antagonizes acid secretion in response to histamine but also inhibits responses to gastrin and vagal stimulation (see Chapter 49).

CNS

Histamine-containing neurons affect both homeostatic and higher brain functions, including regulation of the sleep-wake cycle, circadian and feeding rhythms, immunity, learning, memory, drinking, and body temperature. However, no human disease has yet been directly linked to dysfunction of the brain histamine system. Histamine, histidine decarboxylase, enzymes that metabolize histamine, and H₁, H₂, and H₃ receptors are distributed widely but nonuniformly in the CNS. H₁ receptors are associated with both neuronal and nonneuronal cells and are concentrated in regions that control neuroendocrine function, behavior, and nutritional state. Distribution of H₂ receptors is more consistent with histaminergic projections than that of H₁ receptors, suggesting that they mediate many of the postsynaptic actions of histamine. H₃ receptors are concentrated in areas known to receive histaminergic projections, consistent with their function as presynaptic autoreceptors. Histamine inhibits appetite and increases wakefulness via H₁ receptors.

TABLE 39–1 ■ CHARACTERISTICS OF HISTAMINE RECEPTORS

	H ₁	H ₂	H ₃ ^a	H ₄
Size (amino acids)	487	359	329–445	390
G protein coupling (second messengers)	G _{q/11} (↑ Ca ²⁺ ; ↑ NO and ↑ cGMP)	G _s (↑ cAMP)	G _{i/o} (↓ cAMP; ↑ MAP kinase)	G _{i/o} (↓ cAMP; ↑ Ca ²⁺)
Distribution	Smooth muscle, endothelial cells, CNS	Gastric parietal cells, cardiac muscle, mast cells, CNS	CNS: pre- and post-synaptic	Cells of hematopoietic origin
Representative agonist	2-CH ₃ -histamine	Amthamine	(R)-α-CH ₃ -histamine	4-CH ₃ -histamine
Representative antagonist	Chlorpheniramine	Ranitidine	Tiprolisat	JNJ777120

^aAt least 20 alternately spliced H₃ isoforms have been detected at the mRNA level. Eight of these isoforms, ranging in size from 329 to 445 residues, were found to be functionally competent by binding or signaling assays (see Esbenshade et al., 2008).

Physiological and Pharmacological Effects

Receptor-Effector Coupling and Mechanisms of Action

Histamine receptors are GPCRs, coupling to second-messenger systems and producing effects (Simons, 2004) as noted in Table 39–1. H_1 receptors couple to $G_q/11$ and activate the PLC-IP₃-Ca²⁺ pathway and its many possible sequelae, including activation of PKC, Ca²⁺-calmodulin-dependent enzymes (eNOS and various protein kinases), and PLA₂. H_2 receptors link to G_s to activate the adenylyl cyclase–cyclic AMP–PKA pathway; H_3 and H_4 receptors couple to G_i/o to inhibit adenylyl cyclase and decrease cellular cyclic AMP. Activation of H_3 receptors also can activate MAP kinase and inhibit the Na⁺/H⁺ exchanger; activation of H_4 receptors can mobilize stored Ca²⁺ (Simons and Simons, 2011). H_3 and H_4 receptors have about 1000-fold higher affinity for histamine (low nanomolar range) than do H_1 and H_2 receptors (low micromolar range). Activation of H_1 receptors on vascular endothelium stimulates eNOS to produce NO, which diffuses to nearby smooth muscle cells to increase cyclic GMP and cause relaxation. Stimulation of H_1 receptors on smooth muscle will mobilize Ca²⁺ and cause contraction, whereas activation of H_2 receptors on the same smooth muscle cell will link via G_s to enhanced cyclic AMP accumulation, activation of PKA, and then to relaxation.

Pharmacological definition of H_1 , H_2 , and H_3 receptors was possible through the use of relatively specific agonists and antagonists. Because the H_4 receptor exhibits 35%–40% homology to isoforms of the H_3 receptor, the two were initially harder to distinguish pharmacologically, but this has been resolved by the development of several H_3 - and H_4 -selective antagonists (Sander et al., 2008; Thurmond, 2015). 4-Methylhistamine and dimaprit, previously identified as specific H_2 agonists, are actually more potent H_4 agonists.

H_1 and H_2 Receptors

H_1 and H_2 receptors are distributed widely in the periphery and in the CNS and their activation by histamine can exert local or widespread effects (Simons and Simons, 2011). For example, histamine causes itching and stimulates secretion from nasal mucosa. It contracts many smooth muscles, such as those of the bronchi and gut, but markedly relaxes others, including those in small blood vessels. Histamine also is a potent stimulus of gastric acid secretion. Other, less-prominent effects include formation of edema and stimulation of sensory nerve endings. Bronchoconstriction and contraction of the gut are mediated by H_1 receptors. In the CNS, H_1 activation inhibits appetite and increases wakefulness. Gastric secretion results from the activation of H_2 receptors. Some responses, such as vascular dilation, are mediated by both H_1 and H_2 receptor stimulation.

H_3 and H_4 Receptors

The H_3 receptors are expressed mainly in the CNS, especially in the basal ganglia, hippocampus, and cortex (Haas et al., 2008). Presynaptic H_3 receptors function as autoreceptors on histaminergic neurons, inhibiting histamine release and modulating the release of other neurotransmitters. H_3 receptors are also found postsynaptically, especially in the basal ganglia, but their function is still being unraveled (Ellenbroek and Ghiabi, 2014). H_3 agonists promote sleep, and H_3 antagonists promote wakefulness.

The H_4 receptors primarily are found in eosinophils, dendritic cells, mast cells, monocytes, basophils, and T cells but have also been detected in the GI tract, dermal fibroblasts, CNS, and primary sensory afferent neurons (Thurmond, 2015). Activation of H_4 receptors has been associated with induction of cellular shape change, chemotaxis, secretion of cytokines, and upregulation of adhesion molecules, suggesting that H_4 antagonists may be useful inhibitors of allergic and inflammatory responses (Thurmond, 2015).

Although specific H_3 and H_4 receptor antagonists have been developed, none of these agents has yet been FDA-approved for clinical use. Based on the functions of H_3 receptors in the CNS, H_3 antagonists have potential in the treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer disease. Because of the unique localization and function of H_4 receptors, H_4 antagonists are promising candidates to treat inflammatory conditions such as allergic

rhinitis, asthma, rheumatoid arthritis, and possibly pruritus and neuropathic pain.

Feedback Regulation of Release

Stimulation of H_2 receptor increases cyclic AMP and leads to feedback inhibition of histamine release from mast cells and basophils, whereas activation of H_3 and H_4 receptors has the opposite effect by decreasing cellular cyclic AMP. Activation of presynaptic H_3 receptors inhibits histamine release from histaminergic neurons. Because H_3 receptors have high constitutive activity, histamine release is tonically inhibited. H_3 inverse agonists thus reduce receptor activation and increase histamine release from histaminergic neurons.

Cardiovascular System

Histamine dilates resistance vessels, increases capillary permeability, and lowers systemic blood pressure. In some vascular beds, histamine constricts veins, contributing to the extravasation of fluid and edema formation upstream in capillaries and postcapillary venules.

Vasodilation. Vasodilation is the most important vascular effect of histamine in humans and can result from activation of either the H_1 or H_2 receptor. H_1 receptors have a higher affinity for histamine and cause Ca²⁺-dependent activation of eNOS in endothelial cells; NO diffuses to vascular smooth muscle, increasing cyclic GMP (see Table 39–1) and causing rapid and short-lived vasodilation. By contrast, activation of H_2 receptors on vascular smooth muscle stimulates the cyclic AMP–PKA pathway, causing dilation that develops more slowly and is more sustained. As a result, H_1 antagonists effectively counter small dilator responses to low concentrations of histamine but blunt only the initial phase of larger responses to higher concentrations of the amine.

Increased Capillary Permeability. Histamine's effect on small vessels results in efflux of plasma protein and fluid into the extracellular spaces and an increase in lymph flow, causing edema. H_1 receptor activation on endothelial cells is the major mediator of this response, leading to G_q -mediated activation of RhoA and ROCK, which stimulates the contractile machinery of the cells and disrupts interendothelial junctions (Mikelis et al., 2015). The gaps between endothelial cells also may permit passage of circulating cells recruited to tissues during the mast cell response. Recruitment of circulating leukocytes is enhanced by H_1 receptor-mediated expression of adhesion molecules (e.g., P-selectin) on endothelial cells.

Triple Response of Lewis. If histamine is injected intradermally, it elicits a characteristic phenomenon known as the *triple response*. This consists of the following:

- a localized “reddening” around the injection site, appearing within a few seconds, and maximal at about 1 min;
- a “flare” or red flush extending about 1 cm beyond the original red spot and developing more slowly; and
- a “wheal” or swelling that is discernible in 1–2 min at the injection site.

The initial red spot (a few millimeters) results from the direct vasodilating effect of histamine (H_1 receptor-mediated NO production). The flare is due to histamine-induced stimulation of axon reflexes that cause vasodilation indirectly, and the wheal reflects histamine's capacity to increase capillary permeability (edema formation).

Heart. Histamine affects both cardiac contractility and electrical events directly. It increases the force of contraction of both atrial and ventricular muscle by promoting the influx of Ca²⁺, and it speeds heart rate by hastening diastolic depolarization in the SA node. It also directly slows AV conduction to increase automaticity and, in high doses, can elicit arrhythmias. The slowed AV conduction involves mainly H_1 receptors, while the other effects are largely attributable to H_2 receptors and cyclic AMP accumulation. The direct cardiac effects of histamine given intravenously are overshadowed by baroreceptor reflexes stimulated by reduced blood pressure.

Extravascular Smooth Muscle

Histamine directly contracts or, more rarely, relaxes various extravascular smooth muscles. Contraction is due to activation of H_1 receptors on smooth muscle to increase intracellular Ca²⁺, and relaxation is mainly due

to activation of H_2 receptors. Although the spasmogenic influence of H_1 receptors is dominant in human bronchial muscle, H_2 receptors with dilator function also are present. Thus, histamine-induced bronchospasm in vitro is potentiated slightly by H_2 blockade. Patients with bronchial asthma and certain other pulmonary diseases are much more sensitive to the bronchoconstrictor effects of histamine.

Peripheral Nerve Endings

Histamine stimulates various nerve endings, causing sensory effects. In the epidermis, it causes itch; in the dermis, it evokes pain, sometimes accompanied by itching. Stimulant actions on nerve endings, including autonomic afferents and efferents, contribute to the “flare” component of the triple response and to indirect effects of histamine on the bronchi and other organs.

Histamine Shock

Histamine given in large doses or released during systemic anaphylaxis causes a profound and progressive fall in blood pressure. As the small blood vessels dilate, they trap large amounts of blood, their permeability increases, and plasma escapes from the circulation. These effects, resembling surgical or traumatic shock, diminish effective blood volume, reduce venous return, and greatly lower cardiac output.

Histamine Toxicity From Ingestion

Histamine is the toxin in food poisoning from spoiled scombroid fish such as tuna. Symptoms include severe nausea, vomiting, headache, flushing, and sweating. Histamine toxicity also can follow red wine consumption in persons with a diminished ability to degrade histamine. The symptoms of histamine poisoning can be suppressed by H_1 antagonists.

Histamine Receptor Antagonists

H_1 Receptor Antagonists

HISTORY

Antihistamine activity was first demonstrated by Bovet and Staub in 1937 with one of a series of amines with a phenolic ether moiety. The substance, 2-isopropyl-5-methylphenoxy-ethyldiethyl-amine, protected guinea pigs against several lethal doses of histamine but was too toxic for clinical use. By 1944, Bovet and his colleagues had described *pyrilamine maleate*, an effective histamine antagonist of this category. The discovery of highly effective *diphenhydramine* and *tripelennamine* soon followed. In the 1980s, non-sedating H_1 histamine receptor antagonists were developed for treatment of allergic diseases. Despite success in blocking allergic responses to histamine, the H_1 antihistamines failed to inhibit a number of other responses, notably gastric acid secretion. The discovery of H_2 receptors and H_2 antagonists by Black and colleagues provided a new class of agents that antagonized histamine-induced acid secretion (Black et al., 1972); the pharmacology of these drugs (e.g., *cimetidine*, *famotidine*) is described in Chapter 49.

Pharmacological Properties

All the available H_1 receptor “antagonists” are actually inverse agonists (see Chapter 3) that reduce constitutive activity of the receptor and compete with histamine binding to the receptor (Simons, 2004). The pharmacological actions and therapeutic applications of these antagonists can be largely predicted from knowledge of the location and mode of signaling of the histamine receptors.

Chemistry. Like histamine, many H_1 antagonists contain a substituted ethylamine moiety (the black portion on the figure that follows). Unlike histamine, which has a primary amino group and a single aromatic ring, most H_1 antagonists have a tertiary amino group linked by a two- or

three-atom chain to two aromatic substituents (in red) and conform to the general formula:

where Ar is aryl and X is a nitrogen or carbon atom or a $-C-O-$ ether linkage to the β -aminoethyl side chain. Sometimes, the two aromatic rings are bridged, as in the tricyclic derivatives, or the ethylamine may be part of a ring structure. Figure 39–3 shows the varied structures of representative H_1 antagonists built around this framework and constitute the several generations of compounds.

Effects on Physiological Systems

Smooth Muscle. The H_1 antagonists inhibit most of the effects of histamine on smooth muscles, especially the constriction of respiratory smooth muscle. H_1 antagonists inhibit the more rapid vasodilator effects mediated by activation of H_1 receptors on endothelial cells (synthesis/release of NO and other mediators) at lower doses of histamine. They also inhibit venous constriction seen in some vascular beds.

Capillary Permeability. H_1 antagonists strongly block the increased capillary permeability and formation of edema and wheal caused by histamine.

Flare and Itch. H_1 antagonists suppress the action of histamine on nerve endings, including the flare component of the triple response and the itching caused by intradermal injection.

Exocrine Glands. H_1 antagonists do not suppress gastric secretion. However, the antimuscarinic properties of many H_1 antagonists may contribute to lessened secretion in cholinergically innervated glands and reduce ongoing secretion in, for example, the respiratory tree.

Immediate Hypersensitivity Reactions: Anaphylaxis and Allergy. During hypersensitivity reactions, histamine is one of the many potent autacoids released, and its relative contribution to the ensuing symptoms varies widely with species and tissue. The protection afforded by H_1 antagonists varies accordingly. In humans, edema formation and itch are effectively suppressed. Other effects, such as hypotension, are less well antagonized. H_1 antagonists are ineffective in blocking bronchoconstriction due to asthma.

Mast Cell–Stabilizing and Anti-inflammatory Properties. Many second-generation H_1 antagonists (e.g., cetirizine, desloratadine, fexofenadine, olopatadine, ketotifen, alcaftadine, and others) exhibit mast cell–stabilizing effects, resulting in reduced release of mast cell mediators during an allergic response (Levi-Schaffer and Eliashar, 2009). These agents also have anti-inflammatory properties, which can include reduced cytokine secretion, decreased adhesion molecule expression, and inhibition of eosinophil infiltration. These effects can be both H_1 receptor dependent and independent, but precise mechanisms are still unclear, and it is unknown what role they play at normal therapeutic doses of these drugs. There is some evidence that H_1 antagonists with these additional properties may be more effective in the topical treatment of allergic conjunctivitis (Abelson et al., 2015).

CNS. The first-generation H_1 antagonists can both stimulate and depress the CNS (Simons and Simons, 2011). Stimulation occasionally is encountered in patients given conventional doses; the patients become restless, nervous, and unable to sleep. Central excitation also is a striking feature of overdose, which commonly results in convulsions, particularly in infants. Central depression, on the other hand, usually accompanies therapeutic doses of the older H_1 antagonists. Diminished alertness, slowed reaction times, and somnolence are common manifestations. Patients vary in their susceptibility and responses to individual drugs. The ethanolamines (e.g., diphenhydramine) are particularly prone to causing sedation. Because of

Figure 39–3 Representative H₁ antagonists.

the sedation that occurs with first-generation antihistamines, these drugs cannot be tolerated or used safely by many patients except at bedtime. Even then, patients may experience an antihistamine “hangover” in the morning, resulting in sedation with or without psychomotor impairment. Second-generation H₁ antagonists are termed *non-sedating* because they do not cross the blood-brain barrier appreciably. This is due to their decreased lipophilicity and because they are substrates of P-glycoprotein, which pumps them out of the blood-brain barrier capillary endothelial cells and back into the capillary lumen (see Chapter 5 and Simons and Simons, 2011).

Many antipsychotic agents are H₁ and H₂ receptor antagonists, but it is unclear whether this property plays a role in the antipsychotic effects of these agents. In test systems, the atypical antipsychotic agent *clozapine* is an effective H₁ antagonist, a weak H₃ antagonist, and an H₄ receptor agonist. The H₁ antagonist activity of typical and atypical antipsychotic drugs is responsible for the propensity of these agents to cause weight gain.

Anticholinergic Effects. Many of the first-generation H₁ antagonists tend to inhibit muscarinic cholinergic responses and may be manifest during clinical use (Simons and Simons, 2011). Some H₁ antagonists also can be used to treat motion sickness (see Chapters 9 and 50), probably as a result of their anticholinergic properties. Indeed, promethazine has perhaps the strongest muscarinic-blocking activity among these agents and is the most effective H₁ antagonist in combating motion sickness. The second-generation H₁ antagonists have no effect on muscarinic receptors (Simons and Simons, 2011).

Local Anesthetic Effect. Some H₁ antagonists have local anesthetic activity, and a few are more potent than procaine. Promethazine is especially active. However, the concentrations required for this effect are much higher than those that antagonize histamine's interactions with its receptors.

ADME. The H₁ antagonists are well absorbed from the GI tract. Following oral administration, peak plasma concentrations are achieved in 1–3 h, and effects usually last 4–6 h for first-generation agents; however, some of the drugs are much longer acting, as are most second-generation H₁

antagonists (del Cuvillo et al., 2006; Simons, 2004) (Table 39–2). These agents are distributed widely throughout the body, including the CNS for the first-generation agents. Peak concentrations of these drugs in the skin may persist long after plasma levels have declined. Thus, inhibition of “wheal-and-flare” responses to the intradermal injection of histamine or allergen can persist for 36 h or more after initial treatment and up to 7 days after discontinuation of treatment in patients who regularly use an H₁ antagonist for 1 week or more (del Cuvillo et al., 2006).

All first-generation and most second-generation H₁ antagonists are metabolized by CYPs and little, if any, is excreted unchanged in the urine; most appears there as metabolites (Bartra et al., 2006; Simons, 2004). Exceptions are cetirizine and acrivastine (<40% metabolized) and fexofenadine, levocetirizine, and epinastine (<10% metabolized). Cetirizine, levocetirizine, and acrivastine are excreted primarily into the urine; fexofenadine is mainly excreted in the feces, and epinastine is excreted in both urine (55%) and feces (30%).

The H₁ antagonists that are metabolized are eliminated more rapidly by children than by adults and more slowly in those with severe liver disease. These antagonists also have higher potential for drug interactions. For example, plasma levels of H₁ antagonists may be reduced when coadministered with drugs that induce CYP synthesis (e.g., benzodiazepines) or elevated when taken with drugs that compete with or inhibit the same CYP isoform (e.g., erythromycin, ketoconazole, antidepressants) (Bartra et al., 2006; Simons, 2004). Clinically relevant interactions are more likely with first-generation than second-generation drugs, which have a higher therapeutic index. However, two second-generation H₁ antagonists marketed previously, *terfenadine* and *astemizole*, were found in rare cases to prolong the QTc interval and induce a potentially fatal arrhythmia, torsade de pointes, due to their capacity to inhibit a cardiac K⁺ channel, I_{Kr}, when their metabolism was impaired and their plasma concentrations rose too high, due, for instance, to liver disease or to drugs that inhibited the CYP3A family (Bartra et al., 2006; Simons, 2004) (see Chapter 30). This led to the withdrawal of terfenadine and astemizole from the market. Astemizole and an active hydroxylated metabolite naturally have very long half-lives. Terfenadine is a prodrug,

TABLE 39-2 ■ PREPARATIONS AND DOSAGE OF REPRESENTATIVE H₁ RECEPTOR ANTAGONISTS^a

CLASS <i>Generic name</i>	DURATION OF ACTION (h) ^b	PREPARATIONS ^c	SINGLE DOSE (adult)
First-generation agents			
<i>Tricyclic dibenzoxepins</i>			
Doxepin HCl	6–24	O, L, T	10–150 mg; insomnia: 6 mg (O) Pruritus: thin film 4 times/d (T)
<i>Ethanolamines</i>			
Carbinoxamine maleate	3–6	O, L	4–8 mg; 6–16 mg (SR)
Clemastine fumarate	12	O, L	1.34–2.68 mg
Diphenhydramine HCl	12	O, L, I, T	25–50 mg (O/L/I)
Dimenhydrinate ^d	4–6	O, I	50–100 mg
<i>Ethylenediamines</i>			
Pyrimamine maleate (only in combination products)	4–6	O, L	7.5–30 mg
<i>Alkylamines</i>			
Chlorpheniramine maleate	24	O, L, I, SR	4 mg, 12 mg (SR)
Brompheniramine maleate	4–6	O, L, I, SR	2 mg
<i>Piperazines</i>			
Hydroxyzine HCl	6–24	O, L, I	25–100 mg
Hydroxyzine pamoate	6–24	O, L (not in the U.S.)	25–100 mg
Cyclizine HCl	4–6	O	50 mg
Cyclizine lactate (not in the U.S.)	4–6	I	50 mg
Meclizine HCl	12–24	O	25–50 mg
<i>Phenothiazines</i>			
Promethazine HCl	4–6	O, L, I, S	12.5–50 mg
<i>Piperidines</i>			
Cyproheptadine HCl ^e	4–6	O, L	1–6.5 mg
Second-generation agents			
<i>Tricyclic dibenzoxepins</i>			
Olopatadine HCl	6–12	T	2 sprays/nostril; 1 drop/eye
<i>Alkylamines</i>			
Acrivastine ^f	6–8	O	8 mg
<i>Piperazines</i>			
Cetirizine HCl ^g	12–24	O, L	5–10 mg
Levocetirizine HCl	12–24	O, L	2.5–5 mg
<i>Piperidines</i>			
Alcaftadine	16–24	T	1 drop/eye
Bepotastine besilate	8	T	1 drop/eye
Desloratadine	24	O, L	5 mg
Fexofenadine HCl	12–24	O, L	60–180 mg
Ketotifen fumarate	8–12	T	1 drop/eye
Loratadine	24	O, L	10 mg
<i>Other second-generation drugs</i>			
Azelastine HCl ^h	12–24	T	2 sprays/nostril; 1 drop/eye
Emedastine	8–12	T	1 drop/eye
Epinastine	8–12	T	1 drop/eye

^aFor a discussion of phenothiazines, see Chapter 16.^bDuration of action of H₁ antihistamines by objective assessment of suppression of histamine- or allergen-induced symptoms is longer than expected from measurement of plasma concentrations or terminal elimination $t_{1/2}$ values.^cPreparations are designated as follows: O, oral solids; L, oral liquids; I, injection; S, suppository; SR, sustained release; T, topical. Many H₁ receptor antagonists also are available in preparations that contain multiple drugs. SR forms dissuade pseudoephedrine extraction for methamphetamine production.^dDimenhydrinate is a combination of diphenhydramine and 8-chlorotheophylline in equal molecular proportions.^eAlso has antiserotonin properties.^fHas mild sedating effects.

metabolized by hepatic CYP3A4 to fexofenadine, which is its replacement and lacks noticeable cardiotoxicity. In vitro testing for a new drug's capacity to inhibit I_{Kr} is now available.

Therapeutic Uses

The H_1 antagonists are used for treatment of various immediate hypersensitivity reactions. The central properties of some of the drugs also are of therapeutic value for suppressing motion sickness or for sedation.

Allergic Diseases. H_1 antagonists are useful in acute types of allergy that present with symptoms of rhinitis, urticaria, and conjunctivitis (Simons and Simons, 2011). Their effect is confined to the suppression of symptoms attributable to the histamine released by the antigen-antibody reaction. In bronchial asthma, histamine antagonists have limited efficacy and are not used as sole therapy (see Chapters 38 and 40). In the treatment of systemic anaphylaxis, where autacoids other than histamine are important, the mainstay of therapy is *epinephrine*; histamine antagonists have only a subordinate and adjuvant role. The same is true for severe angioedema, in which laryngeal swelling constitutes a threat to life (see Chapter 12).

Certain allergic dermatoses respond favorably to H_1 antagonists. The benefit is most striking in acute urticaria. H_1 antagonists are also first-line therapy for chronic urticaria but may require doses up to four times higher than that approved for treating rhinitis; patients refractory to high-dose H_1 antagonists should be switched to drugs targeting the immune response (Viegas et al., 2014). H_1 antagonists have a place in the treatment of pruritus. Some relief may be obtained in many patients with atopic and contact dermatitis (although topical corticosteroids are more effective) and in such diverse conditions as insect bites and poison ivy. The urticarial and edematous lesions of serum sickness respond to H_1 antagonists, but fever and arthralgia often do not.

Common Cold. H_1 antagonists are without value in combating the common cold. The weak anticholinergic effects of the older agents may tend to lessen rhinorrhea, but this drying effect may do more harm than good, as may their tendency to induce somnolence.

Motion Sickness, Vertigo, and Sedation. Scopolamine, the muscarinic antagonist, given orally, parenterally, or transdermally, is the most effective drug for the prophylaxis and treatment of motion sickness. Some H_1 antagonists are useful for milder cases and have fewer adverse effects. These drugs include dimenhydrinate and the piperazines (e.g., cyclizine, meclizine). Promethazine, a phenothiazine, is more potent and more effective, and its additional antiemetic properties may be of value in reducing vomiting; however, its pronounced sedative action usually is disadvantageous. Whenever possible, the various drugs should be administered about 1 h before the anticipated motion. Treatment after the onset of nausea and vomiting rarely is beneficial. Some H_1 antagonists, notably dimenhydrinate and meclizine, often are of benefit in vestibular disturbances such as Ménière disease and in other types of true vertigo. Only promethazine is useful in treating the nausea and vomiting subsequent to chemotherapy or radiation therapy for malignancies; however, other, more effective, antiemetic drugs (e.g., 5HT₃ antagonists) are available (see Chapter 50). Diphenhydramine can reverse the extrapyramidal side effects caused by antipsychotics (see Chapter 16). The tendency of some H_1 receptor antagonists to produce somnolence has led to their use as hypnotics. H_1 antagonists, principally diphenhydramine, often are present in various proprietary over-the-counter remedies for insomnia. The sedative and mild antianxiety activities of hydroxyzine contribute to its use as an anxiolytic.

Adverse Effects

The most frequent side effect of first-generation H_1 antagonists is sedation. Concurrent ingestion of alcohol or other CNS depressants produces an additive effect that impairs motor skills. Other untoward central actions include dizziness, tinnitus, lassitude, incoordination, fatigue, blurred vision, diplopia, euphoria, nervousness, insomnia, and tremors. Other potential side effects, including loss of appetite, nausea, vomiting, epigastric distress, and constipation or diarrhea, may be reduced by taking the

drug with meals. H_1 antagonists such as cyproheptadine may increase appetite and cause weight gain. Other side effects, owing to the antimuscarinic actions of some first-generation H_1 antagonists, include dryness of the mouth and respiratory passages (sometimes inducing cough), urinary retention or frequency, and dysuria. These effects are not observed with second-generation H_1 antagonists. Allergic dermatitis is not uncommon; other hypersensitivity reactions include drug fever and photosensitization. Hematological complications, such as leukopenia, agranulocytosis, and hemolytic anemia, are very rare.

Because H_1 antihistamines cross the placenta, caution is advised for women who are or may become pregnant (Simons and Simons, 2011). Several antihistamines (e.g., azelastine, hydroxyzine, fexofenadine) had teratogenic effects in animal studies, whereas others (e.g., chlorpheniramine, diphenhydramine, cetirizine, loratadine) did not. A recent systematic review concluded that antihistamines are unlikely to be strong risk factors for major birth defects (Gilboa et al., 2014). A combination drug consisting of the H_1 antagonist doxylamine and vitamin B₆ (pyridoxine) was approved in 1956 for treating the nausea and vomiting of pregnancy and then voluntarily removed in 1983 due to concerns over birth defects. Subsequent analyses showed the drug caused no increased risk of birth defects, and in 2013 it was reapproved for the same indication in a fixed-dose, delayed-release formulation. Antihistamines can be excreted in small amounts in breast milk, and first-generation antihistamines taken by lactating mothers may cause symptoms such as irritability, drowsiness, or respiratory depression in the nursing infant.

In acute poisoning with first-generation H_1 antagonists, their central excitatory effects constitute the greatest danger. The syndrome includes hallucinations, excitement, ataxia, incoordination, athetosis, and convulsions, fixed, dilated pupils with a flushed face, together with sinus tachycardia, urinary retention, dry mouth, and fever. The syndrome exhibits a remarkable similarity to that of atropine poisoning. Terminally, there is deepening coma with cardiorespiratory collapse and death usually within 2–18 h. Treatment is along general symptomatic and supportive lines. Overdoses of second-generation H_1 antagonists have not been associated with significant toxicity (Simons and Simons, 2011).

Pediatric and Geriatric Indications and Problems. Although little clinical testing has been done, second-generation antihistamines are preferred for elderly patients (>65 years of age), especially those with impaired cognitive function, because of the sedative and anticholinergic effects of first-generation drugs (Simons, 2004). In addition, a recent prospective study in participants 65 years old and older without dementia showed a significant 10-year cumulative dose-response relationship between use of anticholinergics (first-generation H_1 antagonists among the most common) and risk of dementia, primarily Alzheimer disease (Gray et al., 2015).

First-generation antihistamines are not recommended for use in children because their sedative effects can impair learning and school performance. The second-generation drugs have been approved by the FDA for use in children and are available in appropriate lower-dose formulations (e.g., chewable or rapidly dissolving tablets, syrup). Use of over-the-counter cough and cold medicines (containing mixtures of antihistamines, decongestants, antitussives, expectorants) in young children has been associated with serious side effects and deaths. In 2008, the FDA recommended that they should not be used in children less than 2 years of age, and drug manufacturers affiliated with the Consumer Healthcare Products Association voluntarily relabeled products “do not use” for children less than 4 years of age.

Available H_1 Antagonists

Summarized next are notable properties of a number of H_1 antagonists, grouped by their chemical structures. Representative preparations are listed in Table 39–2.

First-Generation Dibenzoxepin Tricyclic (Doxepin). Doxepin is marketed as a tricyclic antidepressant (see Chapter 15). It also is one of the most potent H_1 antagonists and has significant H_2 antagonist activity, but this does not translate into greater clinical effectiveness. It can cause

drowsiness and is associated with anticholinergic effects. Doxepin is better tolerated by patients with depression than those who are not depressed, for whom even small doses may cause disorientation and confusion.

Second-Generation Dibenzoxepin Tricyclic (Olopatadine). Olopatadine is a topical H_1 antagonist with additional mast cell-stabilizing and anti-inflammatory properties. In drop form, it is an effective treatment of allergic conjunctivitis and as a spray helps reduce the nasal symptoms of allergic rhinitis.

Ethanolamines (Prototype: Diphenhydramine). The ethanolamines possess significant antimuscarinic activity and have a pronounced tendency to induce sedation. About half of those treated acutely with conventional doses experience somnolence. The incidence of GI side effects, however, is low with this group.

Ethylenediamine (Prototype: Pyrilamine). Pyrilamine is among the most specific H_1 antagonists. Although its central effects are relatively feeble, somnolence occurs in a fair proportion of patients. GI side effects are common.

First-Generation Alkylamines (Prototype: Chlorpheniramine). The first-generation alkylamines are among the most potent H_1 antagonists. The drugs are less prone to produce drowsiness and are more suitable for daytime use, but a significant proportion of patients still experience sedation. Side effects involving CNS stimulation are more common than with other groups.

Second-Generation Alkylamine (Acrivastine). The second-generation alkylamine is a derivative of the first-generation alkylamine triprolidine and may exhibit a somewhat higher incidence of mild sedation than other second-generation H_1 antagonists.

First-Generation Piperazines. Hydroxyzine is a long-acting compound that is used widely for skin allergies; its considerable CNS-depressant activity may contribute to its prominent antipruritic action, and it is also used as a sedative and antianxiety agent. Cyclizine and meclizine have been used primarily to counter motion sickness, although promethazine and diphenhydramine are more effective (as is the antimuscarinic scopolamine).

Second-Generation Piperazines (Cetirizine). Cetirizine has minimal anticholinergic effects. It also has negligible penetration into the brain but is associated with a somewhat higher incidence of drowsiness than most other second-generation H_1 antagonists. The active enantiomer levocetirizine has slightly greater potency and may be used at half the dose with less resultant sedation. Cetirizine and levocetirizine have additional mast cell-stabilizing and anti-inflammatory properties.

Phenothiazines (Prototype: Promethazine). Promethazine, which has prominent sedative and considerable anticholinergic effects, and its many congeners are used primarily for their antiemetic effects (see Chapter 50).

First-Generation Piperidine (Cyproheptadine). Cyproheptadine uniquely has both antihistamine and antiserotonin activity by antagonizing the $5HT_{2A}$ receptor. Cyproheptadine causes drowsiness; it also has significant anticholinergic effects and can increase appetite.

Second-Generation Piperidines (Prototype: Loratadine). Terfenadine and astemizole, early second-generation drugs, are no longer marketed because of their potential for causing a rare, but potentially fatal, arrhythmia, torsade de pointes (see previous discussion). Terfenadine was replaced by fexofenadine, an active metabolite that lacks the toxic side effects of terfenadine, is not sedating, and retains the antiallergic properties of the parent compound. Another antihistamine of this class developed using this strategy is *desloratadine*, an active metabolite of loratadine. These agents lack significant anticholinergic actions and penetrate poorly into the CNS. Taken together, these properties appear to account for the low incidence of side effects of piperidine antihistamines. All members of this class have mast cell-stabilizing and anti-inflammatory properties. Although the therapeutic significance of these additional effects are unclear for the drugs administered orally, they appear to provide additional benefit when used in topical formulations to treat allergic conjunctivitis. Alcaftadine has additional antagonist activity on H_4 receptors, which likely explains

its superiority to other topical H_1 antagonists in reducing the ocular itch of allergic conjunctivitis (Thurmond, 2015).

Other Second-Generation H_1 Antagonists. Drugs in this group (azelastine, emedastine, and epinastine) have divergent structures with therapeutic efficacy and side effects similar to other second-generation H_1 antagonists. They all are marketed as topical eye drops for the treatment of allergic conjunctivitis; azelastine is also available as a nasal spray for treating symptoms of allergic or vasomotor rhinitis. Epinastine has both H_1 and H_2 antagonist activity, which may help reduce eyelid edema. Epinastine and azelastine exhibit mast cell-stabilizing and anti-inflammatory properties. Emedastine is a highly selective H_1 antagonist without these additional actions.

H_2 Receptor Antagonists

The pharmacology and clinical utility of H_2 antagonists (e.g., cimetidine, ranitidine) for inhibiting gastric acid secretion in the treatment of GI disorders are described in Chapter 50.

H_3 Receptor Antagonists

The H_3 receptors are presynaptic autoreceptors on histaminergic neurons that originate in the tuberomammillary nucleus in the hypothalamus and project throughout the CNS, most prominently to the hippocampus, amygdala, nucleus accumbens, globus pallidus, striatum, hypothalamus, and cortex (Haas et al., 2008; Sander et al., 2008). The activated H_3 receptor depresses neuronal firing at the level of cell bodies/dendrites and decreases histamine release from depolarized terminals. Thus, H_3 agonists decrease histaminergic transmission, and antagonists increase it.

The H_3 receptors also are presynaptic heteroreceptors on a variety of neurons in brain and peripheral tissues, and their activation inhibits transmitter release from noradrenergic, serotonergic, GABAergic, cholinergic, and glutamatergic neurons, as well as pain-sensitive C fibers. H_3 receptors in the brain have significant constitutive activity in the absence of agonist; consequently, inverse agonists reduce this constitutive activity, withdraw inhibition of transmitter release, and thereby promote transmitter release (activation of these neurons).

The H_3 antagonists/inverse agonists have a wide range of central effects; for example, they promote wakefulness, improve cognitive function (e.g., enhance memory, learning, and attention), and reduce food intake. As a result, there is considerable interest in developing H_3 antagonists for possible treatment of sleeping disorders, ADHD, epilepsy, cognitive impairment, schizophrenia, obesity, neuropathic pain, and Alzheimer disease (Haas et al., 2008; Sander et al., 2008). Thioperamide was the first “specific” H_3 antagonist/inverse agonist available experimentally, but it was equally effective at the H_4 receptor. A number of other imidazole derivatives have been developed as H_3 antagonists, including clobenpropit, ciproxifan, and proxyfan, but the imidazole ring enhances binding to the H_4 receptor and CYPs. Because of this, more selective nonimidazole H_3 antagonists/inverse agonists (e.g., tiprolisant) were developed (Haas et al., 2008; Sander et al., 2008), and some are now in phase 2 and 3 clinical trials.

H_4 Receptor Antagonists

The H_4 receptors are expressed on cells with inflammatory or immune functions and can mediate histamine-induced chemotaxis, induction of cell shape change, secretion of cytokines, and upregulation of adhesion molecules (Thurmond et al., 2008). The H_4 receptors also have a role in pruritus and neuropathic pain. Because of the unique localization and function of H_4 receptors, H_4 antagonists are promising candidates to treat inflammatory conditions and possibly pruritus and neuropathic pain (Thurmond, 2015). The H_4 -specific antagonist JNJ-39758979 has been tested in phase 1 and 2 clinical trials for treatment of persistent asthma, pruritus, dermatitis, and rheumatoid arthritis.

The H_4 receptor has the highest homology with the H_3 receptor and binds many H_3 ligands, especially those with imidazole rings, although sometimes with different effects (Thurmond et al., 2008). For example, thioperamide is an effective inverse agonist at both H_3 and H_4 receptors, whereas H_3 inverse agonist clobenpropit is a partial agonist of the H_4

Bradykinin, Kallidin, and Their Antagonists

In the 1920s and 1930s, Frey, Kraut, and Werle characterized a hypotensive substance in urine, which was also found in other fluids and tissues, and named this material *kallikrein* after a Greek synonym for the pancreas, an especially rich source (Werle, 1970). It was established that kallikrein generates a pharmacologically active substance from an inactive precursor present in plasma; the active substance, *kallidin*, proved to be a polypeptide cleaved from a plasma globulin (Werle, 1970). Rocha e Silva, Beraldo, and associates later reported that trypsin and certain snake venoms acted on plasma globulin to produce a substance that lowered blood pressure and caused a slowly developing contraction of the gut (Rocha e Silva et al., 1949); they named it *bradykinin*, derived from the Greek words *bradys*, meaning “slow,” and *kinein*, meaning “to move.” In 1960, bradykinin, a nine amino acid peptide, was isolated and synthesized; shortly thereafter, kallidin was identified as bradykinin with an additional N-terminal Lys residue. The kinins have short half-lives because they are destroyed by plasma and tissue peptidases (Erdös and Skidgel, 1997). Two types of kinin receptors, B₁ and B₂, were identified based on the rank order of potency of kinin analogues and later validated by cloning (Leeb-Lundberg et al., 2005). The development of receptor-specific antagonists and receptor knockout mice have furthered our understanding of the role of kinins in the regulation of cardiovascular homeostasis and inflammatory processes (Leeb-Lundberg et al., 2005).

Tissue damage, allergic reactions, viral infections, and other inflammatory events activate a series of proteolytic reactions that generate bradykinin and kallidin in tissues. These peptides contribute to inflammatory responses as autacoids that act locally to produce pain, vasodilation, and increased vascular permeability but can also have beneficial effects, for example, in the heart, kidney, and circulation (Bhoola et al., 1992). Much of their activity is due to stimulation of the release of potent mediators such as prostaglandins, NO, or EDHF.

The Endogenous Kallikrein-Kininogen-Kinin System

The nonapeptide bradykinin and decapeptide kallidin (*lysyl-bradykinin*) (Table 39–3) are cleaved from α₂ globulins termed *kininogens* (Figure 39–4). There are two kininogens: HMW kininogen and LMW kininogen. A number of serine proteases will generate kinins, but the two highly specific proteases that release bradykinin and kallidin from the kininogens are termed *kallikreins*.

Kallikreins

Bradykinin and kallidin are cleaved from HMW or LMW kininogens by plasma or tissue kallikrein, respectively (see Figure 39–4). Plasma kallikrein and tissue kallikrein are distinct enzymes that are activated by different mechanisms (Bhoola et al., 1992). Plasma prekallikrein is an inactive protein of about 88 kDa that complexes with its substrate, HMW kininogen. The ensuing proteolytic cascade is normally restrained by the protease inhibitors present in plasma, most importantly the activated first component of complement (C1-INH) and α₂ macroglobulin. Under experimental conditions, the kallikrein-kinin system is activated by the binding of factor XII (*Hageman factor*) to negatively charged surfaces. Bound factor XII, a protease that is common to both the kinin and the intrinsic coagulation cascades (see Chapter 32), slowly undergoes auto-activation and, in turn, activates prekallikrein. Importantly, kallikrein rapidly further activates factor XII, thereby exerting a positive feedback on the system. In vivo, the order of this process can be reversed. The binding of the HMW kininogen–prekallikrein heterodimer to a multiprotein-receptor complex on endothelial cells leads to activation of the prekallikrein-HMW kininogen complex by either heat shock protein 90 (Hsp90) or prolylcarboxypeptidase to generate kallikrein, which can then activate factor XII to start the positive-feedback loop, and cleave HMW

TABLE 39–3 ■ STRUCTURE OF KININ AGONISTS AND ANTAGONISTS

NAME	STRUCTURE	FUNCTION
Bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B ₂
Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe-Arg	Agonist, B ₂
[des-Arg ⁹]-Bradykinin	Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B ₁
[des-Arg ¹⁰]-Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Phe	Agonist, B ₁
des-Arg ¹⁰ -[Leu ⁹]-Kallidin	Lys-Arg-Pro-Pro-Gly-Phe-Ser-Pro-Leu	Antagonist, B ₁
NPC-349	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-D-Phe-Thi-Arg	Antagonist, B ₂
HOE-140	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-Tic-Oic-Arg	Antagonist, B ₂
[des-Arg ¹⁰]-HOE-140	[D-Arg]-Arg-Pro-Hyp-Gly-Thi-Ser-Tic-Oic	Antagonist, B ₁
FR173657 FR190997 SSR240612	See Figure 32–3 of the 12th edition	Antagonist, B ₂ Agonist, B ₂ Antagonist, B ₁

Hyp, trans-4-hydroxy-Pro; Thi, β-(2-thienyl)-Ala; Tic, [D]-1,2,3,4-tetrahydroisoquinolin-3-yl-carbonyl; Oic, (3as,7as)-octahydroindol-2-yl-carbonyl.

kininogen to generate bradykinin (Kaplan and Joseph, 2014). This process may contribute to the symptoms of hereditary angioedema in patients that lack C1-INH.

Human tissue kallikrein is 1 of 15 gene family members with high sequence identity that are clustered at chromosome 19q13.4 (Prassas et al., 2015). However, the classical “tissue kallikrein,” hK1, is the only family member to readily generate kallidin from LMW kininogen. Tissue kallikrein is synthesized as a 29-kDa preproprotein in the epithelial cells or secretory cells in several tissues, including salivary glands, pancreas, prostate, and renal distal nephron (Bhoola et al., 1992). Tissue kallikrein also is expressed in human neutrophils; it acts locally near its sites of origin. The synthesis of tissue prokallikrein is controlled by a number of factors, including aldosterone in the kidney and salivary gland and androgens in certain other glands. The activation of tissue prokallikrein to kallikrein requires proteolytic cleavage to remove a seven-amino acid propeptide, which can be accomplished in vitro by plasma kallikrein and by some serine and metalloproteases. However, the activating enzyme(s) in vivo is unknown.

Kininogens

The two substrates for the kallikreins, HMW kininogen (120 kDa) and LMW kininogen (66 kDa), are derived from a single gene by alternative splicing. The first 401 amino acids are identical (through the bradykinin sequence and 12 additional residues) and then the sequences diverge, with HMW kininogen containing a 56-kDa C-terminal light chain and LMW kininogen a 4-kDa light chain (Bhoola et al., 1992). HMW kininogen is cleaved by both plasma and tissue kallikrein to yield bradykinin and kallidin, respectively, whereas LMW kininogen is cleaved only by tissue kallikrein to produce kallidin.

Metabolism of Kinins

The decapeptide kallidin is about as active as the nonapeptide bradykinin, even without conversion to bradykinin, which occurs when the N-terminal lysine residue is removed by an aminopeptidase (see Figure 39–4). The t_{1/2} of kinins in plasma is only about 15 sec; 80%–90% of the kinins may

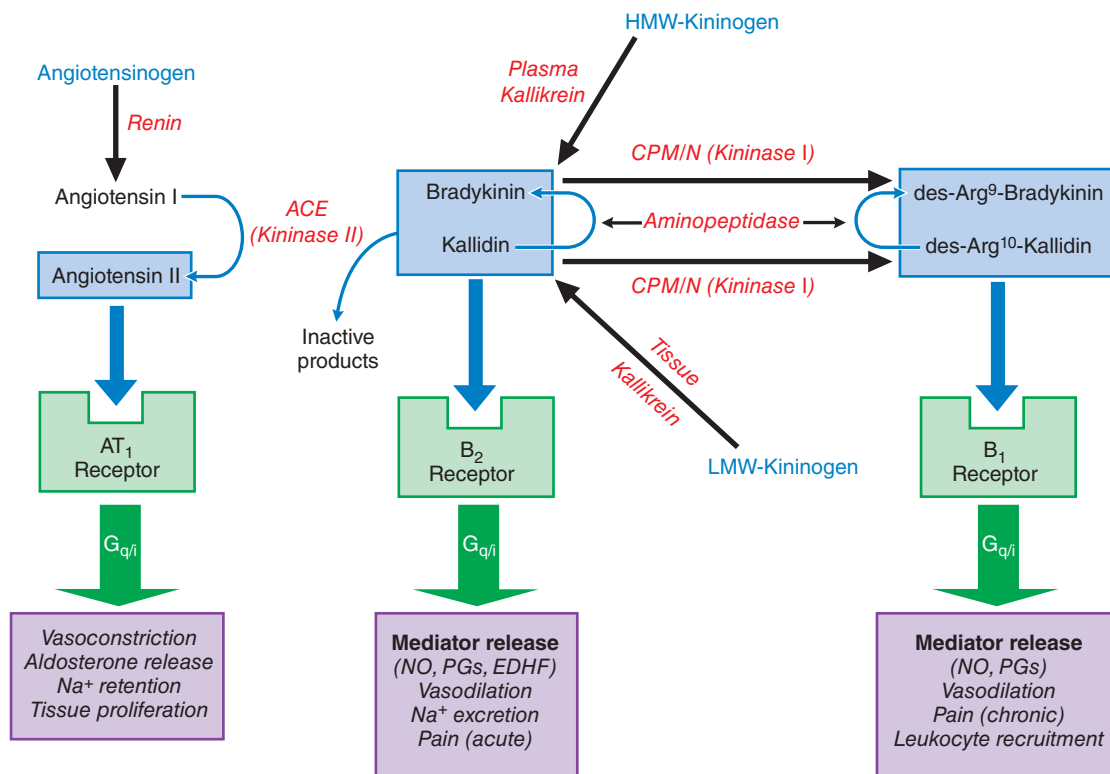

Figure 39–4 Synthesis and receptor interactions of active peptides generated by the kallikrein-kinin and renin-angiotensin systems. Bradykinin is generated by the action of plasma kallikrein on HMW kininogen, whereas kallidin (Lys1-bradykinin) is released by the hydrolysis of LMW kininogen by tissue kallikrein. Kallidin and bradykinin are the natural ligands of the B_2 receptor but can be converted to corresponding agonists of the B_1 receptor by removal of the C-terminal Arg by kininase I-type enzymes: the plasma membrane-bound CPM or soluble plasma CPN. Kallidin or [des-Arg¹⁰]-kallidin can be converted to the active peptides bradykinin or to [des-Arg⁹]-bradykinin by aminopeptidase cleavage of the N-terminal Lys residue. In a parallel fashion, the inactive decapeptide AngI is generated by the action of renin on the plasma substrate angiotensinogen. By removal of the C-terminal His-Leu dipeptide, ACE generates the active peptide AngII. These two systems have opposing effects. AngII is a potent vasoconstrictor that also causes aldosterone release and Na^+ retention via activation of the AT_1 receptor; bradykinin is a vasodilator that stimulates Na^+ excretion by activating the B_2 receptor. ACE generates active AngII and, at the same time, inactivates bradykinin and kallidin; thus, its effects are prohypertensive, and ACE inhibitors are effective antihypertensive agents. The B_2 receptor mediates most of bradykinin's effects under normal circumstances, whereas synthesis of the B_1 receptor is induced by inflammatory mediators in inflammatory conditions. Both B_1 and B_2 receptors couple through G_q to activate PLC and increase intracellular Ca^{2+} ; the physiological response depends on receptor distribution on particular cell types and occupancy by agonist peptides. For instance, on endothelial cells, activation of B_2 receptors results in Ca^{2+} -calmodulin-dependent activation of eNOS and generation of NO, which causes cyclic GMP accumulation and relaxation in neighboring smooth muscle cells. However, in endothelial cells under inflammatory conditions, B_1 receptor stimulation results in prolonged NO production via G_i and an acute MAP kinase-dependent activation of iNOS. On smooth muscle cells, activation of kinin receptors coupling through G_q results in an increased $[Ca^{2+}]_i$ and contraction. B_1 and B_2 receptors also can couple through G_i to activate PLA_2 , causing the release of arachidonic acid and the local generation of prostanoids (PGs) and other metabolites such as EDHF. Kallikrein also plays a role in the intrinsic blood coagulation pathway (see Chapter 32).

be destroyed in a single passage through the pulmonary vascular bed by enzymes present on the large endothelial surface area of the lung (Erdős and Skidgel, 1997). Plasma concentrations of bradykinin are difficult to measure because inadequate inhibition of kininogenases or kininases in the blood can lead to artifactual formation or degradation of bradykinin during blood collection. When care is taken to inhibit these processes, the reported physiological concentrations of bradykinin in blood are in the picomolar range.

The principal catabolizing enzyme in the lung and other vascular beds is kininase II, or ACE, a membrane-anchored peptidase on the surface of endothelial cells (see Chapter 26). Removal of the C-terminal dipeptide by ACE or neutral endopeptidase 24.11 (neprilysin) inactivates kinins (Figure 39–5) (Erdős and Skidgel, 1997). A slower-acting plasma enzyme, carboxypeptidase N (lysine carboxypeptidase, kininase I), releases the C-terminal arginine residue, producing [desArg⁹]-bradykinin or [des-Arg¹⁰]-kallidin (see Table 39–3 and Figures 39–4 and 39–5) (Skidgel and Erdős, 2007), either of which no longer activate B_2 receptors but are potent B_1 receptor agonists. Carboxypeptidase N is expressed in the liver and constitutively secreted into the blood. A rare familial

carboxypeptidase N deficiency was associated with angioedema or urticaria, possibly due to increased bradykinin (Skidgel and Erdős, 2007). Carboxypeptidase M, which cleaves the C-terminal Arg of bradykinin about 3-fold faster than carboxypeptidase N, is a widely distributed plasma membrane-bound enzyme that is also found on lung microvascular endothelial cells (Zhang et al., 2013a). Finally, aminopeptidase P is a membrane enzyme on epithelial and endothelial cells that can cleave the N-terminal arginine of bradykinin, rendering it inactive and susceptible to further cleavage by dipeptidyl peptidase IV (Erdős and Skidgel, 1997) (Figure 39–5).

Kinin Receptors and Their Signaling Pathways

The B_1 and B_2 kinin receptors are GPCRs whose signaling mediates most of the biological effects of the kallikrein-kinin system (Leeb-Lundberg et al., 2005). The B_2 receptor is expressed in most normal tissues, where it selectively binds intact bradykinin and kallidin (see Table 39–3 and Figure 39–4). The B_2 receptor mediates the effects of bradykinin and kallidin under normal circumstances, whereas synthesis of the B_1 receptor is induced by inflammatory conditions. The B_1 receptor is activated by the

Cardiovascular System. Infusion of bradykinin causes vasodilation and lowers blood pressure. Bradykinin causes vasodilation by activating its B₂ receptor on endothelial cells, resulting in the generation of NO.

prostacyclin, and a hyperpolarizing EET that is a CYP-derived metabolite of arachidonate (Campbell and Falck, 2007). The endogenous kallikrein-kinin system plays a minor role in the regulation of normal blood pressure, but it may be important in hypertensive states. Urinary kallikrein concentrations are decreased in individuals with high blood pressure.

The kallikrein-kinin system is cardioprotective. Many of the beneficial effects of ACE inhibitors on heart function are attributable to enhancement of bradykinin effects, such as their antiproliferative activity or ability to increase tissue glucose uptake (Heitsch, 2003; Madeddu et al., 2007). Bradykinin contributes to the beneficial effect of preconditioning to protect the heart against ischemia and reperfusion injury. Bradykinin also stimulates tissue plasminogen activator release from the vascular endothelium and may contribute to the endogenous defense against some cardiovascular events, such as myocardial infarction and stroke (Heitsch, 2003; Madeddu et al., 2007).

Kidney. Renal kinins act in a paracrine manner to regulate urine volume and composition. Kallikrein is synthesized and secreted by the connecting cells of the distal nephron. Tissue kininogen and kinin receptors are present in the cells of the collecting duct. Like other vasodilators, kinins increase renal blood flow. Bradykinin also causes natriuresis by inhibiting Na^+ reabsorption at the cortical collecting duct. Treatment with mineralocorticoids, ACE inhibitors, and neutral endopeptidase (neprilysin) inhibitors increases renal kallikrein.

Other Effects. Kinins promote dilation of the fetal pulmonary artery, closure of the ductus arteriosus, and constriction of the umbilical vessels, all of which occur in the transition from fetal to neonatal circulation. Kinins also affect the CNS, disrupting the blood-brain barrier and allowing increased CNS penetration. Kinins and kinin receptor signaling have been associated with neuroinflammatory disorders, such as neuropathic pain in diabetes, autoimmune encephalomyelitis and Alzheimer disease.

Kallikrein Inhibitors

Aprotinin is a natural proteinase inhibitor that inhibits mediators of the inflammatory response, fibrinolysis, and thrombin generation following cardiopulmonary bypass surgery, including kallikrein and plasmin. Aprotinin was employed clinically to reduce blood loss in patients undergoing coronary artery bypass surgery, but unfavorable survival statistics in retrospective and prospective studies resulted in its discontinuation.

Ecallantide is a synthetic plasma kallikrein inhibitor approved for the treatment of acute attacks of hereditary angioedema in patients 12 years and older. It is administered by a healthcare professional (with appropriate medical support to manage possible anaphylaxis) subcutaneously at a total dose of 30 mg, divided into three 10-mg injections of 1 mL each. An additional dose of 30 mg may be administered within a 24-h period if the attack persists. The most common side effects (~3%–8% of patients) include headache, nausea, diarrhea, fever, injection site reactions, and nasopharyngitis. Safety has not been tested in pregnant or nursing women. Anaphylaxis has been reported in about 4% of treated patients, occurring within 1 h after dosing. Approximately 20% of patients treated

with ecallantide develop antibodies to the drug and may be at a higher risk of hypersensitivity reactions on subsequent exposure. Ecallantide is currently being investigated as a potential treatment of other forms of angioedema (Zuraw et al., 2013).

Bradykinin and the Effects of ACE Inhibitors

The ACE inhibitors, widely used in the treatment of hypertension, congestive heart failure, and diabetic nephropathy, block the conversion of AngI to AngII and also block the degradation of bradykinin by ACE (see Figure 39–4 and Chapter 26). Numerous studies demonstrated that bradykinin contributes to many of the protective effects of ACE inhibitors (Heitsch, 2003; Madeddu et al., 2007). The search is on to find a suitable stable B_2 agonist for clinical evaluation that provides cardiovascular benefit without pro-inflammatory effects.

A rare side effect of ACE inhibitors is angioedema, which is likely due to the inhibition of kinin metabolism by ACE (Zuraw et al., 2013). A common side effect of ACE inhibitors that may be related to enhanced kinin levels is a chronic, nonproductive cough that dissipates when the drug is stopped. Bradykinin may also contribute to the therapeutic effects of the AT_1 receptor antagonists. During AT_1 receptor blockade, AngII signaling through the unopposed AT_2 subtype receptor is enhanced, causing an increase in bradykinin concentrations, which has beneficial effects on cardiovascular and renal function (Padia and Carey, 2013). However, the increase in bradykinin levels is likely more modest than that achieved by ACE inhibitors, as reflected by the lower incidence of angioedema in patients taking AT_1 receptor antagonists (Zuraw et al., 2013).

Kinin Receptor Antagonists

The selective B_2 receptor antagonist *icatibant* has been approved in the E.U. and recently in the U.S. for treatment of acute episodes of swelling in patients more than 18 years of age with hereditary angioedema. It is administered by a healthcare professional, or self-administered by the patient after training, at a dose of 30 mg in 3 mL of solution by subcutaneous injection in the abdomen. Additional doses may be administered at intervals of at least 6 h if the response is inadequate or symptoms recur, not to exceed three doses in any 24-h period. A common side effect experienced by most patients is a local reaction at the injection site (e.g., redness, bruising, swelling, burning, itching, etc.). A small percentage of patients experienced fever, elevated transaminase, dizziness, nausea, headache, or rash. Safety has not been tested in pregnant or nursing women. Although icatibant has the potential to attenuate the antihypertensive effects of ACE inhibitors, it is unclear if this is clinically significant, since patients taking ACE inhibitors were excluded from clinical trials with icatibant. Icatibant is currently being investigated as treatment of ACE inhibitor-induced angioedema, and initial results of small trials and individual case reports indicate that it is effective (Zuraw et al., 2013). Other forms of angioedema are under investigation for responsiveness to icatibant.

Drug Facts for Your Personal Formulary: H_1 Antagonists

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
First-Generation Antihistamines: H_1 receptor inverse agonists • Most have central and anticholinergic effects		
• Use with caution in children and in adults > 65 years of age		
Doxepin	<ul style="list-style-type: none"> • Tricyclic antidepressant • Insomnia • Pruritis (topical cream) • Pruritis (atopic dermatitis, eczema, lichen simplex) (cream) 	<ul style="list-style-type: none"> • Causes significant sedation/drowsiness • Anticholinergic effects • Increased risk of suicidal thoughts (children, adolescents, and young adults)
Carbinoxamine Clemastine Diphenhydramine Dimenhydrinate	<ul style="list-style-type: none"> • Symptoms of allergic response • Mild urticaria • Insomnia (diphenhydramine) • Motion sickness (dimenhydrinate, diphenhydramine) 	<ul style="list-style-type: none"> • Pronounced tendency to cause sedation • Significant anticholinergic effects • GI side effects are low • Carbinoxamine and diphenhydramine: adjunct to epinephrine for anaphylaxis
Pyrilamine (only available as an ingredient in OTC combination preparations)	<ul style="list-style-type: none"> • Symptoms of allergic response 	<ul style="list-style-type: none"> • Anticholinergic effects • Central effects < other first-generation drugs • GI side effects are quite common
Chlorpheniramine Dexchlorpheniramine Brompheniramine Dexbrompheniramine (component of cold medicine)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Allergic rhinitis • Anaphylaxis (adjunct), histamine-mediated angioedema, dermatographism, pruritus, sneezing, urticaria (brompheniramine) • Symptoms of allergic response 	Less drowsiness than other first-generation drugs; CNS stimulation side effects more common
Hydroxyzine	<ul style="list-style-type: none"> • Pruritis • Sedation • Antianxiety • Atopic dermatitis • Antiemetic • Urticaria 	<ul style="list-style-type: none"> • CNS depressant action may contribute to antipruritic effects
Cyclizine (discontinued in the U.S.) Meclizine (not for use in children)	<ul style="list-style-type: none"> • Motion sickness • Nausea/vomiting • Vertigo 	<ul style="list-style-type: none"> • Antinausea properties due to prominent anticholinergic effects • Less likely to cause drowsiness than other first-generation drugs • Meclizine, most used, long effect (≥ 8 h)
Promethazine	<ul style="list-style-type: none"> • Antiemetic • Motion sickness • Pruritus • Sedation • Symptoms of allergic response (off-label use) 	<ul style="list-style-type: none"> • Risk of fatal respiratory depression in children, especially < 2 years • May lower seizure threshold • Has local anesthetic activity • Most potent antihistamine antiemetic
Cyproheptadine	<ul style="list-style-type: none"> • Allergic conjunctivitis • Allergic rhinitis • Anaphylaxis • Histamine-mediated angioedema • Pruritus, allergy • Vasomotor rhinitis • Urticaria • Dermatographism 	<ul style="list-style-type: none"> • May increase appetite, cause weight gain • Has significant anticholinergic activity • Also blocks serotonin effects by antagonizing the $5HT_{2A}$ receptor
Second-Generation Antihistamines: H_1 receptor inverse agonists • Lack significant central and anticholinergic effects		
Olopatadine (nasal and ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Allergic rhinitis • Ocular pruritus • Rhinorrhea • Sneezing 	<ul style="list-style-type: none"> • Approved for once-daily dosing • Eye drops may cause headaches in some • Nasal spray can cause epistaxis and nasal ulceration or septal perforation • Some increase in risk of somnolence with nasal spray • Nasal spray minor side effects include bitter taste and headache
Acrivastine (only marketed in combination with pseudoephedrine)	<ul style="list-style-type: none"> • Allergic rhinitis • Nasal congestion • Allergic symptoms 	<ul style="list-style-type: none"> • ~40% metabolized by CYPs, reducing potential for drug interactions • Somewhat higher risk of mild sedation than other second-generation drugs
Cetirizine Levocetirizine	<ul style="list-style-type: none"> • Allergic rhinitis • Atopic dermatitis (cetirizine) • Urticaria (chronic idiopathic) 	<ul style="list-style-type: none"> • Somewhat higher risk of mild sedation than other second-generation drugs; more potent levocetirizine can be used at lower dose with less risk of sedation • Only ~30% (cetirizine) or ~1% (levocetirizine) metabolized by CYPs, reducing potential for drug interactions

Second-Generation Antihistamines: H₁ receptor inverse agonists • Lack significant central and anticholinergic effects (continued)

Loratadine Desloratadine	<ul style="list-style-type: none"> • Allergic rhinitis • Chronic idiopathic urticaria • Exercise-induced bronchospasm prophylaxis (loratadine) • Pruritus (desloratadine) 	<ul style="list-style-type: none"> • Desloratadine is the active metabolite of loratadine • 24-h duration of activity so only once-a-day dosing is required
Fexofenadine	<ul style="list-style-type: none"> • Allergic rhinitis • Chronic idiopathic urticaria 	<ul style="list-style-type: none"> • Is the active metabolite of terfenadine (withdrawn from the market due to risk of torsades de pointes) • Only ~8% metabolized by CYPs, reducing potential for drug interactions
Alcaftadine (ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Ocular pruritus 	<ul style="list-style-type: none"> • In addition to mast cell–stabilizing and anti-inflammatory properties, its H₁ antagonist activity may give superior relief from ocular itching • Approved for once-daily dosing • Most common adverse reactions (<4%) are eye irritation, redness, and pruritus
Bepotastine (ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Ocular pruritus 	<ul style="list-style-type: none"> • Has mast cell–stabilizing and anti-inflammatory properties • Most common (~25%) adverse reaction is mild taste • Other minor (2%–5%) reactions are eye irritation, headache, and nasopharyngitis
Ketotifen (ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Ocular pruritus 	<ul style="list-style-type: none"> • Has mast cell–stabilizing and anti-inflammatory properties • Most common (~10%–25%) adverse reactions are red eyes and mild headache or rhinitis
Azelastine (nasal and ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Allergic rhinitis (alone and combined with fluticasone) • Ocular pruritus • Vasomotor rhinitis 	<ul style="list-style-type: none"> • Has mast cell–stabilizing and anti-inflammatory properties • Eye drops may cause transient eye burning/stinging • Some increase in risk of somnolence with nasal spray • Minor side effects with eye drops and nasal spray include bitter taste and headache
Emedastine (ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Ocular pruritus 	<ul style="list-style-type: none"> • Lacks mast cell–stabilizing and anti-inflammatory properties • Common side effect: headache (~11%) • Minor reactions (<5%): abnormal dreams, bad taste, eye irritation
Epinastine (ophthalmic only)	<ul style="list-style-type: none"> • Allergic conjunctivitis • Ocular pruritus 	<ul style="list-style-type: none"> • In addition to mast cell–stabilizing and anti-inflammatory properties, its H₂ antagonist activity may reduce eyelid edema • Common side effect (~10%): symptoms of upper respiratory infection • Minor ocular reactions: burning sensation, folliculosis, hyperemia, and pruritus

DRUGS FOR DYSPNEA AND VENTILATORY CONTROL

- Drugs for Dyspnea
- Ventilatory Stimulants

Pulmonary pharmacology concerns understanding how drugs act on the lung and the pharmacological therapy of pulmonary diseases. Much of pulmonary pharmacology is concerned with the effects of drugs on the airways and the therapy of airway obstruction, particularly asthma and COPD, which are among the most common chronic diseases in the world. Both asthma and COPD are characterized by chronic inflammation of the airways, although there are marked differences in inflammatory mechanisms and response to therapy between these diseases (Barnes, 2008b; Postma and Rabe, 2015). This chapter discusses the pharmacotherapy of obstructive airways disease, particularly therapy with bronchodilators, which act mainly by reversing airway smooth muscle contraction, and anti-inflammatory drugs, which suppress the inflammatory response in the airways. This chapter focuses on the pulmonary pharmacology of β_2 adrenergic agonists and corticosteroids; the basic pharmacology of these classes of agents is presented elsewhere (Chapters 12 and 46).

This chapter also discusses other drugs used to treat obstructive airway diseases, such as mucolytics and respiratory stimulants, and covers the drug therapy of cough, the most common respiratory symptom. Drugs used in the treatment of pulmonary hypertension (Chapter 31) or lung infections, including tuberculosis (Chapter 60), are covered elsewhere.

Mechanisms of Asthma

Asthma is a chronic inflammatory disease of the airways that is characterized by activation of *mast cells*, infiltration of *eosinophils*, *T helper 2* (T_H2) *lymphocytes*, and *innate type 2 lymphocytes* (ILC2) (Figure 40–1)

(Barnes, 2011b; Lambrecht and Hammad, 2015). Mast cell activation by allergens and physical stimuli releases *bronchoconstrictor mediators*, such as *histamine*, *LTD₄*, and *prostaglandin D₂*, which cause bronchoconstriction, microvascular leakage, and plasma exudation. Increased numbers of mast cells in airway smooth muscle are a characteristic of asthma.

Many of the symptoms of asthma are due to airway smooth muscle contraction, and therefore bronchodilators are important as symptom relievers. Whether airway smooth muscle is intrinsically abnormal in asthma is not clear, but increased contractility of airway smooth muscle may contribute to airway hyperresponsiveness, the physiological hallmark of asthma.

The mechanism of chronic inflammation in asthma is still not well understood. It may initially be driven by allergen exposure, but it appears to become autonomous so that asthma is essentially incurable. The inflammation may be orchestrated by dendritic cells that regulate T_H2 cells that drive eosinophilic inflammation and also IgE formation by B lymphocytes.

Airway epithelium plays an important role through the release of multiple inflammatory mediators and through the release of growth factors in an attempt to repair the damage caused by inflammation. The inflammatory process in asthma is mediated through the release of more than 100 inflammatory mediators (Hall and Agrawal, 2014). Complex cytokine networks, including chemokines and growth factors, play important roles in orchestrating the inflammation process (Barnes, 2008a).

Chronic inflammation may lead to structural changes (remodeling) in the airways, including an increase in the number and size of airway smooth muscle cells, blood vessels, and mucus-secreting cells. A characteristic

Abbreviations

AC: adenylyl cyclase
ACh: acetylcholine
ALT: alanine aminotransferase
BDP: beclomethasone dipropionate
cAMP: cyclic adenosine monophosphate
CCR3: C-C chemokine receptor type 3
COMT: catechol-O-methyl transferase
COPD: chronic obstructive pulmonary disease
CRTh2: chemokine receptor homologous molecule expressed on Th2 lymphocytes
CXCR2: C-X-C motif chemokine receptor 2
cys-LT: cysteinyl-leukotriene
DPI: dry powder inhaler
FDA: Food and Drug Administration
FEV₁: forced expiratory volume in 1 second
FFA: free fatty acid
GABA: γ -aminobutyric acid
GR: glucocorticoid receptor
HDAC2: histone deacetylase 2
HFA: hydrofluoroalkane
ICS: inhaled corticosteroid
Ig: immunoglobulin
IL: interleukin
ILC2: innate type 2 lymphocyte
IM: intramuscular
IP₃: inositol 1,4,5-trisphosphate
IV: intravenous
LABA: long-acting inhaled β_2 agonist
LAMA: long-acting muscarinic antagonist
5-LO: 5'-lipoxygenase
LT: leukotriene
MAO: monoamine oxidase
MDI: metered-dose inhaler
MMAD: mass median aerodynamic diameter
MMP: matrix metalloproteinase
MOR: μ opioid receptor
NF-κB: nuclear factor kappa B
NMDA: N-methyl-D-aspartate
PAF: platelet-activating factor
PDE: phosphodiesterase
PG: prostaglandin
PKA: protein kinase A
PLC: phospholipase C
pMDI: pressurized metered-dose inhaler
SABA: short-acting β_2 agonists
SAMA: short-acting muscarinic antagonist
TAS2R: taste 2 receptor
Tc1 cell: cytotoxic T lymphocyte
Th17: T helper-17 cell
T_H2: T helper 2 lymphocyte
TNF: tumor necrosis factor
TRP: transient receptor potential
VIP: vasoactive intestinal polypeptide

histological feature of asthma is collagen deposition (fibrosis) below the basement membrane of the airway epithelium (Figure 49-1). This appears to be the result of eosinophilic inflammation and is found even at the onset of asthmatic symptoms. The complex inflammation of asthma is suppressed by corticosteroids in most patients, but even if asthma is well controlled, the inflammation and symptoms return if corticosteroids

are discontinued. Asthma usually starts in early childhood, then may disappear during adolescence and reappear in adulthood. It is characterized by variable airflow obstruction and typically shows a good therapeutic response to bronchodilators and corticosteroids. Asthma severity usually does not change, so that patients with mild asthma rarely progress to severe asthma and patients with severe asthma usually have this from the onset, although some patients, particularly with late-onset asthma, show a progressive loss of lung function like patients with COPD. Patients with severe asthma may have a pattern of inflammation more similar to COPD and are characterized by reduced responsiveness to corticosteroids (Trejo Bittar et al., 2015).

Mechanisms of COPD

Chronic obstructive pulmonary disease involves inflammation of the respiratory tract with a pattern that differs from that of asthma. In COPD, there is a *predominance of neutrophils, macrophages, cytotoxic T lymphocytes (Tc1 cells), and T helper-17 (Th17) cells*. The inflammation *predominantly affects small airways*, resulting in progressive small-airway narrowing and fibrosis (chronic obstructive bronchiolitis) and destruction of the lung parenchyma with destruction of the alveolar walls (emphysema) (Figure 40-2) (Barnes et al., 2015). These pathological changes result in airway closure on expiration, leading to air trapping and hyperinflation, particularly on exercise (dynamic hyperinflation). This accounts for shortness of breath on exertion and exercise limitation that are characteristic symptoms of COPD.

Bronchodilators reduce air trapping by dilating peripheral airways and are the mainstay of treatment in COPD. In contrast to asthma, the airflow obstruction of COPD tends to be progressive. The inflammation in the peripheral lung of patients with COPD is mediated by multiple inflammatory mediators and cytokines, although the pattern of mediators differs from that of asthma (Barnes, 2004). In contrast to asthma, the inflammation in patients with COPD is largely corticosteroid resistant, and there are currently no effective anti-inflammatory treatments. Many patients with COPD have comorbidities, including ischemic heart disease, hypertension, congestive heart failure, diabetes, osteoporosis, skeletal muscle wasting, depression, chronic renal disease, and anemia (Barnes and Celli, 2009). These diseases may occur together as part of multimorbidity, as diseases of accelerated aging with common pathogenetic mechanisms (Barnes, 2015).

Routes of Drug Delivery to the Lungs

Drugs may be delivered to the lungs by oral or parenteral routes and also by inhalation. The choice depends on the drug and on the respiratory disease.

Inhaled Route

Inhalation (Figure 40-3) is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and COPD (Sanchis et al., 2013). It is the only way to deliver some drugs, such as cromolyn sodium and anticholinergic drugs, and is the preferred route of delivery for β_2 agonists and corticosteroids to reduce systemic side effects. Antibiotics may be delivered by inhalation in patients with chronic respiratory sepsis (e.g., in cystic fibrosis). The major advantage of inhalation is the delivery of drug to the airways in doses that are effective with a much lower risk of systemic side effects. This is particularly important with the use of ICS, which largely avoids systemic side effects. In addition, inhaled bronchodilators have a more rapid onset of action than when taken orally.

Particle Size

The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2- to 5- μ m MMAD. Larger particles settle out in the upper airways, whereas smaller particles remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma (Usmani and

Figure 40-1 Cellular mechanisms of asthma. Myriad inflammatory cells are recruited and activated in the airways, where they release multiple inflammatory mediators, which can also arise from structural cells. These mediators lead to bronchoconstriction, plasma exudation and edema, vasodilation, mucus hypersecretion, and activation of sensory nerves. Chronic inflammation leads to structural changes, including subepithelial fibrosis (basement membrane thickening), airway smooth muscle hypertrophy and hyperplasia, angiogenesis, and hyperplasia of mucus-secreting cells.

Barnes, 2012). This involves delivering drug particles of about 1- μ m MMAD, which is now possible using drugs formulated in HFA propellant.

Pharmacokinetics

Of the total drug delivered, only 10%–20% enters the lower airways with a conventional pMDI. Drugs are absorbed from the airway lumen and have direct effects on target cells of the airway. Drugs may also be absorbed into the bronchial circulation and then distributed to more peripheral airways. Drugs with higher molecular weights tend to be retained to a

greater extent in the airways. Nevertheless, several drugs have greater therapeutic efficacy when given by the inhaled route. The ICS *ciclesonide* is a prodrug activated by esterases in the respiratory tract to the active principle des-ciclesonide. More extensive pulmonary distribution of a drug with a smaller MMAD increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation, resulting in more systemic side effects. Thus, although HFA pMDIs deliver more ICS to smaller airways, there is also increased systemic absorption, so that the therapeutic ratio may not be changed.

Figure 40-2 Cellular mechanisms in COPD. Cigarette smoke and other irritants activate epithelial cells and macrophages in the lung to release mediators that attract circulating inflammatory cells, including monocytes (which differentiate to macrophages within the lung), neutrophils, and T lymphocytes (T_H1 , T_C1 , and T_H17 cells). Fibrogenic factors released from epithelial cells and macrophages lead to fibrosis of small airways. Release of proteases results in alveolar wall destruction (emphysema) and mucus hypersecretion (chronic bronchitis).

Figure 40–3 Schematic representation of the deposition of inhaled drugs (e.g., corticosteroids, β_2 agonists). Inhalation therapy deposits drugs directly, but not exclusively, in the lungs. Distribution between lungs and oropharynx depends mostly on the particle size and the efficiency of the delivery method. Most material will be swallowed and absorbed, entering systemic circulation after undergoing the first-pass effect in the liver. Some drug will also be absorbed into the systemic circulation from the lungs. Use of a large-volume spacer will reduce the amount of drug deposited on the oropharynx, thereby reducing the amount swallowed and absorbed from the GI tract, thus limiting systemic effects.

Delivery Devices

Pressurized Metered-Dose Inhalers. Drugs are propelled from a canister in the pMDI with the aid of a propellant, previously with a chlorofluorocarbon (Freon) but now replaced by an HFA that is “ozone friendly.” These devices are convenient, portable, and typically deliver 50–200 doses of drug.

Spacer Chambers. Large-volume spacer devices between the pMDI and the patient reduce the velocity of particles entering the upper airways and the size of the particles by allowing evaporation of liquid propellant. This reduces the amount of drug that impinges on the oropharynx and increases the proportion of drug inhaled into the lower airways. Application of spacer chambers is useful in the reduction of the oropharyngeal deposition of ICS and the consequent reduction in the local side effects of these drugs. Spacer devices are also useful in delivering inhaled drugs to small children who are not able to use a pMDI. Children as young as 3 years of age are able to use a spacer device fitted with a face mask.

Dry Powder Inhalers. Drugs may also be delivered as a dry powder using devices that scatter a fine powder dispersed by air turbulence on inhalation. Children less than 7 years of age find it difficult to use a DPI. DPIs have been developed to deliver peptides and proteins, such as insulin, systemically but have proved to be problematic because of consistency of dosing.

Nebulizers. Two types of nebulizer are available. *Jet nebulizers* are driven by a stream of gas (air or oxygen), whereas *ultrasonic nebulizers* use a rapidly vibrating piezoelectric crystal and thus do not require a source of compressed gas. The nebulized drug may be inspired during tidal breathing, and it is possible to deliver much higher doses of drug compared with a pMDI. Nebulizers are therefore useful in treating acute exacerbations of asthma and COPD, for delivering drugs when airway obstruction is extreme (e.g., in severe COPD), for delivering inhaled drugs to infants and small children who cannot use the other inhalation devices, and for giving drugs such as antibiotics when relatively high doses must be delivered.

Oral Route

Drugs for treatment of pulmonary diseases may also be given orally. The oral dose is much higher than the inhaled dose required to achieve the same effect (typically by a ratio of about 20:1), so that systemic side effects are more common. *When there is a choice of inhaled or oral route for a drug (e.g., β_2 agonist or corticosteroid), the inhaled route is always preferable*, and the oral route should be reserved for the few patients unable to use inhalers (e.g., small children, patients with physical problems such as severe arthritis of the hands). Theophylline is ineffective by the inhaled route and therefore must be given systemically.

Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases).

Parenteral Route

The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the GI tract. Side effects are generally frequent due to the high plasma concentrations.

Bronchodilators

Bronchodilator drugs relax constricted airway smooth muscle in vitro and cause immediate reversal of airway obstruction in asthma in vivo (Cazzola et al., 2012). They also prevent bronchoconstriction (and thereby provide bronchoprotection). Three main classes of bronchodilator are in current clinical use:

- β_2 Adrenergic agonists (sympathomimetics)
- Theophylline (a methylxanthine)
- Anticholinergic agents (muscarinic receptor antagonists)

Drugs such as *cromolyn sodium*, which prevent bronchoconstriction, have no direct bronchodilator action and are ineffective once bronchoconstriction has occurred. *Anti-LTs* (LT receptor antagonists and 5'-lipoxygenase inhibitors) have a small bronchodilator effect in some asthmatic patients and appear to prevent bronchoconstriction. *Corticosteroids*, although gradually improving airway obstruction, have no direct effect on contraction of airway smooth muscle and are not therefore considered to be bronchodilators.

β_2 Adrenergic Agonists

Inhaled β_2 agonists are the bronchodilator treatment of choice in asthma because they are the most effective bronchodilators and have minimal side effects when used correctly. Systemic, short-acting, and nonselective β agonists, such as isoproterenol (isoprenaline) or metaproterenol, should only be used as a last resort.

Chemistry

The development of β_2 agonists is based on substitutions in the catecholamine structure of norepinephrine and epinephrine (see Chapters 8 and 12). The catechol ring consists of hydroxyl groups in the 3 and 4 positions of the benzene ring. Norepinephrine differs from epinephrine only in the terminal amine group; in general, further modification at this site confers β receptor selectivity. Many β_2 -selective agonists have now been introduced, and although there may be differences in potency, there are no clinically significant differences in selectivity. Inhaled β_2 -selective drugs in current clinical use have a similar duration of action (3–6 h).

The inhaled LABAs, salmeterol and formoterol, have a much longer duration of effect, providing bronchodilation and bronchoprotection for more than 12 h (Cazzola et al., 2013b). Formoterol has a bulky substitution in the aliphatic chain and has moderate lipophilicity, which appears to keep the drug in the membrane close to the receptor, so it behaves as a slow-release drug. Salmeterol has a long aliphatic chain, and its long duration may be due to binding within the receptor binding cleft ("exosite") that anchors the drug in the binding cleft. Once-daily β_2 agonists, such as indacaterol, vilanterol, and olodaterol, with a duration of action more than 24 h have now been developed.

Mode of Action

Occupation of β_2 receptors by agonists results in the activation of the G_s -adenylyl cyclase-cAMP-PKA pathway, resulting in phosphorylative events leading to bronchial smooth muscle relaxation (Figure 40–4). β_2 Receptors are localized to several different airway cells, where they may have additional effects. β_2 Agonists may cause bronchodilation also *indirectly* by inhibiting the release of bronchoconstrictor mediators from inflammatory cells and of bronchoconstrictor neurotransmitters from airway nerves. These mechanisms include the following:

- Prevention of mediator release from isolated human lung mast cells (via β_2 receptors)
- Prevention of microvascular leakage and thus the development of bronchial mucosal edema after exposure to mediators, such as histamine, LTD₄, and prostaglandin D₂
- Increase in *mucus secretion* from submucosal glands and *ion transport* across airway epithelium (may enhance mucociliary clearance, reversing defective clearance found in asthma)
- *Reduction in neurotransmission* in human airway *cholinergic nerves* by an action at presynaptic β_2 receptors to inhibit ACh release

Although these additional effects of β_2 agonists may be relevant to the prophylactic use of these drugs against various challenges, their rapid bronchodilator action is probably attributable to a direct effect on smooth muscle of all airways.

Anti-inflammatory Effects

Whether β_2 agonists have anti-inflammatory effects in asthma is controversial. The inhibitory effects of β_2 agonists on mast cell mediator release and microvascular leakage are clearly anti-inflammatory, suggesting that β_2 agonists may modify *acute* inflammation. However, β_2 agonists do not

appear to have a significant inhibitory effect on the *chronic* inflammation of asthmatic airways, which is suppressed by corticosteroids. This has now been confirmed by several biopsy and bronchoalveolar lavage studies in patients with asthma who are taking regular β_2 agonists (including LABAs), that demonstrated no significant reduction in the number or activation in inflammatory cells in the airways, in contrast to resolution of the inflammation that occurs with ICS. This may be related to the fact that effects of β_2 agonists on macrophages, eosinophils, and lymphocytes are rapidly desensitized.

Clinical Use

Short-Acting β_2 Agonists. Inhaled SABAs are the most widely used and effective bronchodilators in the treatment of asthma due to their functional antagonism of bronchoconstriction. When inhaled from pMDIs or DPIs, they are convenient, easy to use, rapid in onset, and without significant systemic side effects. These agents are effective in protecting against various asthma triggers, such as exercise, cold air, and allergens. SABAs are the bronchodilators of choice in treating acute severe asthma. The nebulized route of administration is easier and safer than intravenous administration and just as effective. Inhalation is preferable to oral administration because systemic side effects are less. *SABAs, such as albuterol, should be used "as required" by symptoms and not on a regular basis in the treatment of mild asthma; increased use indicates the need for more anti-inflammatory therapy.*

Oral β_2 agonists are occasionally indicated as an additional bronchodilator. Slow-release preparations (e.g., slow-release albuterol and bambuterol [not available in the U.S.]) may be indicated in nocturnal asthma; however, these agents have an increased risk of side effects. Several SABAs are available; they are resistant to uptake and enzymatic degradation by COMT and MAO; all are usable by inhalation and orally, have a similar duration of action (~3–4 h; less in severe asthma), and similar side effects. Differences in β_2 receptor selectivity have been claimed but are not clinically important. Drugs in clinical use include *albuterol (salbutamol), levalbuterol, metaproterenol, terbutaline, pirbuterol*, as well as several not available in the U.S. (*fenoterol, tulobuterol, and rimiterol*).

Long-Acting Inhaled β_2 Agonists. The LABAs *salmeterol, formoterol, and arformoterol* have proved to be a significant advance in asthma and COPD therapy. These drugs have a bronchodilator action of more than 12 h and also protect against bronchoconstriction for a similar period

Figure 40–4 Molecular actions of β_2 agonists to induce relaxation of airway smooth muscle cells. Activation of β_2 receptors (β_2 AR) results in activation of AC via G_s , leading to an increase in intracellular cAMP and activation of PKA. PKA phosphorylates a variety of target substrates, resulting in opening of Ca^{2+} -activated K^+ channels (K_{Ca}), thereby facilitating hyperpolarization, decreased PI hydrolysis, increased $\text{Na}^+/\text{Ca}^{2+}$ exchange, increased Na^+ , Ca^{2+} -ATPase activity, and decreased myosin light chain kinase (MLCK) activity and increased myosin light chain (MLC) phosphatase. β_2 Receptors may also couple to K_{Ca} via G_s , PDE, cyclic nucleotide phosphodiesterase.

(Cazzola et al., 2013b). They improve asthma control (when given twice daily) compared with regular treatment with SABAs (four to six times daily). Once-daily LABAs, such as *indacaterol*, *vilanterol*, and *olodaterol*, with a duration of over 24 h have now been developed and are more effective in patients with COPD than twice-daily LABAs and more frequent SABAs.

Tolerance to the bronchodilator effect of formoterol and the bronchoprotective effects of formoterol and salmeterol have been demonstrated but is of doubtful clinical significance. Although both formoterol and salmeterol have a similar duration of effect in clinical studies, there are differences. Formoterol has a more rapid onset of action and is an almost-full agonist, whereas salmeterol is a partial agonist with a slower onset of action. These differences might confer a theoretical advantage for formoterol in more severe asthma, whereas it may also make it more likely to induce tolerance. However, no significant clinical differences between salmeterol and formoterol have been found in the treatment of patients with severe asthma (Nightingale et al., 2002).

In COPD, LABAs are effective bronchodilators that may be used alone or in combination with anticholinergics or ICSs. LABAs improve symptoms and exercise tolerance by reducing both air trapping and exacerbations. *In patients with asthma, LABAs should never be used alone because they do not treat the underlying chronic inflammation, and this may increase the risk of life-threatening and fatal asthma exacerbations; rather, LABAs should always be used in combination with an ICS in a fixed-dose combination inhaler.* LABAs are an effective add-on therapy to ICSs and are more effective than increasing the dose of an ICS when asthma is not controlled at low doses.

Combination Inhalers. Combination inhalers that contain a LABA and a corticosteroid (e.g., *fluticasone/salmeterol*, *budesonide/formoterol*) are now widely used in the treatment of asthma and COPD. In asthma, combining a LABA with a corticosteroid offers complementary synergistic actions (Barnes, 2002). The combination inhaler is more convenient for patients, simplifies therapy, and improves adherence with the ICS. Also, delivering the two drugs in the same inhaler ensures they are delivered simultaneously to the same cells in the airways, allowing the beneficial molecular interactions between LABAs and corticosteroids to occur. Combination inhalers are now the preferred therapy for patients with persistent asthma. These combination inhalers are also more effective in patients with COPD than a LABA and an ICS alone, but the mechanisms accounting for this beneficial interaction are less well understood than in patients with asthma.

Stereoselective β_2 Agonists. Albuterol is a racemic mixture of active *R*- and inactive *S*-isomers. Although *R*-albuterol (levalbuterol) was more potent than racemic *R/S*-albuterol in some studies, careful dose responses showed no advantage in terms of efficacy and no evidence that the *S*-albuterol is detrimental in asthmatic patients (Lotvall et al., 2001). Because levalbuterol is usually more expensive than normally used racemic albuterol, this therapy has no clear clinical advantage. Stereoselective formoterol (*R,R*-formoterol, arformoterol) has now been developed as a nebulized solution but also appears to offer no clinical advantage over racemic formoterol in patients with COPD (Loh et al., 2015).

β_2 Receptor Polymorphisms. Several single-nucleotide polymorphisms and haplotypes of the human *ADRB2*, which affect the structure of β_2 receptors, have been described. The common variants are Gly¹⁶Arg and Gln²⁷Glu, which have in vitro effects on receptor desensitization, but clinical studies have shown inconsistent effects on the bronchodilator responses to SABAs and LABAs (Hawkins et al., 2008). Some studies have shown that patients with the common homozygous Arg¹⁶Arg variant have more frequent adverse effects and a poorer response to SABAs than heterozygotes or Gly¹⁶Gly homozygotes, but overall these differences are small, and there appears to be no clinical value in measuring *ADRB2* genotype. No differences have been found with responses to LABA between these genotypes (Bleecker et al., 2007).

Side Effects. Unwanted effects are dose related and due to stimulation of extrapulmonary β receptors (Table 40–1 and Chapter 12). Side effects

TABLE 40–1 ■ SIDE EFFECTS OF β_2 AGONISTS

- Muscle tremor (direct effect on skeletal muscle β_2 receptors)
- Tachycardia (direct effect on atrial β_2 receptors, reflex effect from increased peripheral vasodilation via β_2 receptors)
- Hypokalemia (direct β_2 effect on skeletal muscle uptake of K^+)
- Restlessness
- Hypoxemia ($\uparrow V/Q$ mismatch due to reversal of hypoxic pulmonary vasoconstriction)
- Metabolic effects (\uparrow FFA, glucose, lactate, pyruvate, insulin)

are not common with inhaled therapy but quite common with oral or intravenous administration.

- *Muscle tremor* due to stimulation of β_2 receptors in skeletal muscle is the most common side effect. It may be more troublesome with elderly patients and so is a more frequent problem in patients with COPD.
- *Tachycardia* and *palpitations* are due to reflex cardiac stimulation secondary to peripheral vasodilation, from direct stimulation of atrial β_2 receptors (human heart has a relatively high proportion of β_2 receptors; see Chapter 12), and possibly also from stimulation of myocardial β_1 receptors as the doses of β_2 agonist are increased.
- *Hypokalemia* is a potentially serious side effect. This is due to β_2 receptor stimulation of potassium entry into skeletal muscle, which may be secondary to a rise in insulin secretion. Hypokalemia might be serious in the presence of hypoxia, as in acute asthma, when there may be a predisposition to cardiac arrhythmias (Chapter 30). In practice, however, significant arrhythmias after nebulized β_2 agonists are rarely observed in acute asthma or patients with COPD.
- *Ventilation-perfusion V/Q mismatch* due to pulmonary vasodilation in blood vessels previously constricted by hypoxia results in the shunting of blood to poorly ventilated areas and a fall in arterial oxygen tension. Although in practice the effect of β_2 agonists on Pao_2 is usually very small (<5 mm Hg fall), occasionally in severe COPD it can be large, although it may be prevented by giving additional inspired oxygen.
- *Metabolic effects* (increase in free fatty acid, insulin, glucose, pyruvate, and lactate) are usually seen only after large systemic doses.

Tolerance. Continuous treatment with an agonist often leads to tolerance, which may be due to downregulation of the receptor (Chapter 12). Tolerance of nonairway β_2 receptor-mediated responses, such as tremor and cardiovascular and metabolic responses, is readily induced in normal and asthmatic subjects. In asthmatic patients, tolerance to the bronchodilator effects of β_2 agonists has not usually been found. However, tolerance develops to the bronchoprotective effects of β_2 agonists, and this is more marked with indirect bronchoconstrictors that activate mast cells (e.g., adenosine, allergen, and exercise) than with direct bronchoconstrictors, such as histamine and methacholine. The reason for the relative resistance of airway smooth muscle β_2 responses to desensitization remains uncertain but may reflect the large receptor reserve: More than 90% of β_2 receptors may be lost without any reduction in the relaxation response. The high level of *ADRB2* expression in airway smooth muscle compared with peripheral lung may also contribute to the resistance to tolerance because a high rate of β receptor synthesis is likely. In addition, the expression of GRK2, which phosphorylates and inactivates occupied β_2 receptors, is very low in airway smooth muscle (Penn et al., 1998). By contrast, there is no receptor reserve in inflammatory cells, GRK2 expression is high, and tolerance to β_2 agonists rapidly develops at these sites.

Experimental studies have shown that corticosteroids prevent the development of tolerance in airway smooth muscle and prevent and reverse the fall in pulmonary β receptor density (Mak et al., 1995). However, ICSs fail to prevent the tolerance to the bronchoprotective effect of inhaled β_2 agonists, possibly because they do not reach airway smooth muscle in a high enough concentration.

Long-Term Safety. Because of a possible relationship between adrenergic drug therapy and the rise in asthma deaths in several countries during the early 1960s, doubts were cast on the long-term safety of β agonists. A particular β_2 agonist, fenoterol, was linked to the rise in asthma deaths in New Zealand in the early 1990s because significantly more of the fatal cases were prescribed fenoterol than the case-matched control patients (Beasley et al., 1999). An epidemiological study examining the links between drugs prescribed for asthma and death or near death from asthma attacks found a marked increase in the risk of death with high doses of all inhaled β_2 agonists. The risk was greater with fenoterol, but when the dose is adjusted to the equivalent dose for albuterol, there is no significant difference in the risk for these two drugs.

The link between high β_2 agonist usage and increased asthma mortality does not prove a causal association because patients with more severe and poorly controlled asthma, who are more likely to have an increased risk of fatal attacks, are more likely to be using higher doses of β_2 agonist inhalers and less likely to be using effective anti-inflammatory treatment. Indeed, in the patients who used regular inhaled steroids, there was a significant reduction in risk of death.

Regular use of inhaled β_2 agonists has also been linked to increased asthma morbidity. Regular use of fenoterol was associated with worse asthma control and a small increase in airway hyperresponsiveness compared with patients using fenoterol “on demand” for symptom control over a 6-month period (Sears, 2002). However, this was not found in a study with regular albuterol (Dennis et al., 2000). There is some evidence that regular inhaled β_2 agonists may increase allergen-induced asthma and sputum eosinophilia (Gauvreau et al., 1997).

SABAs should only be used on demand for symptom control, and if they are required frequently (more than three times weekly), an ICS is needed.

The safety of LABAs in asthma remains controversial. A large study of the safety of salmeterol showed an excess of respiratory deaths and near deaths in patients prescribed salmeterol, but these deaths occurred mainly in African Americans living in inner cities who were not taking ICSs (Nelson and Dorinsky, 2006). Similar data have also raised concerns about formoterol. However, concomitant treatment with an ICS appears to obviate such risk, so it is recommended that LABAs should only be used when ICSs are also prescribed (preferably in the form of a combination inhaler so that the LABAs can never be taken without the ICSs) (Cates et al., 2014). All LABAs approved in the U.S. carry a black-box warning cautioning against overuse. There are fewer safety concerns with LABA use in COPD. No major adverse effects were reported in several large and prolonged studies and no evidence of cardiovascular problems (Kew et al., 2013).

Future Developments

The β agonists will continue to be the bronchodilators of choice for asthma because they are effective in all patients and have few or no side effects when used in low doses. When used as required for symptom control, inhaled β_2 agonists appear safe. Use of large doses of inhaled β_2 agonists indicates poor asthma control; such patients should be assessed and appropriate controller medication used. LABAs are a useful option for long-term control in asthma and COPD. In patients with asthma, LABAs should probably only be used in a fixed combination with an ICS to prevent the potential danger associated with LABAs alone. There is little advantage to be gained by improving β_2 receptor selectivity because most of the side effects of these agents are due to β_2 receptor stimulation (muscle tremor, tachycardia, hypokalemia). Once-daily inhaled β_2 agonists are useful in patients with COPD and may have additive effects with LAMAs.

Methylxanthines

Methylxanthines, such as theophylline, which are related to caffeine, have been used in the treatment of asthma since 1930, and theophylline is still widely used in developing countries because it is inexpensive. Theophylline became more useful with the introduction of reliable slow-release preparations. However, inhaled β_2 agonists are far more effective as bronchodilators, and ICSs have a greater anti-inflammatory effect. In patients

with severe asthma and COPD, it still remains a useful drug as an add-on therapy (Barnes, 2013c).

Chemistry

Theophylline is a methylxanthine similar in structure to the common dietary xanthines caffeine and theobromine. Several substituted derivatives have been synthesized, but only two appear to have any advantage over theophylline: *Enprofylline* is a more potent bronchodilator and may have fewer toxic effects because it does not antagonize adenosine receptors; *doxofylline*, a novel methylxanthine available in some countries, has an inhibitory effect on PDEs similar to that of theophylline but is less active as an adenosine antagonist and has a more favorable side-effect profile (Akram et al., 2012). Many salts of theophylline have also been marketed; the most common is aminophylline. Other salts do not have any advantage. Theophylline remains the major methylxanthine in clinical use.

Mechanism of Action

The mechanisms of action of theophylline are still uncertain. In addition to its bronchodilator action, theophylline has many nonbronchodilator effects that may be relevant to its effects in asthma and COPD (Figure 40–5). Several molecular mechanisms of action have been proposed:

- **Inhibition of PDEs.** Theophylline is a nonselective PDE inhibitor, but the degree of inhibition is relatively minimal at concentrations of theophylline that are within the therapeutic range. PDE inhibition and the concomitant elevation of cellular cAMP and cyclic GMP likely account for the bronchodilator action of theophylline. Several isoenzyme families of PDE have now been recognized, and those important in smooth muscle relaxation include PDE3, PDE4, and PDE5.
- **Adenosine receptor antagonism.** Theophylline antagonizes adenosine receptors at therapeutic concentrations. Adenosine causes bronchoconstriction in airways from asthmatic patients by releasing histamine and LTs. Antagonism of A_1 receptors may be responsible for serious side effects, including cardiac arrhythmias and seizures.
- **Interleukin 10 release.** IL-10 has a broad spectrum of anti-inflammatory effects, and there is evidence that its secretion is reduced in asthma. IL-10 release is increased by theophylline, and this effect may be mediated via inhibition of PDE activities, although this has not been seen at the low doses that are effective in asthma.
- **Effects on gene transcription.** Theophylline prevents the translocation of the pro-inflammatory transcription factor NF- κ B into the nucleus, potentially reducing the expression of inflammatory genes in asthma and COPD (Ichiyama et al., 2001). However, these effects are seen at high concentrations and may be mediated by inhibition of PDE.
- **Effects on apoptosis.** Prolonged survival of granulocytes due to a reduction in apoptosis may be important in perpetuating chronic inflammation in asthma (eosinophils) and COPD (neutrophils). Theophylline promotes apoptosis in eosinophils and neutrophils in vitro. This is associated with a reduction in the antiapoptotic protein Bcl-2 (Chung et al., 2000). This effect is not mediated via PDE inhibition, but in neutrophils may be mediated by antagonism of adenosine A_{2A} receptors (Yasui et al., 2000). Theophylline also induces apoptosis in T lymphocytes via PDE inhibition.
- **Histone deacetylase activation.** Recruitment of HDAC2 by GRs switches off inflammatory genes. Therapeutic concentrations of theophylline activate HDAC, thereby enhancing the anti-inflammatory effects of corticosteroids (Cosio et al., 2004). This mechanism appears to be mediated by inhibition of PI $_3$ -kinase- δ , which is activated by oxidative stress (To et al., 2010).

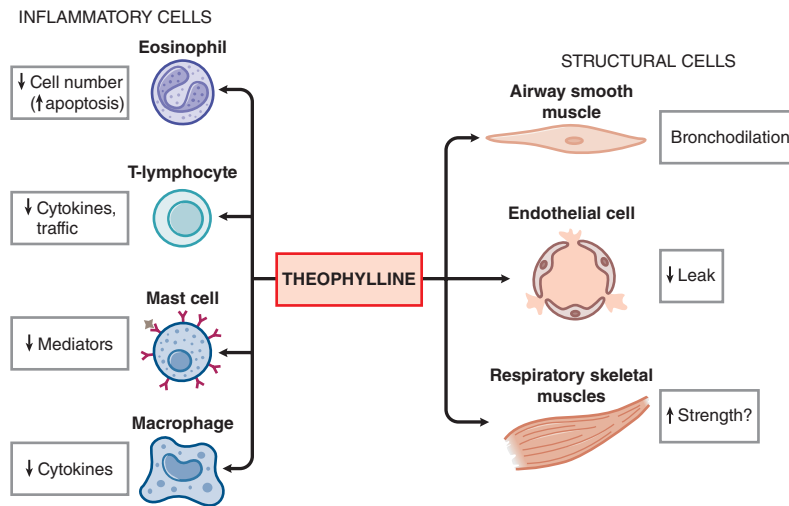

Figure 40–5 Theophylline affects multiple cell types in the airway.

Nonbronchodilator Effects

Theophylline has clinical benefit in asthma and COPD at plasma concentrations less than 10 mg/L, sufficiently low that such effects are unlikely to be explained by theophylline's bronchodilator action. There is increasing evidence that theophylline has anti-inflammatory effects in asthma (Barnes, 2013c). In patients with mild asthma, chronic oral treatment with theophylline inhibits the late response to inhaled allergen and reduces infiltration of eosinophils and CD4⁺ lymphocytes into the airways after allergen challenge (Lim et al., 2001). In patients with COPD, theophylline reduces the total number and proportion of neutrophils in induced sputum, the concentration of IL-8, and neutrophil chemotactic responses (Culpitt et al., 2002). Theophylline withdrawal in patients with COPD results in worsening of disease. In vitro theophylline is able to increase responsiveness to corticosteroids and to reverse corticosteroid resistance in cells from subjects with COPD (Cosio et al., 2004).

Pharmacokinetics and Metabolism

Theophylline has antiasthma effects other than bronchodilation below 10 mg/L, so the therapeutic range is now taken as 5–15 mg/L. The dose of theophylline required to give these therapeutic concentrations varies among subjects, largely because of differences in clearance of the drug. In addition, there may be differences in bronchodilator response to theophylline; furthermore, with acute bronchoconstriction, higher concentrations may be required to produce bronchodilation. Theophylline is rapidly and completely absorbed, but there are large interindividual variations in clearance due to differences in hepatic metabolism. Theophylline is metabolized in the liver, mainly by CYP1A2; myriad factors influence hepatic metabolism and clearance of theophylline (see Table 40–2).

Because of these variations in clearance, individualization of theophylline dosage is required, and plasma concentrations should be measured 4 h after the last dose with slow-release preparations when steady state has been achieved. There is no significant circadian variation in theophylline metabolism, although there may be delayed absorption at night related to supine posture.

Preparations and Routes of Administration

Intravenous aminophylline, an ethylene diamine ester of theophylline that is water soluble, has been used for many years in the treatment of acute severe asthma. The recommended dose is 6 mg/kg given intravenously over 20–30 min, followed by a maintenance dose of 0.5 mg/kg per hour. If the patient is already taking theophylline, or there are any factors that decrease clearance, these doses should be halved and the plasma level checked more frequently. Nebulized β_2 agonists are now preferred over intravenous aminophylline for acute exacerbations of asthma and COPD.

Oral immediate-release theophylline tablets or elixirs, which are rapidly absorbed, give wide fluctuations in plasma levels and are not

recommended. Several sustained-release preparations are now available that are absorbed at a constant rate and provide steady plasma concentrations over a 12- to 24-h period. Both slow-release aminophylline and theophylline are available and are equally effective (although the ethylene diamine component of aminophylline has been implicated in allergic reactions). For continuous treatment, twice-daily therapy (~8 mg/kg twice daily) is needed. For nocturnal asthma, a single dose of slow-release theophylline at night is often effective. Once optimal doses have been determined, routine monitoring of plasma concentrations is usually not necessary unless a change in clearance is suspected or evidence of toxicity emerges.

Clinical Use

In patients with acute asthma, intravenous aminophylline is less effective than nebulized β_2 agonists and should therefore be reserved for those patients who fail to respond to, or are intolerant of, β_2 agonists. Theophylline should not be added routinely to nebulized β_2 agonists because it does not increase the bronchodilator response and may increase their side effects. Theophylline has been used as a controller in the management of mild persistent asthma, although it is usually found to be less effective than low doses of ICSs. Addition of low-dose theophylline to an ICS in patients who are not adequately controlled provides better symptom control and lung function than doubling the dose of inhaled steroid (Lim et al., 2001). LABAs are more effective as an add-on therapy, but theophylline is

TABLE 40–2 ■ FACTORS AFFECTING CLEARANCE OF THEOPHYLLINE

Increased clearance

- Enzyme induction (mainly CYP1A2) by coadministered drugs (e.g., rifampicin, barbiturates, ethanol)
- Smoking (tobacco, marijuana) via CYP1A2 induction
- High-protein, low-carbohydrate diet
- Barbecued meat
- Childhood

Decreased clearance

- CYP inhibition (cimetidine, erythromycin, ciprofloxacin, allopurinol, fluvoxamine, zileuton, zafirlukast)
- Congestive heart failure
- Liver disease
- Pneumonia
- Viral infection and vaccination
- High-carbohydrate diet
- Old age

TABLE 40-3 ■ SIDE EFFECTS OF THEOPHYLLINE AND MECHANISMS

SIDE EFFECT	PROPOSED MECHANISM
Nausea and vomiting	PDE4 inhibition
Headaches	PDE4 inhibition
Gastric discomfort	PDE4 inhibition
Diuresis	A ₁ receptor antagonism
Behavioral disturbance (?)	?
Cardiac arrhythmias	PDE3 inhibition, A ₁ receptor antagonism
Epileptic seizures	A ₁ receptor antagonism

A, adenosine.

considerably less expensive and may be the only affordable add-on treatment when the costs of medication are limiting.

Theophylline is still used as a bronchodilator in COPD, but inhaled anticholinergics and β_2 agonists are preferred. Theophylline tends to be added to these inhaled bronchodilators in patients with more severe disease and has been shown to give additional clinical improvement when added to a LABA.

Side Effects

Unwanted effects of theophylline are usually related to plasma concentration and tend to occur at C_p greater than 15 mg/L. The most common side effects are headache, nausea, and vomiting (due to inhibition of PDE4), abdominal discomfort, and restlessness (Table 40-3). There may also be increased acid secretion (due to PDE inhibition) and diuresis (due to inhibition of adenosine A₁ receptors). Theophylline may lead to behavioral disturbance and learning difficulties in schoolchildren. At high concentrations, cardiac arrhythmias may occur as a consequence of inhibition of cardiac PDE3 and antagonism of cardiac A₁ receptors. At very high concentrations, seizures may occur due to central A₁ receptor antagonism. Use of low doses of theophylline, targeting plasma concentrations of 5–10 mg/L, largely avoids side effects and drug interactions.

Summary and Future Developments

Theophylline use has been declining, partly because of the problems with side effects, but mainly because more effective therapy with β_2 agonists and ICSs have been introduced. Oral theophylline remains a useful add-on treatment in some patients with difficult asthma and appears to have effects beyond those provided by steroids. Rapid-release theophylline preparations are the only affordable antiasthma medication in some developing countries. There is increasing evidence that theophylline has some antiasthma effect at doses that are lower than those needed for bronchodilation, and plasma levels of 5–15 mg/L are recommended.

Muscarinic Cholinergic Antagonists

The basic pharmacology of the antimuscarinic agents is presented in Chapter 9.

HISTORY

Datura stramonium (jimson weed) and related species of the nightshade family contain a mixture of muscarinic antagonists (atropine, hyoscyamine, scopolamine) and were smoked for relief of asthma two centuries ago. Subsequently, the purified plant alkaloid atropine was introduced for treating asthma. Due to the significant side effects of atropine, particularly drying of secretions, less-soluble quaternary compounds, such as atropine methylnitrate and ipratropium bromide, have been developed. These compounds are topically active and are not significantly absorbed from the respiratory or GI tracts.

Mode of Action

As competitive antagonists of endogenous ACh at muscarinic receptors, these agents inhibit the direct constrictor effect on bronchial smooth muscle mediated via the M_3 -G_q-PLC-IP₃-Ca²⁺ pathway (see Chapters 3 and 9). The efficacy stems from the role played by the parasympathetic nervous system in regulating bronchomotor tone. The effects of ACh on the respiratory system include bronchoconstriction and tracheobronchial mucus secretion. Thus, antimuscarinic drugs antagonize these effects of ACh, resulting in bronchodilation and reduced mucus secretion.

Acetylcholine may also be released from other airway cells, including epithelial cells (Wessler and Kirkpatrick, 2008). The synthesis of ACh in epithelial cells is increased by inflammatory stimuli (such as TNF- α), which increase the expression of choline acetyltransferase, which could contribute to cholinergic effects in airway diseases. Muscarinic receptors are expressed in airway smooth muscle of small airways that do not appear to be significantly innervated by cholinergic nerves; these receptors may be a mechanism of cholinergic narrowing in peripheral airways that could be relevant in COPD, responding to locally synthesized, nonneuronal ACh.

Myriad mechanical, chemical, and immunological stimuli elicit reflex bronchoconstriction via vagal pathways, and cholinergic pathways may play an important role in regulating acute bronchomotor responses in animals. Anticholinergic drugs will only inhibit reflex ACh-mediated bronchoconstriction and have no blocking effect on the *direct* effects of inflammatory mediators, such as histamine and LTs, on bronchial smooth muscle. Furthermore, cholinergic antagonists probably have little or no effect on mast cells, microvascular leak, or the chronic inflammatory response.

Clinical Use

In asthmatic patients, anticholinergic drugs are less effective as bronchodilators than β_2 agonists and offer less-efficient protection against bronchial challenges. Anticholinergics are currently used as an additional bronchodilator in asthmatic patients not controlled on a LABA. Nebulized anticholinergic drugs are effective in acute severe asthma but less effective than β_2 agonists. In the acute and chronic treatment of asthma, anticholinergic drugs may have an additive effect with β_2 agonists and should therefore be considered when control of asthma is not adequate with nebulized β_2 agonists. A muscarinic antagonist should be considered when there are problems with theophylline or when inhaled β_2 agonists cause a troublesome tremor in elderly patients.

In COPD, anticholinergic drugs may be as effective as or even superior to β_2 agonists. Their relatively greater effect in COPD than in asthma may be explained by an inhibitory effect on vagal tone, which, although not necessarily increased in COPD, may be the only reversible element of airway obstruction and one that is exaggerated by geometric factors in the narrowed airways of patients with COPD (Figure 40-6). Anticholinergic drugs reduce air trapping and improve exercise tolerance in patients with COPD.

Therapeutic Choices

The SAMA ipratropium bromide is available as a pMDI and nebulized preparation. The onset of bronchodilation is relatively slow and is usually maximal 30–60 min after inhalation but may persist for 6–8 h. It is usually given by MDI three or four times daily on a regular basis, rather than intermittently for symptom relief, in view of its slow onset of action, but has now been replaced by LAMAs, such as tiotropium bromide.

Long-Acting Muscarinic Antagonists

Several LAMAs have now been developed from the treatment of COPD and, more recently, severe asthma. *Tiotropium bromide* is a long-acting anticholinergic drug that is suitable for once-daily dosing as a DPI (Spiriva) or via a soft mist mininebulizer device and was more effective than *ipratropium* four times daily in several studies; it also significantly reduces exacerbations (Cheyne et al., 2015). Tiotropium binds to all muscarinic receptor subtypes but dissociates slowly from M_3 and M_1 receptors, giving it a degree of kinetic receptor selectivity for these receptors compared with M_2 receptors, from which it dissociates more rapidly. Thus, compared with ipratropium, tiotropium is less likely to antagonize M_2 -mediated inhibition of ACh release (the resulting increase in ACh could counteract the

Figure 40–6 Anticholinergic drugs inhibit vagally mediated airway tone, thereby producing bronchodilation. This effect is small in normal airways but is greater in airways of patients with COPD, which are structurally narrowed and have higher resistance to airflow because airway resistance is inversely related to the fourth power of the radius r .

blockade of M_3 receptor–mediated bronchoconstriction) (Chapter 9). Over a 4-year period, tiotropium improved lung function and health status and reduced exacerbations and all-cause mortality, although there was no effect on disease progression (Tashkin et al., 2008).

Glycopyrronium bromide and umeclidinium bromide are also once-daily LAMAs with very similar clinical effects to tiotropium, whereas aclidinium bromide has to be given twice daily (Cazzola et al., 2013a). LAMAs are now becoming the bronchodilators of choice for patients with COPD. LAMAs are also effective as additional bronchodilators in patient with asthma not adequately controlled with maximal ICS/LABA therapy, although not all patients respond (Kerstjens et al., 2015).

Combination Inhalers

There are additive bronchodilator effects between anticholinergics and β_2 agonists in patients with COPD, which has led to the development of fixed-dose combinations. SABA/SAMA combinations, such as albuterol/ipratropium, are popular. Several studies have demonstrated additive effects of these two drugs, thus providing an advantage over increasing the dose of β_2 agonist in patients who have side effects.

LABA/LAMA dual combination inhalers have also been developed, including indacaterol/glycopyrronium, vilanterol/umeclidinium bromide, olodaterol/tiotropium bromide (all once daily), and formoterol/glycopyrronium bromide, formoterol/aclidinium bromide (twice daily), which all show beneficial effects on lung function compared with either LABA or LAMA alone, although they may not be clearly beneficial in terms of reducing exacerbations (Calzetta et al., 2016).

Adverse Effects

Inhaled anticholinergic drugs are generally well tolerated. On stopping inhaled anticholinergics, a small rebound increase in airway responsiveness has been described. Systemic side effects after SAMA or LAMA are uncommon during normal clinical use because there is little systemic absorption. Because cholinergic agonists can stimulate mucus secretion, there has been concern that anticholinergics may reduce secretion and lead to more viscous mucus. However, ipratropium bromide and tiotropium bromide, even in high doses, have no detectable effect on mucociliary

clearance in either normal subjects or in patients with airway disease. A significant unwanted effect is the unpleasant bitter taste of inhaled ipratropium, which may contribute to poor compliance. Nebulized ipratropium bromide may precipitate glaucoma in elderly patients due to a direct effect of the nebulized drug on the eye. This may be prevented by nebulization with a mouthpiece rather than a face mask.

Reports of paradoxical bronchoconstriction with ipratropium bromide, particularly when given by nebulizer, were largely explained as effects of the hypotonic nebulizer solution and by antibacterial additives, such as benzalkonium chloride and EDTA. This problem has not been described with tiotropium bromide or other LAMAs. Occasionally, bronchoconstriction may occur with ipratropium bromide given by MDI. It is possible that this is due to blockade of prejuncional M_2 receptors on airway cholinergic nerves that normally inhibit ACh release.

LAMAs cause dryness of the mouth in 10%–15% of patients, but this usually disappears during continued therapy. Urinary retention is occasionally seen in elderly patients.

Future Developments

The LABA/LAMA fixed-combination inhalers are likely to become the bronchodilators of choice in patients with COPD, and LAMAs are added to ICS/LABA combinations in severe asthma. Some triple inhalers that have the ICS/LABA/LAMA combination, such as budesonide/formoterol/glycopyrronium, mometasone/indacaterol/glycopyrronium, and fluticasone furoate/umeclidinium/vilanterol, are in development for use in patients with severe asthma and asthma-COPD overlap. Dual-action drugs that are both muscarinic antagonists and β_2 agonist are also in clinical development, but it has proved difficult to balance the β agonist and anticholinergic activities (Ray and Alcaraz, 2009).

Novel Classes of Bronchodilator

Currently, the most effective bronchodilators are LABAs for asthma and a LAMA for COPD. Inventing new classes of bronchodilator has been difficult; several agents have had problems with vasodilator side effects because they relax vascular smooth muscle to a greater extent than airway smooth muscle. Nonetheless, there are several classes of bronchodilators under development, as described next.

Magnesium Sulfate

Magnesium sulfate ($MgSO_4$) is useful as an additional bronchodilator in children and adults with acute severe asthma. Intravenous or nebulized $MgSO_4$ benefits adults and children with severe exacerbations ($FEV_1 < 30\%$ of predicted value), giving improvement in lung function when added to nebulized β_2 agonist and a reduction in hospital admissions (Kew et al., 2014). The treatment is cheap and well tolerated, although the clinical benefit appears small. Side effects include flushing and nausea but are usually minor. Magnesium sulfate appears to act as a bronchodilator and may reduce cytosolic Ca^{2+} concentrations in airway smooth muscle cells. The concentration of magnesium is lower in serum and erythrocytes of asthmatic patients than in normal controls and correlates with airway hyper-responsiveness, although the improvement in acute severe asthma after magnesium does not correlate with plasma concentrations. The effects of intravenous $MgSO_4$ in COPD are minimal, and there are too few studies to make any firm recommendation (Shivathan and Rajapakse, 2014).

Potassium Channel Openers

The K^+ channel openers such as cromakalim or levcromakalim (the levo-isomer of cromakalim) open ATP-dependent K^+ channels in smooth muscle, leading to membrane hyperpolarization and relaxation of airway smooth muscle. This suggests that K^+ channel activators may be useful as bronchodilators (Pelaia et al., 2002). Clinical studies in asthma, however, have been disappointing, with no bronchodilation or protection against bronchoconstrictor challenges. The cardiovascular side effects of these drugs (postural hypotension, flushing) limit the oral dose; furthermore, inhaled formulations are problematic. New developments include K^+ channel openers that open Ca^{2+} -activated large conductance K^+ channels (maxi- K channels) that are also opened by β_2 agonists; these drugs may be better tolerated. Maxi- K channel openers also inhibit mucus secretion and

cough, and they may be of particular value in the treatment of COPD. So far, none of these drugs has been studied in patients with airway disease.

Vasoactive Intestinal Polypeptide Analogues

Vasoactive intestinal polypeptide is a peptide that has 28 amino acids; it binds to two GPCRs, VPAC₁ and VPAC₂, both of which couple primarily to G_s to stimulate the adenylyl cyclase-cAMP-PKA pathway leading to relaxation of smooth muscle. VIP is a potent dilator of human airway smooth muscle in vitro but is not effective in patients because it is rapidly metabolized (plasma $t_{1/2} \sim 2$ min); in addition, VIP causes vasodilator side effects. More stable analogues of VIP, such as Ro 25-1533, which selectively stimulates VIP receptors in airway smooth muscle (via VPAC₂), have been synthesized. Inhaled Ro 25-1533 has a rapid bronchodilator effect in asthmatic patients, but it is not as prolonged as formoterol (Linden et al., 2003).

Bitter Taste Receptor Agonists

Bitter taste receptors (TAS2R) are GPCRs that are expressed in airway smooth muscle and mediate bronchodilation in response to agonists, such as *quinine* and *chloroquine*, even after β_2 receptor desensitization (An et al., 2012). However, these agonists are weak, so more potent drugs are needed.

Other Inhibitors of Smooth Muscle Contraction

Agents that inhibit the contractile machinery of airway smooth muscle, including rho kinase inhibitors, inhibitors of myosin light chain kinase, and myosin inhibitors, are also in development. Because these agents also cause vasodilation, it will be necessary to administer them by inhalation.

Corticosteroids

The introduction of ICSs, as a way of reducing the requirement and side effects of oral steroids, has revolutionized the treatment of chronic asthma (Barnes et al., 1998b). Because asthma is a chronic inflammatory disease, ICSs are considered first-line therapy in all but patients with the

mildest disease. In marked contrast, ICSs are much less effective in COPD and should only be used in patients with severe disease who have frequent exacerbations. Oral corticosteroids remain the mainstay of treatment of several other pulmonary diseases, such as sarcoidosis, interstitial lung diseases, and pulmonary eosinophilic syndromes. The general pharmacology of corticosteroids is presented in Chapter 46.

Mechanism of Action

Corticosteroids enter target cells and bind to GRs in the cytoplasm (Chapter 46). There is only one type of GR that binds corticosteroids and no evidence for the existence of subtypes that might mediate different aspects of corticosteroid action (Barnes, 2011a). The steroid-GR complex moves into the nucleus, where it binds to specific sequences on the upstream regulatory elements of certain target genes, resulting in increased (or, rarely, decreased) transcription of the gene, with subsequent increased (or decreased) synthesis of the gene products.

The GRs may also interact with protein transcription factors and coactivator molecules in the nucleus and thereby influence the synthesis of certain proteins independently of any direct interaction with DNA. The repression of transcription factors, such as AP-1 and NF- κ B, is likely to account for many of the anti-inflammatory effects of steroids in asthma. In particular, corticosteroids reverse the activating effect of these pro-inflammatory transcription factors on histone acetylation by recruiting HDAC2 to inflammatory genes that have been activated through acetylation of associated histones (Figure 40–7). GRs are acetylated when corticosteroids are bound and bind to DNA in this acetylated state as dimers, whereas the acetylated GR has to be deacetylated by HDAC2 to interact with inflammatory genes and NF- κ B (Ito et al., 2006).

There may be additional mechanisms that are also important in the anti-inflammatory actions of corticosteroids. Corticosteroids have potent inhibitory effects on MAP kinase signaling pathways through the induction of MAP kinase phosphatase 1, which may inhibit the expression of multiple inflammatory genes (Clark, 2003)

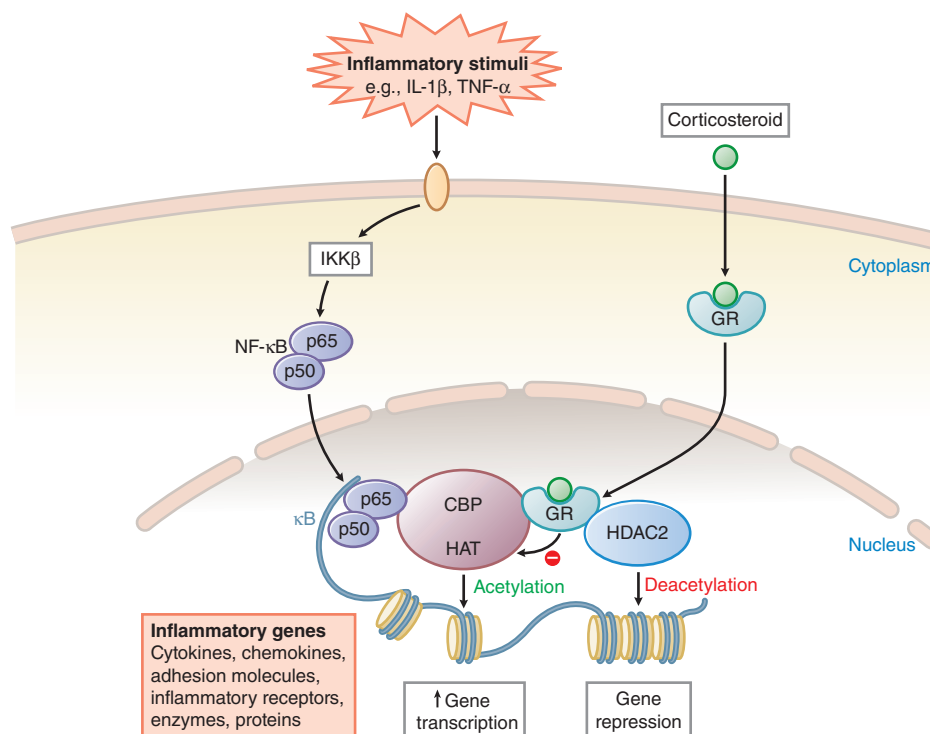

Figure 40–7 Mechanism of anti-inflammatory action of corticosteroids in asthma. Inflammatory stimuli (IL-1 β , TNF- α , etc.) activate IKK β , which activates the transcription factor NF- κ B. A dimer of p50 and p65 NF- κ B proteins translocates to the nucleus and binds to specific κ B recognition sites and to coactivators, such as the CREB-binding protein (CBP), which have intrinsic histone acetyltransferase (HAT) activity. This results in acetylation of core histones and consequent increased expression of genes encoding multiple inflammatory proteins. Cytosolic GRs bind corticosteroids; the receptor-ligand complexes translocate to the nucleus and bind to coactivators to inhibit HAT activity in two ways: directly and, more importantly, by recruiting HDAC2, which reverses histone acetylation, leading to the suppression of activated inflammatory genes.

Anti-inflammatory Effects in Asthma

Corticosteroids have widespread effects on gene transcription, increasing the transcription of several anti-inflammatory genes and suppressing transcription of many inflammatory genes. Steroids have inhibitory effects on many inflammatory and structural cells that are activated in asthma and prevent the recruitment of inflammatory cells into the airways (Figure 40–8). In patients with mild asthma, the inflammation may be completely resolved after inhaled steroids.

Steroids potently inhibit the formation of multiple inflammatory cytokines, particularly cytokines released from T_H2 cells. Corticosteroids also decrease eosinophil survival by inducing apoptosis. Corticosteroids inhibit the expression of multiple inflammatory genes in airway epithelial cells, probably the most important action of ICSs in suppressing asthmatic inflammation. Corticosteroids also prevent and reverse the increase in vascular permeability due to inflammatory mediators and may therefore lead to resolution of airway edema. Steroids have a direct inhibitory effect on mucus glycoprotein secretion from airway submucosal glands, as well as indirect inhibitory effects by downregulation of inflammatory stimuli that stimulate mucus secretion.

Corticosteroids have no direct effect on contractile responses of airway smooth muscle; improvement in lung function after ICSs is presumably due to an effect on the chronic airway inflammation, edema, and airway hyperresponsiveness. A single dose of an ICS has no effect on the early response to allergen (reflecting the ICSs lack of effect on mast cell mediator release) but inhibits the late response (which may be due to an effect on macrophages, eosinophils, and airway wall edema) and also inhibits the increase in airway hyperresponsiveness.

The ICSs have rapid anti-inflammatory effects, reducing airway hyperresponsiveness and inflammatory mediator concentrations in sputum within a few hours (Erin et al., 2008). However, it may take several weeks or months to achieve maximal effects on airway hyperresponsiveness, presumably reflecting the slow healing of the damaged inflamed airway. It is important to recognize that corticosteroids *suppress* inflammation in the airways but do not cure the underlying disease. When steroids are withdrawn, there is a recurrence of the same degree of airway hyperresponsiveness, although in patients with mild asthma it may take several months to return.

Effect on β_2 Adrenergic Responsiveness

Steroids potentiate the effects of β agonists on bronchial smooth muscle and prevent and reverse β receptor desensitization in airways *in vitro* and

in vivo (Barnes, 2002; Black et al., 2009). At a molecular level, corticosteroids increase the transcription of the β_2 receptor gene in human lung *in vitro* and in the respiratory mucosa *in vivo* and also increase the stability of its messenger RNA. They also prevent or reverse uncoupling of β_2 receptors to G_s . In animal systems, corticosteroids prevent downregulation of β_2 receptors.

β_2 Agonists also enhance the action of GRs, resulting in increased nuclear translocation of liganded GR receptors and enhancing the binding of GRs to DNA. This effect has been demonstrated in sputum macrophages of asthmatic patients after an ICS and inhaled LABA (Barnes, 2011a). This suggests that β_2 agonists and corticosteroids enhance each other's beneficial effects in asthma therapy.

Pharmacokinetics

The pharmacokinetics of oral corticosteroids are described in Chapter 46. The pharmacokinetics of ICSs are important in relation to systemic effects (Barnes et al., 1998b). The fraction of steroid that is inhaled into the lungs acts locally on the airway mucosa but may be absorbed from the airway and alveolar surface. Thus, a portion of an inhaled dose reaches the systemic circulation. Furthermore, the fraction of inhaled steroid that is deposited in the oropharynx is swallowed and absorbed from the gut. The absorbed fraction may be metabolized in the liver (first-pass metabolism) before reaching the systemic circulation (Figure 40–3). The use of a spacer chamber reduces oropharyngeal deposition and therefore reduces systemic absorption of ICSs, although this effect is minimal in corticosteroids with a high first-pass metabolism. Mouth rinsing and discarding the rinse have a similar effect, and this procedure should be used with high-dose dry powder steroid inhalers when spacer chambers cannot be used.

Beclomethasone dipropionate and *ciclesonide* are prodrugs that release the active corticosteroid after the ester group is cleaved by esterases in the lung. *Ciclesonide* is available as an MDI for asthma and as a nasal spray for allergic rhinitis. *Budesonide* and *fluticasone propionate* have a greater first-pass metabolism than BDP and are therefore less likely to produce systemic effects at high inhaled doses.

Routes of Administration and Dosing

Inhaled Corticosteroids in Asthma

Inhaled corticosteroids are recommended as first-line therapy for patients with persistent asthma. They should be started in any patient who needs to use a β_2 agonist inhaler for symptom control more than twice weekly.

Figure 40–8 Effect of corticosteroids on inflammatory and structural cells in the airways.

They are effective in mild, moderate, and severe asthma and in children as well as adults (Barnes et al., 1998b).

Most of the benefit may be obtained from doses of less than 400 μg BDP or equivalent. However, some patients (with relative corticosteroid resistance) may benefit from higher doses (up to 2000 $\mu\text{g}/\text{d}$). For most patients, ICSs should be used twice daily, a regimen that improves adherence once control of asthma has been achieved (which may require four-time daily dosing initially or a course of oral steroids if symptoms are severe). Administration once daily of some steroids (e.g., budesonide, mometasone, and ciclesonide in mild asthma and fluticasone furoate in all patients) is effective when doses of 400 μg or less are needed. If a dose greater than 800 μg daily via pMDI is used, a spacer device should be employed to reduce the risk of oropharyngeal side effects. ICSs may be used in children in the same way as in adults; at doses of 400 $\mu\text{g}/\text{d}$ or less, there is no evidence of significant growth suppression (Pedersen, 2001). The dose of ICS should be the minimal dose that controls asthma; once control is achieved, the dose should be slowly reduced (Hawkins et al., 2003). Nebulized corticosteroids (e.g., budesonide) are useful in the treatment of small children who are not able to use other inhaler devices.

Inhaled Corticosteroids in COPD

Patients with COPD occasionally respond to steroids, and these patients are likely to have concomitant asthma. Corticosteroids do not appear to have any significant anti-inflammatory effect in COPD; there appears to be an active resistance mechanism, which may be explained by impaired activity of HDAC2 as a result of oxidative stress (Barnes, 2013a). ICSs have no effect on the progression of COPD, even when given to patients with presymptomatic disease; in addition, ICSs have no effect on mortality (Yang et al., 2012). ICSs reduce the number of exacerbations in patients with severe COPD ($\text{FEV}_1 < 50\%$ predicted) who have frequent exacerbations and are recommended in these patients, although there is debate about whether these effects are due to inappropriate analysis of the data (Ernst et al., 2015). Oral corticosteroids are used to treat acute exacerbations of COPD, but the effect is very small (Niewoehner et al., 1999).

Patients with cystic fibrosis and bronchiectasis, which involve chronic neutrophilic inflammation of the airways, are also resistant to high doses of ICS.

Systemic Steroids

Intravenous steroids are indicated in acute asthma if lung function is less than 30% predicted and in patients who show no significant improvement with nebulized β_2 agonist. *Hydrocortisone* is the steroid of choice because it has the most rapid onset (5–6 h after administration), compared with 8 h with *prednisolone*. It is common to give hydrocortisone 4 mg/kg initially, followed by a maintenance dose of 3 mg/kg every 6 h. *Methylprednisolone* is also available for intravenous use. Intravenous therapy is usually given until a satisfactory response is obtained, and then oral prednisolone may be substituted. *Oral prednisone* or *prednisolone* (40–60 mg) has a similar effect to intravenous hydrocortisone and is easier to administer. A high dose of *inhaled fluticasone propionate* (2000 μg daily) is as effective as a course of oral prednisolone in controlling acute exacerbations of asthma in a family practice setting and in children in an emergency department setting, although this route of delivery is more expensive (Manjra et al., 2000).

Prednisone and *prednisolone* are the most commonly used oral steroids. Maximal beneficial effect is usually achieved with 30–40 mg prednisone daily, although a few patients may need 60–80 mg daily to achieve control of symptoms. The usual maintenance dose is about 10–15 mg/d. Short courses of oral steroids (30–40 mg prednisolone daily for 1–2 weeks) are indicated for exacerbations of asthma; the dose may be tapered over 1 week after the exacerbation is resolved (the taper is not strictly necessary after a short course of therapy, but patients find it reassuring). Oral steroids are usually given as a single dose in the morning because this coincides with the normal diurnal increase in plasma cortisol and produces less adrenal suppression than if given in divided doses or at night.

Adverse Effects

Corticosteroids inhibit corticotropin and cortisol secretion by a negative-feedback effect on the pituitary gland (see Chapter 46).

Hypothalamic-pituitary-adrenal (HPA) axis suppression depends on dose and usually only occurs with doses of prednisone greater than 7.5–10 mg/d. Significant suppression after short courses of corticosteroid therapy is not usually a problem, but prolonged suppression may occur after several months or years. *Steroid doses after prolonged oral therapy must be reduced slowly.* Symptoms of “steroid withdrawal syndrome” include lassitude, musculoskeletal pains, and, occasionally, fever. HPA suppression with inhaled steroids is usually seen only when the daily inhaled dose exceeds 2000 μg BDP or its equivalent daily.

Side effects of long-term oral corticosteroid therapy include fluid retention, increased appetite, weight gain, osteoporosis, capillary fragility, hypertension, peptic ulceration, diabetes, cataracts, and psychosis. Their frequency tends to increase with age. Very occasionally adverse reactions (such as anaphylaxis) to intravenous hydrocortisone have been described, particularly in aspirin-sensitive asthmatic patients.

The incidence of systemic side effects after ICSs is an important consideration, particularly in children (Lipworth, 1999) (Table 40–4). Initial studies suggested that adrenal suppression occurred only with inhaled doses greater than 1500–2000 $\mu\text{g}/\text{d}$. More sensitive measurements of systemic effects include indices of bone metabolism, such as serum osteocalcin and urinary pyridinium cross-links, and in children, knemometry, which may be increased with inhaled doses as low as 400 $\mu\text{g}/\text{d}$ BDP in some patients. The clinical relevance of these measurements is not yet clear, however. Nevertheless, it is important to reduce the likelihood of systemic effects by using the lowest dose of inhaled steroid needed to control the asthma and by use of a large-volume spacer to reduce oropharyngeal deposition.

Several systemic effects of inhaled steroids have been described and include dermal thinning and skin capillary fragility (relatively common in elderly patients after high-dose inhaled steroids). Other side effects, such as cataract formation and osteoporosis, are reported but often in patients who are also receiving courses of oral steroids. There is some evidence that use of high-dose ICSs is associated with cataract and glaucoma, but it is difficult to dissociate the effects of ICS from the effects of courses of oral steroids that these patients usually require. There has been particular concern about the use of inhaled steroids in children because of growth suppression (Zhang et al., 2014).

The ICSs may have *local side effects* due to the deposition of inhaled steroid in the oropharynx. The most common problem is hoarseness and weakness of the voice (dysphonia) due to atrophy of the vocal cords following laryngeal deposition of steroid; it may occur in up to 40% of patients and is noticed particularly by patients who need to use their voices during their work (lecturers, teachers, and singers). Throat irritation and coughing after inhalation are common with MDIs and appear to be due to additives because these problems are not usually seen if the patient switches to a DPI. There is no evidence for atrophy of the lining of the airway. Oropharyngeal candidiasis occurs in about 5% of patients. There is no evidence for increased lung infections, including tuberculosis, in patients with asthma.

TABLE 40–4 ■ SIDE EFFECTS OF INHALED CORTICOSTEROIDS

Local side effects

- Dysphonia
- Oropharyngeal candidiasis
- Cough

Systemic side effects

- Adrenal suppression and insufficiency
- Growth suppression
- Bruising
- Osteoporosis
- Cataracts
- Glaucoma
- Metabolic abnormalities (glucose, insulin, triglycerides)
- Psychiatric disturbances (euphoria, depression)
- Pneumonia

Growing evidence suggests that high doses of ICSs increase the risk of pneumonia in patients with COPD (Finney et al., 2014); the risk appears to be higher with fluticasone propionate than budesonide.

Corticosteroid MDIs with HFA propellants produce smaller aerosol particles and may have a more peripheral deposition, making them useful in treating patients with more severe asthma.

Therapeutic Choices

Numerous ICSs are now available, including *BDP*, *triamcinolone*, *flunisolide*, *budesonide*, *hemihydrate*, *fluticasone propionate*, *mometasone furoate*, *ciclesonide*, and *fluticasone furoate*. All are equally effective as antiasthma drugs, but there are differences in their pharmacokinetics: Budesonide, fluticasone, mometasone, and ciclesonide have a lower oral bioavailability than BDP because they are subject to greater first-pass hepatic metabolism; this results in reduced systemic absorption from the fraction of the inhaled drug that is swallowed (Derendorf et al., 2006) and thus reduced adverse effects. At high doses (>1000 µg), budesonide and fluticasone propionate have fewer systemic effects than BDP and triamcinolone (not marketed in the U.S.), and they are preferred in patients who need high doses of ICSs and in children. Ciclesonide is another choice; it is a prodrug that is converted to the active metabolite by esterases in the lung, giving it low oral bioavailability and a high therapeutic index (Derendorf, 2007). Fluticasone furoate has the longest duration of action and is suitable for once-daily dosing (Woodcock et al., 2011).

When doses of inhaled steroid exceed 800 µg BDP or equivalent daily, a large-volume spacer is recommended to reduce oropharyngeal deposition and systemic absorption in the case of BDP. All currently available ICSs are absorbed from the lung into the systemic circulation, so that some systemic absorption is inevitable. However, the amount of drug absorbed does not appear to have clinical effects in doses of less than 800 µg BDP equivalent. Although there are potency differences among corticosteroids, there are relatively few comparative studies, partly because dose comparison of corticosteroids is difficult due to their long time course of action and the relative flatness of their dose-response curves.

Future Developments

Early treatment with ICSs in both adults and children may give a greater improvement in lung function than if treatment is delayed (Busse et al., 2008), likely reflecting the fact that corticosteroids are able to modify the underlying inflammatory process and prevent structural changes (fibrosis, smooth muscle hyperplasia, etc.). ICSs are currently recommended for patients with persistent asthmatic symptoms (e.g., need for an inhaled β_2 agonist more than twice a week).

Developing new corticosteroids with fewer systemic effects is desirable. It has been possible to develop corticosteroids that dissociate the DNA-binding effect of corticosteroids (which mediates most of the adverse effects) from the inhibitory effect on transcription factors such as NF- κ B (which mediates much of the anti-inflammatory effect). Such “dissociated steroids” or selective GR agonists should, theoretically, retain anti-inflammatory activity but have a reduced risk of adverse effects; achieving this separation of desired and adverse effects is difficult in vivo (Belvisi et al., 2001). Nonsteroidal selective GR agonists are now in development.

Corticosteroid resistance is a major barrier to effective therapy in patients with severe asthma, in asthmatic patients who smoke, and in patients with COPD and cystic fibrosis (Barnes, 2013a; Barnes and Adcock, 2009). “Steroid-resistant” asthma is thought to be due to reduced anti-inflammatory actions of corticosteroids. In those with COPD and some patients with severe asthma, there is a reduction in HDAC2 expression that reduces corticosteroid responsiveness; this is potentially reversible by existing treatments, such as low-dose theophylline and nortriptyline.

Cromones

Cromolyn sodium (*sodium cromoglycate*) is a derivative of *khellin*, an Egyptian herbal remedy, and was found to protect against allergen challenge without any bronchodilator effect. A structurally related drug, *nedocromil*

sodium, which has a similar pharmacological profile to cromolyn, was subsequently developed. Although cromolyn was popular in the past because of its good safety profile, its use has sharply declined with the more widespread use of the more effective ICSs, particularly in children.

Phosphodiesterase Inhibitors

The PDE inhibitors relax smooth muscle and inhibit inflammatory cells through an increase in cellular cAMP. PDE4 is the predominant PDE isoform in inflammatory cells, including mast cells, eosinophils, neutrophils, T lymphocytes, macrophages, and structural cells such as sensory nerves and epithelial cells (Hatzelmann et al., 2010), suggesting that PDE4 inhibitors could be useful as an anti-inflammatory treatment in both asthma and COPD.

In animal models of asthma, PDE4 inhibitors reduce eosinophil infiltration and responses to allergen, whereas in COPD they are effective against smoke-induced inflammation and emphysema. In COPD, an oral PDE4 inhibitor, *roflumilast*, has been approved for patients with COPD with severe disease ($FEV_1 < 50\%$ predicted, frequent exacerbations, and chronic bronchitis). Given once daily by mouth, it reduces exacerbations but has little effect on symptoms and lung function (Calverley et al., 2009), although it is effective on top of long-acting bronchodilators and ICSs (Martinez et al., 2015). The relatively weak efficacy is due to dose limitations as a result of side effects, particularly diarrhea, headaches, and nausea.

Of the four subfamilies of PDE4, PDE4D is the major form whose inhibition is associated with vomiting; inhibition of PDE4B is important for anti-inflammatory effects. Thus, selective PDE4B inhibitors may have a greater therapeutic index. Inhaled PDE4 inhibitors, to reduce systemic absorption and adverse responses, have proved to be ineffective. A dual PDE3/4 inhibitor gives bronchodilation in patients with COPD when given by nebulization, but it is uncertain whether there are significant anti-inflammatory effects (Franciosi et al., 2013).

Mediator Antagonists

Both H_1 antihistamines and anti-LTs have been applied to airway disease, but their added benefit over β_2 agonists and corticosteroids is slight (Barnes, 2004; Barnes et al., 1998a).

Antihistamines

Histamine mimics many of the features of asthma and is released from mast cells in acute asthmatic responses, suggesting that antihistamines may be useful in asthma therapy. There is little evidence that histamine H_1 receptor antagonists provide any useful clinical benefit, as demonstrated by a meta-analysis (van Ganse et al., 1997). Newer antihistamines, including *cetirizine* and *azelastine*, have some beneficial effects, but this may be unrelated to H_1 receptor antagonism. Antihistamines are not recommended in the routine management of asthma.

Antileukotrienes

There is considerable evidence that cys-LTs are produced in asthma and that they have potent effects on airway function, inducing bronchoconstriction, airway hyperresponsiveness, plasma exudation, mucus secretion, and eosinophilic inflammation (Figure 40–9; also see Chapter 37). These findings led to the development of 5'-lipoxygenase (5-LO) enzyme inhibitors (of which *zileuton* is the only drug marketed) and several antagonists of the cys-LT $_1$ receptor, including *montelukast* (s, *zafirlukast*, and *pranlukast* (not available in the U.S.)).

Clinical Studies

In patients with mild-to-moderate asthma, anti-LTs cause a significant improvement in lung function and asthma symptoms, with a reduction in the use of rescue inhaled β_2 agonists. Several studies showed evidence for a bronchodilator effect, with an improvement in baseline lung function, suggesting that LTs are contributing to the baseline bronchoconstriction

Figure 40-9 Effects of cysteinyl-LTs on the airways and their inhibition by anti-LTs. AS, aspirin sensitive.

in asthma, although this varies among patients. However, anti-LTs are considerably less effective than ICSs in the treatment of mild asthma and cannot be considered the treatment of first choice (Chauhan and Ducharme, 2012). Anti-LTs are indicated as an add-on therapy in patients who are not well controlled on ICSs. The added benefit is small, equivalent to doubling the dose of ICS, and less effective than adding a LABA. Anti-LTs have a beneficial effect in allergic rhinitis and have a similar efficacy to antihistamines (Grayson and Korenblat, 2007).

In patients with severe asthma who are not controlled on high doses of ICS and LABA, anti-LTs do not appear to provide any additional benefit (Robinson et al., 2001). Theoretically, anti-LTs should be of particular value in patients with aspirin-sensitive asthma because they block the airway response to aspirin challenge; however, their benefit is no greater here than in other types of asthma.

Anti-LTs are effective in preventing exercise-induced asthma, with efficacy similar to that of LABAs (Coreno et al., 2000). Anti-LTs appear to act mainly as antibronchoconstrictor drugs, and they are clearly less broadly effective than β_2 agonists because they antagonize only one of several bronchoconstrictor mediators.

The cys-LT₁ receptor antagonists have no role in the therapy of COPD. By contrast, LTB₄, a potent neutrophil chemoattractant, is elevated in COPD, indicating that 5-LO inhibitors that inhibit LTB₄ synthesis may have some potential benefit by reducing neutrophil inflammation. However, a pilot study failed to indicate any clear benefit of a 5-LO inhibitor in patients with COPD (Bernstein et al., 2011).

Adverse Effects

Zileuton, zafirlukast, and montelukast are all associated with rare cases of hepatic dysfunction; thus, liver-associated enzymes should be monitored. Several cases of Churg-Strauss syndrome have been associated with the use of zafirlukast and montelukast. Churg-Strauss syndrome is a rare vasculitis that may affect the heart, peripheral nerves, and kidney and is associated with increased circulating eosinophils and asthma. Cases of Churg-Strauss syndrome have been described in patients on anti-LTs who were not on concomitant corticosteroid therapy, suggesting there is a causal link (Nathani et al., 2008).

Future Developments

One of the major advantages of anti-LTs is their effectiveness in tablet form. This may increase compliance with chronic therapy and makes treatment of children easier. Montelukast is effective as a once-daily preparation (10 mg in adults, 5 mg in children). In addition, oral administration may treat concomitant allergic rhinitis. However, the clinical studies indicated a modest effect on lung function and symptom control. This is not surprising. There are many mediators besides cys-LTs involved in the pathophysiology of asthma, and anti-LTs are unlikely to be as effective as a β_2 agonist, which will counteract bronchoconstriction regardless of the spasmogen. It is likely that anti-LTs will be used less in the future because combination inhalers are the mainstay of asthma therapy.

Some patients appear to show better responses than others, suggesting that LTs may play a more important role in some patients. The variability in response to anti-LTs may reflect differences in production of or responses to LTs in different patients, and this in turn may be related to polymorphisms of 5-LO, LTC₄ synthase, or cys-LT₁ receptors that are involved in the synthesis of LTs (Tantisira and Drazen, 2009).

Immunomodulatory Therapies

Immunosuppressive Therapy

Immunosuppressive therapy (e.g., methotrexate, cyclosporine A, gold, intravenous immunoglobulin) has been considered in asthma when other treatments have been unsuccessful or to reduce the dose of oral steroids required. However, immunosuppressive treatments are less effective and have a greater propensity for side effects than oral corticosteroids and therefore cannot be routinely recommended.

Anti-IgE Receptor Therapy

Increased specific IgE is a fundamental feature of allergic asthma. *Omalizumab* is a humanized monoclonal antibody that blocks the binding of IgE to high-affinity IgE receptors (FcεR1) on mast cells and thus prevents their activation by allergens (Figure 40-10). It also blocks binding on IgE to low-affinity IgE receptors (FcεRII, CD23) on other inflammatory cells, including T and B lymphocytes, macrophages, and possibly eosinophils, to inhibit chronic inflammation. *Omalizumab* also reduces levels of circulating IgE.

Figure 40-10 Immunoglobulin E plays a central role in allergic diseases. Blocking IgE using an antibody, such as omalizumab, is a rational therapeutic approach. IgE may activate high-affinity receptors (FcεR1) on mast cells as well as low-affinity receptors (FcεRII, CD23) on other inflammatory cells. Omalizumab prevents these interactions and the resulting inflammation.

Clinical Use

Omalizumab is used for the treatment of patients with severe asthma (Humbert et al., 2014). The antibody is administered by subcutaneous injection every 2–4 weeks, and the dose is determined by the titer of circulating total IgE. *Omalizumab* reduces the requirement for oral and ICSs and markedly reduces asthma exacerbations. Not all patients respond, and there are no clear clinical predictors of clinical response, necessitating a trial of therapy (usually over 4 months). Because of its high cost, this treatment is generally used only in patients with very severe asthma who are poorly controlled even on oral corticosteroids and in patients with very severe concomitant allergic rhinitis (Normansell et al., 2014). It may also be of value in protecting against anaphylaxis during specific immunotherapy. A recent study suggested that *omalizumab* may be effective in preventing asthma exacerbations if administered prior to the exacerbation season (Teach et al., 2015); this is linked to increased expression of type I interferons, which boost antiviral immunity. The major side effect of *omalizumab* is an anaphylactic response, which is uncommon (<0.1%).

Specific Immunotherapy

Although specific immunotherapy is effective in allergic rhinitis due to single allergens, there is little evidence that desensitizing injections to common allergens are effective in controlling chronic asthma (Rolland et al., 2009). Specific immunotherapy induces the secretion of the anti-inflammatory cytokine IL-10 from regulatory helper T lymphocytes, and this blocks costimulatory signal transduction in T cells (via CD28) so that they are unable to react to allergens presented by antigen-presenting cells (Ozdemir et al., 2016). Applying an understanding of the cellular processes involved might lead to safer and more effective approaches in the future. More specific immunotherapies may be developed with cloned allergen epitopes, T-cell peptide fragments of allergens, CpG oligonucleotides, and vaccines of conjugates of allergen and toll-like receptor 9 to stimulate T_H1 immunity and suppress T_H2 immunity (Broide, 2009).

New Drugs in Development for Airway Disease

Several new classes of drug are in development for asthma and COPD, but clinical development has been slow, and many treatments have either proved to be ineffective or are limited by toxicology and side-effect profiles (Barnes, 2012, 2013b).

Novel Mediator Antagonists

Blocking the receptors or synthesis of inflammatory mediators is a logical approach to the development of new treatments for asthma and COPD. However, in both diseases many different mediators are involved, and therefore blocking a single mediator is unlikely to be effective unless it plays a unique and key role in the disease process. Several specific mediator antagonists have been found to be ineffective in asthma, including antagonists/inhibitors of thromboxane, platelet-activating factor, bradykinin, and tachykinins. However, these blockers have often not been tested in COPD, in which different mediators are involved. A number of other approaches are under study, as noted next.

CRTh2 Antagonists

The chemotactic factor for T_H2 cells has been identified as prostaglandin D_2 , which acts on a DP_2 receptor (Chapter 37). Several DP_2 /CRTh2 antagonists are now in development for asthma, with some promising initial results in patients with eosinophilic inflammation (Townley and Agrawal, 2012).

Antioxidants

Oxidative stress is important in severe asthma and COPD and may contribute to corticosteroid resistance. Existing antioxidants include vitamins C and E and *N*-acetyl-cysteine. These drugs have weak effects, but more potent antioxidants are in development, including activators of the transcription factor Nrf2 (Kirkham and Barnes, 2013).

Cytokine Modifiers

Cytokines play a critical role in perpetuating and amplifying the inflammation in asthma and COPD, suggesting that anticytokines may be beneficial as therapies (Barnes, 2008a). Although most attention has focused on inhibition of cytokines, some cytokines are anti-inflammatory and may have therapeutic potential. Several cytokine or cytokine receptor-blocking antibodies are in clinical development for asthma (Chung, 2015), but there has been less progress in COPD.

Interleukin 5 plays a pivotal role in eosinophilic inflammation and is also involved in eosinophil survival and priming. Anti-IL-5 and anti-IL-5 receptor (IL-5R α) antibodies inhibit eosinophilic inflammation and airway hyperresponsiveness in patients with mild asthma but has no effect on allergen challenge (Leckie et al., 2000) or clinical benefits in unselected asthmatic patients (Flood-Page et al., 2007). In carefully selected patients with severe asthma and persistent eosinophilia despite high doses of corticosteroids, there is a significant reduction in exacerbations and sparing of oral steroids with an anti-IL-5 antibody, *mepolizumab* (Castro et al., 2014; Pavord et al., 2012). *Mepolizumab* has now been FDA approved for use in highly selected patients with severe asthma.

Blocking IL-4, which determines IgE synthesis and eosinophilic inflammation, has been ineffective in clinical studies. However, blocking IL-13 or its shared receptor with IL-4 (IL-4R α) provides some clinic benefit and reduces exacerbations but is not yet approved (Hanania et al., 2015; Wenzel et al., 2013).

Production of TNF- α is increased in asthma and COPD and may play a key role in amplifying airway inflammation, through the activation of NF- κ B, AP-1, and other transcription factors. However, in patients with COPD and in patients with severe asthma, anti-TNF- α blocking antibodies have been ineffective, at the expense of increasing infections and malignancies (Rennard et al., 2007; Wenzel et al., 2009).

Chemokine Receptor Antagonists

Many chemokines are involved in asthma and COPD and play a key role in recruitment of inflammatory cells, such as eosinophils, neutrophils, macrophages, and lymphocytes, into the lungs. Chemokine receptors are attractive targets because they are GPCRs; small-molecule inhibitors are now in development (Donnelly and Barnes, 2006). In asthma, *CCR3* antagonists, which should block eosinophil recruitment into the airways, are the most favored target, but several small-molecule *CCR3* antagonists have failed in development because of toxicity. In COPD, *CXCR2* antagonists, which prevent neutrophil and monocyte chemotaxis due to CXC chemokines, such as CXCL1 and CXCL8, have been effective in animal models of COPD and in neutrophilic inflammation in normal subjects, but in clinical trials in patients with COPD, an oral *CXCR2* antagonist provided little clinical benefit (Rennard et al., 2015).

Protease Inhibitors

Several proteolytic enzymes are involved in the chronic inflammation of airway diseases. Mast cell tryptase has several effects on airways, including increasing responsiveness of airway smooth muscle to constrictors, increasing plasma exudation, potentiating eosinophil recruitment, and stimulating fibroblast proliferation. Some of these effects are mediated by activation of protease-activated receptor, PAR2. Tryptase inhibitors have so far proved to be disappointing in clinical studies.

Proteases are involved in the degradation of connective tissue in COPD, particularly enzymes that break down elastin fibers, such as neutrophil elastase and MMPs, which are involved in emphysema. Neutrophil elastase inhibitors have been difficult to develop, and there are no positive clinical studies in patients with COPD. MMP9 appears to be the predominant elastolytic enzyme in emphysema, and several selective inhibitors are now in development.

New Anti-inflammatory Drugs

NF- κ B Inhibitors

An important role is played by NF- κ B in the orchestration of chronic inflammation (Figure 40–7); many of the inflammatory genes that are expressed in asthma and COPD are regulated by this transcription factor.

This has prompted a search for specific blockers of these transcription factors. NF- κ B is naturally inhibited by I κ B, which is degraded after activation by specific kinases. Small-molecule inhibitors of the I κ B kinase IKK2 (or IKK β) are in clinical development (Ziegelbauer et al., 2005). These drugs may be of particular value in COPD, for which corticosteroids are largely ineffective. However, there are concerns that inhibition of NF- κ B may cause side effects such as increased susceptibility to infections, which has been observed in gene disruption studies when components of NF- κ B are inhibited.

Mitogen-Activated Protein Kinase Inhibitors

The MAP kinase pathways are involved in chronic inflammation. There has been particular interest in the p38 MAP kinase pathway that is blocked by a novel class of drugs, such as *losmapimod* (Norman, 2015). These drugs inhibit the synthesis of many inflammatory cytokines, chemokines, and inflammatory enzymes. The p38 MAP kinase inhibitors are in development for the treatment of asthma (they inhibit T_H2 cytokine synthesis) and for COPD (they inhibit neutrophilic inflammation and signaling of inflammatory cytokines and chemokines). However, clinical studies have given disappointing results in patients with COPD, and the dose is limited by side effects (MacNee et al., 2013). Several inhaled p38 inhibitors are in development to reduce the risk of side effects (Millan, 2011).

Mucoregulators

Mucus hypersecretion occurs in chronic bronchitis, COPD, cystic fibrosis, and asthma (Fahy and Dickey, 2010). In chronic bronchitis, mucus hypersecretion is related to chronic irritation by cigarette smoke and may involve neural mechanisms and the activation of neutrophils to release enzymes such as neutrophil elastase and proteinase 3 that have powerful stimulatory effects on mucus secretion. Mast cell-derived chymase is also a potent mucus secretagogue. This suggests that several classes of drugs may be developed to control mucus hypersecretion. Mucus secretion is regulated by epidermal growth factor receptors, which lead to increased mucin gene *MUC5AC* expression, but a nebulized epidermal growth factor receptor inhibitor has been ineffective in COPD (Woodruff et al., 2010).

Systemic anticholinergic drugs appear to reduce mucociliary clearance, but this is not observed with either ipratropium bromide or tiotropium bromide, presumably reflecting their poor absorption from the respiratory tract. β_2 Agonists increase mucus production and mucociliary clearance and have been shown to increase ciliary beat frequency in vitro. Because inflammation leads to mucus hypersecretion, anti-inflammatory treatments should reduce mucus hypersecretion; ICSs are very effective in reducing increased mucus production in asthma.

Mucolytics

Several agents can reduce the viscosity of sputum in vitro. One group consists of derivatives of cysteine that reduce the disulfide bridges that bind glycoproteins to other proteins, such as albumin and secretory IgA. These drugs also act as antioxidants and may therefore reduce airway inflammation. Only *N*-acetylcysteine is available in the U.S.; *carbocysteine*, *methylcysteine*, *erdosteine*, and *bromhexine* are available elsewhere. Orally administered, these agents are relatively well tolerated, but clinical studies in chronic bronchitis, asthma, and bronchiectasis have been disappointing. A large controlled study of oral *N*-acetylcysteine in patients with COPD showed no effect in disease progression or in preventing exacerbations, although there was some benefit in the patients not treated with ICSs (Decramer et al., 2005), as confirmed in a subsequent studies of carbocysteine and *N*-acetylcysteine in patients with COPD not treated with other medications (Zheng et al., 2008, 2014). *N*-Acetylcysteine is not currently recommended for COPD management.

DNase (dornase alfa) reduces mucus viscosity in sputum of patients with cystic fibrosis and is indicated if there is significant symptomatic and lung function improvement after a trial of therapy (Henke and Ratjen, 2007). There is no evidence that dornase alfa is effective in COPD or asthma, however.

Expectorants

Expectorants are oral drugs that are supposed to enhance the clearance of mucus. Although expectorants were once commonly prescribed, there is little or no objective evidence for their efficacy. Such drugs are often emetics that are given in subemetic doses on the basis that gastric irritation may stimulate an increase in mucus clearance via a reflex mechanism. Lacking evidence for their efficacy, the FDA has removed most expectorants from the market in a review of over-the-counter drugs. With the exception of *guaifenesin*, no agents are approved as expectorants in the U.S. In patients who find it difficult to clear mucus, adequate hydration and inhalation of steam may be of some benefit.

Antitussives

Despite the fact that cough is a common symptom of airway disease, its mechanisms are poorly understood, and current treatment is unsatisfactory (Pavord and Chung, 2008). Viral infections of the upper respiratory tract are the most common cause of cough; postviral cough is usually self-limiting and commonly patient medicated. Their wide use notwithstanding, over-the-counter cough medications are largely ineffective (Dicpinigaitis et al., 2014). Because cough is a defensive reflex, its suppression may be inappropriate in bacterial lung infection. Before treatment with antitussives, it is important to identify underlying causal mechanisms that may require therapy.

Whenever possible, treat the underlying cause, not the cough. Asthma commonly presents as cough, and the cough will usually respond to ICSs. A syndrome characterized by cough in association with sputum eosinophilia but no airway hyperresponsiveness, termed *eosinophilic bronchitis*, also responds to ICSs (Birring et al., 2003). Nonasthmatic cough does not respond to ICSs but sometimes responds to anticholinergic therapy. The cough associated with postnasal drip of sinusitis responds to antibiotics (if warranted), nasal decongestants, and intranasal steroids. The cough associated with ACE inhibitors (in ~15% of patients treated) responds to lowering the dose or withdrawal of the drug and substitution of an AT₁ receptor antagonist (see Chapter 26). Gastroesophageal reflux is a common cause of cough through a reflex mechanism and occasionally as a result of acid aspiration into the lungs. This cough may respond to suppression of gastric acid with an H₂ receptor antagonist or a proton pump inhibitor (see Chapter 49). Some patients have a chronic cough with no obvious cause, and this chronic idiopathic cough or cough hypersensitivity syndrome may be due to airway sensory neural hyperesthesia (Haque et al., 2005). There are several treatments that have been assessed in the treatment of refractory cough (Gibson et al., 2016).

Opiates

Opiates have a central mechanism of action on MORs in the medullary cough center, but there is some evidence that they may have additional peripheral action on cough receptors in the proximal airways. *Codeine* and *pholcodine* (not available in the U.S.) are commonly used, but there is little evidence that they are clinically effective, particularly on postviral cough; in addition, they are associated with sedation and constipation. *Morphine* and *methadone* are effective but indicated only for intractable cough associated with bronchial carcinoma.

Dextromethorphan

Dextromethorphan is a centrally active NMDA receptor antagonist. It may also antagonize opioid receptors. Despite the fact that it is in numerous over-the-counter cough suppressants and used commonly to treat cough, it is poorly effective. In children with acute nocturnal cough, it is not significantly different from placebo in reducing cough (Dicpinigaitis et al., 2014). It can cause hallucinations at higher doses and has significant abuse potential.

Local Anesthetics

Benzonatate, a local anesthetic, acts peripherally by anesthetizing the stretch receptors located in the respiratory passages, lungs, and pleura. By dampening the activity of these receptors, benzonatate may reduce the cough reflex. The recommended dose is 100 mg, three times per day,

and up to 600 mg/d, if needed. Although clinical studies shortly after its approval showed some efficacy, benzonatate (200 mg) was not effective in suppressing experimentally induced cough (Dicpinigaitis et al., 2009). Side effects include dizziness and dysphagia. Seizures and cardiac arrest have occurred following an acute ingestion. Severe allergic reactions have been reported in patients allergic to *para-aminobenzoic acid*, a metabolite of benzonatate.

Neuromodulators

Gabapentin and *pregabalin* are GABA analogues that inhibit neurotransmission and have been used in neuropathic pain syndromes. They have been shown to benefit chronic idiopathic cough, which also involved neural hypersensitivity (Gibson and Vertigan, 2015). Side effects of somnolence and dizziness are common at higher doses, so it is usual to initiate therapy at lower doses.

Other Drugs

Several other drugs reportedly have small benefits in protecting against cough challenges or in reducing cough in pulmonary diseases. These drugs include *moguisteine* (not available in the U.S.), which acts peripherally and appears to open ATP-sensitive K⁺ channels. *Theobromine*, a naturally occurring methylxanthine, reduces cough induced by tussive agents. Although the expectorant *guaifenesin* is not typically known as a cough suppressant, it is significantly better than placebo in reducing acute viral cough and inhibits cough-reflex sensitivity in patients with upper respiratory tract infections (Dicpinigaitis et al., 2009).

Novel Antitussives

There is clearly a need to develop new, more effective therapies for cough, particularly drugs that act peripherally to avoid sedation. There are close analogies between chronic cough and sensory hyperesthesia, so new therapies with novel antitussives are likely to arise from pain research.

Transient Receptor Potential Antagonists

Several types of TRP ion channels have been described on airway sensory nerves and may be activated by various mediators and physical factors, resulting in cough. TRPV1 (previously called the *vanilloid receptor*) is activated by capsaicin, H⁺, and bradykinin, all of which are potent tussive agents. TRPV1 inhibitors block cough induced by capsaicin and bradykinin and are effective in some models of cough (McLeod et al., 2008). In a clinical study of an oral TRPV1 inhibitor, there was protection against capsaicin-induced cough but no clinical improvement in chronic idiopathic cough after long-term treatment (Khalid et al., 2014). A side effect of these drugs is loss of temperature regulation and hyperthermia, which has prevented clinical development.

Transient receptor potential A1 is emerging as a more promising novel target for antitussives (Grace and Belvisi, 2011). This channel is activated by oxidative stress and many irritants and may be sensitized by inflammatory cytokines (Bonvini et al., 2015). Several selective TRPA1 antagonists are now in development. TRPV4 may also activate cough and may be activated by ATP (Bonvini et al., 2016).

ATP Receptor Antagonists

Adenosine triphosphate is a potent tussive agent and stimulates cough in patients with asthma and COPD via activation of P2X3 receptors on afferent nerves (Basoglu et al., 2015). A P2X3 antagonist (AF-219) is effective in reducing chronic idiopathic cough, although abnormal taste (dysgeusia) is a frequent side effect (Abdulqawi et al., 2015).

Drugs for Dyspnea and Ventilatory Control

Drugs for Dyspnea

Bronchodilators should reduce breathlessness in patients with airway obstruction. Chronic oxygen use may have a beneficial effect, but in a

few patients dyspnea may be extreme. Drugs that reduce breathlessness may also depress ventilation in parallel and may therefore be dangerous in severe asthma and COPD. Some patients show a beneficial response to dihydrocodeine and diazepam; however, these drugs must be used with great caution because of the risk of ventilatory depression (Cunha et al., 2014). Slow-release morphine tablets may also be helpful in patients with COPD with extreme dyspnea (Cunha and Abernethy, 2007). Nebulized morphine may also reduce breathlessness in COPD and could act in part on opioid receptors in the lung. Nebulized furosemide has some efficacy in treating dyspnea from a variety of causes, but the evidence is not yet sufficiently convincing to recommend this as routine therapy (Newton et al., 2008).

Ventilatory Stimulants

Selective respiratory stimulants are indicated if ventilation is impaired as a result of overdose with sedatives, in postanesthetic respiratory depression, and in idiopathic hypoventilation. Respiratory stimulants are rarely indicated in COPD because respiratory drive is already maximal, and further stimulation of ventilation may be counterproductive because of the increase in energy expenditure caused by the drugs.

Doxapram

At low doses (0.5 mg/kg IV), doxapram stimulates carotid chemoreceptors; at higher doses, it stimulates medullary respiratory centers. Its effect is transient; thus, intravenous infusion (0.3–3 mg/kg per min) is needed for sustained effect. Unwanted effects include nausea, sweating, anxiety, and hallucinations. At higher doses, increased pulmonary and systemic pressures may occur. Both the kidney and the liver participate in the clearance of doxapram, which should be used with caution if hepatic or renal function is impaired. In COPD, the infusion of doxapram is restricted to 2 h. The use of doxapram to treat ventilatory failure in COPD has now largely been replaced by noninvasive ventilation.

Almitrine

Almitrine bismesylate is a piperazine derivative that appears to selectively stimulate peripheral chemoreceptors and is without central actions. Almitrine stimulates ventilation only when there is hypoxia. Long-term use of almitrine is associated with peripheral neuropathy, limiting its availability in most countries, including the U.S.

Acetazolamide

The carbonic anhydrase inhibitor acetazolamide (see Chapter 25) induces metabolic acidosis and thereby stimulates ventilation, but it is not widely used because the metabolic imbalance it produces may be detrimental in the face of respiratory acidosis. It has a small beneficial effect in respiratory failure in patients with COPD. The drug has proved useful in prevention of high-altitude (mountain) sickness (Faisy et al., 2016).

Naloxone

Naloxone is a competitive opioid antagonist that is indicated only if ventilatory depression is due to overdose of opioids.

Flumazenil

Flumazenil is a benzodiazepine receptor antagonist that can reverse respiratory depression due to overdose of benzodiazepines (Veiraiah et al., 2012).

Drug Facts for Your Personal Formulary: Asthma and COPD Therapeutics

Drug	Therapeutic Uses	Clinical Tips
Short-Acting β_2 Agonists: Inhaled bronchodilators for symptom relief and acute bronchodilation		
Albuterol (salbutamol)	<ul style="list-style-type: none">Asthma, COPD, and exercise-induced bronchospasmInhaled: 180 μg (2 puffs) every 4 to 6 h as neededNebulized: 2.5 mg via oral inhalation every 6–8 h as needed over 5 to 15 minOral: 2–4 mg by mouth every 6–8 h	<ul style="list-style-type: none">Also available nebulized and inhaled as levalbuterol (active isomer, so half the dose)May need to be nebulized with oxygen in severe exacerbationAdverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Levalbuterol (L-albuterol)	<ul style="list-style-type: none">BronchodilatorInhaled (MDI nebulizer)	<ul style="list-style-type: none">Half of doses of racemic albuterolNo advantage over racemic albuterolAdverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Pirbuterol	<ul style="list-style-type: none">400 μg (2 puffs) every 4–6 h as neededInhaled (MDI nebulizer)	<ul style="list-style-type: none">Similar to albuterolAdverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Long-Acting β_2 Agonists: Add-on therapy to ICSs in asthma; can be used alone in COPD		
Formoterol	<ul style="list-style-type: none">Asthma as add-on to ICSMaintenance and treatment of severe COPDInhaled: 12 μg (contents of 1 capsule) every 12 hNebulized 20 μg in 2 mL, twice per day	<ul style="list-style-type: none">Used as maintenance, usually in a combination with an ICSCan also be used as a reliever of bronchospasmAdverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Arformoterol Salmeterol Indacaterol Olodaterol	<ul style="list-style-type: none">Arformoterol for severe COPDMaintenance treatment for COPDArformoterol, inhaled (nebulized), 15 μg in 2 mL twice dailySalmeterol, inhaled 50 μg twice dailyIndacaterol, inhaled (DPI) 75 cetazolamide once dailyOlodaterol, inhaled 2.5 cetazolamide once daily	<ul style="list-style-type: none">Cannot be used as a reliever, only for maintenance treatment for COPDAdverse effects: tachycardia, palpitations, muscle tremors, and hyperkalemia
Anticholinergics: Muscarinic receptor antagonists inhaled as bronchodilators		
Ipratropium bromide Albuterol/ipratropium combination	<ul style="list-style-type: none">Inhaled, 2 puffs (17 $\mu\text{g}/\text{puff}$) 3–4 times/dCombination albuterol 103 $\mu\text{g}/\text{ipratropium}$ 18 $\mu\text{g}/\text{puff}$; 2 puffs 4 times daily	<ul style="list-style-type: none">Largely replaced by LAMAsAvoid spraying in eyesAdverse effects include dry mouth, tachycardia, urinary retention, glaucomaCombination with albuterol may be used as a reliever
Tiotropium Bromide	<ul style="list-style-type: none">2.5 μg via oral inhalation (2 puffs of 1.25 $\mu\text{g}/\text{actuation}$) once daily	<ul style="list-style-type: none">Caution in patients with urinary retention or glaucoma history
Umeclidinium bromide	<ul style="list-style-type: none">Inhaled (DPI) 62.5 μg (1 puff) once daily	
Acclidinium bromide	<ul style="list-style-type: none">Inhaled (DPI) 400 μg (1 puff) twice daily	
Glycopyrrolate	<ul style="list-style-type: none">Inhaled (DPI) 1 capsule (15.6 μg) inhaled twice daily	
LAMA-LABA Combination Inhalers: Maintenance treatment for COPD		
Glycopyrrolate/ indacaterol	<ul style="list-style-type: none">Inhaled (DPI) 1 inhalation (glycopyrrolate 15.6 $\mu\text{g}/\text{indacaterol}$ 27.5 μg) twice daily	<ul style="list-style-type: none">Side effects of anticholinergics and β_2 agonists as aboveMaintenance treatment for COPD
Umeclidinium/ vilanterol	<ul style="list-style-type: none">Inhaled (DPI) 1 inhalation (umeclidinium 62.5 $\mu\text{g}/25$ μg vilanterol) once daily	
Tiotropium/olodaterol	<ul style="list-style-type: none">Inhaled (mist inhaler), 2 inhalations (containing 2.5 μg tiotropium/2.5 μg of olodaterol per inhalation) once daily	
Inhaled Corticosteroids: Maintenance treatment for asthma		
Beclomethasone dipropionate (BDP)	<ul style="list-style-type: none">Inhaled (MDI, DPI); 88 μg (1 spray = 44 μg) twice dailyNot to exceed 440 μg twice daily	<ul style="list-style-type: none">More systemic effects than other ICSs: orally bioavailable BDP is converted to an active metabolite, beclomethasone monopropionate, following absorptionLocal effects: hoarse voice, candidiasisSystemic effects: growth suppression, bruising, adrenal suppression
Fluticasone propionate	<ul style="list-style-type: none">Inhaled (MDI, DPI); 50, 100, 250 μg 2 puffs, twice dailyDo not exceed 1000 μg daily	<ul style="list-style-type: none">Fewer systemic effects than BDPLocal: hoarse voice, candidiasis
Budesonide	<ul style="list-style-type: none">Inhaled via jet nebulizer either once daily or divided into 2 doses (maximum daily dose 0.5 mg/d)	<ul style="list-style-type: none">Fewer systemic effects than BDPUsed in children less than 8 who cannot use PDILocal: hoarse voice, candidiasis
Ciclesonide	<ul style="list-style-type: none">Inhaled (MDI) 80 μg twice daily	<ul style="list-style-type: none">Least-systemic effects of all ICSs; may be effective once dailyLocal: hoarse voice, candidiasis

Drug Facts for Your Personal Formulary: Asthma and COPD Therapeutics (continued)

Drug	Therapeutic Uses	Clinical Tips
ICS/LABA Combination Inhalers: Maintenance treatment in asthma and COPD		
Fluticasone propionate/salmeterol	<ul style="list-style-type: none"> Inhaled (DPI) Starting dosage based on asthma severity 	<ul style="list-style-type: none"> Use lowest dose that maintains asthma control Use only in severe COPD or asthma-COPD overlap Adverse effects as for ICSs and LABAs
Budesonide/formoterol	<ul style="list-style-type: none"> Inhaled (MDI) (80 µg budesonide and 4.5 µg formoterol per inhalation) twice daily 	
Fluticasone furoate/vilanterol	<ul style="list-style-type: none"> Inhaled (DPI) 1 inhalation (fluticasone furoate 100 µg/vilanterol 25 µg) once daily 	
Systemic Corticosteroids: Short course or oral maintenance for asthma (and COPD)		
Prednisone Prednisolone	<ul style="list-style-type: none"> Oral: 40–80 mg once daily or divided dose for 3–10 days for acute exacerbation Minimal dose for maintenance 	<ul style="list-style-type: none"> Prednisone converted to prednisolone in the liver Bruising, weight gain, edema, osteoporosis, diabetes, cataracts, adrenal suppression (see Chapter 46)
Hydrocortisone succinate	<ul style="list-style-type: none"> IM/IV: 100–500 mg every 12 h for acute severe asthma 	<ul style="list-style-type: none"> Only if patient not able to take oral steroids
Methylprednisolone	<ul style="list-style-type: none"> IV: 100–1000 mg for acute severe asthma 	<ul style="list-style-type: none"> Rarely indicated because of steroid side effects
Antileukotrienes (Leukotriene Modifiers) for Asthma Maintenance		
Montelukast (10 Zafirlukast) Zileuton	<ul style="list-style-type: none"> Oral: montelukast (10 mg once/d); zafirlukast (20 mg twice/d); zileuton (600 mg four times/d or 1200 mg twice/d) 	<ul style="list-style-type: none"> Less effective than ICS in asthma Headache, Churg-Strauss syndrome Zileuton may cause hepatic dysfunction (do not use if ALT increased)
Methylxanthines: Add-on maintenance treatment of severe asthma and COPD		
Theophylline (oral) Aminophylline (IV)	<ul style="list-style-type: none"> Aminophylline (IV) is indicated for severe exacerbation that does not respond to nebulized β agonists; shorter action than theophylline 	<ul style="list-style-type: none"> Interaction with drugs that affect CYP450 Nausea, headaches, diuresis, arrhythmias, seizures
Phosphodiesterase 4 Inhibitor: Maintenance for severe COPD		
Roflumilast	<ul style="list-style-type: none"> Severe COPD Oral administration 500 µg once daily 	<ul style="list-style-type: none"> Add to maximal inhaled therapy if severe disease with acute exacerbations and chronic bronchitis
Anti-IgE: Maintenance Treatment for severe asthma		
Omalizumab	<ul style="list-style-type: none"> Severe asthma Subcutaneous administration Dose depends on total IgE; given every 2–4 weeks 	<ul style="list-style-type: none"> Expensive, so mainly indicated in severe asthma that is difficult to control Well tolerated; occasional headache Occasional anaphylaxis

Chapter 41

Hematopoietic Agents: Growth Factors, Minerals, and Vitamins

Kenneth Kaushansky and Thomas J. Kipps

HEMATOPOIESIS

GROWTH FACTOR PHYSIOLOGY

ERYTHROPOIESIS-STIMULATING AGENTS

- Erythropoietin

MYELOID GROWTH FACTORS

- Granulocyte-Macrophage Colony-Stimulating Factor
- Granulocyte Colony-Stimulating Factor

THROMBOPOIETIC GROWTH FACTORS

- Interleukin 11
- Thrombopoietin Receptor Agonists

IRON DEFICIENCY AND OTHER HYPOCHROMIC ANEMIAS

- Bioavailability of Iron
- Metabolism of Iron
- Iron Requirements; Availability of Dietary Iron
- Treatment of Iron Deficiency
- Copper, Pyridoxine, and Riboflavin

VITAMIN B₁₂, FOLIC ACID, AND MEGALOBLASTIC ANEMIAS

- Cellular Roles of Vitamin B₁₂ and Folic Acid
- Vitamin B₁₂ and Human Health
- Folic Acid and Human Health

Hematopoiesis

The finite life span of most mature blood cells requires their continuous replacement, a process termed *hematopoiesis*. New cell production must respond to basal needs and states of increased demand. Erythrocyte production can increase more than 20-fold in response to anemia or hypoxemia, leukocyte production increases dramatically in response to systemic infections, and platelet production can increase 10- to 20-fold when platelet consumption results in thrombocytopenia.

The regulation of blood cell production is complex. Hematopoietic stem cells are rare marrow cells that manifest self-renewal and lineage commitment, resulting in cells destined to differentiate into the 10 or more distinct blood cell lineages. For the most part, this process occurs in the marrow cavities of the skull, vertebral bodies, pelvis, and proximal long bones; it involves interactions among hematopoietic stem and progenitor cells and the cells and complex macromolecules of the marrow stroma and is influenced by a number of soluble and membrane-bound hematopoietic growth factors. Several hormones and cytokines have been identified and cloned that affect hematopoiesis, permitting their production in quantities sufficient for research and, in some cases, therapeutic use. Clinical applications range from the treatment of primary hematologic diseases (e.g., aplastic anemia, congenital neutropenia) to use as adjuncts in the treatment of severe infections and in the management of patients with kidney failure or those undergoing cancer chemotherapy or marrow transplantation.

Hematopoiesis also requires an adequate supply of minerals (e.g., iron, cobalt, and copper) and vitamins (e.g., folic acid, vitamin B₁₂, pyridoxine, ascorbic acid, and riboflavin); deficiencies generally result in characteristic anemias or, less frequently, a general failure of hematopoiesis (Hoffbrand and Herbert, 1999). Therapeutic correction of a specific deficiency state depends on the accurate diagnosis of the anemic state and on knowledge about the correct dose, the use of these agents in appropriate combinations, and the expected response.

Growth Factor Physiology

Steady-state hematopoiesis encompasses the tightly regulated production of more than 400 billion blood cells each day. The hematopoietic organ also is unique in adult physiology in that several mature cell types are derived from a much smaller number of multipotent progenitors, which develop from a more limited number of pluripotent hematopoietic stem cells. Such cells are capable of maintaining their own number and differentiating under the influence of cellular and humoral factors to produce the large and diverse number of mature blood cells.

Our understanding of stem cell differentiation owes much to the *in vitro* culture of marrow cells. Using the results from clonal cultures in semisolid medium, stem cell differentiation can be described as a series of developmental steps that produce mixed blood cell lineage colonies, which give rise to large, immature and small, mature single-lineage burst-forming units (BFUs) and colony-forming units (CFUs), respectively, for each of the major blood cell types. These early progenitors (BFUs and CFUs) are capable of further proliferation and differentiation, increasing their number by some 30-fold. It is at this most mature stage of development that the lineage-committed growth factors (G-CSF, M-CSF, erythropoietin, and thrombopoietin) exert their primary proliferative and differentiative effects. Overall, proliferation and maturation of the CFU for each cell line can amplify the resulting mature cell product by another 30-fold or more, generating more than 1000 mature cells from each committed stem cell.

Hematopoietic and lymphopoietic growth factors are glycoproteins produced by a number of marrow cells and peripheral tissues. They are active at very low concentrations and typically affect more than one committed cell lineage. Most interact synergistically with other factors and stimulate production of additional growth factors, a process termed *networking*. Growth factors generally exert actions at several points in the processes of cell proliferation and differentiation and in mature cell function. However, the network of growth factors that contributes to any given cell lineage depends absolutely on a nonredundant, lineage-specific

Abbreviations

BFU: burst-forming units
BFU-E: BFU erythrocyte
CFU: colony-forming units
CFU-E: CFU erythrocyte
CFU-GEMM: CFU granulocyte, erythrocyte, monocyte and megakaryocyte
CFU-GM: CFU granulocyte and macrophage
CFU-Meg: CFU megakaryocyte
CH₃B₁₂: methylcobalamin
CH₃H₄PteGlu: methyltetrahydrofolate
CSF: colony stimulating factor
dTMP: thymidylate
dUMP: deoxyuridylate
EPO: erythropoietin
ESA: erythropoiesis-stimulating agent
FIGLU: formiminoglutamic acid
FL: FLT3 (FMS tyr kinase 3) ligand
FMS3: FMS tyr kinase 3
G-CSF: granulocyte colony-stimulating factor
GM-CSF: granulocyte-macrophage colony-stimulating factor
GVHD: graft-versus-host disease
HAART: highly active antiretroviral therapy
HFE: high Fe, hemochromatosis protein
HIF: hypoxia-inducible factor
HIV: human immunodeficiency virus
IFN: interferon
IL: interleukin
LAK: lymphokine-activated killer cell
M-CSF: monocyte-/macrophage-stimulating factor
NK: natural killer
PBSC: peripheral blood stem cell
PteGlu: pteroylglutamic acid, folic acid
SAM: S-adenosylmethionine
SCF: stem cell factor
TcII: transcobalamin II
TRA: thrombopoietin receptor agonist

factor, such that absence of factors that stimulate developmentally early progenitors is compensated for by redundant cytokines, but loss of the lineage-specific factor leads to a specific cytopenia.

Some of the overlapping and nonredundant effects of the more important hematopoietic growth factors are illustrated in Figure 41-1 and Table 41-1.

Erythropoiesis-Stimulating Agents

Erythropoiesis-stimulating agent (ESA) is the term given to a pharmacological substance that stimulates red blood cell production.

Erythropoietin

Erythropoietin is the most important regulator of the proliferation of committed erythroid progenitors (CFU-E) and their immediate progeny. In its absence, severe anemia is invariably present, commonly seen in patients with renal failure. Erythropoiesis is controlled by a feedback system in which a sensor in the kidney detects changes in oxygen delivery to modulate the erythropoietin secretion. The sensor mechanism is now understood at the molecular level (Haase, 2010).

Hypoxia-inducible factor, a heterodimeric (HIF-1 α and HIF-1 β) transcription factor, enhances expression of multiple hypoxia-inducible genes,

HISTORICAL PERSPECTIVE

Modern concepts of hematopoietic cell growth and differentiation derive from experiments done in the 1950s. Till and McCulloch demonstrated that individual hematopoietic cells could form macroscopic hematopoietic colonies in the spleens of irradiated mice, thereby establishing the concept of discrete hematopoietic stem cells (i.e., the presence of a multilineage clonal splenic colony appearing 11 days after transplantation implied that a single cell lodged and expanded into several cell lineages). This concept now has been expanded to include normal human marrow cells. Moreover, such cells now can be prospectively identified.

The basis for identifying soluble growth factors was provided by Sachs and independently by Metcalf, who developed clonal, in vitro assays for hematopoietic progenitor cells. Such hematopoietic colonies first developed only in the presence of conditioned culture medium from leukocytes or tumor cell lines. Individual growth factors then were isolated based on their activities in clonal in vitro assays, assays that were instrumental in purifying a hierarchy of progenitor cells committed to individual and combinations of mature blood cells (Kondo et al., 2003).

In 1906, Paul Carnot postulated the existence of a circulating growth factor that controls red blood cell development. He observed an increase in the red cell count in rabbits injected with serum obtained from anemic animals and postulated the existence of a factor that he called hemopoietin. Only in the 1950s did Reissmann, Erslev, and Jacobsen and coworkers define the origin and actions of the hormone, now called erythropoietin. Subsequently, extensive studies of erythropoietin were carried out in patients with anemia and polycythemia, leading to the purification of erythropoietin from urine and the subsequent cloning of the erythropoietin gene. The high-level expression of erythropoietin in cell lines has allowed for its purification and use in humans with anemia.

Similarly, the existence of specific leukocyte growth factors was suggested by the capacity of different conditioned culture media to induce the in vitro growth of colonies containing different combinations of granulocytes and monocytes. An activity that stimulated the production of both granulocytes and monocytes was purified from murine lung-conditioned medium, leading to cloning of GM-CSF, first from mice (Gough et al., 1984) and subsequently from humans (Wong et al., 1985). Finding an activity that stimulated the exclusive production of neutrophils permitted the cloning of G-CSF (Welte et al., 1985). Subsequently, a megakaryocyte colony-stimulating factor termed thrombopoietin was purified and cloned (Kaushansky, 1998).

Growth factors that support lymphocyte growth were identified using assays that measured the capacity of the cytokine to promote lymphocyte proliferation in vitro. This permitted the identification of the growth-promoting properties of IL-7, IL-4, or IL-15 for all lymphocytes, B cells, or NK cells, respectively (Goodwin et al., 1989; Grabstein et al., 1994). Recombinant expression of these complementary DNAs permitted production of sufficient quantities of biologically active growth factors for clinical investigations, allowing for the demonstration of the potential clinical utility of such factors.

such as vascular endothelial growth factor and erythropoietin. HIF-1 α is labile due to its prolyl hydroxylation and subsequent polyubiquitination and degradation, aided by the von Hippel-Lindau (VHL) *protein*. During states of hypoxia, the prolyl hydroxylase is inactive, allowing the accumulation of HIF-1 α and activating erythropoietin expression, which in turn stimulates rapid expansion of erythroid progenitors. Specific alteration of VHL leads to an oxygen-sensing defect, characterized by constitutively elevated levels of HIF-1 α and erythropoietin, with resultant polycythemia (Gordeuk et al., 2004). A second isoform of HIF, HIF-2 α , is an important

Figure 41-1 Sites of action of hematopoietic growth factors in the differentiation and maturation of marrow cell lines. A self-sustaining pool of marrow stem cells differentiates under the influence of specific hematopoietic growth factors to form a variety of hematopoietic and lymphopoietic cells. SCF, FL, IL-3, and GM-CSF, together with cell-cell interactions in the marrow, stimulate stem cells to form a series of BFUs and CFUs: CFU-GEMM, CFU-GM, CFU-Meg, BFU-E, and CFU-E. After considerable proliferation, further differentiation is stimulated by synergistic interactions with growth factors for each of the major cell lines—G-CSF, M-CSF, thrombopoietin, and erythropoietin. Each of these factors also influences the proliferation, maturation, and in some cases the function, of the derivative cell line (Table 41-1).

regulator of the expression of genes that contribute to iron absorption (Mastrogiannaki et al., 2013); a genetic gain-of-function mutation in HIF-2 α also induces erythrocytosis in patients (Percy et al., 2008).

Erythropoietin is expressed primarily in peritubular interstitial cells of the kidney. Erythropoietin contains 193 amino acids, of which the first 27 are cleaved during secretion. The final hormone is heavily glycosylated and has a molecular mass of about 30 kDa. After secretion, erythropoietin binds to a receptor on the surface of committed erythroid progenitors in the marrow and is internalized. With anemia or hypoxemia, synthesis rapidly increases by 100-fold or more, serum erythropoietin levels rise, and marrow progenitor cell survival, proliferation, and maturation are dramatically stimulated. This finely tuned feedback loop can be disrupted by kidney disease, marrow damage, or a deficiency in iron or an essential vitamin. With an infection or an inflammatory state, erythropoietin secretion, iron delivery, and progenitor proliferation all are suppressed by inflammatory cytokines, but this accounts for only part of the resultant anemia; interference with iron metabolism also is an effect of inflammatory mediator effects on the hepatic protein *hepcidin* (Drakesmith and Prentice, 2012). Loss of hepcidin-producing liver mass or genetic or acquired conditions that repress hepcidin production by the liver may lead to iron overload (Pietrangelo, 2016).

Preparations

Preparations of recombinant human erythropoietin include *epoetin alfa*, *epoetin beta*, *epoetin omega*, and *epoetin zeta*, which differ almost exclusively in carbohydrate modifications due to manufacturing differences and are supplied in single-use vials or syringes containing 500–40,000 units for intravenous or subcutaneous administration. When injected intravenously, epoetin alfas are cleared from plasma with a $t_{1/2}$ of 4–8 h. However, the effect on marrow progenitors lasts much longer, and once-weekly dosing can be sufficient to achieve an adequate response. An engineered epoetin

alfa, darbepoetin, which displays a longer circulatory half-life, is also available for use in patients with indications similar to those for other epoetins. Based on phage display technology, small peptide agonists of the erythropoietin receptor were identified and developed into clinical agents by coupling to polyethylene glycol. One such erythropoiesis-stimulating peptide, peginesatide, was approved for the treatment of anemia due to chronic kidney disease; postmarketing reports of serious hypersensitivity reactions and anaphylaxis necessitated its removal from the market.

Recombinant human erythropoietin (*epoetin alfa*) is nearly identical to the endogenous hormone. The carbohydrate modification pattern of epoetin alfa differs slightly from the native protein, but this difference apparently does not alter kinetics, potency, or immunoreactivity of the drug. Modern assays can detect these differences and thereby identify athletes who use the recombinant product for “blood doping.”

Therapeutic Uses, Monitoring, and Adverse Effects

Recombinant erythropoietin therapy, in conjunction with adequate iron intake, can be highly effective in a number of anemias, especially those associated with poor erythropoietic response. Epoetin alfa is effective in the treatment of anemias associated with surgery, AIDS, cancer chemotherapy, prematurity, and certain chronic inflammatory conditions. Darbepoetin alfa also has been approved for use in patients with anemia associated with chronic kidney disease. A Cochrane analysis could not demonstrate the superiority of one form of ESA over any another.

During erythropoietin therapy, absolute or functional iron deficiency may develop. Functional iron deficiency (i.e., normal ferritin levels but low transferrin saturation) presumably results from the inability to mobilize iron stores rapidly enough to support the increased erythropoiesis. Supplemental iron therapy is recommended for all patients whose serum ferritin is less than 100 $\mu\text{g/L}$ or whose serum transferrin saturation is below 20%. During initial therapy and after any dosage adjustment, the

TABLE 41-1 ■ HEMATOPOIETIC GROWTH FACTORS**Erythropoietin (EPO)**

- Stimulates proliferation and maturation of committed erythroid progenitors to increase red cell production

Stem cell factor (SCF, c-kit ligand, Steel factor) and FLT 3 ligand (FL)

- Act synergistically with a wide range of other colony-stimulating factors and interleukins to stimulate pluripotent and committed stem cells
- FL also stimulates both dendritic and NK cells (antitumor response)
- SCF also stimulates mast cells and melanocytes

Interleukins

IL-1, IL-3, IL-5, IL-6, IL-9, and IL-11

- Act synergistically with each other and SCF, GM-CSF, G-CSF, and EPO to stimulate BFU-E, CFU-GEMM, CFU-GM, CFU-E, and CFU-Meg growth
- Numerous immunologic roles, including stimulation of B-cell and T-cell growth

IL-5

- Controls eosinophil survival and differentiation

IL-6

- IL-6 stimulates human myeloma cells to proliferate
- IL-6 and IL-11 stimulate BFU-Meg to increase platelet production

IL-1, IL-2, IL-4, IL-7, and IL-12

- Stimulate growth and function of T cells, B cells, NK cells, and monocytes
- Costimulate B, T, and LAK cells

IL-8 and IL-10

- Numerous immunological activities involving B- and T-cell functions
- IL-8 acts as a chemotactic factor for basophils and neutrophils

Granulocyte-macrophage colony-stimulating factor (GM-CSF)

- Acts synergistically with SCF, IL-1, IL-3, and IL-6 to stimulate CFU-GM and CFU-Meg to increase neutrophil and monocyte production
- With EPO may promote BFU-E formation
- Enhances migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils
- Prevents alveolar proteinosis

Granulocyte colony-stimulating factor (G-CSF)

- Stimulates CFU-G to increase neutrophil production
- Enhances phagocytic and cytotoxic activities of neutrophils

Monocyte/macrophage colony-stimulating factor (M-CSF, CSF-1)

- Stimulates CFU-M to increase monocyte precursors
- Activates and enhances function of monocyte/macrophages

Macrophage colony-stimulating factor (M-CSF)

- Stimulates CFU-M to increase monocyte/macrophage precursors
- Acts in concert with tissues and other growth factors to determine the proliferation, differentiation, and survival of a range of cells of the mononuclear phagocyte system

Thrombopoietin (TPO, *Mpl* ligand)

- Stimulates the self-renewal and expansion of hematopoietic stem cells
- Stimulates stem cell differentiation into megakaryocyte progenitors
- Selectively stimulates megakaryocytopoiesis to increase platelet production
- Acts synergistically with other growth factors, especially IL-6 and IL-11

hematocrit is determined once a week (patients infected with HIV and those with cancer) or twice a week (patients with renal failure) until it has stabilized in the target range and the maintenance dose has been established; the hematocrit then is monitored at regular intervals. If the hematocrit increases by more than 4 points in any 2-week period, the dose should be decreased. Due to the time required for erythropoiesis and the erythrocyte half-life, hematocrit changes lag behind dosage adjustments by 2–6 weeks. The dose of darbepoetin should be decreased if the hemoglobin increase exceeds 1 g/dL in any 2-week period because of the association of excessive rate of rise of hemoglobin with adverse cardiovascular events.

During hemodialysis, patients receiving epoetin alfa or darbepoetin may require increased anticoagulation. The risk of thrombotic events is higher in adults with ischemic heart disease or congestive heart failure receiving epoetin alfa therapy with the goal of reaching a normal hematocrit (42%) than in those with a lower target hematocrit of 30% (Bennett et al., 2008). ESA use is associated with increased rates of cancer recurrence and decreased on-study survival in patients in whom the drugs are administered for cancer-induced or for chemotherapy-induced anemia (Bohlius et al., 2009). The most common side effect of epoetin alfa therapy is aggravation of hypertension, which occurs in 20%–30% of patients and most often is associated with a rapid rise in hematocrit. ESAs should not be used in patients with preexisting uncontrolled hypertension. Patients may require initiation of, or increases in, antihypertensive therapy. Hypertensive encephalopathy and seizures have occurred in patients with chronic renal failure treated with epoetin alfa. Headache, tachycardia, edema, shortness of breath, nausea, vomiting, diarrhea, injection site stinging, and flu-like symptoms (e.g., arthralgias and myalgias) also have been reported in conjunction with epoetin alfa therapy.

Anemia of Chronic Renal Failure Patients with anemia secondary to chronic kidney disease are ideal candidates for epoetin alfa therapy as the disease represents a true hormone deficiency state. The response in predialysis, peritoneal dialysis, and hemodialysis patients depends on the severity of the renal failure, the erythropoietin dose and route of administration, and iron availability (Besarab et al., 1999; Kaufman et al., 1998). The subcutaneous route of administration is preferred over the intravenous route because absorption is slower and the amount of drug required is reduced by 20%–40%. The dose of epoetin alfa should be adjusted to obtain a gradual rise in the hematocrit over a 2- to 4-month period to a final hematocrit of 33%–36%. Treatment to hematocrit levels greater than 36% is not recommended.

Patients are started on doses of 80–120 units/kg of epoetin alfa, given subcutaneously, three times a week. The final maintenance dose of epoetin alfa can vary from 10 units/kg to more than 300 units/kg, with an average dose of 75 units/kg, three times a week. Children less than 5 years of age generally require a higher dose. Resistance to therapy is common in patients who develop an inflammatory illness or become iron deficient, so close monitoring of general health and iron status is essential. Less-common causes of resistance include occult blood loss, folic acid deficiency, carnitine deficiency, inadequate dialysis, aluminum toxicity, and osteitis fibrosa cystica secondary to hyperparathyroidism. Darbepoetin alfa is approved for use in patients who are anemic secondary to chronic kidney disease. The recommended starting dose is 0.45 µg/kg administered intravenously or subcutaneously once weekly or 0.75 µg/kg administered every 2 weeks, with dose adjustments depending on the response. Like epoetin alfa, side effects tend to occur when patients experience a rapid rise in hemoglobin concentration; a rise of less than 1 g/dL every 2 weeks generally is considered safe.

Anemia in Patients With AIDS Epoetin alfa therapy has been approved for the treatment of HIV-infected patients, especially those on zidovudine therapy (Fischl et al., 1990). Excellent responses to doses of 100–300 units/kg, given subcutaneously three times a week, generally are seen in patients with zidovudine-induced anemia. However, a more recent analysis of erythropoietin therapy in patients with HIV infection failed to support its routine use (Martí-Carvajal et al., 2011). The reason for the difference between 1990 and 2011 may lay in far more effective therapy for HIV in

the HAART era, such that the origin of anemia in HIV-infected individuals today is different from what it was at the onset of the AIDS epidemic.

Cancer-Related Anemias Epoetin alfa therapy, 150 units/kg three times a week or 450–600 units/kg once a week, can reduce the transfusion requirement in patients with cancer undergoing chemotherapy as well as lead to reduced anemia-related symptoms. Previous therapeutic guidelines (Rizzo et al., 2002) recommended the use of epoetin alfa in patients with chemotherapy-associated anemia when hemoglobin levels fall below 10 g/dL, basing the decision to treat less-severe anemia (hemoglobin 10–12 g/dL) on clinical circumstances. For anemia associated with hematologic malignancies, the guidelines support the use of recombinant erythropoietin in patients with low-grade myelodysplastic syndrome. In this setting, neutropenia often dictates the use of G-CSF, which frequently augments the erythroid response to erythropoietin. In responding patients, the response duration is usually 2–3 years. A baseline serum erythropoietin level may help to predict the response; most patients with blood levels greater than 500 IU/L are unlikely to respond to any dose of the drug. Most patients treated with epoetin alfa experience an improvement in their anemia and their sense of well-being (Littlewood et al., 2001). Following these recommendations, case reports suggested a direct effect of both epoetin alfa and darbepoetin alfa in stimulation of tumor cells. A meta-analysis of a large number of patients and clinical trials estimated the risk at about 10% higher than for cancer patients not treated (Bohlius et al., 2009). Following on these results, new guidelines were issued (Rizzo et al., 2010). This finding is continuing to be evaluated by the FDA and warrants serious attention.

Use in Perioperative Patients Epoetin alfa has been used perioperatively to treat anemia (hematocrit 30%–36%) and reduce the need for allogeneic erythrocyte transfusion in nonanemic patients during and following surgery in patients with moderate or large anticipated blood loss. Patients undergoing elective orthopedic and cardiac procedures have been treated with 150–300 units/kg of epoetin alfa once daily for the 10 days preceding surgery, on the day of surgery, and for 4 days after surgery. As an alternative, 600 units/kg can be given on days 21, 14, and 7 before surgery, with an additional dose on the day of surgery. Using these dosing regimens, an average of four units of autologous blood can be obtained for postoperative use in a typical, nonanemic patient.

Other Uses Epoetin alfa has received orphan drug status from the FDA for the treatment of the anemia of prematurity, HIV infection, and myelodysplasia. In the last case, even very high doses (>1000 units/kg two to three times a week) sometimes have limited success. Highly competitive athletes have used epoetin alfa to increase their hemoglobin levels (“blood doping”) and improve performance. Unfortunately, this misuse of the drug has been implicated in the deaths of several athletes and is strongly discouraged.

Myeloid Growth Factors

The myeloid growth factors are glycoproteins that stimulate the proliferation and differentiation of one or more myeloid cell types. Recombinant forms of several growth factors have been produced, including GM-CSF, G-CSF, IL-3, M-CSF or CSF-1, and stem cell factor (SCF) (see Table 41-1), although only G-CSF and GM-CSF have found meaningful clinical applications.

Myeloid growth factors are produced naturally by a number of different cells, including fibroblasts, endothelial cells, macrophages, and T cells (Figure 41-2). These factors are active at extremely low concentrations and act via membrane receptors of the cytokine receptor superfamily to activate the Jak/STAT signal transduction pathway. GM-CSF can stimulate proliferation, differentiation, and function of a number of the myeloid cell lineages (see Figure 41-1). It acts synergistically with other growth factors, including erythropoietin, at the level of the BFU. GM-CSF stimulates CFU-GM, CFU-M, CFU-E, and CFU-Meg to increase cell production. GM-CSF also enhances the migration, phagocytosis, superoxide production, and antibody-dependent cell-mediated toxicity of neutrophils, monocytes, and eosinophils (Weisbart et al., 1987).

Figure 41-2 Cytokine-cell interactions. Macrophages, T cells, B cells, and marrow stem cells interact via several cytokines (IL-1, IL-2, IL-3, IL-4, IFN- γ , GM-CSF, and G-CSF) in response to a bacterial or a foreign antigen challenge. See Table 41-1 for the functional activities of these various cytokines.

The activity of G-CSF is restricted to neutrophils and their progenitors, stimulating their proliferation, differentiation, and function. It acts primarily on CFU-G, although it also can play a synergistic role with IL-3 and GM-CSF in stimulating other cell lines. G-CSF enhances phagocytic and cytotoxic activities of neutrophils. G-CSF reduces inflammation by inhibiting IL-1, tumor necrosis factor, and interferon gamma. G-CSF also mobilizes primitive hematopoietic cells, including hematopoietic stem cells, from the marrow into the peripheral blood (Sheridan et al., 1992). This observation has virtually transformed the practice of stem cell transplantation, such that more than 90% of all such procedures today use G-CSF-mobilized peripheral blood cells as the donor stem cell product.

Granulocyte-Macrophage Colony-Stimulating Factor

Recombinant human GM-CSF (*sargramostim*) is a glycoprotein with 127 amino acids. The primary therapeutic effect of sargramostim is to stimulate myelopoiesis.

The initial clinical application of sargramostim was in patients undergoing autologous marrow transplantation. By shortening the duration of neutropenia, transplant morbidity was significantly reduced without a change in long-term survival or risk of inducing an early relapse of the malignant process (Brandt et al., 1988).

The role of GM-CSF therapy in allogeneic transplantation is less clear. Its effect on neutrophil recovery is less pronounced in patients receiving prophylactic treatment of graft-versus-host disease (GVHD). However, it may improve survival in transplant patients who exhibit early graft failure (Nemunaitis et al., 1990).

It also has been used to mobilize CD34-positive progenitor cells for peripheral blood stem cell (PBSC) collection for transplantation after myeloablative chemotherapy (Haas et al., 1990). Sargramostim has been used to shorten the period of neutropenia and reduce morbidity in patients receiving intensive cancer chemotherapy (Gerhartz et al., 1993). It also stimulates myelopoiesis in some patients with cyclic neutropenia, myelodysplasia, aplastic anemia, or AIDS-associated neutropenia.

Sargramostim is administered by subcutaneous injection or slow intravenous infusion at doses of 125–500 $\mu\text{g}/\text{m}^2/\text{d}$. Plasma levels of GM-CSF rise rapidly after subcutaneous injection and then decline with a $t_{1/2}$ of 2–3 h. When given intravenously, infusions should be maintained over 3–6 h. With the initiation of therapy, there is a transient decrease in the absolute leukocyte count secondary to cell margination and pulmonary vascular sequestration. This is followed by a dose-dependent, biphasic increase in leukocyte counts over the next 7–10 days. Once the drug is discontinued, the leukocyte count returns to baseline within 2–10 days. When GM-CSF is given in lower doses, the response is primarily neutrophilic, whereas monocytosis and eosinophilia are observed at larger doses. After hematopoietic stem cell transplantation or intensive chemotherapy, sargramostim

is given daily during the period of maximum neutropenia until a sustained rise in the granulocyte count is observed. Frequent blood counts are essential to avoid an excessive rise in the granulocyte count. Higher doses are associated with more pronounced side effects, including bone pain, malaise, flu-like symptoms, fever, diarrhea, dyspnea, and rash. An acute reaction to the first dose, characterized by flushing, hypotension, nausea, vomiting, and dyspnea, with a fall in arterial oxygen saturation due to granulocyte sequestration in the pulmonary circulation, occurs in sensitive patients. With prolonged administration, a few patients may develop a capillary leak syndrome, with peripheral edema and pleural and pericardial effusions. Other serious side effects include transient supraventricular arrhythmia, dyspnea, and elevation of serum creatinine, bilirubin, and hepatic enzymes.

Granulocyte Colony-Stimulating Factor

Recombinant human G-CSF, *filgrastim*, is a glycoprotein with 175 amino acids. The principal action of filgrastim is the stimulation of CFU-G to increase neutrophil production (see Figure 41-1). Several forms of G-CSF are now available, including two longer-acting pegylated forms, pegfilgrastim and lippegfilgrastim.

Filgrastim is effective in the treatment of severe neutropenia after autologous hematopoietic stem cell transplantation and high-dose cancer chemotherapy (Lieschke and Burgess, 1992). Like GM-CSF, filgrastim shortens the period of severe neutropenia and reduces morbidity secondary to bacterial and fungal infections (Hammond et al., 1989). G-CSF also is effective in the treatment of severe congenital neutropenias. Filgrastim therapy can improve neutrophil counts in some patients with myelodysplasia or marrow damage (moderately SAA or tumor infiltration of the marrow). The neutropenia of patients with AIDS receiving zidovudine also can be partially or completely reversed.

Filgrastim is routinely used in patients undergoing PBSC collection for stem cell transplantation. It promotes the release of CD34⁺ progenitor cells from the marrow, reducing the number of collections necessary for transplant. G-CSF-induced mobilization of stem cells into the circulation also has the potential to enhance repair of other damaged organs in which PBSCs might play a role. PBSC grafts have a higher cell dose and somewhat more committed progenitor cells than steady-state marrow grafts, resulting in faster engraftment and faster immunological reconstitution.

Filgrastim is administered by subcutaneous injection or intravenous infusion over at least 30 min at doses of 1–20 µg/kg/d. The usual starting dose in a patient receiving myelosuppressive chemotherapy is 5 µg/kg/d. The distribution and clearance rate from plasma ($t_{1/2}$ of 3.5 h) are similar for both routes of administration. The recommended dose for pegfilgrastim is fixed at 6 mg for patients weighing more than 20 kg, administered subcutaneously once per chemotherapy cycle. As with GM-CSF therapy, G-CSF administered after hematopoietic stem cell transplantation or intensive cancer chemotherapy will increase granulocyte production and shorten the period of severe neutropenia. Frequent blood cell counts should be obtained to determine the effectiveness of the treatment and guide dosage adjustment. In patients who received intensive myelosuppressive cancer chemotherapy, daily administration of G-CSF for 14–21 days or more may be necessary to correct the neutropenia.

Adverse Reactions

Adverse reactions to filgrastim include mild-to-moderate bone pain in patients receiving high doses over a protracted period, local skin reactions following subcutaneous injection, and rare cutaneous necrotizing vasculitis. Patients with a history of hypersensitivity to proteins produced by *Escherichia coli* should not receive the drug; the same holds for patients with sickle cell anemia, as it has been known to precipitate severe crises and even death. Mild-to-moderate splenomegaly has been observed in patients on long-term therapy.

Patients with sickle cell anemia should not be administered G-CSF as it is reported to trigger severe crises. In 2004 and 2006, two papers were published suggesting that previously healthy stem cell donors receiving human G-CSF for mobilization displayed marrow cell changes concerning for the development of future malignancy. Previous studies have shown an increase in

myeloid leukemia in patients with breast cancer receiving G-CSF for neutropenia. However, careful follow-up has failed to reveal any meaningful increase in myeloid leukemia in normal stem cell donors administered G-CSF.

Thrombopoietic Growth Factors

Interleukin 11

Interleukin 11 is a cytokine that stimulates hematopoiesis, intestinal epithelial cell growth, and osteoclastogenesis and inhibits adipogenesis. IL-11 also enhances megakaryocyte maturation in vitro. Recombinant human IL-11, *oprelvekin*, $t_{1/2}$ about 7 h, leads to a thrombopoietic response in 5–9 days when administered daily to normal subjects.

The drug is administered to patients at 25–50 µg/kg per day subcutaneously. Oprelvekin is approved for use in patients undergoing chemotherapy for nonmyeloid malignancies with severe thrombocytopenia (platelet count $< 20 \times 10^9/L$), and it is administered until the platelet count returns to more than $100 \times 10^9/L$. The major complications of therapy are fluid retention and associated cardiac symptoms, such as tachycardia, palpitation, edema, and shortness of breath; this is a significant concern in elderly patients and often requires concomitant therapy with diuretics. Also reported are blurred vision, injection site rash or erythema, and paresthesias.

Thrombopoietin Receptor Agonists

Thrombopoietin

Thrombopoietin, a glycoprotein produced by the liver, marrow stromal cells, and other organs, is the primary regulator of platelet production. Two forms of recombinant thrombopoietin have been tested for clinical use. One is a truncated version of the native protein, termed recombinant human megakaryocyte growth and development factor (rHuMGDF) that is covalently modified with polyethylene glycol to increase the circulatory $t_{1/2}$. The second is the full-length polypeptide termed recombinant human thrombopoietin (rHuTPO).

While use in thrombocytopenic clinical trial subjects was found to be safe, the use of rHuMGDF in a clinical trial of normal platelet donors, designed to boost the quantity of donated platelets, led to donor thrombocytopenia in several subjects due to the immunogenicity of this agent (Li et al., 2001). This experience led to both agents being abandoned for clinical use and to the development of small-molecular mimics of recombinant thrombopoietin, termed TRAs. Two of these agents are FDA approved for use in patients with immune thrombocytopenia (ITP), and one of the TRAs is also approved for use in patients with severe aplastic anemia (SAA) who have failed to respond to more conventional treatments. *Romiplostim* contains four copies of a small peptide that binds with high affinity to the thrombopoietin receptor, grafted onto an immunoglobulin scaffold. Romiplostim is safe and efficacious in patients with ITP (Kuter et al., 2008). The drug is administered weekly by subcutaneous injection, starting with a dose of 1 µg/kg, titrated to a maximum of 10 µg/kg, until the platelet count increases above $50 \times 10^9/L$. *Eltrombopag* is a small organic TRA that is administered orally; the recommended starting dose is 50 mg/d, titrated to 75 mg depending on platelet response. These and additional TRAs are undergoing clinical trials, in ITP and SAA, as well as in chemotherapy-induced thrombocytopenia and in several marrow disorders, including myelodysplastic syndromes.

Iron Deficiency and Other Hypochromic Anemias

The Bioavailability of Iron

Iron exists in the environment largely as ferric oxide, ferric hydroxide, and polymers. In this state, its biological availability is limited unless solubilized by acid or chelating agents. For example, bacteria and some plants produce high-affinity chelating agents that extract iron from the surrounding environment. Most mammals have little difficulty in acquiring iron; this is explained by ample iron intake and perhaps also by a greater efficiency in absorbing iron. Humans, however, appear to be an exception. Although total dietary intake of elemental iron in humans usually exceeds requirements, the bioavailability of the iron in the diet is limited.

HISTORICAL PERSPECTIVE

The modern understanding of iron metabolism began in 1937 with the work of McCance and Widdowson on iron absorption and excretion and Heilmeyer and Plotner's measurement of iron in plasma (Beutler, 2002). In 1947, Laurell described a plasma iron transport protein that he called *transferrin* (Laurell, 1951). Around the same time, Hahn and coworkers used radioisotopes to measure iron absorption and define the role of the intestinal mucosa to regulate this function (Hahn, 1948). In the next decade, Huff and associates initiated isotopic studies of internal iron metabolism. The subsequent development of practical clinical measurements of serum iron, transferrin saturation, plasma ferritin, and red cell protoporphyrin permitted the definition and detection of the body's iron store status and iron-deficient erythropoiesis. In 1994, Feder and colleagues identified the HFE gene, which is mutated in type 1 hemochromatosis (Feder et al., 1996). Subsequently, Ganz and colleagues discovered a peptide produced by the liver, which was termed *hepcidin* (Park et al., 2001), now known to be the master regulator of iron homeostasis and to play a role in anemia of chronic disease (Ganz and Nemeth, 2011).

Iron deficiency is the most common nutritional cause of anemia in humans. It can result from inadequate iron intake, malabsorption, blood loss, or an increased requirement, as with pregnancy. When severe, it results in a characteristic microcytic, hypochromic anemia. In addition to its role in hemoglobin, iron is an essential component of myoglobin, heme enzymes (e.g., cytochromes, catalase, and peroxidase), and the metalloflavoprotein enzymes (e.g., xanthine oxidase and α -glycerophosphate oxidase). Iron deficiency can affect metabolism in muscle independently of the effect of anemia on O_2 delivery. This may reflect a reduction in the activity of iron-dependent mitochondrial enzymes. Iron deficiency also has been associated with behavioral and learning problems in children, abnormalities in catecholamine metabolism, and possibly impaired heat production.

Metabolism of Iron

The body store of iron is divided between essential iron-containing compounds and excess iron, which is held in storage (Table 41-2). *Hemoglobin* dominates the essential fraction. Each hemoglobin molecule contains four atoms of iron, amounting to 1.1 mg (20 μ mol) of iron/mL of red blood cells. Other forms of essential iron include *myoglobin* and a variety of heme and nonheme iron-dependent enzymes. *Ferritin* is a protein-iron storage complex that exists as individual molecules or as aggregates. *Apo-ferritin* (MW ~ 450 kDa) is composed of 24 polypeptide subunits that form an outer shell around a storage cavity for polynuclear hydrous ferric oxide phosphate. More than 30% of the weight of ferritin may be iron (4000 atoms of iron per ferritin molecule). Ferritin aggregates, referred to as *hemosiderin* and visible by light microscopy, constitute about one-third of normal stores. The two predominant sites of iron storage are the reticuloendothelial system and the hepatocytes.

TABLE 41-2 ■ THE BODY CONTENT OF IRON

	BODY WEIGHT, mg/kg	
	MALE	FEMALE
Essential iron		
Hemoglobin	31	28
Myoglobin and enzymes	6	5
Storage iron	13	4
Total	50	37

Internal exchange of iron is accomplished by the plasma protein *transferrin*, a 76-kDa glycoprotein that has two binding sites for ferric iron. Iron is delivered from transferrin to intracellular sites by means of specific transferrin receptors in the plasma membrane. The iron-transferrin complex binds to the receptor, and the ternary complex is internalized through clathrin-coated pits by receptor-mediated endocytosis. A proton-pumping ATPase lowers the pH of the intracellular vesicular compartment (the endosomes) to about 5.5. Iron subsequently dissociates, and the receptor returns the apotransferrin to the cell surface, where it is released into the extracellular environment. Cells regulate their expression of transferrin receptors and intracellular ferritin in response to the iron supply (De Domenico et al., 2008). The synthesis of apoferritin and transferrin receptors is regulated posttranscriptionally by two iron-regulating proteins, IRP1 and IRP2. These IRPs are cytosolic RNA-binding proteins that bind to iron-regulating elements (IREs) present in the 5' or 3' untranslated regions of mRNA encoding apoferritin or the transferrin receptors, respectively. Binding of these IRPs to the 5' IRE of apoferritin mRNA represses translation, whereas binding to the 3' IRE of mRNA encoding the transferrin receptors enhances transcript stability, thereby increasing protein production.

The flow of iron through the plasma amounts to a total of 30–40 mg/d in the adult (~0.46 mg/kg of body weight). The major internal circulation of iron involves the erythron and reticuloendothelial cells (Figure 41-3). About 80% of the iron in plasma goes to the erythroid marrow to be packaged into new erythrocytes; these normally circulate for about 120 days before being catabolized by the reticuloendothelial system. At that time, a portion of the iron is immediately returned to the plasma bound to transferrin, while another portion is incorporated into the ferritin stores of reticuloendothelial cells and returned to the circulation more gradually. With abnormalities in erythrocyte maturation, the predominant portion of iron assimilated by the erythroid marrow may be rapidly localized in the reticuloendothelial cells as defective red cell precursors are broken down; this is termed *ineffective erythropoiesis*. The rate of iron turnover in plasma may be reduced by half or more with red cell aplasia, with all the iron directed to the hepatocytes for storage.

The human body conserves its iron stores to a remarkable degree. Only 10% of the total is lost per year by normal men (i.e., ~ 1 mg/d). Two-thirds of this iron is excreted from the GI tract as extravasated red cells, iron in bile, and iron in exfoliated mucosal cells. The other third is accounted for by small amounts of iron in desquamated skin and in the urine. Additional losses of iron occur in women due to menstruation. Although the average loss in menstruating women is about 0.5 mg per day, 10% of menstruating

Figure 41-3 Iron metabolism in humans (excretion omitted).

TABLE 41-3 ■ IRON REQUIREMENTS FOR PREGNANCY

	AVERAGE (mg)	RANGE (mg)
External iron loss	170	150–200
Expansion of red cell mass	450	200–600
Fetal iron	270	200–370
Iron in placenta and cord	90	30–170
Blood loss at delivery	150	90–310
Total requirement ^a	980	580–1340
Cost of pregnancy ^b	680	440–1050

^aBlood loss at delivery not included.
^bIron lost by the mother; expansion of red cell mass not included.

women lose more than 2 mg per day. Pregnancy and lactation impose an even greater requirement for iron (Table 41-3). Other causes of iron loss include blood donation, the use of anti-inflammatory drugs that cause bleeding from the gastric mucosa, and GI disease with associated bleeding.

The limited physiological losses of iron point to the primary importance of absorption in determining the body's iron content (Garrick and Garrick, 2009). After acidification and partial digestion of food in the stomach, iron is presented to the intestinal mucosa as either inorganic iron or heme iron. A ferriredutase, duodenal cytochrome B, located on the luminal surface of absorptive cells of the duodenum and upper small intestine, reduces the iron to the ferrous state, which is the substrate for divalent metal (ion) transporter 1 (DMT1, SLC11A2). DMT1 transports the iron to the basolateral membrane, where it is taken up by another transporter, *ferroportin* (Fpn; SLC40A1), and subsequently reoxidized to Fe³⁺, primarily by *hephaestin* (Hp; *HEPH*), a transmembrane copper-dependent ferroxidase. Apotransferrin binds the resultant oxidized Fe³⁺. The hepatic protein, hepcidin, binds to ferroportin, inducing its internalization and degradation, thus limiting the amount of iron released into the blood (Camaschella, 2013). Conditions that enhance the levels of hepcidin, such as inflammation, can result in decreased gut iron absorption, reduced serum iron, and inadequate iron available for developing red blood cells. Conversely, when hepcidin levels are low, such as in hemochromatosis, iron overload occurs due to excessive ferroportin-mediated iron influx.

Genetic polymorphism and consequent dysfunction in hepcidin or in proteins regulating its expression can result in inadequate levels of hepcidin and cause hereditary hemochromatosis (Pietrangelo, 2016). This can be due to polymorphism in *HFE*, resulting in a Cys→Tyr change at position 282 (C282Y) in the HFE protein, or pathogenic mutations in

hepcidin (*HAMP*), ferroportin (*FPN*), hemojuvelin (*HJV*), or transferrin receptor 2 (*TfR2*). The phenotype may vary, ranging from severe, as in *HJV*- or *HAMP*-juvenile-onset hemochromatosis, to relatively milder forms of adult-onset hemochromatosis, resulting from defects in *FPN* or *TfR2*. Acquired hemochromatosis can result from excessive amounts of parenteral iron, such as may occur in multiple transfusions for hereditary anemia or acquired aplastic anemia, from loss of hepcidin-producing liver mass, or with disease factors such as hepatitis C or chronic alcoholism that impair the production of hepcidin.

Iron Requirements; Availability of Dietary Iron

Adult men must absorb only 13 µg of iron/kg of body weight/d (~1 mg/d), whereas menstruating women require about 21 µg/kg (~1.4 mg) per day. In the last two trimesters of pregnancy, requirements increase to about 80 µg/kg (5–6 mg) per day; infants have similar requirements due to their rapid growth (Table 41-4).

The difference between dietary supply and requirements is reflected in the size of iron stores, which are low or absent when iron balance is precarious and high when iron balance is favorable. In infants after the third month of life and in pregnant women after the first trimester, stores of iron are negligible. Menstruating women have approximately one-third the stored iron found in adult men (see Table 41-2).

Although the iron content of the diet obviously is important, of greater nutritional significance is the bioavailability of iron in food. Heme iron, which constitutes only 6% of dietary iron, is far more available and is absorbed independent of the diet composition; it therefore represents 30% of iron absorbed (Conrad and Umbreit, 2000). The nonheme fraction represents the larger amount of dietary iron ingested by the economically underprivileged. In a vegetarian diet, nonheme iron is absorbed poorly because of the inhibitory action of a variety of dietary components, particularly phosphates. Ascorbic acid and meat facilitate the absorption of nonheme iron. In developed countries, the normal adult diet contains about 6 mg of iron per 1000 calories, providing an average daily intake for adult men of between 12 and 20 mg and for adult women of between 8 and 15 mg. Foods high in iron (>5 mg/100 g) include organ meats such as liver and heart, brewer's yeast, wheat germ, egg yolks, oysters, and certain dried beans and fruits; foods low in iron (<1 mg/100 g) include milk and milk products and most nongreen vegetables. Iron also may be added from cooking in iron pots. In assessing dietary iron intake, it is important to consider not only the amount of iron ingested but also its bioavailability.

Iron Deficiency

The prevalence of iron deficiency anemia in the U.S. is on the order of 1%–4% and depends on the economic status of the population (McLean et al., 2009). In developing countries, up to 20%–40% of infants and pregnant women may be affected. Better iron balance has resulted from the practice of fortifying flour, the use of iron-fortified formulas

TABLE 41-4 ■ DAILY IRON ABSORPTION REQUIREMENT

SUBJECT	IRON REQUIREMENT (µg/kg)	AVAILABLE IRON POOR DIET–GOOD DIET (µg/kg)	SAFETY FACTOR: AVAILABLE/REQUIREMENT
Infant	67	33–66	0.5–1
Child	22	48–96	2–4
Adolescent (male)	21	30–60	1.5–3
Adolescent (female)	20	30–60	1.5–3
Adult (male)	13	26–52	2–4
Adult (female)	21	18–36	1–2
Mid-to-late pregnancy	80	18–36	0.22–0.45

The numbers in columns 2 and 3 refer to iron absorption via the GI tract in micrograms per kilogram body weight. As noted in Figure 41-3, of 14.4 mg of dietary iron presented to the GI tract each day, only about 1 mg is absorbed. See text concerning factors influencing iron absorption and differential absorption of heme versus nonheme iron.

for infants, and the prescription of medicinal iron supplements during pregnancy.

Iron deficiency anemia results from dietary intake of iron that is inadequate to meet normal requirements (nutritional iron deficiency), blood loss, or interference with iron absorption (Camaschella, 2015). More severe iron deficiency is usually the result of blood loss, either from the GI tract or, in women, from the uterus. Finally, treatment of patients with erythropoietin can result in a functional iron deficiency. Iron deficiency in infants and young children can lead to behavioral disturbances and can impair development, which may not be fully reversible. Iron deficiency in children also can lead to an increased risk of lead toxicity secondary to pica and an increased absorption of heavy metals. Premature and low-birthweight infants are at greatest risk for developing iron deficiency, especially if they are not breast fed or do not receive iron-fortified formula (Finch, 2015). After the age of 2–3 years, the requirement for iron declines until adolescence, when rapid growth combined with irregular dietary habits again increase the risk of iron deficiency. Adolescent girls are at greatest risk; the dietary iron intake of most girls ages 11–18 is insufficient to meet their requirements.

Treatment of Iron Deficiency

General Therapeutic Principles

The response of iron deficiency anemia to iron therapy is influenced by several factors, including the severity of anemia, the ability of the patient to tolerate and absorb medicinal iron, and the presence of other complicating illnesses. Therapeutic effectiveness is best measured by the resulting increase in the rate of production of red cells. The magnitude of the marrow response to iron therapy is proportional to the severity of the anemia (level of erythropoietin stimulation) and the amount of iron delivered to marrow precursors.

The patient's ability to tolerate and absorb medicinal iron is a key factor in determining the rate of response to therapy. The small intestine regulates absorption and, with increasing doses of oral iron, limits the entry of iron into the bloodstream. This provides a natural ceiling on how much iron can be supplied by oral therapy. In the patient with moderately severe iron deficiency anemia, tolerable doses of oral iron will deliver, at most, 40–60 mg of iron per day to the erythroid marrow. This is an amount sufficient for production rates of two to three times normal.

Clinically, the effectiveness of iron therapy is best evaluated by tracking the reticulocyte response and the rise in the hemoglobin or the hematocrit. An increase in the reticulocyte count is not observed for at least 4–7 days after beginning therapy. A measurable increase in the hemoglobin level takes even longer. A decision regarding the effectiveness of treatment should not be made for 3–4 weeks after the start of treatment. An increase of 20 g/L or more in the concentration of hemoglobin by that time should be considered a positive response, assuming that no other change in the patient's clinical status can account for the improvement and that the patient has not been transfused.

If the response to oral iron is inadequate, the diagnosis must be reconsidered. A full laboratory evaluation should be conducted, and poor compliance by the patient or the presence of a concurrent inflammatory disease must be explored. A source of continued bleeding obviously should be sought. If no other explanation can be found, an evaluation of the patient's ability to absorb oral iron should be considered. There is no justification for merely continuing oral iron therapy beyond 3–4 weeks if a favorable response has not occurred.

Once a response to oral iron is demonstrated, therapy should be continued until the hemoglobin returns to normal. Treatment may be extended if it is desirable to replenish iron stores. This may require a considerable period of time because the rate of absorption of iron by the intestine will decrease markedly as iron stores are reconstituted. The prophylactic use of oral iron should be reserved for patients at high risk, including pregnant women, women with excessive menstrual blood loss, and infants. Iron supplements also may be of value for rapidly growing infants who are consuming substandard diets and for adults with a recognized cause of chronic blood loss. Except for infants, in whom the use of supplemented

formulas is routine, the use of over-the-counter mixtures of vitamins and minerals to prevent iron deficiency should be discouraged.

Therapy With Oral Iron

Orally administered ferrous sulfate is the treatment of choice for iron deficiency. Ferrous salts are absorbed about three times as well as ferric salts. Variations in the particular ferrous salt have relatively little effect on bioavailability; the sulfate, fumarate, succinate, gluconate, aspartate, other ferrous salts, and polysaccharide-ferrihydrite complex are absorbed to approximately the same extent. The effective dose of all of these preparations is based on iron content.

Other iron compounds have utility in fortification of foods. Reduced iron (metallic iron, elemental iron) is as effective as ferrous sulfate, provided that the material employed has a small particle size. Large-particle ferrum reductum and iron phosphate salts have much lower bioavailability. Ferric edetate has been shown to have good bioavailability and to have advantages for maintenance of the normal appearance and taste of food. The amount of iron in iron tablets is important. It also is essential that the coating of the tablet dissolve rapidly in the stomach. Delayed-release preparations are available, but absorption from such preparations varies. Ascorbic acid (≥ 200 mg) increases the absorption of medicinal iron by at least 30%. However, the increased uptake is associated with an increase in the incidence of side effects. Preparations that contain other compounds with therapeutic action, such as vitamin B₁₂, folate, or cobalt, are not recommended because the patient's response to the combination cannot easily be interpreted.

The average dose for the treatment of iron deficiency anemia is about 200 mg of iron per day (2–3 mg/kg), given in three equal doses of 65 mg. Children weighing 15–30 kg can take half the average adult dose; small children and infants can tolerate relatively large doses of iron (e.g., 5 mg/kg). When the object is the prevention of iron deficiency in pregnant women, for example, doses of 15 to 30 mg of iron per day are adequate. Bioavailability of iron is reduced with food and by concurrent antacids. For a rapid response or to counteract continued bleeding, as much as 120 mg of iron may be administered four times a day.

The duration of treatment is governed by the rate of recovery of hemoglobin (Table 41–5) and the desire to create iron stores. The former depends on the severity of the anemia. With a daily rate of repair of 2 g of hemoglobin per liter of whole blood, the red cell mass usually is reconstituted within 1–2 months. Thus, an individual with a hemoglobin of 50 g per liter may achieve a normal complement of 150 g/L in about 50 days, whereas an individual with a hemoglobin of 100 g/L may take only half that time. The creation of stores of iron requires many months of oral iron administration. The rate of absorption decreases rapidly after recovery from anemia, and after 3–4 months of treatment, stores may increase at a rate of not much more than 100 mg/month. Much of the strategy of continued therapy depends on the estimated future iron balance. Patients with an inadequate diet may require continued therapy with low doses of iron. If the bleeding has stopped, no further therapy is required after the hemoglobin has returned to normal. With continued bleeding, long-term, high-dose therapy clearly is indicated.

Untoward Effects of Oral Preparations of Iron. Side effects of oral iron preparations include heartburn, nausea, upper gastric discomfort, and diarrhea or constipation. A good policy is to initiate

TABLE 41–5 ■ AVERAGE RESPONSE TO ORAL IRON

TOTAL DOSE OF IRON (mg/d)	ESTIMATED ABSORPTION		INCREASE IN BLOOD HEMOGLOBIN (g/L/d)
	%	mg	
35	40	14	0.7
105	24	25	1.4
195	18	35	1.9
390	12	45	2.2

therapy at a small dosage and then gradually to increase the dosage to that desired. Only individuals with underlying disorders that augment the absorption of iron run the hazard of developing iron overload (hemochromatosis).

Iron Poisoning. Large amounts of ferrous salts are toxic, but fatalities are rare in adults. Most deaths occur in children, particularly between the ages of 12 and 24 months. As little as 1–2 g of iron may cause death, but 2–10 g usually is ingested in fatal cases. All iron preparations should be kept in childproof bottles. Signs and symptoms of severe poisoning may occur within 30 min after ingestion or may be delayed for several hours. They include abdominal pain, diarrhea, or vomiting of brown or bloody stomach contents containing pills. Of particular concern are pallor or cyanosis, lassitude, drowsiness, hyperventilation due to acidosis, and cardiovascular collapse. If death does not occur within 6 h, there may be a transient period of apparent recovery, followed by death in 12–24 h. The corrosive injury to the stomach may result in pyloric stenosis or gastric scarring.

In the evaluation of a child thought to have ingested iron, a color test for iron in the gastric contents and determination of the concentration of iron in plasma can be performed. If the latter is less than 63 μmol (3.5 mg/L), the child is not in immediate danger. However, vomiting should be induced when there is iron in the stomach, and an X-ray should be taken to evaluate the number of pills remaining in the small bowel (iron tablets are radiopaque). When the plasma concentration of iron is greater than the total iron-binding capacity (63 μmol ; 3.5 mg/L), *deferoxamine* should be administered (see Chapter 71). The speed of diagnosis and therapy is important. With early treatment, the mortality from iron poisoning can be reduced from 45% to about 1%. *Deferiprone* and *deferasirox* are oral iron chelators approved by the FDA for treatment of patients with thalassemia who have iron overload.

Therapy With Parenteral Iron

When oral iron therapy fails, parenteral iron administration may be an effective alternative. Common indications are iron malabsorption (e.g., sprue, short-bowel syndrome), severe oral iron intolerance, as a routine supplement to total parenteral nutrition, and in patients who are receiving erythropoietin. Parenteral iron can be given to iron-deficient patients and pregnant women to create iron stores, something that would take months to achieve by the oral route. The indications for parenteral iron therapy include documented iron deficiency and intolerance or irresponsiveness to oral iron.

The rate of hemoglobin response is determined by the balance between the severity of the anemia (the level of erythropoietin stimulus) and the delivery of iron to the marrow from iron absorption and iron stores. When a large intravenous dose of iron dextran is given to a severely anemic patient, the hematologic response can exceed that seen with oral iron for 1–3 weeks. Subsequently, however, the response is no better than that seen with oral iron.

Parenteral iron therapy should be used only when clearly indicated because acute hypersensitivity, including anaphylactic and anaphylactoid reactions, can occur. Other reactions to intravenous iron include headache, malaise, fever, generalized lymphadenopathy, arthralgias, urticaria, and, in some patients with rheumatoid arthritis, exacerbation of the disease.

Several iron formulations are available in the U.S. (Larson and Coyne, 2014). These include iron dextran, sodium ferric gluconate, ferumoxytol, iron sucrose, and ferric carboxymaltose. Ferumoxytol is a semisynthetic carbohydrate-coated superparamagnetic iron oxide nanoparticle approved for treatment of iron deficiency anemia in patients with chronic kidney disease; the ferumoxytol has to be administered safely as a 1.02-g infusion over a relatively short infusion time of 15 min (Auerbach et al., 2013). Indications for ferric gluconate and iron sucrose are limited to patients with chronic kidney disease and documented iron deficiency, although broader applications are being advocated (Larson and Coyne, 2014).

Iron Dextran. Iron dextran injection is a colloidal solution of ferric oxyhydroxide complexed with polymerized dextran (molecular weight $\sim 180,000$ Da) that contains 50 mg/mL of elemental iron. The use of

low-molecular-weight iron dextran has reduced the incidence of toxicity relative to that observed with high-molecular-weight preparations. Iron dextran can be administered by intravenous (preferred) or intramuscular injection. Injection of a therapeutic dose should be initiated only after a test dose of 0.5 mL (25 mg of iron). Given intravenously in a dose less than 500 mg, the iron dextran complex is cleared with a plasma $t_{1/2}$ of 6 h. When 1 g or more is administered intravenously as total-dose therapy, reticuloendothelial cell clearance is constant at 10–20 mg/h.

Intramuscular injection of iron dextran should be initiated only after a test dose of 0.5 mL (25 mg of iron). If no adverse reactions are observed, the injections can proceed. The daily dose ordinarily should not exceed 0.5 mL (25 mg of iron) for infants weighing less than 4.5 kg, 1 mL (50 mg of iron) for children weighing less than 9 kg, and 2 mL (100 mg of iron) for other patients. However, local reactions and the concern about malignant change at the site of injection make intramuscular administration inappropriate except when the intravenous route is inaccessible. The patient should be observed for signs of immediate anaphylaxis and for an hour after injection for any signs of vascular instability or hypersensitivity, including respiratory distress, hypotension, tachycardia, or back or chest pain. Delayed hypersensitivity reactions also are observed, especially in patients with rheumatoid arthritis or a history of allergies. Fever, malaise, lymphadenopathy, arthralgias, and urticaria can develop days or weeks following injection and last for prolonged periods of time. Use iron dextran with extreme caution in patients with rheumatoid arthritis or other connective tissue diseases and during the acute phase of an inflammatory illness. Once hypersensitivity is documented, iron dextran therapy must be abandoned.

With multiple total-dose infusions such as those sometimes used in the treatment of chronic GI blood loss, accumulations of slowly metabolized iron dextran stores in reticuloendothelial cells can be impressive. The plasma ferritin level also can rise to levels associated with iron overload. It seems prudent, however, to withhold the drug whenever the plasma ferritin rises above 800 $\mu\text{g/L}$.

Sodium Ferric Gluconate. Sodium ferric gluconate is an intravenous iron preparation with a molecular size of about 295 kDa and an osmolality of 990 mOsm/kg⁻¹. Administration of ferric gluconate at doses ranging from 62.5 to 125 mg during hemodialysis is associated with transferrin saturation exceeding 100%. Unlike iron dextran, which requires processing by macrophages that may require several weeks, about 80% of sodium ferric gluconate is delivered to transferrin within 24 h. Sodium ferric gluconate also has a lower risk of inducing serious anaphylactic reactions than iron dextran (Sengolge et al., 2005).

Iron Sucrose. Iron sucrose is a complex of polynuclear iron (III)-hydroxide in sucrose (Beguin and Jaspers, 2014). Following intravenous injection, the complex is taken up by the reticuloendothelial system, where it dissociates into iron and sucrose. Iron sucrose is generally administered in daily amounts of 100–200 mg within a 14-day period to a total cumulative dose of 1000 mg. Like sodium ferric gluconate, iron sucrose appears to be better tolerated and to cause fewer adverse events than iron dextran (Hayat, 2008). This agent is FDA-approved for the treatment of iron deficiency in patients with chronic kidney disease. Chronic use has the potential to cause renal tubulointerstitial damage (Agarwal, 2006).

Ferric Carboxymaltose. Ferric carboxymaltose is an iron complex consisting of a ferric hydroxide core and a carbohydrate shell (Keating, 2015). With this preparation, a replenishment dose of up to 1000 mg of iron can be administered in 15 min. Intravenous administration results in transient elevations in serum iron, serum ferritin, and transferrin saturation, with subsequent correction in hemoglobin levels and replenishment of depleted iron stores. Ferric carboxymaltose is rapidly cleared from the circulation, becoming distributed ($\sim 80\%$) in the marrow, as well as the liver and spleen. Common reported drug-related adverse effects include headache, dizziness, nausea, abdominal pain, constipation, diarrhea, rash, and injection site reactions. However, the incidence of drug-related adverse events appears similar to those of patients treated with oral ferrous sulfate.

Ferric carboxymaltose is FDA-approved for therapy of iron deficiency anemia.

Copper, Pyridoxine, and Riboflavin

Copper

Copper has redox properties similar to those of iron, which simultaneously are essential and potentially toxic to the cell. Cells have virtually no free copper. Instead, copper is stored by metallothioneins and distributed by specialized chaperones to sites that make use of its redox properties. Transfer of copper to nascent cuproenzymes is performed by individual or collective activities of P-type ATPases, ATP7A and ATP7B, which are expressed in all tissues (Nevitt et al., 2012). In mammals, the liver is the organ most responsible for the storage, distribution, and excretion of copper. Mutations in ATP7A or ATP7B that interfere with this function have been found responsible for Wilson disease or Menkes syndrome (steely hair syndrome) (de Bie et al., 2007), respectively, which can result in life-threatening hepatic failure.

Copper deficiency is extremely rare; the amount present in food is more than adequate to provide the needed body complement of slightly more than 100 mg. Even in clinical states associated with hypocupremia (sprue, celiac disease, and nephrotic syndrome), effects of copper deficiency usually are not demonstrable. Anemia due to copper deficiency has been described in individuals who have undergone intestinal bypass surgery, in those who are receiving parenteral nutrition, in malnourished infants, and in patients ingesting excessive amounts of zinc (Willis et al., 2005). Copper deficiency interferes with the absorption of iron and its release from reticuloendothelial cells. In humans, the prominent findings have been leukopenia, particularly granulocytopenia, and anemia. Concentrations of iron in plasma are variable, and the anemia is not always microcytic. When a low plasma copper concentration is determined in the presence of leukopenia and anemia, a therapeutic trial with copper is appropriate. Daily doses up to 0.1 mg/kg of cupric sulfate have been given by mouth, or 1–2 mg per day may be added to the solution of nutrients for parenteral administration.

Pyridoxine

Patients with either hereditary or acquired sideroblastic anemia characteristically have impaired hemoglobin synthesis and accumulate iron in the perinuclear mitochondria of erythroid precursor cells, so-called ringed sideroblasts. Hereditary sideroblastic anemia is an X-linked recessive trait with variable penetrance and expression that results from mutations in the erythrocyte form of δ -aminolevulinate synthase.

Oral therapy with pyridoxine is of proven benefit in correcting the sideroblastic anemias associated with the antituberculosis drugs isoniazid and pyrazinamide, which act as vitamin B₆ antagonists. A daily dose of 50 mg of pyridoxine completely corrects the defect without interfering with treatment, and routine supplementation of pyridoxine often is recommended (see Chapter 56). In contrast, if pyridoxine is given to counteract the sideroblastic abnormality associated with administration of levodopa, the effectiveness of levodopa in controlling Parkinson disease is decreased. Pyridoxine therapy does not correct the sideroblastic abnormalities produced by chloramphenicol or lead. Patients with idiopathic acquired sideroblastic anemia generally fail to respond to oral pyridoxine, and those individuals who appear to have a pyridoxine-responsive anemia require prolonged therapy with large doses of the vitamin, 50–500 mg/d. The occasional patient who is refractory to oral pyridoxine may respond to parenteral administration of pyridoxal phosphate. However, oral pyridoxine in doses of 200–300 mg per day produces intracellular concentrations of pyridoxal phosphate equal to or greater than those generated by therapy with the phosphorylated vitamin.

Riboflavin

The spontaneous appearance in humans of red cell aplasia due to riboflavin deficiency undoubtedly is rare, if it occurs at all. Riboflavin deficiency has been described in combination with infection and protein deficiency, both of which are capable of producing hypoproliferative anemia. However, it seems reasonable to include riboflavin in the nutritional management of patients with gross, generalized malnutrition.

Vitamin B₁₂, Folic Acid, and the Treatment of Megaloblastic Anemias

Vitamin B₁₂ and folic acid are dietary essentials. A deficiency of either vitamin impairs DNA synthesis in any cell in which chromosomal replication and division are taking place. Because tissues with the greatest rate of cell turnover show the most dramatic changes, the hematopoietic system is especially sensitive to deficiencies of these vitamins.

Cellular Roles of Vitamin B₁₂ and Folic Acid

The major roles of vitamin B₁₂ and folic acid in intracellular metabolism are summarized in Figure 41–4. Intracellular vitamin B₁₂ is maintained as two active coenzymes: *methylcobalamin* and *deoxyadenosylcobalamin*.

Methylcobalamin (CH₃B₁₂) supports the *methionine synthetase* reaction, which is essential for normal metabolism of folate (Weissbach, 2008). Methyl groups contributed by methyltetrahydrofolate (CH₃H₄PteGlu) are used to form methylcobalamin, which then acts as a methyl group donor for the conversion of homocysteine to methionine. This folate-cobalamin interaction is pivotal for normal synthesis of purines and pyrimidines, and therefore of DNA. The methionine synthetase reaction is largely responsible for the control of the recycling of folate cofactors; the maintenance of intracellular concentrations of folylpolyglutamates; and, through the synthesis of methionine and its product SAM, the maintenance of a number of methylation reactions.

Deoxyadenosylcobalamin (deoxyadenosyl B₁₂) is a cofactor for the *mitochondrial mutase* enzyme that catalyzes the isomerization of l-methylmalonyl CoA to succinyl CoA, an important reaction in

HISTORY

The discovery of vitamin B₁₂ and folic acid is a dramatic story that began almost 200 years ago and includes two Nobel Prize-winning discoveries. Beginning in 1824, Combe and Addison wrote a series of case reports describing what must have been megaloblastic anemias (still known as Addisonian pernicious anemia). Austin Flint in 1860 first described a severe gastric atrophy and called attention to its possible relationship to the anemia. After Whipple's observation in 1925 that liver is a source of a potent hematopoietic substance for iron-deficient dogs, Minot and Murphy carried out Nobel Prize-winning experiments that demonstrated the effectiveness of the feeding of liver to reverse pernicious anemia. Soon thereafter, Castle defined the need for both intrinsic factor, a substance secreted by the parietal cells of the gastric mucosa, and extrinsic factor, the vitamin-like material provided by crude liver extracts. Nearly 20 years passed before Rickes and coworkers and Smith and Parker isolated and crystallized vitamin B₁₂; Dorothy Hodgkin received the Nobel Prize for determining its X-ray crystal structure.

As attempts were being made to purify extrinsic factor, Wills and her associates described a macrocytic anemia in women in India that responded to a factor present in crude liver extracts but not in the purified fractions known to be effective in pernicious anemia. This factor, first called Wills' factor and later vitamin M, is now known to be folic acid. The term *folic acid* was coined by Mitchell and coworkers in 1941, after its isolation from leafy vegetables. From more recent work, we know that neither vitamin B₁₂ nor folic acid as purified from foodstuffs is the active coenzyme in humans. During extraction, active labile forms are converted to stable congeners of vitamin B₁₂ and folic acid, cyanocobalamin and PteGlu, respectively. These congeners must be modified *in vivo* to be effective. Despite our knowledge of the intracellular metabolic pathways in which these vitamins function as required cofactors, many questions remain, among them, What is the relationship of vitamin B₁₂ deficiency to the neurological abnormalities that occur in megaloblastic anemia?

Figure 41-4 Interrelationships and metabolic roles of vitamin B₁₂ and folic acid. See text for explanation and Figure 41-5 for structures of the various folate coenzymes. FIGLU, formiminoglutamic acid, which arises from the catabolism of histidine; TcII, transcobalamin II.

carbohydrate and lipid metabolism. This reaction has no direct relationship to the metabolic pathways that involve folate.

Because methyltetrahydrofolate is the principal folate congener supplied to cells, the transfer of the methyl group to cobalamin is essential for the adequate supply of tetrahydrofolate (H₄PteGlu₁). Tetrahydrofolate is a precursor for the formation of intracellular folylpolyglutamates; it also acts as the acceptor of a one-carbon unit in the conversion of serine to glycine, with the resultant formation of 5,10-methylenetetrahydrofolate (5,10-CH₂H₄PteGlu). The last derivative donates the methylene group to dUMP for the synthesis of dTMP—an extremely important reaction in DNA synthesis. In the process, the 5,10-CH₂H₄PteGlu is converted to dihydrofolate (H₂PteGlu). The cycle then is completed by the reduction of the H₂PteGlu to H₄PteGlu by dihydrofolate reductase, the step that is blocked by folate antagonists such as methotrexate (see Chapter 66). As shown in Figure 41-4, other pathways also lead to the synthesis of 5,10-methylenetetrahydrofolate. These pathways are important in the metabolism of FIGLU and purines and pyrimidines.

Deficiency of either vitamin B₁₂ or folate decreases the synthesis of methionine and SAM and consequently interferes with protein biosynthesis, a number of methylation reactions, and the synthesis of polyamines. In addition, the cell responds to the deficiency by redirecting folate metabolic pathways to supply increasing amounts of methyltetrahydrofolate; this tends to preserve essential methylation reactions at the expense of nucleic acid synthesis. With vitamin B₁₂ deficiency, methylenetetrahydrofolate reductase activity increases, directing available intracellular folates into the methyltetrahydrofolate pool (not shown in Figure 41-4). The methyltetrahydrofolate then is trapped by the lack of sufficient vitamin B₁₂ to accept and transfer methyl groups, and subsequent steps in folate metabolism that require tetrahydrofolate are deprived of substrate. This process provides a common basis for the development of megaloblastic anemia with deficiency of either vitamin B₁₂ or folic acid.

The mechanisms responsible for the neurological lesions of vitamin B₁₂ deficiency are less well understood (Solomon, 2007). Damage to the myelin sheath is the most obvious lesion in this neuropathy. This observation led to the early suggestion that the deoxyadenosyl B₁₂-dependent methylmalonyl CoA mutase reaction, a step in propionate metabolism, is related to the abnormality. However, other evidence suggests that the deficiency of methionine synthetase and the block of the conversion of methionine to SAM are more likely to be responsible.

Vitamin B₁₂ and Human Health

Humans depend on exogenous sources of vitamin B₁₂ (see structure in Figure 41-5). In nature, the primary sources are certain microorganisms that grow in soil or the intestinal lumen of animals that synthesize the vitamin. The daily nutritional requirement of 3–5 µg must generally be obtained from animal by-products in the diet. However, some vitamin B₁₂ is available from legumes, which are contaminated with bacteria that can synthesize vitamin B₁₂, and vegetarians often fortify their diets with a wide range of vitamins and minerals; thus, strict vegetarians rarely develop vitamin B₁₂ deficiency. The terms *vitamin B₁₂* and *cyanocobalamin* are used interchangeably as generic terms for all of the cobamides active in humans. Preparations of vitamin B₁₂ for therapeutic use contain either cyanocobalamin or hydroxocobalamin because only these derivatives remain active after storage.

Metabolic Functions. The active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin are essential for cell growth and replication. Methylcobalamin is required for the conversion of homocysteine to methionine and its derivative S-adenosylmethionine. In addition, when concentrations of vitamin B₁₂ are inadequate, folate becomes “trapped” as methyltetrahydrofolate to cause a functional deficiency of other required intracellular forms of folic acid. The hematologic abnormalities in vitamin B₁₂-deficient patients result from this process. Deoxyadenosylcobalamin is required for the rearrangement of methylmalonyl CoA to succinyl CoA.

ADME and Daily Requirements

In the presence of gastric acid and pancreatic proteases, dietary vitamin B₁₂ is released from food and salivary-binding protein and bound to gastric intrinsic factor. When the vitamin B₁₂-intrinsic factor complex reaches the ileum, it interacts with a receptor on the mucosal cell surface and is actively transported into circulation. Vitamin B₁₂ deficiency in adults is rarely the result of a deficient diet per se; rather, it usually reflects a defect in one or another aspect of this complex sequence of absorption (Figure 41-6). Antibodies to parietal cells or intrinsic factor complex also can play a prominent role in producing a deficiency. Several intestinal conditions can interfere with absorption, including pancreatic disorders (loss of pancreatic protease secretion), bacterial overgrowth, intestinal parasites, sprue, and localized damage to ileal mucosal cells by disease or as a result of surgery.

Absorbed vitamin B₁₂ binds to transcobalamin II, a plasma β globulin, for transport to tissues. The supply of vitamin B₁₂ available for tissues is

Figure 41-5 The structures and nomenclature of vitamin B₁₂ congeners. The vitamin B₁₂ molecule has three major portions: (1) a planar group porphyrin-like ring structure with four reduced pyrrole rings (A–D) linked to a central cobalt atom and extensively substituted with methyl, acetamide, and propionamide residues; (2) a 5,6-dimethylbenzimidazolyl nucleotide, which links almost at right angles to the planar nucleus with bonds to the cobalt atom and to the propionate side chain of the C pyrrole ring; and (3) a variable R group—the most important of which are found in the stable compounds cyanocobalamin and hydroxocobalamin and the active coenzymes methylcobalamin and 5-deoxyadenosylcobalamin.

directly related to the size of the hepatic storage pool and the amount of vitamin B₁₂ bound to transcobalamin II (see Figure 41-6). Vitamin B₁₂ bound to transcobalamin II is rapidly cleared from plasma and preferentially distributed to hepatic parenchymal cells. As much as 90% of the body's stores of vitamin B₁₂, from 1 to 10 mg, is in the liver. Vitamin B₁₂ is stored as the active coenzyme with a turnover rate of 0.5–8 µg per day. The recommended daily intake of the vitamin in adults is 2.4 µg. Approximately 3 µg of cobalamins are secreted into bile each day, 50%–60% of which is not destined for reabsorption. Interference with reabsorption by intestinal disease can progressively deplete hepatic stores of the vitamin.

Vitamin B₁₂ Deficiency

The plasma concentration of vitamin B₁₂ is the best routine measure of B₁₂ deficiency and normally ranges from 150 to 660 pM (~200–900 pg/mL).

Figure 41-6 Absorption and distribution of vitamin B₁₂. Deficiency of vitamin B₁₂ can result from a congenital or acquired defect in (1) inadequate dietary supply; (2) inadequate secretion of intrinsic factor (classical pernicious anemia); (3) ileal disease; (4) congenital absence of TcII; or (5) rapid depletion of hepatic stores by interference with reabsorption of vitamin B₁₂ excreted in bile. The utility of measurements of the concentration of vitamin B₁₂ in plasma to estimate supply available to tissues can be compromised by liver disease and (6) the appearance of abnormal amounts of TcI and TcIII in plasma. The formation of methylcobalamin requires (7) normal transport into cells and an adequate supply of folic acid as CH₃H₄PteGlu.

Deficiency should be suspected whenever the concentration falls below 150 pM. The correlation is excellent except when the plasma concentrations of transcobalamin I and III are increased, as occurs with hepatic disease or a myeloproliferative disorder. Inasmuch as the vitamin B₁₂ bound to these transport proteins is relatively unavailable to cells, tissues can become deficient when the concentration of vitamin B₁₂ in plasma is normal or even high. In subjects with congenital absence of transcobalamin II, megaloblastic anemia occurs despite relatively normal plasma concentrations of vitamin B₁₂; the anemia will respond to parenteral doses of vitamin B₁₂ that exceed the renal clearance.

Vitamin B₁₂ deficiency is recognized clinically by its impact on the hematopoietic and nervous systems. The sensitivity of the hematopoietic system relates to its high rate of cell turnover. Other tissues with high rates of cell turnover (e.g., mucosa and cervical epithelium) also have high requirements for the vitamin. As a result of an inadequate supply of vitamin B₁₂, DNA replication becomes highly abnormal. Once a hematopoietic stem cell is committed to enter a programmed series of cell divisions, the defect in chromosomal replication results in an inability of maturing cells to complete nuclear divisions while cytoplasmic maturation continues at a relatively normal rate. This results in the production of morphologically abnormal cells and death of cells during maturation, a phenomenon referred to as *ineffective hematopoiesis*. Severe deficiency affects all cell lines, and pronounced pancytopenia results.

The diagnosis of a vitamin B₁₂ deficiency usually can be made using measurements of the serum vitamin B₁₂ or serum methylmalonate (which is somewhat more sensitive and useful in identifying metabolic deficiency in patients with normal serum vitamin B₁₂ levels). In managing a patient with severe megaloblastic anemia, a therapeutic trial using very small doses of the vitamin can be used to confirm the diagnosis. Serial measurements of the reticulocyte count, serum iron, and hematocrit are performed to define the characteristic recovery of normal red cell production. The *Schilling test* can be used to measure the absorption of the vitamin and delineate the mechanism of the disease. By performing the Schilling test with and without added intrinsic factor, it is possible to discriminate between intrinsic factor deficiency by itself and primary ileal cell disease. *Vitamin B₁₂ deficiency can irreversibly damage the nervous system*. Because the neurological damage can be dissociated from the changes in the hematopoietic system, vitamin B₁₂ deficiency must be considered in elderly patients with dementia or psychiatric disorders, even if they are not anemic (Spence, 2016).

Vitamin B₁₂ Therapy

Vitamin B₁₂ has an undeserved reputation as a health tonic and has been used for a number of disease states. A number of multivitamin

preparations are marketed either as nutritional supplements or for the treatment of anemia; many are supplemented with intrinsic factor. Although the combination of oral vitamin B₁₂ and intrinsic factor would appear to be ideal for patients with an intrinsic factor deficiency, such preparations are not reliable.

Vitamin B₁₂ is available for injection or oral administration; combinations with other vitamins and minerals also can be given orally or parenterally. The choice of a preparation always depends on the cause of the deficiency. Oral administration cannot be relied on for effective therapy in the patient with a marked deficiency of vitamin B₁₂ and abnormal hematopoiesis or neurological deficits. The treatment of choice for vitamin B₁₂ deficiency is cyanocobalamin administered by intramuscular or subcutaneous injection, never intravenously. Cyanocobalamin is administered in doses of 1–1000 µg. Tissue uptake, storage, and utilization depend on the availability of transcobalamin II. Doses greater than 100 µg are cleared rapidly from plasma into the urine, and administration of larger amounts of vitamin B₁₂ will not result in greater retention of the vitamin. Administration of 1000 µg is of value in the performance of the Schilling test. After isotopically labeled vitamin B₁₂ is administered orally, the compound that is absorbed can be quantitatively recovered in the urine if 1000 µg of cyanocobalamin is administered intramuscularly. This unlabeled material saturates the transport system and tissue binding sites, so more than 90% of the labeled and unlabeled vitamin is excreted during the next 24 h.

Effective use of the vitamin B₁₂ depends on accurate diagnosis and an understanding of the following general principles of therapy:

- Vitamin B₁₂ should be given prophylactically only when there is a reasonable probability that a deficiency exists or will exist (i.e., dietary deficiency in the strict vegetarian, the predictable malabsorption of vitamin B₁₂ in patients who have had a gastrectomy, and certain diseases of the small intestine) (Del Villar Madrigal et al., 2015). When GI function is normal, an oral prophylactic supplement of vitamins and minerals, including vitamin B₁₂, may be indicated. Otherwise, the patient should receive monthly injections of cyanocobalamin.
- The relative ease of treatment with vitamin B₁₂ should not prevent a full investigation of the etiology of the deficiency. The initial diagnosis usually is suggested by macrocytic anemia or an unexplained neuropsychiatric disorder.
- Therapy always should be as specific as possible. Although a large number of multivitamin preparations are available, the use of shotgun vitamin therapy in the treatment of vitamin B₁₂ deficiency can be dangerous: Sufficient folic acid may be given to result in a hematologic recovery that can mask continued vitamin B₁₂ deficiency and permit neurological damage to develop or progress.
- Although a classical therapeutic trial with small amounts of vitamin B₁₂ can help confirm the diagnosis, acutely ill elderly patients may not be able to tolerate the delay in the correction of a severe anemia. Such patients require supplemental blood transfusions and immediate therapy with folic acid and vitamin B₁₂ to guarantee rapid recovery.
- Long-term therapy with vitamin B₁₂ must be evaluated at intervals of 6–12 months in patients who are otherwise well. If there is an additional illness or a condition that may increase the requirement for the vitamin (e.g., pregnancy), reassessment should be performed more frequently.

Treatment of the Acutely Ill Patient. The therapeutic approach depends on the severity of the illness. In uncomplicated pernicious anemia, in which the abnormality is restricted to a mild or moderate anemia without leukopenia, thrombocytopenia, or neurological signs or symptoms, the administration of vitamin B₁₂ alone will suffice. Moreover, therapy may be delayed until other causes of megaloblastic anemia have been excluded and sufficient studies of GI function have been performed to reveal the underlying cause of the disease. In this situation, a therapeutic trial with small amounts of parenteral vitamin B₁₂ (1–10 µg per day) can confirm the presence of an uncomplicated vitamin B₁₂ deficiency.

In contrast, patients with neurological changes or severe leukopenia or thrombocytopenia associated with infection or bleeding require emergency treatment. Effective therapy must not wait for detailed diagnostic tests. Once

the megaloblastic erythropoiesis has been confirmed and sufficient blood collected for later measurements of vitamin B₁₂ and folic acid, the patient should receive intramuscular injections of 100 µg of cyanocobalamin and 1–5 mg of folic acid. For the next 1–2 weeks, the patient should receive daily intramuscular injections of 100 µg of cyanocobalamin, together with a daily oral supplement of 1 to 2 mg of folic acid. Because an effective increase in red cell mass will not occur for 10–20 days, the patient with a markedly depressed hematocrit and tissue hypoxia also should receive a transfusion of 2–3 units of packed red blood cells. If congestive heart failure is present, diuretics can be administered to prevent volume overload.

The first objective hematologic change is the disappearance of the megaloblastic morphology of the marrow. As the ineffective erythropoiesis is corrected, the concentration of iron in plasma falls dramatically as the metal is used in the formation of hemoglobin, usually within the first 48 h. Full correction of precursor maturation in marrow with production of an increased number of reticulocytes begins about the second or third day and peaks 3–5 days later. Patients with complicating iron deficiency, an infection or other inflammatory state, or renal disease may be unable to correct their anemia. Therefore, it is important to monitor the reticulocyte index over the first several weeks. If it does not continue at elevated levels while the hematocrit is below 35%, plasma concentrations of iron and folic acid should again be determined and the patient reevaluated for an illness that could inhibit the response of the marrow. The degree and rate of improvement of neurological signs and symptoms depend on the severity and the duration of the abnormalities. Those that have been present for only a few months usually disappear relatively rapidly. When a defect has been present for many months or years, full return to normal function may never occur.

Long-Term Therapy With Vitamin B₁₂. Once begun, vitamin B₁₂ therapy must be maintained for life. This fact must be impressed on the patient and family, and a system must be established to guarantee continued monthly injections of cyanocobalamin.

Intramuscular injection of 100 µg of cyanocobalamin every 4 weeks is usually sufficient. Patients with severe neurological symptoms and signs may be treated with larger doses of vitamin B₁₂ in the period immediately after the diagnosis. Doses of 100 µg per day or several times per week may be given for several months with the hope of encouraging faster and more complete recovery. It is important to monitor vitamin B₁₂ concentrations in plasma and to obtain peripheral blood counts at intervals of 3–6 months to confirm the adequacy of therapy. Because refractoriness to therapy can develop at any time, evaluation must continue throughout the patient's life. Intranasal preparations are available for maintenance following normalization of vitamin B₁₂-deficient patients without nervous system involvement.

Folic Acid and Human Health

Biochemical Roles of Folate

Pteroylglutamic acid (Figure 41–7) is the common pharmaceutical form of folic acid. It is not the principal folate congener in food or the active coenzyme for intracellular metabolism. After absorption, PteGlu is rapidly reduced at the 5, 6, 7, and 8 positions to *tetrahydrofolic acid* (H₄PteGlu), which then acts as an acceptor of a number of one-carbon units. These are attached at either the 5 or the 10 position of the pteridine ring or may bridge these atoms to form a new five-member ring. The most important forms of the coenzyme that are synthesized by these reactions are listed in Figure 41–4, and each plays a specific role in intracellular metabolism:

- **Conversion of Homocysteine to Methionine.** This reaction requires CH₃H₄PteGlu as a methyl donor and uses vitamin B₁₂ as a cofactor.
- **Conversion of Serine to Glycine.** This reaction requires tetrahydrofolate as an acceptor of a methylene group from serine and uses pyridoxal phosphate as a cofactor. It results in the formation of 5,10-CH₂H₄PteGlu, an essential coenzyme for the synthesis of dTMP.
- **Synthesis of Thymidylate.** 5,10-CH₂H₄PteGlu donates a methylene group and reducing equivalents to dUMP for the synthesis of dTMP—a rate-limiting step in DNA synthesis.

Figure 41-7 The structures and nomenclature of PteGlu (folic acid) and its congeners. X represents additional residues of glutamate; polyglutamates are the storage and active forms of the vitamin. The number of residues of glutamate is variable.

- **Histidine Metabolism.** H₄PteGlu also acts as an acceptor of a formimino group in the conversion of FIGLU to glutamic acid.
- **Synthesis of Purines.** Two steps in the synthesis of purine nucleotides require the participation of 10-CHOH₄PteGlu as a formyl donor in reactions catalyzed by ribotide transformylases: the formylation of glycine ribonucleotide and the formylation of 5-aminoimidazole-4-carboxamide ribonucleotide. By these reactions, carbon atoms at positions 8 and 2, respectively, are incorporated into the growing purine ring.
- **Utilization or Generation of Formate.** This reversible reaction uses H₄PteGlu and 10-CHOH₄PteGlu.

Daily Requirements. Many food sources are rich in folates, especially fresh green vegetables, liver, yeast, and some fruits. However, lengthy cooking can destroy up to 90% of the folate content of such food. Generally, a standard U.S. diet provides 50–500 µg of absorbable folate per day, although individuals with high intakes of fresh vegetables and meats will ingest as much as 2 mg per day. In the normal adult, the recommended daily intake is 400 µg; pregnant or lactating women and patients with high rates of cell turnover (such as patients with a hemolytic anemia) may require 500–600 µg or more per day. For the prevention of neural tube defects, a daily intake of at least 400 µg of folate in food or in supplements beginning a month before pregnancy and continued for at least the first trimester is recommended. Folate supplementation also is being considered in patients with elevated levels of plasma homocysteine.

ADME. As with vitamin B₁₂, the diagnosis and management of deficiencies of folic acid depend on an understanding of the transport pathways and intracellular metabolism of the vitamin (Figure 41-8). Folates present in food are largely in the form of reduced polyglutamates, and absorption requires transport and the action of a *pteroylglutamyl carboxypeptidase* associated with mucosal cell membranes. The mucosae of the duodenum and upper part of the jejunum are rich in *dihydrofolate reductase* and can methylate most or all of the reduced folate that is absorbed. Because most absorption occurs in the proximal portion of the small intestine, it is not unusual for folate deficiency to occur when the jejunum is diseased. Both nontropical and tropical sprues are common causes of folate deficiency and megaloblastic anemia.

Once absorbed, folate is transported rapidly to tissues as CH₃H₄PteGlu. Although certain plasma proteins do bind folate derivatives, they have a greater affinity for nonmethylated analogues. The role of such binding proteins in folate homeostasis is not well understood. An increase in binding capacity is detectable in folate deficiency and in certain disease states,

such as uremia, cancer, and alcoholism. A constant supply of CH₃H₄PteGlu is maintained by food and by an enterohepatic cycle of the vitamin. The liver actively reduces and methylates PteGlu (and H₂ or H₄PteGlu) and then transports the CH₃H₄PteGlu into bile for reabsorption by the gut and subsequent delivery to tissues. This pathway may provide 200 µg or more of folate each day for recirculation to tissues. The importance of the enterohepatic cycle was suggested by animal studies that showed a rapid reduction of the plasma folate concentration after either drainage of bile or ingestion of alcohol, which apparently blocks the release of CH₃H₄PteGlu from hepatic parenchymal cells.

Folate Deficiency. Folate deficiency is a common complication of diseases of the small intestine that interferes with the absorption of folate

Figure 41-8 Absorption and distribution of folate derivatives. Dietary sources of folate polyglutamates are hydrolyzed to the monoglutamate, reduced, and methylated to CH₃H₄PteGlu, during GI transport. Folate deficiency commonly results from (1) inadequate dietary supply and (2) small intestinal disease. In patients with uremia, alcoholism, or hepatic disease, there may be defects in (3) the concentration of folate-binding proteins in plasma and (4) the flow of CH₃H₄PteGlu₁ into bile for reabsorption and transport to tissue (the folate enterohepatic cycle). Finally, vitamin B₁₂ deficiency will (5) “trap” folate as CH₃H₄PteGlu, thereby reducing the availability of H₄PteGlu₁ for its essential roles in purine and pyrimidine synthesis.

from food and the recirculation of folate through the enterohepatic cycle. The prevalence of folate deficiency in persons over age 65 is relatively high due to reduced dietary intake or intestinal malabsorption (Araujo et al., 2015). In acute or chronic alcoholism, daily intake of folate in food may be severely restricted, and the enterohepatic cycle of the vitamin may be impaired by toxic effects of alcohol on hepatic parenchymal cells; this is the most common cause of folate-deficient megaloblastic erythropoiesis and the most amenable to therapy, via reinstitution of a normal diet. Disease states characterized by a high rate of cell turnover, such as hemolytic anemias, also may be complicated by folate deficiency. In addition, drugs that inhibit dihydrofolate reductase (e.g., methotrexate and trimethoprim) or that interfere with the absorption and storage of folate in tissues (e.g., certain anticonvulsants and oral contraceptives) can lower the concentration of folate in plasma and may cause a megaloblastic anemia (Hesdorffer and Longo, 2015).

Folate deficiency is recognized by its impact on the hematopoietic system. As with vitamin B₁₂, this fact reflects the increased requirement associated with high rates of cell turnover. The megaloblastic anemia that results from folate deficiency cannot be distinguished from that caused by vitamin B₁₂ deficiency. In contrast to vitamin B₁₂ deficiency, folate deficiency is rarely, if ever, associated with neurological abnormalities. After deprivation of folate, megaloblastic anemia develops much more rapidly than it does following interruption of vitamin B₁₂ absorption (e.g., gastric surgery). This observation reflects the fact that body stores of folate are limited. Although the rate of induction of megaloblastic erythropoiesis may vary, a folate-deficiency state may appear in 1–4 weeks, depending on the individual's dietary habits and stores of the vitamin.

Folate deficiency is implicated in the incidence of neural tube defects (Wallingford et al., 2013). An inadequate intake of folate also can result in elevations in plasma homocysteine. Because even moderate hyperhomocysteinemia is considered an independent risk factor for coronary artery and peripheral vascular disease and for venous thrombosis, the role of folate as a methyl donor in the homocysteine-to-methionine conversion is receiving increased attention (Stanger and Wonisch, 2012).

General Principles of Therapy. The therapeutic use of folic acid is limited to the prevention and treatment of deficiencies of the vitamin. As with vitamin B₁₂ therapy, effective use of the vitamin depends on accurate diagnosis and an understanding of the mechanisms that are operative in a specific disease state. The following general principles of therapy should be respected:

- Dietary supplementation is necessary when there is a requirement that may not be met by a “normal” diet. The daily ingestion of a multivitamin preparation containing 400–500 µg of folic acid has become standard practice before and during pregnancy to reduce the incidence of neural tube defects and for as long as a woman is breastfeeding. In women with a history of a pregnancy complicated by a neural tube defect, an even larger dose of 4 mg/d has been recommended. Patients on total parenteral nutrition should receive folic acid supplements as part of their fluid regimen because liver folate stores are limited. Adult patients with a disease state characterized by high cell turnover (e.g., hemolytic anemia) generally require 1 mg of folic acid given once or twice a day. The 1-mg dose also has been used in the treatment of patients with elevated levels of homocysteine.
- Any patient with folate deficiency and a megaloblastic anemia should be evaluated carefully to determine the underlying cause of the deficiency state. This should include evaluation of the effects of medications, the amount of alcohol intake, the patient's history of travel, and the function of the GI tract.
- Therapy always should be as specific as possible. Multivitamin preparations should be avoided unless there is good reason to suspect deficiency of several vitamins.
- The potential danger of mistreating a patient who has vitamin B₁₂ deficiency with folic acid must be kept in mind. The administration of large doses of folic acid can result in an apparent improvement of the megaloblastic anemia, inasmuch as PteGlu is converted by dihydrofolate

reductase to H₄PteGlu; this circumvents the methylfolate “trap.” However, folate therapy does not prevent or alleviate the neurological defects of vitamin B₁₂ deficiency, and these may progress and become irreversible.

Therapeutic Use of Folate. Folic acid is marketed as oral tablets containing PteGlu or L-methylfolate, as an aqueous solution for injection (5 mg/mL), and in combination with other vitamins and minerals. Folinic acid (leucovorin calcium, citrovorum factor) is the 5-formyl derivative of tetrahydrofolic acid. The principal therapeutic uses of folinic acid are to circumvent the inhibition of dihydrofolate reductase as a part of high-dose methotrexate therapy and to potentiate fluorouracil in the treatment of colorectal cancer (see Chapter 66). It also has been used as an antidote to counteract the toxicity of folate antagonists such as pyrimethamine or trimethoprim. Folinic acid provides no advantage over folic acid, is more expensive, and therefore is not recommended. A single exception is the megaloblastic anemia associated with congenital dihydrofolate reductase deficiency.

Evaluation of the serum folate level can help exclude folate deficiency, but only in patients whose serum folate levels exceed 5.0 ng/mL; 2%–5% of healthy adults can have serum folate levels that are below this level. Red cell folate levels (reference range > 140 ng/mL) reflect chronic folate levels, are less affected by acute ingestion of folate than are serum levels, but are more time consuming and costly to measure. Serum folate concentrations more frequently show a higher correlation with serum homocysteine, which is a sensitive marker of deficiency (Farrell et al., 2013). In any case, a patient with a low serum or red cell folate level should have follow-up tests that include serum homocysteine (reference range 5–16 mmol/L), which is elevated in B₁₂ and folate deficiency, and serum methylmalonic acid (reference range 70–270 mmol/L), which is elevated only in B₁₂ deficiency.

Untoward Effects. There have been rare reports of reactions to parenteral injections of folic acid and leucovorin. Oral folic acid usually is not toxic. Folic acid in large amounts may counteract the antiepileptic effect of phenobarbital, phenytoin, and primidone and increase the frequency of seizures in susceptible children. The FDA recommends that oral tablets of folic acid be limited to strengths of 1 mg or less.

Endocrinology and Hormones: General Concepts

Endocrinology analyzes the biosynthesis of hormones, their sites of production, and the sites and mechanisms of their action and interaction. The term *hormone* is of Greek origin and classically refers to a chemical messenger that circulates in body fluids and produces specific effects on cells distant from the hormone's point of origin. The major functions of hormones include the regulation of energy storage, production, and utilization; the adaptation to new environments or conditions of stress; the facilitation of growth and development; and the maturation and function of the reproductive system. Although hormones were originally defined as products of ductless glands, we now appreciate that many organs not classically considered as "endocrine" (e.g., the heart, kidneys, GI tract, adipocytes, and brain) synthesize and secrete hormones that play key physiological roles. In addition, the field of endocrinology has expanded to include the actions of growth factors acting by means of autocrine and paracrine mechanisms, the influence of neurons—particularly those in the hypothalamus—that regulate endocrine function, and the reciprocal interactions of cytokines and other components of the immune system with the endocrine system.

Conceptually, hormones may be divided into two classes:

- Hormones that act predominantly via *nuclear receptors* to modulate transcription in target cells (e.g., steroid hormones, thyroid hormone, and vitamin D)
- Hormones that typically act via *membrane receptors* to exert rapid effects on signal transduction pathways (e.g., peptide and amino acid hormones)

The receptors for both classes of hormones provide tractable targets for a diverse group of compounds that are among the most widely used drugs in clinical medicine.

The Hypothalamic-Pituitary-Endocrine Axis

Many of the classic endocrine hormones (e.g., cortisol, thyroid hormone, sex steroids, GH) are regulated by complex reciprocal interactions among the hypothalamus, anterior pituitary, and endocrine glands (Table 42-1). The basic organization of the hypothalamic-pituitary-endocrine axis is summarized in Figure 42-1.

Discrete sets of hypothalamic neurons produce different releasing and inhibiting hormones, which are axonally transported to the median eminence. On stimulation, these neurons secrete their respective hypothalamic hormones into the hypothalamic-adenohypophyseal portal veins, which connect to the anterior pituitary gland. The *hypothalamic hormones* bind to membrane receptors on specific subsets of pituitary cells and regulate the secretion of the corresponding *pituitary hormones*. The pituitary hormones, which can be thought of as the *master signals*, circulate to the target endocrine glands or other tissues, where they activate specific receptors to stimulate the synthesis and secretion of the target *endocrine hormones* or *exert other tissue-specific effects*. These interactions are *feed-forward regulation* in which the master (signal) hormones stimulate the production of target hormones by the endocrine organs.

Superimposed on this positive feed-forward regulation is *negative-feedback* regulation, which permits precise control of hormone levels (see Figures 42-2 and 42-6). Typically, the endocrine target hormone circulates to both the hypothalamus and pituitary, where it acts via specific receptors to inhibit the production and secretion of both its hypothalamic-releasing hormone and the regulatory pituitary hormone. In addition, other brain regions have inputs to the hypothalamic hormone-producing neurons, further integrating the regulation of hormone levels in response to diverse stimuli.

Abbreviations

AC: adenylyl cyclase
ACTH: corticotropin, formerly adrenocorticotrophic hormone
CG: chorionic gonadotropin
CRH: corticotropin-releasing hormone
DA: dopamine
FSH: follicle-stimulating hormone, follitropin
GH: growth hormone
GHRH: growth hormone–releasing hormone
GnRH: gonadotropin-releasing hormone
GPCR: G protein–coupled receptor
hCG: human chorionic gonadotropin
5HT: 5-hydroxytryptamin serotonin
IGF-1: insulin-like growth factor 1
IGFBP: IGF-binding protein
IRS: insulin receptor substrate
LH: luteinizing hormone; lutropin
NPY: neuropeptide Y
OXTR: oxytocin receptor
POMC: pro-opiomelanocortin
PRL: prolactin
SC: subcutaneous
SHC: Src homology-containing protein
SHP2: Src-homology-2-domain-containing protein tyrosine phosphatase 2
SST: somatostatin
SSTR: SST receptor
TRH: thyrotropin-releasing hormone
TSH: thyroid-stimulating hormone, thyrotropin
VIP: vasoactive intestinal peptide

Figure 42–1 Organization of the anterior and posterior pituitary gland. Hypothalamic neurons in the supraoptic (SON) and paraventricular (PVN) nuclei synthesize arginine vasopressin (AVP) or oxytocin (OXY). Most of their axons project directly to the posterior pituitary, from which AVP and OXY are secreted into the systemic circulation to regulate their target tissues. Neurons that regulate the anterior lobe cluster in the mediobasal hypothalamus, including the PVH and the arcuate (ARC) nuclei. They secrete hypothalamic releasing hormones, which reach the anterior pituitary via the hypothalamic-adenohypophyseal portal system and stimulate distinct populations of pituitary cells. These cells, in turn, secrete the trophic (signal) hormones, which regulate endocrine organs and other tissues. ARC, arcuate; AVP, arginine vasopressin; OXY, oxytocin; PVN, paraventricular nuclei; SON, supraoptic nuclei; See Abbreviations list for other abbreviations.

Pituitary Hormones and Their Hypothalamic-Releasing Factors

The anterior pituitary hormones can be classified into three different groups based on their structural features (Table 42–2):

- POMC-derived hormones include *corticotropin* (ACTH) and α -MSH. These are derived from POMC by proteolytic processing (see Chapters 20 and 46).

- Somatotropic family of hormones include *GH* and *PRL*. In humans, the somatotrophic family also includes placental lactogen.
- The glycoprotein hormones—*TSH* (also called thyrotropin), *LH* (also called lutropin), and *FSH* (also called follitropin). In humans, the glycoprotein hormone family also includes *hCG*.

The synthesis and release of *anterior pituitary hormones* are influenced by the CNS. Their secretion is positively regulated by a group of peptides referred to as *hypothalamic-releasing hormones* (see Figure 42–1).

TABLE 42–1 HORMONES THAT INTEGRATE THE HYPOTHALAMIC-PITUITARY-ENDOCRINE AXIS

HYPOTHALAMIC HORMONE	EFFECT ON PITUITARY TROPHIC (SIGNAL) HORMONE	TARGET HORMONE(S)
Growth hormone-releasing hormone	↑↑ Growth hormone	IGF-1
Somatostatin	↓ Growth hormone ↓ Thyroid-stimulating hormone	
Dopamine	↓ Prolactin	—
Corticotropin-releasing hormone	↑ Corticotropin	Cortisol
Thyrotropin-releasing hormone	↑ Thyroid-stimulating hormone ↑ Prolactin	Thyroid hormone
Gonadotropin-releasing hormone	↑ Follicle-stimulating hormone ↑ Luteinizing hormone	Estrogen (f) Progesterone/estrogen (f) Testosterone (m)

f, female; m, male; ↑, increased production; ↓, decreased production.

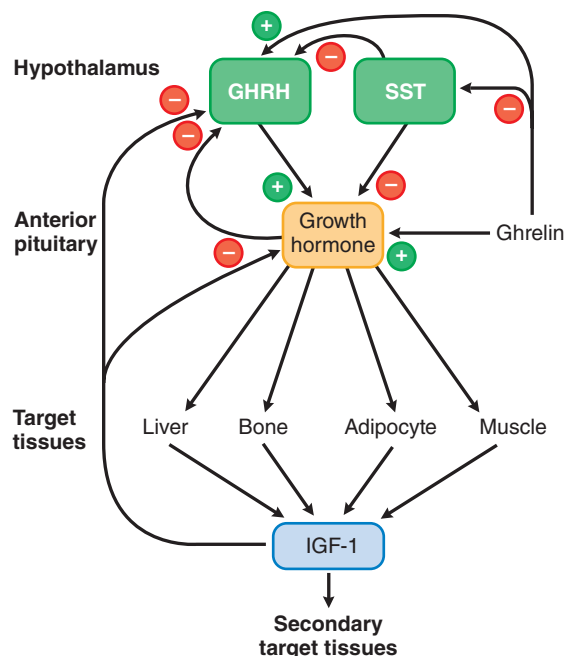

Figure 42–2 Growth hormone secretion and actions. Two hypothalamic factors, GHRH and SST, stimulate or inhibit the release of GH from the pituitary, respectively. IGF-1, a product of GH action on peripheral tissues, causes negative-feedback inhibition of GH release by acting at the hypothalamus and the pituitary. The actions of GH can be direct or indirect (mediated by IGF-1). See text for discussion of the other agents that modulate GH secretion and of the effects of locally produced IGF-1. Inhibition, –; stimulation, +.

These include *CRH*, *GHRH*, *GnRH*, and *TRH*. *SST*, another hypothalamic peptide, negatively regulates secretion of pituitary GH and TSH. The neurotransmitter DA inhibits the secretion of PRL by lactotropes.

The *posterior pituitary gland*, also known as the neurohypophysis, contains the endings of nerve axons arising from the hypothalamus that synthesize either *arginine vasopressin* or *oxytocin* (see Figure 42–1). Arginine vasopressin plays an important role in water homeostasis (see Chapter 25); oxytocin plays important roles in labor and parturition and in milk letdown, as discussed in the sections that follow.

Growth Hormone and Prolactin

Growth hormone and PRL are structurally related members of the somatotrophic hormone family and share many biological features. The somatotropes and lactotropes, the pituitary cells that produce and secrete GH and PRL, respectively, are subject to strong inhibitory input from hypothalamic neurons; for PRL, dopaminergic input is the dominant negative regulator of secretion. GH and PRL act via membrane receptors that belong to the cytokine receptor family and modulate target cell function via very similar signal transduction pathways (see Chapter 3).

Structures of GH and PRL

Table 42–2 presents some features of the somatotrophic family of hormones. GH is secreted by somatotropes as a heterogeneous mixture of peptides; the principal form is a single polypeptide chain of 22 kDa that has two disulfide bonds and is not glycosylated. Alternative splicing produces a smaller form (~20 kDa) with equal bioactivity that makes up 5%–10% of circulating GH. Recombinant human GH consists entirely of the 22-kDa form, which provides a way to detect GH abuse. In the circulation, a 55-kDa protein, which is derived from the extracellular domain of the proteolytically cleaved GHRH receptor, binds approximately 45% of the 22-kDa and 25% of the 20-kDa forms. A second protein unrelated to the GHR also binds approximately 5%–10% of circulating GH with lower affinity. Bound GH is cleared more slowly and has a biological $t_{1/2}$ about 10 times that of unbound GH, suggesting that the bound hormone may provide a GH reservoir that dampens acute fluctuations in GH levels associated with its pulsatile secretion.

Human PRL is synthesized by lactotropes; a portion of the secreted hormone is glycosylated at a single Asn residue. In the circulation, multimeric forms of PRL occur, as do degradation products of 16 kDa and 18 kDa. As with GH, the biological significance of these polymeric and degraded forms is not known.

Human placental lactogen, structurally similar to GH and PRL, occurs in pregnant females, with maximal levels near term. Human placental lactogen alters the mother's metabolism to favor fetal nutrition (mainly elevated blood glucose, secondary to reduced maternal insulin sensitivity).

Regulation of Secretion

GH Secretion

Daily GH secretion varies throughout life. GH secretion is high in children, peaks during puberty, and then decreases in an age-related manner in adulthood. GH is secreted in discrete but irregular pulses.

TABLE 42–2 ■ PROPERTIES OF THE PROTEIN HORMONES OF THE HUMAN ADENOHYPOPHYSIS AND PLACENTA

CLASS Hormone	MASS (daltons)	PEPTIDE CHAINS	AMINO ACID RESIDUES	Comments
POMC-derived hormones ^a				
Corticotropin	4500	1	39	These peptides are derived by proteolytic processing of the common precursor, POMC.
α-Melanocyte-stimulating hormone	1650		13	
Somatotropic family of hormones				
Growth hormone	22,000	1	191	Receptors for these hormones belong to the cytokine superfamily.
Prolactin	23,000		199	
Placental lactogen	22,125		190	
Glycoprotein hormones				
Luteinizing hormone	29,400	2	β-121	These are heterodimeric glycoproteins with a common α subunit of 92 amino acids and unique β subunits that determine biological specificity and $t_{1/2}$.
Follicle-stimulating hormone	32,600		β-111	
Human chorionic gonadotropin	38,600		β-145	
Thyroid-stimulating hormone	28,000		β-118	

^aSee Chapter 46 for further discussion of POMC-derived peptides, including ACTH and α-MSH.

The amplitude of secretory pulses is greatest at night. GH secretion is stimulated by GHRH and ghrelin and subject to feedback inhibition by GH itself, SST, and IGF-1 (Figure 42–2).

Growth Hormone–Releasing Hormone. GHRH, a peptide with 44 amino acids produced by hypothalamic neurons, stimulates GH secretion (see Figure 42–2) by binding to a specific GPCR on somatotropes in the anterior pituitary. The stimulated GHRH receptor couples to G_s to raise intracellular levels of cAMP and Ca^{2+} , thereby stimulating GH synthesis and secretion. Loss-of-function mutations of the GHRH receptor cause a rare form of short stature in humans.

Ghrelin. Ghrelin, a 28-amino-acid peptide, stimulates GH secretion through actions on a GPCR called the GH secretagogue receptor. Ghrelin is synthesized predominantly in endocrine cells in the fundus of the stomach but also is produced at lower levels at a number of other sites, including the pituitary and hypothalamus. Hypothalamic ghrelin is thought to be a stimulus for GH release through actions on pituitary somatotrophs and hypothalamic GHRH-secreting neurons.

Both fasting and hypoglycemia increase circulating stomach-derived ghrelin levels, and this, in turn, stimulates appetite and increases food intake, apparently by central actions on NPY and agouti-related peptide neurons in the hypothalamus. The role of stomach-derived ghrelin in GH secretion is unclear because clinical studies attempting to correlate circulating levels of ghrelin with GH secretion have produced conflicting results (Nass et al., 2011).

Other Stimuli. Several neurotransmitters, drugs, metabolites, and other stimuli modulate the release of GHRH or SST and thereby affect GH secretion. DA, 5HT, and α_2 adrenergic receptor agonists stimulate GH release, as do hypoglycemia, exercise, stress, emotional excitement, and ingestion of protein-rich meals. In contrast, β adrenergic receptor agonists, free fatty acids, glucose, IGF-1, and GH itself inhibit release. Many of the physiological factors that influence PRL secretion also affect GH secretion. Thus, sleep, stress, hypoglycemia, exercise, and estrogen increase the secretion of both hormones.

Feedback Control of GH Secretion. Growth hormone and its major peripheral effector, IGF-1, act in negative-feedback loops to suppress GH secretion (Figure 42–2).

Insulin-like Growth Factor 1. The negative effect of IGF-1 is predominantly through direct effects on the anterior pituitary gland but also at the hypothalamus via stimulation of SST secretion. The negative-feedback action of GH is mediated in part by SST, synthesized in more widely distributed neurons (Ergun-Longmire and Wajnrajch, 2013).

After its synthesis and release, IGF-1 interacts with receptors on the cell surface that mediate its biological activities. The type 1 IGF receptor is closely related to the insulin receptor and consists of a heterotetramer with intrinsic tyrosine kinase activity. This receptor is present in essentially all tissues and binds IGF-1 and the related growth factor, IGF-2, with high affinity; insulin also can activate the type 1 IGF receptor but with an affinity approximately two orders of magnitude less than that of the IGFs. The signal transduction pathway for the insulin receptor is described in detail in Chapter 47.

Somatostatin. Somatostatin is synthesized as a 92-amino-acid precursor and processed by proteolytic cleavage to generate two peptides: SST-28 and SST-14 (Figure 42–3). SST exerts its effects by binding to and activating a family of five related GPCRs that signal through G_i to inhibit cAMP formation and to activate K^+ channels and protein phosphotyrosine phosphatases.

There are five SSTR subtypes. SSTR_{1–4} bind the two forms of SST with approximately equal affinity; SSTR₅ has a 10- to 15-fold greater affinity for SST-28. SSTR₂ and SSTR₅ are the most important for regulation of GH secretion, and recent studies suggested that these two SSTRs form functional heterodimers with distinctive signaling behavior (Grant et al., 2008). SST exerts direct effects on somatotropes in the pituitary and indirect effects mediated via GHRH neurons in the arcuate nucleus.

PRL Secretion

Prolactin is unique among the anterior pituitary hormones in that hypothalamic regulation of its secretion is predominantly inhibitory. The major regulator of PRL secretion is DA, which interacts with the D_2 receptor, a

Figure 42–3 Structures of SST-14 and selected synthetic analogues. Residues that play key roles in binding to SST receptors are shown in red. Octreotide, lanreotide, and pasireotide are clinically available synthetic analogues of SST. APro, [(2-aminoethyl) aminocarboxyl oxy]-L-proline; D-Nal, 3-(2-naphthyl)-D-alanyl; PGly, phenylglycine; BTyr, benzytyrosine.

GPCR on lactotropes, to inhibit PRL secretion (Figure 42–4). TRH and hypothalamic VIP have PRL-releasing properties, but their physiologic significance is uncertain. PRL acts predominantly in women, both during pregnancy and in the postpartum period in women who breastfeed. During pregnancy, the maternal serum PRL level starts to increase at 8 weeks of gestation, peaks to 150–250 ng/mL at term, and declines thereafter to prepregnancy levels unless the mother breastfeeds the infant. Suckling or breast manipulation in nursing mothers transmits signals from the breast to the hypothalamus via the spinal cord and the median forebrain bundle, causing elevation of circulating PRL levels. PRL levels can rise 10-fold within 30 min of stimulation. This response is distinct from milk letdown, which is mediated by oxytocin release from the posterior pituitary gland. The suckling response becomes less pronounced after several months of breastfeeding, and PRL concentrations eventually decline to prepregnancy levels. PRL also is synthesized by decidual cells early in pregnancy (accounting for the high levels of PRL in amniotic fluid during the first trimester of human pregnancy).

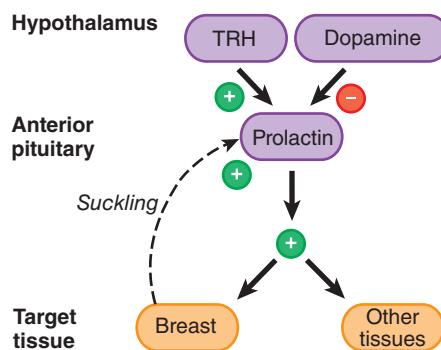

Figure 42–4 Prolactin secretion and actions. PRL is the only anterior pituitary hormone for which a unique stimulatory releasing factor has not been identified. TRH and VIP, however, can stimulate PRL release; DA inhibits it. Suckling induces PRL secretion, and PRL not only affects lactation and reproductive functions but also has effects on many other tissues. PRL is not under feedback control by peripheral hormones.

Molecular and Cellular Bases of GH and PRL Action

All of the effects of GH and PRL result from their interactions with specific membrane receptors on target tissues (Figure 42–5). Receptors for GH and PRL belong to the cytokine receptor superfamily and thus share structural similarity with the receptors for leptin, erythropoietin, granulocyte-macrophage colony-stimulating factor, and several of the interleukins. These receptors contain an extracellular hormone-binding domain, a single membrane-spanning region, and an intracellular domain that mediates signal transduction.

Growth hormone receptor activation results in the binding of a single GH to two receptor monomers to form a GH-[GHR]₂ ternary complex (initiated by high-affinity interaction of GH with one monomer of the GHR dimer [mediated by GH site 1], followed by a second, lower-affinity interaction of GH with the other GHR [mediated by GH site 2]). These interactions induce a conformational change that activates downstream signaling. The ligand-occupied GHR dimer lacks inherent tyrosine kinase activity but provides docking sites for two molecules of JAK2, a cytoplasmic tyrosine kinase of the Janus kinase family. The juxtaposition of the JAK2 molecules leads to *trans*-phosphorylation and autoactivation of JAK2, with consequent tyrosine phosphorylation of docking sites on the cytoplasmic segments of the GHR and of cytoplasmic proteins that mediate downstream signaling events (Figure 42–5; Chia, 2014). These include STAT proteins, SHC (an adapter protein that regulates the Ras/MAPK signaling pathway), and IRS-1 and IRS-2 (proteins that activate the PI3K pathway). One critical target of STAT5 is the gene encoding IGF-1, a mediator of many of the effects of GH (Figure 42–2). The fine control of GH action also involves feedback regulatory events that subsequently turn off the GH signal. As part of its action, GH induces the expression of a family of suppressor of cytokine signaling (SOC) proteins and a group of protein tyrosine phosphatases (including SHP2) that, by different mechanisms, disrupt the communication of the activated GHR with JAK2 (Flores-Morales et al., 2006).

Pegvisomant is a GH analogue with amino acid substitutions that disrupt the interaction at site 2; pegvisomant binds to the receptor and causes

its internalization but cannot trigger the conformational change that stimulates downstream events in the signal transduction pathway.

The effects of PRL on target cells also result from interactions with a cytokine family receptor that is widely distributed and signals through many of the same pathways as the GHR (Bernard et al., 2015). Alternative splicing of the PRL receptor gene on chromosome 5 gives rise to multiple forms of the receptor that are identical in the extracellular domain but differ in their cytoplasmic domains. In addition, soluble forms that correspond to the extracellular domain of the receptor are found in circulation. Unlike human GH and placental lactogen, which also bind to the PRL receptor and thus are lactogenic, PRL binds specifically to the PRL receptor and has no somatotrophic (GH-like) activity.

Physiological Effects of GH and PRL

The most striking physiological effect of GH is the stimulation of the longitudinal growth of bones. GH also increases bone mineral density after the epiphyses have closed. GH also increases muscle mass, increases the glomerular filtration rate, and stimulates preadipocyte differentiation into adipocytes. GH has potent anti-insulin actions in both the liver and peripheral tissues (e.g., adipocytes and muscle) that decrease glucose utilization and increase lipolysis, but most of its anabolic and growth-promoting effects are mediated indirectly through the induction of IGF-1. IGF-1 interacts with receptors on the cell surface that mediate its biological activities. Circulating IGF-1 is associated with a family of binding proteins (IGFBP) that serve as transport proteins and also may mediate certain aspects of IGF-1 signaling. Most IGF-1 in circulation is bound to IGFBP-3 and another protein called the acid-labile subunit.

The essential role of IGF-1 in growth is evidenced by patients with loss-of-function mutations in both alleles of the *IGF1* gene, whose severe intrauterine and postnatal growth retardation is unresponsive to GH but responsive to recombinant human IGF-1, and by the association of mutations in the IGF-1 receptor with intrauterine growth retardation (Walenkamp and Wit, 2008).

Figure 42–5 Mechanisms of GH and PRL action and of GHR antagonism. **A.** GH and two GHRs form a ternary complex that induces association and Tyr autophosphorylation of JAK2 and of docking sites on the cytoplasmic tail of GHRs. JAK2 phosphorylates cytoplasmic proteins that activate downstream signaling pathways, including STAT5 and mediators upstream of MAPK, which ultimately modulate gene expression. The structurally related PRL receptor also is a ligand-activated homodimer that recruits the JAK-STAT signaling pathway. GHR also activates IRS-1, which may mediate the increased expression of glucose transporters on the plasma membrane. **B.** Pegvisomant, a recombinant pegylated variant of human GH, is a high-affinity GH antagonist that interferes with GH binding.

The PRL effects are limited primarily to the mammary gland, where PRL plays an important role in inducing growth and differentiation of the ductal and lobuloalveolar epithelia and is essential for lactation. Target genes, by which PRL induces mammary development, include those encoding milk proteins (e.g., caseins and whey acidic protein), genes important for intracellular structure (e.g., keratins), and genes important for cell-cell communication (e.g., amphiregulin). PRL receptors are present in many other sites, including the hypothalamus, liver, adrenal, testes, ovaries, prostate, and immune system, suggesting that PRL may play multiple roles outside the breast. The physiological effects of PRL at these sites remain poorly characterized.

Pathophysiology of GH and PRL

Distinct endocrine disorders result from either excessive or deficient GH production. In contrast, PRL predominantly affects endocrine function when produced in excess.

Excess Production

Syndromes of excess secretion of GH and PRL typically are caused by somatotrope or lactotrope adenomas that oversecrete the respective hormones. These adenomas often retain some features of the normal regulation described previously, thus permitting pharmacological modulation of secretion—an important modality in therapy.

Clinical Manifestations of Excess GH. GH excess causes distinct clinical syndromes depending on the age of the patient. If the epiphyses are unfused, GH excess causes increased longitudinal growth, resulting in *gigantism*. In adults, GH excess causes *acromegaly*. The symptoms and signs of acromegaly (e.g., arthropathy, carpal tunnel syndrome, generalized visceromegaly, macroglossia, hypertension, glucose intolerance, headache, lethargy, excess perspiration, and sleep apnea) progress slowly, and diagnosis often is delayed. Mortality is increased at least 2-fold relative to age-matched controls, predominantly due to increased death from cardiovascular disease. Treatments that normalize GH and IGF-1 levels reverse this increased risk of mortality and ameliorate most of the other symptoms and signs.

Clinical Manifestations of Excess Prolactin. Hyperprolactinemia is a relatively common endocrine abnormality that can result from hypothalamic or pituitary diseases that interfere with the delivery of inhibitory dopaminergic signals, from renal failure, from primary hypothyroidism associated with increased TRH levels, or from treatment with DA receptor antagonists. Most often, hyperprolactinemia is caused by PRL-secreting pituitary adenomas. Manifestations of PRL excess in women include galactorrhea, amenorrhea, and infertility. In men, hyperprolactinemia causes loss of libido, erectile dysfunction, and infertility.

Diagnosis of Growth Hormone and Prolactin Excess. Although acromegaly should be suspected in patients with the appropriate symptoms and signs, diagnostic confirmation requires the demonstration of increased circulating GH or IGF-1. The “gold standard” diagnostic test for acromegaly is the oral glucose tolerance test. Whereas normal subjects suppress their GH level to less than 1 ng/mL in response to an oral glucose challenge (the absolute value may vary depending on the sensitivity of the assay), patients with acromegaly either fail to suppress or show a paradoxical increase in GH level.

In patients with hyperprolactinemia, the major question is whether conditions other than a PRL-producing adenoma are responsible for the elevated PRL level. A number of medications that inhibit DA signaling can cause moderate elevations in PRL (e.g., antipsychotics, metoclopramide), as can primary hypothyroidism, pituitary mass lesions that interfere with DA delivery to the lactotropes, and pregnancy. Thus, thyroid function and pregnancy tests are indicated, as is MRI to look for a pituitary adenoma or other defect that might elevate serum PRL.

Impaired Production

Clinical Manifestations of Growth Hormone Deficiency. Children with GH deficiency present with short stature, delayed bone age, and a low age-adjusted growth velocity. GH deficiency in adults is associated

with decreased muscle mass and exercise capacity, decreased bone density, impaired psychosocial function, and increased mortality from cardiovascular causes. The diagnosis of GH deficiency should be entertained in children with height more than 2 to 2.5 standard deviations below normal, delayed bone age, a decreased growth velocity, and a predicted adult height substantially below the mean parental height. In adults, overt GH deficiency usually results from pituitary lesions caused by a functioning or nonfunctioning pituitary adenoma, secondary to trauma, or related to surgery or radiotherapy for a pituitary or suprasellar mass (Ergun-Longmire and Wajnrajch, 2013). Almost all patients with multiple deficits in other pituitary hormones also have deficient GH secretion.

Clinical Manifestations of Prolactin Deficiency. PRL deficiency may result from conditions that damage the pituitary gland. Inasmuch as the sole clinical manifestation of PRL deficiency is failure of postpartum lactation, PRL is not given as part of endocrine replacement therapy.

Pharmacotherapy of Disorders GH and PRL

Treatment of Growth Hormone Excess

The initial treatment modality in gigantism/acromegaly is selective removal of the adenoma by transsphenoidal surgery. Radiation and drugs that inhibit GH secretion or action are given if surgery does not result in cure (Katznelson et al., 2014). Pituitary irradiation may be associated with significant long-term complications, including visual deterioration and pituitary dysfunction. Thus, increased attention has been given to the pharmacological management of acromegaly.

Somatostatin Analogues

The development of synthetic analogues of SST has revolutionized the medical treatment of acromegaly. The goal of treatment is to decrease GH levels to less than 2.5 ng/mL after an oral glucose tolerance test and to bring IGF-1 levels to within the normal range for age and sex. The two SST analogues used widely are *octreotide* and *lanreotide*, synthetic derivatives that have longer half-lives than SST and bind preferentially to SST₂ and SST₅ receptors (see Figure 42–3).

Octreotide. Octreotide exerts pharmacologic actions similar to those of SST. Octreotide (100 µg) administered subcutaneously three times daily is 100% bioactive; peak effects are seen within 30 min, serum $t_{1/2}$ is about 90 min, and duration of action is about 12 h. An equally effective long-acting, slow-release form, *octreotide LAR*, is administered intramuscularly in a dose of 10, 20, or 30 mg once every 4 weeks. In addition to its effect on GH secretion, octreotide can decrease tumor size, although tumor growth generally resumes after octreotide treatment is stopped.

Lanreotide. Lanreotide autogel is a long-acting octapeptide SST analogue that causes prolonged suppression of GH secretion when administered by deep subcutaneous injection every 4 weeks. Its efficacy appears comparable to that of the long-acting formulation of octreotide. It is supplied in prefilled syringes containing 60, 90, or 120 mg.

Pasireotide. Pasireotide is a long-acting cyclohexapeptide SST analogue that is approved for the treatment of Cushing disease (excessive cortisol production triggered by increases in ACTH release due to a pituitary adenoma; see Chapter 46) in patients who are ineligible for pituitary surgery or in whom surgery has failed. Pasireotide binds to multiple SST receptors (1, 2, 3, and 5) but has its highest affinity for the SST₅ receptor. In a head-to-head study, a greater percentage of subjects administered pasireotide LAR reached treatment goals compared to those given octreotide LAR. Pasireotide LAR also is approved for treatment of acromegaly.

Adverse Effects. Gastrointestinal side effects—including diarrhea, nausea, and abdominal pain—occur in up to 50% of patients receiving all three SST analogues; the incidence and severity of these side effects are similar for the three analogues. The symptoms usually diminish over time and do not require cessation of therapy. Approximately 25% of patients receiving these drugs develop multiple tiny gallstones, presumably due

to decreased gallbladder contraction and bile secretion. Bradycardia and QT prolongation may occur in patients with underlying cardiac disease. Inhibitory effects on TSH secretion rarely lead to hypothyroidism, but thyroid function should be evaluated periodically. Pasireotide suppresses ACTH secretion in Cushing disease and may lead to a decrease in cortisol secretion and to hypocortisolism. All SST analogues decrease insulin secretion, but the simultaneous reduction in GH levels results in a reduction in insulin resistance. For octreotide and lanreotide, most patients will experience no change in glucose tolerance; however, depending on the relative effects on insulin secretion versus resistance, some patients may experience a worsening and others an improvement in glucose tolerance. Pasireotide, in addition, decreases the secretion of glucagon-like peptide 1 and glucose insulinotropic peptide, two incretins that facilitate insulin secretion and inhibit glucagon secretion. As a result, glucose tolerance usually worsens significantly and antihyperglycemic therapy is often needed.

Other Therapeutic Uses. SST blocks not only GH secretion but also the secretion of other hormones, growth factors, and cytokines. Thus, the slow-release formulations of SST analogues have been used to treat symptoms associated with metastatic carcinoid tumors (e.g., flushing and diarrhea) and adenomas secreting VIP (e.g., watery diarrhea). Octreotide and lanreotide also can be used to treat patients who have failed surgery who have thyrotrope adenomas that oversecrete TSH. Octreotide is used for treatment of acute variceal bleeding and for perioperative prophylaxis in pancreatic surgery. Modified forms of octreotide labeled with indium or technetium have been used for diagnostic imaging of neuroendocrine tumors, such as pituitary adenomas and carcinoids; modified forms labeled with β emitters such as ^{90}Y have been used in selective destruction of SST₂ receptor-positive tumors.

Growth Hormone Antagonists

Pegvisomant. Pegvisomant is a GHR antagonist approved for the treatment of acromegaly. Pegvisomant binds to the GHR but does not activate JAK-STAT signaling or stimulate IGF-1 secretion (see Figure 42–5).

The drug is administered subcutaneously as a 40-mg loading dose, followed by administration of 10 mg/d. Based on serum IGF-1 levels, the dose is titrated at 4- to 6-week intervals to a maximum of 30 mg/d. Pegvisomant should not be used in patients with an unexplained elevation of hepatic transaminases, and liver function tests should be monitored in all patients. In addition, lipohypertrophy has occurred at injection sites, sometimes requiring cessation of therapy; this is believed to reflect the inhibition of direct actions of GH on adipocytes. Because of concerns that loss of negative feedback by GH and IGF-1 may increase the growth of GH-secreting adenomas, careful follow-up by pituitary MRI is strongly recommended.

Pegvisomant can also be given weekly, in addition to SST analogues, when IGF-1 levels are not fully controlled by the latter drugs (Lim and Fleseriu, 2017). Pegvisomant differs structurally from native GH and induces the formation of specific antibodies in about 15% of patients. Nevertheless, the development of tachyphylaxis due to these antibodies has not been reported.

Treatment of Prolactin Excess

The therapeutic options for patients with prolactinomas include transphenoidal surgery, radiation, and treatment with DA receptor agonists that suppress PRL production via activation of D₂ receptors. Because of the very high efficacy of DA receptor agonists, they are generally regarded as the initial treatment of choice, with surgery and radiation reserved for patients who either do not respond or are intolerant of DA receptor agonists (Melled et al., 2011).

Dopamine Receptor Agonists

Bromocriptine, *cabergoline*, and *quinagolide* effectively reduce PRL levels, thereby relieving the inhibitory effect of hyperprolactinemia on ovulation and permitting most patients with prolactinomas to become pregnant. Quinagolide should not be used when pregnancy is intended. These agents generally decrease both PRL secretion and the size of the adenoma. Over

time, especially with cabergoline, the prolactinoma may decrease in size to the extent that the drug can be discontinued without recurrence of the hyperprolactinemia.

Bromocriptine. Bromocriptine is the DA receptor agonist against which newer agents are compared. Bromocriptine is a semisynthetic ergot alkaloid (see Chapter 13) that interacts with D₂ receptors to inhibit release of PRL; to a lesser extent, it also activates D₁ dopamine receptors. The oral dose of bromocriptine is well absorbed; however, only 7% of the dose reaches the systemic circulation because of extensive first-pass metabolism in the liver. Bromocriptine has a short elimination $t_{1/2}$ (between 2 and 8 h) and thus is usually administered in divided doses. To avoid the need for frequent dosing, a slow-release oral form is available outside the U.S. Bromocriptine may be administered vaginally (2.5 mg once daily), with fewer GI side effects.

Bromocriptine normalizes serum PRL levels in 70%–80% and decreases tumor size in more than 50% of patients with prolactinomas. Hyperprolactinemia and tumor growth recur on cessation of therapy in most patients. At higher concentrations, bromocriptine is used in the management of Parkinson disease (see Chapter 18). Bromocriptine mesylate (1.6–4.8 mg/d) is approved as an adjunct to diet and exercise to improve glycemic control in adults with type 2 diabetes mellitus.

Adverse Effects. Frequent side effects include nausea and vomiting, headache, and postural hypotension, particularly on initial use. Less frequently, nasal congestion, digital vasospasm, and CNS effects such as psychosis, hallucinations, nightmares, or insomnia are observed. These adverse effects can be diminished by starting at a low dose (1.25 mg) administered at bedtime with a snack and then slowly increasing the dose as needed by monitoring PRL levels. Patients often develop tolerance to the adverse effects.

Cabergoline. Cabergoline is an ergot derivative with a longer $t_{1/2}$ (~65 h), higher affinity, and greater selectivity for the DA D₂ receptor compared to bromocriptine. Cabergoline undergoes significant first-pass metabolism in the liver.

Cabergoline is the preferred drug for the treatment of hyperprolactinemia because of greater efficacy and lower adverse effects. Therapy is initiated at a dose of 0.25 mg twice a week or 0.5 mg once a week. The dose can be increased to 1.5–2 mg two or three times a week as tolerated; the dose should be increased only once every 4 weeks. Doses of 2 mg/week or less normalize PRL levels in 80% of patients. Cabergoline induces remission in a significant number of patients with prolactinomas. At higher doses, cabergoline is used in some patients with acromegaly alone or in conjunction with SST analogues.

Adverse Effects. Compared to bromocriptine, cabergoline has a much lower tendency to induce nausea, although it still may cause hypotension and dizziness. Cabergoline has been linked to valvular heart disease, an effect proposed to reflect agonist activity at the serotonin 5HT_{2B} receptor; however, this is seen primarily at the high doses used in patients being treated for Parkinson disease and is not seen in the conventionally used doses (≤ 2 mg/week) for patients with prolactinomas.

Quinagolide. Quinagolide is a nonergot D₂ receptor agonist with a $t_{1/2}$ of about 22 h. Quinagolide is administered once daily at doses of 0.1–0.5 mg/d. It is not approved for use in the U.S. but has been used in the E.U. and Canada.

Treatment of Growth Hormone Deficiency

Somatropin

Replacement therapy is well established in GH-deficient children (Richmond and Rogol, 2010) and is gaining wider acceptance for GH-deficient adults (Molitch et al., 2011).

Humans do not respond to GH from nonprimate species. In the past, when GH for therapeutic use was purified from human cadaver pituitaries, GH was available in limited quantities and was ultimately linked to the transmission of Creutzfeldt-Jakob disease. Currently, human GH is produced by recombinant DNA technology. *Somatropin* refers to the many GH preparations whose sequences match that of native GH.

Pharmacokinetics. As a peptide hormone, GH is administered subcutaneously, with a bioavailability of 70%. Although the circulating $t_{1/2}$ of GH is only 20 min, its biological $t_{1/2}$ is considerably longer, and once-daily administration is sufficient.

Indications for Treatment. GH deficiency in children is a well-accepted cause of short stature. With the advent of essentially unlimited supplies of recombinant GH, therapy has been extended to children with other conditions associated with short stature despite adequate GH production, including Turner syndrome, Noonan syndrome, Prader-Willi syndrome, chronic renal insufficiency, children born small for gestational age, and children with idiopathic short stature (i.e., > 2.25 standard deviations below mean height for age and sex but with normal laboratory indices of GH levels). Severely affected GH-deficient adults may benefit from GH replacement therapy. The FDA also has approved GH therapy for AIDS-associated wasting and for malabsorption associated with the short-bowel syndrome (based on the finding that GH stimulates the adaptation of GI epithelial cells). Adults considered for GH treatment should have organic etiologies for the GH deficiency and must demonstrate low GH production in response to standardized stimulation tests or have at least three other pituitary hormone deficiencies.

Contraindications. GH should not be used in patients with acute critical illness due to complications after open heart or abdominal surgery, multiple accidental trauma, or acute respiratory failure. GH also should not be used in patients who have any evidence of active malignancy. GH replacement does not cause regrowth of pituitary tumor remnants when given to patients whose tumors have been resected. Other contraindications include proliferative retinopathy or severe nonproliferative diabetic retinopathy. In treating Prader-Willi syndrome, GH therapy must be carefully supervised. Sudden death has been observed when GH was given to children who were severely obese or who had severe respiratory impairment.

Therapeutic Uses. In GH-deficient children, somatropin typically is administered in a dose of 25–50 $\mu\text{g/kg/d}$ subcutaneously in the evening; higher daily doses (e.g., 50–67 $\mu\text{g/kg}$) are employed for patients with Noonan syndrome or Turner syndrome, who have partial GH resistance. In children with overt GH deficiency, measurement of serum IGF-1 levels sometimes is used to monitor initial response and compliance; long-term response is monitored by close evaluation of height, sometimes in conjunction with measurements of serum IGF-1 levels. GH is continued until the epiphyses are fused and also may be extended into the transition period from childhood to adulthood. Children with idiopathic rather than organic GH deficiency need retesting after growth has ceased before continuing GH treatment as adults; many with this diagnosis will have normal GH levels on stimulation testing as adults.

Benefits of GH treatment in GH-deficient adults include increases in muscle mass, exercise capacity, energy, bone mineral density, and quality of life and a decrease in fat mass. For adults, a typical starting dose is 150–300 $\mu\text{g/d}$ (these doses may vary depending on brand product), with higher doses used in younger patients transitioning from pediatric therapy. Either an elevated serum IGF-1 level or persistent side effects mandates a decrease in dose; conversely, the dose can be increased (typically by 100–200 $\mu\text{g/d}$) if serum IGF-1 has not reached the normal range after 2 months of GH therapy. Because estrogen inhibits GH action, women taking oral—but not transdermal—estrogen may require larger GH doses to achieve the target IGF-1 level.

Adverse Effects. In children, GH therapy is associated with remarkably few side effects. Rarely, patients develop intracranial hypertension, with papilledema, visual changes, headache, nausea, or vomiting. Because of this, funduscopic examination is recommended at the initiation of therapy and at periodic intervals thereafter. The consensus is that GH should not be administered in the first year after treatment of pediatric tumors, including leukemia, or during the first 2 years after therapy for medulloblastomas or ependymomas. Because an increased incidence of type 2 diabetes mellitus has been reported, fasting glucose levels should be

followed periodically during therapy. Finally, too-rapid growth may be associated with slipped epiphyses or scoliosis.

Side effects associated with the initiation of GH therapy in adults (peripheral edema, carpal tunnel syndrome, arthralgias, and myalgias) occur most frequently in older or obese patients and generally respond to a decrease in dose. Estrogens (e.g., birth control medications and estrogen supplements) inhibit GH action so that a larger dose is needed to maintain the same IGF-1 level. GH therapy can increase the metabolic inactivation of cortisol in the liver.

Drug Interactions. The effects of estrogen on GH therapy were noted above. This effect is much less marked with transdermal estrogen preparations. Recent studies suggested that GH therapy can increase the metabolic inactivation of glucocorticoids in the liver. Thus, GH may precipitate adrenal insufficiency in patients with occult secondary adrenal insufficiency or in patients receiving replacement doses of glucocorticoids. This has been attributed to the inhibition of the type 1 isozyme of steroid 11β -hydroxysteroid dehydrogenase, which normally converts inactive cortisone into the active 11-hydroxy derivative cortisol (see Chapter 46).

Insulin-like Growth Factor 1

Based on the hypothesis that GH predominantly acts via increases in IGF-1 (see Figure 42–2), IGF-1 has been developed for therapeutic use (Cohen et al., 2014). Recombinant human IGF-1 (*mecasermin*) and a combination of recombinant human IGF-1 with its binding protein, IGFBP-3 (*mecasermin rifabate*), are FDA-approved. The latter formulation was subsequently discontinued for use in short stature due to patent issues, although it remains available for other conditions, such as severe insulin resistance, muscular dystrophy, and HIV-related adipose redistribution syndrome.

ADME. Mecasermin is administered by subcutaneous injection, and absorption is virtually complete. IGF-1 in circulation is bound by six proteins; a ternary complex that includes IGFBP-3 and the acid labile subunit accounts for more than 80% of the circulating IGF-1. This protein binding prolongs the $t_{1/2}$ of IGF-1 to about 6 h. Both the liver and kidney have been shown to metabolize IGF-1.

Therapeutic Uses. Mecasermin is FDA-approved for patients with impaired growth secondary to mutations in the GHR or postreceptor signaling pathway, patients who develop antibodies against GH that interfere with its action, and patients with IGF-1 gene defects that lead to primary IGF-1 deficiency. Typically, the starting dose is 40–80 $\mu\text{g/kg}$ twice daily by subcutaneous injection, with a maximum of 120 $\mu\text{g/kg}$ per dose twice daily. In patients with impaired growth secondary to GH deficiency or with idiopathic short stature, mecasermin stimulates linear growth but is less effective than conventional therapy using recombinant GH.

Adverse Effects. Side effects of mecasermin include hypoglycemia and lipohypertrophy. To diminish the frequency of hypoglycemia, mecasermin should be administered shortly before or after a meal or snack. Lymphoid tissue hypertrophy, including enlarged tonsils, also is seen and may require surgical intervention. Other adverse effects are similar to those associated with GH therapy.

Contraindications. Mecasermin should not be used for growth promotion in patients with closed epiphyses. It should not be given to patients with active or suspected neoplasia and should be stopped if evidence of neoplasia develops.

Growth Hormone–Releasing Hormone

Tesamorelin. Tesamorelin is a synthetic N-terminally modified form of human GHRH that is resistant to degradation by dipeptidyl peptidase 4 and therefore has a prolonged duration of action. Tesamorelin is able to increase the levels of GH and IGF-1, but its clinical effects are primarily to reduce visceral fat accumulation, with minimal effects on insulin resistance. Tesamorelin is FDA-approved for treatment of HIV-associated lipodystrophy but not for GH deficiency (Spooner and Olin, 2012).

The Glycoprotein Hormones: TSH and the Gonadotropins

The gonadotropins include *LH*, *FSH*, and *CG*. They are referred to as the gonadotropins because of their actions on the gonads. Together with TSH, they constitute the glycoprotein family of pituitary hormones (see Table 42–2). LH and FSH were named initially based on their actions on the ovary; appreciation of their roles in male reproductive function came later. LH and FSH are synthesized and secreted by gonadotropes, which make up about 10% of the hormone-secreting cells in the anterior pituitary. CG is produced by the placenta only in primates and horses. GnRH stimulates pituitary gonadotropin production, which is further regulated by feedback effects of the gonadal hormones (Figure 42–6; see Figure 44–2 and Chapters 44 and 45). TSH is measured in the diagnosis of thyroid disorders, and recombinant TSH (thyrotropin alfa) is used in the evaluation and treatment of well-differentiated thyroid cancer (see Chapter 43).

Structure-Function Aspects of the Gonadotropins

Each gonadotropic hormone is a glycosylated heterodimer containing a common α subunit and a distinct β subunit that confers specificity of action (see Table 42–2). The heterogeneity of glycosylation on the subunits produces myriad isoforms of these hormones and may affect receptor binding and signal transduction; terminal sialate residues seem to increase plasma half-lives of these gonadotropins (Mullen et al., 2013). Among the gonadotropin β subunits, that of CG is most divergent because it contains a carboxy-terminal extension of 30 amino acids and extra carbohydrate residues that prolong its $t_{1/2}$. The longer $t_{1/2}$ of hCG has some clinical relevance for its use in assisted reproduction technologies.

Figure 42–6 The hypothalamic-pituitary-gonadal axis. A single hypothalamic-releasing factor, GnRH, controls the synthesis and release of both gonadotropins (LH and FSH) in males and females. Gonadal steroid hormones (androgens, estrogens, and progesterone) exert feedback inhibition at the level of the pituitary and the hypothalamus. However, these feedback effects are dependent on sex, concentration, and time; the preovulatory surge of estrogen also can exert a stimulatory effect at the level of the pituitary and the hypothalamus. Inhibins, a family of polypeptide hormones produced by the gonads, specifically inhibit FSH secretion by the pituitary.

Physiology of the Gonadotropins

In men, LH acts on testicular Leydig cells to stimulate the de novo synthesis of androgens, primarily *testosterone*, from cholesterol. FSH acts on the Sertoli cells to stimulate the production of proteins and nutrients required for sperm maturation. In women, the actions of FSH and LH are more complex. FSH stimulates the growth of developing ovarian follicles and induces the expression of LH receptors on theca and granulosa cells. FSH also regulates the expression of aromatase in granulosa cells, thereby stimulating the production of *estradiol*. LH acts on the theca cells to stimulate the de novo synthesis of *androstenedione*, the major precursor of ovarian estrogens in premenopausal women (see Figure 44–1). LH also is required for the rupture of the dominant follicle during ovulation and for the synthesis of progesterone by the corpus luteum.

Regulation of Gonadotropin Synthesis and Secretion

The predominant regulator of gonadotropin synthesis and secretion is the hypothalamic peptide GnRH, a decapeptide with blocked amino and carboxyl termini derived by proteolytic cleavage of a precursor peptide with 92 amino acids.

Gonadotropin-releasing hormone release is pulsatile and is governed by a hypothalamic neural pulse generator (primarily in the arcuate nucleus) that controls the frequency and amplitude of GnRH release. Shortly before puberty, CNS inhibition decreases and the amplitude and frequency of GnRH pulses increase, particularly during sleep. As puberty progresses, the GnRH pulses increase further in amplitude and frequency until the normal adult pattern is established. The intermittent release of GnRH is crucial for the proper synthesis and release of the gonadotropins; the continuous administration of GnRH leads to desensitization and downregulation of GnRH receptors on pituitary gonadotropes.

Molecular and Cellular Bases of GnRH Action. GnRH signals through a specific GPCR on gonadotropes that activates the $G_{q/11}$ -PLC-IP₃-Ca²⁺ pathway (see Chapter 3), resulting in increased synthesis and secretion of LH and FSH. Although cAMP is not the major mediator of GnRH action, binding of GnRH to its receptor also increases adenyl cyclase activity. GnRH receptors also are present in the ovary, testis, and other sites, where their physiological significance remains to be determined.

Other Regulators of Gonadotropin Production. Gonadal steroids regulate gonadotropin production at the level of the pituitary and the hypothalamus, but effects on the hypothalamus predominate (see Figure 42–6). The feedback effects of gonadal steroids are dependent on sex, concentration, and time. In women, low levels of estradiol and progesterone inhibit gonadotropin production, largely through opioid action on the neural pulse generator. Higher and more sustained levels of estradiol have positive-feedback effects that ultimately result in the gonadotropin surge that triggers ovulation. In men, testosterone inhibits gonadotropin production, in part through direct actions and in part via its conversion by aromatase to estradiol. Gonadotropin production also is regulated by the *inhibins*, which are members of the bone morphogenetic protein family of secreted signaling proteins. *Inhibin A* and *B* are made by granulosa cells in the ovary and Sertoli cells in the testis in response to the gonadotropins and local growth factors. They act directly in the pituitary to inhibit FSH secretion without affecting that of LH. Inhibin A exhibits variation during the menstrual cycle, suggesting that it acts as a dynamic regulator of FSH secretion.

Molecular and Cellular Bases of Gonadotropin Action

The actions of LH and hCG on target tissues are mediated by the LH receptor; those of FSH are mediated by the FSH receptor. The FSH and LH receptors couple to G_s to activate the adenyl cyclase-cAMP pathway. At higher ligand concentrations, the agonist-occupied gonadotropin receptors also activate PKC and Ca²⁺ signaling pathways via G_q -mediated effects on PLC β . Most actions of the gonadotropins can be mimicked by cAMP analogues.

Clinical Disorders of the Hypothalamic-Pituitary-Gonadal Axis

Clinical disorders of the hypothalamic-pituitary-gonadal axis can manifest either as alterations in levels and effects of sex steroids (hyper- or hypogonadism) or as impaired reproduction. This section focuses on those conditions that specifically affect the hypothalamic-pituitary components of the axis and those for which gonadotropins are used diagnostically or therapeutically.

Deficient sex steroid production resulting from hypothalamic or pituitary defects is termed *hypogonadotropic hypogonadism* because circulating levels of gonadotropins are either low or undetectable. Hypogonadotropic hypogonadism in some patients results from GnRH receptor mutations; some of these mutations impair targeting of the GnRH receptor to the plasma membrane of gonadotropes, prompting efforts to develop pharmacological strategies to correct receptor trafficking and restore function (Conn et al., 2007). Many other disorders can impair gonadotropin secretion, including pituitary tumors, genetic disorders such as Kallmann syndrome, infiltrative processes such as sarcoidosis, and functional disorders such as exercise-induced amenorrhea.

In contrast, reproductive disorders caused by processes that directly impair gonadal function are termed *hypergonadotropic* because the impaired production of sex steroids leads to a loss of negative-feedback inhibition, thereby increasing the synthesis and secretion of gonadotropins.

- **Precocious Puberty.** Puberty normally is a sequential process requiring several years over which the GnRH neurons escape CNS inhibition and initiate pulsatile secretion of GnRH. This stimulates the secretion of gonadotropins and gonadal steroids, thus directing the development of secondary sexual characteristics appropriate for sex. Normally, the initial signs of puberty (breast development in girls and testes enlargement in boys) do not occur before age 8 in girls or age 9 in boys; the initiation of sexual maturation before this time is termed “precocious.” GnRH-dependent excessive secretion of gonadotropins is rare and causes precocious puberty in children. This condition may be due to GnRH-producing hamartomas or other CNS abnormalities, but often no specific abnormality is found. This central precocious puberty must be

differentiated from that due to hormone-producing tumors of the gonads, in which case gonadotropin levels will be low. GnRH-independent precocious puberty results from peripheral production of sex steroids in a manner not driven by pituitary gonadotropins; etiologies include adrenal or gonadal tumors, activating mutations of the LH receptor in boys, and congenital adrenal hyperplasia. Synthetic GnRH analogues play important roles in the diagnosis and treatment of GnRH-dependent precocious puberty (see further discussion). In contrast, drugs that interfere with the production of sex steroids, including ketoconazole and aromatase inhibitors, are used in patients with GnRH-independent precocious puberty (Shulman et al., 2008), with varying success.

- **Sexual Infantilism.** The converse of precocious puberty is a failure to initiate the processes of pubertal development at the normal time. This can reflect defects in the GnRH neurons or gonadotropes (secondary hypogonadism) or primary dysfunction in the gonads. In either case, induction of sexual maturation using sex steroids (estrogen followed by estrogen/progesterone in females, testosterone in males) is standard therapy. This suffices to direct sex differentiation in the normal manner. If fertility is the goal, then therapy with either GnRH or gonadotropins is needed to stimulate appropriate germ cell maturation.
- **Infertility.** Infertility, or a failure to conceive after 12 months of unprotected intercourse, is seen in up to 10%–15% of couples and is increasing in frequency as women choose to delay childbearing. When the infertility is due to impaired synthesis or secretion of gonadotropins (hypogonadotropic hypogonadism), various pharmacological approaches are employed. In contrast, when infertility results from intrinsic processes affecting the gonads, pharmacotherapy generally is less effective. Therapeutic approaches to male infertility are described further in this chapter; strategies for female infertility are described in Chapter 44.

Treatment and Diagnosis of Gonadal Disorders

GnRH and Its Synthetic Agonist Analogues

A synthetic peptide comprising the native sequence of GnRH has been used both diagnostically and therapeutically in human reproductive disorders. In addition, a number of GnRH analogues with structural modifications have been synthesized and brought to market (Table 42-3).

TABLE 42-3 ■ STRUCTURES OF GONADOTROPIN-RELEASING HORMONE AND GNRH ANALOGUES

GNRH CONGENER	AMINO ACID RESIDUE										DOSAGE FORMS
	1	2	3	4	5	6	7	8	9	10	
Agonists

Ac, acetyl; Aph, aminophenyl alanine; Bzl, benzyl; AzGly, azaglycyl; Cbm, carbamoyl; Cpa, chlorophenylalanine; D-Nal, 3-(2-naphthyl)-D-alanine; EtNH₂, N-ethylamide; hArg(Et)₂, ethyl homoarginine; Hor, hydroxyethyl; Lys(iPr), isopropyl-lysine; Pal, 3-pyridylalanine; tBu, t butyl. A dash (—) denotes amino acid identity with GnRH. IM, intramuscular; IN, intranasal; IV, intravenous; SC, subcutaneous.

^aNot available in the U.S.

GnRH Congeners

Synthetic agonist congeners of GnRH have longer half-lives than native GnRH. After a transient stimulation of gonadotropin secretion, they downregulate the GnRH receptor and inhibit gonadotropin secretion. The available GnRH agonists contain substitutions of the native sequence at position 6 that protect against proteolysis and substitutions at the carboxyl terminus that improve receptor-binding affinity. Compared to GnRH, these analogues exhibit enhanced potency and prolonged duration of action (Table 42-3).

Pharmacokinetics. The myriad formulations of GnRH agonists provide for diverse applications, including relatively short-term effects (e.g., assisted reproduction technology) and more prolonged action (e.g., depot forms that inhibit gonadotropin secretion in GnRH-dependent precocious puberty). The rates and extents of absorption thus vary considerably. The intranasal formulations have bioavailability (~4%) that is considerably lower than that of the parenteral formulations, which include products for implantation and injection (subcutaneous and intramuscular).

Clinical Uses. The depot form of the GnRH agonist leuprolide has been used diagnostically to differentiate between GnRH-dependent and GnRH-independent precocious puberty. Leuprolide depot (3.75 mg) is injected subcutaneously, and serum LH is measured 2 h later. A plasma LH level of more than 6.6 mIU/mL is diagnostic of GnRH-dependent (central) disease. Clinically, the various GnRH agonists are used to achieve pharmacological castration in disorders that respond to reduction in gonadal steroids (Fuqua, 2013). A clear indication is in children with GnRH-dependent precocious puberty, whose premature sexual maturation can be arrested with minimal side effects by chronic administration of a depot form of a GnRH agonist (Li et al., 2014).

Long-acting GnRH agonists are used for palliative therapy of hormone-responsive tumors (e.g., prostate or breast cancer), generally in conjunction with agents that block steroid biosynthesis or action to avoid transient increases in hormone levels (see Chapters 46 and 68). The GnRH agonists also are used to suppress steroid-responsive conditions such as endometriosis, uterine fibroids, acute intermittent porphyria, and priapism. They also have been evaluated off label for their potential to preserve follicles in women undergoing therapy with cytotoxic drugs for cancer treatment, although efficacy in this setting has not been established. Depot preparations can be administered subcutaneously or intramuscularly monthly or every 3 months. The long-lasting GnRH agonists have been used to avoid a premature LH surge, and thus ovulation, in various ovarian stimulation protocols for in vitro fertilization.

Adverse Effects. The long-acting agonists generally are well tolerated, and side effects are those that would be predicted to occur when gonadal steroidogenesis is inhibited (e.g., hot flashes and decreased bone density in both sexes, vaginal dryness and atrophy in women, and erectile dysfunction in men). Because of these effects, therapy in non-life-threatening diseases such as endometriosis or uterine fibroids generally is limited to 6 months. GnRH agonists are contraindicated in pregnant women.

Formulations and Indications. **Leuprolide.** Leuprolide is formulated in multiple doses for injection: subcutaneous (1 mg/d), subcutaneous depot (7.5 mg/month; 22.5 mg/3 months; 30 mg/4 months; 45 mg/6 months), and intramuscular depot (3.75 mg/month; 11.25 mg/3 months). It is approved for endometriosis, uterine fibroids, advanced prostate cancer, and precocious puberty. For endometriosis, leuprolide once-monthly injections (3.75 mg) or 3-month injections (11.25 mg) are also copackaged in combination with once-daily norethindrone (a steroidal progestin) 5-mg tablets for oral administration. Pediatric formulations of leuprolide also are approved for central precocious puberty.

Goserelin. Goserelin is formulated as a subcutaneous implant (3.6 mg/month; 10.8 mg/12 weeks). It is approved for endometriosis, for use as an endometrial-thinning agent prior to endometrial ablation for dysfunctional uterine bleeding, and for advanced prostate and breast cancer.

Histrelin. Histrelin is formulated as a subcutaneous implant (50 mg/12 months). It is approved for central precocious puberty and advanced prostate cancer.

Nafarelin. Nafarelin is formulated as a nasal spray (200 µg/spray). It is approved for endometriosis (400 µg/d) and central precocious puberty (1600 µg/d).

Triptorelin. Triptorelin is formulated for depot intramuscular injection (3.75 mg/month; 11.25 mg/12 weeks, 22.5 mg/24 weeks) and approved for advanced prostate cancer. *Buserelin* and *deslorelin* are not available in the U.S.

GnRH Antagonist Analogues

Ganirelix and Cetrorelix. Ganirelix acetate and cetrorelix acetate are FDA-approved to suppress the LH surge and thus prevent premature ovulation in ovarian-stimulation protocols as part of assisted reproduction technology (see Chapter 44).

Both GnRH antagonists are formulated for subcutaneous administration. Bioavailability exceeds 90% within 1–2 h, and the $t_{1/2}$ varies depending on the dose. Once-daily administration suffices for therapeutic effect. Hypersensitivity reactions, including anaphylaxis, have been noted in postmarketing surveillance, some with the initial dose. When used in conjunction with gonadotropin injections for assisted reproduction, the effects of estrogen withdrawal (e.g., hot flashes) are not seen. GnRH antagonists are contraindicated in pregnant women.

Cetrorelix is also used off label for endometriosis and uterine fibroids, both of which are estrogen dependent. As antagonists rather than agonists, these drugs do not transiently increase gonadotropin secretion and sex steroid biosynthesis.

Degarelix. Degarelix acetate is FDA-approved for treatment of advanced prostate cancer. Degarelix suppresses testosterone levels to 50 ng/dL or less (i.e., medical castration) and lowers prostate-specific antigen more rapidly than GnRH agonists without an initial testosterone surge (Shore, 2013).

ADME. Degarelix forms a depot gel at the site of injection and, as a consequence, is released in a biphasic pattern with a median plasma $t_{1/2}$ of 42 days for the starting dose and 28 days for the maintenance dose. Degarelix is distributed throughout total body water, is 90% protein bound, and is degraded by proteolysis via the hepatobiliary system; degraded protein fragments are eliminated in the feces, and unmetabolized drug is eliminated via the kidneys.

Adverse Effects. Adverse effects include injection site reactions, hot flashes, weight gain, increases in transaminase and γ -glutamyltransaminase levels, prolonged QT interval, and decreased bone mineral density.

Dosage and Route of Administration. Degarelix is administered subcutaneously in the abdomen, with the site of injection varied on a regular basis. The starting dose is 240 mg administered as two injections of 120 mg on each side of the abdomen, followed by a maintenance dose of 80 mg every 28 days.

Natural and Recombinant Gonadotropins

The gonadotropins are used for both diagnosis and therapy in reproductive endocrinology. For further discussion of the uses of gonadotropins in female reproduction, see Chapter 44.

The original gonadotropin preparations for clinical therapy were prepared from human urine and included *chorionic gonadotropin*, obtained from the urine of pregnant women, and *menotropins*, obtained from the urine of postmenopausal women. Because of their relatively low purity, these gonadotropins were administered intramuscularly to decrease the incidence of hypersensitivity reactions. Subsequently, urine-derived preparations were developed with sufficient purity to be administered subcutaneously. Highly purified preparations of human gonadotropins now are prepared using recombinant DNA technology and exhibit less batch-to-batch variation. This technology is being used to produce forms of gonadotropins with increased half-lives or higher clinical efficacy. One such “designer” gonadotropin, FSH-CTP, contains the β subunit of FSH fused to the carboxy-terminal extension of hCG, thereby increasing considerably the $t_{1/2}$ of the recombinant protein. In clinical trials, FSH-CTP has been shown to stimulate follicle maturation in vivo when injected weekly (Macklin et al., 2006).

Follicle-Stimulating Hormone

Follicle-stimulating hormone has long been a mainstay of regimens for either ovarian stimulation or in vitro fertilization. The original *menotropins* formulations contained roughly equal amounts of FSH and LH, as well as a number of other urinary proteins, and were administered intramuscularly to diminish local reactions. *Urofollitropin*, prepared by immunoconcentration of FSH with monoclonal antibodies, is pure enough to be administered subcutaneously. The amount of LH contained in such preparations is diminished considerably.

Recombinant FSH is prepared by expressing cDNAs encoding the α and β subunits of human FSH in mammalian cell lines, yielding products whose glycosylation pattern mimics that of FSH produced by gonadotropes. The two available recombinant FSH preparations, *folitropin alfa* and *folitropin beta*, differ slightly in their carbohydrate structures. Both are more pure and exhibit less interbatch variability than do preparations purified from urine; thus, they can be administered subcutaneously. The relative advantages (i.e., efficacy, lower frequency of side effects such as ovarian hyperstimulation) of recombinant FSH versus urine-derived gonadotropins have not been definitively established (van Wely et al., 2011).

Human Chorionic Gonadotropin

The hCG used clinically originally came from the urine of pregnant women. Several urine-derived preparations are available; all of them are administered intramuscularly due to local reactions. Recombinant hCG (choriogonadotropin alfa) also is used clinically.

Recombinant Human LH

Menotropins contain considerable LH activity, thereby providing any LH activity that is needed to promote follicle maturation. Traditionally, LH was not used for ovulation induction because hCG produced identical effects via the LH receptor and had a longer $t_{1/2}$. Human LH produced using recombinant DNA technology and designated lutropin alfa has been discontinued from the U.S. market but is available elsewhere.

Diagnostic Uses

Pregnancy Testing

During pregnancy, the placenta produces significant amounts of hCG, which can be detected in maternal urine. Over-the-counter pregnancy kits containing antibodies specific for the unique β subunit of hCG qualitatively assay for the presence of hCG and can detect pregnancy within a few days after a woman's first missed menstrual period. Quantitative measurements of plasma hCG concentration by radioimmunoassay can indicate whether pregnancy is proceeding normally and can help to detect the presence of an ectopic pregnancy, hydatidiform mole, or choriocarcinoma. Such assays also are used to follow the therapeutic response of malignancies that secrete hCG, such as germ cell tumors.

Timing of Ovulation

Ovulation occurs about 36 h after the onset of the LH surge. Therefore, urinary concentrations of LH, as measured with an over-the-counter radioimmunoassay kit, can be used to predict the time of ovulation. Urine LH levels are measured every 12–24 h, beginning on day 10–12 of the menstrual cycle (assuming a 28-day cycle), to detect the rise in LH and estimate the time of ovulation. This estimate facilitates the timing of sexual intercourse to optimize the chance of achieving pregnancy.

Localization of Endocrine Disease

Measurements of plasma LH and FSH levels with β -subunit-specific radioimmunoassays are useful in the diagnosis of several reproductive disorders. Low or undetectable levels of LH and FSH are indicative of hypogonadotropic hypogonadism and suggest hypothalamic or pituitary disease, whereas high levels of gonadotropins suggest primary gonadal diseases. A plasma FSH level of 10–12 mIU/mL or greater on day 3 of the menstrual cycle is associated with reduced fertility. Elevated FSH levels also are diagnostic of menopause in women with amenorrhea in the appropriate age range.

Human CG can be used to stimulate testosterone production and thus to assess Leydig cell function in males suspected of having primary hypogonadism (e.g., in delayed puberty). A diminished response to multiple injections of hCG indicates Leydig cell failure; a normal response suggests a hypothalamic-pituitary disorder and normal Leydig cells.

Therapeutic Uses

Male Infertility

In men with impaired fertility secondary to gonadotropin deficiency (hypogonadotropic hypogonadism), gonadotropins can establish or restore fertility (Farhat et al., 2010). Treatment typically is initiated with hCG (1500–2000 IU intramuscularly or subcutaneously) three times per week until the plasma testosterone levels indicate full induction of steroidogenesis. Thereafter, the dose of hCG is reduced to 2000 IU twice a week or 1000 IU three times a week. If spermatogenesis does not occur with hCG alone, then recombinant FSH (typical dose of 150 IU) is added to fully induce spermatogenesis.

The most common side effect of gonadotropin therapy in males is gynecomastia, which occurs in up to a third of patients and presumably reflects increased production of estrogens due to the induction of aromatase. Maturation of the prepubertal testes typically requires treatment for more than 6 months, and optimal spermatogenesis in some patients may require treatment for up to 2 years. Once spermatogenesis has been initiated, ongoing treatment with hCG alone usually is sufficient to support sperm production.

Cryptorchidism

Cryptorchidism, the failure of one or both testes to descend into the scrotum, affects up to 3% of full-term male infants and becomes less prevalent with advancing postnatal age. Cryptorchid testes have defective spermatogenesis and are at increased risk for developing germ cell tumors. Hence, the current approach is to reposition the testes as early as possible, typically at 1 year of age but definitely before 2 years of age. The local actions of androgens stimulate descent of the testes; thus, hCG has been used by some to induce testicular descent if the cryptorchidism is not secondary to anatomical blockage. Therapy usually consists of injections of hCG (3000 IU/m² body surface area) intramuscularly every other day for six doses.

Posterior Pituitary Hormones: Oxytocin and Vasopressin

The neurohypophyseal hormones oxytocin and arginine vasopressin (also called antidiuretic hormone or ADH) are cyclic nonapeptides that differ by only two amino acids (Figure 42–7). The physiology and pharmacology of vasopressin are presented in Chapter 25.

Figure 42–7 The structures of vasopressin and oxytocin. Vasopressin and oxytocin are cyclic nonapeptides that differ from each other by two amino acids (red).

Physiology of Oxytocin

Oxytocin is synthesized as a larger precursor in neurons whose cell bodies reside in the paraventricular nucleus and, to a lesser extent, the supraoptic nucleus in the hypothalamus. The precursor peptide is rapidly cleaved to the active hormone and its neurophysin, packaged into secretory granules as an oxytocin-neurophysin complex, and secreted from nerve endings that terminate primarily in the posterior pituitary gland (neurohypophysis). In addition, oxytocinergic neurons that regulate the autonomic nervous system project to regions of the hypothalamus, brainstem, and spinal cord. Other sites of oxytocin synthesis include the luteal cells of the ovary, the endometrium, and the placenta, but the physiologic significance of this is not known. Oxytocin acts via a specific GPCR (OXTR) closely related to the V_{1a} and V_2 vasopressin receptors. In the human myometrium, OXTR couples to G_q/G_{11} , activating the PLC_β - IP_3 - Ca^{2+} pathway and enhancing activation of voltage-sensitive Ca^{2+} channels, stimulating muscle contraction (Figure 42–8). Oxytocin also increases local prostaglandin production, which further stimulates uterine contraction.

Stimuli for oxytocin secretion include sensory stimuli arising from dilation of the cervix and vagina and from suckling at the breast. Increases in circulating oxytocin in women in labor are difficult to detect, partly because of the pulsatile nature of oxytocin secretion and partly because of the activity of circulating oxytocinase. Nevertheless, increased oxytocin in maternal circulation is detected in the second stage of labor, likely triggered by sustained distension of the uterine cervix and vagina.

Estradiol stimulates oxytocin secretion, whereas the ovarian polypeptide relaxin inhibits its release. The inhibitory effect of relaxin appears to be the net result of a direct effect on oxytocin-producing cells and an inhibitory action mediated indirectly by endogenous opiates. Other factors that primarily affect vasopressin secretion also have some impact on oxytocin release: Ethanol inhibits release; pain, dehydration, hemorrhage, and hypovolemia stimulate release. Although peripheral actions of oxytocin appear to play no significant role in the response to dehydration,

hemorrhage, or hypovolemia, oxytocin may participate in the central regulation of blood pressure. Pharmacological doses of oxytocin can inhibit free water clearance by the kidney through arginine vasopressin-like activity at vasopressin V_2 receptors. As judged by the effects of intravenously administered oxytocin during labor induction, the plasma $t_{1/2}$ of oxytocin is about 13 min.

Sites of Oxytocin Action

Uterus

During the third trimester of pregnancy, spontaneous motor activity increases progressively until the sharp rise that constitutes the initiation of labor. Oxytocin stimulates the frequency and force of uterine contractions. Uterine responsiveness to oxytocin roughly parallels this increase in spontaneous activity and is highly dependent on estrogen, which increases the expression of the OXTRs.

Because of difficulties associated with the measurement of oxytocin levels and because loss of pituitary oxytocin apparently does not compromise labor and delivery, the physiological role of oxytocin in pregnancy is debated. Exogenous oxytocin can enhance rhythmic contractions at any time, but an 8-fold increase in uterine sensitivity to oxytocin occurs in the last half of pregnancy and is accompanied by a 30-fold increase in OXTR numbers. Progesterone antagonizes the stimulatory effect of oxytocin in vitro, and refractoriness to progesterone in late pregnancy may contribute to the normal initiation of human parturition.

Breast

Oxytocin plays an important physiological role in milk ejection. Stimulation of the breast through suckling or mechanical manipulation induces oxytocin secretion, causing contraction of the myoepithelium that surrounds alveolar channels in the mammary gland. This action forces milk from the alveolar channels into large collecting sinuses, where it is available to the suckling infant.

Figure 42–8 Sites of action of oxytocin and tocolytic drugs in the uterine myometrium. The elevation of cellular Ca^{2+} promotes contraction via the Ca^{2+} /calmodulin-dependent activation of myosin light chain kinase (MLCK). Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of MLCK. Pharmacological manipulations to reduce myometrial contraction include the following: (1) inhibiting Ca^{2+} entry (Ca^{2+} channel blockers, $MgSO_4$); (2) reducing mobilization of intracellular Ca^{2+} by antagonizing GPCR-mediated activation of the G_q - PLC - IP_3 - Ca^{2+} pathway (with antagonists of the FP and OXT receptors) or reducing production of the FP agonist $PGF_{2\alpha}$ (with COX inhibitors); and (3) enhancing relaxation by elevating cellular cAMP (with β_2 adrenergic agonists that activate G_s -AC) and cGMP (with NO donors that stimulate soluble guanylyl cyclase).

Studies in rodents have implicated oxytocin as an important CNS regulator of trust and of autonomic systems linked to anxiety and fear, but its importance in humans in this regard remains to be established.

Brain regions proposed to be critical in the response to fearful stimuli, including the amygdala, midbrain, and striatum, showed decreased activation in response to stressful stimuli following oxytocin treatment (Baumgartner et al., 2008; Huber et al., 2005). The role of perturbations of oxytocin signaling in mental conditions such as social phobia and autism and the possible therapeutic benefit of drugs that manipulate CNS oxytocin effects are exciting areas of ongoing investigation (Romano et al., 2016).

Clinical Use of Oxytocin

Oxytocin is used therapeutically only to induce or augment labor and to treat or prevent postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm.” In the U.S., the FDA-approved label contains this notice:

Elective induction of labor is defined as the initiation of labor in a pregnant individual who has no medical indications for induction. Since the available data are inadequate to evaluate the benefits-to-risks considerations, Pitocin is not indicated for elective induction of labor.

Induction of Labor

Induction of labor is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of pharmacological induction. Oxytocin is the drug of choice for induction of labor for women with a suitably ripened cervix (see Chapter 37 for a discussion of prostaglandins in cervical ripening). It is administered by intravenous infusion of a diluted solution, has a $t_{1/2}$ of 12–15 min and achieves a steady-state uterine response after about 30 min. Both a high-dose protocol (starting with an infusion of 6 mU/min) and low-dose protocols (starting with an infusion dose of 0.5–2 mU/min) have been used

(American College of Obstetricians and Gynecologists, 2009). Uterine hyperstimulation is an adverse effect of oxytocin that should be avoided. Oxytocin at high doses activates the vasopressin V_2 receptor and has antidiuretic effects. Vasodilating actions of oxytocin also have been noted that may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Dysfunctional Labor

Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions, an infusion rate of 10 mU/min typically is sufficient. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion.

Prevention and Treatment of Postpartum Hemorrhage

Oxytocin (10 units IM) is given immediately after delivery to help maintain uterine contractions and tone. Alternatively, oxytocin (20 units) is diluted in 1 L of intravenous solution (yielding a concentration of 20 mU/mL) and infused at a rate of 10 mU/min until the uterus is contracted. The infusion rate then is reduced to 1–2 mU/min until the mother is ready for transfer to the postpartum unit.

Tocolytic Therapy for Established Preterm Labor

Inhibition of uterine contractions of preterm labor, or *tocolysis*, has been a focus of therapy (Figure 42–8). Although tocolytic agents delay delivery in ~80% of women, they neither prevent premature births nor improve adverse fetal outcomes, such as respiratory distress syndrome. Specific tocolytic agents include β adrenergic receptor agonists, $MgSO_4$, Ca^{2+} channel blockers, COX inhibitors, NO donors, and the oxytocin receptor antagonist *atosiban*. Atosiban is widely used in Europe but is not FDA-approved in the U.S. Chapter 44 presents additional information on tocolytic therapy.

Drug Facts for Your Personal Formulary: Pituitary-Related Drugs

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Pituitary Hormones (Recombinant)		
Growth hormone (somatotropin)	<ul style="list-style-type: none"> Stimulating growth in childhood In GH-deficient adults, replacing GH 	<ul style="list-style-type: none"> Given by daily SC injection to stimulate body growth, primarily through stimulation of IGF-1. As growth ceases, test for GH deficiency to determine if GH should be continued into adulthood. Given only to adults with GH deficiency proven by GH stimulation tests or known organic childhood GH deficiency and low IGF-1 levels on testing off GH treatment. Treatment in adults decreases fat mass, increases muscle mass, increases bone mass, and improves quality of life.
Oxytocin	<ul style="list-style-type: none"> Augmentation of labor Management of postpartum hemorrhage 	<ul style="list-style-type: none"> Administered by intravenous infusion. Hyperstimulating the uterus should be avoided during augmentation of labor. May provoke hypotension and reflex tachycardia.
Other Peptide Hormones		
Human chorionic gonadotropin	<ul style="list-style-type: none"> Testing of Leydig cell function Male infertility Cryptorchidism in children 	<ul style="list-style-type: none"> Stimulates LH receptor, causing increased testicular testosterone production. Induces testicular descent in children with cryptorchidism.
Tesamorelin	<ul style="list-style-type: none"> Treatment of HIV-associated lipodystrophy 	<ul style="list-style-type: none"> N-Terminally modified version of human GHRH with primary effect of reducing visceral and other body fat in patients with HIV lipodystrophy.
Insulinlike growth factor 1 (mecasermin)	<ul style="list-style-type: none"> Treatment of children with mutations in the GH receptor or transduction mechanisms mediating GH action or IGF-1 gene defects 	<ul style="list-style-type: none"> Adverse effects include hypoglycemia and lipohypertrophy.

Other Peptide Hormones (continued)		
Gonadotropin-releasing hormone agonist analogues <ul style="list-style-type: none"> Goserelin Histrelin Leuprolide Nafarelin Triptorelin 	<ul style="list-style-type: none"> Endometriosis Diagnosis and treatment of precocious puberty Palliative treatment of hormone-responsive tumors (prostate and breast cancer) 	<ul style="list-style-type: none"> Prolonged stimulation of the GnRH receptor by analogues results in downregulation of those receptors with decreased gonadotropin secretion.
Gonadotropin-releasing hormone antagonist analogues <ul style="list-style-type: none"> Ganirelix Cetrorelix Degarelix 	<ul style="list-style-type: none"> Suppression of gonadotropin secretion and used in conjunction with exogenous gonadotropins for assisted reproduction Palliative treatment of advanced prostate cancer (degarelix) 	<ul style="list-style-type: none"> Antagonism at the GnRH receptor results in decreased gonadotropin secretion without initial LH surge as seen with agonist analogues.
Somatostatin Analogues: Act on somatostatin receptors to reduce hormone secretion		
Octreotide	<ul style="list-style-type: none"> Acromegaly 	Long-acting release form is the standard type; given monthly.
Lanreotide	<ul style="list-style-type: none"> Acromegaly 	<ul style="list-style-type: none"> Long-acting release form is the only available standard type; given monthly.
Pasireotide	<ul style="list-style-type: none"> Acromegaly Cushing disease 	<ul style="list-style-type: none"> Short-acting subcutaneous form is the only version FDA-approved for Cushing disease. LAR form given monthly is the only version FDA-approved for acromegaly. Additional adverse effects include significant hyperglycemia in many patients.
Dopamine Agonists: Act on dopamine receptors (D ₂) to decrease prolactin secretion and prolactinoma size		
Bromocriptine	<ul style="list-style-type: none"> Treatment of hyperprolactinemia Reduction in size of prolactinomas Treatment of Parkinson disease 	<ul style="list-style-type: none"> An ergot derivative that has to be given one or more times daily. Common adverse effects include nausea, vomiting, headache, and postural hypotension.
Cabergoline	<ul style="list-style-type: none"> Treatment of hyperprolactinemia Reduction in size of prolactinomas Parkinson disease Acromegaly 	<ul style="list-style-type: none"> A long-acting ergot derivative given once or twice weekly. Has greater efficacy and tolerability than bromocriptine and may be active in patients who do not respond to bromocriptine. At high doses used in patients with Parkinson disease; it cross reacts at the 5HT_{2B} receptor, causing cardiac valve abnormalities (not seen when used for patients with prolactinomas).
Quinagolide	<ul style="list-style-type: none"> Treatment of hyperprolactinemia Reduction in size of prolactinomas 	<ul style="list-style-type: none"> Not available in the U.S.
Hormone Receptor Blockers		
Pegvisomant	<ul style="list-style-type: none"> Treatment of acromegaly 	<ul style="list-style-type: none"> Blocks GH receptor and thus the activity of high GH levels and the generation of IGF-1 in acromegaly. Given by subcutaneous injections daily alone or weekly in combination with somatostatin analogues.

- General Comments

Thyroid hormone is essential for normal development, especially of the CNS. In the adult, thyroid hormone maintains metabolic homeostasis and influences the functions of virtually all organ systems. Thyroid hormone contains iodine, which must be supplied by nutritional intake. The thyroid gland contains large stores of thyroid hormone in the form of *thyroglobulin*. These stores maintain adequate systemic concentrations of thyroid hormone despite significant variations in iodine availability and nutritional intake. The thyroidal secretion is predominantly the prohormone T_4 , which is converted in the liver and other tissues to supply the plasma with the active form, T_3 . Local activation of T_4 also occurs in target tissues (e.g., brain and pituitary) and is increasingly recognized as an important regulatory step in thyroid hormone action. Similarly, local deactivation of T_3 is an important regulatory step. Serum concentrations of thyroid hormones are precisely regulated by the pituitary hormone *TSH* in a negative-feedback system. The predominant actions of thyroid hormone are mediated via nuclear TRs that modulate the transcription of specific genes.

Overt *hyperthyroidism* and *hypothyroidism*, thyroid hormone excess and deficiency, respectively, are associated with numerous clinical manifestations. Milder disease often has a subtler clinical presentation and may be identified based solely on abnormal biochemical tests of thyroid function. Maternal and neonatal hypothyroidism, due to iodine deficiency, remains a major preventable cause of mental retardation worldwide (Zimmermann, 2009). Treatment of the hypothyroid patient consists of thyroid hormone replacement (Biondi and Wartofsky, 2014). Treatments for hyperthyroidism include antithyroid drugs to decrease hormone synthesis and secretion, destruction of the gland by the administration of radioactive iodine, and surgical removal (Brent, 2008). In most patients, disorders of thyroid function can be either cured or controlled.

Likewise, thyroid malignancies are most often localized and resectable (Haugen and Sherman, 2013; Haugen et al., 2016). Metastatic disease often responds to radioiodine treatment but may become highly aggressive. Radioiodine-refractory, progressive thyroid cancers may respond to targeted chemotherapies such as tyrosine kinase inhibitors.

Thyroid Hormones

The thyroid gland produces two fundamentally different types of hormones. The thyroid follicle produces the iodothyronine hormones T_4 and T_3 . The thyroid's parafollicular cells (C cells) produce *calcitonin*, a peptide with 32 amino acids that is not an important endogenous hormone but can be useful as a therapeutic agent in hypercalcemia and osteoporosis (see Chapter 48). Figures 43–1 and 43–2 show the structures of the thyroid hormones and their pathways of synthesis, storage, and release.

Chemistry of Thyroid Hormones

The principal hormones of the thyroid gland are the iodine-containing amino acid derivatives of thyronine (Figure 43–1). Following the isolation and the chemical identification of T_4 , it was generally thought that all the hormonal activity of thyroid tissue could be accounted for by its content of T_4 . However, careful studies revealed that crude thyroid preparations possessed greater calorogenic activity than could be accounted for by their T_4 content. The presence of a “second” thyroid hormone was debated, but T_3 was finally detected, isolated, and synthesized by Gross and Pitt-Rivers in 1952. T_3 has a much higher affinity for the nuclear TR compared with T_4 and is much more potent biologically on a molar basis. The subsequent demonstration of T_3 production from T_4 in athyreotic humans led to the practice of effective replacement in hypothyroidism with levothyroxine only.

Biosynthesis of Thyroid Hormones

The thyroid hormones are synthesized and stored as amino acid residues of *thyroglobulin*, a complex glycoprotein made up of two apparently identical subunits (330 kDa each) and constituting the vast majority of the thyroid follicular colloid. The thyroid gland is unique in storing great quantities of hormone precursor in this way, and extracellular thyroglobulin is proportional to the thyroid mass. The major steps in the synthesis,

Abbreviations

ADME: absorption, distribution, metabolism, excretion
Akt: protein kinase B
BAT: brown adipose tissue
CNS: central nervous system
CYP: cytochrome P450
D #: type # deiodinase, where # = 1, 2, or 3
DIT: diiodotyrosine
EOL: enzyme-linked species
ERK: extracellular signal-regulated kinase
FT₄: free thyroxine
HCN: hyperpolarization-activated, cyclic nucleotide-gated cation channel
HOL: hypoidous acid
IP₃: inositol 1,4,5-trisphosphate
KISS: potassium iodide saturated solution
LDL: low-density lipoprotein
L-T₃: liothyronine
L-T₄: levothyroxine
MAP kinase: mitogen-activated protein kinase
MCT: monocarboxylic acid transporter
MHC: myosin heavy chain
MIT: monoiodotyrosine
MMI: methimazole
NIS: sodium iodide symporter
NO: nitric oxide
OATP1C1: solute carrier organic anion transporter family, member 1C1
PI3K: phosphoinositide 3-kinase
PKC: protein kinase C
PLC: phospholipase C
PTU: propylthiouracil
RAIU: radioactive iodine uptake
rT₃: 3,3',5'-triiodothyronine, reverse T₃
SCN: thiocyanate
SECIS: selenocysteine insertion sequence
SST: somatostatin
T₃: 3,5,3'-triiodothyronine
T₄: thyroxine
TBG: thyroxine-binding globulin
Tetrac: tetraiodothyroacetic acid
Tg: thyroglobulin
T₃G: T₃ glucuronide
T₄G: T₄ glucuronide
T₃K: T₃ pyruvic acid
T₄K: T₄ pyruvic acid
TPO: thyroid peroxidase
TR: thyroid hormone receptor
TRH: thyrotropin-releasing hormone
Triac: triiodothyroacetic acid
T₃S: T₃ sulfate
T₄S: T₄ sulfate
TSH: thyroid-stimulating hormone, thyrotropin

storage, release, and interconversion of thyroid hormones are summarized in Figure 43–2 and described next.

Uptake of Iodide

Iodine ingested in the diet reaches the circulation in the form of iodide ion (I[−]). Normally, the I[−] concentration in the blood is very low (0.2–0.4 µg/dL; ~ 15–30 nM). The thyroid actively transports the ion via

HISTORICAL PERSPECTIVE

The thyroid is named for the Greek word for “shield shaped,” from the shape of the nearby tracheal cartilage. The gland was first recognized as an organ of importance when thyroid enlargement was observed to be associated with changes in the eyes and heart in the condition we now call *hyperthyroidism*. Parry saw his first patient in 1786 but did not publish his findings until 1825. Graves reported the disorder in 1835, Basedow in 1840. Hypothyroidism was described later, in 1874, when Gull associated atrophy of the gland with the symptoms characteristic of *hypothyroidism*. The term *myxedema* was applied to the clinical syndrome in 1878 by Ord, in the belief that the characteristic thickening of the subcutaneous tissues was due to excessive formation of mucus. In 1891, Murray first treated a case of hypothyroidism by injecting an extract of sheep thyroid gland, later shown to be fully effective when given by mouth. The successful treatment of thyroid deficiency by administering thyroid extract was an important step toward modern endocrinology.

Extirpation experiments to elucidate the function of the thyroid were at first misinterpreted because of the simultaneous removal of the parathyroids. However, Gley's research on the parathyroid glands in the late 19th century allowed the functional differentiation of these two endocrine glands. The structure of parathyroid hormone, however, was not reported until the early 1970s. Calcitonin was discovered in 1961, demonstrating that the thyroid gland produced a second hormone.

a specific membrane-bound protein, termed the *NIS* (Kogai and Brent, 2012; Portulano et al., 2014). As a result, the ratio of [I[−]]_{thyroid} to [I[−]]_{plasma} is usually between 20 and 50 and can exceed 100 when the gland is stimulated. Iodide transport is inhibited by a number of ions, such as thiocyanate and perchlorate. TSH stimulates *NIS* gene expression and promotes insertion of *NIS* protein into the membrane in a functional configuration. Thus, decreased stores of thyroid iodine enhance iodide uptake, and the administration of iodide can reverse this situation by decreasing *NIS* protein expression. Iodine is accumulated by other tissues, including the salivary glands, gut, and lactating breast, and it is all mediated by a single *NIS* gene. Individuals with congenital *NIS* gene mutations have absent or defective iodine concentration in all tissues known to concentrate iodine.

Oxidation and Iodination

Transport of iodine from the thyroid follicular cell to the colloid is facilitated by the apical transporter *pendrin*. The oxidation of iodide to its active form is accomplished by *thyroid peroxidase*. The reaction results in the formation of MIT and DIT residues in thyroglobulin, a process referred to as *organification of iodine*, just prior to its extracellular storage in the lumen of the thyroid follicle.

Formation of Thyroxine and Triiodothyronine from Iodotyrosines

The remaining synthetic step is the coupling of two DIT residues to form T₄ or of an MIT and a DIT residue to form T₃. These oxidative reactions are also catalyzed by *thyroid peroxidase*. Intrathyroidal and secreted T₃ are also generated by the 5'-deiodination of T₄.

Synthesis and Secretion of Thyroid Hormones

Because T₄ and T₃ are synthesized and stored within thyroglobulin, proteolysis is an important part of the secretory process. This process is initiated by endocytosis of colloid from the follicular lumen at the apical surface of the cell, with the participation of a thyroglobulin receptor, *megalyn*. This “ingested” thyroglobulin appears as intracellular colloid droplets, which apparently fuse with lysosomes containing the requisite proteolytic enzymes. TSH enhances the degradation of thyroglobulin by increasing the activity of lysosomal *thiol endopeptidases*, which selectively cleave thyroglobulin, yielding hormone-containing intermediates that subsequently are processed by exopeptidases. The liberated hormones then exit the cell

Figure 43-1 Thyronine, thyroid hormones, and precursors.

primarily as T_4 along with some T_3 . The T_3 secreted by the thyroid derives partly from T_3 within mature thyroglobulin and partly from deiodination of T_4 (Figure 43-3), which also occurs peripherally (Figure 43-4).

Conversion of T_4 to T_3 in Peripheral Tissues

The normal daily production of T_4 is estimated to range between 80 and 100 μg ; that of T_3 is between 30 and 40 μg . Although T_3 is secreted by the thyroid, metabolism of T_4 by 5', or outer ring, deiodination in the peripheral tissues accounts for about 80% of circulating T_3 (Gereben et al., 2008). In contrast, removal of the iodine on position 5 of the inner ring produces the metabolically inactive 3,3',5'-triiodothyronine (rT_3 ; Figure 43-3). Under normal conditions, about 40% of T_4 is converted to each of T_3 and rT_3 , and about 20% is metabolized via other pathways, such as glucuronidation in the liver and excretion in the bile. Normal circulating concentrations of T_4 in plasma range from 4.5 to 11 $\mu\text{g}/\text{dL}$; those of T_3 are about 1/100 of that (60–180 ng/dL). T_3 has a much higher affinity for the nuclear TR compared with T_4 and is much more potent biologically on a molar basis.

There are three *iodothyronine deiodinases* (Marsili et al., 2011). Types 1 and 2 (D1, D2) convert T_4 to T_3 . D1 is expressed primarily in the liver and kidney and also in the thyroid and pituitary (Figure 43-4). It is upregulated in hyperthyroidism, downregulated in hypothyroidism, and inhibited by the antithyroid drug *propylthiouracil*. D2 is expressed primarily in the CNS (including the pituitary and hypothalamus) and brown adipose tissue, also in the thyroid, and at low levels in skeletal muscle and other tissues. The activity of D2 is unaffected by propylthiouracil. D2 localizes to the endoplasmic reticulum, which facilitates access of D2-generated T_3 to the nucleus. Organs that express D2 use the locally generated T_3 in addition to plasma T_3 and therefore may have a relatively high fractional occupancy of TRs by T_3 . T_4 induces ubiquitination and degradation of the D2 enzyme. This results in suppressed levels of D2 in hyperthyroidism and elevated levels in hypothyroidism, thus helping to maintain T_3 homeostasis. D3 catalyzes inner ring or 5-deiodination, the main inactivating pathway of T_3 metabolism; D1 performs this function to some extent. D3 is found at highest levels in the CNS and placenta and is also expressed in skin and uterus. D3 can be induced locally by inflammation and hypoxia and is highly expressed in certain tumors. Both D2 and D3 are expressed during development in time- and spatially-restricted patterns.

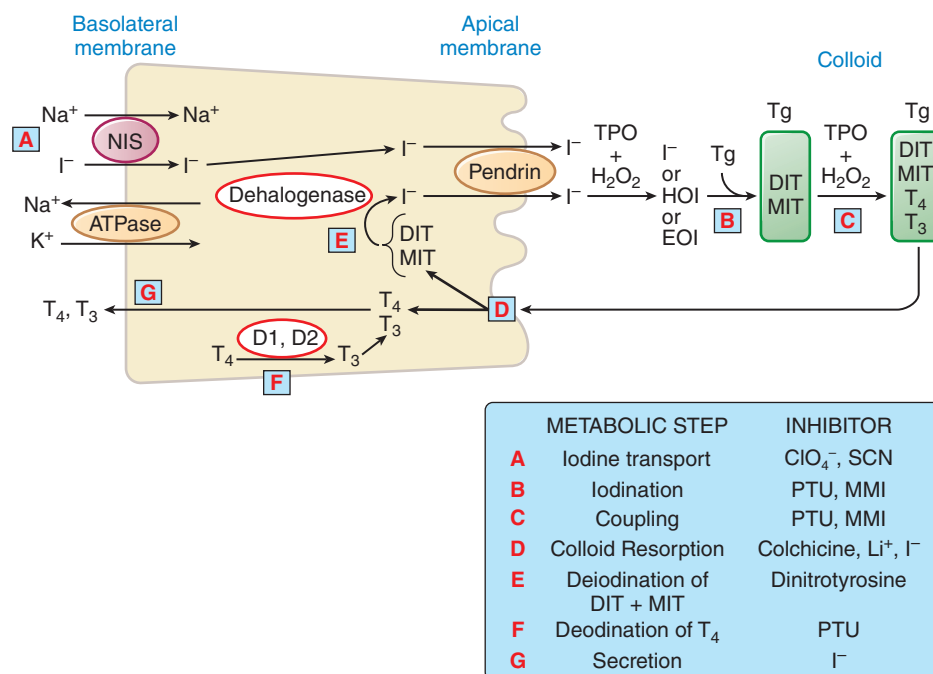

Figure 43-2 Major pathways of thyroid hormone biosynthesis, storage as colloid, and release.

Figure 43-3 Pathways of iodothyronine deiodination.

The three deiodinases contain the rare amino acid *selenocysteine* in their active sites. Incorporation of selenocysteine into the growing peptide chain is a complex process involving multiple proteins. Mutations in one such protein, SECIS binding protein 2, are associated with abnormal circulating thyroid hormone levels (Dumitrescu et al., 2010).

Transport of Thyroid Hormones in the Blood

Iodine in the circulation is normally present in several forms, with 95% as organic iodine and about 5% as iodide. Most (90%–95%) organic iodine is T_4 ; T_3 represents a relatively minor fraction (~5%). The thyroid hormones are transported in the blood in strong but noncovalent association with several plasma proteins.

Thyroxine-binding globulin is the major carrier of thyroid hormones. It is a glycoprotein (mass of ~ 63,000 Da) that binds one molecule of T_4 per molecule of protein with a very high affinity (K_d is ~ 10^{-10} M); T_3 is bound less avidly. T_4 , but not T_3 , also is bound by *transthyretin* (thyroxine-binding prealbumin), a retinol-binding protein. This protein is present in higher concentration than is TBG and binds T_4 with a K_d about 10^{-7} M. Albumin also can bind T_4 when the more avid carriers are saturated, but its physiological importance is unclear. Binding of thyroid hormones to plasma proteins protects the hormones from metabolism and excretion, resulting in their long half-lives in the circulation. The free (unbound) hormone is a small percentage (~0.03% of T_4 and ~ 0.3% of T_3) of the total hormone in plasma. The differential binding affinities for serum proteins also contribute to establishing the 10- to 100-fold differences in circulating hormone concentrations and half-lives of T_4 and T_3 .

Figure 43-4 Peripheral $T_4 \rightarrow T_3$ conversion by deiodinase enzymes.

Essential to understanding the regulation of thyroid function is the “free hormone” concept: Only the unbound hormone has metabolic activity. Because of the high degree of binding of thyroid hormones to plasma proteins, changes in either the concentrations of these proteins or the affinities of the hormone-protein interactions have major effects on the total serum hormone levels. Certain drugs and a variety of pathological and physiological conditions can alter both the binding of thyroid hormones to plasma proteins and the amounts of these proteins (Table 43-1).

Degradation and Excretion of Thyroid Hormones

T_3 and T_4 not only can be deiodinated but also can be metabolized by ether cleavage, conjugation, and oxidative decarboxylation (Figure 43-5). T_4 is eliminated slowly from the body, with a $t_{1/2}$ of 6–8 days. In hyperthyroidism, the $t_{1/2}$ is shortened to 3–4 days, whereas in hypothyroidism it may be 9–10 days. In conditions associated with increased binding to TBG, such as pregnancy, clearance is retarded. The opposite effect is observed when binding to protein is inhibited by certain drugs (see Table 43-1). T_3 , which is less avidly bound to protein, has a $t_{1/2}$ of about 1 day.

The liver is the major site of nondeiodinative degradation of thyroid hormones; T_4 and T_3 are conjugated with glucuronic and sulfuric acids and excreted in the bile. Some thyroid hormone is liberated by hydrolysis of the conjugates in the intestine and reabsorbed. A portion of the

conjugated material reaches the colon unchanged, where it is hydrolyzed and eliminated in feces as the free compounds.

Factors Regulating Thyroid Hormone Secretion

Thyrotropin is a glycoprotein hormone that consists of an α subunit, common to pituitary glycoproteins such as gonadotropins, and a unique β subunit. TSH is secreted in a pulsatile manner and in a circadian pattern (levels are slightly higher during sleep at night) that is the inverse of the cortisol circadian pattern, reflecting the fact that cortisol reduces TSH secretion. TSH secretion is controlled by the hypothalamic peptide TRH and by the concentration of free thyroid hormones in the circulation. Increased thyroid hormone inhibits transcription of both the TRH gene and the genes encoding the α and β subunits of TSH, which suppresses the secretion of TSH and causes the thyroid to become inactive and regress. Any decrease in the normal rate of thyroid hormone secretion by the thyroid evokes an enhanced secretion of TSH. Additional mechanisms mediating the effect of thyroid hormone on TSH secretion appear to be a reduction in TRH secretion by the hypothalamus and a reduction in the number of TRH receptors on pituitary cells (Figure 43-6).

Thyrotropin-Releasing Hormone

Thyrotropin-releasing hormone stimulates the release of preformed TSH from secretory granules and also stimulates the subsequent synthesis of both α and β subunits of TSH. TRH is a tripeptide (L-pyroglutamyl-L-histidyl-L-proline amide) synthesized by the hypothalamus and released into the hypophyseal-portal circulation, where it interacts with TRH receptors on thyrotropes in the anterior pituitary. The binding of TRH to its receptor, a GPCR, stimulates the G_q -PLC-IP₃-Ca²⁺ pathway and activates PKC, ultimately stimulating the synthesis and release of TSH. Two TRH receptors have now been identified, TRH-R1 and TRH-R2, and there are receptor-selective TRH analogues. Somatostatin, dopamine, and glucocorticoids inhibit TRH-stimulated TSH secretion.

Actions of TSH on the Thyroid

Thyroid-stimulating hormone increases the synthesis and secretion of thyroid hormone. These effects follow the binding of TSH to its receptor (a GPCR) on the plasma membrane of thyroid cells. Binding of TSH to its receptor stimulates the G_s -adenylyl cyclase-cyclic AMP pathway. Higher concentrations of TSH activate the G_q -PLC pathway. Multiple mutations of the TSH receptor result in clinical thyroid dysfunction.

Iodine and Thyroid Function

Adequate iodine intake is essential for normal thyroid hormone production. When iodine intake is low, thyroid hormone production is reduced, TSH is secreted in excess, and the thyroid becomes hyperplastic and hypertrophic. The enlarged and stimulated thyroid becomes remarkably efficient at extracting the residual traces of iodide from the blood, developing an iodine gradient that may be 10 times normal; in mild-to-moderate iodine deficiency, the thyroid usually succeeds in producing sufficient hormone and preferentially secreting T_3 . In more severe iodine deficiency,

Figure 43-6 Regulation of thyroid hormone secretion. Myriad neural inputs influence hypothalamic secretion of TRH. TRH stimulates release of TSH from the anterior pituitary; TSH stimulates the synthesis and release of the thyroid hormones T_3 and T_4 . T_3 and T_4 feed back to inhibit the synthesis and release of TRH and TSH. SST can inhibit TRH action, as can dopamine and high concentrations of glucocorticoids. Low levels of I^- are required for T_4 synthesis, but high levels inhibit T_4 synthesis and release.

adult hypothyroidism and cretinism may occur. High levels of iodine inhibit T_4 synthesis and release. In some areas of the world, simple or nontoxic goiter is prevalent because of insufficient dietary iodine. The addition of iodate to table salt (NaCl) provides a convenient iodine supplement. In the U.S., iodized salt provides 100 μ g of iodine per gram. The recommended daily allowances for iodine range from 90 to 120 μ g for children, 150 μ g for adults, 220 μ g for pregnancy, and 290 μ g for lactation (Public Health Committee of the American Thyroid Association et al., 2006). Vegetables, meat, and poultry contain minimal amounts of iodine, whereas dairy products and fish are relatively high in iodine.

Iodized Salt

Iodine has been used empirically for the treatment of iodine-deficiency goiter for 150 years; however, its modern use evolved from extensive studies using iodine to prevent goiter in schoolchildren in Akron, Ohio, where endemic iodine-deficiency goiter was prevalent. The success of these experiments led to the adoption of iodine prophylaxis and therapy in many regions throughout the world where iodine-deficiency goiter was endemic. The most practical method for providing small supplements of iodine for large segments of the population is the addition of iodide or iodate to table salt; iodate is now preferred. The use of iodized salt is required by law in some countries, but in others, such as the U.S., the use is optional.

Transport of Thyroid Hormones Into and Out of Cells

The passage of thyroid hormones across the cell membrane is mediated by specific transporters, the most well-documented of which are two members of the SLC16A family of MCTs, MCTs 8 and 10 (Adjianto and Philip, 2012; van der Deure et al., 2010). MCT8 is widely expressed, including in liver, heart, and brain. MCT8 mutations cause Allan-Herndon-Dudley syndrome, characterized by neurodevelopmental defects that are likely

due to impaired entry of T_4 and T_3 into the brain. MCT8 is also important for transport of T_4 out of the thyroid gland, which explains the finding of reduced serum T_4 concentration in patients with *Allan-Herndon-Dudley syndrome* (Bernal et al., 2015). MCT10 transports both T_4 and T_3 and is widely expressed, but its physiological importance for thyroid hormone transport in vivo is unknown. The organic anion transporter OATP1C1 preferentially transports T_4 over T_3 and is highly expressed in brain capillaries; in mice, OATP1C1 plays an important role in the transport of T_4 across the blood-brain barrier.

Mediation of Effects by Nuclear Receptors

Thyroid hormone action is mediated largely by the binding of T_3 to TRs, which are members of the nuclear receptor superfamily of transcription factors (Brent, 2012). This superfamily includes the receptors for steroid hormones, vitamin D, retinoic acid, a variety of small-molecule metabolites such as certain fatty acids and bile acids, and well as a number of “orphan receptors” (see Chapter 3).

The TRs have the classic nuclear receptor structure: an amino terminal domain, a centrally located zinc finger DNA-binding domain, and a ligand-binding domain that occupies the carboxyl terminal half of the protein. T_3 binds to TRs with about 10-fold greater affinity than does T_4 , and T_4 is not thought to be biologically active in normal physiology. TRs bind to specific DNA sequences (thyroid hormone response elements) in the promoter/regulatory regions of target genes. The transcription of most target genes is repressed by unliganded TRs and induced in response to the binding of T_3 . In the unliganded state, the TR ligand-binding domain interacts with a corepressor complex that includes *histone deacetylases* and other proteins. The binding of T_3 causes replacement of the corepressor complex by a coactivator complex that includes *histone acetyltransferases*, *methyltransferases*, and other proteins. Other thyroid hormone target genes, such as those encoding TRH and the TSH subunits, are negatively regulated by T_3 . The mechanism is not well defined, but these genes tend to be induced by the unliganded TR in addition to being repressed by T_3 .

Two genes encode TRs: *THRA* and *THRB*. *THRA* encodes the receptor TR α 1. TR α 1 is expressed in most cell types, but its major activities are in the regulation of heart rate, body temperature, skeletal muscle function, and the development of bone and small intestine. Patients with *THRA* mutations have been described with short stature, bony abnormalities, and chronic constipation, along with normal circulating TSH and low-normal T_4 levels, a syndrome termed *resistance to thyroid hormone alpha* (Refetoff et al., 2014; van Mullem et al., 2014).

The *THRB* gene has two promoters that lead to the production of TR β 1 and TR β 2. These receptors have unique amino terminal domains but otherwise are identical. TR β 1 is ubiquitous; TR β 2 has a highly restricted pattern of expression, including the pituitary and hypothalamus. TR β 1 mediates specific effects in liver metabolism (including the hypocholesterolemic effect of T_3); TR β 2 has roles in the negative feedback by T_3 on hypothalamic TRH and pituitary TSH and in the development of retinal cones and the inner ear. Mutations in *THRB* cause the syndrome of *resistance to thyroid hormone beta*. This syndrome is associated with goiter, tachycardia, impaired hearing, attention-deficit/hyperactivity disorder, and other abnormalities, and laboratory evaluation shows elevated levels of TSH, T_4 , and T_3 (Refetoff, 1989).

Nongenomic Effects of Thyroid Hormone

Although nuclear receptors are generally thought of as DNA-binding transcription factors, nuclear receptors such as TRs also are found outside the nucleus where they can exert biological effects via rapid nongenomic mechanisms. A truncated form of TR α 1 is palmitoylated and localizes to the plasma membrane, where it causes rapid T_3 -dependent NO production as well as activation of ERK and Akt signaling (Kalyanaraman et al., 2014). Full-length TR α 1 and TR β 1 reportedly associate in a T_3 -dependent manner with the p85 α subunit of PI3K, resulting in Akt activation (Hiroi et al., 2006). It is interesting to note that T_3 administration causes rapid vasodilation, which might be explained by the aforementioned generation of NO. There also is evidence for nongenomic actions of thyroid hormone

via a plasma membrane receptor within integrin $\alpha V\beta 3$ (Lin et al., 2011). This putative receptor binds extracellular T_4 in preference to T_3 , resulting in activation of MAP kinase. The importance of nongenomic actions in thyroid hormone physiology and pathophysiology remains uncertain.

Endogenous Thyroid Hormone–Related Compounds

3-Iodothyronamine and thyronamine are naturally occurring decarboxylated and deiodinated analogues of thyroid hormone that do not bind to TRs (Piehl et al., 2011). These compounds can serve as ligands for the GPCR trace amine–associated receptor 1, an interaction of unknown relevance in humans.

Major Clinical Effects of Thyroid Hormones

Growth and Development

Perhaps the most dramatic example of thyroid hormone action is amphibian metamorphosis, in which the tadpole is transmogrified into a frog by the actions of T_3 . Not only does the animal grow limbs, lungs, and other terrestrial accoutrements, but also T_3 causes the tail to regress.

In humans, thyroid hormone plays a critical role in brain development by mechanisms that are incompletely understood (Abduljabbar and Afifi, 2012; Mayerl et al., 2014). The absence of thyroid hormone during the period of active neurogenesis (up to 6 months postpartum) leads to irreversible mental retardation (cretinism) and is accompanied by multiple morphological alterations in the brain. These severe morphological alterations result from disturbed neuronal migration, deranged axonal projections, and decreased synaptogenesis. Thyroid hormone supplementation begun during the first 2 weeks of postnatal life can prevent the development of these morphological changes. The actions of thyroid hormones are not limited to the brain; most tissues are affected by the administration of thyroid hormone or by its deficiency. The extensive defects in growth and development in cretins vividly illustrate the pervasive effects of thyroid hormones in normal individuals.

Cretinism is usually classified as *endemic* (caused by extreme iodine deficiency) or *sporadic* (a consequence of abnormal thyroid development or a defect in the synthesis of thyroid hormone). The affected child is dwarfed, with short extremities, mentally retardation, and listlessness. Other manifestations include puffy face, enlarged tongue, dry and doughy skin, slow heart rate, constipation, and decreased body temperature. For treatment to be fully effective, the diagnosis must be made shortly after birth and T_4 treatment initiated, long before these clinical manifestations are apparent. In regions of endemic iodine deficiency, iodine replacement is best instituted before pregnancy. Screening of newborn infants for deficient thyroid function is carried out in the U.S. and in most industrialized countries.

Thermogenic Effects

Thyroid hormone is necessary for both obligatory thermogenesis (the heat resulting from vital processes) and facultative or adaptive thermogenesis (Yehuda-Shnaidman et al., 2014). Only a few organs, including the brain, gonads, and spleen, are unresponsive to the thermogenic effects of T_3 . Obligatory thermogenesis is the result of T_3 making most biological processes thermodynamically less efficient for the sake of producing heat. It is likely that multiple mechanisms contribute to this effect, such as the induction of futile cycling and changes in mitochondrial energetics, but the specific pathways involved and their quantitative contributions have yet to be fully defined. Although the induction by T_3 of uncoupling protein 1 is an important thermogenic mechanism in rodent brown adipose tissue, there is no convincing evidence that induction of uncoupling proteins plays a significant role in T_3 -induced thermogenesis in other tissues (skeletal muscle, etc.). Regardless of the mechanism, thermogenesis is highly sensitive to thyroid hormone around the physiological range: Small changes in levothyroxine replacement doses may significantly alter resting energy expenditure in the hypothyroid patient. The capacity of

T_3 to stimulate thermogenesis has evolved along with ancillary effects to support this action, such as the stimulation of appetite and lipogenesis.

Cardiovascular Effects

Hyperthyroid patients have tachycardia, increased stroke volume, increased cardiac index, cardiac hypertrophy, decreased peripheral vascular resistance, and increased pulse pressure (Grais and Sowers, 2014). Hyperthyroidism is a relatively common cause of atrial fibrillation. Hypothyroid patients have bradycardia, decreased cardiac index, pericardial effusion, increased peripheral vascular resistance, decreased pulse pressure, and elevation of mean arterial pressure.

T_3 regulates myocardial gene expression primarily through TR α 1, which is expressed at a higher level in cardiomyocytes than TR β . T_3 shortens diastolic relaxation (lusitropic effect) by inducing expression of the sarcoplasmic reticulum ATPase SERCA2 and decreasing phospholamban, a SERCA2 inhibitor. T_3 increases the force of myocardial contraction (inotropic effect) in part by inducing expression of the ryanodine channel, the calcium channel of the sarcoplasmic reticulum (see Figure 29–6). T_3 induces the gene encoding the α isoform of MHC (MHC α) and decreases expression of the MHC β gene. Because MHC α endows the myosin holoenzyme with greater ATPase activity, this is one mechanism by which T_3 enhances the velocity of contraction. The chronotropic effect of T_3 is mediated by increases in the pacemaker ion current I_f in the sinoatrial node (see Chapter 30). Several proteins that comprise the I_f channel are induced by T_3 , including HCN2 and HCN4. T_3 also appears to have a direct nongenomic vasodilating effect on vascular smooth muscle, which may contribute to the decreased systemic vascular resistance and increased cardiac output of hyperthyroidism.

Metabolic Effects

Thyroid hormone stimulates the expression of hepatic LDL receptors and reduces apolipoprotein B levels through non-LDL receptor pathways (Goldberg et al., 2012; Mullur et al., 2014), such that hypercholesterolemia is a characteristic feature of hypothyroidism.

Thyroid hormone has complex effects on carbohydrate metabolism. Thyrotoxicosis is an insulin-resistant state. Postreceptor defects in the liver and peripheral tissues are manifested by depleted glycogen stores, enhanced gluconeogenesis, and an increase in the rate of glucose absorption from the gut. Compensatory increases in insulin secretion result in hyperinsulinemia. There may be impaired glucose tolerance or even diabetes, but the vast majority of hyperthyroid patients are euglycemic. Conversely, hypothyroidism results in decreased absorption of glucose from the gut, decreased insulin secretion, and a reduced rate of peripheral glucose uptake. Glucose metabolism generally is not affected in a clinically significant manner in nondiabetic hypothyroid patients, although insulin requirements may decrease in the hypothyroid patient with diabetes.

Disorders of Thyroid Function

Thyroid Hypofunction

Hypothyroidism, known as *myxedema* when severe, is the most common disorder of thyroid function. Worldwide, hypothyroidism resulting from iodine deficiency remains a common problem. In nonendemic areas where iodine is sufficient, chronic autoimmune thyroiditis (Hashimoto thyroiditis) accounts for most cases. This disorder is characterized by circulating antibodies directed against thyroid peroxidase and, sometimes, against thyroglobulin. These conditions are examples of *primary hypothyroidism*, failure of the thyroid gland itself. *Central hypothyroidism* occurs much less often and results from diminished stimulation of the thyroid by TSH because of pituitary failure (*secondary hypothyroidism*) or hypothalamic failure (*tertiary hypothyroidism*). Hypothyroidism present at birth (*congenital hypothyroidism*) is an important preventable cause of mental retardation in the world (Gruters and Krude, 2012).

Common symptoms of hypothyroidism include fatigue, lethargy, cold intolerance, mental slowness, depression, dry skin, constipation, mild

weight gain, fluid retention, muscle aches and stiffness, irregular menses, and infertility. Common signs include goiter (primary hypothyroidism only), bradycardia, delayed relaxation phase of the deep tendon reflexes, cool and dry skin, hypertension, nonpitting edema, and facial puffiness. Deficiency of thyroid hormone during the first few months of life causes feeding problems, failure to thrive, constipation, and sleepiness. Retardation of mental development is irreversible if not treated promptly. Childhood hypothyroidism impairs linear growth and bone maturation. Because the signs and symptoms of hypothyroidism are nonspecific, diagnosis requires the finding of an elevated serum TSH level and reduced or low-normal serum free T_4 or, in cases of central hypothyroidism, only a decreased serum free T_4 .

Thyroid Hyperfunction

Thyrotoxicosis is a condition caused by elevated concentrations of circulating free thyroid hormones. Increased thyroid hormone production is the most common cause, with the common link of TSH receptor stimulation and increased iodine uptake by the thyroid gland, as established by the measurement of the percentage uptake of ^{123}I or ^{131}I in a 24-h RAIU test.

Thyroid-stimulating hormone receptor stimulation is either the result of TSH receptor stimulating antibodies in Graves disease or somatic activating TSH receptor mutations in autonomously functioning nodules or a toxic goiter. In contrast, thyroid inflammation or destruction resulting in excess “leak” of thyroid hormones or excess exogenous thyroid hormone intake results in a low 24-h RAIU test. The term *subclinical hyperthyroidism* is defined as those with a subnormal serum TSH and normal concentrations of free T_4 and T_3 . Atrial arrhythmias, excess cardiac mortality, and excessive bone loss have been associated with this profile of thyroid function tests.

Graves disease is the most common cause of high RAIU thyrotoxicosis, accounting for 60%–90% of cases, depending on age and geographic region. Graves disease is an autoimmune disorder characterized by increased thyroid hormone production, diffuse goiter, and IgG antibodies that bind to and activate the TSH receptor. As with most types of thyroid dysfunction, women are affected more than men, with a ratio ranging from 5:1 to 7:1. Graves disease is more common between the ages of 20 and 50 but may occur at any age. Graves disease is commonly associated with other autoimmune diseases. The characteristic exophthalmos associated with Graves disease is an infiltrative ophthalmopathy and is considered an autoimmune-mediated inflammation of the periorbital connective tissue and extraocular muscles. Toxic uninodular/multinodular goiter accounts for 10%–40% of cases of hyperthyroidism and is more common in older patients. A low RAIU value is seen in the destructive thyroiditides and in thyrotoxicosis in patients taking excessive doses of thyroid hormone.

Most of the signs and symptoms of thyrotoxicosis stem from the excessive production of heat, increased motor activity, and increased sensitivity to catecholamines produced by the sympathetic nervous system. The skin is flushed, warm, and moist; the muscles are weak and tremulous; the heart rate is rapid, the heartbeat is forceful, and the arterial pulses are prominent and bounding. Increased expenditure of energy gives rise to increased appetite and, if intake is insufficient, to loss of weight. There also may be insomnia, difficulty in remaining still, anxiety and apprehension, intolerance to heat, and increased frequency of bowel movements. Angina, arrhythmias, and heart failure may be present in older patients. Older patients may experience less manifestations of sympathetic nervous system stimulation and reduced symptoms compared to younger individuals, sometimes referred to as “apathetic hyperthyroidism.” Some individuals may show extensive muscular wasting as a result of thyroid myopathy. The most severe form of hyperthyroidism is thyroid storm (see section that follows on therapeutic uses of antithyroid drugs).

Thyroid Function Tests

Measurement of the total hormone concentration in plasma may not give an accurate picture of the activity of the thyroid gland; total hormone

concentration changes with alterations in amount and affinity of TBG in plasma. Although equilibrium dialysis of undiluted serum and radioimmunoassay for FT₄ in the dialysate represent the gold standard for determining FT₄ concentrations, this assay is costly and typically unavailable in routine clinical laboratories. The most common assays used for estimating the free T₄ and free T₃ concentrations employ labeled analogues of these iodothyronines in chemiluminescence and enzyme-linked immunoassays. These assays are subject to influences of altered serum-binding proteins, nonthyroid disease states, acute illnesses, and other drugs. In individuals with normal pituitary function, serum measurement of TSH is the thyroid function test of choice because pituitary secretion of TSH is sensitively regulated in response to circulating concentrations of thyroid hormones. TSH is suppressed in patients with thyrotoxicosis and elevated in those with primary hypothyroidism, and these changes generally precede abnormalities in free T₄ and free T₃.

Therapeutic Uses of Thyroid Hormone

The major indications for the therapeutic use of thyroid hormone are for hormone replacement therapy in patients with hypothyroidism and for TSH suppression therapy in patients with thyroid cancer.

Thyroid Hormone Preparations

Synthetic preparations of the sodium salts of the natural isomers of the thyroid hormones are used for thyroid hormone therapy (Biondi and Wartofsky, 2014).

Levothyroxine

Levothyroxine sodium is available in tablets and liquid-filled capsules for oral administration and as a lyophilized powder for injection. Table 43-2 lists drugs and other factors that may influence levothyroxine dosage requirements. Absorption of levothyroxine occurs in the stomach and small intestine and is incomplete (~80% of the tablet dose is absorbed). Absorption

TABLE 43-2 ■ FACTORS INFLUENCING ORAL LEVOTHYROXINE THERAPY

Drugs and other factors that may increase levothyroxine dosage requirements

Impaired levothyroxine absorption

- Aluminum-containing antacids, proton pump inhibitors, sucralfate
- Bile acid sequestrants (cholestyramine, colestipol, colestevlam)
- Calcium carbonate (effect generally small), phosphate binders (lanthanum carbonate, sevelamer)
- Chromium picolinate, raloxifene, iron salts
- Food, soy products (effect generally very small), lactose intolerance (single case report)

Increased thyroxine metabolism, CYP3A4 induction

- Rifampin, carbamazepine, phenytoin, sertraline

Impaired T₄ → T₃ conversion

- Amiodarone

Mechanisms uncertain or multifactorial

- Estrogen, pregnancy, lovastatin, simvastatin, ethionamide, Tyr kinase inhibitors

Drugs and other factors that may decrease levothyroxine dosage requirements

- Advancing age (>65 years), androgen therapy in women

Drugs that may decrease TSH without changing free T₄ in levothyroxine-treated patients

- Metformin

is slightly increased when the hormone is taken on an empty stomach, and it is associated with less variability in TSH levels when taken this way regularly (Bach-Huynt et al., 2009). Patients with gastrointestinal problems that result in poor absorption of tablet formulations may achieve better absorption with liquid-filled capsules (Vita et al., 2014). Serum T₄ peaks 2–4 h after oral ingestion, but changes are barely discernible with once-daily dosing due to the plasma $t_{1/2}$ of about 7 days. Given this long $t_{1/2}$, omission of one day's dose has only marginal effects on the serum TSH and free T₄, but to maintain consistent dosing, the patient should be instructed to take a double dose the next day. For any given serum TSH, the serum T₄/T₃ ratio is slightly higher in patients taking levothyroxine than in patients with endogenous thyroid function due to the fact that about 20% of circulating T₃ normally is supplied by direct thyroidal secretion (Gullo et al., 2011; Jonklaas et al., 2008). Follow-up blood tests typically are done about 6 weeks after any dosage change due to the 1-week plasma $t_{1/2}$ of T₄. If patients cannot take oral medications or intestinal absorption is in question, levothyroxine may be given intravenously once daily at a dose of about 80% of the patient's daily oral requirement.

Liothyronine

Liothyronine sodium is the salt of T₃ and is available in tablets and in an injectable form. Liothyronine absorption is nearly 100%, with peak serum levels 2–4 h following oral ingestion. Liothyronine may be used occasionally when a more rapid onset of action is desired, such as in the rare presentation of myxedema coma, or if rapid termination of action is desired, such as when preparing a patient with thyroid cancer for ¹³¹I therapy. Liothyronine is less desirable for chronic replacement therapy due to the requirement for more-frequent dosing (plasma $t_{1/2}$ is 18–24 h), higher cost, and transient elevations of serum T₃ concentrations above the normal range. In addition, organs that express the D2 use the locally generated T₃ in addition to plasma T₃; hence, there is theoretical concern that these organs will not maintain physiological intracellular T₃ levels in the absence of plasma T₄. On a weight basis, the required daily dose of liothyronine (given three times a day to achieve steady serum T₃ levels) is about one-third that of L-T₄ to achieve an equivalent TSH level in hypothyroid patients (Celi et al., 2011). However, normalization of circulating TSH results in an almost 2-fold higher serum T₃ compared with levothyroxine therapy because negative feedback on TSH normally relies in part on the local generation of T₃ from circulating T₄.

Other Preparations

A mixture of levothyroxine and T₃ around 4:1 by weight and desiccated thyroid preparations with a similar T₄:T₃ ratio also are available. A 60-mg (1-grain) desiccated thyroid tablet is approximately equivalent in activity to 80 µg of levothyroxine.

Thyroid Hormone Replacement Therapy in Hypothyroidism

Thyroxine is the hormone of choice for thyroid hormone replacement therapy due to its consistent potency and prolonged duration of action (Jonklaas et al., 2014). This therapy relies on D1 and D2 to convert T₄ to T₃ to maintain a steady serum level of free T₃.

The average daily adult full replacement dose of L-T₄ is 1.7 µg/kg body weight (0.8 µg/lb). Dosing should generally be based on lean body mass. The goal of therapy is to normalize the serum TSH (in primary hypothyroidism) or free T₄ (in secondary or tertiary hypothyroidism) and to relieve symptoms of hypothyroidism. In primary hypothyroidism, generally it is sufficient to follow TSH without free T₄. A patient with mild primary hypothyroidism will achieve a normal TSH with substantially less than a full replacement dose, but as the endogenous thyroid function declines, the dose will need to be increased. In individuals older than 60 years and those with known or suspected cardiac disease or with areas of autonomous thyroid function, institution of therapy at a subreplacement dose of L-T₄ (12.5–50 µg/d) is appropriate. The dose can be increased by 25 µg/d every 6 weeks until the TSH is normalized. The vast majority of controlled trials do not support the hypothesis that combination therapy with T₄ plus T₃ provides a better therapeutic response than does T₄ alone (Grozinsky-Glasberg et al., 2006), although for unclear reasons occasional

patients say they feel better when taking combination therapies, such as desiccated thyroid. A double-blind crossover study of hypothyroid patients comparing levothyroxine and desiccated thyroid, maintaining the same reference range TSH, found that those who preferred desiccated thyroid had lost weight on this preparation (Hoang et al., 2013). Monotherapy with levothyroxine most closely mimics normal physiology and generally is preferred (Jonklaas et al., 2014).

Hypothyroidism During Pregnancy

Due to the increased serum concentration of TBG induced by estrogen, the expression of D3 by the placenta, and the small amount of transplacental passage of L-T₄ from mother to fetus, a higher dose of levothyroxine is usually required in pregnant patients. Overt hypothyroidism during pregnancy is associated with increased risk of miscarriage, fetal distress, preterm delivery, and impaired psychoneural and motor development in the progeny. Even mild maternal hypothyroidism may have subtle adverse effects. As part of prepregnancy planning, the dose of levothyroxine should be adjusted to maintain the TSH in the lower portion of the reference range. Women should increase their levothyroxine dose by about 30% as soon as pregnancy is confirmed, thus anticipating the increased need (Jonklaas et al., 2014). This can be achieved by taking two extra levothyroxine tablets per week. The serum TSH is measured in the first trimester, and the levothyroxine dose is further adjusted with the goal of maintaining the TSH in the lower portion of the reference range. Subsequent dosage adjustments are based on serum TSH, measured 4–6 weeks after each adjustment. TSH should be monitored periodically through to 20 weeks' gestation, when the dose adjustment is usually maximal, and then once between weeks 26 and 32 to confirm an adequate levothyroxine dose. The levothyroxine dose can be changed back to prepregnancy levels the day after delivery, with a follow-up TSH checked about 6 weeks later.

Isolated *hypothyroxinemia* during pregnancy, defined by a low serum free T₄ concentration and normal serum TSH concentration, has been associated in a few studies with adverse neurocognitive development in the offspring. There are currently insufficient studies to recommend routine treatment of isolated hypothyroxinemia in pregnancy. Evaluation and treatment are further complicated by the influence of the elevated serum-binding proteins in pregnancy and lower values obtained for free T₄ by the analogue method, especially in the second and third trimesters. TSH remains the best test during pregnancy to evaluate thyroid status in pregnancy and response to treatment.

Myxedema Coma

Myxedema coma is a rare syndrome that represents the extreme expression of severe, long-standing hypothyroidism. Common precipitating factors include infection, congestive heart failure, and medical noncompliance. Myxedema coma occurs most often in elderly patients during the winter months. Cardinal features of myxedema coma are *hypothermia*, *respiratory depression*, and *decreased consciousness*.

Intravenous administration of thyroid hormone is advised (Jonklaas et al., 2014). Therapy with levothyroxine is begun with a loading dose of 200–400 µg followed by a daily full replacement dose. Some clinicians recommend adding liothyronine (10 µg intravenously followed by 2.5 to 10 µg every 8 h) until the patient is stable and conscious. Other important aspects of therapy include ventilatory support, passive warming with blankets, correction of hyponatremia, and treatment of the precipitating cause. Treatment with intravenous glucocorticoids is recommended until coexisting adrenal insufficiency is excluded.

Congenital Hypothyroidism

Success in the treatment of congenital hypothyroidism depends on the age at which therapy is started and the speed with which hypothyroidism is corrected. If therapy is instituted within the first 2 weeks of life, normal physical and mental development can be achieved (Gruters and Krude, 2012; Rose et al., 2006).

To rapidly normalize the serum T₄ concentration in the congenitally hypothyroid infant, an initial daily dose of levothyroxine of 10–15 µg/kg is recommended (Jonklaas et al., 2014; Leger et al., 2014). Because rapid normalization is even more important in infants with severe hypothyroidism,

doses on the higher side of the range mentioned are preferred in those infants. One published study found that brand-name and generic levothyroxine were not bioequivalent in infants with severe congenital hypothyroidism (Carswell et al., 2013), and this has led some experts to recommend against generic levothyroxine in this situation (Leger et al., 2014). The goal is to achieve a free T₄ in the upper half of the reference range and a TSH in the lower half, although some infants maintain a high TSH that seems to reflect mis-set feedback regulation. Laboratory evaluations of TSH and free T₄ are performed 2 and 4 weeks after treatment is initiated, every 1–2 months in the first 6 months, every 2–3 months between 6 months and 3 years of age, and every 6–12 months from age 3 years until the end of growth. Monitoring should be more frequent if the results are abnormal. Soy formula may impair levothyroxine absorption, necessitating a dosage increase.

Thyroid Hormone Replacement Therapy in Thyroid Cancer

The mainstays of therapy for well-differentiated thyroid cancer (papillary, follicular) are surgical thyroidectomy, radioiodine (discussed in material that follows), and levothyroxine to maintain a low TSH (Haugen et al., 2016). The rationale for TSH suppression is that TSH is a growth factor for thyroid cancer, but there are no randomized controlled trials that addressed the optimal TSH target range. A reasonable approach is to adjust the levothyroxine dose to maintain a low-normal TSH value in patients without persistent disease and at low risk for recurrence (Wang et al., 2015), a mildly subnormal TSH value (~0.1 mU/L) in patients at high risk for recurrence, and a more subnormal TSH level for patients with persistent disease. The benefits of TSH suppression need to be weighed against the risks, including osteoporosis and atrial fibrillation.

Thyroid Nodules

Nodular thyroid disease is the most common endocrinopathy. Thyroid nodules usually are asymptomatic, although they can cause neck discomfort, dysphagia, and a choking sensation. As with other forms of thyroid disease, nodules are more frequent in women. Exposure to ionizing radiation, especially in childhood, increases the rate of nodule development. Approximately 5% of thyroid nodules that come to medical attention are malignant. Most patients with thyroid nodules are euthyroid, which should be confirmed by TSH measurement. The most useful diagnostic procedures generally are ultrasound imaging and a fine-needle aspiration biopsy. The use of levothyroxine to suppress TSH in euthyroid individuals with thyroid nodules cannot be recommended as a general practice. However, if the TSH is elevated, it is appropriate to administer levothyroxine to bring the TSH into the lower portion of the reference range.

Adverse Effects of Thyroid Hormone

Adverse effects of thyroid hormone generally occur only on overtreatment and are similar to the consequences of hyperthyroidism. An excess of thyroid hormone can increase the risk of atrial fibrillation, especially in the elderly, and can increase the risk of osteoporosis, especially in postmenopausal women.

Antithyroid Drugs and Other Thyroid Inhibitors

Myriad compounds are capable of interfering, directly or indirectly, with the synthesis, release, or action of thyroid hormones (Tables 43–2 and 43–3). Several types are clinically useful:

- Antithyroid drugs, which interfere directly with the synthesis of thyroid hormones
- Ionic inhibitors, which block the iodide transport mechanism
- High concentrations of iodine, which decrease release of thyroid hormones from the gland and also may decrease hormone synthesis
- Radioactive iodine, which damages the thyroid gland with ionizing radiation

TABLE 43-3 ■ AGENTS THAT DISRUPT THYROID HORMONE SYNTHESIS, RELEASE, AND METABOLISM

MECHANISM	AGENT
Iodide uptake	Perchlorate, fluoroborate, thiocyanate, nitrate
Organification of iodine	Thionamides (propylthiouracil, methimazole, carbimazole), thiocyanate, sulfonamides
Coupling reaction	Sulfonamides, thionamides
Hormone release	Li ⁺ salts, iodide
Peripheral iodothyronine deiodination	Propylthiouracil, amiodarone, oral cholecystographic agents
Accelerated hepatic metabolism	Phenobarbital, rifampin, carbamazepine, phenytoin, sertraline, bexarotene

Adjuvant therapy with drugs that have no specific effects on thyroid hormone synthesis is useful in controlling the peripheral manifestations of thyrotoxicosis, including inhibitors of the peripheral deiodination of T₄ to T₃, β adrenergic receptor antagonists, and Ca²⁺ channel blockers.

Antithyroid Drugs

The antithyroid drugs with clinical utility are the *thioureylenes*, which belong to the family of thioamides. *Propylthiouracil* is the prototype (Figure 43-7).

HISTORICAL PERSPECTIVE

Studies on the mechanism of the development of goiter began with the observation that rabbits fed a diet composed largely of cabbage often developed goiters. This result was probably due to the presence of precursors of the thiocyanate ion in cabbage leaves. Later, two pure compounds were shown to produce goiter: sulfaguanidine, a sulfanilamide antimicrobial used to treat enteric infections, and phenylthiourea. Investigation of the effects of thiourea derivatives revealed that rats became hypothyroid despite hyperplastic changes in their thyroid glands that were characteristic of intense thyrotropic stimulation. After treatment was begun, no new hormone was made, and the goitrogen had no visible effect on the thyroid gland following hypophysectomy or the administration of thyroid hormone. This suggested that the goiter was a compensatory change resulting from the induced state of hypothyroidism and that the primary action of the compounds was to inhibit the formation of thyroid hormone. The therapeutic possibilities of such agents in hyperthyroidism were evident, and the substances so used became known as *antithyroid drugs*.

Mechanism of Action

Antithyroid drugs inhibit the formation of thyroid hormones by interfering with the incorporation of iodine into tyrosyl residues of thyroglobulin; they also inhibit the coupling of these iodotyrosyl residues to form iodothyronines (see Figure 43-2). These drugs are thought to inhibit the peroxidase enzyme. Inhibition of hormone synthesis results in the depletion of stores of iodinated thyroglobulin as the protein is hydrolyzed and the hormones are released into the circulation. In addition to blocking hormone synthesis, propylthiouracil partially inhibits the peripheral deiodination of T₄ to T₃. *Methimazole* does not have this effect; this provides a rationale for the choice of propylthiouracil over other antithyroid drugs in the treatment of severe hyperthyroid states or of thyroid storm (Angell et al., 2015).

Figure 43-7 Structures of antithyroid drugs of the thioamide type.

ADME

The antithyroid compounds currently used in the U.S. are propylthiouracil (6-*n*-propylthiouracil) and methimazole (1-methyl-2-mercaptoimidazole). In Europe, carbimazole, a carbethoxy derivative of methimazole, is available, and its antithyroid action is due to its conversion to methimazole after absorption (Figure 43-7). Pharmacological properties of propylthiouracil and methimazole are shown in Table 43-4.

Absorption of effective amounts of propylthiouracil occurs within 20–30 min of an oral dose; the duration of action is brief. The effect of a dose of 100 mg of propylthiouracil begins to wane in 2–3 h; even a 500-mg dose is completely inhibitory for only 6–8 h. As little as 0.5 mg of methimazole similarly decreases the organification of radioactive iodine in the thyroid gland, but a single dose of 10–25 mg is needed to extend the inhibition to 24 h.

The *t*_{1/2} of propylthiouracil in plasma is about 75 min; that of methimazole is 4–6 h. The drugs are concentrated in the thyroid, and methimazole, derived from the metabolism of carbimazole, accumulates after carbimazole is administered. Drugs and metabolites appear largely in the urine.

Therapeutic Uses

The antithyroid drugs are used in the treatment of hyperthyroidism in the following ways:

- As definitive treatment, to control the disorder in anticipation of a spontaneous remission in Graves disease
- In conjunction with radioactive iodine, to hasten recovery while awaiting the effects of radiation
- To control the disorder in preparation for surgical treatment

Methimazole is the drug of choice for Graves disease; it is effective when given as a single daily dose, has improved adherence, and is less toxic than propylthiouracil. Methimazole has a relatively long plasma and intrathyroidal *t*_{1/2}, as well as a long duration of action. The usual starting dose for methimazole is 15–40 mg per day. The usual starting dose of propylthiouracil is 100 mg every 8 h. When doses greater than 300 mg daily are

TABLE 43-4 ■ PHARMACOKINETIC FEATURES OF ANTITHYROID DRUGS

	PROPYLTHIOURACIL	METHIMAZOLE
Plasma protein binding	~75%	Nil
Plasma <i>t</i> _{1/2}	75 min	~4–6 h
Volume of distribution	~0.4 L/kg	~0.7 L/kg
Concentrated in thyroid	Yes	Yes
Metabolism of drug during illness		
Severe liver disease	Normal	Decreased
Severe kidney disease	Normal	Normal
Dosing frequency	1–4 times daily	Once or twice daily
Transplacental passage	Low	Low
Levels in breast milk	Low	Low

needed, further subdivision of the time of administration to every 4–6 h is occasionally helpful. Once euthyroidism is achieved, usually within 12 weeks, the dose of antithyroid drug can be reduced, but not stopped, lest an exacerbation of Graves disease occur.

Response to Treatment

The thyrotoxic state usually improves within 3–6 weeks after the initiation of antithyroid drugs. The clinical response is related to the dose of antithyroid drug, the size of the goiter, and pretreatment serum T_3 concentration. The rate of response is determined by the quantity of stored hormone, the rate of turnover of hormone in the thyroid, the $t_{1/2}$ of the hormone in the periphery, and the completeness of the block in synthesis imposed by the dosage given. Hypothyroidism may develop as a result of overtreatment. After treatment is initiated, patients should be examined and thyroid function tests (serum FT_4 and total or free T_3 concentrations) measured every 2–4 months. Once euthyroidism is established, follow-up every 4–6 months is reasonable. Control of the hyperthyroidism is usually associated with a decrease in goiter size and normalization of serum TSH concentration. When this occurs, the dose of the antithyroid drug should be significantly decreased to avoid hypothyroidism.

Untoward Reactions

The incidence of side effects from propylthiouracil and methimazole as currently used is relatively low. Agranulocytosis is the most serious reaction, usually occurring in the first few weeks or months of therapy but sometimes later. Because agranulocytosis usually occurs rapidly and is not associated with a gradual reduction in granulocyte count, periodic prospective monitoring of granulocyte count is not generally helpful. Patients should be instructed to immediately report the development of sore throat or fever and should discontinue their antithyroid drug and obtain a granulocyte count. Agranulocytosis is reversible on discontinuation of the offending drug, and the administration of recombinant human granulocyte colony-stimulating factor may hasten recovery. Mild granulocytopenia, if noted, may be due to thyrotoxicosis or may be the first sign of this dangerous drug reaction; frequent leukocyte counts are then required.

The most common reaction is a mild urticarial papular rash that often subsides spontaneously without interrupting treatment but sometimes requires administration of an antihistamine and corticosteroids and changing to another antithyroid drug. Other less-frequent complications are pain and stiffness in the joints, paresthesias, headache, nausea, skin pigmentation, and loss of hair. Drug fever, hepatitis, and nephritis are rare, although abnormal liver function tests are not infrequent with higher doses of propylthiouracil. Although vasculitis was previously thought to be a rare complication, Antineutrophilic cytoplasmic antibodies (ANCA) have been reported to occur in about 50% of patients receiving propylthiouracil and rarely with methimazole.

Thyrotoxicosis in Pregnancy

Thyrotoxicosis occurs in about 0.2% of pregnancies and is caused most frequently by Graves disease. Antithyroid drugs are the treatment of choice; radioactive iodine is clearly contraindicated. Both propylthiouracil and methimazole cross the placenta equally, and either may be used safely in the pregnant patient. Methimazole is usually avoided in the first trimester in favor of propylthiouracil due to methimazole-associated embryopathy, and then methimazole is used for the remainder of the pregnancy due to the concern for propylthiouracil-associated liver failure in pregnancy. Carbimazole is used in the E.U. during pregnancy and is rarely associated with congenital abnormalities. The antithyroid drug dosage should be minimized to keep the serum FT_4 index in the upper half of the normal range or slightly elevated. As pregnancy progresses, Graves disease often improves. Relapse or worsening of Graves disease is common after delivery, and patients should be monitored closely. Methimazole in nursing mothers, up to 20 mg daily, reportedly has no effect on thyroid function in the infant; propylthiouracil is thought to partition into breast milk even less than methimazole.

Adjuvant Therapy

Several drugs that have no intrinsic antithyroid activity are useful in the symptomatic treatment of thyrotoxicosis.

The β Adrenergic receptor antagonists (see Chapter 12) are effective in antagonizing the sympathetic/adrenergic effects of thyrotoxicosis—thereby reducing the tachycardia, tremor, and stare—and relieving palpitations, anxiety, and tension. Either propranolol, 20–40 mg four times daily, or atenolol, 50–100 mg daily, is usually given initially.

The Ca^{2+} channel blockers (diltiazem, 60–120 mg four times daily) can be used to control tachycardia and decrease the incidence of supraventricular tachyarrhythmias. Usually, only short-term treatment with β adrenergic receptor antagonists or Ca^{2+} channel blockers is required, 2–6 weeks, and it should be discontinued once the patient is euthyroid.

Immunotherapy has been used for Graves hyperthyroidism and ophthalmopathy. The B-lymphocyte-depleting agent rituximab, when used with methimazole, prolongs remission of Graves disease.

Thyroid Storm

Thyroid storm is an uncommon but life-threatening complication of thyrotoxicosis in which a severe form of the disease is usually precipitated by an intercurrent medical problem. It occurs in untreated or partially treated thyrotoxic patients. Precipitating factors associated with thyrotoxic crisis include infections, stress, trauma, thyroidal or nonthyroidal surgery, diabetic ketoacidosis, labor, heart disease, and, rarely, radioactive iodine treatment.

Clinical features are similar to those of thyrotoxicosis but more exaggerated. Cardinal features include fever (temperature usually $>38.5^\circ\text{C}$) and tachycardia out of proportion to the fever. Nausea, vomiting, diarrhea, agitation, and confusion are frequent presentations. Coma and death may ensue in up to 20% of patients. Thyroid function abnormalities are similar to those found in uncomplicated hyperthyroidism. Therefore, thyroid storm is primarily a clinical diagnosis.

Treatment includes supportive measures such as intravenous fluids, antipyretics, cooling blankets, and sedation. Antithyroid drugs are given in large doses. Propylthiouracil is preferred over methimazole because it also impairs peripheral conversion of $T_4 \rightarrow T_3$. Oral iodides are used after the first dose of an antithyroid drug has been administered. Treatment of the underlying precipitating illness is essential.

Ionic Inhibitors

The ionic inhibitors are substances that interfere with the concentration of iodide by the thyroid gland. These agents are anions that resemble iodide: thiocyanate, perchlorate, and fluoroborate, all monovalent hydrated anions of a size similar to that of iodide.

Thiocyanate differs from the rest qualitatively; it is not concentrated by the thyroid gland but in large amounts may inhibit the organification of iodine. Perchlorate is 10 times as active as thiocyanate. Perchlorate (ClO_4^-) blocks the entrance of iodide into the thyroid by competitively inhibiting the NIS, and itself can be transported by NIS into the thyroid gland. The various NIS inhibitors (perchlorate, thiocyanate, and nitrate) are additive in inhibiting iodine uptake. Perchlorate can be used to control hyperthyroidism; however, when given in excessive amounts (2–3 g daily), it has caused fatal aplastic anemia. Perchlorate in doses of 750 mg daily has been used in the treatment of Graves disease, although it is not available in North America.

Perchlorate can be used to “discharge” inorganic iodide from the thyroid gland in a diagnostic test of iodide organification. Other ions, selected on the basis of their size, also have been found to be active; fluoroborate (BF_4^-) is as effective as perchlorate.

Lithium decreases secretion of T_4 and T_3 , which can cause overt hypothyroidism in some patients taking Li^+ for the treatment of mania (see Chapter 16).

Iodine

Iodide is the oldest remedy for disorders of the thyroid gland. In high concentration, iodide can influence several of the important functions of the thyroid gland. Iodide limits its own transport and acutely and transiently inhibits the synthesis of iodotyrosines and iodothyronines (the Wolff-Chaikoff effect) (Pramyothin et al., 2011). An important clinical effect of high $[\text{I}^-]_{\text{plasma}}$ is inhibition of the release of thyroid hormone.

This action is rapid and efficacious in severe thyrotoxicosis. The effect is exerted directly on the thyroid gland and can be demonstrated in the euthyroid subject as well as in the hyperthyroid patient.

Response to Iodine in Hyperthyroidism

The response to iodine in patients with hyperthyroidism is often striking and rapid: Release of thyroid hormone into the circulation is rapidly blocked, and its synthesis is mildly decreased. In the thyroid gland, vascularity is reduced, the gland becomes much firmer, the cells become smaller, and colloid reaccumulates in the follicles as iodine concentration increases. The maximal effect occurs after 10–15 days of continuous therapy. Iodide therapy usually does not completely control the manifestations of hyperthyroidism, and the beneficial effect disappears. The uses of iodide in the treatment of hyperthyroidism are in the preoperative period in preparation for thyroidectomy and, in conjunction with antithyroid drugs and propranolol, in the treatment of thyrotoxic crisis.

Another use of iodide is to protect the thyroid from radioactive iodine fallout following a nuclear accident or military exposure. Because the uptake of radioactive iodine is inversely proportional to the serum concentration of stable iodine, the administration of 30–100 mg of iodine daily will markedly decrease the thyroid uptake of radioisotopes. Strong iodine solution (Lugol solution) consists of 5% iodine and 10% potassium iodide, yielding a dose of about 8 mg of iodine per drop. KISS also is available, containing 50 mg per drop. Typical doses include 16–36 mg (2–6 drops) of Lugol solution or 50–100 mg (1–2 drops) of KISS three times a day. A potassium iodide product (Thyroshield) is available over the counter to take in the event of a radiation emergency and block the uptake of radioiodine into the thyroid gland. The adult dose is 2 mL (130 mg) every 24 h, as directed by public health officials.

Euthyroid patients with a history of a wide variety of underlying thyroid disorders may develop iodine-induced hypothyroidism when exposed to large amounts of iodine present in many commonly prescribed drugs (Table 43–5), and these patients do not escape from the acute Wolff-Chaikoff effect (Pramyothin et al., 2011).

TABLE 43–5 ■ IODIDE CONTENT OF COMMONLY USED DRUGS AND COMPOUNDS

DRUGS	IODINE CONTENT
Oral or local	
Amiodarone	75 mg/200 mg tablet
Iodoquinol (diiodohydroxyquin)	134 mg/tablet
Echothiophate iodide ophthalmic solution	5–41 µg/drop
Iodoquinol	134 mg/tablet
Idoxuridine ophthalmic solution	18 µg/drop
Lugol solution	5–6 mg/drop
KI, saturated solution (KISS)	38 mg/drop
Topical antiseptics	
Clinoquinol cream	12 mg/g
Povidone-iodine	10 mg/mL
Radiographic contrast agents	
Diatrizoate meglumine sodium	370 mg/mL
Iothalamate	320 mg/mL
Ioxaglate	370 mg/mL
Iopamidol	370 mg/mL
Iohexol	350 mg/mL
Ioxilan	370 mg/mL

Untoward Reactions

Occasional individuals show a marked sensitivity to iodine. Angioedema is the prominent symptom, and laryngeal edema may lead to suffocation. Multiple cutaneous hemorrhages may be present; manifestations of the serum-sickness type of hypersensitivity (e.g., fever, arthralgia, lymph node enlargement, and eosinophilia) may appear. Thrombotic thrombocytopenic purpura and fatal periarthritis nodosa attributed to hypersensitivity to iodide also have been described.

The severity of symptoms of chronic intoxication with iodide (*iodism*) is related to the dose. The symptoms start with an unpleasant brassy taste and burning in the mouth and throat as well as soreness of the teeth and gums. Increased salivation, coryza, sneezing, and irritation of the eyes with swelling of the eyelids commonly occur. Mild iodism simulates a “head cold.” Excess transudation into the bronchial tree may lead to pulmonary edema. In addition, the parotid and submaxillary glands may become enlarged and tender, and the syndrome may be mistaken for mumps parotitis. Skin lesions are common and vary in type and intensity. Rarely, severe and sometimes-fatal eruptions (ioderma) may occur after the prolonged use of iodides. The lesions are bizarre; they resemble those caused by bromism and generally involute quickly when iodide is withdrawn. Symptoms of gastric irritation are common, and diarrhea, which is sometimes bloody, may occur. Fever, anorexia, and depression may be present. The symptoms of iodism disappear within a few days after stopping the administration of iodide. Renal excretion of I^- can be increased by procedures that promote Cl^- excretion (e.g., osmotic diuresis, chloruretic diuretics, and salt loading). These procedures may be useful when the symptoms of iodism are severe.

Radioactive Iodine

The primary isotopes used for the diagnosis and treatment of thyroid disease are ^{123}I and ^{131}I . ^{123}I is primarily a short-lived γ -emitter with a $t_{1/2}$ of 13 h and is used in diagnostic studies. ^{124}I has been used successfully with positron emission tomographic/computed tomographic scanning for more precise dosimetry in high-risk thyroid cancer (Jentzen et al., 2014). ^{131}I has a $t_{1/2}$ of 8 days and emits both γ rays and β particles. More than 99% of its radiation is expended within 56 days. ^{131}I is used therapeutically for thyroid destruction of an overactive or enlarged thyroid and in thyroid cancer for thyroid ablation and treatment of metastatic disease.

The chemical behavior of the radioactive isotopes of iodine is identical to that of the stable isotope, ^{127}I . ^{131}I is rapidly and efficiently trapped by the thyroid, incorporated into the iodoamino acids, and deposited in the colloid of the follicles, from which it is slowly liberated. Thus, the destructive β particles originate within the follicle and act almost exclusively on the parenchymal cells of the thyroid, with little or no damage to surrounding tissue. The γ radiation passes through the tissue and can be quantified by external detection. The effects of the radiation depend on the dosage. With properly selected doses of ^{131}I , it is possible to destroy the thyroid gland completely without detectable injury to adjacent tissues.

Therapeutic Uses

Radioactive iodine finds its widest use in the treatment of hyperthyroidism and in the diagnosis of disorders of thyroid function. The clearest indication for radioactive iodine treatment is hyperthyroidism in older patients and in those with heart disease. Radioactive iodine also is an effective treatment when Graves disease has persisted or recurred after subtotal thyroidectomy and when prolonged treatment with antithyroid drugs has not led to remission. Finally, radioactive iodine is effective in patients with toxic nodular goiter. Sodium iodide ^{131}I is available as a solution or in capsules containing carrier-free ^{131}I suitable for oral administration. Sodium iodide ^{123}I is available for scanning procedures.

Hyperthyroidism

Radioactive iodine is a valuable alternative or adjunctive treatment of hyperthyroidism (Ross, 2011). Stable iodide (nonradioactive) may preclude treatment and imaging with radioactive iodine for weeks after the stable iodide has been discontinued. In those patients exposed to stable

iodide, a 24-h radioiodine measurement of a tracer dose of ^{123}I should be performed before ^{131}I administration to ensure there is sufficient uptake to accomplish the desired ablation. The optimal dose of ^{131}I , expressed amount taken up, varies in different laboratories from 80 to 150 μCi per gram of thyroid tissue. The usual total dose is 4–15 mCi with a recommended target of delivering 8 mCi to the thyroid gland based on the 24-h radioiodine uptake (Alexander and Larsen, 2002; Brent, 2008).

Beginning a few weeks after treatment, the symptoms of hyperthyroidism gradually abate over a period of 2–3 months. If therapy has been inadequate, the necessity for further treatment is apparent within 6–12 months. It is not uncommon, however, for the serum TSH to remain low for several months after ^{131}I therapy. Thus, assessing radioactive iodine failure based on TSH concentrations alone may be misleading and should always be accompanied by determination of free T_4 and usually serum T_3 concentrations. Depending to some extent on the dosage schedule adopted, 80% of patients are cured by a single dose, about 20% require two doses, and a very small fraction require three or more doses before the disorder is controlled. β Adrenergic antagonists, antithyroid drugs, or both can be used to hasten the control of hyperthyroidism.

Advantages

With radioactive iodine treatment, the patient is spared the risks and discomfort of surgery. The cost is low, hospitalization is not required in the U.S., and patients can participate in their customary activities during the entire procedure, although there are recommendations to limit exposure in young children.

Disadvantages

The chief consequence of the use of radioactive iodine is the high incidence of delayed hypothyroidism. Although cancer death rate is not increased after radioiodine therapy, some studies suggest a small but significant increase in specific types of cancer, including stomach, kidney, and breast. This finding is especially significant because these tissues all express the iodine transporter NIS and may thus be especially susceptible to effects of radioactive iodine. Radioactive iodine treatment can induce a radiation thyroiditis, with release of preformed T_4 and T_3 into the circulation. In most patients, this is asymptomatic, but in some there can be worsening of symptoms of hyperthyroidism; rarely, cardiac manifestations (e.g., atrial fibrillation or ischemic heart disease); and very rarely thyroid storm. Pretreatment with antithyroid drugs should reduce or eliminate this complication.

The main contraindication for the use of ^{131}I therapy is pregnancy. After the first trimester, the fetal thyroid will concentrate the isotope and thus suffer damage; even during the first trimester, radioactive iodine is best avoided because there may be adverse effects of radiation on fetal tissues. In addition, the use of radioiodine to treat hyperthyroidism in children is controversial due to theoretical concern about causing neoplastic changes in the thyroid gland or other organs. Data are insufficient to resolve this issue, as the number of children who have been treated with radioiodine is relatively small. Many clinics decline to treat younger patients and reserve radioactive iodine for patients older than 25–30 years.

Thyroid Carcinoma

Because most well-differentiated thyroid carcinomas accumulate very little iodine, stimulation of iodine uptake with TSH is required to treat metastases effectively (Haugen and Sherman, 2013; Haugen et al., 2016). Endogenous TSH stimulation is promoted by withdrawal of thyroid hormone replacement therapy in patients previously treated with near-total or total thyroidectomy. An ablative dose of ^{131}I ranging from 30 to 150 mCi is administered, and a repeat total body scan is obtained several days to 1 week later.

Recombinant thyrotropin alpha (recombinant human TSH) can be used instead of thyroid hormone withdrawal to prepare a patient for radioiodine ablation of thyroid remnant tissue or to test the capacity of thyroid tissue, both normal and malignant, to take up radioactive iodine and to secrete thyroglobulin. Recombinant human TSH is not currently approved to prepare patients for radioiodine ablation of metastatic disease.

Papillary and Follicular Carcinomas

The majority of thyroid cancers derive from the thyroid follicular cells and are classified histologically as papillary or follicular carcinomas. Most of these carcinomas are adequately treated by surgery, radioiodine, and levothyroxine to suppress TSH. However, a small fraction progress despite these therapies, in which case they can be treated with the oral tyrosine kinase inhibitors *sorafenib* (Brose et al., 2014) or *lenvatinib* (Schlumberger et al., 2015) (see Chapter 67). The response to these drugs does not seem to be dependent on the presence or absence of specific oncogene mutations.

The recommended daily dose of sorafenib is 400 mg twice daily without food. Adverse reactions include palmar-plantar erythrodysesthesia, diarrhea, alopecia, fatigue, weight loss, hypertension, and others. The recommended daily dose of lenvatinib is 24 mg once daily with or without food, reduced to 14 mg in those with severe renal or hepatic impairment. Common adverse reactions include hypertension, diarrhea, fatigue, decreased appetite, decreased weight, nausea, stomatitis, and musculoskeletal pain, although there are multiple other toxicities, including treatment-related deaths.

Medullary Thyroid Carcinoma

A minor fraction of thyroid cancers originate from the parafollicular cells (C cells) that produce calcitonin and are denoted medullary thyroid carcinomas. Because they derive from the parafollicular cells, medullary carcinomas are not responsive to radioiodine or TSH suppression. Medullary carcinomas that progress despite surgery can be treated with either of the oral tyrosine kinase inhibitors *vandetanib* (Wells et al., 2012) and *cabozantinib* (Elisei et al., 2013) (see Chapter 67). These drugs can be prescribed for both the sporadic and inherited forms of medullary thyroid carcinoma without regard for *RET* gene mutational status because patients can respond even in the absence of *RET* mutations. However, the phase III vandetanib trial suggested a higher response rate in patients with tumors harboring the *RET* M918T mutation. The phase III cabozantinib trial demonstrated a longer progression-free survival in patients with *RET* M918T tumors and possibly also in patients with tumors harboring RAS mutations.

The dose of vandetanib is 300 mg once daily with or without food. The dose is reduced to 200 mg in moderate-to-severe renal impairment, and vandetanib is not recommended in moderate or severe hepatic impairment. Vandetanib has a black-box warning for QT prolongation. Additional adverse reactions include diarrhea, rash, nausea, hypertension, headache, and others.

The starting dose of cabozantinib is typically 60 to 100 mg on an empty stomach, which may be titrated to 140 mg as tolerated. It is not recommended in moderate or severe hepatic impairment. Cabozantinib has black-box warnings for GI perforations and fistulas (especially in patients receiving prior radiation therapy) and hemorrhage. Additional adverse reactions include diarrhea, palmar-plantar erythrodysesthesia, decreased weight and appetite, nausea, fatigue, and stomatitis.

General Comments

Treatment of thyroid cancer with tyrosine kinase inhibitors should continue until the patient is no longer clinically benefiting or until unacceptable toxicity occurs. Dosage reductions can mitigate toxicity. Resistance to one tyrosine kinase inhibitor does not necessarily imply resistance to another. *It is important to note that levothyroxine dosage requirements often increase in patients taking protein tyrosine kinase inhibitors; therefore, TSH levels should be monitored carefully* (Brose et al., 2014; Elisei et al., 2013; Schlumberger et al., 2015; Wells et al., 2012). The use of tyrosine kinase inhibitors is described in Chapter 67.

Drug Facts for Your Personal Formulary: *Thyroid and Antithyroid Drugs*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Thyroid Hormone Preparations: Replace T_4 or T_3 normally produced by the thyroid		
Levothyroxine (T_4)	<ul style="list-style-type: none"> Hypothyroidism TSH suppression in thyroid cancer 	<ul style="list-style-type: none"> Plasma $t_{1/2} \sim 1$ week Deiodinases convert circulating T_4 to the bioactive hormone T_3 Dosage generally needs to increase during pregnancy Congenital hypothyroidism requires rapid diagnosis and correction to allow normal physical and mental development Overtreatment can lead to osteoporosis and atrial fibrillation
Liothyronine (T_3)	<ul style="list-style-type: none"> When rapid onset of action is desired (sometimes for myxedema coma) When rapid termination of action is desired (preparing patients with thyroid cancer for radioiodine therapy) 	<ul style="list-style-type: none"> Plasma $t_{1/2} \sim 18$–24 h Multiple daily doses needed to achieve needed C_{ps} Levothyroxine (T_4) generally preferred over liothyronine (T_3) for the long-term therapy of hypothyroidism
Desiccated thyroid and T_4 - T_3 mixtures	<ul style="list-style-type: none"> Generally not a preferred therapy, although occasional hypothyroid patients say they feel better than when taking levothyroxine 	<ul style="list-style-type: none"> Mixture of levothyroxine and liothyronine (2–5:1 by weight) Supplies a relative excess of T_3 compared to normal thyroidal secretion, which is $\sim 11:1$ T_4 to T_3 by weight No convincing evidence of greater efficacy than levothyroxine (T_4 alone)
Antithyroid Drugs: Thionamides: Interfere with incorporation of iodine into tyrosyl residues and inhibit iodotyrosyl-coupling reactions		
Methimazole	<ul style="list-style-type: none"> Reduce thyroid hormone production 	<ul style="list-style-type: none"> Carbimazole (available in Europe) converted to methimazole after absorption Long intrathyroidal $t_{1/2}$ allows once-daily dosing for most patients Preferred antithyroid drug Do not use in first trimester of pregnancy due to embryopathy
Propylthiouracil	<ul style="list-style-type: none"> Reduce thyroid hormone production May also reduce T_4 to T_3 conversion 	<ul style="list-style-type: none"> Major concern is liver toxicity; rare but more commonly seen in children and pregnancy Only indications are for thyroid storm due to action on reducing T_4 to T_3 conversion and in the first trimester of pregnancy
Antithyroid Drugs: Ionic Inhibitors: Iodine uptake by antagonizing the sodium-iodide symporter		
Perchlorate	<ul style="list-style-type: none"> Primarily used to enhance the response to thioamides in refractory Graves disease (e.g., that associated with amiodarone) 	<ul style="list-style-type: none"> Not available commercially; must be specialty compounded
Antithyroid Drugs: Iodide: Acute reduction in thyroid hormone		
Lugol solution	<ul style="list-style-type: none"> Acutely reduce the secretion and synthesis of thyroid hormone 	<ul style="list-style-type: none"> “Escape” from thyroid inhibition after 7–10 days Strictly contraindicated in pregnancy
KISS: potassium iodide saturated solution (or SSKI)	<ul style="list-style-type: none"> Acutely reduce the secretion and synthesis of thyroid hormone 	<ul style="list-style-type: none"> “Escape” from thyroid inhibition after 7–10 days Strictly contraindicated in pregnancy
Antithyroid Drugs: Radioactive Iodine: Used to destroy hyperfunctioning thyroid tissue		
^{131}I	<ul style="list-style-type: none"> Effective for permanent treatment of Graves disease and toxic nodule or toxic goiter Destruction of iodide-avid thyroid cancer 	<ul style="list-style-type: none"> Highly effective for permanent cure to hyperthyroidism Effective treatment of hyperthyroidism usually results in permanent hypothyroidism and lifelong requirement for levothyroxine replacement Absolutely contraindicated in pregnancy Treatment of thyroid cancer requires TSH stimulation (endogenous or exogenous)
Recombinant Human TSH Agonist for the TSH Receptor		
Thyrotropin alpha	<ul style="list-style-type: none"> Stimulate radioiodine uptake and thyroglobulin release in patients with thyroid cancer after thyroidectomy Prepare patients for radioiodine ablation of thyroid remnants after thyroidectomy for thyroid cancer 	<ul style="list-style-type: none"> Allows assessment of residual or recurrent thyroid cancer without stopping levothyroxine and becoming clinically hypothyroid Allows radioiodine therapy of thyroid remnants without stopping levothyroxine and becoming clinically hypothyroid
Thyroid Cancer Chemotherapeutics: Tyrosine kinase inhibitors		
Sorafenib	<ul style="list-style-type: none"> Radioiodine-resistant, progressive papillary, or follicular thyroid cancer 	<ul style="list-style-type: none"> Response not predicted by presence or absence of specific oncogene mutations Lack of response to one kinase inhibitor does not necessarily predict lack of response to others
Lenvatinib		
Vandetanib	<ul style="list-style-type: none"> Progressive medullary thyroid cancer 	<ul style="list-style-type: none"> Can be used in hereditary or sporadic medullary thyroid cancer Responses may be seen in patients with or without <i>RET</i> gene mutations
Cabozantinib

Chapter 44

Estrogens, Progestins, and the Female Reproductive Tract

Ellis R. Levin, Wendy S. Vitek, and Stephen R. Hammes

ESTROGENS

- Chemistry and Synthesis
- Physiological Actions
- Estrogen Receptors
- Pharmacology

SELECTIVE ESTROGEN RECEPTOR MODULATORS AND ANTIESTROGENS

- Selective Estrogen Receptor Modulators: Tamoxifen, Raloxifene, and Toremifene
- Antiestrogens: Clomiphene and Fulvestrant
- Estrogen Synthesis Inhibitors

PROGESTINS

- Chemistry
- Biosynthesis and Secretion
- Physiologic Actions
- Pharmacology

ANTIPROGESTINS AND PROGESTERONE RECEPTOR MODULATORS

- Mifepristone
- Ulipristal

THERAPEUTIC USES OF ESTROGENS AND PROGESTINS

- Hormonal Contraception
- Postcoital Contraception
- Termination of Pregnancy
- Induction of Sexual Maturation
- Induction of Ovulation

DRUG THERAPY IN OBSTETRICS

- Pregnancy-Induced Hypertension/Preeclampsia
- Prevention or Arrest of Preterm Labor
- Initiation of Labor

MENOPAUSE AND HORMONE THERAPY

- Estrogens
- Menopausal Hormone Therapy
- Menopausal Hormone Regimens
- Untoward Responses

DRUG THERAPY IN ENDOMETRIOSIS, HIRSUTISM, AND GENDER TRANSITION

- Endometriosis
- Hirsutism
- Gender Transition

Estrogens and *progestins* are endogenous hormones that produce numerous physiological actions. In women, these include developmental effects, neuroendocrine actions involved in the control of ovulation, the cyclical preparation of the reproductive tract for fertilization and implantation, and major actions on mineral, carbohydrate, protein, and lipid metabolism. Estrogens also have important actions in males, including effects on bone, spermatogenesis, and behavior. Well-characterized receptors for each hormone mediate biological actions in both the unliganded and the liganded states.

The most common uses of estrogens and progestins are for contraception and menopausal hormone therapy (MHT) in women, but the specific compounds and dosages used in these two settings differ substantially. Antiestrogens are used in the treatment of hormone-responsive breast cancer and infertility. Selective estrogen receptor modulators (SERMs) that display tissue-selective agonist or antagonist activities are useful to prevent breast cancer and osteoporosis. The main use of antiprogestins has been for medical abortion.

A number of naturally occurring and synthetic environmental chemicals mimic, antagonize, or otherwise affect the actions of estrogens in experimental test systems. The precise effect of these agents on humans is unknown but is an area of active investigation.

with two receptors of the nuclear receptor superfamily, termed ER α and ER β . The most potent naturally occurring estrogen in humans, for both ER α - and ER β -mediated actions, is *17 β -estradiol*, followed by *estrone* and *estriol*. Each contains a phenolic A ring with a hydroxyl group at carbon 3 and a β -OH or ketone in position 17 of ring D.

The phenolic A ring is the principal structural feature responsible for selective high-affinity binding to both receptors. Most alkyl substitutions on the A ring impair binding, but substitutions on ring C or D may be tolerated. Ethinyl substitutions at the C17 position greatly increase oral potency by inhibiting first-pass hepatic metabolism. Models for the ligand-binding sites of both ERs have been determined from structure-activity relationships and structural analysis (Pike et al., 2000). Selective ligands for ER α and ER β are available for experimental studies but are not yet used therapeutically (Harrington et al., 2003).

Biosynthesis

Steroidal estrogens arise from androstenedione or testosterone (Figure 44–1) by aromatization of the A ring. The reaction is catalyzed by aromatase (CYP19), which uses NADPH and molecular oxygen as cosubstrates. A ubiquitous flavoprotein, NADPH-cytochrome P450 reductase, also is essential. Both proteins are localized in the endoplasmic reticulum of ovarian granulosa cells, testicular Sertoli and Leydig cells, adipose stroma, placental syncytiotrophoblasts, preimplantation blastocysts, bone, various brain regions, and many other tissues (Simpson et al., 2002).

The ovaries are the principal source of circulating estrogen in premenopausal women, with estradiol the main secretory product. Ovarian estradiol production is traditionally thought to require two cell types: theca cells and granulosa cells. The gonadotropin LH acts via receptors that couple to the G $_s$ -adenylyl cyclase-cyclic AMP pathway to increase

Estrogens

Chemistry and Synthesis

Chemistry

Many steroidal and nonsteroidal compounds, some of which are shown in Table 44–1 and Figure 44–1, possess estrogenic activity. Estrogens interact

Abbreviations

AF: activation function
CHD: coronary heart disease
COMT: catechol-*O*-methyl transferase
DES: diethylstilbestrol
ER: estrogen receptor
ER α : estrogen receptor α
ER β : estrogen receptor β
ERE: estrogen response element
ERT: estrogen replacement therapy
FP: PGF_{2 α} receptor
FSH: follicle-stimulating hormone
GABA: γ -aminobutyric acid
GnRH: gonadotropin-releasing hormone
GPCR: G protein-coupled receptor
hCG: human chorionic gonadotropin
HDL: high-density lipoprotein
HERS: Heart and Estrogen/Progestin Replacement Study
HRT: hormone replacement therapy
HSP: heat shock protein
IGF: insulinlike growth factor
IU: intrauterine
IUD: intrauterine device
IUI: intrauterine insemination
IUS: intrauterine system
LDL: low-density lipoprotein
LH: luteinizing hormone
LN α : levonorgestrel, as in LN α -IUS
LN α 14 or 20: LN α , 14 or 20 μ g/24h
LPA: lipoprotein A
MHT: menopausal hormone therapy
MPA: medroxyprogesterone acetate
MWS: Million Women Study
NcoR: nuclear hormone receptor corepressor
NE: norepinephrine
OHSS: ovarian hyperstimulation syndrome
PAI-1: plasminogen activator inhibitor 1
PCOS: polycystic ovary syndrome
PG: prostaglandin
PID: pelvic inflammatory disease
PR: progesterone receptor
PRE: progesterone response element
PRM: progesterone receptor modulator
ROS: reactive oxygen species
SERM: selective estrogen receptor modulator
SHBG: sex hormone-binding globulin
SRC-1: steroid-receptor coactivator 1
WHI: Women's Health Initiative
WHIMS: Women's Health Initiative Memory Study

cholesterol (the precursors of all steroids) transport into the mitochondria of cells, where androgen precursors are produced. FSH then stimulates CYP19 production and activity in the granulosa cells, which converts the androgen precursors to estrogens. Notably, theca cells of the ovary contain a form of 17 β -hydroxysteroid dehydrogenase (type I) that favors the production of testosterone and estradiol from androstenedione and estrone, respectively. However, in the liver, another form of this enzyme (type II) favors oxidation of circulating estradiol to estrone (Peltoketo et al., 1999), and both of these steroids are then converted to estriol (Figure 44-1). All three of these estrogens are excreted in the urine along with their glucuronide and sulfate conjugates.

HISTORY Hormones in the Female Reproductive System

The hormonal nature of the ovarian control of the female reproductive system was firmly established in 1900 by Knauer when he found that ovarian transplants prevented the symptoms of gonadectomy, and by Halban, who showed that normal sexual development and function occurred when glands were transplanted. In 1923, Allen and Doisy devised a bioassay for ovarian extracts based on the vaginal smear of the rat. Frank and associates in 1925 detected an active sex principle in the blood of sows in estrus, and Loewe and Lange discovered in 1926 that a female sex hormone varied in the urine of women throughout the menstrual cycle. The excretion of estrogen in the urine during pregnancy also was reported by Zondek in 1928 and enabled Butenandt and Doisy in 1929 to crystallize an active substance. Early investigations indicated that the ovary secretes two substances. Beard had postulated in 1897 that the corpus luteum serves a necessary function during pregnancy, and Fraenkel showed in 1903 that destruction of the corpora lutea in pregnant rabbits caused abortion. Several groups then isolated progesterone from mammalian corpora lutea in the 1930s.

In the early 1960s, pioneering studies by Jensen and colleagues suggested the presence of intracellular receptors for estrogens in target tissues. This was the first demonstration of receptors of the steroid/thyroid superfamily and provided techniques to identify receptors for the other steroid hormones. A second ER was identified in 1996 and was termed ER β to distinguish it from the receptor identified by Jensen and others, termed ER α . Two protein isoforms, A and B, of the PR arise from a single gene by transcription initiation from different promoters.

In postmenopausal women, the principal source of circulating estrogen is adipose tissue stroma, where estrone is synthesized from dehydroepiandrosterone secreted by the adrenals. In men, estrogens are produced by the testes, but extragonadal production by aromatization of circulating C19 steroids (e.g., androstenedione and dehydroepiandrosterone) accounts for most circulating estrogens (Simpson, 2003).

Estrogens may be locally produced from androgens by the actions of aromatase or from estrogen conjugates by hydrolysis. Such local production of estrogens could play a causal or promotional role in the development of certain diseases, such as breast cancer, because mammary tumors contain both aromatase and hydrolytic enzymes. Estrogens also may be produced from androgens via aromatase in the CNS and other tissues and exert local effects near their production site (e.g., in bone, they affect bone mineral density).

The placenta uses fetal dehydroepiandrosterone and its 16 α -hydroxyl derivative to produce large amounts of estrone and estriol. Human urine during pregnancy is thus an abundant source of natural estrogens. Pregnant mare's urine is the source of *conjugated equine estrogens*, which have been widely used therapeutically for many years.

Physiological Actions

Developmental Actions

Estrogens are largely responsible for pubertal changes in girls and secondary sexual characteristics. Estrogens cause growth and development of the vagina, uterus, and fallopian tubes and contribute to breast enlargement. They also contribute to molding the body contours, shaping the skeleton, and causing the pubertal growth spurt of the long bones and epiphyseal closure. Growth of axillary and pubic hair, pigmentation of the genital region, and the regional pigmentation of the nipples and areolae that occur after the first trimester of pregnancy are also estrogenic actions. Androgens may also play a secondary role in female sexual development (Chapter 45).

Estrogens appear to play important developmental roles in males. In boys, estrogen deficiency diminishes the pubertal growth spurt and delays

skeletal maturation and epiphyseal closure so that linear growth continues into adulthood. Estrogen deficiency in men leads to elevated gonadotropins, macroorchidism, and increased testosterone levels and also may affect carbohydrate and lipid metabolism and fertility in some individuals (Grumbach and Auchus, 1999).

Neuroendocrine Control of the Menstrual Cycle

A neuroendocrine cascade involving the hypothalamus, pituitary, and ovaries controls the menstrual cycle (Figure 44–2). A neuronal oscillator, or “clock,” in the hypothalamus fires at intervals that coincide with bursts of GnRH release into the hypothalamic-pituitary portal vasculature (Chapter 42). GnRH interacts with its cognate receptor on pituitary gonadotropes to cause release of LH and FSH. The frequency of the GnRH pulses, which varies in the different phases of the menstrual cycle, controls the relative synthesis of the unique β subunits of FSH and LH.

The gonadotropins (LH and FSH) regulate the growth and maturation of the graafian follicle in the ovary and the ovarian production of estrogen and progesterone, which exert feedback regulation on the pituitary and hypothalamus. Because the release of GnRH is intermittent, LH and FSH secretion is pulsatile. The pulse frequency is determined by the neural clock (Figure 44–2), termed the *hypothalamic GnRH pulse generator* (Knobil, 1981), but the amount of gonadotropin released in each

pulse (i.e., the pulse *amplitude*) is largely controlled by the actions of estrogens and progesterone on the pituitary. The intermittent, *pulsatile* nature of hormone release is essential for the maintenance of normal ovulatory menstrual cycles because constant infusion of GnRH results in cessation of gonadotropin release and ovarian steroid production (Chapter 42). The neuropeptide kisspeptin 1, which is released from the hypothalamic anteroventral periventricular nucleus and the arcuate nucleus, may regulate GnRH pulsatility through its G protein–coupled receptor, GPR54, expressed in GnRH neurons. Inactivating mutations in GPR54 have been associated with hypogonadotropic hypogonadism (Seminara, 2006).

Although the precise mechanism that regulates the timing of GnRH release (i.e., pulse frequency) is unclear, hypothalamic cells appear to have an intrinsic ability to release GnRH episodically. The overall pattern of GnRH release likely is regulated by the interplay of intrinsic mechanism(s) and extrinsic synaptic inputs from opioid, catecholamine, and GABAergic neurons (Figure 44–2). Ovarian steroids, primarily progesterone, regulate the frequency of GnRH release, but the cellular and molecular mechanisms of this regulation are not well established.

At *puberty* the pulse generator is activated and establishes cyclic profiles of pituitary and ovarian hormones. Although the mechanism of activation is not entirely established, it may involve increases in circulating IGF-1

Figure 44–2 Neuroendocrine control of gonadotropin secretion in females. The hypothalamic pulse generator located in the arcuate nucleus of the hypothalamus functions as a neuronal “clock” that fires at regular hourly intervals (A). This results in the periodic release of GnRH from GnRH-containing neurons into the hypothalamic-pituitary portal vasculature (B). GnRH neurons (B) receive inhibitory input from opioid, dopamine, and GABA neurons and stimulatory input from noradrenergic neurons. The pulses of GnRH trigger the intermittent release of LH and FSH from pituitary gonadotropes (C), resulting in the pulsatile plasma profile (D). FSH and LH regulate ovarian production of estrogen and progesterone, which exert feedback controls (E). (See text and Figure 44–3 for additional details.)

and leptin levels, the latter acting to inhibit neuropeptide Y in the arcuate nucleus to relieve an inhibitory effect on GnRH neurons.

Figure 44–3 provides a schematic diagram of the profiles of gonadotropin and gonadal steroid levels in the menstrual cycle. The “average” plasma levels of LH throughout the cycle are shown in panel A of Figure 44–3; inserts illustrate the pulsatile patterns of LH during the proliferative and secretory phases in more detail. The average LH levels are similar throughout the early (follicular) and late (luteal) phases of the cycle, but the frequency and amplitude of the LH pulses are quite different in the two phases. This characteristic pattern of hormone secretions results from complex positive- and negative-feedback mechanisms (Hotchkiss and Knobil, 1994).

In the early follicular phase of the cycle, (1) the pulse generator produces bursts of neuronal activity with a frequency of about one per hour that

correspond with pulses of GnRH secretion; (2) these cause a corresponding pulsatile release of LH and FSH from pituitary gonadotropes; and (3) FSH in particular causes the graafian follicle to mature and secrete estrogen. The effects of estrogens on the pituitary are inhibitory at this time and cause the amount of LH and FSH released from the pituitary to decline (i.e., the amplitude of the LH pulse decreases), so gonadotropin levels gradually fall (Figure 44–3). *Inhibin*, produced by the ovary, exerts negative feedback to selectively decrease serum FSH (Chapter 42). Activin and follistatin, two other peptides released from the ovary, may also regulate FSH production and secretion to a lesser extent, although their levels do not vary appreciably during the menstrual cycle.

At midcycle, serum estradiol rises above a threshold level of 150–200 pg/mL for about 36 h. This sustained elevation of estrogen no longer inhibits gonadotropin release but exerts a brief positive-feedback effect on the

Figure 44–3 Hormonal relationships of the human menstrual cycle. **A.** Average daily values of LH, FSH, estradiol (E_2), and progesterone in plasma samples from women exhibiting normal 28-day menstrual cycles. Changes in the ovarian follicle (top) and endometrium (bottom) also are illustrated schematically. Frequent plasma sampling reveals pulsatile patterns of gonadotropin release. Characteristic profiles are illustrated schematically for the follicular phase (day 9, inset on left) and luteal phase (day 17, inset on right). Both the frequency (number of pulses per hour) and amplitude (extent of change of hormone release) of pulses vary throughout the cycle. (Modified from and reproduced with permission from Thornycroft IH, et al. *Am J Obstet Gynecol*, 1971, 111:947–951. Copyright © Elsevier). **B.** Major regulatory effects of ovarian steroids on hypothalamic-pituitary function. Estrogen decreases the amount of FSH and LH released (i.e., gonadotropin pulse amplitude) during most of the cycle and triggers a surge of LH release only at midcycle. Progesterone decreases the frequency of GnRH release from the hypothalamus and thus decreases the frequency of plasma gonadotropin pulses. Progesterone also increases the amount of LH released (i.e., the pulse amplitude) during the luteal phase of the cycle.

pituitary to trigger the preovulatory surge of LH and FSH. This effect primarily involves a change in pituitary responsiveness to GnRH. Progesterone may contribute to the midcycle LH surge.

The midcycle surge in gonadotropins stimulates follicular rupture and ovulation within 1–2 days. The ruptured follicle then develops into the corpus luteum, which produces large amounts of progesterone and lesser amounts of estrogen under the influence of LH during the second half of the cycle. In the absence of pregnancy, the corpus luteum ceases to function, steroid levels drop, and menstruation occurs. When steroid levels drop, the pulse generator reverts to a firing pattern characteristic of the follicular phase, the entire system then resets, and a new ovarian cycle occurs.

Regulation of the frequency and amplitude of gonadotropin secretions by steroids may be summarized as follows: Estrogens act primarily on the pituitary to control the amplitude of gonadotropin pulses, and they may also contribute to the amplitude of GnRH pulses secreted by the hypothalamus.

In the *follicular phase* of the cycle, estrogens inhibit gonadotropin release but then have a brief midcycle stimulatory action that increases the amount released and causes the LH surge. Progesterone, acting on the hypothalamus, exerts the predominant control of the frequency of LH release. It decreases the firing rate of the hypothalamic pulse generator, an action thought to be mediated largely via inhibitory opioid neurons (containing PRs) that synapse with GnRH neurons. Progesterone also exerts a direct effect on the pituitary to oppose the inhibitory actions of estrogens and thus enhance the amount of LH released (i.e., to increase the amplitude of the LH pulses). These steroid feedback effects, coupled with the intrinsic activity of the hypothalamic GnRH pulse generator, lead to relatively frequent LH pulses of small amplitude in the follicular phase of the cycle and less-frequent pulses of larger amplitude in the luteal phase. Studies in knockout mice indicated that ER α (Hewitt and Korach, 2003) and PR-A (Conneely et al., 2002) mediate the major actions of estrogens and progestins, respectively, on the hypothalamic-pituitary axis.

When the ovaries are removed or cease to function, there is overproduction of FSH and LH, which are excreted in the urine. Measurement of urinary or plasma LH is valuable to assess pituitary function and the effectiveness of therapeutic doses of estrogen.

Effects of Cyclical Gonadal Steroids on the Reproductive Tract

The cyclical changes in estrogen and progesterone production by the ovaries regulate corresponding events in the fallopian tubes, uterus, cervix, and vagina. Physiologically, these changes prepare the uterus for implantation, and the proper timing of events in these tissues is essential for pregnancy. If pregnancy does not occur, the endometrium is shed as the menstrual discharge.

The uterus is composed of an *endometrium* and a *myometrium*. The endometrium contains an epithelium lining the uterine cavity and an underlying stroma; the myometrium is the smooth muscle component responsible for uterine contractions. These cell layers, the fallopian tubes, cervix, and vagina display a characteristic set of responses to both estrogens and progestins. The changes typically associated with menstruation occur largely in the endometrium (Figure 44–3).

The *luminal surface* of the endometrium is a layer of simple columnar epithelial secretory and ciliated cells that is continuous with the openings of numerous glands that extend through the underlying stroma to the myometrial border. Fertilization normally occurs in the fallopian tubes, so ovulation, transport of the fertilized ovum through the fallopian tube, and preparation of the endometrial surface must be temporally coordinated for successful implantation.

The *endometrial stroma* is a highly cellular connective tissue layer containing a variety of blood vessels that undergo cyclic changes associated with menstruation. The predominant cells are fibroblasts, but macrophages, lymphocytes, and other resident and migratory cell types also are present.

Menstruation marks the start of the menstrual cycle. During the follicular (or proliferative) phase of the cycle, estrogen begins the rebuilding

of the endometrium by stimulating proliferation and differentiation. An important response to estrogen in the endometrium and other tissues is induction of the PR, which enables cells to respond to this hormone during the second half of the cycle.

In the *luteal (or secretory) phase* of the cycle, elevated progesterone limits the proliferative effect of estrogens on the endometrium by stimulating differentiation. Major effects include stimulation of epithelial secretions important for implantation of the blastocyst and the characteristic growth of the endometrial blood vessels seen at this time. These effects are mediated by PR-A in animal models (Conneely et al., 2002). Progesterone is thus important in preparation for implantation and for the changes that take place in the uterus at the implantation site (i.e., the decidual response). There is a narrow “window of implantation,” spanning days 19–24 of the endometrial cycle, when the epithelial cells of the endometrium are receptive to blastocyst implantation. If implantation occurs, hCG (Chapter 42), produced initially by the trophoblast and later by the placenta, interacts with the LH receptor of the corpus luteum to maintain steroid hormone synthesis during the early stages of pregnancy. Later, the placenta becomes the major site of estrogen and progesterone synthesis.

Estrogens and progesterone have important effects on the fallopian tube, myometrium, and cervix. In the fallopian tube, estrogens stimulate proliferation and differentiation, whereas progesterone inhibits these processes. Also, estrogens increase and progesterone decreases tubal muscular contractility, which affects transit time of the ovum to the uterus. Estrogens increase the amount of cervical mucus and its water content to facilitate sperm penetration of the cervix, whereas progesterone generally has opposite effects. Estrogens favor rhythmic contractions of the uterine myometrium, and progesterone diminishes contractions. These effects are physiologically important and may also play a role in the action of some contraceptives.

Metabolic Effects

Estrogens affect many tissues and have many metabolic actions in humans and animals. Many nonreproductive tissues, including bone, vascular endothelium, liver, CNS, immune system, GI tract, and heart, express low levels of both ERs, and the ratio of ER α to ER β varies in a cell-specific manner. The effects of estrogens on selected aspects of mineral, lipid, carbohydrate, and protein metabolism are particularly important for understanding their pharmacological actions.

Estrogens have positive effects on bone mass (Riggs et al., 2002). Bone is continuously remodeled at sites called *bone-remodeling units* by the resorptive action of osteoclasts and the bone-forming action of osteoblasts (Chapter 48). Estrogens directly regulate osteoblasts and increase osteocyte survival by inhibiting apoptosis (Kousteni et al., 2002; Levin, 2008). However, a major effect of estrogens is to decrease the number and activity of osteoclasts. Much of the action of estrogens on osteoclasts appears to be mediated by altering cytokine (both paracrine and autocrine) signals from osteoblasts. Estrogens also increase osteoblast production of the cytokine osteoprotegerin (OPG), a soluble, non-membrane-bound member of the tumor necrosis factor superfamily. OPG acts as a “decoy” receptor that antagonizes the binding of OPG-ligand (OPG-L) to its receptor (termed RANK, or *receptor activator of NF- κ B*) and prevents the differentiation of osteoclast precursors to mature osteoclasts. Estrogens increase osteoclast apoptosis, either directly or by increasing OPG. Estrogens affect bone growth and epiphyseal closure in both sexes. The importance of estrogen in the male skeleton is illustrated by a man with a completely defective ER who had osteoporosis, unfused epiphyses, increased bone turnover, and delayed bone age (Smith et al., 1994).

Estrogens slightly elevate serum triglycerides and slightly reduce total serum cholesterol levels. They increase HDL levels and decrease the levels of LDL and LPA (Chapter 33). This beneficial alteration of the ratio of HDL to LDL is an attractive but unproven effect of estrogen therapy in postmenopausal women. At relatively high concentrations, estrogens have antioxidant activity and may inhibit the oxidation of LDL by affecting superoxide dismutase. Estrogen actions on the

vascular wall include increased production of NO, which occurs within minutes via a mechanism involving activation of Akt (protein kinase B) and induction of NO synthase (Simoncini et al., 2000). All of these changes promote vasodilation and retard atherogenesis. Estrogens also promote endothelial cell growth while inhibiting the proliferation of vascular smooth muscle cells.

The presence of ERs in the liver suggests that the beneficial effects of estrogen on lipoprotein metabolism are due partly to direct hepatic actions. Estrogens also alter bile composition by increasing cholesterol secretion and decreasing bile acid secretion. This leads to increased saturation of bile with cholesterol and appears to be the basis for increased gallstone formation in some women receiving estrogens. In general, estrogens increase plasma levels of cortisol-binding globulin, thyroxine-binding globulin, and SHBG, which binds both androgens and estrogens.

Estrogens alter a number of metabolic pathways that affect the clotting cascade (Mendelsohn and Karas, 1999). Systemic effects include changes in hepatic production of plasma proteins. Estrogens cause a small increase in coagulation factors II, VII, IX, X, and XII, and they decrease the anticoagulation factors protein C, protein S, and antithrombin III (Chapter 32). Fibrinolytic pathways also are affected, and several studies of women treated with estrogen alone or estrogen with a progestin have demonstrated decreased levels of PAI-1 protein with a concomitant increase in fibrinolysis (Koh et al., 1997). Thus, estrogens increase both coagulation and fibrinolytic pathways, and imbalance in these two opposing activities may cause adverse effects.

Estrogen Receptors

Estrogens exert their effects by interaction with receptors that are members of the superfamily of nuclear receptors. The two ER genes are located on separate chromosomes: *ESR1* encodes ER α , and *ESR2* encodes ER β . Both ERs are estrogen-dependent nuclear transcription factors that have different tissue distributions and transcriptional regulatory effects on a wide number of target genes (Hanstein et al., 2004). Both ER α and ER β exist as multiple mRNA isoforms due to differential promoter use and alternative splicing (reviewed by Kos et al., 2001; Lewandowski et al., 2002). The two human ERs are 44% identical in overall amino acid sequence and share the domain structure common to members of this family. There are significant differences between the two receptor isoforms in the ligand-binding domains and in both trans-activation domains. Human ER β does not appear to contain a functional AF-1 domain. The receptors appear to have different biological functions and respond differently to various estrogenic compounds (Kuiper et al., 1997). However, their high homology in the DNA-binding domains suggests that both receptors recognize similar DNA sequences and hence regulate many of the same target genes.

Estrogen receptor α is expressed most abundantly in the female reproductive tract—especially the uterus, vagina, and ovaries—as well as in the mammary gland, the hypothalamus, endothelial cells, and vascular smooth muscle. ER β is expressed most highly in the prostate and ovaries, with lower expression in lung, brain, bone, and vasculature. Many cells express both ER α and ER β , which can form either homo- or heterodimers. Both forms of ER are expressed on breast cancers, although ER α is believed to be the predominant form responsible for growth regulation (Chapter 67). When coexpressed with ER α , ER β can inhibit ER α -mediated transcriptional activation in many cases (Hall and McDonnell, 1999). Polymorphic variants of ER have been identified, but attempts to correlate specific polymorphisms with the frequency of breast cancer (Han et al., 2003), bone mass (Kurabayashi et al., 2004), endometrial cancer (Weiderpass et al., 2000), or cardiovascular disease (Herrington and Howard, 2003) have led to contradictory results.

A cloned G protein-coupled receptor, GPR30, also appears to interact with estrogens in some cell systems, and its participation in the rapid effects of estrogen is an attractive idea. There may be interaction/cross-talk between membrane-associated ER α and membrane-localized GPR30 in some cancer cells, but in vivo confirmation is lacking (Levin, 2008; Olde and Leeb-Lundberg, 2009).

Mechanism of Action

Both ERs are ligand-activated transcription factors that increase or decrease the transcription of target genes (Figure 44–4). After entering the cell by passive diffusion through the plasma membrane, the hormone binds to an ER in the nucleus. In the nucleus, the ER is present as an inactive monomer bound to HSP90, and on binding estrogen, a change in ER conformation dissociates the HSPs and causes receptor dimerization, which increases the affinity and the rate of receptor binding to DNA (Cheskis et al., 1997). Homodimers of ER α or ER β and ER α /ER β heterodimers can be produced depending on the receptor complement in a given cell. The concept of ligand-mediated changes in ER conformation is central to understanding the mechanism of action of estrogen agonists and antagonists. The ER dimer binds to EREs, typically located in the promoter region of target genes. The ER/DNA complex recruits a cascade of coactivator and other proteins to the promoter region of target genes (Figure 44–4B) and allows the proteins that make up the general transcription apparatus to assemble and initiate transcription.

Besides coactivators and corepressors, both ER α and ER β can interact physically with other transcription factors, such as Sp1 (Saville et al., 2000) or AP-1 (Paech et al., 1997), and these protein-protein interactions provide an alternate mechanism of action. In these circumstances, ER-ligand complexes interact with Sp1 or AP-1 that is already bound to its specific regulatory element, such that the ER complex does not interact directly with an ERE. This may explain how estrogens are able to regulate genes that lack a consensus ERE. Responses to agonists and antagonists mediated by these protein-protein interactions also are ER isoform and promoter specific. For example, 17 β -estradiol induces transcription of a target gene controlled by an AP-1 site in the presence of an ER α /AP-1 complex but inhibits transcription in the presence of an ER β /AP-1 complex. Conversely, antiestrogens are potent activators of ER β /AP-1 but not of ER α /AP-1 complexes.

Other signaling systems may activate nuclear ER by ligand-independent mechanisms. Phosphorylation of ER α at serine 118 by MAPK activates the receptor (Kato et al., 1995). Similarly, PI3K-activated Akt directly phosphorylates ER α , causing ligand-independent activation of estrogen target genes (Simoncini et al., 2000). This provides a means of cross-talk between membrane-bound receptor pathways (i.e., EGF/IGF-1) that activate MAPK and the nuclear ER.

Some ERs are located on the plasma membrane of cells. These ERs are encoded by the same genes that encode ER α and ER β but are transported to the plasma membrane and reside mainly in caveolae (Pedram et al., 2006). Translocation to the membrane by all sex steroid receptors is mediated by palmitoylation of a 9-amino acid motif in the respective E domains of the receptors (Levin, 2008). Membrane-localized ERs mediate the rapid activation of some proteins such as MAPK (phosphorylated in several cell types) and the rapid increase in cyclic AMP caused by the hormone. The finding that MAPK is activated by estradiol provides an additional level of cross-talk and complexity in estrogen signaling.

Pharmacology

ADME

Various estrogens are available for oral, parenteral, transdermal, or topical administration. Given the lipophilic nature of estrogens, absorption generally is good with the appropriate preparation. Aqueous or oil-based esters of estradiol are available for intramuscular injection, ranging in frequency from every week to once per month. Conjugated estrogens are available for intravenous or intramuscular administration. Transdermal patches that are changed once or twice weekly deliver estradiol continuously through the skin. Preparations are available for topical use in the vagina or for application to the skin. For many therapeutic uses, estrogen preparations are available in combination with a progestin. All estrogens are labeled with precautionary statements urging the prescribing of the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for each individual patient.

Oral administration is common and may use estradiol, conjugated estrogens, esters of estrone and other estrogens, and *ethinyl estradiol*

Figure 44-4 Molecular mechanism of action of nuclear ER. **A.** Unliganded ER exists as a monomer within the nucleus. **B.** Agonists such as 17β -estradiol (E) bind to the ER and cause a ligand-directed change in conformation that facilitates dimerization and interaction with specific ERE sequences in DNA. The ER-DNA complex recruits coactivators such as SWI/SNF that modify chromatin structure and coactivators such as SRC-1 that has histone acetyltransferase activity that further alters chromatin structure. This remodeling facilitates the exchange of the recruited proteins such that other coactivators (e.g., p300 and the TRAP complex) associate on the target gene promoter and proteins that comprise the general transcription apparatus (GTA) are recruited, with subsequent synthesis of mRNA. **C.** Antagonists such as tamoxifen (T) also bind to the ER but produce a different receptor conformation. The antagonist-induced conformation also facilitates dimerization and interaction with DNA, but a different set of proteins called corepressors, such as NcoR, are recruited to the complex. NcoR further recruits proteins such as histone deacetylase I (HDAC1) that act on histones to stabilize nucleosome structure and prevent interaction with the GTA.

(in combination with a progestin). Estradiol is available in nonmicronized and micronized preparations. The micronized formulations yield a large surface for rapid absorption to partially overcome low absolute oral bioavailability due to first-pass metabolism (Fotherby, 1996). Addition of the ethinyl substituent at C17 (ethinyl estradiol) inhibits first-pass hepatic metabolism. Other common oral preparations contain conjugated equine estrogens, which are primarily the sulfate esters of estrone, equilin, and other naturally occurring compounds; *esterified esters*; or mixtures of synthetic conjugated estrogens prepared from plant-derived sources. These are hydrolyzed by enzymes present in the lower gut that remove the charged sulfate groups and allow absorption of estrogen across the intestinal epithelium. In another oral preparation, *estropipate*, estrone is solubilized as the sulfate and stabilized with piperazine. Due largely to differences in metabolism, the potencies of various oral preparations differ widely; ethinyl estradiol, for example, is much more potent than conjugated estrogens.

A number of foodstuffs and plant-derived products, largely from soy, are available as nonprescription items and often are touted as providing benefits similar to those from compounds with established estrogenic activity. These products may contain flavonoids such as genistein (Table 44-1), which display estrogenic activity in laboratory tests, albeit generally much less than that of estradiol. In theory, these preparations could produce appreciable estrogenic effects, but their efficacy at relevant doses has not been established in human trials (Fitzpatrick, 2003).

Administration of estradiol via transdermal patches provides slow, sustained release of the hormone, systemic distribution, and more constant blood levels than oral dosing. Estradiol is also available as a topical emulsion applied to the upper thigh and calf or as a gel applied once daily to

the arm. The transdermal route does not lead to the high levels of the drug that occur in the portal circulation after oral administration, and it is thus expected to minimize hepatic effects of estrogens (e.g., effects on hepatic protein synthesis, lipoprotein profiles, and triglyceride levels).

When dissolved in oil and injected, esters of estradiol are well absorbed. Preparations available for intramuscular injection include compounds such as *estradiol valerate* or *estradiol cypionate* and may be absorbed over several weeks following a single intramuscular injection.

Preparations of estradiol and conjugated estrogen creams are available for topical administration to the vagina. These are effective locally, but systemic effects also are possible due to significant absorption. A 3-month vaginal ring may be used for slow release of estradiol, and tablets are also available for vaginal use (Vagifem).

Estradiol, ethinyl estradiol, and other estrogens are extensively bound to plasma proteins. Estradiol and other naturally occurring estrogens are bound mainly to SHBG and to a lesser degree to serum albumin. In contrast, ethinyl estradiol is bound extensively to serum albumin but not SHBG. Due to their size and lipophilic nature, unbound estrogens distribute rapidly and extensively.

Variations in estradiol metabolism occur and depend on the stage of the menstrual cycle, menopausal status, and several genetic polymorphisms (Herrington and Klein, 2001). In general, the hormone undergoes rapid hepatic biotransformation, with a plasma $t_{1/2}$ measured in minutes. Estradiol is converted primarily by 17β -hydroxysteroid dehydrogenase to estrone, which undergoes conversion by 16α -hydroxylation and 17-keto reduction to estriol, the major urinary metabolite. A variety of sulfate and glucuronide conjugates also are excreted in the urine. Lesser amounts of estrone or estradiol are oxidized to the 2-hydroxycatechols by CYP3A4 in

the liver and by CYP1A in extrahepatic tissues or to 4-hydroxycatechols by CYP1B1 in extrahepatic sites, with the 2-hydroxycatechol formed to a greater extent. The 2- and 4-hydroxycatechols are largely inactivated by COMTs. However, smaller amounts may be converted by CYP- or peroxidase-catalyzed reactions to yield semiquinones or quinones that are capable of forming DNA adducts or of generating (via redox cycling) ROSs that could oxidize DNA bases (Yue et al., 2003).

Estrogens also undergo enterohepatic recirculation via (1) sulfate and glucuronide conjugation in the liver, (2) biliary secretion of the conjugates into the intestine, and (3) hydrolysis in the gut (largely by bacterial enzymes) followed by reabsorption.

Many other drugs and environmental agents (e.g., cigarette smoke) act as inducers or inhibitors of the various enzymes that metabolize estrogens and thus have the potential to alter their clearance. Consideration of the impact of these factors on efficacy and untoward effects is increasingly important with the decreased doses of estrogens currently employed for both MHT and contraception.

Ethinyl estradiol is cleared much more slowly than estradiol due to decreased hepatic metabolism, and the elimination-phase $t_{1/2}$ in various studies ranges from 13 to 27 h. Unlike estradiol, the primary route of biotransformation of ethinyl estradiol is via 2-hydroxylation and subsequent formation of the corresponding 2- and 3-methyl ethers. *Mestranol*, another semisynthetic estrogen and a component of some combination oral contraceptives, is the 3-methyl ether of ethinyl estradiol. In the body, it undergoes rapid hepatic demethylation to ethinyl estradiol, which is its active form (Fotherby, 1996).

Selective Estrogen Receptor Modulators and Antiestrogens

By altering the conformation of the two different ERs and thereby changing interactions with coactivators and corepressors in cell-specific and promoter-specific contexts, ligands may have a broad spectrum of activities from purely antiestrogenic in all tissues, to partially estrogenic in some tissues with antiestrogenic or no activities in others, to purely estrogenic activities in all tissues. The elucidation of these concepts has been a major breakthrough in estrogen pharmacology and should permit the rational design of drugs with selective patterns of estrogenic activity (Smith and O'Malley, 2004).

Selective Estrogen Receptor Modulators: Tamoxifen, Raloxifene, and Toremifene

Selective ER modulators, or SERMs, are compounds with tissue-selective actions. The pharmacological goal of these drugs is to produce beneficial estrogenic actions in certain tissues (e.g., bone, brain, and liver) during post-MHT but antagonist activity in tissues such as breast and endometrium, where estrogenic actions (e.g., carcinogenesis) might be deleterious. Currently approved drugs in the U.S. in this class are *tamoxifen citrate*, *raloxifene hydrochloride*, and *toremifene*, which is chemically related and has similar actions to tamoxifen. Tamoxifen and toremifene are used for the treatment of breast cancer, and raloxifene is used primarily for the prevention and treatment of osteoporosis and to reduce the risk of invasive breast cancer in high-risk postmenopausal women. They are considered in detail in Chapter 68.

Antiestrogens: Clomiphene and Fulvestrant

The antiestrogen compounds are distinguished from the SERMs in that they are pure antagonists in all tissues studied. Clomiphene is approved for the treatment of infertility in anovulatory women, and fulvestrant is used for the treatment of breast cancer in women with disease progression after tamoxifen.

Chemistry

The structures of the *trans*-isomer of tamoxifen, and of raloxifene, *trans*-clomiphene (enclomiphene), and fulvestrant are as follows:

Tamoxifen is a triphenylethylene with the same stilbene nucleus as DES; compounds of this class display a variety of estrogenic and antiestrogenic activities. In general, the *trans* conformations have antiestrogenic activity, whereas the *cis* conformations display estrogenic activity. However, the pharmacological activity of the *trans* compound depends on the species, target tissue, and gene. Hepatic metabolism produces primarily *N*-desmethyltamoxifen, which has affinity for ER comparable to that of tamoxifen, and lesser amounts of the highly active 4-hydroxy metabolite, which has a 25–50 times higher affinity for both ERα and ERβ than does tamoxifen (Kuiper et al., 1997). Tamoxifen is marketed as the pure *trans*-isomer. Toremifene is a triphenylethylene with a chlorine substitution at the R2 position.

Raloxifene is a polyhydroxylated nonsteroidal compound with a benzothiophene core. Raloxifene binds with high affinity for both ERα and ERβ (Kuiper et al., 1997).

Clomiphene citrate is a triphenylethylene; its two isomers, *zuclomiphene* (*cis* clomiphene) and *enclomiphene* (*trans* clomiphene), are a weak estrogen agonist and a potent antagonist, respectively. Clomiphene binds to both ERα and ERβ, but the individual isomers have not been examined (Kuiper et al., 1997).

Fulvestrant is a 7α-alkylamide derivative of estradiol that interacts with both ERα and ERβ (Van Den Bermd et al., 1999).

Pharmacological Effects

All of these agents bind to the ligand-binding pocket of both ERα and ERβ and competitively block estradiol binding. However, the conformation of the ligand-bound ERs is different with different ligands (Smith and O'Malley, 2004), and this has two important mechanistic consequences. The distinct ER-ligand conformations recruit different coactivators and corepressors onto the promoter of a target gene by differential protein-protein interactions at the receptor surface. The tissue-specific actions of SERMs thus can be explained in part by the distinct conformation of the ER when occupied by different ligands, in combination with different coactivator and corepressor levels in different cell types that together affect the nature of ER complexes formed in a tissue-selective fashion.

Tamoxifen. Tamoxifen exhibits antiestrogenic, estrogenic, or mixed activity depending on the species and target gene measured. In clinical tests or laboratory studies with human cells, the drug's activity depends on the tissue and end point measured. For example, tamoxifen inhibits the proliferation of cultured human breast cancer cells and reduces tumor size and number in women (Jaiyesimi et al., 1995), and yet it stimulates proliferation of endometrial cells and causes endometrial thickening (Lahti et al., 1993). The drug has an antiestrogenic effect on bone, and in humans it decreases total cholesterol, LDL, and LPA but does not increase HDL and triglycerides (Love et al., 1994). Tamoxifen treatment causes a 2- to 3-fold increase in the relative risk of deep vein thrombosis and pulmonary embolism and a roughly 2-fold increase in endometrial carcinoma (Smith, 2003). Tamoxifen produces hot flashes and other adverse effects, including cataracts and nausea. Due to its agonist activity in bone, it does not increase the incidence of fractures when used in this setting.

The conformation of ERs, especially in the AF-2 domain, determines whether a coactivator or a corepressor will be recruited to the ER-DNA complex (Smith and O'Malley, 2004). Tamoxifen induces a conformation that permits the recruitment of the corepressor to both ER α and ER β , in contrast to 17 α -estradiol, which induces a conformation that recruits coactivators to the receptor. The agonist activity of tamoxifen seen in tissues such as the endometrium is mediated by the ligand-independent AF-1 transactivation domain of ER α ; because ER β does not contain a functional AF-1 domain, tamoxifen does not activate ER β (McInerney et al., 1998).

Raloxifene. Raloxifene is an estrogen agonist in bone, where it exerts an antiestrogenic effect. The drug also acts as an estrogen agonist in reducing total cholesterol and LDL, but it does not increase HDL or normalize PAI-1 in postmenopausal women (Walsh et al., 1998). Studies indicated that raloxifene has an antiproliferative effect on ER-positive breast tumors and significantly reduces the risk of ER-positive but not ER-negative breast cancer (Cummings et al., 1999). Raloxifene does not alleviate the vasomotor symptoms associated with menopause. Adverse effects include hot flashes and leg cramps and a 3-fold increase in deep vein thrombosis and pulmonary embolism (Cummings et al., 1999).

Raloxifene acts as a partial agonist in bone but does not stimulate endometrial proliferation in postmenopausal women. Presumably this is due to some combination of differential expression of transcription factors in the two tissues and the effects of this SERM on ER conformation. Raloxifene induces a configuration in ER α that is distinct from that of tamoxifen-ER β (Tamrazi et al., 2003), suggesting that a different set of coactivators/corepressors may interact with ER-raloxifene compared with ER-tamoxifen.

Fulvestrant. Fulvestrant is antiestrogenic. In clinical trials, it is efficacious in treating tamoxifen-resistant breast cancers (Robertson et al., 2003). Fulvestrant binds to ER α and ER β with high affinity comparable to estradiol but represses transactivation. It also increases dramatically the intracellular proteolytic degradation of ER α while apparently protecting ER β from degradation (Van Den Bemd et al., 1999). This effect on ER α protein levels may explain fulvestrant's efficacy in tamoxifen-resistant breast cancer.

Clomiphene. Clomiphene increases gonadotropin secretion and stimulates ovulation. It increases the amplitude of LH and FSH pulses without changing pulse frequency (Kettel et al., 1993). This suggests that the drug is acting largely at the pituitary level to block inhibitory actions of estrogen on gonadotropin release from the gland or is somehow causing the hypothalamus to release larger amounts of GnRH per pulse.

The most prominent effect of clomiphene in women was enlargement of the ovaries and the drug-induced ovulation in many patients with amenorrhea, polycystic ovarian syndrome, and dysfunctional bleeding with anovulatory cycles. Thus, clomiphene's major pharmacological use is to induce ovulation in women with a functional hypothalamic-hypophyseal-ovarian system and adequate endogenous estrogen production. In some cases, clomiphene is used in conjunction with human gonadotropins (Chapter 42) to induce ovulation.

ADME

Tamoxifen is given orally, and peak plasma levels are reached within 4–7 h. It has two elimination phases with half-lives of 7–14 h and 4–11 days. Due to the prolonged $t_{1/2}$, 3–4 weeks of treatment are required to reach steady-state plasma levels. Tamoxifen is metabolized in humans by multiple hepatic CYPs, some of which it also induces (Sridar et al., 2002). In humans and other species, 4-hydroxytamoxifen is produced via hepatic metabolism, and this compound is considerably more potent than the parent drug as an antiestrogen. The major route of elimination from the body involves *N*-demethylation and deamination. The drug undergoes enterohepatic circulation, and excretion is primarily in the feces as conjugates of the deaminated metabolite. Polymorphisms affect the rate of tamoxifen metabolism to its more potent 4-hydroxy metabolite and may affect its therapeutic activity in breast cancer (Chapter 67).

Raloxifene is absorbed rapidly after oral administration and has an absolute bioavailability of about 2%. The drug has a $t_{1/2}$ of about 28 h and is eliminated primarily in the feces after hepatic glucuronidation.

Clomiphene is well absorbed following oral administration, and the drug and its metabolites are eliminated primarily in the feces and to a lesser extent in the urine. The long plasma $t_{1/2}$ (5–7 days) is due largely to plasma-protein binding, enterohepatic circulation, and accumulation in fatty tissues.

Fulvestrant is administered monthly by intramuscular depot injections. Plasma concentrations reach maximal levels in 7 days and are maintained for a month. Numerous metabolites are formed in vivo, possibly by pathways similar to endogenous estrogen metabolism, but the drug is eliminated primarily (90%) via the feces in humans.

Therapeutic Uses

Breast Cancer. Tamoxifen is highly efficacious in the treatment of breast cancer. It is used alone for palliation of advanced breast cancer in women with ER-positive tumors, and it is now indicated as the hormonal treatment of choice for both early and advanced breast cancer in women of all ages (Jaiyesimi et al., 1995). Response rates are about 50% in women with ER-positive tumors. Tamoxifen increases disease-free survival and overall survival; treatment for 5 years reduces cancer recurrence by 50% and death by 27% and is more efficacious than shorter 1- to 2-year treatment periods. Tamoxifen reduces the risk of developing contralateral breast cancer and is approved for primary prevention of breast cancer in women at high risk, in whom it causes a 50% decrease in the development of new tumors. Prophylactic treatment should be limited to 5 years because effectiveness decreases thereafter. The most frequent side effect is hot flashes. Tamoxifen has estrogenic activity in the uterus, increases the risk of endometrial cancer by 2- to 3-fold, and also causes a comparable increase in the risk of thromboembolic disease that leads to serious risks for women receiving anticoagulant therapy (Smith, 2003) and women with a history of deep vein thrombosis or stroke.

Toremifene has therapeutic actions similar to tamoxifen, and fulvestrant may be efficacious in women who become resistant to tamoxifen. Untoward effects of fulvestrant include hot flashes, GI symptoms, headache, back pain, and pharyngitis.

Osteoporosis. Raloxifene reduces the rate of bone loss and may increase bone mass at certain sites. In a large clinical trial, raloxifene increased spinal bone mineral density by more than 2% and reduced the rate of vertebral fractures by 30%–50% but did not significantly reduce nonvertebral fractures (Delmas et al., 2002; Ettinger et al., 1999). Raloxifene does not appear to increase the risk of developing endometrial cancer. The drug has beneficial actions on lipoprotein metabolism, reducing both total cholesterol and LDL; however, HDL is not increased. Adverse effects include hot flashes, deep vein thrombosis, and leg cramps.

Infertility. Clomiphene citrate is a potent antiestrogen that primarily is used for treatment of anovulation in the setting of an intact hypothalamic-pituitary axis and adequate estrogen production (e.g., PCOS) or to induce superovulation in women with unexplained infertility. By inhibiting the negative-feedback effects of estrogen at hypothalamic and pituitary levels,

clomiphene increases FSH levels and thereby enhances follicular maturation. The drug is relatively inexpensive, is orally active, and requires less-extensive monitoring than do other fertility protocols. However, the drug may exhibit untoward effects, including ovarian hyperstimulation, increased incidence of multiple births, ovarian cysts, hot flashes, and blurred vision. Prolonged use (e.g., ≥ 12 cycles) may increase the risk of ovarian cancer. The drug should not be administered to pregnant women due to reports of teratogenicity in animals, but there is no evidence of this when the drug has been used to induce ovulation.

Experimental SERM-Estrogen Combinations. There is considerable interest in MHT using combinations of a pure estrogen agonist (e.g., estradiol) with a SERM that has predominantly antagonist activity in the breast and endometrium but does not distribute to the CNS. The strategy is to obtain the beneficial actions of the agonist (e.g., prevention of hot flashes and bone loss) while the SERM blocks unwanted agonist action at peripheral sites (e.g., proliferative effects in breast and endometrium) but does not enter the brain to cause hot flashes. Animal studies have been encouraging (Labrie et al., 2003), but clinical efficacy and safety of this approach remain to be established.

Estrogen Synthesis Inhibitors

Continual administration of GnRH agonists prevents ovarian synthesis of estrogens but not their peripheral synthesis from adrenal androgens (Chapter 42). *Aminoglutethimide* inhibits aromatase activity, but its use is limited by its lack of selectivity and its side effects (sedation). It was discontinued in the U.S. in 2008.

The recognition that locally produced as well as circulating estrogens may play a significant role in breast cancer has greatly stimulated interest in the use of aromatase inhibitors to selectively block production of estrogens (Chapter 68). Both steroidal (e.g., formestane and exemestane) and nonsteroidal (e.g., anastrozole, letrozole, and vorozole) agents are available. Steroidal, or type I, agents are substrate analogues that act as suicide inhibitors to irreversibly inactivate aromatase, whereas the nonsteroidal, or type II, agents interact reversibly with the heme groups of CYPs (Haynes et al., 2003). *Exemestane*, *letrozole*, and *anastrozole* are currently approved in the U.S. for the treatment of breast cancer.

As discussed in Chapter 68, these agents may be used as first-line treatment of breast cancer or as second-line drugs after tamoxifen. They are highly efficacious and actually superior to tamoxifen in adjuvant use for postmenopausal women (Coombes et al., 2004), and they are indicated either following tamoxifen for 2–5 years or as initial agents. They have the added advantage of not increasing the risk of uterine cancer or venous thromboembolism. Because they dramatically reduce circulating as well as local levels of estrogens, they produce hot flashes. They lack the beneficial effect of tamoxifen to maintain bone density and thus are usually administered with bisphosphonates. Their effects on plasma lipids remain to be established.

Progestins

HISTORY Progestins

Corner and Allen originally isolated a hormone in 1933 from the corpora lutea of sows and named it *progestin*. The next year, several European groups independently isolated the crystalline compound and called it *luteo-sterone*, unaware of the previous name. This difference in nomenclature was resolved in 1935 at a garden party in London given by Sir Henry Dale, who helped persuade all parties that the name *progesterone* was a suitable compromise.

Two major advances overcame the early difficulties and expense of obtaining progesterone from animal sources. The first was the synthesis of progesterone by Russel Marker from the plant product diosgenin in the 1940s, which provided a relatively inexpensive and highly pure product. The second was the synthesis of 19-nor compounds, the first orally active progestins, in the early 1950s by Carl Djerassi, who synthesized norethindrone at Syntex, and Frank Colton, who synthesized the isomer *norethynodrel* at Searle. These advances led to the development of effective oral contraceptives.

Chemistry

Compounds with biological activities similar to those of progesterone are referred to as progestins, progestational agents, progestagens, progestogens, gestagens, or gestogens. The progestins (Figure 44–5) include the naturally occurring hormone progesterone, 17 α -acetoxyprogesterone derivatives in the pregnane series, 19-nortestosterone derivatives in the estrane series, and norgestrel and related compounds in the gonane series. MPA and megestrol acetate are C21 steroids in the pregnane family with selective activity very similar to that of progesterone itself. MPA and oral micronized progesterone are widely used with estrogens for MHT and other situations in which a selective progestational effect is desired. Furthermore, depot MPA is used as a long-acting injectable contraceptive. The 19-nortestosterone derivatives (estrans) were developed for use as progestins in oral contraceptives, and although their predominant activity is progestational, they exhibit androgenic and other activities. The gonanes are another family of “19-nor” compounds, containing an ethyl rather than a methyl substituent in the 13 position. They have diminished androgenic activity relative to the estranes. These two classes of 19-nortestosterone derivatives are the progestational components of most oral and some long-acting injectable contraceptives. The remaining oral contraceptives contain a class of progestins derived from spironolactone (e.g., drospirenone) that have antimineralocorticoid and antiandrogenic properties.

The structural features of several progestins are shown in Figure 44–5. Unlike the ER, which requires a phenolic A ring for high-affinity binding, the PR favors a Δ^4 -3-one A-ring structure in an inverted 1 β ,2 α -conformation. Other steroid hormone receptors also bind this nonphenolic A-ring structure, although the optimal conformation differs from that for the PR. Thus, some synthetic progestins (especially the 19-nor compounds) display limited binding to glucocorticoid, androgen, and mineralocorticoid receptors, a property that probably accounts for some of their nonprogestational activities. The spectrum of activities of these compounds is highly dependent on specific substituent groups, especially the nature of the C17 substituent in the D ring, the presence of a C19 methyl group, and the presence of an ethyl group at position C13.

Biosynthesis and Secretion

Progesterone is secreted by the ovary, mainly from the corpus luteum, during the second half of the menstrual cycle (Figure 44–3). LH, acting via its G protein-coupled receptor, stimulates progesterone secretion during the normal cycle.

Agents Similar to 19-Nortestosterone (Estranes)

Agents Similar to 19-Norgestrel (Gonanes)

Figure 44-5 Structural features of various progestins.

After fertilization, the trophoblast secretes hCG into the maternal circulation, which then stimulates the LH receptor to sustain the corpus luteum and maintain progesterone production. During the second or third month of pregnancy, the developing placenta begins to secrete estrogen and progesterone in collaboration with the fetal adrenal glands, and thereafter the corpus luteum is not essential to continued gestation. Estrogen and progesterone continue to be secreted in large amounts by the placenta up to the time of delivery.

Physiologic Actions

Neuroendocrine Actions

Progesterone produced in the luteal phase of the cycle has several physiological effects, including decreasing the frequency of GnRH pulses. This progesterone-mediated decrease in GnRH pulse frequency is critical for suppressing gonadotropin release and resetting the hypothalamic-pituitary-gonadal axis to transition from the luteal back to the follicular phase. Furthermore, GnRH suppression is the major mechanism of action of progestin-containing contraceptives.

Reproductive Tract. Progesterone decreases estrogen-driven endometrial proliferation and leads to the development of a secretory endometrium (Figure 44-3), and the abrupt decline in progesterone at the end of the cycle is the main determinant of the onset of menstruation. If the duration of the luteal phase is artificially lengthened, either by sustaining luteal function or by treatment with progesterone, decidual changes in the endometrial stroma similar to those seen in early pregnancy can be induced. Under normal circumstances, estrogen antecedes and accompanies progesterone in its action on the endometrium and is essential to the development of the normal menstrual pattern.

Progesterone also influences the endocervical glands, and the abundant watery secretion of the estrogen-stimulated structures is changed to a scant viscid material. As noted previously, these and other effects of progestins decrease penetration of the cervix by sperm.

The estrogen-induced maturation of the human vaginal epithelium is modified toward the condition of pregnancy by the action of progesterone, a change that can be detected in cytological alterations in the vaginal smear. If the quantity of estrogen concurrently acting is known to be adequate, or if it is ensured by giving estrogen, the cytological response to a progestin can be used to evaluate its progestational potency.

Progesterone is important for the maintenance of pregnancy. Progesterone suppresses menstruation and uterine contractility.

Mammary Gland. Development of the mammary gland requires both estrogen and progesterone. During pregnancy and to a minor degree during the luteal phase of the cycle, progesterone, acting with estrogen, brings about a proliferation of the acini of the mammary gland. Toward the end of pregnancy, the acini fill with secretions, and the vasculature of the gland notably increases; however, only after the levels of estrogen and progesterone decrease at parturition does lactation begin.

During the normal menstrual cycle, mitotic activity in the breast epithelium is very low in the follicular phase and then peaks in the luteal phase. This pattern is due to progesterone, which triggers a *single* round of mitotic activity in the mammary epithelium. This effect is transient because continued exposure to the hormone is rapidly followed by arrest of growth of the epithelial cells. Importantly, progesterone may be responsible for the increased risk of breast cancer associated with estrogen-progestin use in postmenopausal women, although controlled studies with only progestin have not been performed (Anderson et al., 2004; Rossouw et al., 2002).

CNS. During a normal menstrual cycle, an increase in basal body temperature of about 0.6°C (1°F) may be noted at midcycle; this correlates with ovulation. This increase is due to progesterone, but the exact mechanism of this effect is unknown. Progesterone also increases the ventilatory response of the respiratory centers to carbon dioxide and leads to reduced arterial and alveolar P_{CO_2} in the luteal phase of the menstrual cycle and during pregnancy. Progesterone also may have depressant and hypnotic actions in the CNS, possibly accounting for reports of drowsiness after hormone administration. This potential untoward effect may be abrogated by giving progesterone preparations at bedtime, which may even help some patients sleep.

Metabolic Effects. Progestins have numerous metabolic actions. Progesterone itself increases basal insulin levels and the rise in insulin after carbohydrate ingestion, but it does not normally alter glucose tolerance. However, long-term administration of more potent progestins, such as norgestrel, may decrease glucose tolerance. Progesterone stimulates lipoprotein lipase activity and seems to enhance fat deposition. Progesterone and analogues such as MPA have been reported to increase LDL and cause either no effects or modest reductions in serum HDL levels. The 19-norprogestins may have more pronounced effects on plasma lipids because of their androgenic activity.

Medroxyprogesterone acetate decreases the favorable HDL increase caused by conjugated estrogens during postmenopausal hormone replacement, but it does not significantly affect the beneficial effect of estrogens to lower LDL. In contrast, micronized progesterone does not significantly alter beneficial estrogen effects on either HDL or LDL profiles (Writing Group for the PEPI Trial, 1995); the spironolactone derivative drospirenone may actually have advantageous effects on the cardiovascular system due to its antiandrogenic and antimineralocorticoid activities. Progesterone also may diminish the effects of aldosterone in the renal tubule and cause a decrease in sodium reabsorption that may increase mineralocorticoid secretion from the adrenal cortex.

Pharmacology

Mechanism of Action

A single gene encodes two isoforms of the PR, PR-A and PR-B. The first 164 N-terminal amino acids of PR-B are missing from PR-A; this occurs

by use of two distinct estrogen-dependent promoters in the PR gene (Giangrande and McDonnell, 1999). The ratios of the individual isoforms vary in reproductive tissues as a consequence of tissue type, developmental status, and hormone levels. Both PR-A and PR-B have AF-1 and AF-2 transactivation domains, but the longer PR-B also contains an additional AF-3 that contributes to its cell- and promoter-specific activity. Because the ligand-binding domains of the two PR isoforms are identical, there is no difference in ligand binding. In the absence of ligand, PR is present primarily in the nucleus in an inactive monomeric state bound to HSP90, HSP70, and p59. When receptors bind progesterone, the HSPs dissociate, and the receptors are phosphorylated and subsequently form dimers (homo- and heterodimers) that bind with high selectivity to PREs located on target genes (Giangrande and McDonnell, 1999). Transcriptional activation by PR occurs primarily via recruitment of coactivators such as SRC-1, NcoA-1, or NcoA-2 (Collingwood et al., 1999). The receptor-coactivator complex then favors further interactions with additional proteins, such as CBP and p300, which mediate other processes, including histone acetylase activity. Histone acetylation causes remodeling of chromatin that increases the accessibility of general transcriptional proteins, including RNA polymerase II, to the target promoter.

The biological activities of PR-A and PR-B are distinct and depend on the target gene. In most cells, PR-B mediates the stimulatory activities of progesterone; PR-A strongly inhibits this action of PR-B and is also a transcriptional inhibitor of other steroid receptors (McDonnell and Goldman, 1994). Current data suggest that coactivators and corepressors interact differentially with PR-A and PR-B (e.g., the corepressor SMRT binds much more tightly to PR-A than to PR-B) (Giangrande et al., 2000), and this may account, at least in part, for the differential activities of the two isoforms. Female PR-A knockout mice are infertile, with impaired ovulation and defective decidualization and implantation. Several uterine genes appear to be regulated exclusively by PR-A, including calcitonin and amphiregulin (Mulac-Jericevic et al., 2000), and the antiproliferative effect of progesterone on the estrogen-stimulated endometrium is lost in PR-A knockout mice. In contrast, knockout studies suggested that PR-B is largely responsible for mediating hormone effects in the mammary gland (Mulac-Jericevic et al., 2003).

Certain effects of progesterone, such as increased Ca^{2+} mobilization in sperm, can be seen in as little as 3 min (Blackmore, 1999) and are therefore considered transcription independent. Similarly, progesterone can promote oocyte maturation (meiotic resumption) independent of transcription (Hammes, 2004).

ADME

Progesterone undergoes rapid first-pass metabolism, but high-dose (e.g., 100–200 mg) preparations of micronized progesterone are available for oral use. Although the absolute bioavailability of these preparations is low (Fotherby, 1996), efficacious plasma levels nevertheless may be obtained. Progesterone also is available in oil solution for injection, as a vaginal gel, as a slow-release IUD for contraception, and as a vaginal insert for assisted reproductive technology.

Esters such as MPA are available for intramuscular administration, and MPA and megestrol acetate may be used orally. The 19-nor steroids have good oral activity because the ethinyl substituent at C17 significantly slows hepatic metabolism. Implants and depot preparations of synthetic progestins are available in many countries for release over very long periods of time (see section on contraceptives).

In the plasma, progesterone is bound by albumin and corticosteroid-binding globulin but is not appreciably bound to SHBG. 19-Nor compounds, such as norethindrone, norgestrel, and desogestrel, bind to SHBG and albumin, and esters such as MPA bind primarily to albumin. Total binding of all these synthetic compounds to plasma proteins is extensive, 90% or less, but the proteins involved are compound specific.

The elimination $t_{1/2}$ of progesterone is about 5 min, and the hormone is metabolized primarily in the liver to hydroxylated metabolites and their sulfate and glucuronide conjugates, which are eliminated in the urine. A major metabolite specific for progesterone is pregnane-3 α ,20 α -diol; its measurement in urine and plasma is used as an index of endogenous

progesterone secretion. The synthetic progestins have much longer half-lives (e.g., ~7 h for norethindrone, 16 h for norgestrel, 12 h for gestodene, and 24 h for MPA). The metabolism of synthetic progestins is thought to be primarily hepatic, and elimination is generally via the urine as conjugates and various polar metabolites.

Antiprogestins and Progesterone Receptor Modulators

The first report of an antiprogesterone, RU 38486 (often referred to as RU-486) or *mifepristone*, appeared in 1981; this drug is available for the termination of pregnancy (Christin-Maitre et al., 2000). In 2010, the FDA approved ulipristal acetate, a partial agonist at the progesterone receptor, for emergency contraception. Antiprogestins also have several other potential applications, including to prevent conception, to induce labor, and to treat uterine leiomyomas, endometriosis, meningiomas, and breast cancer (Spitz and Chwalisz, 2000).

Mifepristone

Chemistry

Mifepristone is a derivative of the 19-norprogesterone norethindrone containing a dimethyl-aminophenol substituent at the 11 β position. It effectively competes with both progesterone and glucocorticoids for binding to their respective receptors. Mifepristone is considered a PRM due to its context-dependent activity. Another widely studied antiprogesterone is onapristone (or ZK 98299), which is similar in structure to mifepristone but contains a methyl substituent in the 13 α rather than 13 β orientation. More selective PRMs, such as asoprisnil, are being studied experimentally (DeManno et al., 2003).

MIFEPRISTONE

Pharmacological Effects

Mifepristone acts primarily as a competitive receptor antagonist for both PRs, although it may have some agonist activity in certain contexts. In contrast, onapristone appears to be a pure progesterone antagonist. PR complexes of both compounds antagonize the actions of progesterone-PR complexes and also appear to preferentially recruit corepressors (Leonhardt and Edwards, 2002).

When administered in the early stages of pregnancy, mifepristone causes decidual breakdown by blockade of uterine PRs. This leads to detachment of the blastocyst, which decreases hCG production. This in turn causes a decrease in progesterone secretion from the corpus luteum, which further accentuates decidual breakdown. Decreased endogenous progesterone coupled with blockade of PRs in the uterus increases uterine PG levels and sensitizes the myometrium to their contractile actions. Mifepristone also causes cervical softening, which facilitates expulsion of the detached blastocyst.

Mifepristone can delay or prevent ovulation depending on the timing and manner of administration. These effects are due largely to actions on the hypothalamus and pituitary rather than the ovary, although the mechanisms are unclear.

If administered for one or several days in the mid- to late luteal phase, mifepristone impairs the development of a secretory endometrium and produces menses. PR blockade at this time is the pharmacological equivalent of progesterone withdrawal, and bleeding normally ensues within several days and lasts for 1–2 weeks after antiprogesterone treatment.

Mifepristone also binds to glucocorticoid and androgen receptors and exerts antiglucocorticoid and antiandrogenic actions. A predominant effect in humans is blockade of the feedback inhibition by cortisol of adrenocorticotrophic hormone secretion from the pituitary, thus increasing both corticotropin and adrenal steroid levels in the plasma.

ADME

Mifepristone is orally active with good bioavailability. Peak plasma levels occur within several hours, and the drug is slowly cleared, with a plasma $t_{1/2}$ of 20–40 h. In plasma, it is bound by α_1 -acid glycoprotein, which contributes to the drug's long $t_{1/2}$. Metabolites are primarily the mono- and didemethylated products (thought to have pharmacological activity) formed via CYP3A4. The drug undergoes hepatic metabolism and enterohepatic circulation; metabolic products are found predominantly in the feces (Jang and Benet, 1997).

Therapeutic Uses

Mifepristone, in combination with misoprostol or other PGs, is available for the termination of early pregnancy. When mifepristone is used to produce a medical abortion, a PG is given 48 h after the antiprogesterin to further increase myometrial contractions and ensure expulsion of the detached blastocyst. Intramuscular *sulprostone*, intravaginal *gemeprost*, and oral misoprostol have been used. The success rate with such regimens is greater than 90% among women with pregnancies of 49 days' duration or less. The most severe untoward effect is vaginal bleeding, which most often lasts 8–17 days but is only rarely (0.1% of patients) severe enough to require blood transfusions. High percentages of women also have experienced abdominal pain and uterine cramps, nausea, vomiting, and diarrhea due to the PG. Women receiving chronic glucocorticoid therapy should not be given mifepristone because of its antiglucocorticoid activity. In fact, due to its high affinity for the glucocorticoid receptor, high doses of mifepristone can result in adrenal insufficiency.

Perspective: Too Many People?

The incredible growth of the earth's human population stands out as one of the fundamental events of the last two centuries. The Old Testament dictum "be fruitful and multiply" (Genesis 9:1) has been followed too religiously by readers and nonreaders of the Bible alike. In 1798, Malthus started a great controversy by opposing the prevailing view of unlimited progress for humankind by making two postulates and a conclusion. Malthus postulated "that food is necessary for the existence of man" and that sexual attraction between female and male is necessary and likely to persist because "toward the extinction of the passion between the sexes, no progress whatever has hitherto been made," barring "individual exceptions." Malthus concluded that "the power of populations is infinitely greater than the power of the earth to produce subsistence for man," producing a "natural inequality" that would someday loom "insurmountable in the way to perfectibility of society."

Malthus was right: Passion between the sexes persists, and the power of populations is very great indeed, so much so that our sheer numbers have increased to the point that they are straining Earth's capacity to supply food, energy, and raw materials and to absorb the detritus of its human burden. Marine fisheries are being depleted, forests and aquifers are disappearing, and the atmosphere is accumulating greenhouse gases from combustion of the fossil fuels that provide the energy needs of 7 billion people, up from 1 billion in Malthus's day. Perhaps some of the blame can be laid at the feet of medical science: Advances in public health and medicine have led to a significant decline in mortality and an increased life expectancy. However, medical science has also begun to assume a portion of the responsibility for overpopulation and its adverse effects. To this end, drugs in the form of hormones and their analogues have been developed to control human fertility.

Ulipristal

Chemistry

Ulipristal, a derivative of 19-norprogesterone, functions as a selective progesterone receptor modulator, acting as a partial agonist at PRs. Unlike mifepristone, ulipristal appears to be a relatively weak glucocorticoid antagonist.

Pharmacological Effects

In high doses, ulipristal has antiproliferative effects in the uterus; however, its most relevant actions to date involve its capacity to inhibit ovulation. Ulipristal's antiovarian actions likely occur due to progesterone regulation at many levels, including inhibition of LH release through the hypothalamus and pituitary and inhibition of LH-induced follicular rupture within the ovary.

A 30-mg dose of ulipristal can inhibit ovulation when taken up to 5 days after intercourse. Ulipristal can block ovarian rupture at or even just after the time of the LH surge, confirming that at least some of its effects are directly in the ovary. Ulipristal may also block endometrial implantation of the fertilized egg, although whether this contributes to its effects as an emergency contraceptive is not clear.

Therapeutic Uses

Ulipristal acetate is licensed in the E.U. and the U.S. as an emergency contraceptive. Studies comparing ulipristal to levonorgestrel (progesterone-only emergency contraception) demonstrate that ulipristal is at least as effective when taken up to 72 h after unprotected sexual intercourse. In addition, ulipristal remains effective up to 120 h (5 days) after intercourse, making ulipristal a more versatile emergency contraceptive than levonorgestrel, which does not work well beyond 72 h after unprotected intercourse. The most severe side effect in clinical trials using ulipristal has been a self-limited headache and some abdominal pain.

Therapeutic Uses of Estrogens and Progestins

Hormonal Contraception

Types of Hormonal Contraceptives

Combination Oral Contraceptives. The most frequently used agents in the U.S. are combination oral contraceptives containing both an estrogen and a progestin. These agents come in a variety of formulations and strengths (Table 44–2). Their theoretical efficacy generally is considered to be 99.9%. In practice, the 1-year failure rates of oral contraceptives are somewhat greater than 0.1% (Table 44–3). Combination oral contraceptives are available in many formulations. Almost all contain ethinyl estradiol as the estrogen and a 17 α -alkyl-19-nortestosterone derivative as the progestin. Monophasic, biphasic, or triphasic pills are generally provided in 21-day packs. (Virtually all preparations come as 28-day packs, with the pills for the last 7 days containing only inert ingredients.) For the monophasic agents, fixed amounts of the estrogen and progestin are present in each pill, which is taken daily for 21 days, followed by a 7-day "pill-free" period. The biphasic and triphasic preparations provide two or three different pills containing varying amounts of active ingredients, to be taken at different times during the 21-day cycle. This reduces the total amount of steroids administered and more closely approximates the estrogen-to-progestin ratios that occur during the menstrual cycle. With these preparations, predictable menstrual bleeding generally occurs during the 7-day "off" period each month. However, several oral contraceptives are now available whereby progestin withdrawal is only induced every 3 months.

The estrogen content of current preparations ranges from 20 to 50 μ g; most contain 30–35 μ g. Preparations containing 35 μ g or less of an estrogen are generally referred to as "low-dose" or "modern" pills. The dose of progestin is more variable because of differences in potency of the compounds used.

A transdermal preparation of norelgestromin and ethinyl estradiol is marketed for weekly application to the buttock, abdomen, upper arm, or torso for the first 3 consecutive weeks followed by a patch-free week for

Hormonal Contraception: A Brief History

Around the beginning of the 20th century, a number of European scientists, including Beard, Prenant, and Loeb, developed the concept that secretions of the corpus luteum suppressed ovulation during pregnancy. The Austrian physiologist Haberlandt then produced temporary sterility in rodents in 1927 by feeding them ovarian and placental extracts—a clear example of an oral contraceptive. In 1937, Makepeace and colleagues demonstrated that pure progesterone blocked ovulation in rabbits, and Astwood and Fevold found a similar effect in rats in 1939.

In the 1950s, Pincus, Garcia, and Rock found that progesterone and 19-norproggestins prevented ovulation in women. Ironically, this finding grew out of their attempts to treat infertility with estrogen-progestin combinations. The initial findings were that these treatments effectively blocked ovulation in most women. However, concern about cancer and other possible side effects of the estrogen they used (i.e., DES) led to the use of a progestin alone in their studies. One of the compounds used was norethynodrel, and early batches of this compound were contaminated with a small amount of mestranol. When mestranol was removed, it was noted that treatment with pure norethynodrel led to increased breakthrough bleeding and less-consistent inhibition of ovulation. Mestranol was thus reincorporated into the preparation, and this combination was employed in the first large-scale clinical trial of combination oral contraceptives.

Clinical studies in the 1950s in Puerto Rico and Haiti established the virtually complete contraceptive success of the norethynodrel/mestranol combination. In early 1961, Enovid (norethynodrel plus mestranol; no longer marketed in the U.S.) was the first “Pill” approved by the FDA for use as a contraceptive agent in the U.S.; this was followed in 1962 by approval for Ortho-Novum (norethindrone plus mestranol). By 1966, numerous preparations using either mestranol or ethinyl estradiol with a 19-norprogesterone were available. In the 1960s, the progestin-only minipill and long-acting injectable preparations were developed and introduced.

Millions of women began using oral contraceptives, and frequent reports of untoward effects began appearing in the 1970s. The recognition that these side effects were dose dependent and the realization that estrogens and progestins synergistically inhibited ovulation led to the reduction of doses and the development of so-called low-dose or second-generation contraceptives. The increasing use of biphasic and triphasic preparations throughout the 1980s further reduced steroid dosages; it may be that currently used doses are the lowest that will provide reliable contraception. In the 1990s, the “third-generation” oral contraceptives, containing progestins with reduced androgenic activity (e.g., norgestimate and desogestrel), became available in the U.S. after being used in Europe. A variety of contraceptive formulations are currently available, including pills, injections, skin patches, subdermal implants, vaginal rings, and IUDs that release hormones.

each 28-day cycle. A similar 3-week on/1-week off cycle is employed for the intravaginal ring containing ethinyl estradiol and etonogestrel.

Progestin-Only Contraceptives. Several agents are available for progestin-only contraception, with theoretical efficacies of 99%. Specific preparations include the “minipill”; low doses of progestins (e.g., 350 µg of norethindrone) taken daily without interruption; subdermal implants of 216 mg of norgestrel for long-term contraceptive action (e.g., up to 5 years) or 68 mg of etonogestrel for contraception lasting 3 years; and crystalline suspensions of MPA for intramuscular injection of 104 mg or 150 mg of drug. Each provides effective contraception for 3 months.

Intrauterine Devices. Two doses of levonorgestrel-releasing intrauterine systems (IUSs) are available in the U.S. The LNG20 contains 52 mg of levonorgestrel, which is initially released at a rate of 20 µg/d and declines

gradually to 10–14 µg/d after 5 years. A smaller LNG IUS is available for women with a small uterine cavity or cervical stenosis and may result in less pain with insertion. The LNG14 contains 13.5 mg of levonorgestrel, which is initially released at a rate of 14 µg/d and declines to 5 µg/d after 3 years. A copper IUD, TCu380A, is also available in the U.S. It contains 380 mm² of copper and is approved for 10 year use. The TCu380A may be preferred over an LNG IUS in women who desire long-term contraception and wish to avoid exogenous hormones and hormonal side effects and can also be used as an emergency contraceptive.

Mechanism of Action

Combination Oral Contraceptives. Combination oral contraceptives act by preventing ovulation. Direct measurements of plasma hormone levels indicate that LH and FSH levels are suppressed, a midcycle surge of LH is absent, endogenous steroid levels are diminished, and ovulation does not occur. Although either component alone can be shown to exert these effects in certain situations, the combination synergistically decreases plasma gonadotropin levels and suppresses ovulation more consistently than either alone.

Given the multiple actions of estrogens and progestins on the hypothalamic-pituitary-ovarian axis during the menstrual cycle, several effects probably contribute to the blockade of ovulation.

Hypothalamic actions of steroids play a major role in the mechanism of oral contraceptive action. Progesterone diminishes the frequency of GnRH pulses. Because the proper frequency of LH pulses is essential for ovulation, this effect of progesterone likely plays a major role in the contraceptive action of these agents.

Multiple pituitary effects of both estrogen and progestin components are thus likely to contribute to oral contraceptive action. Oral contraceptives seem likely to decrease pituitary responsiveness to GnRH. Estrogens also suppress FSH release from the pituitary during the follicular phase of the menstrual cycle, and this effect seems likely to contribute to the lack of follicular development in oral contraceptive users. The progestin component may also inhibit the estrogen-induced LH surge at midcycle. Other effects may contribute to a minor extent to the extraordinary efficacy of oral contraceptives. Transit of sperm, the egg, and fertilized ovum are important to establish pregnancy, and steroids are likely to affect transport in the fallopian tube. In the cervix, progestin effects also are likely to produce a thick, viscous mucus to reduce sperm penetration and in the endometrium to produce a state that is not receptive to implantation. However, it is difficult to assess quantitatively the contributions of these effects because the drugs block ovulation so effectively.

Progestin-Only Contraceptives. Progestin-only pills and levonorgestrel implants are highly efficacious but block ovulation in only 60%–80% of cycles. Their effectiveness is thought to be due largely to a thickening of cervical mucus, which decreases sperm penetration, and to endometrial alterations that impair implantation; such local effects account for the efficacy of IUDs that release progestins. Depot injections of MPA are thought to exert similar effects, but they also yield plasma levels of drug high enough to prevent ovulation in virtually all patients, presumably by decreasing the frequency of GnRH pulses.

Intrauterine Devices. While the contraceptive benefit of the LNG IUS is attributed to the progestin-mediated effects of thickening of cervical mucous and endometrial alterations, the contraceptive mechanism of the copper IUD is related to an inflammatory reaction within the endometrium that impairs sperm viability, motility, and fertilization.

Untoward Effects

Combination Oral Contraceptives. Untoward effects of early hormonal contraceptives fell into several major categories: adverse cardiovascular effects, including hypertension, myocardial infarction, hemorrhagic or ischemic stroke, and venous thrombosis and embolism; breast, hepatocellular, and cervical cancers; and a number of endocrine and metabolic effects. The current consensus is that low-dose preparations pose minimal health risks in women who have no predisposing risk factors, and these drugs also provide many beneficial health effects (Burkman et al., 2004).

TABLE 44-2 ■ FORMULATIONS OF REPRESENTATIVE ORAL CONTRACEPTIVES

PRODUCT	FORMULATION	
COMBINATION ^b MONOPHASIC	ESTROGEN (μg)	PROGESTIN (mg)

PROGESTIN ONLY	ESTROGEN (μg)	PROGESTIN (mg)
Norethindrone	—	0.35 ^c
Norgestrel	—	0.075 ^c

Unless otherwise indicated, the products are packaged with 21 active (hormone-containing) pills and 7 placebo tablets. For formulations that differ from this standard (e.g., multiphasic pills, extended-cycle formulations), the number of tablets of each pill strength are indicated.

^aSome formulations also contain iron to diminish the risk of iron deficiency anemia; these are not listed separately here.

^bCombination formulations contain both an estrogen and a progestin.

^cDenotes continuous administration of active pills.

TABLE 44-3 ■ ONE-YEAR FAILURE RATE WITH VARIOUS FORMS OF CONTRACEPTION

BIRTH CONTROL METHOD	FAILURE (<i>Perfect Use</i>)	RATE (%) (<i>Typical Use</i>)
Combination oral contraceptive pills	0.3	8
Progestin-only minipill	0.5	8

Spermicides	18	9
Tubal ligation	0.5	0.5
Vasectomy	0.1	0.15
None	85	85

Cardiovascular Effects. The question of cardiovascular side effects has been reexamined for the newer low-dose oral contraceptives (Burkman et al., 2004). For nonsmokers without other risk factors such as hypertension or diabetes, there is no significant increase in the risk of myocardial infarction or stroke. There is a 28% increase in relative risk for venous thromboembolism, but the estimated absolute increase is very small because the incidence of these events in women without other predisposing factors is low (e.g., roughly half that associated with the risk of venous thromboembolism in pregnancy). The risk is significantly increased in women who smoke or have other factors that predispose to thrombosis or thromboembolism (Castelli, 1999). Postmarketing epidemiologic studies indicated that women using transdermal contraceptives have a higher-than-expected exposure to estrogen and are at increased risk for the development of venous thromboembolism. Early high-dose combination oral contraceptives caused hypertension in 4%–5% of normotensive women and increased blood pressure in 10%–15% of those with preexisting hypertension. This incidence is much lower with newer low-dose preparations, and most reported changes in blood pressure are not significant. Estrogens increase serum HDL and decrease LDL levels, and progestins tend to have the opposite effect. Recent studies of several low-dose preparations have not found significant changes in total serum cholesterol or lipoprotein profiles, although slight increases in triglycerides have been reported.

Cancer. Given the growth-promoting effects of estrogens, there has been a long-standing concern that oral contraceptives might increase the incidence of endometrial, cervical, ovarian, breast, and other cancers. These concerns were further heightened in the late 1960s by reports of endometrial changes caused by sequential oral contraceptives, which have since been removed from the market in the U.S. However, it is now clear that there is *not* a widespread association between oral contraceptive use and cancer (Burkman et al., 2004; Westhoff, 1999).

Epidemiological evidence suggests that combined oral contraceptive use may increase the risk of cervical cancer by about 2-fold but only in long-term (>5 years) users with persistent human papilloma virus infection (Moodley, 2004).

There have been reports of increases in the incidence of hepatic adenoma and hepatocellular carcinoma in oral contraceptive users. Current estimates indicate there is about a doubling in the risk of liver cancer after 4–8 years of use. However, these are rare cancers, and the absolute increases are small.

The major present concern about the carcinogenic effects of oral contraceptives is focused on breast cancer. The risk of breast cancer in women

of childbearing age is very low, and current oral contraceptive users in this group have only a very small increase in relative risk of 1.1–1.2, depending on other variables. This small increase is not substantially affected by duration of use, dose or type of component, age at first use, or parity. Importantly, 10 years after discontinuation of oral contraceptive use, there is no difference in breast cancer incidence between past users and never users. In addition, breast cancers diagnosed in women who have ever used oral contraceptives are more likely to be localized to the breast and thus easier to treat (Westhoff, 1999).

Combination oral contraceptives decrease the incidence of endometrial cancer by 50%, an effect that lasts 15 years after the pills are stopped. This is thought to be due to the inclusion of a progestin, which opposes estrogen-induced proliferation, throughout the entire 21-day cycle of administration. These agents also decrease the incidence of ovarian cancer. There are accumulating data that oral contraceptive use decreases the risk of colorectal cancer (Fernandez et al., 2001).

Metabolic and Endocrine Effects. The effects of sex steroids on glucose metabolism and insulin sensitivity are complex (Godsland, 1996) and may differ among agents in the same class (e.g., the 19-norprogestins). Early studies with high-dose oral contraceptives generally reported impaired glucose tolerance; these effects have decreased as steroid dosages have been lowered, and current low-dose combination contraceptives may even improve insulin sensitivity. Similarly, the high-dose progestins in early oral contraceptives did raise LDL and reduce HDL levels, but modern low-dose preparations do not produce unfavorable lipid profiles (Sherif, 1999). There also have been periodic reports that oral contraceptives increase the incidence of gallbladder disease, but any such effect appears to be weak and limited to current or very long-term users (Burkman et al., 2004).

The estrogenic component of oral contraceptives may increase hepatic synthesis of a number of serum proteins, including those that bind thyroid hormones, glucocorticoids, and sex steroids. Although physiological feedback mechanisms generally adjust hormone synthesis to maintain normal “free” hormone levels, these changes can affect the interpretation of endocrine function tests that measure *total* plasma hormone levels and may necessitate dose adjustment in patients receiving thyroid hormone replacement.

The ethinyl estradiol present in oral contraceptives appears to cause a dose-dependent increase in several serum factors known to increase coagulation. However, in healthy women who do not smoke, there also is an increase in fibrinolytic activity, which exerts a countereffect so that overall there is a minimal effect on hemostatic balance. This compensatory effect is diminished in smokers (Fruzzetti, 1999).

Miscellaneous Effects. Nausea, edema, and mild headache occur in some individuals, and more severe migraine headaches may be precipitated by oral contraceptive use in a smaller fraction of women. Some patients may experience breakthrough bleeding during the 21-day cycle when the active pills are being taken. Withdrawal bleeding may fail to occur in a small fraction of women during the 7-day off period, thus causing confusion about a possible pregnancy. Acne and hirsutism are thought to be mediated by the androgenic activity of the 19-norprogestins.

Progestin-Only Contraceptives. Episodes of irregular, unpredictable spotting and breakthrough bleeding are the most frequently encountered untoward effect and the major reason women discontinue use of all three types of progestin-only contraceptives. With time, the incidence of these bleeding episodes decreases.

No evidence indicates that the progestin-only minipill preparations increase thromboembolic events, which are thought to be related to the estrogenic component of combination preparations. Acne may be a problem because of the androgenic activity of norethindrone-containing preparations. These preparations may be attractive for nursing mothers because they do not decrease lactation as do products containing estrogens.

Headache is the most commonly reported untoward effect of depot MPA. Mood changes and weight gain also have been reported, but controlled clinical studies of these effects are not available. Many studies have found decreases in HDL levels and increases in LDL levels, and there have been several reports of decreased bone density. These effects may be

due to reduced endogenous estrogens because depot MPA is particularly effective in lowering gonadotropin levels. Because of the time required to completely eliminate the drug, the contraceptive effect of this agent may remain for 6–12 months after the last injection.

Progestone-only medications have been associated with decreased bone mineral density, as noted by a black-box warning in the product label. Teenagers and younger women who have not achieved maximal bone density may be particularly at risk, although the data suggest that bone density returns to pretreatment levels fairly quickly after drug cessation.

Implants of norethindrone may be associated with infection, local irritation, pain at the insertion site, and, rarely, expulsion of the inserts. Headache, weight gain, and mood changes have been reported, and acne is seen in some patients. Ovulation occurs fairly soon after implant removal, reaching 50% in 3 months and almost 90% within 1 year.

Intrauterine Devices. Intrauterine devices are generally well tolerated, although complications related to the device and side effects related to the progestin can occur. Expulsion of the device is greatest in the first year and has been reported in 3%–6% of women with an LNg20 and 3.2% in women with an LNg14. Malposition of the device, extending into the myometrium or the endocervical canal, occurs in 10% of women and is associated with difficult placement, uterine distortion, and obesity. Not all malpositioned devices need to be removed, as this condition is often asymptomatic and does not compromise the contraceptive efficacy of the device.

Uterine perforation at the time of IUD insertion complicates approximately 1 in 1000 insertions. Symptoms of perforation may include pelvic pain and bleeding, although perforations are often asymptomatic. Surgical removal of the perforated IUD is preferred to minimize serious complications related to adhesions or perforation into the bowel, bladder, or blood vessels.

Pelvic inflammatory disease is infrequent at the time of insertion (1–10 per 1000 women undergoing insertion) and after insertion (1.4 women per 1000 women after insertion). Infections at the time of insertion or 1 month after insertion are generally related to new sexually transmitted infections. The LNg20 is associated with less risk of PID due to thickening of the cervical mucus. Oral antibiotic therapy may be attempted, and worsening infections should be treated with intravenous antibiotics and IUD removal.

Ectopic and intrauterine pregnancies rarely occur with an IUD in situ. Intrauterine pregnancies with an IUD in situ are at increased risk for adverse pregnancy outcomes if the IUD is left in place or removed. The decision to leave the IUD in place or remove it in pregnancy should be individualized based on the women's obstetrical history, the trimester when it is diagnosed, and the anticipated difficulty of removing the IUD.

While device-related complications are infrequent, side effects related to the progestin are common. Irregular bleeding in the first 3–6 months after insertion and amenorrhea at 1 year after insertion are common. Complaints of side effects such as hirsutism, acne, weight change, nausea, headache, mood change, and breast tenderness are related to systemic effects of levonorgestrel and are the most common reason for discontinuation (approximately 12% of women with the LNg20). The copper IUD may be an alternative for women who discontinue the LNg IUS due to hormonal side effects, but it is associated with intermenstrual bleeding and increased volume of bleeding.

Contraindications

Modern oral contraceptives are considered generally safe in most healthy women; however, *these agents can contribute to the incidence and severity of cardiovascular, thromboembolic, or malignant disease, particularly if other risk factors are present.* Contraindications for combination oral contraceptive use are the following: the presence or history of thromboembolic disease, cerebrovascular disease, myocardial infarction, coronary artery disease, or congenital hyperlipidemia; known or suspected carcinoma of the breast, carcinoma of the female reproductive tract; abnormal undiagnosed vaginal bleeding; known or suspected pregnancy; and past or present liver tumors or impaired liver function. *The risk of serious cardiovascular side effects is particularly marked in women more than 35 years of*

age who smoke heavily (e.g., >15 cigarettes per day); even low-dose oral contraceptives are contraindicated in such patients.

Other relative contraindications include migraine headaches, hypertension, diabetes mellitus, obstructive jaundice of pregnancy or prior oral contraceptive use, and gallbladder disease. If elective surgery is planned, many physicians recommend discontinuation of oral contraceptives for several weeks to a month to minimize the possibility of thromboembolism after surgery. These agents should be used with care in women with prior gestational diabetes or uterine fibroids, and low-dose pills should generally be used in such cases.

Progestin-only contraceptives are contraindicated in the presence of undiagnosed vaginal bleeding, benign or malignant liver disease, and known or suspected breast cancer.

The Centers for Disease Control and Prevention U.S. medical eligibility criteria list all progestin-containing IUDs as category 2 for history of venous thromboembolism, which means a condition for which the advantages of using the method generally outweigh risks. The contraindications to IUDs are severe uterine distortion, active pelvic infection, and unexplained abnormal uterine bleeding. The copper IUD should be avoided in women with Wilson disease or a copper allergy.

Noncontraceptive Health Benefits

Oral contraceptives significantly reduce the incidence of ovarian and endometrial cancer within 6 months of use, and the incidence is decreased 50% after 2 years of use. Depot MPA injections also reduce very substantially the incidence of uterine cancer. This protective effect persists for up to 15 years after oral contraceptive use is discontinued. These agents also decrease the incidence of ovarian cysts and benign fibrocystic breast disease.

Oral contraceptives have major benefits related to menstruation in many women. These include more regular menstruation, reduced menstrual blood loss and less iron-deficiency anemia, and decreased frequency of dysmenorrhea. There also is a decreased incidence of PID and ectopic pregnancies, and endometriosis may be ameliorated. Some women also may obtain these benefits with progestin-only contraceptives. There are suggestions that MPA may improve hematological parameters in women with sickle cell disease (Cullins, 1996).

From a purely statistical perspective, fertility regulation by oral contraceptives is substantially safer than pregnancy or childbirth for most women, even without considering the additional health benefits of these agents.

In addition to effective pregnancy prevention, the LNg20 reduces dysmenorrhea and menstrual blood loss. One year after insertion, 30%–40% of women experience amenorrhea. The LNg20 can also be used to prevent and treat endometrial hyperplasia, although close monitoring is necessary, as endometrial adenocarcinoma has occurred in LNg20 users. While LNg14 is effective at preventing pregnancy, less is known regarding the noncontraceptive benefits of the LNg14.

Postcoital Contraception

Postcoital (or emergency) contraception is indicated for use in cases of mechanical failure of barrier devices or in circumstances of unprotected intercourse (Cheng et al., 2008). Because it is less effective than standard oral contraceptive regimens, it is not intended as a regular method of contraception. The mechanisms of action of the postcoital contraceptives are not fully understood, but their efficacy clearly cannot be accounted for solely by the inhibition of ovulation. Other potential mechanisms of action include effects on gamete function and survival and on implantation. These agents do not affect established pregnancies.

A copper IUD is more effective than oral emergency contraceptive agents and can provide ongoing pregnancy prevention. The copper IUD can be inserted within 5–7 days after an unprotected act after a negative pregnancy test.

Selective progesterone-receptor modulators (PRMs) such as ulipristal are approved as an emergency contraceptive, effective up to 120 h after unprotected intercourse. Mifepristone in oral doses ranging from 10 to 50 mg when taken within 5 days after unprotected intercourse can also be used, but is not FDA approved.

Plan B, which contains two tablets of the progestin levonorgestrel (0.75 mg each), is marketed specifically for postcoital contraception and may be obtained in the U.S. without a prescription by women 18 years of age and older. Treatment is most effective if the first dose is taken within 72 h of intercourse, followed by a second dose 12 h later; a single dose of 1.5 mg within 72 h of intercourse appears to be equally effective.

Termination of Pregnancy

If contraception is not used or fails, either mifepristone (RU-486) or methotrexate (50 mg/m² intramuscularly or orally) can be used to terminate an unwanted pregnancy in settings outside surgical centers. A PG then is administered to stimulate uterine contractions and expel the detached conceptus; in the U.S., PGs used include dinoprostone (PGE₂) administered vaginally or the PGE₁ analogue misoprostol given orally or vaginally, both of which are used off label for this purpose. PGs used in other countries include the PGE₂ analogue sulprostone and the PGE₁ analogue gemeprost.

Mifepristone (600 mg) is FDA-approved for pregnancy termination within 49 days after the start of a woman's last menstrual period. The synthetic PGE₁ analogue misoprostol (400 µg) is administered orally 48 h later; vaginal administration is at least as effective but is not FDA approved. Complete abortion using this procedure exceeds 90%; when termination of pregnancy fails or is incomplete, surgical intervention is required. Other published regimens include lower doses of mifepristone (200 or 400 mg) and different time intervals between the mifepristone and misoprostol. Finally, repeated doses of misoprostol alone (e.g., 800 µg vaginally or sublingually every 3 h or every 12 h for three doses) also have been effective in settings where mifepristone is unavailable. Vaginal bleeding follows pregnancy termination and typically lasts from 1 to 2 weeks but rarely (in 0.1% of patients) is severe enough to require blood transfusion. A high percentage of women also experience abdominal pain and uterine cramps, nausea and vomiting, and diarrhea secondary to the PG. Myocardial ischemia and infarction have been reported in association with sulprostone and gemeprost.

Because mifepristone carries a risk of serious, and sometimes fatal, infections and bleeding following its use for medical abortion, a black-box warning has been added to the product labeling. Fulminant septic shock associated with *Clostridium sordellii* infections may result and is attributable to the combined effects of uterine infection and inhibition of glucocorticoid action by mifepristone (Cohen et al., 2007). Patients who develop symptoms and signs of infection, especially marked leukocytosis even without fever, should be treated aggressively with antibiotics effective against anaerobic organisms such as *C. sordellii* (e.g., penicillin, ampicillin, a macrolide, clindamycin, a tetracycline, or metronidazole).

Induction of Sexual Maturation

Estrogen Treatment in the Failure of Ovarian Development

In several conditions (e.g., Turner syndrome), the ovaries do not develop, and puberty does not occur. Therapy with estrogen at the appropriate time replicates the events of puberty, and androgens (Chapter 45) or growth hormone (Chapter 42) may be used concomitantly to promote normal growth. Although estrogens and androgens promote bone growth, they also accelerate epiphyseal fusion, and their premature use can thus result in shorter ultimate height.

Types of estrogens used and the treatment regimens may vary by country or individual preference. Examples include conjugated estrogens, 0.3–1.25 mg; micronized 17β-estradiol, 0.5–2.0 mg; ethinyl estradiol, 5–20 µg; and transdermal 17β-estradiol, 25–50 µg. To achieve optimal breast development, treatment typically is initiated with a low dose of estrogen (e.g., conjugated estrogens at a starting dosage of 0.3 mg/d or ethinyl estradiol at 5 µg/d) starting in patients between ages 10 and 12 years or immediately if the diagnosis is made after this age. After 3–6 months, the dosage is increased (e.g., 0.9–1.25 mg/d of conjugated estrogens or 20 µg/d of ethinyl estradiol). Once this is achieved, a progestin (e.g., medroxyprogesterone, 10 mg/d, or micronized progesterone,

200–400 µg/d) for 12 days each cycle is added to the regimen to optimize breast development and permit cyclical menses, thereby avoiding endometrial hyperplasia and its consequent risk of uterine cancer. Once menses are established, many clinicians will switch to a standard low-dose oral contraceptive pill or even may use an extended-cycle formulation.

Short stature, a universal feature of nonmosaic Turner syndrome, usually is treated with human growth hormone, often together with an androgen such as oxandrolone (see Chapter 45). Initiating treatment with human growth hormone and androgen and delaying the onset of estrogen therapy generally produces better growth response. Doses for growth hormone treatment in this context are higher than those in growth hormone-deficient children (e.g., 67 µg/kg/d; see Chapter 42 for further discussion of growth hormone replacement therapy).

Induction of Ovulation

Infertility (i.e., the failure to conceive after 1 year of unprotected sex) affects about 10%–15% of couples in developed nations and is increasing in incidence as more women choose to delay childbearing until later in life. The cause of infertility is attributed primarily to the woman in approximately one-third of cases, to the man in approximately one-third, and to both in approximately one-third.

Anovulation accounts for about 50% of female infertility and is a major focus of pharmacological interventions used to achieve conception. Although a history of regular cyclic bleeding is strong presumptive evidence for ovulation, assessment of urine LH levels with an ovulation predictor kit or measurement of the serum progesterone levels during the luteal phase provides more definitive information. Evaluation of anovulation may uncover PCOS, thyroid disorders, hyperprolactinemia, or hypogonadism, but the cause is often idiopathic.

A number of approaches have been used to stimulate ovulation in anovulatory women. Often, a stepwise approach is taken, initially using simpler and less-expensive treatments, followed by more complex and expensive regimens if initial therapy is unsuccessful.

Clomiphene

Clomiphene citrate was reviewed previously in this chapter. A typical regimen is 50 mg/d orally for 5 consecutive days starting between days 2 and 5 of the cycle in women who have spontaneous uterine bleeding or following a bleed induced by progesterone withdrawal in women who do not. If this regimen fails to induce ovulation, the dose of clomiphene is increased, first to the FDA-approved maximum of 100 mg/d and possibly to higher levels of 150 or 200 mg/d. Although clomiphene is effective in inducing ovulation in perhaps 75% of women, successful pregnancy ensues in only 40%–50% of those who ovulate. This has been attributed to clomiphene's inhibition of estrogen action on the endometrium, resulting in an environment that is not optimal for fertilization or implantation.

Aromatase Inhibitors

Aromatase inhibitors (e.g., letrozole, 2.5–7.5 mg/d for 5 days, typically starting on day 3 of the cycle) induce follicle development by inhibiting estrogen biosynthesis, thus decreasing estrogen negative feedback and increasing FSH levels and follicle development. In comparing letrozole and clomiphene for ovulation induction in women with PCOS and infertility, letrozole was associated with a higher pregnancy and live birth rate (Legro et al., 2014). Letrozole is associated with fewer estrogen deprivation side effects (hot flashes, mood change) and possibly fewer multifetal gestations than clomiphene.

Gonadotropins

The preparations of gonadotropins available for clinical use are detailed in Chapter 42. Gonadotropins are indicated for ovulation induction in anovulatory women with hypogonadotropic hypogonadism secondary to hypothalamic or pituitary dysfunction, gonadotropins also are used to induce ovulation in women with PCOS who do not respond to clomiphene.

Given the marked increases in maternal and fetal complications associated with multifetal gestation, the goal of ovulation induction in anovulatory women is to induce the formation and ovulation of a single dominant

follicle. Generally, the increased risks of twin gestation will be accepted if two follicles are present.

As shown in Figure 44–6, a typical regimen for ovulation induction is to administer 75 IU of FSH daily in a “low-dose, step-up protocol.” The dose is titrated based on the rise in estradiol and the growth rate of follicles as determined by estradiol levels and transvaginal ultrasonography. If three or more mature follicles are induced, gonadotropin therapy can be canceled, and barrier contraception can be used to prevent pregnancy, thereby avoiding multifetal pregnancy.

To complete follicular maturation and induce ovulation, hCG (5000–10,000 IU) is given 1 day after the last dose of gonadotropin. Fertilization of the oocyte(s) at 36 h after hCG administration then is attempted, by either intercourse or intrauterine insemination.

Gonadotropin induction also is used for ovarian stimulation in conjunction with IVF (Figure 44–6; Macklon et al., 2006). In this setting, larger doses of FSH (typically 225–300 IU/d) are administered to induce the maturation of multiple (ideally at least 5 and up to 20) oocytes that

can be retrieved for IVF. To prevent the LH surge and subsequent premature luteinization of the ovarian follicles, gonadotropins typically are administered in conjunction with a GnRH agonist or a GnRH antagonist. The length of the IVF protocol is predicated by the initial flare of gonadotropin secretion that occurs in response to the GnRH agonists. In the long protocol, the agonist is started in the luteal phase of the previous cycle (generally on cycle day 21) and then maintained until the time of hCG injection to induce ovulation. Alternatively, in the “flare” protocol, the GnRH agonist is started on cycle day 2 (immediately after the start of menses), and gonadotropin injections are added 1 day later. In the GnRH antagonist “short protocol,” the antagonist can be used to inhibit endogenous LH secretion and is typically started after follicular recruitment is initiated. Current regimens include daily injection in a dose of 0.25 mg (ganirelix or cetrorelix) starting on the fifth or sixth day of gonadotropin stimulation or a single dose of 3 mg of cetrorelix administered on day 8 or 9 of the late follicular phase. Adequate follicle maturation typically takes 8–12 days after gonadotropin therapy is initiated.

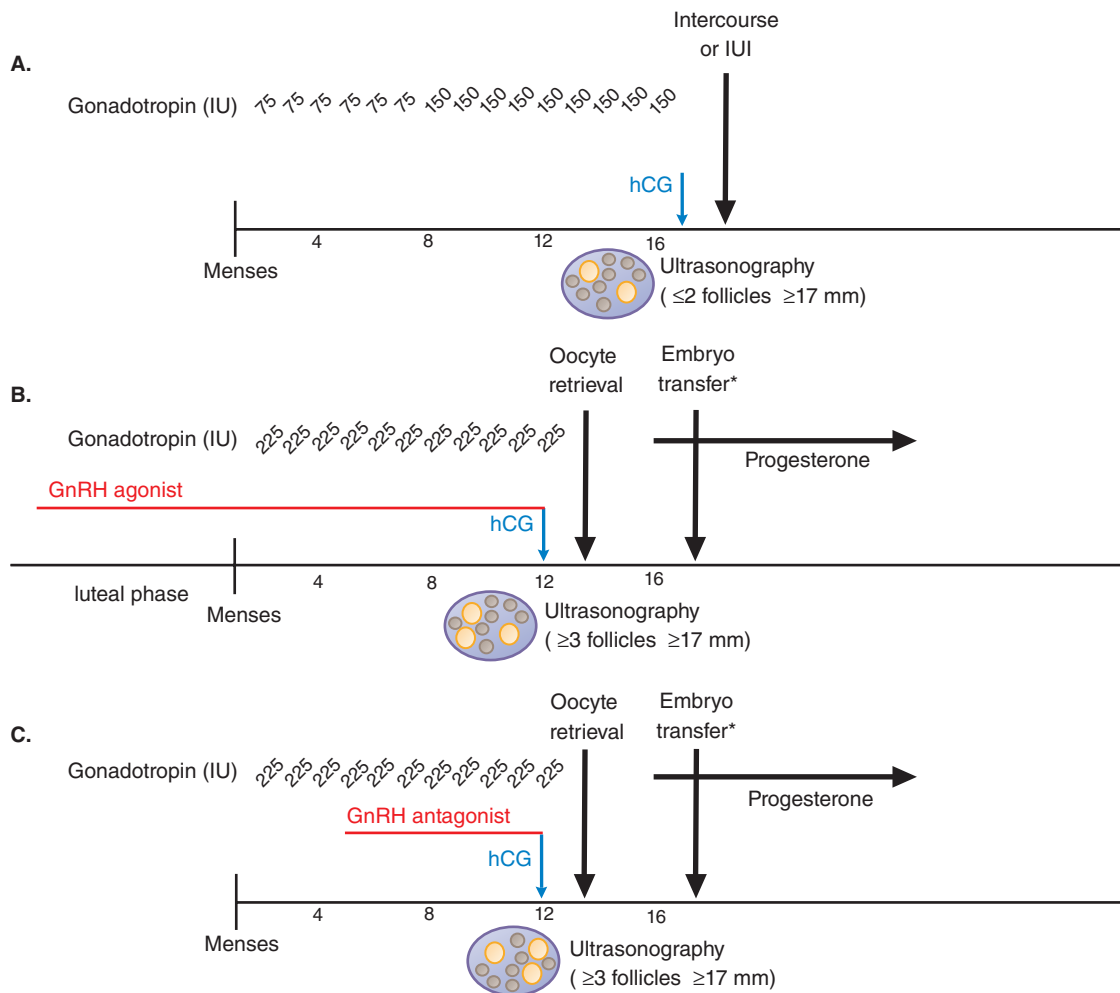

Figure 44–6 Idealized regimens using exogenous gonadotropins for induction of fertility. **A.** Step-up regimen for ovulation induction. After menses, daily injections of gonadotropin (75 IU) are started. Follicle maturation is assessed by serial measurement of plasma estradiol and follicle size, as discussed in the text. If an inadequate response is seen, the dose of gonadotropin is increased to 112 or 150 IU/d. When one or two follicles have achieved a diameter of 17 mm or greater, final follicle maturation and ovulation are induced by injection of hCG. Fertilization then is achieved at 36 h after hCG injection by intercourse or intrauterine insemination (IUI). If more than two mature follicles are seen, the cycle is terminated, and barrier contraception is used to avoid triplets or higher degrees of multifetal gestation. **B.** Long protocol for ovarian hyperstimulation using a gonadotropin-releasing hormone (GnRH) agonist to inhibit premature ovulation, followed by in vitro fertilization (IVF). After the GnRH agonist has inhibited endogenous secretion of gonadotropins, therapy with exogenous gonadotropins is initiated. Follicle maturation is assessed by serial measurements of plasma estradiol and follicle size by ultrasonography. When three or more follicles are 17 mm or larger in diameter, then ovulation is induced by injection of hCG. At 32–36 h after the hCG injection, the eggs are retrieved and used for IVF. Exogenous progesterone is provided to promote a receptive endometrium, followed by embryo transfer at 3–5 days after fertilization. **C.** Protocol for ovarian hyperstimulation in an IVF protocol using a GnRH antagonist. The cycle duration is shorter because the GnRH antagonist does not induce a transient flare of gonadotropin secretion that might disrupt the timing of the cycle, but many other elements of the cycle are analogous to those in **B.**

Using either the long or short protocols, hCG (at typical doses of 5000–10,000 IU of urine-derived product or 250 µg of recombinant hCG) is given to induce final oocyte development, and the mature eggs are retrieved from the preovulatory follicles at 36 h thereafter. The ova are retrieved by transvaginal ultrasound-guided aspiration and fertilized in vitro with sperm (IVF) or by intracytoplasmic sperm injection; one or two embryos then are transferred to the uterus 3–5 days after fertilization.

Because of the inhibitory effects of GnRH agonists or antagonists on pituitary gonadotropes, the secretion of LH that normally sustains the corpus luteum after ovulation does not occur. Repeated injections of hCG, while sustaining the corpus luteum, may increase the risk of OHSS. Thus, standard IVF regimens typically provide exogenous progesterone replacement to support the fetus until the placenta acquires the biosynthetic capacity to take over this function; regimens include progesterone in oil (50–100 mg/d intramuscularly) or micronized progesterone (180–300 mg twice daily vaginally). Vaginal preparations containing 100 or 90 mg of micronized progesterone are approved for administration two or three times daily as part of IVF.

Aside from the attendant complications of multifetal gestation, the major side effect of gonadotropin treatment is OHSS. This potentially life-threatening event is believed to result from increased ovarian secretion of substances that increase vascular permeability and is characterized by rapid accumulation of fluid in the peritoneal cavity, thorax, and even the pericardium. Symptoms and signs include abdominal pain or distention, nausea and vomiting, diarrhea, dyspnea, oliguria, and marked ovarian enlargement on ultrasonography. OHSS can lead to hypovolemia, electrolyte abnormalities, acute respiratory distress syndrome, thromboembolic events, and hepatic dysfunction.

In an effort to minimize OHSS in at-risk patients, the FSH can be withheld for a day or two (“coasting”). The rationale for this approach is that larger follicles become relatively gonadotropin independent and thus will continue to mature, while the smaller follicles undergo atresia in response to gonadotropin deprivation. Alternatively, an endogenous LH surge can be induced with a GnRH agonist during a GnRH antagonist short protocol, which nearly eliminates the incidence of OHSS by avoiding the use of HCG to trigger oocyte maturation.

The potential deleterious effects of gonadotropins are debated. Some studies have suggested that gonadotropins are associated with an increased risk of ovarian cancer, but this conclusion is controversial (Brinton et al., 2005).

Insulin Sensitizers

Polycystic ovary syndrome affects 4%–7% of women of reproductive age and is the most frequent cause of anovulatory infertility. Inasmuch as patients with PCOS often exhibit hyperinsulinemia and insulin resistance, insulin sensitizers such as metformin have been evaluated for their effects on ovulation and fertility (see Chapter 47). Although several small trials suggested that metformin increased ovulation relative to placebo in patients with PCOS, a trial failed to demonstrate a significant effect of metformin on fertility (Legro et al., 2007); metformin was less effective than clomiphene in inducing ovulation, promoting conception, or improving live birth rates, and there was no benefit of combining metformin with clomiphene on live births, except possibly in women resistant to clomiphene. Thus, except in women who exhibit glucose intolerance, the consensus is that metformin generally should not be used for fertility induction in women with PCOS (Thessaloniki ESHRE/ASRM-Sponsored PCOS Consensus Workshop Group, 2008).

Thiazolidinediones also have been evaluated for their ability to induce ovulation in patients with PCOS but are not used for this indication given an increased risk of congestive heart failure and myocardial ischemia.

Drug Therapy in Obstetrics

Pregnancy-Induced Hypertension/Preeclampsia

Hypertension affects up to 10% of pregnant women in the U.S.

Hypertension that precedes pregnancy or manifests before 20 weeks of gestation is believed to overlap considerably in pathogenesis with essential hypertension. These patients appear to be at increased risk for gestational diabetes and need careful monitoring. In contrast, pregnancy-induced hypertension, or preeclampsia, generally presents after 20 weeks of gestation as a new-onset hypertension with proteinuria (> 300 mg of urinary protein/24 h); preeclampsia is thought to involve placenta-derived factors that affect vascular integrity and endothelial function in the mother, thus causing peripheral edema, renal and hepatic dysfunction, and in severe cases, seizures. Chronic hypertension is an established risk factor for preeclampsia. The consensus panel recommended initiation of drug therapy in women with a diastolic blood pressure > 105 mm Hg or a systolic blood pressure > 160 mm Hg. If severe preeclampsia ensues, with marked hypertension and evidence of end-organ damage, then termination of the pregnancy by delivery of the baby is the treatment of choice, provided that the fetus is sufficiently mature to survive outside the uterus. If the baby is very preterm, then hospitalization and pharmacotherapy may be employed in an effort to permit further fetal maturation in utero.

Several drugs commonly used for hypertension in non-pregnant patients (e.g., angiotensin-converting enzyme inhibitors, angiotensin-receptor antagonists) should not be used in pregnant women due to unequivocal evidence of adverse fetal effects. Many experts will convert the patient to the centrally acting α adrenergic agonist α -methyldopa (250 mg twice daily) (FDA Category B), which rarely is used for hypertension in non-pregnant patients. Other drugs with reasonable evidence of safety (Category C) also may be used, including the combination α_1 -selective, β -nonselective adrenergic antagonist labetalol (100 mg twice daily) and the Ca^{2+} channel blocker nifedipine (30 mg once daily).

If severe preeclampsia or impending labor requires hospitalization, blood pressure can be controlled acutely with hydralazine (5 or 10 mg IV or IM, with repeated dosing at 20-min intervals depending on blood pressure response) or labetalol (20 mg IV, with dose escalation to 40 mg at 10 min if blood pressure control is inadequate). In addition to receiving drugs for blood pressure control, women with severe preeclampsia or who have CNS manifestations (e.g., headache, visual disturbance, or altered mental status) are treated as inpatients with magnesium sulfate, based on its documented efficacy in seizure prevention and lack of adverse effects on the mother or baby. Such treatment also should be considered for postpartum women with CNS manifestations: ~20% of episodes of eclampsia occur in women more than 48 h post-delivery.

Prevention or Arrest of Preterm Labor

Scope of the Problem and Etiology

Preterm birth, defined as delivery before 37 weeks of gestation, occurs in more than 10% of pregnancies in the U.S. and is increasing in frequency; it is associated with significant complications, such as neonatal respiratory distress syndrome, pulmonary hypertension, and intracranial hemorrhage.

Although incompletely understood, risk factors for preterm labor include multifetal gestation, premature rupture of the membranes, intrauterine infection, and placental insufficiency. The more premature the baby, the greater the risk of complications, prompting efforts to prevent or interrupt preterm labor.

The therapeutic objective in preterm labor is to delay delivery so that the mother can be transported to a regional facility specializing in the care of premature babies and supportive agents can be administered; such supportive treatments include glucocorticoids to stimulate fetal lung maturation (see Chapter 46) and antibiotics (e.g., erythromycin, ampicillin) to diminish the frequency of neonatal infection with group B β -hemolytic *Streptococcus*. Based on concerns over deleterious effects of antibiotic therapy, it is essential that antibiotics not be administered indiscriminately to all women thought to have preterm labor, but rather be reserved for those with premature rupture of the membranes and evidence of infection.

Prevention of Preterm Labor: Progesterone Therapy

Progesterone levels in some species diminish considerably in association with labor, whereas administration of progesterone inhibits the secretion

of pro-inflammatory cytokines and delays cervical ripening. Thus, progesterone and its derivatives have long been advocated to diminish the onset of preterm labor in women at increased risk due to previous preterm delivery. Despite considerable controversy, recent randomized trials have revived interest in this approach. Hydroxyprogesterone caproate at a dose of 250 mg administered weekly by intramuscular injection has been shown to reduce preterm birth by about one-third in women with a prior preterm birth of a singleton. Vaginal administration of progesterone (200 mg each night) has been shown to reduce preterm birth in women with midtrimester cervical shortening by ultrasound examination. The role of progesterone for prevention of preterm birth in multiple gestations is controversial.

Tocolytic Therapy for Established Preterm Labor

Inhibition of uterine contractions of preterm labor, or *tocolysis*, has been a focus of therapy (Simhan and Caritis, 2007). Although tocolytic agents delay delivery in about 80% of women, they neither prevent premature births nor improve adverse fetal outcomes such as respiratory distress syndrome.

Specific tocolytic agents include β adrenergic receptor agonists, MgSO_4 , Ca^{2+} channel blockers, COX inhibitors, oxytocin receptor antagonists, and NO donors. The mechanisms of action of these agents are illustrated in Figure 44–7.

The β adrenergic receptor agonists relax the myometrium by activating the cyclic AMP-PKA signaling cascade that phosphorylates and inactivates MLCK, a key enzyme in uterine contraction. *Ritodrine*, a selective β_2 agonist, was specifically developed as a uterine relaxant and remains the only tocolytic drug to have gained FDA approval; it was voluntarily withdrawn from the U.S. market. *Terbutaline*, which is FDA-approved for asthma, has been used off label for this purpose and can be administered orally, subcutaneously, or intravenously. Terbutaline may delay births, but only during the first 48 h of treatment, and is associated with a number

of adverse maternal effects, including tachycardia, hypotension, and pulmonary edema.

Similarly, Ca^{2+} channel blockers inhibit the influx of Ca^{2+} through depolarization-activated, voltage-sensitive Ca^{2+} channels in the plasma membrane, thereby preventing the activation of MLCK and the stimulation of uterine contraction. *Nifedipine*, the Ca^{2+} channel blocker used most commonly for this purpose, can be administered parenterally or orally. Relative to β_2 adrenergic agonists, nifedipine is more likely to improve fetal outcomes and less likely to cause maternal side effects.

Based on the role of PGs in uterine contraction, COX inhibitors (e.g., indomethacin) have been used to inhibit preterm labor, and some data suggest that they may reduce the number of preterm births. Because they also can inhibit platelet function and induce closure in utero of the ductus arteriosus, these inhibitors should not be employed in term pregnancies (or in pregnancies beyond 32 weeks of gestation, when the risk of severe complications of prematurity is relatively lower). Short courses of treatment (<72 h) pose less risk for impaired circulation in the fetus.

Despite numerous clinical trials, the superiority of any one therapy has not been established, and none of the drugs has been shown definitively to improve fetal outcome.

Initiation of Labor

Labor induction is indicated when the perceived risk of continued pregnancy to the mother or fetus exceeds the risks of delivery or pharmacological induction.

Prostaglandins and Cervical Ripening

Prostaglandins play key roles in parturition (see Chapter 37). Thus, PGE_1 , PGE_2 , and $\text{PGF}_{2\alpha}$ are used to facilitate labor by promoting ripening and dilation of the cervix. They can be administered either orally or via local administration (either vaginally or intracervically). The ability of certain

Figure 44–7 Sites of action of tocolytic drugs in the uterine myometrium. The elevation of cellular Ca^{2+} promotes contraction via the Ca^{2+} /calmodulin-dependent activation of MLCK. Relaxation is promoted by the elevation of cyclic nucleotides (cAMP and cGMP) and their activation of protein kinases, which cause phosphorylation/inactivation of MLCK. Pharmacological manipulations to reduce myometrial contraction include the following: (1) inhibiting Ca^{2+} entry (Ca^{2+} channel blockers, MgSO_4); (2) reducing mobilization of intracellular Ca^{2+} by antagonizing GPCR-mediated activation of the G_q -PLC- IP_3 - Ca^{2+} pathway (with antagonists of the FP and OXT receptors) or reducing production of the FP agonist, $\text{PGF}_{2\alpha}$ (with COX inhibitors); (3) enhancing relaxation by elevating cellular cAMP (with β_2 adrenergic agonists that activate G_s -AC) and cellular cGMP (with NO donors that stimulate sGC). Note that pharmacological activators of sGC (e.g., riociguat) are contraindicated in pregnancy (see Chapter 31). AC, adenylyl cyclase; COX, cyclooxygenase; FP, the PGF_2 receptor; OXT, the oxytocin receptor; PLC, phospholipase C; sGC, soluble guanylyl cyclase.

PGs to stimulate uterine contractions also makes them valuable agents in the therapy of postpartum hemorrhage.

Available preparations include dinoprostone (PGE_2), which is FDA approved to facilitate cervical ripening. Dinoprostone is formulated as a gel for intracervical administration via syringe in a dose of 0.5 mg or as a vaginal insert (pessary) in a dose of 10 mg; the latter is designed to release active PGE_2 at a rate of 0.3 mg/h for up to 12 h and should be removed at the onset of labor or 12 h after insertion. No more than three doses should be used in a 24-h period. Dinoprostone should not be used in women with a history of asthma, glaucoma, or myocardial infarction. The major adverse effect is uterine hyperstimulation, which may be reversed more rapidly using the vaginal insert by removing it with the attached tape.

Misoprostol, a synthetic derivative of PGE_1 (see Chapter 38) is used off label either orally or vaginally to induce cervical ripening; typical doses are 100 μg (orally) or 25 μg (vaginally). An advantage of misoprostol in this setting is its considerably lower cost. Adverse effects include uterine hyperstimulation and, rarely, uterine rupture. Misoprostol should be discontinued for at least 3 h before initiating oxytocin therapy.

Oxytocin

The structure and physiology of oxytocin are discussed in Chapter 42. This section presents therapeutic uses of oxytocin in obstetrics, which include the induction of labor, the augmentation of labor that is not progressing, and the prophylaxis or treatment of postpartum hemorrhage. Although widely used, oxytocin recently was added to a list of drugs “bearing a heightened risk of harm” (Clark et al., 2009), and its role and specific application to most deliveries in the U.S. remain open to debate. Thus, careful review of the appropriate indications for oxytocin administration and attention to the dose and progress of labor during induction are essential.

Labor Induction. Oxytocin is the drug of choice for labor induction; for this purpose, it is administered by intravenous infusion of a diluted solution, preferably via an infusion pump. Current protocols start with an oxytocin dose of 6 mIU/min, followed by advancement of dose as needed, up to 40 mIU/min. Uterine hyperstimulation should be avoided; however, if it occurs, as evidenced by too-frequent contractions (more than five contractions in a 10-min interval) or the development of uterine tetany, the oxytocin infusion should be discontinued immediately. Because the $t_{1/2}$ of intravenous oxytocin is relatively short (12–15 min), the hyperstimulatory effects of oxytocin will dissipate fairly rapidly after the infusion is discontinued. Thereafter, the infusion can be reinitiated at a dose of half that at which hyperstimulation occurred and increased cautiously as tolerated.

Because of its structural similarity to vasopressin, oxytocin at higher doses activates the vasopressin V_2 receptor and has antidiuretic effects. Particularly if hypotonic fluids (e.g., dextrose in water) are infused too liberally, water intoxication may result in convulsions, coma, and even death. Vasodilating actions of oxytocin also have been noted, particularly at high doses, which may provoke hypotension and reflex tachycardia. Deep anesthesia may exaggerate the hypotensive effect of oxytocin by preventing the reflex tachycardia.

Augmentation of Dysfunctional Labor. Oxytocin also is used when spontaneous labor is not progressing at an acceptable rate. To augment hypotonic contractions in dysfunctional labor, an infusion rate of 10 mIU/min typically is sufficient; doses in excess of 40 mIU/min rarely are effective when lower concentrations fail. As with labor induction, potential complications of uterine overstimulation include trauma of the mother or fetus due to forced passage through an incompletely dilated cervix, uterine rupture, and compromised fetal oxygenation due to decreased uterine perfusion.

Menopause and Hormone Therapy

Menopause refers to the permanent cessation of menstrual periods (i.e., for > 12 months) resulting from the loss of ovarian follicular activity; it usually occurs when women are between 45 and 60 years of age. The decline in estradiol levels produces a variety of symptoms and signs, including vasomotor disturbances (hot flashes or flushes), sweating,

irritability, sleep disturbances, and atrophy of estrogen-dependent tissue. In addition, postmenopausal women are at increased risk for osteoporosis, bone fractures, and CHD and experience increased memory loss and other cognitive difficulties.

Estrogens

Estrogens are most commonly used to treat vasomotor disturbances (“hot flashes”) in postmenopausal women. Other important benefits are amelioration of the effects of urogenital atrophy, a decreased incidence of colon cancer, and prevention of bone loss. A variety of preparations, including oral, transdermal, and vaginal, are available. *Regardless of the specific drug(s) selected, treatment should use the minimum dose and duration for the desired therapeutic end point.*

In postmenopausal women with an *intact uterus*, a progestin is included to prevent endometrial cancer. MPA is used in the U.S., but micronized progesterone is preferred; *norethindrone* and *norgestrel/levonorgestrel* are also commonly used. Women *without a uterus* are administered estrogen alone. Postmenopausal hormone therapy and contraception are the most frequent uses of progestins.

The two major uses of estrogens are for MHT and as components of combination oral contraceptives, and the pharmacological considerations for their use and the specific drugs and doses used differ in these settings. Historically, conjugated equine estrogens have been the most common agents for postmenopausal use (0.625 mg/d). In contrast, most combination oral contraceptives in current use employ 20–35 μg /d of ethinyl estradiol. These preparations differ widely in their oral potencies (e.g., a dose of 0.625 mg of conjugated estrogens generally is considered equivalent to 5–10 μg of ethinyl estradiol). Thus, the “effective” dose of estrogen used for MHT is less than that in oral contraceptives when one considers potency. Furthermore, in the last two decades, the doses of estrogens employed in both settings have decreased substantially. The untoward effects of the 20- to 35- μg doses now commonly used thus have a lower incidence and severity than those reported in older studies (e.g., with oral contraceptives that contained 50–150 μg of ethinyl estradiol or mestranol).

Menopausal Hormone Therapy

The established benefits of estrogen therapy in postmenopausal women include amelioration of vasomotor symptoms and the prevention of bone fractures and urogenital atrophy.

Vasomotor Symptoms

The decline in ovarian function at menopause is associated with vasomotor symptoms in most women. The characteristic hot flashes may alternate with chilly sensations, inappropriate sweating, and (less commonly) paresthesias. Treatment with estrogen is specific and is the most efficacious pharmacotherapy for these symptoms (Belchetz, 1994). If estrogen is contraindicated or otherwise undesirable, other options may be considered. MPA may provide some relief of vasomotor symptoms for certain patients, and the α_2 adrenergic agonist clonidine diminishes vasomotor symptoms in some women, presumably by blocking the CNS outflow that regulates blood flow to cutaneous vessels. In many women, hot flashes diminish within several years; when prescribed for this purpose, the dose and duration of estrogen use should thus be the minimum necessary to provide relief.

Osteoporosis

Osteoporosis is a disorder of the skeleton associated with the loss of bone mass (Chapter 48). The result is thinning and weakening of the bones and an increased incidence of fractures, particularly compression fractures of the vertebrae and minimal-trauma fractures of the hip and wrist. The frequency and severity of these fractures and their associated complications (e.g., death and permanent disability) are a major public health problem, especially as the population continues to age. Osteoporosis is an indication for estrogen therapy, which clearly is efficacious in decreasing the incidence of fractures. However, because of the risks associated with estrogen use, first-line use of other drugs, such as bisphosphonates, should be considered (Chapter 48). Most fractures in the postmenopausal period

occur in women without a prior history of osteoporosis, and estrogens are the most efficacious agents available for prevention of fractures at all sites in such women (Anderson et al., 2004; Rossouw et al., 2002).

Estrogens act primarily to decrease bone resorption; consequently, estrogens are more effective at preventing rather than restoring bone loss (Belchetz, 1994; Prince et al., 1991). Estrogens are most effective if treatment is initiated before significant bone loss occurs, and their maximal beneficial effects require continuous use; bone loss resumes when treatment is discontinued. An appropriate diet with adequate intake of Ca^{2+} and vitamin D and weight-bearing exercise enhance the effects of estrogen treatment.

Vaginal Dryness and Urogenital Atrophy

Loss of tissue lining the vagina or bladder leads to a variety of symptoms in many postmenopausal women (Robinson and Cardozo, 2003). These include dryness and itching of the vagina, dyspareunia, swelling of tissues in the genital region, pain during urination, a need to urinate urgently or often, and sudden or unexpected urinary incontinence. When estrogens are being used solely for relief of vulvar and vaginal atrophy, local administration as a vaginal cream, ring device, or tablets may be considered.

Cardiovascular Disease

The incidence of cardiovascular disease is low in premenopausal women, rising rapidly after menopause, and epidemiological studies consistently showed an association between estrogen use and reduced cardiovascular disease in postmenopausal women. Estrogens produce a favorable lipoprotein profile, promote vasodilation, inhibit the response to vascular injury, and reduce atherosclerosis. However, estrogens promote coagulation and thromboembolic events. Randomized prospective studies unexpectedly have indicated that the incidence of heart disease and stroke in older postmenopausal women treated with conjugated estrogens and a progestin was initially increased, although the trend reversed with time (Grady et al., 2002; Rossouw et al., 2002). Combined estrogen-progestin therapy is associated with a decrease in heart attacks in younger women.

Other Therapeutic Effects

Many other changes occur in postmenopausal women, including a general thinning of the skin; changes in the urethra, vulva, and external genitalia; and a variety of changes, including headache, fatigue, and difficulty concentrating. Chronic lack of sleep created by hot flashes and other vasomotor symptoms may be contributing factors. Estrogen replacement may help alleviate or lessen some of these via direct actions (e.g., improvement of vasomotor symptoms) or secondary effects resulting in an improved feeling of well-being (Belchetz, 1994). The WHI demonstrated that a conjugated estrogen in combination with a progestin reduces the risk of colon cancer by roughly one-half in postmenopausal women (Rossouw et al., 2002).

Menopausal Hormone Regimens

In the 1960s and 1970s, there was an increase in *estrogen-replacement therapy*, or ERT (i.e., estrogens alone) in postmenopausal women, primarily to reduce vasomotor symptoms, vaginitis, and osteoporosis. About 1980, epidemiological studies indicated that this treatment increased the incidence of endometrial carcinoma. This led to the use of *hormone-replacement therapy* (HRT), which includes a progestin to limit estrogen-related endometrial hyperplasia. Postmenopausal HRT, when indicated, should include both an estrogen and progestin for women with a uterus (Belchetz, 1994). For women who have undergone a hysterectomy, endometrial carcinoma is not a concern, and estrogen alone avoids the possible deleterious effects of progestins.

Conjugated estrogens and MPA historically have been used most commonly in menopausal hormone regimens, although estradiol, estrone, and estriol have been used as estrogens, and norethindrone, norgestimate, levonorgestrel, norethisterone, and progesterone also have been widely used (especially in Europe). Various “continuous” or “cyclic” regimens have been used; the latter regimens include drug-free days. An example of a cyclic regimen is as follows: (1) administration of an estrogen for 25 days; (2) the addition of MPA for the last 12–14 days of estrogen treatment; and (3) 5–6 days with no hormone treatment, during which

withdrawal bleeding normally occurs due to breakdown and shedding of the endometrium. Continuous administration of combined estrogen plus progestin does not lead to regular, recurrent endometrial shedding but may cause intermittent spotting or bleeding, especially in the first year of use. Other regimens include a progestin intermittently (e.g., every third month), but the long-term endometrial safety of these regimens remains to be firmly established. Conjugated estrogens plus MPA given as a fixed dose daily and conjugated estrogens given for 28 days plus MPA given for 14 of 28 days are widely used combination formulations. Other combination products available in the U.S. are ethinyl estradiol plus norethindrone acetate, estradiol plus norethindrone, estradiol and norgestimate, and estradiol and drospirenone. Doses and regimens are usually adjusted empirically based on control of symptoms, patient acceptance of bleeding patterns, or other untoward effects.

Another pharmacological consideration is the route of estrogen administration. Oral administration exposes the liver to higher concentrations of estrogens than does transdermal administration and may increase SHBG, other binding globulins, and angiotensinogen and possibly the cholesterol content of the bile. Transdermal estrogen appears to cause smaller beneficial changes in LDL and HDL profiles (~50% of those seen with the oral route) (Walsh et al., 1994).

Tibolone is widely used in the E.U. for treatment of vasomotor symptoms and prevention of osteoporosis but is not currently approved in the U.S. The parent compound itself is devoid of activity, but it is metabolized in a tissue-selective manner to three metabolites that have predominantly estrogenic, progestogenic, and androgenic activities. The effects of this drug on fractures, breast cancer, and long-term outcomes remain to be established (Modelska and Cummings, 2002).

Regardless of the specific agent or regimen, MHT with estrogens should use the lowest dose and shortest duration necessary to achieve an appropriate therapeutic goal.

Untoward Responses

The use of unopposed estrogen for hormone treatment in postmenopausal women increases the risk of endometrial carcinoma by 5- to 15-fold (Shapiro et al., 1985). This increased risk can be prevented if a progestin is coadministered with the estrogen (Pike et al., 1997), and this is now standard practice.

The association between estrogen or estrogen-progestin use and breast cancer is of great concern. The results of two large randomized clinical trials of estrogen/progestin and estrogen only (i.e., the two arms of WHI) in postmenopausal women clearly established a small but significant increase in the risk of breast cancer in the CEE+MPA studies (CEE, conjugated equine estrogens) (Anderson et al., 2004; Rossouw et al., 2002). In the WHI study, CEE+MPA was associated with an increased relative risk of breast cancer by 25%; the absolute increase in attributable cases of disease was 6 per 1000 women and required 3 or more years of treatment. In women without a uterus who received CEE alone, the relative risk of breast cancer was actually decreased by 23%, and the decrease only narrowly missed reaching statistical significance. Interestingly, the incidence of colon cancer was reduced by 26% in the WHI trial.

The Million Women Study (MWS) in the U.K. was a cohort study rather than a clinical trial (Beral et al., 2003). It surveyed more than 1 million women; about half had received some type of hormone treatment, and half had never used this type of treatment. Those receiving an estrogen-progestin combination had an increased relative risk of invasive breast cancer of 2, and those receiving estrogen alone had an increased relative risk of 1.3, but the increase in actual attributable cases of the disease was again small.

Both the WHI and MWS data are thus consistent with earlier studies indicating that the progestin component (e.g., medroxyprogesterone) in combined HRT plays a major role in this increased risk of breast cancer (Ross et al., 2000; Schairer et al., 2000). Importantly, although long-term data have not accumulated for the WHI trials, the available data suggest that the excess risk of breast cancer associated with menopausal hormone use appears to abate 5 years after discontinuing therapy. Thus, HRT for 5 years or less is often prescribed to mitigate hot flashes and likely has a minimal effect on the risk of breast cancer.

Historically, the carcinogenic actions of estrogens were thought to be related to their trophic effects. However, if catechol estrogens, especially the 4-hydroxycatechols, are converted to semiquinones or quinones prior to “inactivation” by COMT, the generation of ROSs may cause direct chemical damage to DNA bases (Yue et al., 2003). In this regard, CYP1B1, which has specific estrogen-4-hydroxylase activity, is present in tissues such as uterus, breast, ovary, and prostate, which often give rise to hormone-responsive cancers.

Metabolic and Cardiovascular Effects

Although they may slightly elevate plasma triglycerides, estrogens themselves generally have favorable overall effects on plasma lipoprotein profiles. However, addition of progestins may reduce the favorable actions of estrogens. Estrogens do increase cholesterol levels in bile and cause a relative 2- to 3-fold increase in gallbladder disease. Currently prescribed doses of estrogens generally do not increase the risk of hypertension, and estrogen engaging the ER β receptor typically reduces blood pressure.

Many studies and clinical trials suggested that estrogen therapy in postmenopausal women would reduce the risk of cardiovascular disease by 35%–50% (Manson and Martin, 2001). However, two recent randomized clinical trials have not found such protection. The HERS study followed women with established CHD and found that estrogen plus a progestin increased the relative risk of nonfatal myocardial infarction or CHD death within 1 year of treatment, but there was no overall change in 5 years (Hulley et al., 1998). The HERS II follow-up found no overall change in the incidence of CHD after 6.8 years of the treatment (Grady et al., 2002). In women *without* existing CHD (WHI trials), treated with an estrogen plus progestin, protective effects were seen but only when hormone replacement was initiated within 10 years of menopause (Rossouw et al., 2002).

It is clear, however, that oral estrogens increase the risk of thromboembolic disease in healthy women and in women with preexisting cardiovascular disease (Grady et al., 2000). The increase in absolute risk is small but significant. In the WHI, for example, an estrogen-progestin combination led to an increase in eight attributable cases of stroke per 10,000 older women and a similar increase in pulmonary embolism (Rossouw et al., 2002). The latter was seen mainly in women who concomitantly smoked cigarettes.

Effects on Cognition

Several retrospective studies had suggested that estrogens had beneficial effects on cognition and delayed the onset of Alzheimer disease (Green and Simpkins, 2000). However, the Women's Health Initiative Memory Study (WHIMS) of a group of women 65 years of age or older found that estrogen-progestin therapy was associated with doubling in the number of women diagnosed with probable dementia, and no benefit of hormone treatment on global cognitive function was observed (Rapp et al., 2003; Shumaker et al., 2003).

Other Potential Untoward Effects

Nausea and vomiting are an initial reaction to estrogen therapy in some women, but these effects may disappear with time and may be minimized by taking estrogens with food or just before sleep. Fullness and tenderness of the breasts and edema may occur, but sometimes can be diminished by lowering the dose.

Drug Therapy in Endometriosis, Hirsutism, and Gender Transition

Endometriosis

Endometriosis is an estrogen-dependent disorder that results from endometrial tissue ectopically located outside the uterine cavity (Farquhar, 2007). It predominantly affects women during their reproductive years, with a prevalence of 0.5%–5% in fertile women and 25%–40% in infertile women. Diagnosis typically is made at laparoscopy, either prompted by unexplained pelvic pain (dysmenorrhea or dyspareunia) or infertility. Although poorly understood, the infertility is thought to reflect

involvement of the fallopian tubes with the underlying process and, possibly, impaired oocyte maturation.

Because the proliferation of ectopic endometrial tissue is responsive to ovarian steroid hormones, many symptomatic approaches to therapy aim to produce a relatively hypoestrogenic state. Combination oral contraceptives have been standard first-line treatment of symptoms of endometriosis, and ample evidence from observational trials supports their benefit. The predominant mechanism of action is believed to be suppression of gonadotropin secretion, with subsequent inhibition of estrogen biosynthesis. Progestins (e.g., medroxyprogesterone, dienogest) also have been used to promote decidualization of the ectopic endometrial tissue. The levonorgestrel IUS, which is approved for contraception, also has been used off label for this indication, as well as for menorrhagia.

Stable GnRH agonists can suppress gonadotropin secretion and thus effect medical castration. Drugs that carry an indication for endometriosis include leuprolide, goserelin, and nafarelin; other GnRH agonists also may be used off label for this purpose (see Chapter 42). Due to significant decreases in bone density and symptoms of estrogen withdrawal, “add-back” therapy with either a low-dose synthetic estrogen (e.g., conjugated equine estrogens, 0.625–1.25 mg) or a high-dose progestin (e.g., norethindrone, 5 mg) has been used when the duration of therapy has exceeded 6 months (Olive, 2008). Danazol, a synthetic androgen that inhibits gonadotropin production via feedback inhibition of the pituitary-ovarian axis, also is FDA approved for endometriosis therapy; it rarely is used now because of its significant adverse effects, including hirsutism and elevation of hepatic transaminases. In Europe and elsewhere, the antiprogestin gestrinone has been employed. By virtue of their ability to block the terminal step in estrogen biosynthesis, inhibitors of aromatase are under investigation for endometriosis (reviewed by Barbieri, 2008).

Hirsutism

Hirsutism, or increased hair growth in the male distribution, affects about 10% of women of reproductive age. It can be a relatively benign, idiopathic process or part of a more severe disorder of androgen excess that includes overt virilization (voice deepening, increased muscle mass, male pattern balding, clitoromegaly) and often results from ovarian or adrenal tumors. Specific etiologies associated with hirsutism include congenital adrenal hyperplasia, PCOS, and Cushing syndrome. After excluding serious pathology such as a steroid-producing malignancy, the treatment largely becomes empirical (Martin et al., 2008).

Pharmacotherapy is directed at decreasing androgen production and action. Initial therapy often involves treatment with combination oral contraceptive pills, which suppress gonadotropin secretion and thus the production of ovarian androgens. The estrogen also increases the concentration of SHBG, thereby diminishing the free concentration of testosterone. The full effect of this suppression may take up to 6–9 months. GnRH agonists downregulate gonadotropin secretion and also may be used to suppress ovarian steroid production.

In patients who fail to respond to ovarian suppression, efforts to block androgen action may be effective. Spironolactone, a mineralocorticoid receptor antagonist, and flutamide (see Chapter 45) inhibit the androgen receptor. In Europe and elsewhere, cyproterone (50–100 mg/d) is used as an androgen receptor blocker, often in conjunction with a combination oral contraceptive. Finasteride, an inhibitor of the type 2 isozyme of 5 α -reductase that blocks the conversion of testosterone to dihydrotestosterone also is effective. Male offspring of women who become pregnant while taking any of these androgen inhibitors are at risk of impaired virilization secondary to impaired synthesis or action of dihydrotestosterone (pregnancy risk FDA category X; see Appendix I). The antifungal ketoconazole, which inhibits CYP steroid hydroxylases (see Chapters 46 and 61), also can block androgen biosynthesis but may cause liver toxicity. Topical eflornithine, an ornithine decarboxylase inhibitor, has been used with some success to decrease the rate of facial hair growth.

Nonpharmacological approaches include bleaching, depilatory treatments (e.g., shaving, treatment with hair-removing chemicals), or methods that remove the entire hair follicle (e.g., plucking, electrolysis, laser ablation).

In the past 10–20 years, sex steroids have been used more frequently in transgender patients. Because no significant clinical trials have been performed, a great deal of variability exists in the approaches taken in both male-to-female and female-to-male transgender patients. In general, younger patients in their early teens are often held from natural puberty through the use of GnRH agonists until the individuals are old and mature enough to be certain of their decision. Once the decision is made, whether the patients are younger or older, the approaches can be myriad, although they follow the same principals: (1) suppress endogenous sex steroid production and (2) promote physical and mental features of the desired gender.

Male-to-Female Transitions

The primary medication used for male-to-female transition is some form of estrogen, whether it be oral estradiol (2–6 mg per day), transdermal estradiol (0.1–0.4 mg every 24 h), or injectable estrogens such as estradiol valerate or estradiol cypionate (5–10 mg IM every 2 weeks). Side effects with estrogens, including thrombosis and breast cancer (not really established in male-to-female transgender patients) must be discussed with patients. Target serum estradiol levels are usually in the range of 100–200 pg/mL. In many patients, estrogen treatment alone will

be sufficient to suppress endogenous androgen production and therefore androgen-mediated effects; however, in patients where this is not possible, antiandrogens such as spironolactone (100–400 mg per day) can be used. Alternatively, endogenous androgen production can be suppressed with GnRH agonists. The advantage of using antiandrogens or GnRH agonists is that the dosages of estradiol can often be significantly lower.

Female-to-Male Transitions

The primary medication used in female-to-male transitions is some form of androgen, whether it be injectable, such as testosterone enanthate or cypionate (50–100 mg IM per week), or androgen gels (25–100 mg per day of testosterone). Target plasma androgen levels should be in the normal male range (300–500 mg per day). Side effects of excess androgens, including polycythemia and lipid abnormalities, should be discussed and monitored with all patients. In general, these doses of androgens are sufficient to suppress endogenous ovarian steroid hormone production; however, if breakthrough uterine bleeding still occurs, patients can be treated with depot medroxyprogesterone (150 mg every 3 months) until bleeding no longer occurs.

Androgens and the Male Reproductive Tract

Peter J. Snyder

TESTOSTERONE AND OTHER ANDROGENS

SECRETION AND TRANSPORT OF TESTOSTERONE

METABOLISM OF TESTOSTERONE TO ACTIVE AND INACTIVE COMPOUNDS

PHYSIOLOGICAL AND PHARMACOLOGICAL EFFECTS OF ANDROGENS

- Effects That Occur Via the Androgen Receptor
- Effects That Occur Via the Estrogen Receptor
- Effects of Androgens at Different Stages of Life

CONSEQUENCES OF ANDROGEN DEFICIENCY

- During Fetal Development
- Before Completion of Puberty
- After Completion of Puberty
- In Women

THERAPEUTIC ANDROGEN PREPARATIONS

- Testosterone Esters
- Alkylated Androgens

- Transdermal Delivery Systems
- Selective Androgen Receptor Modulators

THERAPEUTIC USES OF ANDROGENS

- Male Hypogonadism
- Male Senescence
- Female Hypogonadism
- Enhancement of Athletic Performance
- Catabolic and Wasting States
- Angioedema
- Blood Dyscrasias

ANTIANDROGENS

- Inhibitors of Testosterone Secretion
- Inhibitors of Androgen Action

PHARMACOLOGIC TREATMENT OF ERECTILE DYSFUNCTION

- Erectile Signaling and Erectile Dysfunction
- PDE5 Inhibitors
- Developing Therapies for Erectile Dysfunction

Testosterone and Other Androgens

In men, *testosterone* is the principal secreted androgen. *Leydig cells* synthesize the majority of testosterone by the pathways shown in Figure 45–1. In women, testosterone also is the principal androgen and is synthesized in the corpus luteum and the adrenal cortex by similar pathways. The testosterone precursors *androstenedione* and *DHEA* are weak androgens that can be converted peripherally to testosterone.

Secretion and Transport of Testosterone

Testosterone secretion is greater in men than in women at almost all stages of life, a difference that explains many of the other differences between men and women. In the first trimester in utero, the fetal testes begin to secrete testosterone, the principal factor in male sexual differentiation, probably stimulated by hCG from the placenta. By the beginning of the second trimester, the serum testosterone concentration is close to that of midpuberty, about 250 ng/dL (Figure 45–2). Testosterone production then falls by the end of the second trimester, but by birth the value is again about 250 ng/dL, possibly due to stimulation of the fetal Leydig cells by *LH* from the fetal pituitary gland. The testosterone value falls again in the first few days after birth, but it rises and peaks again at about 250 ng/dL at 2–3 months after birth and falls to less than 50 ng/dL by 6 months, where it remains until puberty. During puberty, from about 12 to 17 years of age, the serum testosterone concentration in males increases so that by early adulthood the serum testosterone concentration is 300 ng/dL to 800 ng/dL in men, compared to 30 ng/dL to 50 ng/dL in women. The magnitude of the testosterone concentration in the male is responsible for the pubertal

changes that further differentiate men from women. As men age, their serum testosterone concentrations gradually decrease, which may contribute to other effects of aging in men.

Luteinizing hormone, secreted by the pituitary gonadotropes (see Chapter 42), is the principal stimulus of testosterone secretion in men, perhaps potentiated by *FSH*, also secreted by gonadotropes. The secretion of *LH* by gonadotropes is positively regulated by hypothalamic *GnRH*; testosterone directly inhibits *LH* secretion in a negative-feedback loop. *LH* is secreted in pulses, which occur approximately every 2 h and are greater in magnitude in the morning (Crowley et al., 1985). The pulsatility appears to result from pulsatile secretion of *GnRH* from the hypothalamus. Testosterone secretion is likewise pulsatile and diurnal, the highest plasma concentrations occurring at about 8 AM and the lowest at about 8 PM. The morning peaks diminish as men age. SHBG binds about 40% of circulating testosterone with high affinity, rendering the bound hormone unavailable for biological effects. Albumin binds almost 60% of circulating testosterone with low affinity, leaving about 2% unbound or free. In women, *LH* stimulates the *corpus luteum* (formed from the follicle after release of the ovum) to secrete testosterone. Under normal circumstances, however, *estradiol* and *progesterone*, not testosterone, are the principal inhibitors of *LH* secretion in women.

Metabolism of Testosterone to Active and Inactive Compounds

Testosterone has many different effects in tissues, both directly and through its metabolism to *dihydrotestosterone* and *estradiol* (Figure 45–3). The enzyme 5 α -reductase catalyzes the conversion of

Abbreviations

AR: androgen receptor
AUC: area under the curve
cGMP: cyclic guanosine monophosphate
CYP: cytochrome P450
DHEA: dehydroepiandrosterone
eNOS: endothelial nitric oxide synthase, NOS3
FSH: follicle-stimulating hormone
GnRH: gonadotropin-releasing hormone
hCG: human chorionic gonadotropin
HDL: high-density lipoprotein
LDL: low-density lipoprotein
LH: luteinizing hormone
NANC: nonadrenergic/noncholinergic
NO: nitric oxide
PDE5: phosphodiesterase 5
PKG: protein kinase G
sGC: soluble guanylate cyclase
SHBG: sex hormone-binding globulin
THG: tetrahydrogestrinone

testosterone to dihydrotestosterone. Dihydrotestosterone binds to the AR with higher affinity than testosterone and activates gene expression more efficiently. Two forms of 5 α -reductase have been identified: *type I*, which is found predominantly in nongenital skin, liver, and bone; and *type II*, which is found predominantly in urogenital tissue in men and genital skin in men and women. The enzyme complex aromatase, present in many tissues, catalyzes the conversion of testosterone to estradiol. This conversion accounts for about 85% of circulating estradiol in men; the remainder is secreted directly by the testes (MacDonald et al., 1979). Hepatic metabolism converts testosterone to the biologically inactive compounds androsterone and etiocholanolone (see Figure 45-3). Dihydrotestosterone is metabolized to androsterone, androstenedione, and androstenediol.

Figure 45-2 Schematic representation of the serum testosterone concentration from early gestation to old age.

Physiological and Pharmacological Effects of Androgens

Testosterone is the principal circulating androgen in men. At least three mechanisms contribute to the varied effects of testosterone:

- direct binding to the AR;
- conversion in certain tissues to dihydrotestosterone, which also binds to the AR; and
- conversion to estradiol, which binds to the estrogen receptor (Figure 45-4).

Effects That Occur Via the Androgen Receptor

Testosterone and dihydrotestosterone act as androgens via a single AR, a member of the nuclear receptor superfamily designated as NR3A. The AR has an amino-terminal domain that contains a polyglutamine repeat of variable length, a DNA-binding domain consisting of two Zn finger motifs, and a carboxyterminal ligand-binding domain. The polyglutamine

Figure 45-1 Pathway of synthesis of testosterone in the Leydig cells of the testes. In Leydig cells, the 11 and 21 hydroxylases (present in adrenal cortex) are absent, but CYP17 (17 α -hydroxylase) is present. Thus, androgens and estrogens are synthesized; corticosterone and cortisol are not formed. Bold arrows indicate favored pathways.

Figure 45-3 Metabolism of testosterone to its major active and inactive metabolites.

repeat of variable length is unique to the AR; a shorter length appears to increase the receptor's activity.

In the absence of a ligand, the AR is located in the cytoplasm associated with a heat shock protein complex. When testosterone or dihydrotestosterone binds to the ligand-binding domain, the AR dissociates from the heat shock protein complex, dimerizes, and translocates to the nucleus. The dimer then binds via the DNA-binding domains to androgen response elements on certain responsive genes. The ligand-receptor complex recruits coactivators and acts as a transcription factor complex, stimulating or repressing expression of those genes (Agoulrik and Weigel, 2008).

Mutations in the hormone or DNA-binding regions of the AR result in resistance to the action of testosterone, beginning in utero (McPhaul and Griffin, 1999); as a consequence, male sexual differentiation and pubertal development are incomplete. Other AR mutations occur in patients with spinal and bulbar muscular atrophy, known as Kennedy disease. These patients have an expansion of the CAG repeat, which codes for glutamine,

at the amino terminus of the molecule (Walcott and Merry, 2002). The result is very mild androgen resistance, manifest principally by gynecomastia, and progressively severe motor neuron atrophy (Dejager et al., 2002). The mechanism by which the neuronal atrophy occurs is unknown. Other mutations in AR may explain why metastatic prostate cancer often regresses initially in response to androgen deprivation treatment, but then becomes unresponsive to continued deprivation. AR continues to be expressed in androgen-independent prostate cancer, and its signaling remains active. The ligand-independent signaling may result from mutations in the AR gene or changes in AR coregulatory proteins. In some patients resistant to standard androgen deprivation therapy, the tumor responds to further depletion of androgens by inhibitors of adrenal androgen synthesis, such as *abiraterone*.

Effects That Occur Via the Estrogen Receptor

Certain effects of testosterone are mediated by its conversion to estradiol, catalyzed by CYP19 (aromatase). In rare cases in males deficient in CYP19 or the estrogen receptor, the epiphyses do not fuse, and long-bone growth continues indefinitely; moreover, such patients are osteoporotic. Administration of estradiol corrects the bone abnormalities in patients with aromatase deficiency but not in those with an estrogen-receptor defect. Because men have larger bones than women, and bone expresses the AR (Colvard et al., 1989), testosterone also may have an effect on bone via the AR. Administration of estradiol to a male with CYP19 deficiency can increase libido, suggesting that the effect of testosterone on male libido may be mediated by conversion to estradiol (Smith et al., 1994).

Suppression of testosterone production with a GnRH analogue and then replacing testosterone with or without *anastrozole*, an inhibitor of CYP19, also illustrates effects of testosterone that require conversion to estradiol. This paradigm demonstrated that the increase in sexual desire and erectile function and decrease in subcutaneous and abdominal fat require conversion of testosterone to estradiol but that the increase in lean mass and muscle strength do not (Finkelstein et al., 2013).

Effects of Androgens at Different Stages of Life

In Utero

When the fetal testes, stimulated by hCG, begin to secrete testosterone at about the eighth week of gestation, the high local concentration of testosterone around the testes stimulates the nearby Wolffian ducts to differentiate into the male internal genitalia: the epididymis, vas deferens,

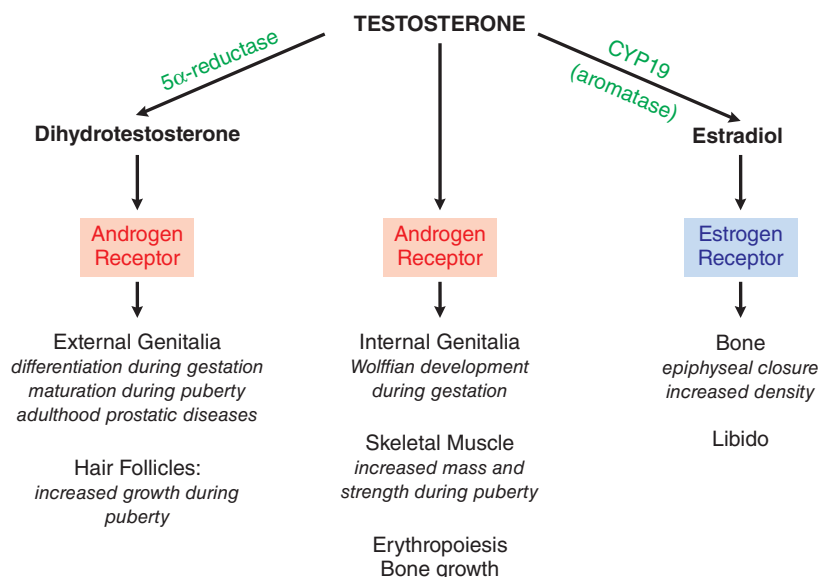

Figure 45-4 Direct effects of testosterone and effects mediated indirectly via dihydrotestosterone or estradiol.

and seminal vesicles. In the anlage of the external genitalia, testosterone is converted to dihydrotestosterone, which causes the development of the male external genitalia. The increase in testosterone at the end of gestation may result in further phallic growth.

Infancy

The consequences of the increase in testosterone secretion by the testes during the first few months of life are not yet known.

Puberty

Puberty in the male begins at a mean age of 12 years with an increase in the secretion of FSH and LH from the gonadotropes, stimulated by increased secretion of GnRH from the hypothalamus. The increased secretion of FSH and LH stimulates the testes. The increase in testosterone production by Leydig cells and the effect of FSH on the Sertoli cells stimulate the development of the seminiferous tubules, which eventually produce mature sperm. Increased secretion of testosterone into the systemic circulation affects many tissues simultaneously, and the changes in most of them occur gradually during the course of several years. The phallus enlarges in length and width, the scrotum becomes rugated, and the prostate begins secreting the fluid it contributes to the semen. The skin becomes coarser and oilier due to increased sebum production, which contributes to the development of acne. Sexual hair begins to grow, initially pubic and axillary hair, then hair on the lower legs, and finally other body hair and facial hair. Muscle mass and strength, especially of the shoulder girdle, increase, and subcutaneous fat decreases. Epiphyseal bone growth accelerates, resulting in the pubertal growth spurt, but epiphyseal maturation leads eventually to slowing and then cessation of growth. Bone also becomes thicker. Erythropoiesis increases, resulting in higher hematocrit and hemoglobin concentrations in men than boys or women. The larynx thickens, resulting in a lower voice. Libido develops. Other changes may result from the increase in testosterone during puberty; men tend to have a better sense of spatial relations than do women and to exhibit behavior that differs in some ways from that of women, including being more aggressive.

Adulthood

The serum testosterone concentration and the characteristics of the adult man are maintained largely during early adulthood and midlife. One change during this time is the gradual development of male pattern baldness, beginning with recession of hair at the temples or at the vertex.

Two other conditions are of great medical significance. One is benign *prostatic hyperplasia*, which occurs to a variable degree in almost all men, sometimes obstructing urine outflow by compressing the urethra as it passes through the prostate. This development is mediated by the conversion of testosterone to dihydrotestosterone by 5 α -reductase II within prostatic cells (Wilson, 1980). The other change is the development of *prostate cancer*. Although no direct evidence suggests that testosterone causes the disease, prostate cancer depends on androgen stimulation. This dependency is the basis of treating metastatic prostate cancer by lowering the serum testosterone concentration or by blocking its action at the receptor.

Senescence

As men age, the serum testosterone concentration gradually declines (see Figure 43–2), and the SHBG concentration gradually increases, so that by age 80, the total testosterone concentration is about 80% and the free testosterone is about 40% of those at age 20 (Harman et al., 2001). This fall in serum testosterone could contribute to several other changes that occur with increasing age in men, including decreases in energy, libido, muscle mass and strength, and bone mineral density, as well as increased fat mass and fractures. Androgen deprivation also leads to insulin resistance, truncal obesity, and abnormal serum lipids, as observed in patients with metastatic prostate cancer receiving this treatment (see also Chapter 68).

Consequences of Androgen Deficiency

The consequences of androgen deficiency depend on the stage of life during which the deficiency first occurs and on the degree of the deficiency.

During Fetal Development

Testosterone deficiency in a male fetus during the first trimester in utero causes incomplete sexual differentiation. Complete deficiency of testosterone secretion results in entirely female external genitalia. Testosterone deficiency at this stage of development also leads to failure of the Wolffian ducts to differentiate into the male internal genitalia, but the Müllerian ducts do not differentiate into the female internal genitalia as long as testes are present and secrete Müllerian inhibitory substance. Similar changes occur if testosterone is secreted normally, but its action is diminished because of an abnormality of the AR or of the 5 α -reductase.

Abnormalities of the AR can have quite varied effects. The most severe form results in complete absence of androgen action and a female phenotype; moderately severe forms result in partial virilization of the external genitalia; and the mildest forms permit normal virilization in utero and result only in impaired spermatogenesis in adulthood (McPhaul and Griffin, 1999). Abnormal 5 α -reductase results in incomplete virilization of the external genitalia in utero but normal development of the male internal genitalia, which requires only testosterone (Wilson et al., 1993). Testosterone deficiency during the third trimester impairs phallus growth. The result, *microphallus*, is a common occurrence in boys later discovered to be unable to secrete LH due to abnormalities of GnRH secretion or action. In addition, with testosterone deficiency, the testes fail to descend into the scrotum; this condition, *cryptorchidism*, occurs commonly in boys whose LH secretion is subnormal (see Chapter 42).

Before Completion of Puberty

When a boy can secrete testosterone normally in utero but loses the capacity to do so before the anticipated age of puberty, the result is failure to complete puberty. All of the pubertal changes previously described, including those of the external genitalia, sexual hair, muscle mass, voice, and behavior, are impaired to a degree proportionate to the abnormality of testosterone secretion. In addition, if growth hormone secretion is normal when testosterone secretion is subnormal during the years of expected puberty, the long bones continue to lengthen because the epiphyses do not close. The result is longer arms and legs relative to the trunk. Another consequence of subnormal testosterone secretion during the age of expected puberty is enlargement of glandular breast tissue, called *gynecomastia*.

After Completion of Puberty

When testosterone secretion becomes impaired after puberty (e.g., castration or antiandrogen treatment), regression of the pubertal effects of testosterone depends on both the degree and the duration of testosterone deficiency. When the degree of testosterone deficiency is substantial, libido and energy decrease within a week or two, but other testosterone-dependent characteristics decline more slowly. A clinically detectable decrease in muscle mass in an individual does not occur for several years. A pronounced decrease in hematocrit and hemoglobin will occur within several months. A decrease in bone mineral density probably can be detected by dual-energy absorptiometry within 2 years, but an increase in fracture incidence would not be likely to occur for many years. A loss of sexual hair takes many years.

In Women

Loss of androgen secretion in women results in a decrease in sexual hair, but not for many years. Androgens may have other important effects in women, and the loss of androgens (especially with the severe loss of ovarian and adrenal androgens that occurs in panhypopituitarism) may result in the loss of effects associated with libido, energy, muscle mass and strength, and bone mineral density.

Therapeutic Androgen Preparations

Ingestion of testosterone is not an effective means of replacing testosterone deficiency due to the rapid hepatic catabolism. Most pharmaceutical preparations of androgens, therefore, are designed to bypass hepatic catabolism of testosterone.

TABLE 45-1 ■ ANDROGENS AVAILABLE FOR THERAPEUTIC USE

Testosterone
Testosterone Esters
Testosterone enanthate/undecanoate/cypionate
17α-Alkylated Androgens
Methyltestosterone, oxandrolone, stanozolol
Fluoxymesterone, danazol
Other
7 α -Methyl-19-nortestosterone, tetrahydrogestrinone

Testosterone Esters

Esterifying a fatty acid to the 17 α -hydroxyl group of testosterone creates a compound that is even more lipophilic than testosterone itself. When an ester, such as testosterone enanthate (heptanoate) or cypionate (cyclopentylpropionate) (Table 45-1), is dissolved in oil and administered intramuscularly every 1–2 weeks to hypogonadal men, the ester hydrolyzes *in vivo* and results in serum testosterone concentrations that range from higher than normal in the first few days after the injection to low normal just before the next injection (Figure 45-5). Attempts to decrease the frequency of injections by increasing the amount of each injection result in wider fluctuations and poorer therapeutic outcomes. The undecanoate ester of testosterone, when dissolved in oil and ingested orally, is absorbed into the lymphatic circulation, thus bypassing initial hepatic catabolism. *Testosterone undecanoate* in oil also can be injected and produces stable serum testosterone concentrations for 2 months.

Alkylated Androgens

Several decades ago, chemists found that adding an alkyl group to the 17 α position of testosterone retards its hepatic catabolism. Consequently, 17 α -alkylated androgens are androgenic when administered orally; however, they are less androgenic than testosterone and cause hepatotoxicity, whereas native testosterone does not. Some 17 α -alkylated androgens show greater anabolic effects than androgenic effects compared to native testosterone in laboratory tests in rats; however, these “anabolic” steroids, so favored by athletes to illicitly improve performance, have not been convincingly demonstrated to have such a differential effect in human beings. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2009; FDA, 2016).

Transdermal Delivery Systems

To avoid the “first-pass” inactivation of testosterone by the liver, chemicals called excipients are used to facilitate the absorption of native testosterone across the skin in a controlled fashion. These transdermal preparations provide more stable serum testosterone concentrations than do injections of testosterone esters. Available preparations include gels applied to the skin or nasal mucosa, a transdermal patch, and a buccal tablet (see Figure 45-5).

Selective Androgen Receptor Modulators

Selective estrogen receptor modulators have been developed (see Chapter 44). Are selective AR modulators possible that exhibit desirable effects of testosterone in some tissues (such as muscle and bone) without the undesirable effects in other tissues, such as prostate? Nonsteroidal

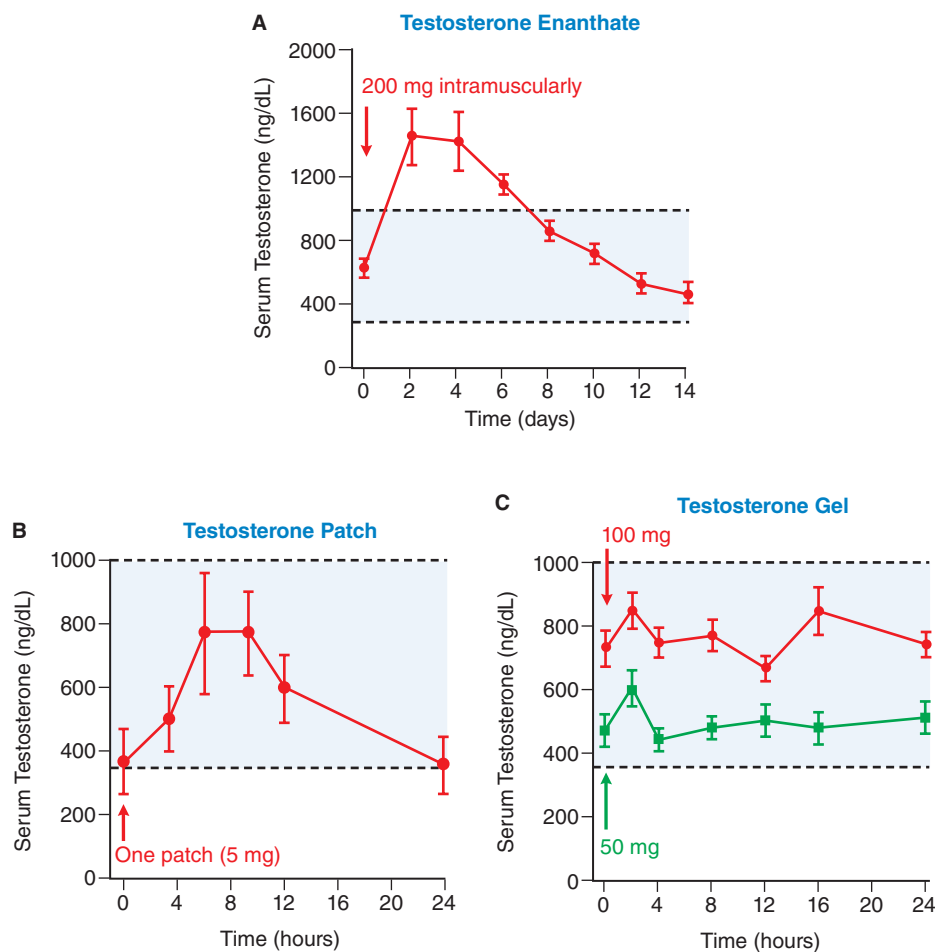

Figure 45-5 Pharmacokinetic profiles of testosterone preparations during chronic administration to hypogonadal men. Doses of each were given at time 0. Shaded areas indicate range of normal levels. (A. Data adapted from Snyder et al. 1980. B. Data adapted from Dobs et al. 1999. C. Data adapted from Swerdloff et al. 2000.)

Therapeutic Uses of Androgens

Male Hypogonadism

The best established indication for administration of androgens is testosterone deficiency in men. Any of the testosterone preparations or testosterone esters described can be used to treat testosterone deficiency.

Monitoring for Efficacy

The goal of administering testosterone to a hypogonadal man is to mimic as closely as possible the normal serum concentration (see Figure 45–5). Therefore, measuring the serum testosterone concentration during treatment is the most important aspect of monitoring testosterone treatment for efficacy. With testosterone gels, the serum testosterone concentration is relatively constant from one application to the next (Swerdlow et al., 2000). When the enanthate or cypionate ester of testosterone is administered once every 2 weeks, the serum testosterone concentration measured midway between doses should be normal; if not, the dosage schedule should be adjusted accordingly. If testosterone deficiency results from testicular disease, as indicated by an elevated serum LH concentration, adequacy of testosterone treatment also can be judged indirectly by the normalization of LH within 2 months of treatment initiation (Snyder and Lawrence, 1980).

Normalization of the serum testosterone concentration induces normal virilization in prepubertal boys and restores virilization in adult men who became hypogonadal as adults. Within a few months, and often sooner, libido, energy, and hematocrit return to normal. Within 6 months, muscle mass increases and fat mass decreases. Bone density, however, continues to increase for 2 years (Snyder et al., 2000).

Monitoring for Deleterious Effects

Testosterone administered by itself as a transdermal preparation has no “side effects” (i.e., no effects that endogenously secreted testosterone does not have), as long as the dose is not excessive. Modified testosterone compounds, such as the 17 α -alkylated androgens, do have undesirable effects even when dosages are targeted at physiological replacement. Some of these undesirable effects occur shortly after testosterone administration is initiated, whereas others usually do not occur until administration has been continued for many years. Raising the serum testosterone concentration can result in undesirable effects similar to those that occur during puberty, including acne, gynecomastia, and more aggressive sexual behavior. Physiological amounts of testosterone do not appear to affect serum lipids or apolipoproteins.

Replacement of physiological levels of testosterone occasionally may have undesirable effects in the presence of concomitant illnesses. If the testosterone dose is excessive, erythrocytosis and, uncommonly, salt and water retention and peripheral edema occur even in men who have no predisposition to these conditions.

When a man is more than 40 years of age, he is subject to certain testosterone-dependent diseases, including benign prostatic hyperplasia and prostate cancer. The principal adverse effects of the 17 α -alkylated androgens are hepatic, including cholestasis and, uncommonly, peliosis hepatis, blood-filled hepatic cysts. Hepatocellular cancer has been reported rarely. The 17 α -alkylated androgens, especially in large amounts, may lower serum HDL cholesterol.

Monitoring at the Anticipated Time of Puberty

Testosterone accelerates epiphyseal maturation, leading initially to a growth spurt but then to epiphyseal closure and permanent cessation of linear growth. Consequently, the height and growth hormone status of the boy being treated must be considered. Boys who are short because of growth hormone deficiency should be treated with growth hormone before their hypogonadism is treated with testosterone.

Male Senescence

Serum testosterone levels decrease as men age, and the parallels between the consequences of aging and those of hypogonadism due to pituitary or

testicular disease, such as decreases in muscle mass and strength, sexual function, bone density, and hemoglobin, suggest the possibility that the decrease in testosterone with aging may contribute to these changes of aging. Several studies demonstrated that testosterone treatment of older men with low testosterone increased their muscle mass and decreased their fat mass. A new study of 788 men 65 years or older with low testosterone concentrations demonstrated that testosterone treatment, compared to placebo, for 1 year improved sexual function, mood, and depressive symptoms (Snyder et al., 2016).

No studies to date have been large enough to determine if testosterone treatment of older men will increase the risk of prostate cancer, urinary tract symptoms, or heart disease. The FDA, however, has become sufficiently concerned about the possible risk of cardiovascular disease, based on epidemiologic studies and small clinical trials, that it has required a label change for testosterone preparations to indicate that they are approved only for men with “classical hypogonadism,” meaning hypogonadism due to discernible pituitary or testicular disease (Ngyuen et al., 2015).

Female Hypogonadism

Few data exist regarding whether increasing the serum testosterone concentrations of women whose serum testosterone concentrations are below normal will improve their libido, energy, muscle mass and strength, or bone mineral density. In a study of women with low serum testosterone concentrations due to panhypopituitarism, increasing the testosterone concentration to normal was associated with small increases in bone mineral density, fat-free mass, and sexual function compared to placebo (Miller et al., 2006).

Enhancement of Athletic Performance

Some athletes take drugs, including androgens, in an attempt to improve their performance. Because androgens for this purpose usually are taken surreptitiously, information about their possible effects is not as complete as that for androgens taken for treatment of male hypogonadism. Citing potentially serious health risks, the FDA has recommended against the use of body-building products that are marketed as containing steroids or steroid-like substances (FDA, 2009 and 2016).

Kinds of Androgens Used

Virtually all androgens produced for human or veterinary purposes have been taken by athletes. When such use by athletes began more than 30 years ago, 17 α -alkylated androgens and other compounds (the so-called anabolic steroids) that were thought to have greater anabolic effects than androgen effects relative to testosterone were used most commonly. Because these compounds can be detected readily by organizations that govern athletic competitions, other agents that increase the serum concentration of testosterone itself, such as the testosterone esters or hCG, have increased in popularity. Testosterone precursors, such as *androstenedione* and DHEA, also have increased in popularity recently because they are treated as nutritional supplements and thus are not regulated by athletic organizations. A new development in use of androgens by athletes is *THG*, a potent androgen that appears to have been designed and synthesized to avoid detection by antidoping laboratories on the basis of its novel structure and rapid catabolism.

Tetrahydrogestrinone (THG)

Efficacy

The few controlled studies of the effects of pharmacological doses of androgens do suggest a dose-dependent effect of testosterone on muscle strength that acts synergistically with exercise (Bhasin et al., 1996). In one controlled study, 43 normal young men were randomized to one of four groups: strength training with or without 600 mg of testosterone enanthate once a week (more than six times the replacement dose) or no exercise with or without testosterone. The men who received testosterone experienced an increase in muscle strength compared to those who received placebo, and the men who exercised simultaneously experienced even greater increases (Bhasin et al., 1996). In another study, normal young men were treated with a GnRH analogue to reduce endogenous testosterone secretion severely and, in a random blinded fashion, weekly doses of testosterone enanthate from 25 to 600 mg. There was a dose-dependent effect of testosterone on muscle strength (Bhasin et al., 2001). In contrast, in a double-blind study of androstenedione, men who took 100 mg three times a day for 8 weeks did not experience an increase in muscle strength compared to men who took placebo. The treatment also did not increase the mean serum testosterone concentration (King et al., 1999).

Side Effects

All androgens suppress gonadotropin secretion when taken in high doses and thereby suppress endogenous testicular function. This decreases endogenous testosterone and sperm production, resulting in diminished fertility. If administration continues for many years, testicular size may diminish. Testosterone and sperm production usually return to normal within a few months of discontinuation but may take longer. High doses of androgens also cause erythrocytosis.

When administered in high doses, androgens that can be converted to estrogens, such as testosterone itself, cause gynecomastia. Androgens whose A ring has been modified so that it cannot be aromatized, such as dihydrotestosterone, do not cause gynecomastia even in high doses.

The 17 α -alkylated androgens are the only androgens that cause hepatotoxicity. These androgens, when administered in high doses, affect serum lipid concentrations, specifically to decrease HDL cholesterol and increase LDL cholesterol. Women and children experience virilization, including facial and body hirsutism, temporal hair recession in a male pattern, and acne. Boys experience phallic enlargement, and women experience clitoral enlargement. Boys and girls whose epiphyses have not yet closed experience premature closure and stunting of linear growth.

Detection

An androgen other than testosterone can be detected by gas chromatography and mass spectroscopy if the athlete is still taking it when tested. Exogenous testosterone itself can be detected by one of two methods. One is the T/E ratio, the ratio of testosterone glucuronide to its endogenous epimer, epitestosterone glucuronide, in urine. Administration of exogenous testosterone suppresses secretion of both testosterone and epitestosterone and replaces them with only testosterone, so the T/E ratio is higher than normal. This technique is limited, however, by heterozygosity in the UDP-glucuronosyl transferase that converts testosterone to testosterone glucuronide. An athlete who has a deletion of one or both copies of the gene coding for this enzyme and who takes exogenous testosterone will have a much lower T/E ratio than one who has both copies (Schulze et al., 2008).

A second technique for detecting administration of exogenous testosterone employs gas chromatography-combustion-isotope ratio mass spectrometry to detect the presence of ^{13}C and ^{12}C compounds. Urinary steroids with a low $^{13}\text{C}/^{12}\text{C}$ ratio are likely to have originated from pharmaceutical sources as opposed to endogenous physiological sources (Aguilera et al., 2001).

Catabolic and Wasting States

Testosterone, because of its anabolic effects, has been used in attempts to ameliorate catabolic and muscle-wasting states, but this has not been generally effective. One exception is in the treatment of muscle wasting associated with AIDS, which often is accompanied by hypogonadism.

Treatment of men with AIDS-related muscle wasting and subnormal serum testosterone concentrations increases their muscle mass and strength (Bhasin et al., 2000).

Angioedema

Chronic androgen treatment of patients with angioedema effectively prevents attacks. The disease is caused by hereditary impairment of C1-esterase inhibitor or acquired development of antibodies against it. The 17 α -alkylated androgens (e.g., stanozolol, danazol) stimulate hepatic synthesis of the esterase inhibitor. In women, virilization is a potential side effect. In children, virilization and premature epiphyseal closure prevent chronic use of androgens for prophylaxis, although they are used occasionally to treat acute episodes. Alternatively, concentrated C1-esterase inhibitor derived from human plasma may be used for protection in patients with hereditary angioedema.

Blood Dyscrasias

Androgens once were employed to attempt to stimulate erythropoiesis in patients with anemias of various etiologies, but the availability of erythropoietin has supplanted that use. Androgens, such as danazol, still are used occasionally as adjunctive treatment of hemolytic anemia and idiopathic thrombocytopenic purpura that are refractory to first-line agents.

Antiandrogens

Because some effects of androgens are undesirable, at least under certain circumstances, agents have been developed specifically to inhibit androgen synthesis or effects. Other drugs, originally developed for different purposes, have been accidentally found to be antiandrogens and now are used intentionally for this indication. See Chapter 68 for a more detailed discussion of androgen deprivation therapy for prostate cancer.

Inhibitors of Testosterone Secretion

Analogues of GnRH effectively inhibit testosterone secretion by inhibiting LH secretion. GnRH analogues, given repeatedly, downregulate the GnRH receptor and are available for treatment of prostate cancer.

Some antifungal drugs of the imidazole family, such as *ketoconazole* (see Chapter 61), inhibit CYPs and thereby block the synthesis of steroid hormones, including testosterone and cortisol. Because they may induce adrenal insufficiency and are associated with hepatotoxicity, these drugs generally are not used to inhibit androgen synthesis, but sometimes are employed in cases of glucocorticoid excess (see Chapter 46).

Inhibitors of Androgen Action

These drugs inhibit the binding of androgens to the AR or inhibit 5 α -reductase.

Androgen Receptor Antagonists

Flutamide, Bicalutamide, Nilutamide, and Enzalutamide. The relatively potent AR antagonists flutamide, bicalutamide, nilutamide, and enzalutamide have limited efficacy when used alone because the increased LH secretion stimulates higher serum testosterone concentrations. They are used primarily in conjunction with a GnRH analogue in the treatment of metastatic prostate cancer (see Chapter 68). In this situation, they block the action of adrenal androgens, which are not inhibited by GnRH analogues. Flutamide also has been used to treat hirsutism in women; however, its association with hepatotoxicity warrants caution against its use for this cosmetic purpose.

Spironolactone. *Spironolactone* (see Chapter 25) is an inhibitor of aldosterone that also is a weak inhibitor of the AR and a weak inhibitor of testosterone synthesis. When the agent is used to treat fluid retention or hypertension in men, gynecomastia is a common side effect. In part because of this adverse effect, the selective mineralocorticoid receptor antagonist *eplerenone* was developed. *Spironolactone* can be used in women to treat hirsutism.

Cyproterone Acetate. *Cyproterone acetate* is a progestin and a weak antiandrogen by virtue of binding to the AR. It is moderately effective in reducing hirsutism alone or in combination with an oral contraceptive but is not approved for use in the U.S.

5 α -Reductase Inhibitors

Finasteride and dutasteride are antagonists of 5 α -reductase. They block the conversion of testosterone to dihydrotestosterone, especially in the male external genitalia. These drugs were developed to treat benign prostatic hyperplasia, and they are approved in the U.S. and many other countries for this purpose. When they are administered to men with moderately severe symptoms due to obstruction of urinary tract outflow, serum and prostatic concentrations of dihydrotestosterone decrease, prostatic volume decreases, and urine flow rate increases (McConnell et al., 1998). Impotence is a documented, albeit infrequent, side effect of this use. Gynecomastia is a rare side effect.

Finasteride also is approved for use in the treatment of male pattern baldness and is effective in the treatment of hirsutism.

Pharmacologic Treatment of Erectile Dysfunction

Normal erectile function depends on a combination of many factors, including visual, psychologic, hormonal, and neurologic factors, that act via the common mechanism of increasing the synthesis of NO by vascular endothelium in the arterioles supplying the corpora cavernosa and in the corpora cavernosa. NO diffuses to adjacent smooth muscle cells and causes vasodilation of arterioles and increased compliance of the cavernosal space, permitting its engorgement with blood. This accumulation of blood also restricts the outflow by compressing the veins against the surrounding sheath (*tunica albuginea*). The overall result is penile erection.

Erectile dysfunction can result from psychologic, hormonal, and vascular causes, including damage to endothelium and from side effects of various drugs, including some that are used in the therapy of hypertension; it is associated with a variety of disease states, including diabetes (Dean and Lue, 2005).

Erectile Signaling and Erectile Dysfunction

Nitric oxide acts by binding and activating sGC, which catalyzes the production of cyclic GMP from cellular GTP. Cyclic GMP is a second messenger that activates PKG, leading to phosphorylation of contractile proteins and ion channels to decrease the concentration of intracellular Ca^{++} , resulting in smooth muscle relaxation and increased blood flow to corpora cavernosa. PDE5 degrades cyclic GMP; thus, erectile dysfunction can be improved by drugs that retard the degradation of cyclic GMP by inhibiting PDE5 (Goldstein et al., 1998) (Figure 45–6).

PDE5 Inhibitors

Available inhibitors of PDE5 include sildenafil, vardenafil, tadalafil, and avanafil. All of these agents compete for cyclic GMP binding at the site of cyclic GMP hydrolysis on PDE5. PDE5 inhibitors are also used in treating pulmonary arterial hypertension (Chapter 31).

ADME

Table 45–2 summarizes a number of pharmacokinetic properties of the available PDE5 inhibitors. These agents are adequately absorbed orally, widely distributed, and act fairly quickly (within ~ 30 min). Their affinities, time to onset, and half-lives differ somewhat, giving patients options for onset and duration of effect. The drugs are cleared by hepatic CYP3A4, with minor contributions by CYP2C9 (20% for sildenafil). Excretion of metabolites is largely via the feces, with urinary excretion playing a secondary role in excretion of tadalafil (36%) (Mehrotra et al., 2007).

Clinical Use

All of these agents produce satisfactory results in most patients. The starting dose recommendations vary, and patients should start at the lowest recommended dose. This is especially important in patients over 65 years.

Adverse Effects, Precautions

Adverse effects are similar but not identical across this drug class owing to their similar mechanism of action but their differing specificities toward PDE5 compared to other PDE isoforms. Common complaints are headache, flushing, dyspepsia, nasal congestion, dizziness, and back pain. Some patients using sildenafil or vardenafil may notice blurred vision and a

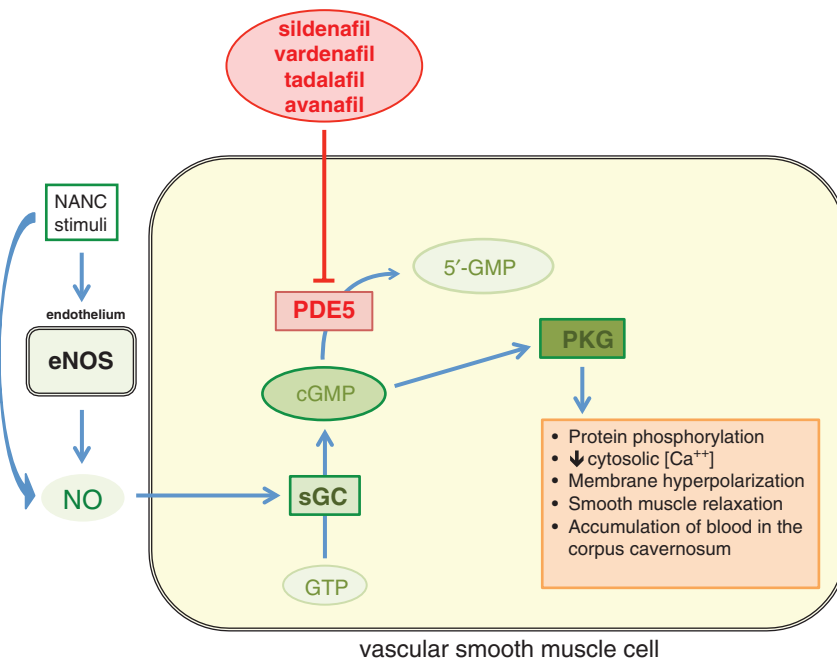

Figure 45–6 Mechanism of action of PDE5 inhibitors in the corpus cavernosum. Physiologically, penile erection is initiated by NANC neural stimulation that results in NO release from neurons and endothelial cells. PDE5 inhibitors enhance signaling through the NO-guanylyl cyclase-cGMP-PKG pathway by inhibiting the degradation of cGMP, thereby enhancing the activation of PKG. PKG activation leads to relaxation of cavernosal smooth muscle, which permits engorgement of the corpus cavernosum with blood, resulting in penile erection.

TABLE 45-2 ■ PHARMACOKINETIC PROPERTIES OF PDE5 INHIBITORS

	SILDENAFIL	VARDENAFIL	TADALAFIL	AVANAFIL
K_i (nM)	4	0.1	2	4
Plasma $t_{1/2}$ (h)	4	4	17.5	1.3–2
Oral bioavailability (%)	40	15	40	70
Onset of action (min)	30–60	30–60	30–120	15–30
Time to C_{pmax} (min)	60	60	120	30
Maximum duration of action (h) ^b	12	10	36	6
Optic effects/PDE6	+	+	–	–
Food ^a alters AUC, C_{pmax} ?	+	+	–	±

^aHigh-fat meal; generally reduces AUC and C_{pmax} but for avanafil, prolongs absorption period and time to C_{pmax} (by 1 h), decreases C_{pmax} (–24%) and increases AUC (+14%).

^bDuration will vary with dose and rate of clearance.

For PK data on PDE5 inhibitors, see FDA, 2012, and Mehrotra et al., 2007.

blue-green tinting of vision, referable to inhibition of retinal PDE6, which is involved in phototransduction (see Figure 69-9).

Concomitant administration of potent CYP3A inducers (e.g., bosentan) will generally cause substantial decreases in plasma levels of drugs in this class. CYP3A inhibitors (e.g., protease inhibitors used in human immunodeficiency virus therapy, erythromycin, and cimetidine) inhibit metabolism of PDE5 inhibitors, thereby prolonging the half-lives and elevating blood levels of these agents. Consistent with their mechanism of action, potentiation of cyclic GMP signaling, PDE5 inhibitors potentiate the hypotensive effects of nitrate vasodilators, producing dangerously low blood pressures. Thus, the administration of PDE5 inhibitors to patients receiving organic nitrates is contraindicated. The patient's underlying cardiovascular status and concurrent use of hypotensive agents (e.g., nitrates, α adrenergic antagonists) must be considered prior to use of this class of drugs. Priapism (erection lasting longer than 4 h) induced by PDE5 inhibitors runs the risk of ischemic damage to the cavernosal smooth muscle and sinusoidal epithelium and requires medical attention.

Developing Therapies for Erectile Dysfunction

In addition to use of PDE5 inhibitors, alternative routes for regulating smooth muscle tone in the corpus cavernosum are being actively explored. For example, direct activators of guanylyl cyclase are now available (e.g., riociguat). Local inhibition of arginase may enhance NO production in cases where arginine, the substrate for NO synthase, limits NO production (Caldwell et al., 2015). Rho A and Rho kinase are highly expressed in penile smooth muscle, where Rho kinase phosphorylates and inhibits the regulatory subunit of myosin light chain phosphatase and helps to maintain a tonic contracted state of the cavernosal smooth muscle (an antierectile state), thereby promoting maintenance of the flaccid state. In experimental preparations, inhibitors of Rho kinase (e.g., fasudil) will elicit penile erection (Sopko et al., 2014). Mirabegron, a β_3 adrenergic agonist used in treatment of overactive bladder, relaxes isolated muscle strips from human and rodent corpus cavernosum (Gur et al., 2016), and H_2S has proerectile activity mediated by its effect on a large-conductance Ca^{2+} -activated K^+ in cavernosal smooth muscle (Jupiter et al., 2015).

Drug Facts for Your Personal Formulary: Androgens; PDE5 Inhibitors

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Testosterone Esters • Effective for weeks to months. Wide fluctuations in serum concentrations		
Testosterone enanthate testosterone cypionate	• Treatment of male hypogonadism	<ul style="list-style-type: none"> Formulated as oils for injection Administer as a deep I.M. injection every 1-2 weeks. Generally effective in causing and maintaining virilization. Fluctuations in serum concentrations result in fluctuations in energy, mood, and libido. Available as gels, implants, buccal tabs
Testosterone undecanoate	• Treatment of male hypogonadism	<ul style="list-style-type: none"> Formulated as oil for injection Administer as a deep I.M. gluteal injection. Observe for 30 min after injection for anaphylaxis or pulmonary microembolism. Administer every 10 weeks.
Testosterone undecanoate for oral administration (not available in the U.S.)	• Treatment of male hypogonadism	<ul style="list-style-type: none"> Taken 2-3 times a day with food Absorbed into lymphatics
Testosterone Transdermal Patch		
Several FDA-approved products	• Treatment of male hypogonadism	<ul style="list-style-type: none"> Worn without interruption and changed once a day High rate of skin rash
Transdermal Testosterone Gels		
Several FDA-approved products	• Treatment of male hypogonadism	<ul style="list-style-type: none"> Applied once a day Relatively steady serum testosterone concentration

INHIBITORS OF ACTH SECRETION AND THE BIOSYNTHESIS AND ACTIONS OF ADRENOCORTICAL STEROIDS

- Inhibitors of ACTH Secretion
- Inhibitors of Steroidogenesis
- Glucocorticoid Antagonist

The major physiological and pharmacological effects of *ACTH* result from the increase in circulating levels of *adrenocortical steroids* that ACTH causes. Synthetic derivatives of ACTH are used principally in the diagnostic assessment of adrenocortical function. Because corticosteroids mimic the therapeutic effects of ACTH, synthetic steroids generally are used therapeutically instead of ACTH.

Corticosteroids and their biologically active synthetic derivatives differ in their metabolic (glucocorticoid) and electrolyte-regulating (mineralocorticoid) activities. These agents are used at physiological doses as replacement therapy when endogenous production is impaired. Glucocorticoids potently suppress inflammation, and their use in inflammatory and autoimmune diseases makes them among the most frequently prescribed classes of drugs. Because glucocorticoids exert effects on almost every organ system, their administration and withdrawal may be complicated by serious side effects. Therefore, the decision to institute therapy with systemic glucocorticoids always requires careful consideration of the relative risks and benefits in each patient.

Corticotropin

Human ACTH, a peptide of 39 amino acids, is synthesized as part of a larger precursor protein, POMC, and is derived from the precursor by proteolytic cleavage at dibasic residues by the *serine endoprotease, prohormone convertase 1* (also known as prohormone convertase 3) (Figure 46–1). Other biologically important peptides, including *endorphins, lipotropins, and the MSHs*, also are produced by proteolytic processing of the same POMC precursor (see Chapter 20 and Takahashi and Mizusawa, 2013).

The actions of ACTH and the other melanocortins derived from POMC are mediated by their specific interactions with five MCR subtypes (MC_1R – MC_5R) comprising a subfamily of GPCRs (Cone, 2006; Montero-Melendez, 2015). The well-known effects of MSH on pigmentation result from interactions with MC_1R on melanocytes. ACTH, which is identical to α -MSH in its first 13 amino acids, exerts its effects on the adrenal cortex through MC_2R . The affinity of ACTH for MC_1R is much lower than for MC_2R ; however, under pathological conditions in which ACTH levels are persistently elevated, such as primary adrenal insufficiency, ACTH also can signal through MC_1R and cause hyperpigmentation. β -MSH and possibly other melanocortins, acting via MC_4R and MC_5R in the hypothalamus, play a role in regulating appetite and body weight. The role of MC_5R is less well defined, but studies in rodents suggest

HISTORICAL PERSPECTIVE

Addison described fatal outcomes in patients with adrenal destruction in a presentation to the South London Medical Society in 1849. These studies were soon extended when Brown-Séquard demonstrated that bilateral adrenalectomy was fatal in laboratory animals. It later was shown that the adrenal cortex, rather than the medulla, was essential for survival in these ablation experiments, and that the adrenal cortex regulated both carbohydrate metabolism and fluid and electrolyte balance. The isolation and identification of the adrenal steroids by Reichstein and Kendall and the effects of these compounds on carbohydrate metabolism (hence the term *glucocorticoids*) culminated with the synthesis of *cortisone*, the first pharmacologically effective glucocorticoid to become readily available. Subsequently, Tait and colleagues isolated and characterized a distinct corticosteroid, *aldosterone*, which potently affected fluid and electrolyte balance and therefore was termed a *mineralocorticoid*. The isolation of distinct corticosteroids that regulated carbohydrate metabolism or fluid and electrolyte balance led to the concept that the adrenal cortex comprises two largely independent units: an outer zone that produces mineralocorticoids and an inner region that synthesizes glucocorticoids and androgen precursors (reviewed by Miller, 2013).

Studies of adrenocortical steroids also played a key part in delineating the role of the anterior pituitary in endocrine function. As early as 1912, Cushing described patients with hypercorticism, and he later recognized that pituitary basophilism caused the adrenal overactivity, thus establishing the link between the anterior pituitary and adrenal function. These studies led to the purification of ACTH and the determination of its chemical structure. ACTH was further shown to be essential for maintaining the structural integrity and steroidogenic capacity of the inner cortical zones. Harris established the role of the hypothalamus in pituitary control and postulated that a soluble factor produced by the hypothalamus activated ACTH release. These investigations culminated with the determination of the structure of CRH, a hypothalamic peptide that, together with AVP, regulates secretion of ACTH from the pituitary (Miller, 2013).

Shortly after synthetic cortisone became available, Hench and colleagues demonstrated its dramatic effect in the treatment of rheumatoid arthritis, setting the stage for the clinical use of corticosteroids in a wide variety of diseases, as discussed in this chapter.

ACh: acetylcholine
ACTH: corticotropin (formerly adrenocorticotrophic hormone)
AngII: angiotensin II
AP-1: activator protein 1
ATPase: adenosine triphosphatase
AVP: arginine vasopressin
CAH: congenital adrenal hyperplasia
CBG: corticosteroid-binding globulin
CIRCI: critical illness-related cortisol insufficiency
CNS: central nervous system
COX: cyclooxygenase
CRF: corticotropin-releasing factor (CRF₁, CRF₂)
CRH: corticotropin-releasing hormone
CYP: cytochrome P450
CYP11A1: cholesterol side-chain cleavage enzyme
CYP11B1: 11 β -hydroxylase
CYP11B2: aldosterone synthase
CYP17: 17 α -hydroxylase
CYP19: aromatase
CYP21: steroid 21-hydroxylase
DHEA: dehydroepiandrosterone
ELAM-1: endothelial-leukocyte adhesion molecule 1
FDA: Food and Drug Administration
GM-CSF: granulocyte-macrophage colony-stimulating factor
GR: glucocorticoid receptor
GRE: glucocorticoid-response element
HPA: hypothalamic-pituitary-adrenal
3 β -HSD: 3 β -hydroxysteroid dehydrogenase
11 β -HSD1: 11 β -hydroxysteroid dehydrogenase (type 1)
11 β -HSD2: 11 β -hydroxysteroid dehydrogenase (type 2)
HSP70: 70-kDa heat shock protein
HSP90: 90-kDa heat shock protein
ICAM-1: intercellular adhesion molecule 1
Ig: immunoglobulin
IL: interleukin
IP: 56-kDa immunophilin
IP₃: inositol trisphosphate
LPH: lipotropin
LT: leukotriene
MCR: melanocortin receptor
MR: mineralocorticoid receptor
mRNA: messenger RNA
MSH: melanocyte-stimulating hormone
NE: norepinephrine
NF- κ B: nuclear factor kappa B
NOS: nitric oxide synthase
PG: prostaglandin
PK: protein kinase
PLC: phospholipase C
POMC: pro-opiomelanocortin
RANK: receptor for activating NF- κ B
SSTR: somatostatin receptor
TNF: tumor necrosis factor

Figure 46-1 Processing of POMC to ACTH. POMC is converted to ACTH and other peptides in the anterior pituitary. The boxes within the ACTH structure indicate regions important for steroidogenic activity (residues 6–10) and binding to the ACTH receptor (15–18). α -MSH also derives from the POMC precursor and contains the first 13 residues of ACTH.

adrenal cortex histologically and functionally can be separated into three zones (Figure 46-2) that produce different steroid products under different regulatory influences:

- The *outer zona glomerulosa* secretes the mineralocorticoid aldosterone.
- The *middle zona fasciculata* secretes the glucocorticoid cortisol.
- The *inner zona reticularis* secretes DHEA and its sulfated derivative DHEA-S (plasma concentration 1000 times that of DHEA). DHEA sulfatase converts DHEA-S to DHEA in the periphery.

Cells of the outer zone have receptors for both ACTH and AngII and express *aldosterone synthase* (CYP11B2), the enzyme that catalyzes the terminal reactions in mineralocorticoid biosynthesis. Although ACTH acutely stimulates mineralocorticoid production by the zona glomerulosa, this zone is regulated predominantly by AngII and *extracellular K⁺* (see Chapter 25) and does not undergo atrophy in the absence of ongoing stimulation by the pituitary gland. With persistently elevated ACTH, mineralocorticoid levels initially increase and then return to normal (a phenomenon termed *ACTH escape*).

Figure 46-2 The three anatomically and functionally distinct compartments of the adrenal cortex. The major functional compartments of the adrenal cortex are shown, along with the steroidogenic enzymes that determine the unique profiles of corticosteroid products. Also shown are the predominant physiological regulators of steroid production: AngII and K⁺ for the zona glomerulosa and ACTH for the zona fasciculata. The physiological regulator(s) of DHEA production by the zona reticularis are not known, although ACTH acutely increases DHEA biosynthesis.

roles in exocrine secretion and pheromone-related aggressive behavior (Morgan and Cone, 2006).

Actions on the Adrenal Cortex

Acting via MC₂R, ACTH stimulates the adrenal cortex to secrete *glucocorticoids*, *mineralocorticoids*, and the androgen precursor DHEA. The

Cells of the zona fasciculata have fewer receptors for AngII and express *steroid 17 α -hydroxylase* (CYP17) and *11 β -hydroxylase* (CYP11B1), enzymes that catalyze the production of glucocorticoids. In the zona reticularis, CYP17 carries out an additional C17–20 lyase reaction that converts C21 corticosteroids to C19 androgen precursors.

In the absence of the anterior pituitary and ACTH stimulation, the inner zones of the cortex atrophy, and the production of glucocorticoids and adrenal androgens is markedly impaired. Persistently elevated levels of ACTH, due either to repeated administration of large doses of ACTH or to excessive endogenous production, induce hypertrophy and hyperplasia of the inner zones of the adrenal cortex, with overproduction of cortisol and adrenal androgens. Adrenal hyperplasia is most marked in congenital disorders of steroidogenesis, in which ACTH levels are continuously elevated as a secondary response to impaired cortisol biosynthesis.

Mechanism of Action

Corticotropin stimulates the synthesis and release of adrenocortical hormones by increasing *de novo* biosynthesis. ACTH, binding to MC₂R, activates the G_s-adenylyl cyclase–cyclic AMP–PKA pathway. Cyclic AMP is the second messenger for most effects of ACTH on steroidogenesis.

Temporally, the response of adrenocortical cells to ACTH has two phases. The *acute phase*, which occurs within seconds to minutes, largely reflects an increased supply of cholesterol substrate to the steroidogenic enzymes. The *chronic phase*, which occurs over hours to days, results largely from increased transcription of the steroidogenic enzymes.

A number of transcriptional regulators participate in the induction of the steroidogenic enzymes by ACTH. Among these is the nuclear receptor NR5A1 (steroidogenic factor 1), a transcription factor required for the development of the adrenal cortex and for the expression of most of the steroidogenic enzymes (Schimmer and White, 2010). Pathways of adrenal steroid biosynthesis and the structures of the major steroid intermediates and products of the human adrenal cortex are shown in Figure 46–3. The rate-limiting step in steroid hormone production is the translocation of *cholesterol* across mitochondrial membranes by the *steroid acute regulatory protein*. Cholesterol is then converted to *pregnenolone* by the side-chain cleavage enzyme, CYP11A1, which represents the first enzymatic step in steroid hormone biosynthesis (Miller and Auchus, 2011). Most of the enzymes required for steroid hormone biosynthesis, including CYP11A1, are members of the cytochrome P450 superfamily (see Chapter 6). To ensure an adequate supply of substrate for steroidogenesis, the adrenal cortex uses multiple sources of cholesterol, including circulating cholesterol and cholesterol esters taken up via the low-density lipoprotein and high-density lipoprotein receptor pathways; endogenous cholesterol liberated from cholesterol ester stores via activation of cholesterol esterase; and endogenous cholesterol from *de novo* biosynthesis.

Extra-adrenal Effects of ACTH

In large doses, ACTH causes a number of metabolic changes in adrenalectomized animals, including ketosis, lipolysis, hypoglycemia (immediately after treatment), and resistance to insulin (later after treatment). Given the large doses of ACTH required, the physiological significance of these extra-adrenal effects is questionable.

Regulation of ACTH Secretion

Hypothalamic-Pituitary-Adrenal Axis

The rate of glucocorticoid secretion is determined by fluctuations in the release of ACTH by the pituitary corticotropes. These corticotropes are regulated by *CRH* and *AVP*, peptide hormones released by specialized neurons of the endocrine hypothalamus into the network of portal veins bathing the anterior pituitary (Papadimitriou and Priftis, 2009). This HPA axis forms an integrated system that maintains appropriate levels of glucocorticoids (Figure 46–4). The three characteristic modes of physiologic regulation of the HPA axis are

- *diurnal rhythm* in basal steroidogenesis
- *negative-feedback regulation* by adrenal corticosteroids
- *marked increases in steroidogenesis in response to stress*.

Pathologic elevation of steroidogenesis is seen in Cushing disease, the ectopic ACTH syndrome, and conditions where GRs or MRs are defective.

The *diurnal rhythm* is determined by circadian clocks in the hypothalamus, suprachiasmatic nucleus, and adrenal gland itself and is entrained by higher neuronal centers in response to sleep–wake cycles, such that levels of ACTH peak in the early morning hours, causing the circulating glucocorticoid levels to peak at about 8 AM. (Leliavski et al., 2015). *Negative-feedback regulation* occurs at multiple levels of the HPA axis and is the major mechanism that maintains circulating glucocorticoid levels in the appropriate range. *Stress* can override the normal negative-feedback control mechanisms, leading to marked increases in plasma concentrations of glucocorticoids.

Following release into the hypophyseal plexus, CRH is transported via this portal system to the anterior pituitary, where it binds to specific membrane receptors on corticotropes. On CRH binding, the CRH receptor activates the G_s-adenylyl cyclase–cyclic AMP pathway within corticotropes, ultimately stimulating both ACTH biosynthesis and secretion. CRH and CRH-related peptides called *urocortins* also are produced at other sites, including the amygdala and hindbrain, gut, skin, adrenal gland, adipose tissue, placenta, and additional sites in the periphery. The classical CRH receptor, now designated CRF₁ receptor, belongs to the class II family of GPCRs that includes receptors for calcitonin, parathyroid hormone, growth hormone–releasing hormone, secretin, glucagon, and glucagon-like peptide. A second CRH receptor, the CRF₂ receptor, is distinguished from the CRF₁ receptor in its binding specificities for CRH and the urocortins. The finding that the HPA axis often is altered in patients suffering from major depressive disorders illustrates the complex relationships between stress and mood and has stimulated considerable interest in the possible use of CRH antagonists in disorders such as anxiety and depression (Holsboer and Ising, 2008).

Arginine Vasopressin

Arginine vasopressin also acts as a secretagogue for corticotropes, significantly potentiating the effects of CRH. AVP is produced in the paraventricular nucleus and secreted into the pituitary portal veins from the median eminence. AVP binds to V_{1b} receptors and activates the G_q-PLC-IP₃-Ca²⁺ pathway to enhance the release of ACTH. In contrast with CRH, AVP does not increase ACTH synthesis.

Negative Feedback of Glucocorticoids

Glucocorticoids inhibit ACTH secretion via direct and indirect actions on CRH neurons to decrease CRH mRNA levels and CRH release and via direct effects on corticotropes. The indirect inhibitory effects on CRH neurons appear to be mediated by both corticosteroid receptors in the hippocampus. At lower cortisol levels, MRs, which have higher affinity for glucocorticoids than GRs, are the major receptor species occupied. As glucocorticoid concentrations rise and saturate MRs, the GRs become increasingly occupied. Both MRs and GRs apparently control the basal activity of the HPA axis, whereas feedback inhibition by glucocorticoids predominantly involves GRs. In the pituitary, glucocorticoids act through GRs to inhibit the release of ACTH from corticotropes and the expression of POMC. These effects are both rapid (occurring within seconds to minutes) and delayed (requiring hours and involving changes in gene transcription mediated through GRs).

The Stress Response

Stress overcomes negative-feedback regulation of the HPA axis, leading to a marked rise in corticosteroid production. Examples of stress signals include injury, hemorrhage, severe infection, major surgery, hypoglycemia, cold, pain, and fear. Although the precise mechanisms that underlie this stress response and the essential actions played by corticosteroids are not fully defined, increased corticosteroid secretion is vital to maintain homeostasis in these settings. As discussed further in the chapter, complex interactions between the HPA axis and the immune system may be a fundamental physiological component of this stress response.

Figure 46-3 Pathways of corticosteroid biosynthesis. The steroidogenic pathways used in the biosynthesis of the corticosteroids are shown, along with the structures of the intermediates and products. The pathways unique to the zona glomerulosa are shown in the orange box; those that occur in the inner zona fasciculata and zona reticularis are shown in the gray box. The zona reticularis does not express 3β-HSD and thus preferentially synthesizes DHEA.

Therapeutic Uses and Diagnostic Applications of ACTH

Corticotropin has limited utility therapeutically. All proven therapeutic effects of ACTH can be achieved with appropriate doses of corticosteroids with a lower risk of side effects. Moreover, therapy with ACTH is less predictable and less convenient than therapy with corticosteroids. ACTH stimulates mineralocorticoid and adrenal androgen secretion and may therefore cause acute retention of salt and water, as well as virilization. Cosyntropin, a synthetic peptide that corresponds to residues 1–24 of human ACTH, is used in testing the integrity of the HPA axis. At the considerably supraphysiological dose of 250 µg, cosyntropin maximally stimulates adrenocortical steroidogenesis. An increase in the circulating

cortisol to a level greater than 18–20 µg/dL indicates a normal response. Cosyntropin may be used diagnostically in adrenal venous sampling to distinguish between unilateral and bilateral aldosterone oversecretion in primary aldosteronism.

CRH Stimulation Test

Ovine CRH (corticotropin-releasing hormone) and human CRH (not available in the U.S.) are used for diagnostic testing of the HPA axis. In patients with documented ACTH-dependent hypercortisolism, CRH testing may help differentiate pituitary (i.e., Cushing disease) from ectopic sources of ACTH.

Assays for ACTH

Immunochemiluminescent assays that use two separate antibodies directed at distinct epitopes on the ACTH molecule now are widely

Figure 46-4 The HPA axis and the immune-inflammatory network. Inputs from higher neuronal centers regulate CRH secretion. + indicates a positive regulator, – indicates a negative regulator, + and – together indicate a mixed effect, as for NE. In addition, AVP stimulates release of ACTH from corticotropes.

available. These assays increase the ability to differentiate patients with primary hypoadrenalism due to intrinsic adrenal disease, who have high ACTH levels due to the loss of normal glucocorticoid feedback inhibition, from those with secondary forms of hypoadrenalism due to low ACTH levels resulting from hypothalamic or pituitary disorders. The immunochemiluminescent ACTH assays also are useful in differentiating ACTH-dependent from ACTH-independent forms of hypercortisolism: High ACTH levels are seen when the hypercortisolism results from pituitary adenomas (e.g., Cushing disease) or nonpituitary tumors that secrete ACTH (e.g., the syndrome of ectopic ACTH), whereas low ACTH levels are seen in patients with excessive glucocorticoid production due to primary adrenal disorders. One problem with the immunoassays for ACTH is that their specificity for intact ACTH can lead to falsely low values in patients with ectopic ACTH secretion; these tumors can secrete aberrantly processed forms of ACTH that have biological activity but do not react in the antibody assays.

Absorption, Fate, and Toxicity

Corticotropin is readily absorbed from parenteral sites. The hormone rapidly disappears from the circulation after intravenous administration; in humans, the $t_{1/2}$ in plasma is about 15 min, primarily due to rapid enzymatic hydrolysis. Aside from rare hypersensitivity reactions, the toxicity of ACTH is primarily attributable to the increased secretion of corticosteroids. Cosyntropin generally is less antigenic than native ACTH.

Adrenocortical Steroids

The adrenal cortex synthesizes two classes of steroids: the *corticosteroids* (glucocorticoids and mineralocorticoids; see Figure 46-3), which have 21 carbon atoms, and the *androgens*, which have 19 carbons (see Figure 45-3). The actions of corticosteroids historically were described as *glucocorticoid* (reflecting their carbohydrate metabolism-regulating activity) and *mineralocorticoid* (reflecting their electrolyte balance-regulating activity). In humans, *cortisol* is the main glucocorticoid, and aldosterone is the physiologic mineralocorticoid. Table 46-1 shows typical rates of secretion of cortisol and aldosterone, as well as their normal circulating concentrations.

Although the adrenal cortex is an important source of androgen precursors in women, patients with adrenal insufficiency can be restored to

TABLE 46-1 ■ NORMAL DAILY PRODUCTION RATES AND CIRCULATING LEVELS OF THE PREDOMINANT CORTICOSTEROIDS

	CORTISOL	ALDOSTERONE
Rate of secretion under optimal conditions	10 mg/d	0.125 mg/d
Concentration in peripheral plasma:

4 AM	4 µg/100 mL	0.01 µg/100 mL

normal life expectancy by replacement therapy with glucocorticoids and mineralocorticoids. Adrenal androgens are not essential for survival. The sulfated derivative DHEA-S is the most highly secreted adrenal steroid; levels of DHEA and DHEA-S peak in the third decade of life and decline progressively thereafter. Moreover, patients with a number of chronic diseases have very low DHEA levels, leading some to propose that DHEA treatment might at least partly alleviate the loss of libido, the decline in cognitive function, the decreased sense of well-being, and other adverse physiological consequences of aging. However, studies on the benefits of addition of DHEA to the standard replacement regimen in women with adrenal insufficiency have been inconclusive. Despite the absence of definitive data, DHEA is widely used as an over-the-counter nutritional supplement for its alleged health benefits.

Physiological Functions and Pharmacological Effects

Corticosteroids have numerous effects, which include alterations in carbohydrate, protein, and lipid metabolism; maintenance of fluid and electrolyte balance; and preservation of normal function of the cardiovascular system, the immune system, the kidney, skeletal muscle, the endocrine system, and the nervous system. In addition, corticosteroids endow the organism with the capacity to resist stressful and noxious stimuli and environmental changes. In the absence of adequate secretion of corticosteroids from the adrenal cortex, stresses such as infection, trauma, and extremes in temperature can be fatal.

The actions of corticosteroids are related to those of other hormones. For example, in the absence of lipolytic hormones, cortisol has virtually no effect on the rate of lipolysis by adipocytes. Conversely, in the absence of glucocorticoids, epinephrine and NE have only minor effects on lipolysis. Administration of a small dose of glucocorticoid, however, markedly potentiates the lipolytic action of these catecholamines. Those effects of corticosteroids that involve concerted actions with other hormonal regulators are termed *permissive* and most likely reflect steroid-induced changes in protein synthesis, which, in turn, modify tissue responsiveness to other hormones.

Corticosteroids are termed either *mineralocorticoids* or *glucocorticoids*, according to their relative potencies in Na^+ retention and effects on carbohydrate metabolism (i.e., hepatic deposition of glycogen and gluconeogenesis). In general, the potencies of steroids on glucose metabolism closely parallel their potencies as anti-inflammatory agents. The effects on Na^+ retention and the carbohydrate/anti-inflammatory actions are not closely related and reflect selective actions at distinct receptors. As noted in further discussion (see structure-activity relationships and Table 46-3), some steroid derivatives provide relative selectivity as stimulants of Na^+ retention or anti-inflammatory effects.

General Mechanisms for Corticosteroid Effects

Corticosteroids bind to specific receptor proteins in target tissues to regulate the expression of corticosteroid-responsive genes, thereby changing the levels and array of proteins synthesized by the various target tissues (Figure 46-5). Many effects of corticosteroids are not immediate but become apparent after several hours; clinically, one often but not invariably sees a delay before beneficial effects of corticosteroid therapy become

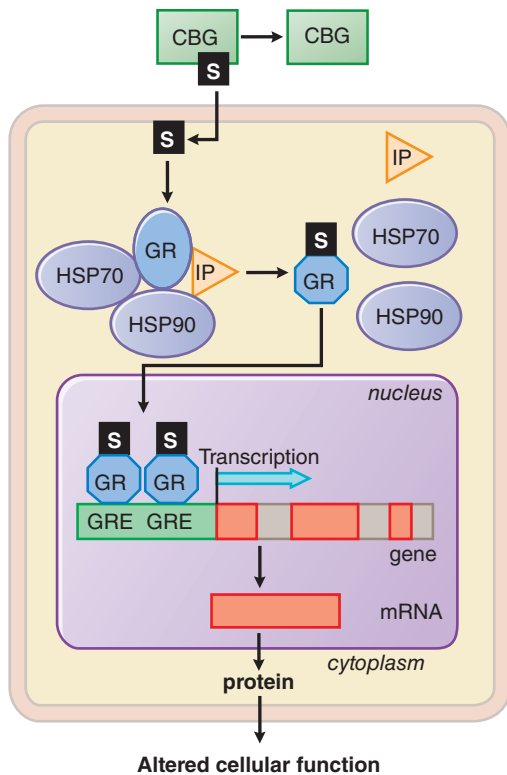

Figure 46-5 Intracellular mechanism of action of the GR. The figure shows the molecular pathway by which cortisol (labeled S) enters cells and interacts with the GR to change GR conformation (indicated by the change in shape of the GR), induce GR nuclear translocation, and activate transcription of target genes. Glucocorticoids also inhibit the expression of certain genes, including POMC expression by corticotropes. Here, GRE indicates the GREs in the DNA that are bound by GR, thus providing specificity to induction of gene transcription by glucocorticoids. Within the gene are introns (gray) and exons (red); transcription and mRNA processing leads to splicing and removal of introns and assembly of exons into mRNA.

manifest. Although corticosteroids predominantly act by increasing gene transcription, there are examples in which glucocorticoids decrease gene transcription. In addition, corticosteroids exert their immediate effects by nongenomic mechanisms, usually via classical GRs or MRs (Prigent et al., 2004).

Glucocorticoid Receptors. The receptors for corticosteroids are members of the nuclear receptor family of transcription factors. GRs (also called NR3C1, nuclear receptor subfamily 3, group C, member 1) reside predominantly in the cytoplasm in an inactive form complexed with other proteins. Steroid binding results in receptor activation and translocation to the nucleus (see Figure 46-5). Several GR isoforms result from alternative RNA splicing and from translation initiation at alternative sites. Of these, GR α is the prototypical glucocorticoid-responsive isoform. A second major GR isoform, GR β , is a truncated, dominant, negative variant that lacks 35 amino acids at the C terminus and is unable to bind glucocorticoids or activate gene expression. Multiple polymorphisms in the human GR are associated with differences in GR function and have been linked to glucocorticoid insensitivity (Vandevyver et al., 2014).

Regulation of Gene Expression by Glucocorticoids. After ligand binding, GRs dissociate from their associated proteins and translocate to the nucleus. There, they interact with specific DNA sequences called GREs, which provide specificity in terms of induction of gene transcription by glucocorticoids. Genes can be activated or inhibited by GR-GRE interactions. The mechanisms whereby GR activate transcription are complex and not completely understood, but they involve interaction with transcriptional coactivators and with proteins that make up the basal transcription apparatus. In an example of transcriptional inhibition GRs

inhibit transcription of POMC by a direct interaction with a GRE in the POMC promoter, thereby contributing to the negative-feedback regulation of the HPA axis. Other genes negatively regulated by glucocorticoids include genes for COX-2, inducible NOS (NOS2), and inflammatory cytokines. Some inhibitory effects of glucocorticoids, such as downregulation of expression of genes encoding a number of cytokines, collagenase, and stromelysin, have been linked to protein-protein interactions between the GRs and other transcription factors (e.g., NF- κ B and AP-1) rather than to negative effects of the GRs at specific GREs. Such protein-protein interactions and their consequent negative effects on gene expression appear to contribute significantly to the anti-inflammatory and immunosuppressive effects of the glucocorticoids (De Bosscher et al., 2003).

Regulation of Gene Expression by Mineralocorticoids. Like GRs, the MR also is a ligand-activated transcription factor and binds to a very similar hormone-responsive element. MRs also associate with HSP90 and GREs to activate the transcription of discrete sets of genes in target tissues. GRs and MRs differ in their ability to inhibit AP-1-mediated gene activation and, in terms of gene transcription, by their differential recruitment of other transcription factors. In addition, GRs are essentially ubiquitous, whereas MRs are expressed in epithelial tissues involved in electrolyte transport (i.e., the kidney, colon, salivary glands, and sweat glands) and in some nonepithelial tissues (e.g., hippocampus, heart, vasculature, and adipose tissue).

Aldosterone exerts its effects on Na⁺ and K⁺ homeostasis primarily via its actions on the principal cells of the distal renal tubules and collecting ducts, whereas effects on H⁺ secretion largely are exerted in the intercalated cells. The binding of aldosterone to the MRs in the kidney initiates a sequence of events that includes the rapid induction of *serum- and glucocorticoid-regulated kinase*, which in turn phosphorylates and activates amiloride-sensitive epithelial Na⁺ channels in the apical membrane. Thereafter, increased Na⁺ influx stimulates the Na⁺, K⁺-ATPase in the basolateral membrane. In addition to these rapid genomic actions, aldosterone increases the synthesis of the individual components of these membrane proteins as part of a more delayed effect.

Receptor-Independent Mechanism for Corticosteroid Specificity.

Aldosterone (a classic mineralocorticoid) and cortisol (generally viewed as predominantly glucocorticoid) bind the MRs with equal affinity. In epithelial cells of the kidney, colon, and salivary glands, aldosterone specifically activates MRs in the face of much higher circulating levels of glucocorticoids due to the coexpression of the type 2 isozyme of 11 β -HSD2. This enzyme metabolizes glucocorticoids such as cortisol to inactive 11-keto derivatives such as cortisone (Figure 46-6). Aldosterone escapes this inactivation and maintains mineralocorticoid activity because its predominant physiological form is the hemiacetal derivative that is resistant to 11 β -HSD action (Figure 46-7). In the absence of 11 β -HSD2, as occurs in the inherited disease *syndrome of apparent mineralocorticoid excess*, the MR is activated by cortisol, leading to severe

Figure 46-6 The 11 β -HSD confers specificity of corticosteroid action. 11 β -HSD2 converts cortisol, which binds to both the MR and the GR, to cortisone, which binds to neither MR nor GR, thereby protecting the MR from the high circulating concentrations of cortisol. This inactivation allows specific responses to aldosterone in sites such as the distal nephron. 11 β -HSD1 catalyzes the reverse reaction, which converts inactive cortisone to active cortisol in such tissues as liver and fat. Only ring C of the corticosteroid is depicted. Aldosterone is resistant to 11 β -HSD2 by virtue of the condensation of its 11 β -hydroxyl group with its 18-aldehyde to form a hemiacetal structure.

Figure 46-7 Structure and nomenclature of GR and MR agonists.

hypokalemia and mineralocorticoid-related hypertension. A state of mineralocorticoid excess also can be induced by inhibiting 11β -HSD with *glycyrrhizic acid*, a component of licorice implicated in licorice-induced hypertension.

Carbohydrate and Protein Metabolism

Glucocorticoids markedly affect carbohydrate and protein metabolism, which can be viewed as protecting glucose-dependent tissues (e.g., the brain and heart) from starvation. Glucocorticoids stimulate the liver to form glucose from amino acids and glycerol and to store glucose as glycogen. In the periphery, glucocorticoids diminish glucose utilization, increase protein breakdown and the synthesis of glutamine, and activate lipolysis, thereby providing amino acids and glycerol for gluconeogenesis. The net result is to increase blood glucose levels. Through their effects on glucose metabolism, glucocorticoids can worsen glycemic control in patients with overt diabetes and can precipitate the onset of hyperglycemia in susceptible patients.

Lipid Metabolism

Two effects of glucocorticoids on lipid metabolism are firmly established. The first is the dramatic redistribution of body fat that occurs in hypercortisolism, such as Cushing syndrome. In this setting, there is increased fat in the back of the neck (“buffalo hump”), face (“moon facies”), and supraclavicular area, coupled with a loss of fat in the extremities. The other is the permissive facilitation of the lipolytic effect of other agents, such as growth hormone and β adrenergic receptor agonists, resulting in an increase in free fatty acids after glucocorticoid administration.

Electrolyte and Water Balance

Aldosterone is by far the most potent endogenous corticosteroid with respect to fluid and electrolyte balance. Mineralocorticoids act on the distal tubules and collecting ducts of the kidney to enhance reabsorption of Na^+ from the tubular fluid; they also increase the urinary excretion of K^+ and H^+ . These actions on electrolyte transport, in the kidney and in other tissues (e.g., colon, salivary glands, and sweat glands), appear to account for the physiological and pharmacological activities that are characteristic of mineralocorticoids. Thus, the primary features of hyperaldosteronism are positive Na^+ balance with consequent expansion of extracellular fluid volume, normal or slight increases in plasma Na^+ concentration, normal or low plasma K^+ , and alkalosis. Mineralocorticoid deficiency, in contrast, leads to Na^+ wasting and contraction of the extracellular fluid volume, hyponatremia, hyperkalemia, and acidosis. Chronically, hyperaldosteronism causes hypertension, whereas aldosterone deficiency can lead to hypotension and vascular collapse.

Glucocorticoids also exert effects on fluid and electrolyte balance, largely due to permissive effects on tubular function and actions that maintain the glomerular filtration rate. Glucocorticoids play a permissive role in the renal excretion of free water. In part, the inability of patients with glucocorticoid deficiency to excrete free water results from the increased secretion of AVP, which stimulates water reabsorption in the kidney. In addition to their effects on monovalent cations and water, glucocorticoids exert multiple effects on Ca^{2+} metabolism, lowering Ca^{2+} uptake from the gut and increasing Ca^{2+} excretion by the kidney, collectively leading to decreased total body Ca^{2+} stores.

Cardiovascular System

The most striking effects of corticosteroids on the cardiovascular system result from mineralocorticoid-induced changes in renal Na^+ retention, as is evident in primary aldosteronism. MR activation has direct effects on the heart and vessel walls; aldosterone induces hypertension and interstitial cardiac fibrosis in animal models. The increased cardiac fibrosis appears to result from direct mineralocorticoid actions in the heart (Zannad and Radauceanu, 2005). The second major action of corticosteroids on the cardiovascular system is to enhance vascular reactivity to other vasoactive substances. Hypoadrenalism is associated with reduced responsiveness to vasoconstrictors such as NE and AngII, perhaps due to decreased expression of adrenergic receptors in the vascular wall. Conversely, hypertension is seen in patients with excessive glucocorticoid secretion, occurring in most patients with Cushing syndrome and in a subset of patients treated with synthetic glucocorticoids (even those lacking any significant mineralocorticoid action).

Skeletal Muscle

Permissive concentrations of corticosteroids are required for the normal function of skeletal muscle, and diminished work capacity is a prominent sign of adrenocortical insufficiency. In patients with Addison disease, weakness and fatigue are frequent symptoms. Excessive amounts of either glucocorticoids or mineralocorticoids also impair muscle function. In primary aldosteronism, muscle weakness results primarily from hypokalemia rather than from direct effects of mineralocorticoids on skeletal muscle. In contrast, glucocorticoid excess over prolonged periods, secondary to either glucocorticoid therapy or endogenous hypercortisolism, causes skeletal muscle wasting. This effect, *steroid myopathy*, accounts in part for weakness and fatigue in patients with glucocorticoid excess.

CNS

Corticosteroids exert a number of indirect effects on the CNS, through maintenance of blood pressure, plasma glucose concentrations, and electrolyte concentrations. Increasingly, direct effects of corticosteroids on the CNS have been recognized, including effects on mood, behavior, and brain excitability. Patients with adrenal insufficiency exhibit a diverse array of neurological manifestations, including apathy, depression, irritability, and even psychosis. Appropriate replacement therapy corrects these abnormalities. Conversely, glucocorticoid administration can induce multiple CNS reactions. Most patients respond with mood elevation, which may impart a sense of well-being despite the persistence of underlying disease. Some patients exhibit more pronounced behavioral changes, such as mania, insomnia, restlessness, and increased motor activity. A smaller but significant percentage of patients treated with glucocorticoids become anxious, depressed, or overtly psychotic. A high incidence of neuroses and psychoses is seen in patients with Cushing syndrome. These abnormalities usually disappear after cessation of glucocorticoid therapy or treatment of the Cushing syndrome.

Formed Elements of Blood

Glucocorticoids exert minor effects on hemoglobin and the erythrocyte content of blood, as evidenced by the frequent occurrence of polycythemia in Cushing syndrome and of normochromic, normocytic anemia

in adrenal insufficiency. More profound effects are seen in the setting of autoimmune hemolytic anemia, in which the immunosuppressive effects of glucocorticoids can diminish erythrocyte destruction.

Corticosteroids also affect circulating white blood cells. Addison disease is associated with an increased mass of lymphoid tissue and lymphocytosis; in contrast, Cushing syndrome is characterized by lymphocytopenia and a decreased mass of lymphoid tissue. The administration of glucocorticoids leads to a decreased number of circulating lymphocytes, eosinophils, monocytes, and basophils. A single dose of hydrocortisone leads to a decline of these circulating cells within 4–6 h; this effect persists for 24 h and results from the redistribution of cells away from the periphery rather than from increased destruction. In contrast, glucocorticoids increase circulating polymorphonuclear leukocytes as a result of increased release from the marrow, diminished rate of removal from the circulation, and decreased adherence to vascular walls. Finally, glucocorticoids are effective in the treatment of certain lymphoid malignancies, possibly related to the capacity of glucocorticoids to activate apoptosis.

Anti-inflammatory and Immunosuppressive Actions

In addition to their effects on lymphocyte number, glucocorticoids profoundly alter the immune responses of lymphocytes. These effects are important facets of the anti-inflammatory and immunosuppressive actions of the glucocorticoids. Although the use of glucocorticoids as anti-inflammatory agents does not address the underlying cause of the disease, the suppression of inflammation is of enormous clinical utility and has made these drugs among the most frequently prescribed agents. Similarly, glucocorticoids are of immense value in treating diseases that result from undesirable immune reactions. These diseases range from conditions that predominantly result from humoral immunity, such as urticaria (see Chapter 70), to those that are mediated by cellular immune mechanisms, such as transplantation rejection (see Chapter 35). The immunosuppressive and anti-inflammatory actions of glucocorticoids are inextricably linked, perhaps because they both involve inhibition of leukocyte functions.

Multiple mechanisms are involved in the suppression of inflammation by glucocorticoids. Glucocorticoids inhibit the production by multiple cells of factors that are critical in generating the inflammatory response. As a result, there is decreased release of vasoactive and chemoattractive factors, diminished secretion of lipolytic and proteolytic enzymes, decreased extravasation of leukocytes to areas of injury, and ultimately, decreased fibrosis. Glucocorticoids can also reduce expression of pro-inflammatory cytokines, as well as COX-2 and NOS2. Some of the cell types and mediators that are inhibited by glucocorticoids are summarized in Table 46–2.

Among the pro-inflammatory cytokines, IL-1, IL-6, and TNF- α stimulate the HPA axis, with IL-1 having the broadest range of actions. IL-1

stimulates the release of CRH by hypothalamic neurons, interacts directly with the pituitary to increase the release of ACTH, and may directly stimulate the adrenal gland to produce glucocorticoids. The increased production of glucocorticoids, in turn, profoundly inhibits the immune system at multiple sites as discussed previously. Thus, the HPA axis and the immune system are capable of bidirectional interactions in response to stress, and these interactions appear to be important for homeostasis (Turnbull and Rivier, 1999).

ADME

Absorption

Hydrocortisone and numerous congeners, including the synthetic analogues, are orally effective. Certain water-soluble esters of hydrocortisone and its synthetic congeners are administered intravenously to achieve high concentrations of drug rapidly in systemic or targeted body fluids. More prolonged effects are obtained by intramuscular injection of suspensions of hydrocortisone, its esters, and congeners. Minor changes in chemical structure may markedly alter the rate of absorption, time of onset of effect, and duration of action. Glucocorticoids also are absorbed systemically from sites of local administration, such as synovial spaces, the conjunctival sac, skin, and respiratory tract. When administration is prolonged, when the site of application is covered with an occlusive dressing, or when large areas of skin are involved, absorption may be sufficient to cause systemic effects, including suppression of the HPA axis.

Distribution, Metabolism, and Excretion

After absorption, 90% or more of cortisol in plasma is reversibly bound to protein under normal circumstances. In most tissues, only the fraction of corticosteroid that is unbound is active and can enter cells. Two plasma proteins account for almost all of the steroid-binding capacity: CBG (also called *transcortin*) and *albumin*. CBG is an α -globulin secreted by the liver that has high affinity for steroids (dissociation constant of ~ 1 nM) but relatively low total binding capacity, whereas albumin, also produced by the liver, has a relatively large binding capacity but low affinity (estimated dissociation constant of 1 mM). In tissues with prolonged capillary transit time (e.g., liver, spleen), steroid dissociates from albumin. At high steroid concentrations, the capacity of CBG binding is exceeded, and a slightly greater fraction of the steroid exists in the free state. CBG has relatively high affinity for cortisol and some of its synthetic congeners and low affinity for aldosterone and glucuronide-conjugated steroid metabolites; thus, greater percentages of these last steroids are found in the free form. A special state of physiological hypercortisolism occurs during pregnancy. The elevated circulating estrogen levels induce CBG production, and CBG and total plasma cortisol increase several-fold; the physiological significance of these changes remains to be established.

TABLE 46–2 ■ INHIBITORY EFFECTS OF GLUCOCORTICOIDS ON INFLAMMATORY/IMMUNE RESPONSES

CELL TYPE	FACTOR INHIBITED	COMMENTS
Macrophages and monocytes	Arachidonic acid, PGs, and LTs Cytokines: IL-1, IL-6, and TNF- α Acute phase reactants	Mediated by glucocorticoid inhibition of COX-2 and PLA ₂ . Production and release are blocked; cytokines exert multiple effects on inflammation (e.g., \uparrow T cells, \uparrow fibroblast proliferation). Including the third component of complement.
Endothelial cells	ELAM-1 and ICAM-1 Acute-phase reactants Cytokines (e.g., IL-1) Arachidonic acid derivatives	ELAM-1 and ICAM-1 are critical for leukocyte localization. Same as above for macrophages and monocytes.
Basophils	Histamine, LTC ₄	IgE-dependent release \downarrow by glucocorticoids.
Fibroblasts	Arachidonic acid metabolites	Same as above for macrophages and monocytes. Glucocorticoids \downarrow growth factor-induced DNA synthesis and fibroblast proliferation.
Lymphocytes	Cytokines (IL-1, IL-2, IL-3, IL-6, TNF- α , GM-CSF, interferon γ)	Same as above for macrophages and monocytes.

The aldosterone levels also rise 3- to 10-fold in pregnancy, reflecting the activity of the elevated progesterone plasma levels as an MR antagonist. Because progesterone is also a GR antagonist, it may contribute to the elevated levels of cortisol.

As a general rule, the metabolism of steroid hormones involves sequential additions of O or H atoms, followed by conjugation to form water-soluble derivatives. Reduction of the 4,5 double bond (Figure 46-3) occurs at both hepatic and extrahepatic sites, yielding inactive compounds. Subsequent reduction of the 3-ketone substituent to the 3-hydroxyl derivative, forming tetrahydrocortisol, occurs only in the liver. Most of these A ring-reduced steroids are conjugated through the 3-hydroxyl group with sulfate or glucuronide by enzymatic reactions that take place in the liver and, to a lesser extent, in the kidney. The resultant sulfate esters and glucuronides are water soluble and are excreted in urine. Neither biliary nor fecal excretion is of quantitative importance in humans.

Synthetic steroids with an 11-keto group, such as cortisone and prednisone, must be enzymatically reduced to the corresponding 11 β -hydroxy derivative before they are biologically active (Figure 46-6). The type 1 isozyme of 11 β -HSD (11 β -HSD1) catalyzes this reduction, predominantly in the liver, but also in specialized sites such as adipocytes, bone, eye, and skin. In settings in which this enzymatic activity is impaired, it is prudent to use steroids that do not require enzymatic activation (e.g., hydrocortisone or prednisolone rather than cortisone or prednisone). Such settings include individuals with severe hepatic failure and patients with the very rare condition of cortisone reductase deficiency.

Structure-Activity Relationships

Chemical modifications of the cortisol molecule have generated derivatives with greater separation of glucocorticoid and mineralocorticoid activity (Table 46-3); for a number of synthetic glucocorticoids, the effects on electrolytes are minimal even at the highest doses used. In addition, these modifications have led to derivatives with greater potencies and with longer durations of action. A vast array of steroid preparations is available for oral, parenteral, and topical use. Some of these are summarized in Table 46-4. None of these currently available derivatives effectively separates anti-inflammatory effects from effects on carbohydrate, protein, and fat metabolism or from suppressive effects on the HPA axis.

Estimates of Na⁺-retaining and anti-inflammatory potencies of representative steroids are listed in Table 46-3. Some steroids that are classified predominantly as glucocorticoids (e.g., cortisol) also possess modest but significant mineralocorticoid activity and thus may affect fluid and electrolyte handling in the clinical setting. At doses used for replacement therapy in patients with primary adrenal insufficiency, the mineralocorticoid effects of these “glucocorticoids” are insufficient to replace that of

aldosterone, and concurrent therapy with a more potent mineralocorticoid generally is needed. In contrast, aldosterone is exceedingly potent with respect to Na⁺ retention but has only minimal effects on carbohydrate metabolism. Even at levels that maximally affect electrolyte balance, aldosterone has no significant glucocorticoid activity and thus acts as a pure mineralocorticoid.

Toxicity of Adrenocortical Steroids

Two categories of toxic effects result from the therapeutic use of glucocorticoids: those resulting from withdrawal of steroid therapy and those resulting from continued use at supraphysiological doses. The side effects from both categories are potentially life threatening and require a careful assessment of the risks and benefits in each patient.

Withdrawal Therapy

The most frequent problem in steroid withdrawal is flare-up of the underlying disease for which steroids were prescribed. Several other complications are associated with steroid withdrawal. The most severe, acute adrenal insufficiency, results from overly rapid withdrawal of corticosteroids after prolonged therapy has suppressed the HPA axis. Many patients recover from glucocorticoid-induced HPA suppression within several weeks to months; however, in some individuals the time to full recovery can be a year or longer.

Protocols for discontinuing corticosteroid therapy in patients receiving long-term treatment have been proposed. Patients who have received supraphysiological doses of glucocorticoids for a period of 2–4 weeks within the preceding year should be considered to have some degree of HPA impairment. A characteristic glucocorticoid withdrawal syndrome consists of fever, myalgia, arthralgia, and malaise, which may be difficult to differentiate from some of the underlying diseases for which steroid therapy was instituted. Finally, *pseudotumor cerebri*, a clinical syndrome that includes increased intracranial pressure with papilledema, is a rare condition that sometimes is associated with reduction or withdrawal of corticosteroid therapy.

Continued Use of Supraphysiological Glucocorticoid Doses

Besides the consequences that result from the suppression of the HPA axis, a number of other complications result from prolonged therapy with glucocorticoids. These include fluid and electrolyte abnormalities, hypertension, hyperglycemia, increased susceptibility to infection, peptic ulcers, osteoporosis, myopathy, behavioral disturbances, cataracts, growth arrest, and the characteristic habitus of steroid overdose, including fat redistribution, striae, and ecchymoses.

Fluid and Electrolyte Handling. Alterations in fluid and electrolyte handling can cause hypokalemic alkalosis and hypertension, particularly

TABLE 46-3 ■ RELATIVE POTENCIES AND EQUIVALENT DOSES OF REPRESENTATIVE CORTICOSTEROIDS

COMPOUND	ANTI-INFLAMMATORY POTENCY	NA ⁺ -RETAINING POTENCY	DURATION OF ACTION ^a	EQUIVALENT DOSE (MG) ^b
Hydrocortisone ^c	1	1	S	20
Cortisone	0.8	0.8	S	25
Fludrocortisone	10	125	I	— ^d
Prednisone	4	0.8	I	5
Prednisolone	4	0.8	I	5
Methylprednisolone	5	0.5	I	4
Triamcinolone	5	0	I	4
Betamethasone	25	0	L	0.75
Dexamethasone	25	0	L	0.75

^aBiological $t_{1/2}$: S, short (8–12 h); I, intermediate (12–36 h); L, long (36–72 h).

^bDose relationships apply only to oral or intravenous administration; potencies may differ greatly following intramuscular or intra-articular administration.

^cThe name for cortisol when used as a drug.

^dThis agent is used for its mineralocorticoid effects, not for glucocorticoid effects.

TABLE 46-4 ■ AVAILABLE PREPARATIONS OF ADRENOCORTICAL STEROIDS AND THEIR SYNTHETIC ANALOGUES

NONPROPRIETARY NAME	TYPE OF PREPARATION
Alclometasone dipropionate	Topical
Amcinonide	Topical
Beclomethasone dipropionate	Inhaled, Nasal
Betamethasone acetate	Injectable
Betamethasone sodium phosphate	Oral, injectable
Betamethasone valerate	Topical
Budesonide	Oral, inhaled, nasal, rectal
Ciclesonide	Inhaled, nasal
Clobetasol propionate	Topical, shampoo
Clocortolone pivalate	Topical
Desonide	Topical
Desoximetasone	Topical
Dexamethasone	Oralophthalmic, ocular implant
Dexamethasone sodium phosphate	Ophthalmic, injectable
Diflorasone diacetate	Topical
Fludrocortisone acetate ^a	Oral
Flunisolide	Inhaled Nasal
Fluocinolone acetonide	Topical, shampoo, otic, intravitreal implant
Fluocinonide	Topical
Fluorometholone	Ophthalmic
Fluorometholone acetate	Ophthalmic
Flurandrenolide	Impregnated dressing, topical
Halcinonide	Topical
Hydrocortisone	Topical, oral, rectal
Hydroxycortisone acetate	Topical, rectal
Hydroxycortisone butyrate	Topical
Hydrocortisone probutate	Topical
Hydrocortisone sodium succinate	Injectable
Hydrocortisone valerate	Topical
Methylprednisolone	Oral
Methylprednisolone acetate	Injectable
Methylprednisolone sodium succinate	Injectable
Mometasone furoate	Inhaled, nasal, topical
Prednisolone	Oral
Prednisolone acetate	Oral, ophthalmic
Prednisolone sodium phosphate	Oral, ophthalmic
Prednisone	Oral
Triamcinolone acetonide	Nasal, topical, injectable, dental
Triamcinolone hexacetonide	Injectable

Note: *Topical* preparations include agents for application to skin or mucous membranes in creams, solutions, ointments, gels, pastes (for oral lesions), and aerosols; *ophthalmic* preparations include solutions, suspensions, and ointments; *inhalation* preparations include agents for nasal or oral inhalation.

^aFludrocortisone acetate is intended for use as a mineralocorticoid.

in patients with primary hyperaldosteronism secondary to an adrenal adenoma or in patients treated with potent mineralocorticoids. Similarly, hypertension is a relatively common manifestation of exogenous glucocorticoid administration, even in patients treated with glucocorticoids lacking appreciable mineralocorticoid activity.

Metabolic Changes. The effects of glucocorticoids on intermediary metabolism were described previously. Hyperglycemia with glycosuria usually can be managed with diet or insulin, and its occurrence should not be a major factor in the decision to continue corticosteroid therapy or to initiate therapy in diabetic patients.

Immune Responses. Because of their multiple effects to inhibit the immune system and the inflammatory response, glucocorticoid use is associated with an increased susceptibility to infection and a risk for reactivation of latent tuberculosis. In the presence of known infections of some consequence, glucocorticoids should be administered only if absolutely necessary and concomitantly with appropriate and effective antimicrobial or antifungal therapy.

Possible Risk of Peptic Ulcers. There is considerable debate about the association between peptic ulcers and glucocorticoid therapy. The possible onset of hemorrhage and perforation in these ulcers and their insidious onset make peptic ulcers a serious therapeutic problem (Chapter 49). Prudence suggests vigilance for peptic ulcer formation in patients receiving therapy with corticosteroids, especially if administered concomitantly with aspirin or coxibs.

Myopathy. Myopathy, characterized by weakness of proximal limb muscles, can occur in patients taking large doses of corticosteroids and also is part of the clinical picture in patients with endogenous Cushing syndrome. It can be of sufficient severity to impair ambulation and is an indication for withdrawal of therapy. Attention also has focused on steroid myopathy of the respiratory muscles in patients with asthma or chronic obstructive pulmonary disease (Chapter 40); this complication can diminish respiratory function. Recovery from the steroid myopathies may be slow and incomplete.

Behavioral Changes. Behavioral disturbances are common after administration of corticosteroids and in patients who have Cushing syndrome secondary to endogenous hypercorticism; these disturbances may take many forms, including nervousness, insomnia, changes in mood or psyche, and overt psychosis.

Cataracts. Cataracts are a well-established complication of glucocorticoid therapy and are related to dosage and duration of therapy. Children appear to be particularly at risk. Cessation of therapy may not lead to complete resolution of opacities, and the cataracts may progress despite reduction or cessation of therapy. Patients on long-term glucocorticoid therapy at prednisone doses of 10–15 mg/d or greater should receive periodic slit-lamp examinations to detect glucocorticoid-induced posterior subcapsular cataracts.

Osteoporosis. Osteoporosis, a frequent serious complication of glucocorticoid therapy, occurs in patients of both genders and all ages and is related to dosage and duration of therapy. About 30%–50% of all patients who receive chronic glucocorticoid therapy ultimately will develop osteoporotic fractures. Glucocorticoids preferentially affect trabecular bone and the cortical rim of the vertebral bodies; the ribs and vertebrae are the most frequent sites of fracture. Glucocorticoids decrease bone density by multiple mechanisms, including inhibition of gonadal steroid hormones, diminished GI absorption of Ca^{2+} , and inhibition of bone formation due to suppressive effects on osteoblasts and stimulation of resorption by osteoclasts via changes in the production of osteoprotegerin and RANK ligand (see Chapter 48). In addition, glucocorticoid inhibition of intestinal Ca^{2+} uptake may lead to secondary increases in parathyroid hormone, thereby increasing bone resorption.

The initiation of glucocorticoid therapy at 5 mg/d or more of prednisone (or its equivalent) for 3 months or longer is an indication for bone densitometry to detect abnormalities in trabecular bone. Because bone loss associated with glucocorticoids predominantly occurs within the first

6 months of therapy, densitometric evaluation of the lumbar spine and hip, along with prophylactic measures, should be initiated. Most authorities advocate maintaining a Ca^{2+} intake of 1500 mg/d by diet plus Ca^{2+} supplementation and vitamin D intake of 800 IU/d, assuming that these measures do not increase urinary calcium excretion above the normal range. An important advance in the prevention of glucocorticoid-related osteoporosis is the successful use of bisphosphonates (e.g., risedronate and zoledronic acid), which have been shown to decrease the decline in bone density and the incidence of fractures in patients receiving glucocorticoid therapy. Additional discussion of these issues is found in Chapters 44 and 48.

Osteonecrosis. Osteonecrosis (also known as avascular or aseptic necrosis) is a relatively common complication of glucocorticoid therapy. The femoral head is affected most frequently, but this process also may affect the humeral head and distal femur. Joint pain and stiffness usually are the earliest symptoms, and this diagnosis should be considered in patients receiving glucocorticoids who abruptly develop hip, shoulder, or knee pain. Although the risk increases with the duration and dose of glucocorticoid therapy, osteonecrosis also can occur when high doses of glucocorticoids are given for short periods of time. Osteonecrosis generally progresses, and most affected patients ultimately require joint replacement.

Regulation of Growth and Development. Growth retardation in children can result from administration of relatively small doses of glucocorticoids. Although the precise mechanism is unknown, there are reports that collagen synthesis and linear growth in these children can be restored by (off-label) treatment with growth hormone; further studies are needed to define the role of concurrent treatment with growth hormone in this setting. In experimental animals, antenatal exposure to glucocorticoids is clearly linked to cleft palate and altered neuronal development, ultimately resulting in complex behavioral abnormalities. The actions of glucocorticoids to promote cellular differentiation play important physiological roles in human development in late gestation and in the neonatal period (e.g., production of pulmonary surfactant and induction of hepatic gluconeogenic enzymes); those actions notwithstanding, antenatal steroids may lead to subtle abnormalities in fetal development. Babies born to women receiving large doses of corticosteroids during pregnancy should be monitored for signs of adrenal insufficiency and appropriate therapy initiated, if necessary.

Therapeutic Uses and Diagnostic Applications in Endocrine Diseases

With the exception of replacement therapy in deficiency states, the use of glucocorticoids largely is empirical. Given the number and severity of potential side effects, the decision to institute therapy with glucocorticoids always requires careful consideration of the relative risks and benefits in each patient. For any disease and in any patient, the optimal dose to achieve a given therapeutic effect must be determined by trial and error and periodic reevaluation as the activity of the underlying disease changes or as complications of therapy arise. *A single dose of glucocorticoid, even a large one, is virtually without harmful effects, and a short course of therapy (up to 1 week), in the absence of specific contraindications, is unlikely to be harmful. As the duration of glucocorticoid therapy is increased beyond 1 week, there are time- and dose-related increases in the incidence of disabling and potentially lethal effects.* Except in patients receiving replacement therapy, glucocorticoids are neither specific nor curative; rather, they are palliative by virtue of their anti-inflammatory and immunosuppressive actions. Finally, *abrupt cessation of glucocorticoids after prolonged therapy is associated with the risk of adrenal insufficiency, which may be fatal.*

When glucocorticoids are to be given over long periods, the dose, determined empirically, must be the lowest that will achieve the desired effect. When the therapeutic goal is relief of painful or distressing symptoms not associated with an immediately life-threatening disease, complete relief is not sought, and the steroid dose is reduced gradually until worsening symptoms indicate that the minimal acceptable dose has been found. Where possible, the substitution of other medications, such as nonsteroidal anti-inflammatory drugs, may facilitate tapering the glucocorticoid

dose once the initial benefit of therapy has been achieved. When therapy is directed at a life-threatening disease (e.g., pemphigus or lupus cerebritis), the initial dose should be a large one aimed at achieving rapid control of the crisis. If some benefit is not observed quickly, then the dose should be doubled or tripled. After initial control in a potentially lethal disease, dose reduction should be carried out under conditions that permit frequent accurate observations of the patient.

The lack of demonstrated deleterious effects of a single dose of glucocorticoids within the conventional therapeutic range justifies their administration to critically ill patients who may have adrenal insufficiency. If the underlying condition does result from deficiency of glucocorticoids, then a single intravenous injection of a soluble glucocorticoid may prevent immediate death and allow time for a definitive diagnosis. If the underlying disease is not adrenal insufficiency, the single dose will not harm the patient. Long courses of therapy at high doses should be reserved for life-threatening disease.

To diminish HPA axis suppression, the intermediate-acting steroid preparations (e.g., prednisone or prednisolone) should be given in the morning as a single dose. Alternate-day therapy with the same glucocorticoids is employed for patients who obtain adequate therapeutic responses on this regimen. Alternatively, pulse therapy with higher glucocorticoid doses (e.g., doses as high as 1–1.5 g/d IV of methylprednisolone for 3 days) frequently is used to initiate therapy in patients with fulminant, immunologically related disorders, such as acute exacerbations of multiple sclerosis, acute transplantation rejection, necrotizing glomerulonephritis, and lupus nephritis.

Replacement Therapy for Adrenal Insufficiency

Adrenal insufficiency can result from structural or functional lesions of the adrenal cortex (primary adrenal insufficiency or Addison disease) or from structural or functional lesions of the anterior pituitary or hypothalamus (secondary adrenal insufficiency). In developed countries, primary adrenal insufficiency most frequently is secondary to autoimmune adrenal disease, whereas tuberculous adrenalitis is the most frequent etiology in developing countries. Other causes include adrenalectomy, bilateral adrenal hemorrhage, neoplastic infiltration of the adrenal glands, AIDS, inherited disorders of the steroidogenic enzymes, and X-linked adrenoleukodystrophy. Secondary adrenal insufficiency resulting from pituitary or hypothalamic dysfunction generally presents in a more insidious manner than does the primary disorder, probably because mineralocorticoid biosynthesis is preserved.

Acute Adrenal Insufficiency. The life-threatening disease of acute adrenal insufficiency is characterized by GI symptoms (nausea, vomiting, and abdominal pain), dehydration, hyponatremia, hyperkalemia, weakness, lethargy, and hypotension. It usually is associated with disorders of the adrenal rather than the pituitary or hypothalamus and sometimes follows abrupt withdrawal of glucocorticoids used at high doses or for prolonged periods.

The immediate management of patients with acute adrenal insufficiency includes intravenous therapy with isotonic NaCl solution supplemented with 5% glucose and corticosteroids and appropriate therapy for precipitating causes such as infection, trauma, or hemorrhage. Because cardiac function often is reduced in the setting of adrenocortical insufficiency, the patient should be monitored for evidence of volume overload, such as rising central venous pressure or pulmonary edema. After an initial intravenous bolus of 100 mg, hydrocortisone should be given by continuous infusion at a rate of 50–100 mg every 8 h, a dose that confers sufficient mineralocorticoid activity to meet all requirements. As the patient stabilizes, the hydrocortisone dose may be decreased to 25 mg every 6–8 h. Thereafter, patients are treated in the same fashion as those with chronic adrenal insufficiency. For the initial management of unconfirmed acute adrenal insufficiency, 4 mg of dexamethasone sodium phosphate can be substituted for hydrocortisone; dexamethasone does not cross-react in the cortisol assay and will not interfere with the measurement of cortisol (either basally or in response to the cosyntropin [ACTH] stimulation test). Failure to respond to cosyntropin in this setting is diagnostic of adrenal insufficiency.

Chronic Adrenal Insufficiency. Patients with chronic adrenal insufficiency present with many of the same manifestations seen in adrenal crisis but with lesser severity. These patients require daily treatment with corticosteroids. The adequacy of corticosteroid replacement therapy is judged by clinical criteria and biochemical measurements. The subjective well-being of the patient is an important clinical parameter in primary and secondary disease. In primary adrenal insufficiency, the disappearance of hyperpigmentation and the resolution of electrolyte abnormalities are valuable indicators of adequate replacement. Overtreatment may cause manifestations of Cushing syndrome in adults and decreased linear growth in children. Plasma ACTH levels may be used to monitor therapy in patients with primary adrenal insufficiency; the early-morning ACTH level should not be suppressed but should be less than 100 pg/mL (22 pmol/L).

Traditional replacement regimens have used hydrocortisone in doses of 20–30 mg/d; however, some authorities use lower doses of 15–20 mg/d based on estimates of daily rates of cortisol production (Table 46–1). *Cortisone acetate*, which is inactive until converted to cortisol by 11 β -HSD1, also has been used in doses ranging from 25 to 37.5 mg/d. In an effort to mimic the normal diurnal rhythm of cortisol secretion, these glucocorticoids generally have been given in divided doses, with two-thirds of the dose given in the morning and one-third given in the afternoon. Although some patients with primary adrenal insufficiency can be maintained on hydrocortisone and liberal salt intake, most of these patients also require mineralocorticoid replacement; fludrocortisone acetate generally is used in doses of 0.05–0.2 mg/d. In secondary adrenal insufficiency, the administration of a glucocorticoid alone is generally adequate because the zona glomerulosa, which makes mineralocorticoids, is usually intact.

When initiating treatment in patients with panhypopituitarism, administer glucocorticoids before initiating treatment with thyroid hormone because the administration of thyroid hormone may precipitate acute adrenal insufficiency by increasing the metabolism of cortisol. Dexamethasone and prednisone also have been used as chronic replacement therapy; however, careful monitoring for hypercorticism is required due to their increased potency and longer durations of action.

Standard doses of glucocorticoids often must be adjusted upward in patients who also are taking drugs that increase their metabolic clearance (e.g., phenytoin, barbiturates, or rifampin) or who suffer the stress of intercurrent illness. *All patients with adrenal insufficiency should wear a medical alert bracelet or tag that lists their diagnosis and carries information about their steroid regimen.* During minor illness, the glucocorticoid dose should be doubled. The patient and family members should also be trained to administer parenteral dexamethasone (4 mg intramuscularly) in the event that severe nausea or vomiting precludes the oral administration of medications; they then should seek medical attention immediately. Glucocorticoid doses also are adjusted when patients with adrenal insufficiency undergo surgery. In this setting, the doses are designed to approximate or exceed the maximal cortisol secretory rate of 200 mg/d; a standard regimen is hydrocortisone 100 mg parenterally every 8 h. Following surgery, the dose is halved each day until it is reduced to routine maintenance levels.

Congenital Adrenal Hyperplasia. CAH is a group of genetic disorders in which there is a deficiency in the activity of one of several enzymes required for the biosynthesis of glucocorticoids. The impaired production of cortisol and the consequent lack of negative-feedback inhibition lead to increased release of ACTH. As a result, other hormonally active steroids that are proximal to the enzymatic block in the steroidogenic pathway are produced in excess. CAH includes a spectrum of disorders for which precise clinical presentation, laboratory findings, and treatment depend on which of the steroidogenic enzymes is deficient. In about 90% of patients, CAH results from mutations in CYP21, the enzyme that carries out the 21-hydroxylation reaction (see Figure 46–3).

Clinically, patients are divided into those with classic CAH, who have severe defects in enzymatic activity and first present during childhood, and those with nonclassic CAH, who present after puberty with signs and symptoms of mild androgen excess, such as hirsutism, amenorrhea, infertility, and acne. Female patients with classic CAH frequently are born with virilized external genitalia (female pseudohermaphroditism) that result

from elevated production of adrenal androgen precursors at critical stages of sexual differentiation in utero and often require reconstructive genital surgery. Some medical centers have experimented with dexamethasone administration in utero with success; however, this approach is highly controversial because of concerns regarding abnormal behavioral development after prenatal exposure to glucocorticoids (Miller and Witchel, 2013). Males appear normal at birth and later may have precocious development of secondary sexual characteristics (isosexual precocious puberty). In both sexes, linear growth is accelerated in childhood, but the adult height is reduced by premature closure of the epiphyses. Some patients with classical CAH are unable to conserve Na⁺ normally and thus are called “salt wasters.”

All patients with classical CAH require replacement therapy with hydrocortisone or a suitable congener, and those with salt wasting also require mineralocorticoid replacement. The goals of therapy are to restore levels of physiological steroid hormones to the normal range and to suppress ACTH and thereby abrogate the effects of overproduction of adrenal androgens. The typical oral dose of hydrocortisone is about 0.6 mg/kg daily in two or three divided doses. The mineralocorticoid used is fludrocortisone acetate (0.05–0.2 mg/d). Many experts also administer table salt to infants (one-fifth of a teaspoon dissolved in formula daily) until the child is eating solid food. Therapy is guided by gain in weight and height, by plasma levels of 17-hydroxyprogesterone, and by blood pressure. Elevated plasma renin activity suggests that the patient is receiving an inadequate dose of mineralocorticoid. Sudden spurts in linear growth often indicate inadequate pituitary suppression and excessive androgen secretion, whereas growth failure suggests overtreatment with glucocorticoid.

Diagnostic Applications of Dexamethasone

In addition to its therapeutic uses, dexamethasone is used as a first-line agent to diagnose hypercortisolism and to differentiate among the different causes of Cushing syndrome (Arnaldi et al., 2003). To determine if patients with clinical manifestations suggestive of hypercortisolism have biochemical evidence of increased cortisol biosynthesis, an overnight dexamethasone suppression test has been devised. Patients are given 1 mg of dexamethasone orally at 11 PM, and cortisol is measured at 8 AM the following morning. Suppression of plasma cortisol to less than 1.8 μ g/dL suggests strongly that the patient does not have Cushing syndrome. Drugs such as barbiturates that enhance dexamethasone metabolism or drugs (estrogens) or conditions (pregnancy) that increase the concentrations of CBG can interfere with suppression and compromise the test.

The formal dexamethasone suppression test is used in the differential diagnosis of biochemically documented Cushing syndrome. Following determination of baseline cortisol levels for 48 h, dexamethasone (0.5 mg every 6 h) is administered orally for 48 h. This dose markedly suppresses cortisol levels in normal subjects, including those who have nonspecific elevations of cortisol due to obesity or stress, but it does not suppress levels in patients with Cushing syndrome. In the high-dose phase of the test, dexamethasone is administered orally at 2 mg every 6 h for 48 h. Patients with pituitary-dependent Cushing syndrome (i.e., Cushing disease) generally respond with decreased cortisol levels. In contrast, patients with ectopic production of ACTH or with adrenocortical tumors generally do not exhibit decreased cortisol levels. Despite these generalities, dexamethasone may suppress cortisol levels in some patients with ectopic ACTH production, particularly with tumors such as bronchial carcinoids, and many experts prefer to use inferior petrosal sinus sampling after CRH administration to make this distinction.

Therapeutic Uses in Nonendocrine Diseases

There are important uses of glucocorticoids in diseases that do not directly involve the HPA axis. The disorders discussed next illustrate the principles governing glucocorticoid use in selected diseases. The dosage of glucocorticoids varies considerably depending on the nature and severity of the underlying disorder. Approximate doses of a representative glucocorticoid (e.g., prednisone) are provided.

Rheumatic Disorders

Glucocorticoids are used widely in the treatment of rheumatic disorders and are a mainstay in the treatment of the more serious inflammatory

rheumatic diseases, such as systemic lupus erythematosus, and a variety of vasculitic disorders, such as polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss syndrome, and giant cell arteritis. For these more serious disorders, the starting dose of glucocorticoids should be sufficient to suppress the disease rapidly and minimize resultant tissue damage. Initially, prednisone (1 mg/kg/d in divided doses) often is used, generally followed by consolidation to a single daily dose, with subsequent tapering to a minimal effective dose as determined by the clinical picture.

Glucocorticoids are often used in conjunction with other immunosuppressive agents such as cyclophosphamide and methotrexate, which offer better long-term control than steroids alone. The exception is giant cell arteritis, for which glucocorticoids remain superior to other agents. Caution should be exercised in the use of glucocorticoids in some forms of vasculitis (e.g., polyarteritis nodosa), for which underlying infections with hepatitis viruses may play a pathogenetic role. Intermediate-acting glucocorticoids, such as prednisone and prednisolone, are generally preferred over longer-acting steroids such as dexamethasone.

In rheumatoid arthritis, because of the serious and debilitating side effects associated with their chronic use, glucocorticoids are used as stabilizing agents for progressive disease that fails to respond to first-line treatments such as physiotherapy and nonsteroidal anti-inflammatory drugs. In this case, glucocorticoids provide relief until other, slower-acting antirheumatic drugs (e.g., methotrexate or agents targeted at TNF) take effect. A typical starting dose is 5–10 mg of prednisone per day. In the setting of an acute exacerbation, higher doses of glucocorticoids may be employed (typically 20–40 mg/d of prednisone or equivalent), with rapid taper thereafter. Alternatively, patients with major symptomatology confined to one or a few joints may be treated with intra-articular steroid injections. Depending on joint size, typical doses are 5–20 mg of the very long-lasting triamcinolone acetonide or its equivalent.

In noninflammatory degenerative joint diseases (e.g., osteoarthritis) or in a variety of regional pain syndromes (e.g., tendinitis or bursitis), glucocorticoids may be administered by local injection for the treatment of episodic disease flare-up. It is important to use a glucocorticoid that does not require bioactivation (e.g., prednisolone rather than prednisone) and to minimize the frequency of local steroid administration whenever possible. In the case of repeated intra-articular injection of steroids, there is a significant incidence of painless joint destruction, resembling Charcot arthropathy. It is recommended that intra-articular injections be performed with intervals of at least 3 months to minimize complications.

Renal Diseases

Patients with nephrotic syndrome secondary to minimal change disease generally respond well to steroid therapy, and glucocorticoids are the first-line treatment in both adults and children. Initial daily doses of prednisone are 1–2 mg/kg for 6 weeks, followed by a gradual tapering of the dose over 6–8 weeks, although some nephrologists advocate alternate-day therapy. Objective evidence of response, such as diminished proteinuria, is seen within 2–3 weeks in 85% of patients, and more than 95% of patients enter remission within 3 months. Patients with renal disease secondary to systemic lupus erythematosus also are generally given a therapeutic trial of glucocorticoids. In the case of membranous glomerulonephritis, many nephrologists recommend a trial of alternate-day glucocorticoids for 8–10 weeks (e.g., prednisone 120 mg every other day), followed by a 1- to 2-month period of tapering.

Allergic Diseases

The onset of action of glucocorticoids in allergic diseases is delayed, and patients with severe allergic reactions such as anaphylaxis require immediate therapy with epinephrine. The manifestations of allergic diseases of limited duration—such as hay fever, serum sickness, urticaria, contact dermatitis, drug reactions, bee stings, and angioneurotic edema—can be suppressed by adequate doses of glucocorticoids given as supplements to the primary therapy. In severe disease, intravenous glucocorticoids (methylprednisolone 125 mg IV every 6 h or equivalent) are appropriate. For allergic rhinitis, many experts recommend intranasal steroids.

Pulmonary Diseases

The use of glucocorticoids in bronchial asthma and other pulmonary diseases is discussed in Chapter 40. Antenatal glucocorticoids are used

frequently in the setting of premature labor, decreasing the incidence of respiratory distress syndrome, intraventricular hemorrhage, and death in infants delivered prematurely. Betamethasone (12 mg IM every 24 h for two doses) or dexamethasone (6 mg IM every 12 h for four doses) is administered to women with definitive signs of premature labor between 26 and 34 weeks of gestation. For women still at risk of preterm birth 7 or more days after receiving the initial glucocorticoid dose, a meta-analysis of 10 randomized clinical trials involving over 4730 women and 5700 infants showed that a second course of treatment reduced the risk of respiratory distress syndrome and serious neonatal morbidity without adverse effects in infants followed for 2 to 3 years after (McKinlay et al., 2012).

Infectious Diseases

Although the use of immunosuppressive glucocorticoids in infectious diseases may seem paradoxical, there are a limited number of settings in which they are indicated in the therapy of specific infectious pathogens. One example is in patients with AIDS with *Pneumocystis carinii* pneumonia and moderate-to-severe hypoxia; addition of glucocorticoids to the antibiotic regimen increases oxygenation and lowers the incidence of respiratory failure and mortality. Similarly, glucocorticoids clearly decrease the incidence of long-term neurological impairment associated with *Haemophilus influenzae* type b meningitis in infants and children 2 months of age or older.

Ocular Diseases

Glucocorticoids frequently are used to suppress inflammation in the eye and can preserve sight when used properly. They are administered topically for diseases of the outer eye and anterior segment and attain therapeutic concentrations in the aqueous humor after instillation into the conjunctival sac. For diseases of the posterior segment, intraocular injection or systemic administration is required. These uses of glucocorticoids are discussed in Chapter 69.

Skin Diseases

Glucocorticoids are remarkably efficacious in the treatment of a wide variety of inflammatory dermatoses. A typical regimen for an eczematous eruption is 1% hydrocortisone ointment applied locally twice daily. Effectiveness is enhanced by application of the topical steroid under an occlusive film, such as plastic wrap; unfortunately, the risk of systemic absorption also is increased by occlusive dressings, and this can be a significant problem when the more potent glucocorticoids are applied to inflamed skin. Glucocorticoids are administered systemically for severe episodes of acute dermatological disorders and for exacerbations of chronic disorders. The dose in these settings is usually 40 mg/d of prednisone. Systemic steroid administration can be lifesaving in pemphigus, which may require daily doses of up to 120 mg of prednisone. Chapter 70 presents the dermatologic uses of glucocorticoids.

Gastrointestinal Diseases

Patients with inflammatory bowel disease (chronic ulcerative colitis and Crohn disease) who fail to respond to more conservative management (i.e., rest, diet, and sulfasalazine) may benefit from glucocorticoids; steroids are most useful for acute exacerbations (see Chapter 51).

Hepatic Diseases

The use of corticosteroids in hepatic disease has been controversial. Glucocorticoids clearly are of benefit in autoimmune hepatitis; as many as 80% of patients show histological remission when treated with prednisone (40–60 mg daily initially, with tapering to a maintenance dose of 7.5–10 mg daily after serum transaminase levels fall). The role of corticosteroids in alcoholic liver disease is not fully defined; the most recent meta-analyses did not support a beneficial role of corticosteroids. In the setting of severe hepatic disease, prednisolone should be used instead of prednisone, which requires hepatic conversion to be active.

Malignancies

Glucocorticoids are used in the chemotherapy of acute lymphocytic leukemia and lymphomas because of their antilymphocytic effects, most commonly as a component of combination therapy (see Chapters 67 and 68). They also are used to manage chemotherapy-induced nausea and

vomiting (Table 50–5) and to reduce hypersensitivity reactions and fluid retention associated with taxane chemotherapy (Chapter 66).

Cerebral Edema

Corticosteroids at very high doses (e.g., dexamethasone 4–16 mg every 6 h) are commonly used in the reduction or prevention of cerebral edema associated with parasites and neoplasms, especially those that are metastatic.

Miscellaneous Uses

Sarcoidosis. Corticosteroids are indicated therapy for patients with debilitating symptoms or life-threatening forms of sarcoidosis. Patients with severe pulmonary involvement are treated with 20–40 mg/d of prednisone, or an equivalent dose of alternative steroids, to induce remission. Higher doses may be required for other forms of this disease. Maintenance doses may be as low as 5 mg/d of prednisone. All patients who require chronic glucocorticoid therapy at doses exceeding the normal daily production rate are at increased risk of secondary tuberculosis; therefore, patients with a positive tuberculin reaction or other evidence of tuberculosis should be considered for prophylactic antituberculosis therapy.

Thrombocytopenia. In thrombocytopenia, prednisone (0.5 mg/kg) is used to decrease the bleeding tendency. In more severe cases, and for initiation of treatment of idiopathic thrombocytopenia, daily doses of prednisone (1–1.5 mg/kg) are employed. Patients with refractory idiopathic thrombocytopenia may respond to pulsed high-dose glucocorticoid therapy.

Autoimmune Destruction of Erythrocytes. Patients with autoimmune destruction of erythrocytes (i.e., hemolytic anemia with a positive Coombs test) are treated with prednisone (1 mg/kg/d). In the setting of severe hemolysis, higher doses may be used, with tapering as the anemia improves. Small maintenance doses may be required for several months in patients who respond.

Organ Transplantation. In organ transplantation, high doses of prednisone (50–100 mg) are given at the time of transplant surgery, in conjunction with other immunosuppressive agents, and most patients are kept on a maintenance regimen that includes lower doses of glucocorticoids (see Chapter 35). For some solid-organ transplants (e.g., pancreas), protocols that either withdraw corticosteroids early after transplantation or that avoid them completely have become more common (Niederhaus et al., 2013).

Spinal Cord Injury. Large doses of methylprednisolone sodium succinate (30 mg/kg initially followed by an infusion of 5.4 mg/kg/h for 23 h) are a treatment option for patients with acute spinal cord injury. Although, multicenter controlled trials have demonstrated decreases in neurological defects in patients with acute spinal cord injury treated within 8 h of injury (Bracken, 2012), concerns regarding statistical analysis, reproducibility of data, and potential side effects of treatment have caused some experts to advocate against use of methylprednisolone in this setting (Hurlbert et al., 2013).

Inhibitors of ACTH Secretion and the Biosynthesis and Actions of Adrenocortical Steroids

Hypercortisolism with its attendant morbidity and mortality is most frequently caused by corticotroph adenomas that overproduce ACTH (Cushing disease) or by adrenocortical tumors or bilateral hyperplasias that overproduce cortisol (Cushing syndrome). Less frequently, hypercortisolism may result from adrenocortical carcinomas or ectopic ACTH- or CRH-producing tumors. Although surgery is the treatment of choice, it is not always effective, and adjuvant therapy with pharmacological inhibitors becomes necessary. In these settings, inhibitors of ACTH secretion and of adrenal steroidogenesis are clinically useful. All of these agents pose the common risk of precipitating acute adrenal insufficiency; thus, they must be used in appropriate doses, and the status of the patient's HPA axis

must be carefully monitored. Most of the inhibitors discussed here are considered in detail in other chapters; mineralocorticoid antagonists are not considered here but are discussed in Chapter 25.

Inhibitors of ACTH Secretion

Pasireotide

Pasireotide is a somatostatin analogue that is an agonist at four of the five subtypes of SSTR, with especially high affinity for SSTR5. Through these interactions, pasireotide effectively inhibits growth hormone secretion and is used in the treatment of acromegaly (Chapter 42). Pasireotide also inhibits ACTH secretion and reduces the circulating levels of cortisol in patients with ACTH-producing pituitary tumors; the agent is FDA-approved for use in those patients with Cushing disease who are not candidates for surgery or who have recurrent disease. At subcutaneous doses of 0.6 or 0.9 mg twice daily, pasireotide reduces urinary free cortisol levels by at least 50% in approximately half the treated patients; depending on the dose, cortisol levels reach the normal range in 15%–26% of patients. Treatment improves signs and symptoms of hypercortisolism, including blood pressure, low-density lipoprotein cholesterol, and body mass index. Common adverse effects include hyperglycemia, gallstones, and transient GI discomfort (Colao et al., 2012).

Cabergoline

Cabergoline is a potent long-acting dopamine D_2 receptor agonist used primarily to treat hyperprolactinemia (Chapter 42). Cabergoline also inhibits ACTH secretion from corticotroph tumors, which are often D_2 receptor positive. Several small studies have shown that 37% of patients with recurrent Cushing disease achieve normal levels of free urinary cortisol when treated with cabergoline. The FDA has not yet approved cabergoline for this use.

Inhibitors of Steroidogenesis

Ketoconazole

Ketoconazole is an antifungal agent (see Chapter 61). In doses higher than those employed in antifungal therapy, it is an effective inhibitor of adrenal and gonadal steroidogenesis, primarily because it inhibits the activity of CYP17 (17 α -hydroxylase). At even higher doses, ketoconazole also inhibits CYP11A1, effectively blocking steroidogenesis in all primary steroidogenic tissues. Ketoconazole is an effective inhibitor of steroid hormone biosynthesis in patients with hypercortisolism (although the FDA has not approved use for this indication). In most cases, a dosage regimen of 600–800 mg/d (in two divided doses) is required, and some patients may require up to 1200 mg/d (in two or three doses). Side effects include hepatic dysfunction with the possibility of severe hepatic injury. The potential of ketoconazole to alter drug transport and metabolism by inhibiting P-glycoprotein and CYP3A4 can lead to serious drug interactions (see Chapters 5 and 6).

Metyrapone

Metyrapone is a relatively selective inhibitor of CYP11B1 and thus inhibits the conversion of 11-deoxycortisol to cortisol, thereby reducing cortisol production and elevating precursor levels (e.g., 11-deoxycortisol and its precursor 11-deoxycorticosterone). Although the biosynthesis of aldosterone also is impaired, the elevated levels of 11-deoxycorticosterone and 11-deoxycortisol sustain mineralocorticoid-dependent functions. In a diagnostic test of the entire HPA axis, metyrapone (30 mg/kg, maximum dose of 3 g) is administered orally with a snack at midnight, and plasma cortisol and 11-deoxycortisol are measured at 8 AM the next morning. A plasma cortisol less than 8 μ g/dL validates adequate inhibition of CYP11B1; in this setting, an 11-deoxycortisol level less than 7 μ g/dL is highly suggestive of impaired HPA function.

Metyrapone has been used off label to treat the hypercortisolism resulting from either adrenal neoplasms or tumors ectopically producing ACTH. Maximal suppression of steroidogenesis requires doses of 4 g/d. More frequently, metyrapone is used as adjunctive therapy in patients who have received pituitary irradiation or in combination with other agents that inhibit steroidogenesis. In this setting, a dose of 500–750 mg three

or four times daily is employed. The use of metyrapone in the treatment of Cushing syndrome secondary to pituitary hypersecretion of ACTH is more controversial. Chronic administration of metyrapone can cause hirsutism, which results from increased synthesis of adrenal androgens upstream from the enzymatic block, and hypertension, which results from elevated levels of 11-deoxycortisol/11-deoxycorticosterone. Other side effects include nausea, headache, sedation, and rash.

Etomidate

Etomidate, a substituted imidazole used primarily as an anesthetic agent and sedative, inhibits cortisol secretion at subhypnotic doses primarily by inhibiting CYP11B1 activity. Etomidate has been used off label to treat hypercortisolism when rapid control is required in a patient who cannot take medication by the oral route. Etomidate is administered as a bolus of 0.03 mg/kg intravenously, followed by an infusion of 0.1 mg/kg/h to a maximum of 0.3 mg/kg/h (Biller et al., 2008).

Mitotane

Mitotane is an adrenocorticolytic agent used to treat inoperable adrenocortical carcinoma. Its cytolytic action is due to its metabolic conversion to a reactive acyl chloride by adrenal mitochondrial CYPs and subsequent reactivity with cellular proteins. It also inhibits CYP11A1 (cholesterol side-chain cleavage enzyme), thereby reducing steroid synthesis. Initial doses range from 2 to 6 g/d administered orally in three or four divided doses. The maintenance dose is 9–10 g/d in three or four divided doses. The maximal dose can be as high as 16 g/d, if tolerated. Its onset of action takes weeks to months, and GI disturbances and ataxia are its major toxicities. See Chapter 66 for the structure of mitotane and additional details on its use.

Glucocorticoid Antagonist

Mifepristone

Mifepristone (RU-486), is a progesterone receptor antagonist used to terminate early pregnancy (see Chapter 44). At higher doses, mifepristone also inhibits the GRs, blocking feedback regulation of the HPA axis and secondarily increasing endogenous ACTH and cortisol levels. Because of its capacity to inhibit glucocorticoid action, mifepristone also has been studied as a potential therapeutic agent in a small number of patients with hypercortisolism. Mifepristone has been granted orphan drug status in the U.S. for the treatment of hyperglycemia secondary to endogenous Cushing syndrome in patients who have type 2 diabetes mellitus or glucose intolerance and have failed surgery or are not candidates for surgery.

Drug Facts for Your Personal Formulary: Adrenal Related

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Replacement Therapy		
Hydrocortisone/cortisone	Primary and secondary chronic adrenal insufficiency	<ul style="list-style-type: none"> Hydrocortisone is the synthetic equivalent of cortisol. Daily oral dose of hydrocortisone is 20–30 mg, preferably as divided doses. Although nonphysiologic glucocorticoids are sometimes used, hydrocortisone or cortisone is preferred for replacement therapy. Tip: Two-thirds of dose in the morning, one-third of dose in the evening.
Hydrocortisone, other glucocorticoids	Acute adrenal insufficiency Critical illness-related cortisol insufficiency (CIRCI)	<ul style="list-style-type: none"> CIRCI reflects inadequate cortisol production or may occur with abrupt cessation of administered glucocorticoids. High-dose intravenous hydrocortisone (50–100 mg/6 h) or a constant infusion of 10 mg/h is needed. An alternative is prednisone at 1 mg/kg/d.
Fludrocortisone (9 α -fluorocortisol)	Mineralocorticoid replacement	<ul style="list-style-type: none"> Doses of 0.05–0.2 mg/d. Lower dose is used initially and is titrated upward as required by blood pressure, plasma renin levels, and response to upright posture. Fludrocortisone has a $t_{1/2} \geq 24$ h so divided doses are not necessary.
Anti-inflammatory Agents: Systemic		
Prednisolone, methylprednisolone Dexamethasone, budesonide Others	Across the spectrum of inflammatory disease Preterm (24–34 weeks) delivery	<ul style="list-style-type: none"> Initial high-dose tapering to low dose in short-course therapy. In early therapy—insomnia, weight gain, emotional lability With high-dose/long-term therapy: psychosis, increased susceptibility to infection, osteoporosis, osteonecrosis, myopathy, HPA axis suppression. On cessation of therapy: acute hypocortisolism. Tip: Constant vigilance.
Anti-inflammatory Agents: Topical		
Betamethasone Hydrocortisone Beclomethasone Dexamethasone Triamcinolone acetonide	Dermatitis, pemphigus, atopic dermatitis, vitiligo, psoriasis, etc.	<ul style="list-style-type: none"> Fluorinated steroids have better skin penetration than hydrocortisone. Effects are magnified by occlusive dressings. Local adverse events: atrophy, striae, and exacerbation of skin infection. Tip: Skin-lightening cosmetics include corticosteroids and may produce serious systemic adverse events.

Drug Facts for Your Personal Formulary: Adrenal Related (continued)

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Anti-inflammatory Agents: Ophthalmic		
Dexamethasone Triamcinolone acetonide Fluocinolone acetate (implant)	Macular disease (degeneration, edema, retinal vein occlusion) Postoperative inflammation Corneal injury Uveitis	<ul style="list-style-type: none"> Commonly repeated at 3-month intervals Adverse effects: glaucoma, cataract formation Contraindications: glaucoma, eye infections
Anti-inflammatory Agents: Inhaled		
Beclomethasone, budesonide, ciclesonide, flunisolide, fluticasone, mometasone, triamcinolone acetonide	Asthma, chronic obstructive pulmonary disease	<ul style="list-style-type: none"> Rapid metabolism postabsorption into blood is the key for lung selectivity and lower incidence of adverse events. Chronic use in children may slow growth velocity without compromising final height. Tip: Ciclesonide, a pro-drug converted to active des-ciclesonide in the lung, has low oral bioavailability and less HPA suppression.
Anti-inflammatory Agents: Intranasal		
Mometasone furoate Fluticasone furoate Fluticasone propionate	Allergic rhinitis, rhinosinusitis, rhinoconjunctivitis, nasal polyposis, postoperatively for sinus ostia stenosis surgery	<ul style="list-style-type: none"> Potent localized activity, minimal systemic risk. Tip: Avoid frequent use.
Anti-inflammatory Steroids: Intra-articular		
Hydrocortisone	Relief of joint pain	<ul style="list-style-type: none"> Local and systemic adverse events rare. Success varies with difficulty (e.g., vertebral facet joints versus knees).
Chemotherapy		
Dexamethasone Prednisolone Methylprednisolone Prednisone	Acute lymphatic leukemia Chronic lymphatic leukemia Thymoma Non-Hodgkin lymphoma Multiple myeloma, breast cancer	<ul style="list-style-type: none"> Used in combination with a variety of chemotherapeutic agents. Used for primary cytotoxic effects, plus relief of pain and nausea and appetite stimulation. Tip: No place in acute or chronic myelogenous leukemia.
Diagnostics		
Dexamethasone	Cushing disease	<ul style="list-style-type: none"> ↓ ACTH secretion from pituitary corticotrophs but not from ectopic sources.
Metyrapone	Integrity of entire HPA axis	<ul style="list-style-type: none"> Inhibits CYP11B1, thereby reducing cortisol and ↑ levels of precursor steroids. Failure to adequately ↑ precursor levels indicates impaired HPA function.
Cosyntropin (synthetic ACTH)	Ectopic ACTH secretion Adrenal insufficiency Lateralization of aldosterone overproduction	<ul style="list-style-type: none"> Cosyntropin is a truncated synthetic form of ACTH used to test adrenal reserve. Tip: Cosyntropin is commonly used as either a bolus before or a continuous infusion during adrenal venous sampling to distinguish between unilateral and bilateral aldosterone oversecretion in primary aldosteronism.
Stimulant of ACTH Secretion		
Corticotropin	Peritumoral brain edema postsurgery (off-label use); diagnostic testing	<ul style="list-style-type: none"> A synthetic CRH, preferred to high-dose dexamethasone in relieving peritumoral brain edema. Used diagnostically to distinguish Cushing disease from ectopic ACTH syndrome.
Inhibitors of ACTH Secretion		
Pasireotide	ACTH oversecretion (Cushing disease)	<ul style="list-style-type: none"> Targets SSTR₅ (abundant on corticotrophs), ↓ ACTH secretion; used for recurrent or non-resectable ACTH-secreting adenomas
Cabergoline	ACTH oversecretion and hyperprolactinemia	<ul style="list-style-type: none"> D₂ receptor agonist; ↓ ACTH secretion, ↓ prolactin secretion; useful but not FDA-approved for Cushing disease
Inhibitors of Corticosteroid Production		
Ketoconazole	Hypercortisolism (off-label use) (Used at lower doses as antifungal agent; see Chapter 61)	<ul style="list-style-type: none"> ↓ CYP17 (17α-hydroxylase) and CYP11A1 (cholesterol side chain cleavage), ↓ adrenal and gonadal steroidogenesis Adverse effects: hepatic toxicity; drug interactions due to inhibition of CYP3A4 and P-glycoprotein
Metyrapone	Hypercortisolism; adjunctive therapy after pituitary irradiation	<ul style="list-style-type: none"> Inhibits CYP11B1 (11-deoxy cortisol → cortisol), ↓ cortisol; 4 g/d to maximally ↓ steroidogenesis chronic use may cause hirsutism & hypertension
Etomidate	Rapid control of hypercortisolism (off label use) (Also a short-acting anesthetic; see Chapter 21)	<ul style="list-style-type: none"> Inhibits CYP11B1 (11-deoxy cortisol → cortisol), ↓ cortisol production at sub-anesthetic doses Administer as IV bolus, 0.03 mg/kg

Inhibitors of Corticosteroid Production (continued)		
Mitotane	Treating inoperable adrenocortical carcinoma (See also Chapter 66)	<ul style="list-style-type: none"> Activated by adrenal cortical CYPs to an acyl chloride with cytolytic effects Inhibits CYP11A1 (cholesterol side chain cleavage), ↓ steroidogenesis
Glucocorticoid Antagonist		
Mifepristone (RU486)	Hypercortisolism (Used at lower doses as anti-progesterone for termination of early pregnancy; see Chapter 44)	<ul style="list-style-type: none"> GR antagonist, $IC_{50} \sim 2.2$ nM (IC_{50} for anti-progesterone effect, ~ 0.025 nM) Used at 300–1200 mg/d to treat inoperable hypercortisolism that is resistant to other agents

- Somatostatin

Diabetes mellitus is a spectrum of metabolic disorders arising from myriad pathogenic mechanisms, all resulting in hyperglycemia. Both genetic and environmental factors contribute to its pathogenesis, which involves insufficient insulin secretion, reduced responsiveness to endogenous or exogenous insulin, increased glucose production, or abnormalities in fat and protein metabolism. The resulting hyperglycemia may lead to both acute symptoms and metabolic abnormalities. Major sources of the morbidity of diabetes are the chronic complications that arise from prolonged hyperglycemia, including retinopathy, neuropathy, nephropathy, and cardiovascular disease. These chronic complications can be mitigated in many patients by sustained control of the blood glucose and treatment of comorbidities such as hypertension and dyslipidemia (Nathan, 2014; Orchard et al., 2015). There are now a wide variety of treatment options for hyperglycemia that target different processes involved in glucose regulation or dysregulation (Nathan, 2015).

Physiology of Glucose Homeostasis

Regulation of Blood Glucose

The maintenance of glucose homeostasis, termed *glucose tolerance*, is a highly developed systemic process involving the integration of several major organs (Figure 47-1). Although the actions of insulin are of central importance, webs of interorgan communication via other hormones, nerves, local factors, and substrates also play vital roles. The pancreatic β cell is central in this homeostatic process, adjusting the amount of insulin secreted very precisely to promote glucose uptake after meals and to regulate glucose output from the liver during fasting.

In the *fasting state* (Figure 47-1A), the fuel demands of the body are met by the oxidation of fatty acids. The brain does not effectively use fatty acids to meet energy needs and in the fasting state requires glucose for normal function; glucose requirements are about 2 mg/kg/min in adult humans, largely to supply the CNS with an energy source. *Fasting glucose*

requirements are primarily provided by the liver. Liver glycogen stores provide some of this glucose; conversion of lactate, alanine, and glycerol into glucose accounts for the remainder. The dominant regulation of hepatic *glycogenolysis* and *gluconeogenesis* is controlled by the pancreatic islet hormones *insulin* and *glucagon*. Insulin inhibits hepatic glucose production, and the decline of circulating insulin concentrations in the postabsorptive state (fasting) is permissive for higher rates of glucose output. Glucagon maintains blood glucose concentrations at physiological levels in the absence of exogenous carbohydrate (overnight and in between meals) by stimulating gluconeogenesis and glycogenolysis by the liver. Insulin secretion is stimulated by *food ingestion*, nutrient absorption, and elevated blood glucose, and insulin promotes glucose, lipid, and protein anabolism (Figure 47-1B). The centrality of insulin in glucose metabolism is emphasized by the fact that all the forms of human diabetes have as a root cause some abnormality of insulin secretion or action.

Pancreatic β cell function is primarily controlled by plasma glucose concentrations. Elevations of blood glucose are necessary for insulin release above basal levels, and other stimuli are relatively ineffective when plasma glucose is in the fasting range (4.4–5.5 mM or 80–100 mg%). These other stimuli include nutrient substrates, *insulinotropic hormones* released from the GI tract, and autonomic neural pathways. Neural stimuli cause some increase of insulin secretion prior to food consumption. Neural stimulation of insulin secretion occurs throughout the meal and contributes significantly to glucose tolerance. Arrival of nutrient chyme to the intestine leads to the release of insulinotropic peptides from specialized endocrine cells in the intestinal mucosa. *GIP* and *GLP-1*, together termed *incretins*, are the essential gut hormones contributing to *glucose tolerance*. They are secreted in proportion to the nutrient load ingested and relay this information to the islet as part of a feed-forward mechanism that allows an insulin response appropriate to meal size. Insulin secretion rates in healthy humans are highest in the early digestive phase of meals, preceding and limiting the peak in blood glucose. This pattern of premonitory insulin secretion is an essential feature of normal glucose tolerance. Mimicking this pattern is one of the key challenges for successful insulin therapy in diabetic patients.

AC:	adenylyl cyclase
A1c:	hemoglobin A _{1c}
ADA:	American Diabetes Association
BP:	blood pressure
CHF:	congestive heart failure
CNS:	central nervous system
CSII:	continuous subcutaneous insulin infusion
CV:	cardiovascular
CVD:	cardiovascular disease
DPP-4:	dipeptidyl peptidase IV
EPI:	epinephrine
GDM:	gestational diabetes mellitus
GEF:	guanine nucleotide exchange factor
GFR:	glomerular filtration rate
GIP:	glucose-dependent insulinotropic polypeptide
GIRK:	G protein–coupled inwardly rectifying K ⁺ channel
GK:	glucokinase (hexokinase IV)
GLP:	glucagon-like peptide
GLP-1RA:	GLP-1 receptor agonist
GLUT:	glucose transporter
G6P:	glucose-6-phosphate
GPCR:	G protein–coupled receptor
GRPP:	glucagon-like peptide
Hb:	hemoglobin
HbA_{1c}:	hemoglobin A _{1c}
HDL:	high-density lipoprotein
HGP:	hepatic glucose production
HNF:	hepatocyte nuclear transcription factor
IAPP:	islet amyloid polypeptide
ICU:	intensive care unit
IFG:	impaired fasting glucose
IFN:	interferon
IGF-1:	insulinlike growth factor 1
IGT:	impaired glucose tolerance
IL:	interleukin
IRS:	insulin receptor substrate
K_r:	inward rectifying K ⁺ channel
LDL:	low-density lipoprotein
MAOI:	monoamine oxidase inhibitor
MODY:	maturity onset diabetes of the young
mTOR:	mammalian target of rapamycin
NE:	norepinephrine
NPH:	neutral protamine Hagedorn
NSAID:	nonsteroidal anti-inflammatory drug
OCT:	organic cation transporter
PC:	prohormone convertase
PI3K:	phosphatidylinositol-3-kinase
PIP3:	phosphatidylinositol 3,4,5-trisphosphate
PLC:	phospholipase
PPAR:	peroxisome proliferator-activated receptor
SGLT2:	sodium-glucose cotransporter 2
Shc:	Src-homology-2-containing (protein)
SST:	somatostatin
SUR:	sulfonylurea receptor
TGF:	transforming growth factor
TNF:	tumor necrosis factor

Elevated circulating insulin concentrations lower glucose in blood by inhibiting hepatic glucose production (HGP) and stimulating the uptake and metabolism of glucose by muscle and adipose tissue. Production of glucose is inhibited half-maximally by an insulin concentration of about 120 pmol/L, whereas glucose utilization is stimulated half-maximally at about 300 pmol/L. Some of the effects of insulin on the liver occur rapidly, within the first 20 min of meal ingestion, whereas stimulation of peripheral glucose uptake may require up to an hour to reach significant rates. Insulin has potent effects to reduce lipolysis from adipocytes, primarily through the inhibition of hormone-sensitive lipase; insulin also increases lipid storage by promoting lipoprotein-lipase synthesis and adipocyte glucose uptake. In muscle and other tissues, insulin stimulates amino acid uptake and protein synthesis and inhibits protein degradation.

The limited glycogen stores in skeletal muscle are mobilized at the onset of physical activity, but most of the glucose support for exercise comes from hepatic gluconeogenesis. The dominant regulation of hepatic glucose production during exercise comes from EPI and NE. The catecholamines stimulate glycogenolysis and gluconeogenesis, inhibit insulin secretion, and enhance release of glucagon, all contributing to increased hepatic glucose output. In addition, catecholamines promote lipolysis, freeing fatty acids for oxidation in exercising muscle and glycerol for hepatic gluconeogenesis.

Pancreatic Islet Physiology and Insulin Secretion

The pancreatic islets comprise 1%–2% of the pancreatic volume. The pancreatic islet is a highly vascularized, highly innervated miniorgan containing five endocrine cell types: α cells that secrete *glucagon*, β cells that secrete *insulin*, δ cells that secrete *SST*, *PP* cells that secrete *pancreatic polypeptide*, and ϵ cells that secrete *ghrelin*.

Insulin is initially synthesized as a single polypeptide chain, *preproinsulin* (110 amino acids), which is processed first to *proinsulin* and then to *insulin* and *C-peptide* (Figure 47–2). This complex and highly regulated process involves the Golgi complex, the endoplasmic reticulum, and the secretory granules of the β cell. Secretory granules are critical in the cleavage and processing of the prohormone to the final secretion products, insulin and C-peptide, and in bringing insulin to the cell membrane for exocytosis. Equimolar quantities of insulin and C-peptide (31 amino acids) are cosecreted. Insulin has a $t_{1/2}$ of 5–6 min due to extensive hepatic clearance. C-peptide, in contrast, with no known physiological function or receptor, has a $t_{1/2}$ of about 30 min. The C-peptide is useful in assessment of β cell secretion and to distinguish endogenous and exogenous hyperinsulinemia (e.g., in the evaluation of insulin-induced hypoglycemia). The β cell also synthesizes and secretes IAPP or *amylin*, a 37-amino acid peptide. IAPP influences GI motility and the speed of glucose absorption. *Pramlintide* is an agent used in the treatment of diabetes that mimics the action of IAPP.

Insulin secretion is tightly regulated to provide stable concentrations of glucose in blood during both fasting and feeding. This regulation is achieved by the coordinated interplay of various nutrients, GI hormones, pancreatic hormones, and autonomic neurotransmitters. Glucose, amino acids, fatty acids, and ketone bodies promote the secretion of insulin. Glucose is the primary insulin secretagogue, and insulin secretion is tightly coupled to the extracellular glucose concentration. Insulin secretion is much greater when the same amount of glucose is delivered orally compared to intravenously, a response termed the *incretin effect* and attributed to insulinotropic GI peptides. Islets are richly innervated by both adrenergic and cholinergic nerves. Stimulation of α_2 adrenergic receptors inhibits insulin secretion, whereas β_2 adrenergic receptor agonists and vagal nerve stimulation enhance release. In general, any condition that activates the sympathetic branch of the autonomic nervous system (such as hypoxia, hypoglycemia, exercise, hypothermia, surgery, or severe burns) suppresses the secretion of insulin by stimulation of α_2 adrenergic receptors.

The molecular events controlling glucose-stimulated insulin secretion begin with the transport of glucose into the β cell via GLUT, a facilitative glucose transporter, primarily GLUT1 in human β cells (Figure 47–3). On entry into the β cell, glucose is quickly phosphorylated by GK (hexokinase

Figure 47-1 Insulin, glucagon, and glucose homeostasis. **A. Fasting State**—In healthy humans, plasma glucose is maintained in a range from 4.4 to 5 mM and fatty acids near 400 μM. In the absence of nutrient absorption from the GI tract, glucose is supplied primarily from the liver and fatty acids from adipose tissue. With fasting, plasma insulin levels are low, and plasma glucagon is elevated, contributing to increased hepatic glycogenolysis and gluconeogenesis; low insulin also releases adipocytes from inhibition, permitting increased lipolysis. Most tissues oxidize primarily fatty acids during fasting, sparing glucose for use by the CNS. **B. Prandial State**—During feeding, nutrient absorption causes an increase in plasma glucose, resulting in release of incretins from the gut and neural stimuli that promote insulin secretion. Under the control of insulin, the liver, skeletal muscle, and adipose tissue actively take up glucose. Hepatic glucose production and lipolysis are inhibited, and total body glucose oxidation increases. The brain senses plasma glucose concentrations and provides regulatory inputs contributing to fuel homeostasis. The boldness of the arrows reflects relative intensity of action; a dashed line indicates little or no activity.

IV); this phosphorylation is the rate-limiting step in glucose metabolism in the β cell. GK's distinctive affinity for glucose leads to a marked increase in glucose metabolism over the range of 5–10 mM glucose, where glucose-stimulated insulin secretion is most pronounced. The G6P produced by GK activity enters the glycolytic pathway, producing changes in NADPH

Figure 47-2 Synthesis and processing of insulin. The initial peptide, preproinsulin (110 amino acids) consists of a signal peptide (SP), B chain, C-peptide, and A chain. The SP is cleaved and S-S bonds form as the proinsulin folds. Two prohormone convertases, PC1 and PC2, cleave proinsulin into insulin, C-peptide, and two dipeptides. Insulin and C-peptide are stored in granules and cosecreted in equimolar quantities.

and the ratio of ADP/ATP. Elevated ATP inhibits an ATP-sensitive K^+ channel (K_{ATP} channel), leading to cell membrane depolarization. This heteromeric K_{ATP} channel consists of an inward rectifying K^+ channel (Kir6.2) and a closely associated protein known as the SUR. Mutations in the K_{ATP} channel are responsible for specific types of neonatal diabetes and hyperinsulinemic hypoglycemia. Membrane depolarization following K_{ATP} closure leads to opening of a voltage-dependent Ca^{2+} channel and increased intracellular Ca^{2+} , resulting in exocytotic release of insulin from storage vesicles. These intracellular events are modulated by changes in cAMP production, amino acid metabolism, and the level of transcription factors. GPCRs for glucagon, GIP, and GLP-1 and other regulatory peptides couple to G_s to stimulate adenyl cyclase and insulin secretion; receptors for SST and α_2 adrenergic agonists couple to G_i to reduce cellular cAMP production and secretion.

The pancreatic α cell secretes glucagon, primarily in response to hypoglycemia. Glucagon biosynthesis begins with *preproglucagon*, which is processed in a cell-specific fashion to several biologically active peptides, such as glucagon, GLP-1, and GLP-2 (see Figure 47-9). In general, glucagon and insulin secretion are regulated in a reciprocal fashion; that is, the agents or processes that stimulate insulin secretion inhibit glucagon secretion. Notable exceptions are arginine and SST: Arginine stimulates and SST inhibits the secretion of both hormones.

Insulin Action

The insulin receptor is expressed on virtually all mammalian cell types. Tissues that are critical for regulation of blood glucose are liver, skeletal muscle, fat (Figure 47-1), and specific regions of the brain and the pancreatic islet. The actions of insulin are anabolic, and insulin signaling is critical for promoting the uptake, use, and storage of the major nutrients: glucose, lipids, and amino acids. Insulin stimulates glycogenesis, lipogenesis, and protein synthesis; it also inhibits the catabolism of these compounds. On a

Figure 47-3 Regulation of insulin secretion from a pancreatic β cell. The pancreatic β cell in a resting state (fasting blood glucose) is hyperpolarized. Elevated plasma glucose enters the cell via GLUTs (primarily GLUT1 in humans). The resulting enhanced glucose metabolism elevates cellular ATP, which reduces K^+ conductance through the K_{ATP} channel; the decreased K^+ conductance results in local membrane depolarization and activation of Ca^{2+} and Na^+ channels; the increased $[Ca^{2+}]_i$ stimulates exocytosis of stored insulin, using the basic mechanisms described for exocytosis of neurotransmitters (Figures 8–4 to 8–6). ACh, acting via M_3 receptors, can activate the G_q -PLC-IP₃- Ca^{2+} -PKC pathway; incretins, also acting via GPCRs, can activate the G_s -AC-cAMP-PKA/EPAC2 pathway; both of these GPCR-activated pathways enhance exocytosis. Elevated cAMP also leads to inhibition of the K_{ATP} channel, enhancing depolarization and furthering exocytosis. The depolarization/exocytosis period is limited by closure of voltage-sensitive ion channels, by export of Ca^{2+} and Na^+ , and by sequestration of Ca^{2+} within the SR by the SERCA transporter. SST, acting via SST2 and SST3 that couple to $G_{i/o}$, can aid in restoring the hyperpolarized state of the cell, as can α_2 agonists. The K_{ATP} channel has SUR1 and Kir 6.2 subunits; ATP binds to and inhibits Kir 6.2; sulfonylureas and meglitinides bind to and inhibit SUR1; all three agents thereby promote insulin secretion. Diazoxide and ADP-Mg²⁺ (low ATP) bind to and activate SUR1, thereby inhibiting insulin secretion. Mitochondrial mutations and islet-enriched transcription factors can contribute to the development of diabetes. This schematic is a simplification; Rorsman and Braun (2013) have reviewed the subject in greater detail. G, G protein, with subtype indicated by subscript; AC, adenylyl cyclase; EPAC, exchange protein activated by cAMP; GLUT, GLUT1 glucose transporter; GPCR, G-protein coupled receptor; PKA, protein kinase A; PKC, protein kinase C; PLC, phospholipase C; SST2/3, somatostatin receptors.

cellular level, insulin stimulates transport of substrates and ions into cells, promotes translocation of proteins between cellular compartments, regulates the action of specific enzymes, and controls gene transcription and mRNA translation. Some effects of insulin (e.g., activation of glucose and ion transport systems, phosphorylation or dephosphorylation of specific enzymes) occur within seconds or minutes; other effects (e.g., those promoting protein synthesis and regulating gene transcription and cell proliferation) manifest over minutes to hours to days. The effects of insulin on cell proliferation and differentiation occur over a longer period of time.

The Insulin Receptor

Insulin action is transmitted through a receptor tyrosine kinase that bears functional similarity to the *IGF-1 receptor* (Samuel and Shulman, 2016). The insulin receptor is composed of linked α/β subunit dimers that are products of a single gene; dimers linked by disulfide bonds form a transmembrane heterotetramer glycoprotein composed of two extracellular α subunits and two membrane-spanning β subunits (Figure 47-4). The number of receptors varies from 40/cell on erythrocytes to 300,000/cell on adipocytes and hepatocytes.

The α subunits inhibit the inherent tyrosine kinase activity of the β subunits. Insulin binding to the α subunits releases this inhibition and allows transphosphorylation of one β subunit by the other and autophosphorylation at specific sites from the juxtamembrane region to the intracellular tail of the receptor. Activation of the insulin receptor initiates signaling by phosphorylating a set of intracellular proteins, including the IRSs and Shc protein. These proteins interact with effectors that amplify and extend the signaling cascade.

Insulin action on glucose transport depends on the activation of PI3K. PI3K is activated by interaction with IRS proteins and generates PIP₃, which regulates the localization and activity of several downstream kinases, including PKB (Akt), atypical isoforms of PKC (ζ and λ/τ), and mTOR. The isoform Akt2 appears to control the downstream steps that are important for glucose uptake in skeletal muscle and adipose tissue and to regulate glucose production in the liver. Substrates of Akt2 coordinate the translocation of GLUT4 to the plasma membrane through processes involving actin remodeling and other membrane trafficking systems. Actions of small G proteins, such as Rac and TC10, have also been implicated in the actin remodeling necessary for GLUT4 translocation.

Figure 47-4 Pathways of insulin signaling. The binding of insulin to its plasma membrane receptor activates a cascade of downstream signaling events. Insulin binding activates the intrinsic tyrosine kinase activity of the receptor dimer, resulting in the tyrosine phosphorylation (Y-P indicates the phosphorylated tyrosine residue, Y) of the receptor's β subunits and a small number of specific substrates (yellow shapes): the IRS proteins Gab-1 and Shc; within the membrane, a caveolar pool of insulin receptor phosphorylates Cav, APS, and Cbl. These tyrosine-phosphorylated proteins interact with signaling cascades via SH2 and SH3 domains to mediate the effects of insulin, with specific effects resulting from each pathway. In the target tissues such as skeletal muscle and adipocytes, a key event is the translocation of GLUT4 from intracellular vesicles to the plasma membrane; this translocation is stimulated by both the caveolar and noncaveolar pathways. In the noncaveolar pathway, the activation of PI3K is crucial, and PKB/Akt (anchored at the membrane by PIP₃) or an atypical form of PKC is involved. In the caveolar pathway, caveolar protein flotillin localizes the signaling complex to the caveola; the signaling pathway involves a series of SH2 domain interactions that add the adaptor protein CrkII, the guanine nucleotide exchange protein C3G, and small GTP-binding protein TC10. The pathways are inactivated by specific phosphoprotein phosphatases (e.g., PTB1B). In addition to the actions shown, insulin stimulates the plasma membrane Na⁺, K⁺-ATPase by a mechanism that is still being elucidated; the result is an increase in pump activity and a net accumulation of K⁺ in the cell. APS, adaptor protein with PH and SH2 domains; CAP, Cbl associated protein; CAV, caveolin; CrkII, chicken tumor virus regulator of kinase II; Gab-1, Grb-2 associated binder; GLUT4, glucose transporter 4; PDK, phosphoinositide-dependent kinase; Y-P, phosphorylated tyrosine residue.

GLUT4

GLUT4 is expressed in insulin-responsive tissues such as skeletal muscle and adipose tissue. In the basal state, most GLUT4 resides in the intracellular space; following activation of insulin receptors, GLUT4 is shifted rapidly and in abundance to the plasma membrane (Saltiel, 2016), where it facilitates inward transport of glucose from the circulation. Insulin signaling also reduces GLUT4 endocytosis, increasing the residence time of the protein in the plasma membrane (Saltiel, 2016). Following the facilitated diffusion into cells along a concentration gradient, glucose is phosphorylated to G6P by hexokinases. Hexokinase II is found in association with GLUT4 in skeletal and cardiac muscle and in adipose tissue. Like GLUT4, hexokinase II is regulated transcriptionally by insulin. G6P can be isomerized to G1P and stored as glycogen (insulin enhances the activity of glycogen synthase); G6P can enter the glycolytic pathway (for ATP production) and the pentose phosphate pathway.

Pathophysiology and Diagnosis of Diabetes Mellitus

Glucose Homeostasis and the Diagnosis of Diabetes

Broad categories of glucose homeostasis are defined by the fasting blood glucose or the glucose level following an oral glucose challenge. These include the following:

- Normal glucose homeostasis: fasting plasma glucose < 5.6 mmol/L (100 mg/dL)
- Impaired fasting glucose (IFG) : 5.6–6.9 mmol/L (100–125 mg/dL)

- Impaired glucose tolerance (IGT): glucose level between 7.8 and 11.1 mmol/L (140 and 199 mg/dL) 120 min after ingestion of 75 g liquid glucose solution
- Diabetes mellitus (see Table 47-1)

The American Diabetes Association (ADA) and the World Health Organization (WHO) have adopted criteria for the diagnosis of diabetes based on the fasting blood glucose, the glucose value following an oral glucose challenge, or the level of HbA_{1c} (or more simply, A1c; exposure of

TABLE 47-1 ■ CRITERIA FOR THE DIAGNOSIS OF DIABETES

- Symptoms of diabetes plus random blood glucose concentration ≥ 11.1 mM (200 mg/dL)^a or
- Fasting plasma glucose ≥ 7.0 mM (126 mg/dL)^b or
- Two-hour plasma glucose ≥ 11.1 mM (200 mg/dL) during an oral glucose tolerance test^c
- HbA_{1c} $\geq 6.5\%$

Note: In the absence of unequivocal hyperglycemia and acute metabolic decompensation, these criteria should be confirmed by repeat testing on a different day.

^aRandom is defined as without regard to time since the last meal.

^bFasting is defined as no caloric intake for at least 8 h.

^cThe test should be performed using a glucose load containing the equivalent of 75 g anhydrous glucose dissolved in water; this test is not recommended for routine clinical use.

Criteria compiled from *Diabetes Care*, 2017, 40:S11–524.

proteins to elevated glucose produces nonenzymatic glycation of proteins, including Hb, so the level of A1c represents a measure of the average glucose concentration to which the Hb has been exposed) (see Table 47-1). IFG and IGT portend a markedly increased risk of progressing to type 2 diabetes and are associated with increased risk of cardiovascular disease.

The four categories of diabetes include type 1 diabetes, type 2 diabetes, other forms of diabetes, and GDM (Table 47-2). Although hyperglycemia is common to all forms of diabetes, the pathogenic mechanisms leading to diabetes are quite distinct.

Screening for Diabetes and Categories of Increased Risk of Diabetes

Many individuals with type 2 diabetes are asymptomatic at the time of diagnosis, and diabetes is often found on routine blood testing for non-glucose-related reasons. The ADA recommends widespread screening for type 2 diabetes of adults with the following features:

- Age more than 45 years, or
- Body mass index greater than 25 kg/m² (or greater than 23 kg/m² in persons of Asian descent) with one of these additional risk factors: physical inactivity; hypertension; low HDL value; family history of type 2 diabetes; high-risk ethnic group (African American, Latino, Native American, Asian American, and Pacific Islander); abnormal glucose testing (IFG, IGT, A1c of 5.7%–6.4%); cardiovascular disease; features

TABLE 47-2 ■ DIFFERENT FORMS OF DIABETES MELLITUS

I. Type 1 diabetes β-cell destruction , usually leading to absolute insulin deficiency
A. Immune mediated
B. Idiopathic
II. Type 2 diabetes (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)
III. Other specific types of diabetes
A. Monogenic disorders of β-cell function
1. HNF-4α (MODY 1)
2. Glucokinase (MODY 2)
3. HNF-1α (MODY 3)
4. Other forms of MODY: insulin promoter factor 1, HNF-1β, NeuroD1, and others
5. Permanent neonatal diabetes KCNJ11 gene encoding Kir6.2 subunit of β-cell K _{ATP} channel, insulin gene
6. Mitochondrial DNA
B. Genetic defects in insulin action, including type A insulin resistance, leprechaunism, Rabson-Mendenhall syndrome, lipodystrophy syndromes
C. Diseases of the exocrine pancreas—pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy, mutations in carboxyl ester lipase
D. Endocrinopathies—acromegaly, Cushing syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma
E. Drug or chemical induced—pyrinuron (a rodenticide no longer sold in the U.S.); see drugs listed in Table 47-3
F. Infections—congenital rubella, cytomegalovirus
G. Uncommon forms of immune-mediated diabetes—“stiff-person” syndrome, anti-insulin receptor antibodies
H. Other genetic syndromes sometimes associated with diabetes—Wolfram, Down, Klinefelter, Laurence-Moon-Biedl, Prader-Willi, and Turner syndromes; Friedreich ataxia; Huntington disease; myotonic dystrophy; porphyria
IV. Gestational diabetes mellitus

of insulin resistance; or women with polycystic ovary syndrome or who have previously delivered a large infant or had GDM

In screening for diabetes, fasting plasma glucose, A1c, and plasma glucose after an oral glucose tolerance test are equally valid, but the fasting glucose and A1c are used most commonly. Early diagnosis and treatment of type 2 diabetes should delay diabetes-related complications and reduce the burden of the disease. A number of interventions, including pharmacological agents and lifestyle modification, are effective. Screening for type 1 diabetes is not currently recommended.

Pathogenesis of Type 1 Diabetes

Type 1 diabetes accounts for 5%–10% of diabetes and results from autoimmune-mediated destruction of the β cells of the islet, leading to total or near-total insulin deficiency (Atkinson et al., 2014). Prior terminology included juvenile-onset diabetes mellitus or insulin-dependent diabetes mellitus. Type 1 diabetes can occur at any age. Individuals with type 1 diabetes and their families have an increased prevalence of autoimmune diseases such as Addison, Graves, and Hashimoto diseases; pernicious anemia; vitiligo; and celiac sprue. The concordance of type 1 diabetes in genetically identical twins is 40%–60%, indicating a significant genetic component. The major genetic risk (40%–50%) is conferred by HLA class II genes encoding HLA-DR and HLA-DQ. However, there likely is a critical interaction of genetics and an environmental or infectious agent. Most individuals with type 1 diabetes (about 75%) do not have a family member with type 1 diabetes, and the genes conferring genetic susceptibility are found in a significant fraction of the nondiabetic population.

Genetically susceptible individuals are thought to have a normal β cell number or mass until β cell-directed autoimmunity develops and β cell loss begins. The initiating or triggering stimulus for the autoimmune process is not known, but most favor exposure to viruses (enterovirus, etc.) or other ubiquitous environmental agents. The β cell destruction is likely cell mediated, and there is also evidence that infiltrating cells produce local inflammatory agents such as TNF-α, IFN-γ, and IL-1, all of which can lead to β cell death. The β cell destruction occurs over a period of months to years and when more than 80% of the β cells are destroyed, hyperglycemia ensues and the clinical diagnosis of type 1 diabetes is made. The ADA and others now recognize three stages of type 1 diabetes: 1) autoimmunity plus normal insulin secretion; 2) autoimmunity with dysglycemia; 3) autoimmunity with hyperglycemia (diabetes). Most patients report several weeks of polyuria and polydipsia, fatigue, and often abrupt and significant weight loss. Some adults with the phenotypic appearance of type 2 diabetes (obese, not insulin-requiring initially) have islet cell autoantibodies suggesting autoimmune-mediated β cell destruction and are diagnosed as having latent-autoimmune diabetes of adults (LADA).

Pathogenesis of Type 2 Diabetes

The type 2 diabetes condition is best thought of as a heterogeneous syndrome of dysregulated glucose homeostasis associated with impaired insulin secretion and action. Overweight or obesity is a common correlate of type 2 diabetes that occurs in about 80% of affected individuals. For the vast majority of persons developing type 2 diabetes, there is no clear inciting incident; rather, the condition is thought to develop gradually over years, with progression through an identifiable prediabetic stage. Type 2 diabetes results when there is insufficient insulin action to maintain plasma glucose levels in the normal range. Insulin action is the composite effect of plasma insulin concentrations (determined by islet β cell function) and insulin sensitivity of key target tissues (liver, skeletal muscle, and adipose tissue). These sites of regulation are all impaired to variable extents in patients with type 2 diabetes (Figure 47-5). The etiology of type 2 diabetes has a strong genetic component. It is a heritable condition with a relative 4-fold increased risk of disease for persons having a diabetic parent or sibling, increasing to 6-fold if both parents have type 2 diabetes. Although more than 80 genetic loci with clear associations to type 2 diabetes have been identified through recent genome-wide association studies, the contribution of each is relatively small (Fuchsberger et al., 2016).

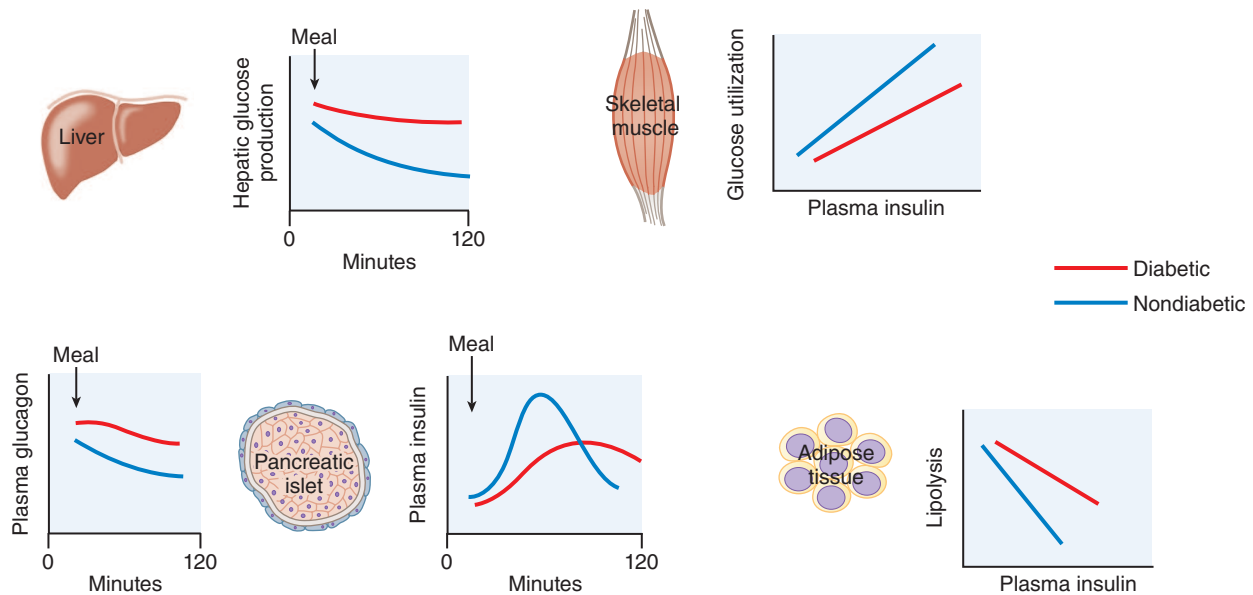

Figure 47-5 Pathophysiology of type 2 diabetes mellitus. Graphs show data from nondiabetic individuals (blue lines) and from individuals with diabetes (red lines), comparing postprandial insulin and glucagon secretion and hepatic glucose production, and comparing the sensitivities of muscle glucose use and adipocyte lipolysis to insulin.

Impaired β Cell Function

In type 2 diabetes, the sensitivity of the β cell to glucose is impaired, and there is also a loss of responsiveness to other stimuli, such as insulinotropic GI hormones and neural signaling. This results in delayed secretion of insufficient amounts of insulin, allowing the blood glucose to rise dramatically after meals, and failure to restrain liver glucose release during fasting. The absolute mass of β cells also is reduced in patients with type 2 diabetes. Progressive reduction of β cell mass and function explains the natural history of type 2 diabetes in most patients who require steadily increasing therapy to maintain glucose control.

Type 2 diabetic patients sometimes have elevated levels of fasting insulin, a result of their higher fasting glucose levels and insulin resistance. Another factor contributing to apparently high insulin levels early in the course of the disease is the presence of increased amounts of proinsulin. Proinsulin, the precursor to insulin, is inefficiently processed in the diabetic islet. Whereas healthy subjects have only 2%–4% of total circulating insulin as proinsulin, patients with type 2 diabetes can have 10%–20% of the measurable plasma insulin in this form. Proinsulin has a considerably attenuated effect for lowering blood glucose compared to insulin. Excessive and dysregulated glucagon secretion is another prominent feature of type 2 diabetes (D'Alessio, 2011).

Insulin Resistance

Insulin sensitivity is measured as the amount of glucose cleared from the blood in response to a fixed dose of insulin. The failure of normal amounts of insulin to elicit the expected response is referred to as *insulin resistance*. There is inherent variability of insulin sensitivity amongst cells, tissues, and individuals. Insulin sensitivity is affected by many factors, including age, body weight, physical activity levels, illness, and medications. Nonetheless, persons with type 2 diabetes or glucose intolerance have reduced responses to insulin and can be distinguished from groups with normal glucose tolerance (Samuel and Shulman, 2016).

The major insulin-responsive tissues are skeletal muscle, adipose tissue, and liver. Insulin resistance in muscle and fat is generally marked by a decrease in transport of glucose from the circulation. Hepatic insulin resistance generally refers to a blunted ability of insulin to suppress glucose production. Insulin resistance in adipocytes causes increased rates of lipolysis and release of fatty acids into the circulation, which can contribute to insulin resistance in liver and muscle, hepatic steatosis, and dyslipidemia. The sensitivity of humans to the effects of insulin administration is

inversely related to the amount of fat stored in the abdominal cavity; more visceral adiposity leads to more insulin resistance. Intracellular lipid or its by-products may have direct effects to impede insulin signaling. Enlarged collections of adipose tissue, visceral or otherwise, are often infiltrated with macrophages and can become sites of chronic inflammation. Adipocytokines, secreted from adipocytes and immune cells, including TNF- α , IL-6, resistin, and retinol-binding protein 4, can also cause systemic insulin resistance.

Sedentary persons are more insulin resistant than active ones, and physical training can improve insulin sensitivity. Physical activity can decrease the risk of developing diabetes and improve glycemic control in persons who have diabetes. Insulin resistance is more common in the elderly, and within populations, insulin sensitivity decreases linearly with age. At the cellular level, insulin resistance involves blunted steps in the cascade from the insulin receptor tyrosine kinase to translocation of GLUT4 transporters, but the molecular mechanisms are incompletely defined. There have been more than 75 different mutations in the insulin receptor discovered, most of which cause significant impairment of insulin action. These mutations affect insulin receptor number, ligand binding, receptor phosphorylation, and trafficking. Mutations involving the insulin binding domains of the extracellular α -chain cause the most severe syndromes. Insulin sensitivity is under genetic control, but it is unclear whether insulin-resistant individuals have mutations in specific components of the insulin signaling cascade or whether they have a complement of signaling effectors that operate at the lower range of normal. Regardless, it is apparent that insulin resistance clusters in families and is a major risk factor for the development of diabetes.

Dysregulated Hepatic Glucose Metabolism

In type 2 diabetes, hepatic glucose output is excessive in the fasting state and inadequately suppressed after meals. Abnormal secretion of the islet hormones—insufficient insulin and excessive glucagon—accounts for a significant portion of dysregulated hepatic glucose metabolism in type 2 diabetes. Increased concentrations of glucagon, especially in conjunction with hepatic insulin resistance, can lead to excessive hepatic gluconeogenesis and glycogenolysis and abnormally high fasting glucose concentrations. The liver is resistant to insulin action in type 2 diabetes, and the capacity of insulin to suppress HGP and promote hepatic glucose uptake and glycogen synthesis after meals is reduced. Despite ineffective insulin effects on hepatic glucose metabolism, the lipogenic effects of insulin in the

870 liver are maintained and even accentuated by fasting hyperinsulinemia. This contributes to hepatic steatosis and further worsening of insulin resistance.

Pathogenesis of Other Forms of Diabetes

Mutations in key genes involved in glucose homeostasis cause monogenic diabetes, which is inherited in an autosomal dominant fashion (Hattersley and Patel, 2017). These fall in two broad categories: diabetes onset in the immediate neonatal period (<6 months of age) and diabetes in children or adults. Some forms of neonatal diabetes are caused by mutations in SUR or its accompanying inward rectifying K⁺ channel or mutations in the insulin gene. Monogenic diabetes beyond the first year of life may appear clinically similar to type 1 or type 2 diabetes. In other instances, children, adolescents, and young adults may present with monogenic forms of diabetes known as MODY (maturity onset diabetes of the young). Phenotypically, these individuals are not obese or insulin resistant and may initially have only modest hyperglycemia. The most common causes are mutations in key islet-enriched transcription factors or GK (Table 47-2). Most individuals with MODY are treated similarly to those with type 2 diabetes; some may respond to a sulfonylurea.

Chronic diseases of the pancreas, such as pancreatitis or cystic fibrosis, or endocrinopathies such as acromegaly and Cushing disease (see Table 47-2) can cause diabetes. A number of medications promote hyperglycemia or lead to diabetes by impairing either insulin secretion or insulin action (Table 47-3).

Diabetes-Related Complications

Untreated diabetes can lead to severe metabolic disturbances that can be acutely life threatening, such as diabetic ketoacidosis and a hyperglycemic hyperosmolar state. These require hospitalization for insulin administration, rehydration with intravenous fluids, and careful monitoring of electrolytes and metabolic parameters. Chronic end-organ effects of diabetes are commonly divided into microvascular and macrovascular complications. Microvascular complications occur only in individuals with diabetes and include retinopathy, nephropathy, and neuropathy, which are specific to diabetes. Macrovascular complications related to atherosclerosis, such as myocardial infarction and stroke, occur more frequently in individuals with diabetes but are not diabetes specific. In the U.S., diabetes is the leading cause of blindness in adults, the leading reason for renal failure requiring dialysis or renal transplantation, and the leading cause of nontraumatic lower extremity amputations. Evidence from clinical trials indicated that most of these diabetes-related complications can be prevented, delayed, or reduced by chronic, effective glucose lowering.

The mechanisms by which long-standing hyperglycemia causes end-organ complications are unclear. There is experimental evidence to suggest roles for AGEs (advanced glycosylation end products), increased glucose

metabolism via the sorbitol pathway, increased formation of diacylglycerol leading to PKC activation, and increased flux through the hexosamine pathway. Growth factors such as VEGF-A (vascular endothelial growth factor-A) may be involved in diabetic retinopathy and TGF-β in diabetic nephropathy.

Therapy of Diabetes

Goals of Therapy

The goals of therapy for diabetes are to alleviate the symptoms related to hyperglycemia (fatigue, polyuria, weight loss) and to prevent or reduce the acute metabolic decompensation and chronic end-organ complications.

Glycemic control is assessed using both short-term (blood glucose self-monitoring; continuous glucose monitoring) and long-term (A1c, fructosamine) metrics. Using capillary blood glucose measurements, patients can measure capillary blood glucose throughout their usual fasting and feeding periods and report these values to the diabetes management team. Continuous glucose monitoring of interstitial glucose is a rapidly evolving technology that allows near real-time tracking of blood glucose levels and is being used more frequently in the management of type 1 diabetes. A1c reflects glycemic control over the prior 3 months, whereas measures of glycosylated serum proteins or albumin (fructosamine) reflect glycemic control over the preceding 2 weeks.

The term *comprehensive diabetes care* describes optimal therapy, which involves more than glucose management and includes treatment of abnormalities in blood pressure and lipids and detection and management of diabetes-related complications (Figure 47-6). Table 47-4 shows the ADA-recommended treatment goals for comprehensive diabetes care for glucose, blood pressure, and lipids (see Chapters 28 and 33). The treatment goals should be individualized to the patient and take into account factors such as risk of hypoglycemia, life expectancy, age, other medical conditions, duration of diabetes, and advanced macrovascular/microvascular complications of diabetes (Cahn et al., 2015). (see Table 47-4). Also, the patient's attitude toward diabetes, expectations, resources, and support systems should be considered. Costs of the various agents are compared in Table 47-8.

Nonpharmacologic Aspects of Diabetes Therapy

The patient with diabetes should be educated about nutrition, exercise, and medications aimed at lowering the plasma glucose (American Diabetes Association, 2017). In type 1 diabetes, matching caloric intake and insulin dosing is important. In type 2 diabetes, the diet is directed at weight loss and reduction of blood pressure and atherosclerotic risk. There is now compelling evidence that metabolic surgery can prevent or even reverse type 2 diabetes, with clinical trials showing greater efficacy than medical management (Rubino et al., 2016).

Insulin Therapy

Insulin is the mainstay for treatment of virtually all patients with type 1 and many with type 2 diabetes (Cefalu et al., 2015). Although there are specific preparations of insulin that may be administered intramuscularly,

TABLE 47-3 ■ SOME DRUGS THAT MAY PROMOTE HYPERGLYCEMIA OR HYPOGLYCEMIA	
HYPERGLYCEMIA	HYPOGLYCEMIA
Glucocorticoids; thyroid hormone	β Adrenergic antagonists
Antipsychotics (atypical, others)	Theophylline
Protease inhibitors	ACE inhibitors
β Adrenergic agonists; epinephrine	Salicylates, NSAIDs
Thiazide diuretics	LiCl
Hydantoins (phenytoin, others)	Ethanol
Opioids (fentanyl, morphine, others)	Pentamidine
Diazoxide; nicotinic acid	Bromocriptine
Interferons; amphotericin B	
Acamprosate; basiliximab; asparaginase	

For details and discussion of these issues, see Murad et al., 2009.

Figure 47-6 Components of comprehensive diabetes care.

TABLE 47-4 ■ GOALS OF THERAPY FOR DIABETES IN NONPREGNANT ADULTS

INDEX	GOAL ^a
Glycemic control^b	
A _{1c}	<7.0%
Preprandial capillary plasma glucose	4.4–7.2 mmol/L (80–130 mg/dL)
Peak postprandial capillary plasma glucose	<10.0 mmol/L (<180 mg/dL) ^c
Blood pressure	<140/90 ^d
Intensity of statin therapy for lipids^e	
Age < 40 years	
-No ASCVD risk factors	None
-ASCVD risk factors	Moderate or high
-ASCVD	High
Age 40–75 years	
-No ASCVD risk factors	Moderate
-ASCVD risk factors	High
-ASCVD	High
Age > 75 years	
-No ASCVD risk factors	Moderate
-ASCVD risk factors	Moderate or high
-ASCVD	High

^aGoals should be individualized for each patient and may be different for certain patient populations (lower or higher). According to the ADA, “Goals should be individualized based on duration of diabetes, age/life expectancy, comorbid conditions, known CVD or advanced microvascular complications, hypoglycemia unawareness, and individual patient considerations.”

^bAchieving A_{1c} value is primary goal.

^cAt 1–2 h after beginning of a meal.

^dLower BP targets (<130/80) may be appropriate for certain individuals with diabetes.

^eFor individuals with acute coronary syndrome and LDL > 50 mg/dL (1.3 mmol/L) or who cannot tolerate high-dose statins, see Chapter 33. More detailed recommendations can be found in American Diabetes Association, 2017. ASCVD, arteriosclerotic cardiovascular disease.

intravenously, or nasally, long-term treatment relies predominantly on subcutaneous injection. Subcutaneous administration of insulin delivered into the peripheral circulation can lead to near-normal glycemia but differs from physiological secretion of insulin in two major ways:

- The absorption kinetics do not reproduce the rapid rise and decline of endogenous insulin in response to changes in blood glucose.
- Injected insulin is delivered into the peripheral circulation instead of being released into the portal circulation. Thus, the portal/peripheral insulin concentration is not physiological, and this may alter the influence of insulin on hepatic metabolism.

Insulin Preparation and Chemistry

Human insulin, produced by recombinant DNA technology, is soluble in aqueous solution. Doses and concentrations of clinically used insulin preparations are expressed in international units. One international unit of insulin is defined as the bioequivalent of 34.7 µg of crystalline insulin; this is equivalent to the older working definition of a U.S. Pharmacopeia unit as the amount required to reduce the blood glucose concentration to 45 mg/dL (2.5 mM) in 2.2-kg rabbit fasted for 24 h. Most preparations of insulin are supplied in solution or suspension at a concentration of 100 units/mL, which is about 3.6 mg insulin per milliliter (0.6 mM) and termed U-100. Insulin also is available in more concentrated preparations (200 [degludec and lispro insulins], 300 [glargine insulin], or 500 [regular insulin] units/mL) for patients who are resistant to the hormone and require higher doses.

Insulin Formulations

Preparations of insulin are classified according to their duration of action into *short acting* and *long acting* (Table 47-5). Within the short-acting category, it is common to distinguish the *very rapid-acting insulins* (aspart, glulisine, lispro) from regular insulin. Likewise, some distinguish formulations with a *longer duration of action* (degludec, detemir, glargine) from NPH insulin. Two approaches are used to modify the absorption and pharmacokinetic profile of insulin. The first approach is based on formulations that slow the absorption following subcutaneous injection. The other approach is to alter the amino acid sequence or protein structure of human insulin so that it retains its ability to bind to the insulin receptor, but its behavior in solution or following injection is either accelerated or prolonged in comparison to native or regular insulin (Figure 47-7). There is wide variability in the kinetics of insulin action amongst individuals and even with repeated doses in the same individual. The time to peak hypoglycemic effect and insulin levels can vary by 50%, due in part by large variations in the rate of subcutaneous absorption.

Short-Acting Regular Insulin. Native or regular insulin molecules associate as hexamers in aqueous solution at a neutral pH, and this aggregation slows absorption following subcutaneous injection. Regular insulin should be injected 30–45 min before a meal. Regular, unbuffered, 100-units/mL insulin also may be given intravenously or intramuscularly. However, unbuffered, regular insulin (500 units/mL) is for subcutaneous injection only and should not be given by intravenous or intramuscular injection.

Short-Acting Insulin Analogues. The short-acting insulin analogues are absorbed more rapidly from subcutaneous sites than regular insulin (see Figures 47-7 and 47-8; see Table 47-5) (Kerr et al., 2013). Insulin analogues should be injected 15 min or less before a meal. The time-action profile of these insulin analogues is similar. When used to treat glycemia after meals, the short-acting analogues have lower rates of hypoglycemia and modestly improved A_{1c} levels compared to regular insulin.

Insulin lispro is identical to human insulin except at positions B28 and B29. Unlike regular insulin, lispro dissociates into monomers almost instantaneously following injection. This property results in the characteristic rapid absorption and shorter duration of action compared with regular insulin.

Insulin aspart is formed by the replacement of proline at B28 with aspartic acid, reducing self-association. Like lispro, insulin aspart dissociates rapidly into monomers following injection.

Insulin glulisine is formed when glutamic acid replaces lysine at B29 and lysine replaces asparagine at B3; these substitutions result in a reduction in self-association and rapid dissociation into active monomers.

Long-Acting Insulins. NPH insulin (insulin isophane) is a suspension of native insulin complexed with zinc and protamine in a phosphate buffer. This produces a cloudy or whitish solution in contrast to the clear appearance of other insulin solutions. NPH insulin dissolves more gradually when injected subcutaneously; thus, its duration of action is prolonged. NPH insulin is usually given either once a day (at bedtime) or twice a day in combination with short-acting insulin.

Insulin glargine is a long-acting analogue of human insulin. Two arginine residues are added to the C terminus of the B chain, and an asparagine molecule in position 21 on the A chain is replaced with glycine. Insulin glargine is a clear solution with a pH of 4.0, which stabilizes the insulin hexamer. When injected into the neutral pH of the subcutaneous space, aggregation occurs, resulting in prolonged, predictable, absorption from the injection site. Owing to insulin glargine's acidic pH, it cannot be mixed with short-acting insulin preparations that are formulated at a neutral pH. Glargine has a sustained peakless absorption profile and provides more predictable 24-h insulin coverage than NPH insulin when injected once daily. Clinical trial data suggest that glargine has a lower risk of hypoglycemia, particularly overnight compared to NPH insulin. Glargine may be administered at any time during the day with equivalent efficacy and does not accumulate after several injections. Different preparations are

TABLE 47-5 ■ TIME-ACTION PROFILES OF INSULIN PREPARATIONS

TYPE	PREPARATION	TIMES		
		ONSET (h)	PEAK (h)	EFFECTIVE DURATION (h)
Short acting				
	Aspart Glulisine Lispro Regular	<0.25 0.5–1.0	0.5–1.5 2–3	3–4 4–6

Inhaled insulin				
	Afrezza	<0.25	0.5–1.5	2–3

^aGlargine, degludec, and detemir have minimal peak activity at steady-state.
^bAvailable as a U-100 and U-300 preparation.
^cSome mixtures will have dual peaks, one at 2–3 h, the second one several hours later.
^dDiscontinued by manufacturer in the US.

Figure 47-7 Insulin analogues. Modifications of native insulin can alter its pharmacokinetic profile. Reversing amino acids 28 and 29 in the B chain (lispro) or substituting Asp for Pro^{28B} (aspart) gives analogues with reduced tendencies for molecular self-association that are faster acting. Altering Asp^{31B} to Lys and Lys^{29B} to Glu produces an insulin (glulisine) with a more rapid onset and a shorter duration of action. Substituting Gly for Asn^{21A} and lengthening the B chain by adding Arg³¹ and Arg³² produces a derivative (glargine) with reduced solubility at pH 7.4 that is, consequently, absorbed more slowly and acts over a longer period of time. Deleting Thr^{30B} and adding a myristoyl group to the ε-amino group of Lys^{29B} (detemir) enhances reversible binding to albumin, thereby slowing transport across vascular endothelium to tissues and providing prolonged action. *Insulin degludec* is LysB29(Nε-hexadecanoyl-γ-Glu) des(B30) human insulin. When degludec is injected subcutaneously, it forms multihexameric complexes that slow absorption; degludec also binds well to albumin; these two characteristics contribute to the prolonged effect of degludec (>24 h at steady state).

formulated at different concentrations: *Lantus* is formulated at 100 units/mL and a new formulation, *Toujeo*, at 300 units/mL. *Toujeo* may have a longer duration of action than *Lantus*. *Basiglar* is a glargine biosimilar formulation.

Insulin detemir is an insulin analogue modified by the addition of a saturated fatty acid to the ε amino group of LysB29, yielding a myristoylated insulin. When insulin detemir is injected subcutaneously, it binds to albumin via its fatty acid chain. In patients with type 1 diabetes, insulin detemir, administered twice a day, has a smoother time-action profile and produces a reduced prevalence of hypoglycemia than NPH insulin. The absorption profiles of glargine and detemir insulin are similar, but detemir often requires twice-daily administration.

Insulin degludec is a modified insulin with one amino acid deleted (threonine at position B30) and is conjugated to hexadecanedioic acid via γ-L-glutamyl spacer at the amino acid lysine at position B29. Degludec, which is active at a physiologic pH, forms multihexamers after injection subcutaneously. It has less severe hypoglycemia than glargine.

Other Insulin Formulations. Stable combinations of short-acting and long-acting insulins provide convenience by reducing the number of daily injections.

Inhaled insulin (Afrezza) is formulated for inhalation using a manufacturer-specific device (Leahy, 2015). This formulation should be used in combination with a long-acting insulin and has a more rapid onset and shorter duration than injected insulin analogues. It is not widely used. Adverse events include cough and throat irritation. It should not be used in individuals who smoke.

Insulin Delivery

Most insulin is injected subcutaneously. Pen devices containing prefilled insulin have proven to be popular. Jet injector systems that enable patients to receive subcutaneous insulin injections without a needle are available. Intravenous infusions of insulin are useful in patients with ketoacidosis or when requirements for insulin may change rapidly, such as during the perioperative period, during labor and delivery, and in intensive care situations. Long-acting insulin should not be given intravenously or intramuscularly or in an infusion device.

Figure 47-8 Commonly used insulin regimens. Panel A shows administration of a long-acting insulin like glargine (detemir or *degludec* could also be used; detemir may require twice-daily administration; *degludec* is used once daily; see text for details) to provide basal insulin and a premeal short-acting insulin analogue (see Table 47-5). Panel B shows a less-intensive insulin regimen with twice-daily injection of NPH insulin providing basal insulin and regular insulin or an insulin analogue providing mealtime insulin coverage. Only one type of short-acting insulin would be used. Panel C shows the insulin level attained following subcutaneous insulin (short-acting insulin analogue) by an insulin pump programmed to deliver different basal rates. At each meal, an insulin bolus is delivered. Here, B indicates breakfast, L lunch, S supper, and HS bedtime. An upward arrow shows insulin administration at mealtime. (Reprinted with permission from Kaufman FR, ed. *Medical Management of Type 1 Diabetes*, 6th ed. American Diabetes Association, Alexandria, VA, 2012. Copyright © 2012 by the American Diabetes Association.)

Continuous Subcutaneous Insulin Infusion. Short-acting insulins are the only form of the hormone used in subcutaneous insulin infusion devices. A number of pumps are available for CSII therapy; this technology is rapidly evolving with improvements in hardware and software (McAdams and Rizvi, 2016). Insulin infusion devices provide a constant basal infusion of insulin and have the option of different infusion rates during the day and night to help avoid the rise in blood glucose that occurs just prior to awakening from sleep (the dawn phenomenon) and bolus injections that are programmed according to the size and nature of a meal. Selection of the most appropriate patients is extremely important for success with CSII. Pump insulin infusion devices can produce a more physiological profile of insulin replacement during exercise (where insulin production is decreased) and thus less hypoglycemia than traditional subcutaneous insulin injections provide. The technology for combining an insulin infusion device and continuous glucose monitoring is rapidly evolving with algorithms that alter the infusion rate (Thabit and Hovorka, 2016).

Factors That Affect Insulin Absorption

Factors that determine the rate of absorption of insulin after subcutaneous administration include the site of injection, the type of insulin, subcutaneous blood flow, smoking, regional muscular activity at the site of the injection, the volume and concentration of the injected insulin, and depth of injection (insulin has a more rapid onset of action if delivered intramuscularly rather than subcutaneously). Increased subcutaneous blood flow (brought about by massage, hot baths, or exercise) increases the rate of absorption. The abdomen currently is the preferred site of injection in the morning because insulin is absorbed 20%–30% faster from that site than from the arm. Rotation of insulin injection sites is recommended to avoid or limit subcutaneous scarring, lipohypertrophy, or lipodystrophy.

Insulin Dosing and Regimens

A number of commonly used dosage regimens that include mixtures of insulin given in two or more daily injections are depicted in Figure 47-8. For most patients, insulin-replacement therapy includes long-acting insulin (basal) and a short-acting insulin to provide postprandial needs. In a mixed population of patients with type 1 diabetes, the average dose of insulin is usually 0.6–0.7 units/kg body weight per day, with a range of 0.4–1 units/kg/d. Obese patients generally and pubertal adolescents may require more (about 1–2 units/kg/d) because of resistance of peripheral tissues to insulin. Patients who require less insulin than 0.5 units/kg/d may have some endogenous production of insulin or may be more sensitive to the hormone because of good physical conditioning. The basal dose is usually 40%–50% of the total daily dose, with the remainder as prandial or premeal insulin. The insulin dose at mealtime should reflect the anticipated carbohydrate intake. A supplemental scale of short-acting

insulin is added to the prandial insulin dose to allow correction of the blood glucose. *Insulin administered as a single daily dose of long-acting insulin, alone or in combination with short-acting insulin, is rarely sufficient to achieve euglycemia. More complex regimens that include multiple injections of long-acting or short-acting insulin are needed to reach this goal. In all patients, careful monitoring of therapeutic end points directs the insulin dose used. This approach is facilitated by self-monitoring of glucose, measurements of A1c, and individualization of the patient's therapeutic regimen (Table 47-4).* In patients who have gastroparesis or loss of appetite, injection of a short-acting analogue postprandially, based on the amount of food actually consumed, may provide smoother glycemic control.

Adverse Events

Hypoglycemia is the major risk that must be weighed against benefits of efforts to normalize glucose control. Insulin treatment of both type 1 and type 2 diabetes is associated with modest weight gain. Although uncommon, allergic reactions to recombinant human insulin may still occur as a result of reaction to the small amounts of aggregated or denatured insulin in preparations, to minor contaminants, or because of sensitivity to a component added to insulin in its formulation (protamine, Zn^{2+} , etc.). Atrophy of subcutaneous fat at the site of insulin injection (lipodystrophy) was a rare side effect of older insulin preparations. Lipohypertrophy (enlargement of subcutaneous fat depots) has been ascribed to the lipogenic action of high local concentrations of insulin.

Insulin Treatment of Ketoacidosis and Other Special Situations

Intravenous administration of insulin is most appropriate in patients with ketoacidosis or severe hyperglycemia with a hyperosmolar state (Umpierrez and Korytkowski, 2016). Insulin infusion inhibits lipolysis and gluconeogenesis completely and produces near-maximal stimulation of glucose uptake. In most patients with diabetic ketoacidosis, blood glucose concentrations will fall by about 10% per hour; the acidosis is corrected more slowly. As treatment proceeds, it often is necessary to administer glucose along with the insulin not only to prevent hypoglycemia but also to allow clearance of all ketones. Patients with a nonketotic hyperglycemic hyperosmolar state may be more sensitive to insulin than are those with ketoacidosis. Appropriate replacement of fluid and electrolytes, particularly K^+ , is an integral part of the therapy in both situations because there is always a major K^+ deficit. A long-acting insulin should be administered subcutaneously before the insulin infusion is discontinued.

Treatment of Diabetes in Children or Adolescents

Diabetes is one of the most common chronic diseases of childhood, and rates of type 1 diabetes in American youth are estimated at 1 in 300. An unfortunate corollary of the growing rates of obesity over the past three decades

is an increase in the numbers of children and adolescents with non-autoimmune, or type 2, diabetes. Current estimates are that 15%–20% of new cases of pediatric diabetes may be of type 2 diabetes; rates vary by ethnicity, with disproportionately high rates in Native Americans, African Americans, and Latinos. Current practice for type 1 diabetes is for intensive, physiologically based insulin replacement using combinations of basal and prandial insulin replacement or CSII with a goal of near-normal glucose control while avoiding hypoglycemia (Figure 47–7). The primary limiting factor of aggressive insulin therapy is hypoglycemia. In children and adolescents with type 1 diabetes, the recommended A1c goal is less than 7.5%, with a lower goal as appropriate. Insulin infusion devices and continuous glucose monitoring are being used with increasing frequency in the pediatric diabetic population and in older children and adolescents.

Because of the association of type 2 diabetes with obesity in the pediatric age group, lifestyle management is the recommended first step in therapy. Goals of reducing body weight and increasing physical activity are broadly recommended. The only medication currently approved by the FDA specifically for medical treatment of type 2 diabetes is *metformin*. Metformin is approved for children as young as 10 years of age and is available in a liquid formulation (100 mg/mL). Insulin is the typical second line of therapy after metformin; basal insulin can be added to oral agent therapy or multiple daily injections can be used when simpler regimens are not successful. Weight gain is a more significant problem than hypoglycemia with insulin treatment in pediatric type 2 diabetes.

Management of Diabetes in Hospitalized Patients

Hyperglycemia is common in hospitalized patients. Prevalence estimates of elevated blood glucose amongst inpatients with and without a prior diagnosis of diabetes range between 20% and 100% for patients treated in ICUs and 30% and 83% outside the ICU. Stress of illness has been associated with insulin resistance, possibly the result of counterregulatory hormone secretion, cytokines, and other inflammatory mediators. Food intake is often variable due to concurrent illness or preparation for diagnostic testing. Medications used in the hospital, such as glucocorticoids or dextrose-containing intravenous solutions, can exacerbate tendencies toward hyperglycemia. Finally, fluid balance and tissue perfusion can affect the absorbance of subcutaneous insulin and the clearance of glucose. Therapy of hyperglycemia in hospitalized patients needs to be adjusted for these variables. Emerging data indicate that hyperglycemia portends poor outcomes in hospitalized patients.

Insulin is the cornerstone of treatment of hyperglycemia in hospitalized patients. Oral agents have a limited place in treatment of hyperglycemic patients in the hospital because of slow onset of action, insufficient potency, need for intact GI function, and side effects. In noncritically ill hospitalized patients, a basal plus bolus correction insulin regimen, adjusted for oral intake, is optimal (Jacobi et al., 2012; McDonnell and Umpierrez, 2012). Using only short-acting insulins administered in response to hyperglycemia (i.e., sliding-scale regimens) to treat diabetes in the inpatient hospital setting is not appropriate therapy. For critically ill patients and those with variable blood pressure, edema, and tissue perfusion, intravenous insulin is the treatment of choice. Intravenous administration of insulin also is well suited to the treatment of diabetic patients during the perioperative period and during childbirth. The ADA suggests blood glucose targets of 140–180 m/dL (7.8–10.0 mM) in most hospitalized patients with more stringent goals, such as 110–140 mg/dL (6.1–7.8 mmol/L) in some critically ill patients (if achievable without significant hypoglycemia).

Insulin Secretagogues and Glucose-Lowering Agents

A variety of *sulfonylureas*, *meglitinides*, *GLP-1 agonists*, and *inhibitors of DPP-4* are used as secretagogues to stimulate insulin release (Table 47–6).

K_{ATP} Channel Modulators: Sulfonylureas

First-generation sulfonylureas (*tolbutamide*, *tolazamide*, and *chlorpropamide*) are rarely used now in the treatment of type 2 diabetes. The second, more potent, generation of hypoglycemic sulfonylureas includes *glyburide*

(*glibenclamide*), *glipizide*, and *glimepiride* (Kalra et al., 2015; Thule and Umpierrez, 2014). Some are available in an extended-release (*glipizide*) or a micronized (*glyburide*) formulation.

Mechanism of Action. Sulfonylureas stimulate insulin release by binding to a specific site on the β cell K_{ATP} channel complex (SUR) and inhibiting its activity. K_{ATP} channel inhibition causes cell membrane depolarization and the cascade of events leading to insulin secretion (see Figure 47–3). The acute administration of sulfonylureas to patients with type 2 diabetes increases insulin release from the pancreas. With chronic administration, circulating insulin levels decline to those that existed before treatment, but despite this reduction in insulin levels, reduced plasma glucose levels are maintained. The absence of acute stimulatory effects of sulfonylureas on insulin secretion during chronic treatment is attributed to downregulation of cell surface receptors for sulfonylureas on the pancreatic β cell.

ADME. Sulfonylureas are effectively absorbed from the GI tract. Food and hyperglycemia can reduce absorption. Sulfonylureas in plasma are largely (90%–99%) bound to protein, especially albumin. The volumes of distribution of most of the sulfonylureas are about 0.2 L/kg. Although their half-lives are short (3–5 h), their hypoglycemic effects are evident for 12–24 h, and they often can be administered once daily. The liver metabolizes all sulfonylureas, and the metabolites are excreted in the urine. Thus, sulfonylureas should be administered with caution to patients with either renal or hepatic insufficiency.

Therapeutic Uses. Sulfonylureas are used to treat hyperglycemia in type 2 diabetes. Of properly selected patients, 50%–80% respond to this class of agents. All members of the class appear to be equally efficacious. A significant number of patients who respond initially later cease to respond

TABLE 47–6 ■ PROPERTIES OF INSULIN SECRETAGOGUES

CLASS Generic name	DAILY DOSAGE ^a (mg)	DURATION OF ACTION (hours or dosing frequency)
Sulfonylureas^b		
Glimepiride	1–8	24
Glipizide	5–40	12–18
Glipizide (extended release)	5–20	24
Glyburide	1.25–20	12–24
Glyburide (micronized)	0.75–12	12–24
Nonsulfonylureas (Meglitinides)^c		
Nateglinide	180–360	2–4
Repaglinide	0.5–16	2–6
GLP-1 Agonists		
Albiglutide	30–50	Weekly
Dulaglutide	0.75–1.5	Weekly
Exenatide ^b	2	Weekly
Liraglutide	0.6–1.8	Daily
Lixisenatide	0.010–0.020	Daily
Dipeptidyl Peptidase-4 Inhibitors		
Alogliptin	25	Daily
Linagliptin	5	Daily
Saxagliptin	2.5–5	Daily
Sitagliptin	25–100	12–16
Vildagliptin	50–100	Twice daily

^aDose should be lower in some patients.

^bOlder sulfonylureas are available, but rarely used (see text). Doses > 30 mg/d usually are divided into two doses.

^cLabeled for administration 3–4 times daily.

to the sulfonylurea and develop unacceptable hyperglycemia (so-called secondary failure). This may occur as a result of a change in drug metabolism or more likely from a progression of β cell failure. Some individuals with neonatal diabetes or MODY-3 respond to these agents. Contraindications to the use of these drugs include type 1 diabetes, pregnancy, lactation, and, for the older forms, significant hepatic or renal insufficiency.

Adverse Effects; Drug Interactions. Sulfonylureas may cause hypoglycemic reactions, including coma. Weight gain of 1–3 kg is a common side effect of improving glycemic control with sulfonylurea treatment. Less-frequent side effects include nausea and vomiting, cholestatic jaundice, agranulocytosis, aplastic and hemolytic anemias, generalized hypersensitivity reactions, and dermatological reactions. Rarely, patients treated with these drugs develop an alcohol-induced flush similar to that caused by disulfiram or hyponatremia. Whether this class of drugs is associated with an increase in cardiovascular mortality remains controversial.

The hypoglycemic effect of sulfonylureas may be enhanced by various mechanisms (decreased hepatic metabolism or renal excretion, displacement from protein-binding sites). Some drugs (sulfonamides, clofibrate, and salicylates) displace the sulfonylureas from binding proteins, thereby transiently increasing the concentration of free drug. Ethanol may enhance the action of sulfonylureas and cause hypoglycemia. Hypoglycemia may be more frequent in patients taking a sulfonylurea in combination with one or more of these agents: androgens, anticoagulants, azole antifungals, chloramphenicol, fenfluramine, fluconazole, gemfibrozil, H_2 antagonists, magnesium salts, methyl dopa, MAOIs, probenecid, sulfapyrazole, sulfonamides, tricyclic antidepressants, and urinary acidifiers. Other drugs may decrease the glucose-lowering effect of sulfonylureas by increasing hepatic metabolism, increasing renal excretion, or inhibiting insulin secretion (β blockers, Ca^{2+} channel blockers, cholestyramine, diazoxide, estrogens, hydantoins, isoniazid, nicotinic acid, phenothiazines, rifampin, sympathomimetics, thiazide diuretics, and urinary alkalizers).

Dosage Forms Available. Treatment is initiated at the lower end of the dose range and titrated upward based on the patient's glycemic response. Some have a longer duration of action and can be prescribed in a single daily dose (glimepiride), whereas others are formulated as extended-release or micronized formulations to extend their duration of action (see Table 47–6). Sulfonylureas such as glipizide or glimepiride appear safer than longer-acting sulfonylureas in elderly individuals with type 2 diabetes, but even the short-duration agents should be used with caution in elderly patients.

K_{ATP} Channel Modulators: Nonsulfonylureas

Repaglinide. Repaglinide is an oral insulin secretagogue of the meglitinide class (see Table 47–6). Like sulfonylureas, it stimulates insulin release by closing K_{ATP} channels in pancreatic β cells (Chen et al., 2015).

The drug is absorbed rapidly from the GI tract, and peak blood levels are obtained within 1 h. The $t_{1/2}$ is about 1 h. These features allow for multiple preprandial use. Repaglinide is metabolized primarily by the liver (CYP3A4) to inactive derivatives. Because a small proportion (~10%) is metabolized by the kidney, dosing of the drug in patients with renal insufficiency also should be performed cautiously.

The major side effect of repaglinide is hypoglycemia. Repaglinide also is associated with a decline in efficacy (secondary failure) after initially improving glycemic control. Certain drugs may potentiate the action of repaglinide by displacing it from plasma protein-binding sites (β blockers, chloramphenicol, coumarin, MAOIs, NSAIDs, probenecid, salicylates, and sulfonamide) or altering its metabolism (gemfibrozil, itraconazole, trimethoprim, cyclosporine, simvastatin, clarithromycin).

Nateglinide. Nateglinide is an orally effective insulin secretagogue. Nateglinide stimulates insulin secretion by blocking K_{ATP} channels in pancreatic β cells (Chen et al., 2015). Nateglinide promotes a more rapid but less-sustained secretion of insulin than other available oral antidiabetic agents. The drug's major therapeutic effect is reducing postprandial glycemic elevations in patients with type 2 diabetes.

Nateglinide is most effective when administered at a dose of 120 mg, three times daily, 1–10 min before a meal. It is metabolized primarily by hepatic CYPs (2C9, 70%; 3A4, 30%) and should be used cautiously in patients with hepatic insufficiency. About 16% of an administered dose is excreted by the kidney as unchanged drug. Some drugs reduce the glucose-lowering effect of nateglinide (corticosteroids, rifamycins, sympathomimetics, thiazide diuretics, thyroid products); others (alcohol, NSAIDs, salicylates, MAOIs, and nonselective β blockers) may increase the risk of hypoglycemia with nateglinide. Nateglinide therapy may produce fewer episodes of hypoglycemia than other currently available oral insulin secretagogues, including repaglinide. As with sulfonylureas and repaglinide, secondary failure occurs.

Biguanides

Metformin is the only member of the biguanide class of oral hypoglycemic drugs available for use today. Previously available biguanides, phenformin and buformin, were removed from the market in the 1970s due to unacceptable rates of associated lactic acidosis.

Mechanism of Action. Several mechanisms have been proposed to explain the central pharmacologic action of metformin, the reduction of HGP primarily by limiting gluconeogenesis. Metformin has specific actions on mitochondrial respiration that reduce intracellular ATP and increase AMP. Experimental evidence supports activation of AMP-dependent protein kinase (AMPK) by metformin, leading to stimulation of hepatic fatty acid oxidation, glucose uptake, and nonoxidative glucose metabolism and reduction of lipogenesis and gluconeogenesis. Metformin also inhibits the mitochondrial glycerol phosphate dehydrogenase, thereby changing the redox state of the cell. More recent evidence implicates other mechanisms, including blunting the effects of glucagon, inhibiting conversion of lactate and glycerol to glucose, and shifting the liver toward negative lipid balance.

Most of the pharmacologic effects of metformin are mediated in the liver with little effect on glucose metabolism or insulin sensitivity in skeletal muscle. Metformin has little effect on blood glucose in normoglycemic states, does not stimulate the release of insulin or other islet hormones, and rarely causes hypoglycemia. However, even in persons with only mild hyperglycemia, metformin lowers blood glucose by reducing HGP and increasing glucose clearance. This last effect is not well understood because of the modest action of metformin to promote glucose uptake in peripheral tissues (e.g., skeletal muscle and adipose tissue). There is little information to support a direct effect of metformin on hepatic insulin signaling, but there are at least complementary effects of the drug to improve the dose-response relationship between insulin and hepatic glucose production.

ADME. Fixed-dose combinations of metformin in conjunction with glipizide, glyburide, pioglitazone, repaglinide, rosiglitazone, linagliptin, saxagliptin, sitagliptin, alogliptin, canagliflozin, dapagliflozin, and empagliflozin are available. Based on the pharmacokinetics of the common immediate-release form of metformin, it is now recommended for twice-daily administration at doses of 0.5–1.0 g. The maximum dose is 2550 mg, but therapeutic benefit starts to plateau at 2000 mg. A sustained-release preparation is available for once-daily dosing starting at 500 mg daily, with titration up to 2000 mg as necessary.

Metformin is absorbed primarily from the small intestine with a bioavailability of 70%–80%. Peak concentrations after an oral dose occur at about 2 h; the drug's plasma $t_{1/2}$ is 4–5 h. The drug does not bind to plasma proteins and is excreted unchanged in the urine. The transport of metformin into hepatocytes is mediated primarily by OCT 1; renal uptake is mediated by OCT 2. Export into the urine is by MATE1/2 (multidrug and toxin extrusion proteins).

Therapeutic Uses. Metformin is generally accepted as the first-line treatment of type 2 diabetes and is currently the most commonly used oral agent for this condition. Metformin is effective as monotherapy and in combination with other glucose lowering medications (Mearns et al., 2015). African Americans may have a better response to metformin than Caucasians.

Metformin has superior or equivalent efficacy of glucose lowering compared to other oral agents used to treat diabetes and reduces microvascular complications in patients with type 2 diabetes; more limited data support a beneficial effect to reduce macrovascular disease as well. Metformin does not typically cause weight gain and in some cases causes mild weight reduction. In persons with IGT, treatment with metformin delays the progression to diabetes. Metformin has been used as a treatment of infertility in women with polycystic ovarian syndrome. Although not formally approved for this purpose, metformin demonstrably improves ovulation and menstrual cyclicity and reduces circulating androgens and hirsutism.

Adverse Effects; Drug Interactions. The most common side effects (10%–25%) of metformin are GI: nausea, indigestion, abdominal cramps or bloating, diarrhea, or some combination of these. Metformin has direct effects on GI function, including interference with the absorption of glucose and bile salts. Use of metformin is also associated with 20%–30% lower blood levels of vitamin B₁₂ and these levels should be monitored. Most adverse GI effects of metformin abate over time with continued use and can be minimized by starting at low doses and gradually titrating to a target dose over several weeks, as well as by having patients take the drug with meals. Most studies indicated that extended-release metformin has decreased GI side effects and can be substituted for immediate-release metformin in patients who are having difficulty tolerating the drug.

Because the previously available biguanides phenformin and buformin caused lactic acidosis, metformin has been carefully scrutinized for this side effect. Lactic acidosis associated with metformin has been rarely reported in patients with the setting of concurrent conditions that can cause poor tissue perfusion (e.g., sepsis, myocardial infarction, and congestive heart failure). However, recent analyses have raised doubts regarding whether the association of metformin with lactic acidosis is causal. Renal failure is a common comorbidity in patients with lactic acidosis associated with metformin use, and plasma metformin levels are inversely related to GFR due to reduced clearance of drug from the circulation (e.g., levels rise above the usual therapeutic range when creatinine clearance drops below 40–50 mL/min). However, in recent studies of patients with severe renal failure, including some requiring dialysis, rates of lactic acidosis were not increased in those taking metformin. The ADA suggests that metformin may be used safely when the GFR is greater than 45 mL/min/1.73 m², and that the dose should be reduced by 50%–75% when GFR is 30–45 mL/min/1.73 m².

It is important to assess renal function before starting metformin and to monitor function at least annually. Metformin should be discontinued preemptively if renal function could decline precipitously, such as before radiographic procedures that use contrast dyes and during admission to the hospital for severe illness. Metformin should not be used in patients with severe pulmonary disease, decompensated heart failure, severe liver disease, or chronic alcohol abuse. Cationic drugs that are eliminated by renal tubular secretion have the potential for interaction with metformin by competing for common renal tubular transport systems. Adjustment of metformin is recommended in patients who are taking cationic medications such as cimetidine, furosemide, and nifedipine.

Thiazolidinediones

Thiazolidinediones are ligands for the PPAR γ receptor, a nuclear hormone receptor that has two isoforms and is involved in the regulation of genes related to glucose and lipid metabolism. Two thiazolidinediones are currently available to treat patients with type 2 diabetes, *rosiglitazone* and *pioglitazone*; a third, *trogliptazone*, was removed from the market in 2000 due to hepatotoxicity.

Mechanism of Action; Pharmacological Effects. Thiazolidinediones activate PPAR γ receptors, which are expressed primarily in adipose tissue with lesser expression in cardiac, skeletal, and smooth muscle cells; islet β cells; macrophages; and vascular endothelial cells. The endogenous ligands for PPAR γ include small lipophilic molecules such as oxidized linoleic acid, arachidonic acid, and the prostaglandin metabolite 15d-PGJ₂. Ligand binding to PPAR γ causes heterodimer formation with the retinoid X receptor and interaction with PPAR response elements on specific genes (see Chapter 3). The principal response to PPAR γ activation is

adipocyte differentiation. PPAR γ activity also promotes uptake of circulating fatty acids into fat cells and shifts of lipid stores from extra-adipose sites to adipose tissue.

One consequence of the cellular responses to PPAR γ activation is increased tissue sensitivity to insulin. Pioglitazone and rosiglitazone are insulin sensitizers and increase insulin-mediated glucose uptake by 30%–50% in patients with type 2 diabetes. Although adipose tissue seems to be the primary target for PPAR γ agonists, both clinical and preclinical models support a role for skeletal muscle, the major site for insulin-mediated glucose disposal, in the response to thiazolidinediones. In addition to promoting glucose uptake into muscle and adipose tissue, the thiazolidinediones reduce HGP and increase hepatic glucose uptake. It is not clear whether thiazolidinedione-induced improvement of insulin resistance is due to direct effects on key target tissues (skeletal muscle and liver), indirect effects mediated by secreted products of adipocytes (e.g., adiponectin), or some combination of these.

Thiazolidinediones also affect lipid metabolism. Treatment with rosiglitazone or pioglitazone reduces plasma levels of fatty acids by increasing clearance and reducing lipolysis. These drugs also cause a shift of triglyceride stores from nonadipose to adipose tissues and from visceral to subcutaneous fat depots. Pioglitazone reduces plasma triglycerides by 10%–15%, raises HDL cholesterol levels, and increases LDL cholesterol. In contrast, rosiglitazone has minimal effects on plasma triglycerides, and the only consistent effect on circulating lipids is an increase of LDL cholesterol.

ADME. Rosiglitazone and pioglitazone are dosed once daily. The starting dose of rosiglitazone is 4 mg, and the maximum dose should not exceed 8 mg daily. The starting dose of pioglitazone is 15–30 mg, increased up to a maximum of 45 mg daily. Both agents are absorbed within 2–3 h, and bioavailability is unaffected by food. The thiazolidinediones are metabolized by the liver and may be administered to patients with renal insufficiency, but should not be used if there is active hepatic disease. Rifampin induces hepatic CYPs and causes a significant decrease in plasma concentrations of rosiglitazone and pioglitazone; gemfibrozil impedes metabolism of the thiazolidinediones and can increase plasma levels by about 2-fold; a dose reduction is suggested with this combination. The onset of action of thiazolidinediones is relatively slow; maximal effects on glucose homeostasis develop gradually over the course of 1–3 months.

Therapeutic Uses. Thiazolidinediones enhance insulin action on liver, adipose tissue, and skeletal muscle; confer improvements in glycemic control in persons with type 2 diabetes; and cause average reductions in A1c of 0.5%–1.4%. Thiazolidinediones require the presence of insulin for pharmacological activity and are not used to treat type 1 diabetes. Both pioglitazone and rosiglitazone are effective as monotherapy and as additive therapy to metformin, sulfonylureas, or insulin. In addition, pioglitazone is marketed in a fixed-dose combination with alogliptin.

Adverse Effects; Drug Interactions. The most common adverse effects of the thiazolidinediones are weight gain and edema. Thiazolidinediones cause an increase in body adiposity and an average weight gain of 2–4 kg over the first year of treatment. The use of insulin with thiazolidinedione treatment roughly doubles the incidence of edema and amount of weight gain compared with either drug alone. Macular edema has been reported in patients using both rosiglitazone and pioglitazone, but this was not a consistent finding in recent clinical trials (Ambrosius et al., 2010).

As with other side effects of thiazolidinediones, fluid retention is dose related. Use of thiazolidinediones is associated with a mild reduction of hematocrit, which may be an effect of fluid retention, although a primary effect on hematopoiesis has not been excluded.

Exposure to these drugs over several years in clinical trials has been associated with an increased incidence of heart failure of up to 2-fold (Home, 2012; Horita et al., 2015). This has generally been attributed to the effect of the drugs to cause plasma volume expansion in patients with type 2 diabetes who have an increased risk for heart failure. There does not appear to be an acute effect of pioglitazone or rosiglitazone to reduce myocardial contractility or ejection fraction.

The use of thiazolidinediones in diabetic patients without a history of heart failure, or with compensated heart failure, can be initiated, but monitoring for signs and symptoms of congestive heart failure is important, especially when insulin is also used. Thiazolidinediones should not be used in patients with moderate-to-severe heart failure. In the past, evidence suggested that rosiglitazone increased the risk of cardiovascular events (myocardial infarction, stroke). For this reason, the FDA restricted its use for several years, but this regulation has now been lifted. The connection of the drug to cardiovascular disease remains controversial; most evidence supports either mild beneficial effects of pioglitazone on overall cardiovascular events or a neutral impact. In a trial of nondiabetic individuals who had insulin resistance and a recent history of ischemic stroke or TIA, pioglitazone reduced the risk of subsequent stroke or myocardial infarction and diabetes (Kernan et al., 2016).

Treatment with thiazolidinediones has been associated with a consistent increased risk of bone fracture in women, with some studies also showing effects in men (Gilbert and Pratley, 2015). Therefore, the presence of osteoporosis and other risks for fracture should be considered before starting thiazolidinediones.

Pioglitazone and rosiglitazone are associated with a lowering of transaminases, probably reflective of reductions in hepatic steatosis (Singh et al., 2015); thus, thiazolidinediones should be withheld from patients with clinically apparent liver disease, and liver function should be monitored intermittently during treatment.

GLP-1–Based Agents

Incretins are GI hormones that are released after meals and stimulate insulin secretion. The best-known incretins are GLP-1 and GIP. GIP has reduced efficacy to stimulate insulin release and lower blood glucose in persons with type 2 diabetes, whereas GLP-1 is effective, and the GLP-1 signaling system has been a successful drug target.

Both GLP-1 and glucagon are derived from proglucagon, a 180-amino acid precursor with five separately processed domains (Figure 47–9). An amino-terminal signal peptide is followed by glicentin-related pancreatic peptide, glucagon, GLP-1, and GLP-2. Processing of the protein is sequential and occurs in a tissue-specific fashion. Pancreatic α cells cleave proglucagon into glucagon and a large C-terminal peptide that includes both of the GLPs. Intestinal L cells and specific hindbrain neurons process proglucagon into a large N-terminal peptide that includes glucagon or GLP-1 and GLP-2. GLP-2 affects the proliferation of epithelial cells lining the GI tract. Teduglutide, a GLP-2 analogue, is approved for treatment of short-bowel syndrome (see Chapter 50).

Given intravenously to diabetic subjects in supraphysiologic amounts, GLP-1 stimulates insulin secretion, inhibits glucagon release, delays gastric emptying, reduces food intake, and normalizes fasting and postprandial insulin secretion. The insulinotropic effect of GLP-1 is glucose dependent in that insulin secretion at fasting glucose concentrations, even with high levels of circulating GLP-1, is minimal. GLP-1 is rapidly inactivated by the

enzyme DPP-4, yielding a plasma $t_{1/2}$ of 1–2 min; thus, the natural peptide, itself, is not a useful therapeutic agent. Two broad strategies have been taken to applying GLP-1 to therapeutics: the development of injectable, DPP-4-resistant peptide agonists of the GLP-1 receptor and the creation of small-molecule inhibitors of DPP-4 (Figure 47–10; see Table 47–6).

GLP-1 Receptor Agonists

Five GLP-1RAs have been approved for treatment of diabetic patients in the U.S (Table 47–6); a fifth, lixisenatide, is available in Europe (Madsbad, 2016; Trujillo and Nuffer, 2014).

Exenatide. Exendin-4, is a naturally occurring 39-amino acid reptilian peptide with 53% sequence homology to GLP-1. This peptide is a potent GLP-1RA that shares many of the physiological and pharmacological effects of GLP-1. It is not metabolized by DPP-4 and so has extended activity following injection. Synthetic exendin-4, exenatide, is approved for use as monotherapy and as adjunctive therapy for patients with type 2 diabetes not achieving glycemic targets with other drugs.

In clinical trials, exenatide, alone or in combination with metformin, sulfonylurea, or thiazolidinedione, was associated with improved glycemic control, as reflected in an about 1% decrease in A1c and weight loss that averaged 2.5–4 kg. Evidence from clinical trials indicated that exenatide can also be used in conjunction with basal insulin. An extended-release form of exenatide is administered by subcutaneous injection once a week with greater effectiveness than twice-daily treatment.

Liraglutide. The liraglutide peptide is a long-acting, DPP-4-resistant form of GLP-1, but with a Lys34Arg substitution and addition of an α -glutamic acid spacer coupled to a C16 fatty acyl group at Lys²⁶. The fatty acid side chain permits binding to albumin and other plasma proteins and accounts for an extended $t_{1/2}$ that permits once-daily administration; the fatty acid also seems to offer some protection from cleavage of the N-terminus by DPP-4. The pharmacodynamic profile of liraglutide mimics GLP-1 and exenatide. In clinical trials, liraglutide caused both improvement in glycemic control and weight loss. In a single comparative trial, liraglutide reduced A1c about 30% more than exenatide (Buse et al., 2009). Liraglutide is indicated for adjunctive therapy in patients not achieving glycemic control with oral agents. Liraglutide can be added to oral agents or basal insulin. In a recent report, liraglutide reduced the risk of cardiovascular death, nonfatal myocardial infarction, or nonfatal stroke in patients with type 2 diabetes and established cardiovascular disease. Similar positive effects on cardiovascular risk have also been demonstrated in a trial of semaglutide, a compound in development with similarities to liraglutide. Other GLP-1 receptor agonists (exenatide and lixisenatide) are neutral with regards to cardiovascular risk in the trials completed to date.

Albiglutide. Albiglutide is a fusion protein that includes two sequential GLP-1 moieties linked to human albumin; the GLP-1 sequences are modified to prevent DPP-4 cleavage. Albiglutide is also indicated for patients

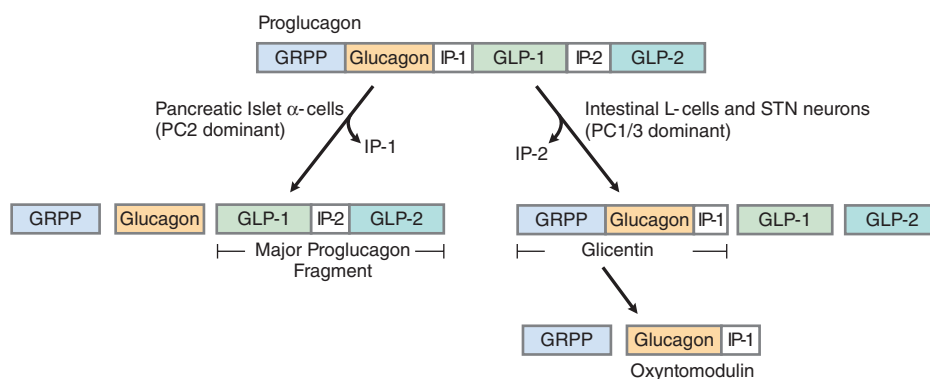

Figure 47–9 Processing of proglucagon to glucagon, GLP-1, GLP-2, and GRPP. Proglucagon is synthesized in islet α cells, intestinal enteroendocrine cells (L cells), and a subset of neurons in the hindbrain. In α cells, prohormone processing is primarily by proconvertase 2, releasing glucagon, GRPP, and a major proglucagon fragment containing the two GLPs. In L cells and neurons, proglucagon cleavage is mostly through proconvertase 1/3, giving glicentin, oxyntomodulin, GLP-1, and GLP-2. IP-1, intervening peptide—1; STN, solitary tract nucleus.

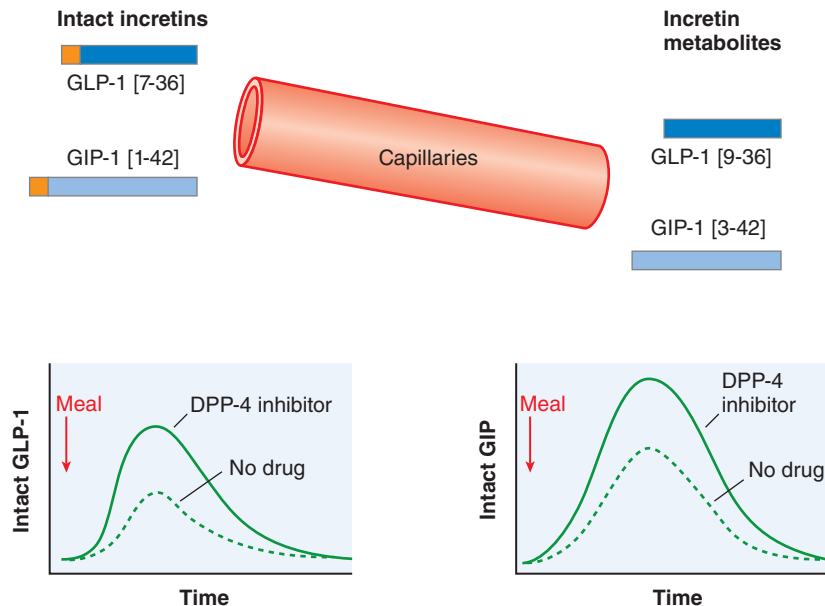

Figure 47-10 Pharmacological effects of DPP-4 inhibition. DPP-4, an ectoenzyme located on the luminal side of capillary endothelial cells metabolizes the incretins, GLP-1, and GIP, by removing the two N-terminal amino acids. The target for DPP-4 cleavage is a proline or alanine residue in the second position of the primary peptide sequence. The truncated metabolites GLP-1 [9–36] and GIP [3–42] are the major forms of the incretins in plasma and are inactive as insulin secretagogues. Treatment with a DPP-4 inhibitor increases the concentrations of intact GLP-1 and GIP.

with type 2 diabetes with suboptimal glucose control and can be used in conjunction with oral agents and basal insulin.

Dulaglutide. Dulaglutide is a fusion protein consisting of two linked molecules that have a modified version of GLP-1 linked to the Fc portion of a human immunoglobulin; the GLP-1 sequences are modified to protect against the action of DPP-4. Pharmacodynamics are comparable to other GLP-1RAs, and the drug can be used with other antidiabetic agents.

Lixisenatide. Lixisenatide is a slightly longer form of exendin-4 that has comparable pharmacodynamics. Data from a recent clinical trial of diabetic subjects with a prior history of cardiovascular disease indicated no impact of lixisenatide on recurrent events.

While all of the GLP-1RAs have demonstrated efficacy as monotherapy, none is considered as a first-line agent. While there are several clinical trials available that directly compared different GLP-1RAs, in general the differences in efficacy are small relative to the overall effect of the drugs, and definitive differences await more comprehensive studies.

Mechanism of Action. All GLP-1RAs share a common mechanism, activation of the GLP-1 receptor, a member of glucagon receptor family of GPCRs (class B GPCRs). GLP-1 receptors are expressed by β cells, cells in the peripheral and central nervous systems, the heart and vasculature, kidney, lung, and GI mucosa. Binding of agonists to the GLP-1 receptor activates the cAMP-PKA pathway and several GEFs. GLP-1 receptor activation also initiates signaling via PKC and PI3K and alters the activity of several ion channels. In β cells, the end result of these actions is increased insulin biosynthesis and exocytosis in a glucose-dependent manner (see Figure 47–3). Activation of GLP-1 receptors in the CNS accounts for the effects of receptor agonists on food intake and gastric emptying and for side effects such as nausea.

ADME. Exenatide is given as a subcutaneous injection twice daily, typically before meals. It is rapidly absorbed, reaches peak concentrations in about 2 h, and has a plasma $t_{1/2}$ of 2–3 h. Clearance of the drug occurs primarily by glomerular filtration, with tubular proteolysis and minimal reabsorption. Exenatide is marketed as a pen that delivers 5 or 10 μ g; dosing is typically started at the lower amount and increased as needed. There is a weekly preparation based on the embedding of exenatide in a polymeric microsphere that releases drug slowly after injection. Weekly exenatide is given as a suspension of 2 mg that is prepared from lyophilized

material and diluent immediately prior to injection. Once in the circulation, the drug is metabolized similarly to short-acting exenatide; however, based on the extended rate of delivery, 5–6 weekly doses are required to reach therapeutic steady state.

Liraglutide is given as a subcutaneous injection once daily. Peak levels occur in 8–12 h; the elimination $t_{1/2}$ is 12–14 h. There is little renal or intestinal excretion of liraglutide; clearance is primarily through the metabolic pathways of large plasma proteins. Liraglutide is supplied in a pen injector that delivers 0.6, 1.2, or 1.8 mg of drug; the lowest dose is for treatment initiation, with elevation to the higher doses based on clinical response.

Albiglutide has a $t_{1/2}$ of 5–7 days and can be dosed weekly. It is delivered through a pen device at doses of 30 or 50 mg following reconstitution. Clearance of the drug is primarily through enzymatic degradation, although renal clearance can be inferred from the increasing plasma levels in some patients with renal impairment.

Dulaglutide has similar pharmacokinetic properties to albiglutide; no effects of hepatic or renal impairment on these has been demonstrated.

Lixisenatide has an elimination $t_{1/2}$ of 3–4 h that involves a significant degree of renal clearance.

Adverse Effects; Drug Interactions. Intravenous or subcutaneous administration of GLP-1 causes nausea and vomiting; this is thought to be mediated through neural activation of specific CNS neurons that are activated following peripheral dosing of peptide. The doses above which GLP-1 causes GI side effects are higher than those needed to regulate blood glucose. Nonetheless, up to 30%–50% of subjects report nausea at the initiation of therapy with any of the GLP-1RAs, although the GI side effects of these drugs wane over time. Activation of GLP-1 receptors in the CNS mediates the typical delay of gastric emptying, and GLP-1 agonists may alter the pharmacokinetics of drugs that require rapid GI absorption, such as oral contraceptives and antibiotics. In the absence of other diabetes drugs that cause low blood glucose, hypoglycemia associated with GLP-1 agonist treatment is rare, but the combination of GLP-1 agonist with sulfonylurea drugs causes an increased rate of hypoglycemia compared to sulfonylurea treatment alone. Because of the reliance on renal clearance, exenatide, and probably lixisenatide, should not be given to persons with moderate-to-severe renal failure (creatinine clearance < 30 mL/min). Based on surveillance data, there is a possible association of exenatide treatment with pancreatitis; therefore, these drugs should not

be used in persons with a history or predisposition to pancreatitis. The GLP-1 receptor is expressed by thyroid C cells. Although there is not an established clinical association with medullary carcinoma of the thyroid, GLP-1 agonists should not be given to these patients.

DPP-4 Inhibitors

Dipeptidyl peptidase IV is a serine protease that is widely distributed throughout the body, expressed as an ectoenzyme on vascular endothelial cells, on the surface of T lymphocytes, and in a circulating form. DPP-4 cleaves the two N-terminal amino acids from peptides with a proline or alanine in the second position (Deacon and Lebovitz, 2016) and seems to be especially critical for the inactivation of GLP-1 and GIP. DPP-4 inhibitors increase the AUC of GLP-1 and GIP as stimulated by ingestion of food (see Figure 47–10). Several agents provide nearly complete and long-lasting inhibition of DPP-4, thereby increasing the proportion of active GLP-1 from 10% to 20% of total circulating GLP-1 immunoreactivity to nearly 100%. *Sitagliptin*, *saxagliptin*, *linagliptin*, and *alogliptin* are available in the U.S.; *vildagliptin*, is available in the E.U.

Mechanism of Action; Pharmacological Effects. Alogliptin, linagliptin, and sitagliptin are competitive inhibitors of DPP-4; vildagliptin and saxagliptin bind the enzyme covalently. All five drugs can be given in doses that lower measurable activity of DPP-4 by more than 95% for 12 h. This causes a greater than 2-fold elevation of plasma concentrations of active GIP and GLP-1 and is associated with increased insulin secretion, reduced glucagon levels, and improvements in both fasting and postprandial hyperglycemia. Inhibition of DPP-4 does not appear to have direct effects on insulin sensitivity, gastric motility, or satiety; chronic treatment with a DPP-4 inhibitor also does not affect body weight. DPP-4 inhibitors, used as monotherapy in type 2 diabetic patients, reduce A1c levels by an average of about 0.8%. These compounds are also effective for chronic glucose control when added to the treatment of diabetic patients receiving metformin, thiazolidinediones, sulfonylureas, and insulin, with a further reduction of A1c by about 0.5%. The effects of DPP-4 inhibitors in combination regimens appear to be additive.

ADME. The recommended doses of the DPP4 inhibitors are alogliptin, 25 mg daily; linagliptin, 5 mg daily; saxagliptin, 5 mg daily; sitagliptin, 100 mg daily; and vildagliptin, 50 mg one or two times daily. DPP-4 inhibitors are absorbed effectively from the small intestine. Alogliptin, saxagliptin, sitagliptin, and vildagliptin circulate primarily in unbound form and are excreted largely unchanged in the urine; lower doses should be given to patients with reduced renal function. Linagliptin binds extensively to plasma proteins and is cleared primarily by the hepatobiliary system, with little renal clearance. Only saxagliptin is metabolized by hepatic microsomal enzymes, and its dose should be lowered to 2.5 mg daily when coadministered with strong CYP3A4 inhibitors (e.g., ketoconazole, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, ritonavir, saquinavir, and telithromycin).

Adverse Effects. There are no consistent adverse effects that have been noted in clinical trials with any of the DPP-4 inhibitors. Large cardiovascular safety studies have been completed for alogliptin, saxagliptin, and sitagliptin. There was no impact of these drugs on the incidence of cardiovascular events in diabetic patients, although patients treated with saxagliptin had an increase in hospitalization for heart failure. The FDA has issued a warning that this class of drugs is rarely associated with severe joint pain. DPP-4 is expressed on lymphocytes; in the immunology literature, the enzyme is referred to as CD26. Effects on immune function bear scrutiny as more patients are treated with these compounds.

Alpha Glucosidase Inhibitors

α -Glucosidase inhibitors reduce intestinal absorption of starch, dextrin, and disaccharides by inhibiting the action of α -glucosidase in the intestinal brush border (Standl and Schnell, 2012). These drugs also increase the release of the glucoregulatory hormone GLP-1 into the circulation, which may contribute to their glucose-lowering effects. The drugs in this class are *acarbose*, *miglitol*, and *voglibose* (not available in the U.S.).

ADME. Dosing of acarbose and miglitol are similar. Both are provided as 25-, 50-, or 100-mg tablets that are taken before meals. Treatment should

start with lower doses and be titrated as indicated by balancing postprandial glucose, A1c, and GI symptoms. Acarbose is minimally absorbed; the small amount of drug reaching the systemic circulation is cleared by the kidney. Miglitol absorption is saturable, with 50%–100% of any dose entering the circulation. Miglitol is cleared almost entirely by the kidney, and dose reductions are recommended for patients with creatinine clearance less than 30 mL/min.

Adverse Effects; Drug Interactions. The most prominent adverse effects are malabsorption, flatulence, diarrhea, and abdominal bloating. Mild-to-moderate elevations of hepatic transaminases are reported with acarbose, but symptomatic liver disease is very rare. Cutaneous hypersensitivity has been described but is also rare. Hypoglycemia has been described when α -glucosidase inhibitors are added to insulin or an insulin secretagogue. Acarbose can decrease the absorption of digoxin; miglitol can decrease the absorption of propranolol and ranitidine. The α -glucosidase inhibitors are contraindicated in patients with stage 4 renal failure.

Therapeutic Use. α -Glucosidase inhibitors are indicated as adjuncts to diet and exercise in type 2 diabetic patients not reaching glycemic targets. They can also be used in combination with other oral antidiabetic agents or insulin. In clinical studies, α -glucosidase inhibitors reduced A1c by 0.5%–0.8%, fasting glucose by about 1 mM, and postprandial glucose by 2.0–2.5 mM. These agents do not cause weight gain or have significant effects on plasma lipids.

Na⁺-Glucose Transporter 2 Inhibitors

SGLT2 is a Na⁺-glucose cotransporter located almost exclusively in the proximal portion of the renal tubule. SGLT2 is a high-affinity, low-capacity transporter that moves glucose against a concentration gradient from the tubular lumen using energy generated from Na⁺ flux through the epithelial cells. Renal retention of glucose is nearly complete in nondiabetic persons, and SGLT2 accounts for 80%–90% of this reclamation; the remainder is recovered by SGLT1 more distally in the tubule. Early studies in diabetic animals demonstrated that hyperglycemia could be nearly ameliorated by the naturally occurring compound *phlorizin*, an SGLT inhibitor. Based on this proof of principle, drugs that are specific inhibitors of SGLT2 have been developed to treat diabetes (Mudaliar et al., 2015; White, 2015). These agents block glucose transport in the proximal tubule and lower blood glucose by promoting urinary loss.

Mechanism of Action; Pharmacological Effects. SGLT2 inhibitors reduce the rate of glucose reclamation in the proximal tubule and shift the renal threshold for glucose excretion from about 180 to 50 mg/dL (10 to 2.8 mM). In monotherapy, they reduce A1c by 0.7%–1.0%, cause weight loss of 2–4 kg, and decrease blood pressure by 2–4 mm Hg. There are currently three SGLP2 inhibitors available for clinical use—*canagliflozin*, *dapagliflozin*, and *empagliflozin*—with several other members of this class still in development. These agents are indicated for use in combination with other oral agents and insulin; such use leads to an additional decrease of A1c of 0.5%–0.7%. SGLT2 inhibitors are available in combination with metformin and DPP-4 inhibitors; a combined SGLT1/SGLT2 inhibitor is under investigation.

ADME. Available SGLT2 inhibitors share favorable pharmacokinetic properties. They have good oral bioavailability (60%–80%) that is not affected by food and reach peak levels 1–2 h after ingestion. They are about 90% bound to circulating proteins with half-lives of about 12 h, making them suitable for once-daily dosing. The compounds are metabolized by glucuronidation and the inactive metabolites renally excreted; there is virtually no renal excretion of the parent drugs. All three drugs are available in two doses, dapagliflozin 5 and 10 mg, canagliflozin 100 and 300 mg, and empagliflozin 10 and 25 mg.

Adverse Effects; Drug Interactions. The side effects of SGLT2 inhibitors are predictable from their mechanism of action. There is a small (1%–2%) increase in lower urinary tract infections and a 3%–5% increase in genital mycotic infections. Urine glucose losses cause mild diuresis, which can lead to hypotension and associated symptoms in a small percentage of, usually older, patients. Importantly, because SGLT2 inhibitors

ultimately depend on the rate of glucose filtration to be effective, potency decreases by 40%–80% across the spectrum of stage 3 kidney disease (GFR 60–30 mL/min). SGLT2 inhibitors do not cause hypoglycemia but can increase that likelihood when combined with drugs that do.

Recent analyses of clinical trials with SGLT inhibitors suggested that they may increase the risk of fractures (FDA warning), and there is preliminary evidence that these drugs affect mineral balance and circulating levels of parathyroid hormone and 1,25-hydroxy vitamin D. Studies are ongoing to see if this is a significant problem. There have been rare cases of diabetic ketoacidosis reported in patients treated with SGLT2 inhibitors. In phase 3 clinical trials, there was no evidence that SGLT2 inhibitors had adverse effects on cardiovascular disease. Data from controlled trials indicate that empagliflozin and canagliflozin reduce the risk for major cardiovascular events. (Zinman et al., 2015; Neal et al., 2017). Canagliflozin is associated with an increased risk of lower extremity amputation.

Other Glucose-Lowering Agents

Pramlintide. Islet amyloid polypeptide (amylin), is a 37-amino acid peptide produced in the pancreatic β cell and secreted with insulin. A synthetic form of amylin with several amino acid modifications to improve bioavailability, *pramlintide*, has been developed as a drug for the treatment of diabetes (Bower and Hay, 2016). Pramlintide likely acts through the amylin receptor in specific regions of the hindbrain. Activation of the amylin receptor reduces glucagon secretion, delays gastric emptying, and fosters a feeling of satiety.

ADME. Pramlintide is administered as a subcutaneous injection prior to meals. The drug is not extensively bound by plasma proteins and has a $t_{1/2}$ of 50 min. Metabolism and clearance are primarily renal. The doses in patients with type 1 diabetes start at 15 μ g and are titrated upward to a maximum of 60 μ g; in type 2 diabetes, the starting dose is 60 μ g, and the maximum is 120 μ g. Because of differences in the pH of the solutions, pramlintide should not be administered in the same syringe as insulin.

Adverse Effects; Drug Interactions. The most common adverse effects are nausea and hypoglycemia. Although pramlintide alone does not lower blood glucose, addition to insulin at mealtimes can cause increased rates of hypoglycemia, occasionally severe. It is currently recommended that prandial insulin doses be reduced 30%–50% at the time of pramlintide initiation and then retitrated. Because of its effects on GI motility, pramlintide is contraindicated in patients with gastroparesis or other disorders of motility. Pramlintide is a pregnancy category C drug. Pramlintide can be used in persons with moderate renal disease (creatinine clearance > 20 mL/min).

Therapeutic Uses. Pramlintide is approved for treatment of types 1 and 2 diabetes as an adjunct in patients who take insulin with meals. Pramlintide is now being evaluated as a drug for weight loss in nondiabetic persons.

Bile Acid–Binding Resins. The only bile acid sequestrant specifically approved for the treatment of type 2 diabetes is *colesevelam*.

Mechanism of Action. Bile acid metabolism is abnormal in patients with type 2 diabetes, and there have been intermittent reports that bile acid–binding resins lower plasma glucose in diabetic patients. The mechanism by which bile acid binding and removal from enterohepatic circulation lowers blood glucose has not been established. Bile acid sequestrants could reduce intestinal glucose absorption, although there is no direct evidence of this. Bile acids also act as signaling molecules through nuclear receptors, some of which may act as glucose sensors.

ADME. Colesevelam is provided as a powder for oral solution and as 625-mg tablets; typical usage is 3 tablets twice daily before lunch and dinner or 6 tablets prior to the patient's largest meal. The drug is absorbed from the intestinal tract only in trace amounts, so its distribution is limited to the GI tract.

Adverse Effects; Drug Interactions. Common side effects of colesevelam are GI, with constipation, dyspepsia, abdominal pain, and nausea affecting up to 10% of treated patients. Like other bile acid–binding resins, colesevelam can increase plasma triglycerides in persons with an inherent tendency to hypertriglyceridemia and should be used cautiously in patients with plasma triglycerides greater than 200 mg/dL. Colesevelam can interfere with the absorption of commonly used agents (e.g., phenytoin, warfarin, verapamil, glyburide, L-thyroxine, and ethinyl estradiol

and fat-soluble vitamins). Colesevelam is a pregnancy category B drug that has no contraindications in patients with renal or liver disease.

Therapeutic Uses. Colesevelam is approved for treatment of hypercholesterolemia and may be used for treatment of type 2 diabetes as an adjunct to diet and exercise. In clinical trials, colesevelam reduced A1c by 0.5% when added to metformin, sulfonylurea, or insulin treatment in type 2 diabetic patients.

Bromocriptine. A formulation of bromocriptine, a dopamine receptor agonist, is approved for the treatment of type 2 diabetes. Bromocriptine is an established treatment of Parkinson disease and hyperprolactinemia (see Chapters 13, 18, and 42). Effects of bromocriptine on blood glucose are modest and may reflect an action in the CNS. The dose range for bromocriptine is 1.6 to 4.8 mg, taken with food in the morning within 3 h of awakening. Side effects include nausea, fatigue, dizziness, orthostatic hypotension, vomiting, and headache.

Combined Pharmacological Approaches to Type 2 Diabetes

Managing the Progression of Type 2 Diabetes.

For most patients, the pathologic changes causing hyperglycemia in type 2 diabetes progress over time. Thus, most patients require step-wise intensification of therapy to maintain glycemic goals. Several academic societies and health organizations have issued guidelines, approaches, algorithms, or flowcharts for the treatment of type 2 diabetes (Chamberlain et al., 2016; Garber et al., 2016). Figure 47–11 presents a simplified version; more details can be found in guidelines from the ADA, European Society for Study of Diabetes, American Association of Clinical Endocrinology, and National Institute for Health and Care Excellence (United Kingdom). Table 47–7 summarizes available pharmacological agents for the treatment of diabetes. While there is no consensus as to preferred combinations or the order in which they are used, in general selection involves consideration of side effect profile, cost and A1C goal. Recent results suggest that individuals with type 2 diabetes who are at high risk for cardiovascular disease benefit from SGLT2 inhibitors and GLP-1 agonists.

There is consensus that metformin and lifestyle changes should be the first interventions. After that, a number of pathways or combination of drugs can be used for treatment of type 2 diabetes if the glucose control does not reach the therapeutic target (Brietze, 2015; Ismail-Beigi, 2012). For example, the addition of a second oral agent may provide good therapeutic results. Combinations of fixed doses of most of the oral agents are now available; while most oral agents have additive effects, no specific combinations have been demonstrated to have particular efficacy that can be predicted for most patients. Another approach is to introduce basal long-acting insulin (at bedtime) in combination with an oral glucose-lowering agent. This combination allows the oral agent to provide postprandial glycemic control, while the basal insulin provides the foundation for normalizing fasting or basal glucose levels. Long-acting insulin can be combined with almost all of the oral antihyperglycemic agents in Table 47–7. The exact combination of therapies can be guided by an estimation of the β cell secretory reserve in the patient (i.e., a measurement of C-peptide level) and individualized patient glycemic goals (Lathief and Inzucchi, 2016). The progressive insulin deficiency in type 2 diabetes often makes it increasingly difficult to achieve the glycemic goal solely with oral antihyperglycemic agents; thus, often insulin is required.

Costs of Diabetes Drugs. Treatment of diabetes can be very expensive, especially because most patients use multiple agents, as well as drugs for associated conditions such as hypertension, dyslipidemia, and cardiovascular disease. Thus, cost has become a key issue in the management of diabetic patients, an issue that can affect adherence to and choice of treatment plans (Table 47–8). Newer agents are more costly, while older drug classes like sulfonylurea and biguanides are inexpensive and available in generic formulations. In recent years, the price of insulins has increased steadily despite the addition of numerous new products to the market. The balance of cost-benefit ratio and adverse

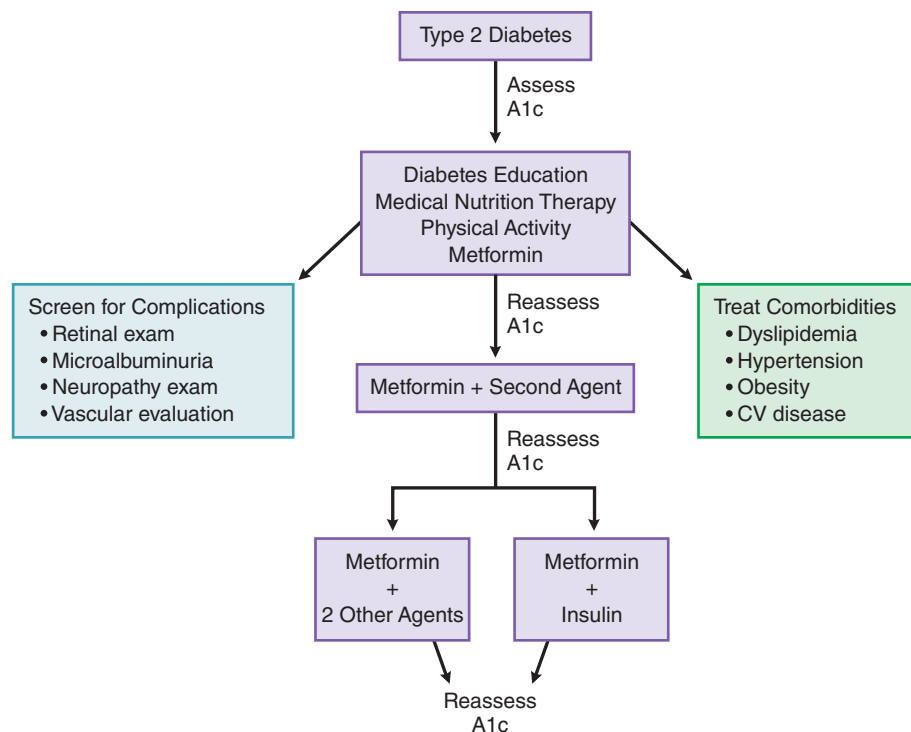

Figure 47-11 Treatment algorithm for management of type 2 diabetes mellitus. Patients diagnosed with type 2 diabetes, by fasting glucose, oral glucose tolerance testing, or A1c measurement, should have diabetes education that includes instruction on medical nutrition therapy and physical activity. Metformin is the consensus first line of therapy and should be started at the time of diagnosis. Failure to reach the glycemic target, generally A1c 7% or less within 2–3 months, should prompt the addition of a second agent (insulin, sulfonylurea, thiazolidinedione, DPP-IV inhibitor, GLP-1 agonist, or SGLT-2 inhibitor). Reinforce lifestyle interventions at every visit and check A1c every 3 months. Treatment may escalate to metformin plus insulin or metformin plus two other agents from the list given. See text for recommendations concerning individuals with, or at high risk for, cardiovascular disease.

profile of the new agents compared to older drugs remains controversial and incompletely defined.

Emerging Therapies for Diabetes

A number of immunomodulatory approaches are being investigated to prevent or block the autoimmune process central to type 1 diabetes, but none has yet shown efficacy outweighing adverse events. Activators of GK, glucagon antagonists, and inhibitors of 11 β -hydroxysteroid dehydrogenase are being investigated as novel therapies for type 2 diabetes (Bailey et al., 2016). Advances in protein chemistry have allowed the development of peptides that activate more than one receptor to improve glucose regulation. Most of these incorporate GLP-1 receptor agonism with the capacity to activate receptors for glucagon, GIP, or gastrin. These compounds have been potent in pre-clinical models and are now in human trials. Some drugs developed for type 2 diabetes are being tested as adjunctive therapy for type 1 diabetes (Frandsen et al., 2016).

Hypoglycemia

In the absence of prolonged fasting, healthy humans almost never have blood glucose levels below 3.5 mM. This is due to a highly adapted neuroendocrine counterregulatory system that prevents acute hypoglycemia, a hazardous and potentially lethal situation. The three major clinical scenarios for hypoglycemia are as follows:

- Treatment of diabetes
- Inappropriate production of endogenous insulin or an insulinlike substance by a pancreatic islet tumor (insulinoma) or a nonislet tumor
- Treatment (purposeful or inadvertent) with a glucose-lowering agent in an individual without diabetes

Hypoglycemia in the first and third scenarios can occur in either the fasting or the fed state, whereas hypoglycemia secondary to neoplasms

occurs almost exclusively in the fasting or postabsorptive state. Some drugs not used for the treatment of diabetes promote hypoglycemia (see Table 47-7).

Hypoglycemia is an adverse reaction to a number of oral therapies and is most pronounced and serious with insulin therapy. Hypoglycemia may result from an inappropriately large dose of insulin, from a mismatch between the time of peak delivery of insulin and food intake, or from superposition of additional factors that increase sensitivity to insulin (e.g., adrenal or pituitary insufficiency) or that increase insulin-independent glucose uptake (e.g., exercise). Hypoglycemia is the major risk that always must be weighed against benefits of efforts to normalize glucose control. Hypoglycemia is especially problematic in the elderly and should be given strong consideration when individualizing glycemic goals.

The first physiological response to hypoglycemia is a reduction of endogenous insulin secretion, which occurs at a plasma glucose level of about 70 mg/dL (3.9 mM); thereafter, the counterregulatory hormones (EPI, NE, glucagon, growth hormone, and cortisol) are released. Symptoms of hypoglycemia are first discerned at a plasma glucose level of 60–70 mg/dL (3.3–3.9 mM). Sweating, hunger, paresthesias, palpitations, tremor, and anxiety, principally of autonomic origin, usually are seen first. Difficulty in concentrating, confusion, weakness, drowsiness, a feeling of warmth, dizziness, blurred vision, and loss of consciousness (i.e., most important neuroglycopenic symptoms) usually occur at lower plasma glucose levels than do autonomic symptoms. Severe hypoglycemia can lead to seizure and coma.

In patients with type 1 and type 2 diabetes of longer duration, the glucagon secretory response to hypoglycemia becomes deficient. Diabetic patients thus become dependent on EPI for counterregulation, and if this mechanism becomes deficient, the incidence of severe hypoglycemia increases, especially in individuals with hypoglycemia unawareness and autonomic neuropathy. With the ready availability of home glucose

TABLE 47-7 ■ COMPARISON OF AGENTS USED FOR TREATMENT OF DIABETES

TYPE Agent	MECHANISM OF ACTION	HbA _{1c} REDUCTION (%) ^a	AGENT-SPECIFIC ADVANTAGES	AGENT-SPECIFIC DISADVANTAGES	CONTRAINDICATIONS AND PRECAUTIONS
Oral					
Biguanides ^c	↓ Hepatic glucose production	1–2	Weight neutral, do not cause hypoglycemia, inexpensive	Diarrhea, nausea, lactic acidosis	GFR < 50 mL/min, CHF, radiographic contrast studies, seriously ill patients, acidosis
Dipeptidyl peptidase 4 inhibitors ^c	Prolong endogenous GLP-1 action	0.5–0.8	Do not cause hypoglycemia	Expensive	↓ Dose with renal disease
α-Glucosidase inhibitors ^c	↓ GI glucose absorption	0.5–0.8	↓ Postprandial glycemia	GI flatulence, liver function tests	Renal/liver disease
Insulin secretagogues—sulfonylureas ^c	↑ Insulin secretion	1–2	Inexpensive	Hypoglycemia, weight gain	Renal/liver disease
Insulin secretagogues—nonsulfonylureas ^c	↑ Insulin secretion	1–2	Rapid onset of action, lower postprandial glucose	Hypoglycemia, precautions for elderly and renal impairment	Renal/liver disease
SGLT2 inhibitors ^c (the <i>gliflozins</i>)	↑ Renal glucose excretion	0.9–1.2	Mild weight loss and BP reduction; do not cause hypoglycemia; CV benefit (empagliflozin, canagliflozin)	↑ Rate of lower urinary tract and genital mycotic infections; hypotension; rarely DKA; see text for canagliflozin	Renal disease
Thiazolidinediones ^c (the <i>glitazones</i>)	↓ Insulin resistance, ↑ glucose utilization	0.5–1.4	Lower insulin requirements	Peripheral edema, CHF, weight gain, fractures in females, macular edema	CHF, liver disease
Parenteral					
Insulin	↑ Glucose utilization, ↓ hepatic glucose production, and other anabolic actions	Not limited	Well-known safety/adverse effect profile from much clinical experience	Injection, weight gain, hypoglycemia	Hypoglycemia
GLP-1R agonists ^c	↑ Insulin, ↓ glucagon, slow gastric emptying, satiety	0.5–1.5	Weight loss, CV benefit (liraglutide)	Injection, nausea, ↑ risk of hypoglycemia with insulin secretagogues	Renal disease, agents that also slow GI motility, pancreatitis, medullary carcinoma of thyroid
Amylin agonists ^{b,c}	Slow gastric emptying, ↓ glucagon	0.25–0.5	Reduce postprandial glycemia; weight loss	Injection, nausea, ↑ risk of hypoglycemia with insulin	Agents that also slow GI motility
Other					
Medical nutrition therapy and physical activity ^c	↓ Insulin resistance, ↑ insulin secretion	1–3	Weight loss, improved CV health	Compliance difficult, long-term success low	
Inhaled insulin ^{c,d}	↑ Glucose utilization, ↓ hepatic glucose production, other anabolic actions	0.25–0.5	Rapid onset of action	Limited clinical experience	Pulmonary disease, smoking

^aA_{1c} reduction (absolute) depends partly on starting A_{1c} value.^bUsed in conjunction with insulin for treatment of type 1 diabetes.^cUsed for treatment of type 2 diabetes.^dMarketing discontinued in the U.S.

DKA, Diabetic ketoacidosis

monitoring, hypoglycemia can be documented in most patients who experience suggestive symptoms. Hypoglycemia that occurs during sleep may be difficult to detect but should be suspected from a history of morning headaches, night sweats, or symptoms of hypothermia. Mild-to-moderate hypoglycemia may be treated simply by ingestion of oral glucose (15–20 g of carbohydrate). When hypoglycemia is severe, it should be treated with intravenous glucose or an injection of glucagon.

Agents Used to Treat Hypoglycemia

Glucagon, a single-chain polypeptide of 29 amino acids now produced by recombinant DNA technology, interacts with the glucagon GPCR on the plasma membrane of target cells, most importantly the hepatocyte, activating the G_s-cAMP-PKA pathway. Glucagon should be prescribed for individuals at risk for severe hypoglycemia, and the patient's family or friends should be trained to inject this in an emergency. Glucagon is

^aMarketing discontinued in the U.S.

used to treat severe hypoglycemia when the diabetic patient cannot safely consume oral glucose and intravenous glucose is not available.

For hypoglycemic reactions, 1 mg is administered intravenously, intramuscularly, or subcutaneously. The intramuscular route is preferred in such an emergency. The hyperglycemic action of glucagon is transient and may be inadequate if hepatic stores of glycogen are depleted. After the initial response to glucagon, patients should be given oral glucose or urged to eat to prevent recurrent hypoglycemia. Nausea and vomiting are the most frequent adverse effects. Formulations of glucagon that can be administered as an intranasal powder have shown promising results in early phase trials.

Other Pancreatic Islet–Related Hormones or Drugs

Diazoxide

Diazoxide is an antihypertensive, antidiuretic benzothiadiazine derivative with potent hyperglycemic actions when given orally. Diazoxide interacts with the K_{ATP} channel on the β cell membrane and either prevents its closing or prolongs the open time. This effect, opposite to that of the sulfonylureas (see Figure 47–3), inhibits insulin secretion.

The usual oral dose is 3–8 mg/kg per day in adults and children and 8 to 15 mg/kg per day in infants and neonates. The drug can cause nausea and vomiting and thus usually is given in divided doses with meals. Diazoxide circulates largely bound to plasma proteins and has a $t_{1/2}$ of about 48 h.

Diazoxide has a number of adverse effects, including retention of Na^+ and fluid, hyperuricemia, hypertrichosis, thrombocytopenia, and leukopenia, which sometimes limit its use. Despite these side effects, the drug may be useful in patients with inoperable insulinomas and in children with neonatal hyperinsulinism.

Somatostatin

Somatostatin is produced by δ cells of the pancreatic islet, by cells of the GI tract, and in the CNS. SST, which circulates primarily as 14- or a 28-amino acid forms, acts through a family of five GPCRs, $SSTR_{1-5}$. SST inhibits a wide variety of endocrine and exocrine secretions, including TSH (thyroid stimulating hormone) and GH (growth hormone) from the pituitary, and gastrin, motilin, VIP, (vasoactive intestinal peptide) glicentin, insulin, glucagon, and pancreatic polypeptide from the GI tract/pancreatic islet. The physiological role of SST has not been defined precisely, but its short $t_{1/2}$ (3–6 min) prevents its use therapeutically. Longer-acting analogues such as octreotide and lanreotide are useful for treatment of severe secretory diarrhea (Chapter 50) and carcinoid tumors, glucagonomas, VIPomas, acromegaly, and Cushing disease (Chapter 42) (Baldelli et al., 2014). Gallbladder abnormalities (stones and biliary sludge) occur frequently with chronic use of the SST analogues, as do GI symptoms.

Acknowledgment: Stephen N. Davis and Daryl K. Granner contributed to this chapter in earlier editions of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: *Agents for Diabetes and Hypoglycemia*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Insulin Formulations		
Insulin—short acting (regular)	<ul style="list-style-type: none"> Type 1 and type 2 diabetes Control prandial rise in blood glucose Acute correction of hyperglycemia Intravenous infusion for DKA and hyperglycemia in hospitalized setting 	<ul style="list-style-type: none"> Injected SC, IM, or IV Onset of action 30–45 min after subcutaneous injection Duration of action of 4–6 h after subcutaneous injection Major adverse event: hypoglycemia
Insulin analogues—short acting (lispro, aspart, glulisine)	<ul style="list-style-type: none"> Type 1 and type 2 diabetes Control prandial rise in blood glucose Used in insulin pump for treatment of diabetes 	<ul style="list-style-type: none"> Genetically modified to accelerate insulin absorption profile Injected SC or IM Onset of action 5–15 min after SC injection Duration of action of 3–4 h after SC injection Major adverse event: hypoglycemia
Insulin—long acting (NPH)	<ul style="list-style-type: none"> Provide basal insulin in type 1 and type 2 diabetes Reduce fasting hyperglycemia in type 2 diabetes 	<ul style="list-style-type: none"> Formulated to prolong insulin absorption Usually requires twice-daily subcutaneous injection to provide 24-h basal insulin coverage Combined with short-acting insulin in basal/bolus regimen Given at bedtime in type 2 diabetes to reduce hepatic glucose production Duration of action of 8–12 h Major adverse event: hypoglycemia
Insulin analogues—long acting (glargine, detemir, degludec)	<ul style="list-style-type: none"> Provide basal insulin in type 1 and type 2 diabetes 	<ul style="list-style-type: none"> Genetically modified to prolong absorption Once-a-day subcutaneous injection \Rightarrow 24-h basal insulin coverage Combined with shorting action insulin in basal/bolus regimen Duration of action of 18–42 h Major adverse event: hypoglycemia
Oral Glucose-Lowering Agents		
Biguanides (metformin)	<ul style="list-style-type: none"> Therapy of type 2 diabetes Usually initial agent in type 2 diabetes 	<ul style="list-style-type: none"> Reduce hepatic glucose production Weight neutral Do not cause hypoglycemia Adverse events include diarrhea, nausea, lactic acidosis (black-box warning) Use cautiously in renal insufficiency, hospitalized patients; temporarily discontinue therapy prior to potential renal insults (e.g., radiocontrast media) Avoid use in patients with hepatic dysfunction Can be combined with other agents Inexpensive
α-Glucosidase inhibitors Acarbose, miglitol, voglibose	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> Reduce carbohydrate breakdown in GI tract Adverse effects: GI flatulence, elevated liver function tests Can be combined with other agents Relatively modest glucose lowering
Dipeptidyl peptidase 4 inhibitors Sitagliptin, saxagliptin, linagliptin, alogliptin, vildagliptin	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> Prolong action of GLP-1; promotes insulin secretion Can be combined with other agents Relatively modest glucose lowering
Insulin secretagogues—sulfonylureas Second generation: glyburide, glibenclamide, glipizide, and others	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> Stimulate insulin secretion Major adverse event is hypoglycemia Adjustments needed in renal/liver disease Newer agents more potent, may have better safety profile than first-generation agents. Can be combined with other agents Modest weight gain Inexpensive
Insulin secretagogues—nonsulfonylureas Repaglinide, nateglinide	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> \uparrow Insulin secretion; quicker onset and shorter duration than sulfonylureas Major adverse event: hypoglycemia Adjustments needed in renal/liver disease Can be combined with other agents
SLGT2 inhibitors Canagliflozin, dapagliflozin, empagliflozin	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> Prevent glucose reabsorption and promote renal glucose excretion Mild weight loss and BP reduction
		<ul style="list-style-type: none"> Do not cause hypoglycemia May \uparrow rate of lower urinary tract and genital mycotic infections, hypotension, and DKA Can be combined with other agents

Other Glucose-Lowering Agents (continued)		
Thiazolidinediones Rosiglitazone, pioglitazone	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> Increase insulin sensitivity Adverse effects: peripheral edema, CHF, weight gain, fractures, macular edema Use with caution in CHF, liver disease Can be combined with other agents
Other Glucose-Lowering Agents		
GLP-1 agonists Albiglutide, dulaglutide, exenatide, liraglutide	<ul style="list-style-type: none"> Therapy of type 2 diabetes 	<ul style="list-style-type: none"> ↑ Insulin secretion, ↓ gastric emptying, ↓ glucagon Injected subcutaneously Often associated with weight loss Adverse events include nausea Do not use with agents that ↓ GI motility Risk of hypoglycemia with insulin
Amylin analogue Pramlintide	<ul style="list-style-type: none"> Adjunctive therapy with insulin in type 1 and type 2 diabetes 	<ul style="list-style-type: none"> Slows gastric emptying, decreases glucagon Injected subcutaneously ↓ Postprandial glycemia Often associated with weight loss Adverse events include nausea Do not use with agents that ↓ GI motility Risk of hypoglycemia with insulin
Drugs to Reverse Hypoglycemia		
Glucagon	<ul style="list-style-type: none"> Emergency treatment of severe hypoglycemia Diagnostic aid for GI radiographic examination 	<ul style="list-style-type: none"> Injected SC, IM, or IV Quickly raises blood glucose Relaxes smooth muscles of the GI tract + Inotropism and chronotropism on heart
Other Pancreatic Islet-Related Hormones or Drugs		
Diazoxide	<ul style="list-style-type: none"> Treatment of hypertensive crisis Treatment of pathologic hyperinsulinemia 	<ul style="list-style-type: none"> Inhibits insulin secretion Adverse events include nausea, vomiting, fluid retention, hyperuricemia, hypertrichosis, thrombocytopenia, and leukopenia
Somatostatin analogues Octreotide, lanreotide	<ul style="list-style-type: none"> Treatment of carcinoid tumors, glucagonomas, VIPomas, acromegaly, and Cushing disease 	<ul style="list-style-type: none"> Injected intramuscularly Inhibits hormone release Adverse events include gallbladder abnormalities

This chapter presents a primer on mineral ion homeostasis and the endocrinology of Ca^{2+} and phosphate metabolism, then some relevant pathophysiology, and finally pharmacotherapeutic options in treating disorders of mineral ion homeostasis.

Physiology of Mineral Ion Homeostasis

Calcium

Elemental calcium is essential for many biological functions, ranging from muscle contraction and intracellular signaling (see Chapter 3) to blood coagulation and supporting the formation and continuous remodeling of the skeleton.

Extracellular free Ca^{2+} is in the millimolar range, whereas intracellular free Ca^{2+} is maintained at submicromolar levels. Different mechanisms evolved that regulate Ca^{2+} over this 10,000-fold concentration span. Changes in cytosolic Ca^{2+} (whether released from intracellular stores or entering via membrane Ca^{2+} channels) can modulate effector targets, often by interacting with the ubiquitous Ca^{2+} -binding protein *calmodulin*. The rapid association-dissociation kinetics of Ca^{2+} permit effective regulation of cytosolic Ca^{2+} over the range of 100 nM to 1 μM .

The body content of calcium in healthy adult men and women, respectively, is about 1300 and 1000 g, of which more than 99% is in bone and teeth. Ca^{2+} in extracellular fluids is stringently regulated within narrow limits. In adult humans, the normal serum Ca^{2+} concentration ranges from 8.5 to 10.4 mg/dL (4.25–5.2 mEq/L, 2.1–2.6 mM) and includes three distinct chemical forms: *ionized* (50%), *protein bound* (40%), and *complexed* (10%). Thus, whereas total plasma Ca^{2+} concentration is about 2.5 mM, the concentration of ionized Ca^{2+} in plasma is about 1.2 mM. The various pools of Ca^{2+} are illustrated schematically in Figure 48–1.

Albumin accounts for some 90% of the serum Ca^{2+} bound to plasma proteins; a change of plasma albumin concentration of 1.0 g/dL from the

normal value of 4.0 g/dL can be expected to alter total Ca^{2+} concentration by about 0.8 mg/dL. The remaining 10% of the serum Ca^{2+} is complexed with small polyvalent anions, primarily phosphate and citrate. Only diffusible Ca^{2+} (i.e., ionized plus complexed) crosses cell membranes. The degree of complex formation depends on the ambient pH and the concentrations of ionized Ca^{2+} and complexing anions. Ionized Ca^{2+} is the physiologically relevant component, mediating calcium's biological effects, and, when perturbed, produces the characteristic signs and symptoms of hypo- or hypercalcemia. Hormones that affect intestinal calcium absorption and renal calcium excretion tightly control the extracellular Ca^{2+} concentration; when needed, these same hormones regulate withdrawal from the large skeletal reservoir.

Calcium Stores

The skeleton contains 99% of total body calcium in a crystalline form resembling the mineral hydroxyapatite; other ions, including Na^+ , K^+ , Mg^{2+} , and F^- , also are present in the crystal lattice. The steady-state content of Ca^{2+} in bone reflects the net effect of bone resorption and bone formation. Although the bulk of skeletal calcium is not readily available for meeting short-term needs, a rapidly exchangeable calcium pool at the endosteal surface can be both mobilized and serve to sequester acute increases of extracellular calcium.

Calcium Absorption and Excretion

In the U.S., about 75% of dietary Ca^{2+} is obtained from milk and dairy products. Guidelines for daily vitamin D and calcium supplementation (Institute of Medicine, 2011) are shown in Table 48–1. Figure 48–2 illustrates the components of whole-body daily Ca^{2+} turnover. Ca^{2+} enters the body only through the intestine. *Vitamin D-dependent Ca^{2+} transport* occurs in the proximal duodenum, whereas most Ca^{2+} uptake is mediated by *passive absorption* throughout the small intestine. When calcium intake is adequate or high, passive calcium absorption in the jejunum and ileum

Abbreviations

- BMD:** bone mineral density
- CaSR:** calcium-sensing receptor
- CGRP:** calcitonin gene-related peptide
- CKD-MBD:** chronic kidney disease–mineral bone disease
- CTR:** calcitonin receptor
- CYP:** cytochrome P450
- DHT:** dihydrotachysterol
- ERK:** extracellular signal-regulated kinase
- FGF:** fibroblast growth factor
- FGF23:** fibroblast growth factor 23
- FGFR:** FGF receptor
- FGFR/KL:** FGF receptor/Klotho
- FRS2α:** FGFR substrate 2α
- HRT:** hormone replacement therapy
- HVDDR:** hereditary 1,25-dihydroxyvitamin D resistance
- Ig:** immunoglobulin
- IL-1:** interleukin 1
- IP₃:** inositol triphosphate
- KL:** klotho
- MTC:** medullary thyroid carcinoma
- NF-κB:** nuclear factor kappa B
- 25-OHD₃:** 25-OH-cholecalciferol
- OPG:** osteoprotegerin
- NPT2:** Sodium-dependent phosphate transport protein 2
- PDDR:** pseudovitamin D–deficiency rickets
- P_i:** inorganic phosphate
- PKC:** protein kinase C
- PLC:** phospholipase C
- PTH:** parathyroid hormone
- PTHrP:** PTH-related protein
- RANK:** receptor for activating NF-κB
- RANKL:** RANK ligand
- RDA:** recommended daily allowance
- REMS:** Risk Evaluation and Mitigation Strategy
- SERM:** selective estrogen receptor modulator
- SGK1:** serum and glucocorticoid–regulated kinase 1
- TK:** tyrosine kinase
- TRPV6:** Transient receptor potential cation channel V6
- VDDR-1:** vitamin D–dependent rickets type I
- VDR:** vitamin D receptor
- XLH:** X-linked hypophosphatemia

is the major absorptive process. Conversely, when intake is low, vitamin D–dependent active calcium absorption is upregulated in the duodenum and accounts for the larger proportion of calcium that is absorbed.

This uptake, whether active or passive, is counterbalanced by an obligatory daily intestinal Ca²⁺ loss of about 150 mg/d that reflects the Ca²⁺ content of mucosal and biliary secretions and in sloughed intestinal cells. The efficiency of intestinal Ca²⁺ absorption is inversely related to calcium intake. Thus, a diet low in calcium leads to a compensatory increase in fractional absorption owing partly to activation of vitamin D. In older persons, this response is considerably less robust. Disease states associated with steatorrhea, chronic diarrhea, or malabsorption promote fecal loss of Ca²⁺. Drugs such as glucocorticoids and phenytoin depress intestinal Ca²⁺ transport.

Urinary Ca²⁺ excretion is the difference between the amount filtered at the glomerulus and the quantity reabsorbed. About 9 g of calcium are filtered each day, of which more than 98% is reabsorbed by the tubules. The efficiency of reabsorption is highly regulated by PTH and is influenced by

Figure 48–1 Pools of calcium in serum. Concentrations are expressed as milligrams per deciliter (top axis) and as millimoles per liter (bottom axis). The total serum calcium concentration is 10 mg/dL or 2.5 mM, divided into three pools: protein bound (40%), complexed with small anions (10%), and ionized calcium (50%). The complexed and ionized pools represent the diffusible forms of calcium that can enter cells.

filtered Na⁺, the presence of nonreabsorbed anions, and diuretic agents (see Chapter 25). Sodium intake, and therefore Na⁺ excretion, is directly related to urinary Ca²⁺ excretion. Diuretics that act on the ascending limb of the loop of Henle (e.g., furosemide) increase Ca²⁺ excretion. By contrast, thiazide diuretics uncouple the relationship between Na⁺ and Ca²⁺ excretion, increasing sodium excretion but diminishing calcium excretion. Urinary Ca²⁺ excretion is a direct function of dietary protein intake, presumably owing to the effect of sulfur-containing amino acids on renal tubular function.

Phosphate

Phosphate is present in plasma, extracellular fluid, cell membrane phospholipids, intracellular fluid, collagen, and bone tissue. More than 80% of total body phosphorus is found in bone; about 15% is in soft tissue. In addition, phosphate is a dynamic constituent of intermediary and energy

TABLE 48–1 ■ RECOMMENDED DAILY ALLOWANCE OF CALCIUM AND VITAMIN D

LIFE STAGE GROUP	CALCIUM (mg/d) ^a	VITAMIN D (IU/d) ^{a,b}
Infants 0 to 6 months	200 ^c	400 ^d
Infants 6 to 12 months	260 ^c	400 ^d
1–3 years old	700	600
4–8 years old	1000	600
9–13 years old	1300	600
14–18 years old	1300	600
19–30 years old	1000	600
31–50 years old	1000	600
51–70 years old	1000	600
51- to 70-year-old females	1200	600
>70 years old	1200	600
14–18 years old, pregnant/lactating	1300	600
19–50 years old, pregnant/lactating	1000	600

^aIntake covering needs of ≥ 97.5% of population.
^bCovers all forms of vitamin D. For details, see Institute of Medicine, 2011.
^cFor infants 0 to 6 months of age, adequate intake is 200 mg/d; it is 260 mg/d for infants 6 to 12 months of age. RDAs have not been established for infants.
^dFor infants 0 to 6 months of age, adequate intake is 400 IU/d; it is 400 IU/d for infants 6 to 12 months of age. RDAs have not been established for infants.

Figure 48-2 Whole-body daily turnover of calcium. In healthy adults, calcium intake is equal to calcium excretion, and no net gain or loss of skeletal calcium occurs. Daily dietary calcium intake averages 800 mg. Net intestinal absorption amounts to 150 mg and is balanced by an equivalent amount of calcium excretion by the kidneys. Fecal calcium excretion amounts to 650 mg. In the absence of a challenge to calcium homeostasis such as lactation, the kidneys are the primary site of calcium metabolism. (Adapted with permission from Yanagawa N, Lee DBN. Renal handling of calcium and phosphorus. In: Coe FL, Favus MJ, eds. *Disorders of Bone and Mineral Metabolism*. Raven Press, New York, 1992, 3–40.)

metabolism and acts as a key regulator of enzyme activity when transferred by protein kinases from ATP to phosphorylatable serine, threonine, and tyrosine residues.

Biologically, phosphorus exists in both organic and inorganic (P_i) forms. Organic forms include phospholipids and various organic esters. In extracellular fluid, the bulk of phosphorus is present as inorganic phosphate in the form of NaH_2PO_4 and Na_2HPO_4 . At pH 7.4, the ratio of disodium to monosodium phosphate is 4:1, so plasma phosphate has an intermediate valence of 1.8. Owing to its relatively low concentration in extracellular fluid, phosphate contributes little to buffering capacity. The aggregate level of P_i modifies tissue concentrations of Ca^{2+} and plays a major role in renal H^+ excretion. Within bone, phosphate is complexed with Ca^{2+} as hydroxyapatites and as calcium phosphate.

Absorption, Distribution, and Excretion

Phosphate is an abundant dietary component; even an inadequate diet rarely causes phosphate depletion. Phosphate is extensively absorbed from the GI tract primarily by passive movement (proportional to the concentration in the intestinal lumen), with a smaller fraction mediated by active vitamin D–dependent transport. The fact that most intestinal phosphate absorption is passive may explain why it continues in the presence of hyperphosphatemia, whereas renal phosphate transport is downregulated by elevated phosphate concentrations. The NPT2B Na-phosphate cotransporter mediates active GI phosphate transport, which proceeds through a classic feedback mechanism: Decreases of serum phosphate enhance the biogenesis of vitamin D, which in turn upregulates NPT2B expression.

In adults, about two-thirds of ingested phosphate is absorbed and is excreted almost entirely into the urine. Small amounts of phosphate are secreted into the intestine. In growing children, phosphate balance is positive, and plasma concentrations of phosphate are higher than in adults.

Renal phosphate excretion is the difference between the amount filtered and that reabsorbed. More than 90% of plasma phosphate is freely filtered at the glomerulus, and 80% is reabsorbed, predominantly by proximal tubules. Renal phosphate absorption is regulated by PTH and FGF23 and by other factors, primarily dietary phosphate. Additional

hormonal regulators of intestinal phosphate absorption include glucocorticoids, estradiol, and epidermal growth factor. Nonhormonal factors contributing to phosphate homeostasis include extracellular volume and acid-base status.

Dietary phosphate deficiency upregulates renal phosphate transporters and decreases excretion, whereas a high-phosphate diet increases phosphate excretion; these changes are independent of effects on plasma P_i , Ca^{2+} , PTH, or FGF23 (Bourgeois et al., 2013). PTH and FGF23 increase urinary phosphate excretion by blocking phosphate reabsorption. Expansion of plasma volume increases urinary phosphate excretion.

Role of Phosphate in Urine Acidification

Phosphate is concentrated progressively as it traverses the renal tubule and becomes the most abundant buffer system in the distal tubule and terminal nephron. The exchange of H^+ and Na^+ in the tubular urine converts Na_2HPO_4 to NaH_2PO_4 , permitting the excretion of large amounts of acid without lowering the urine pH to a degree that would block H^+ transport.

Pharmacological Actions of Phosphate

Phosphate salts are employed as mild laxatives (see Chapter 50) and to acidify the urine and treat hypophosphatemia.

Hormonal Regulation of Calcium and Phosphate Homeostasis

A number of hormones interact to regulate extracellular Ca^{2+} and phosphate balance. The most important are PTH, FGF23, and 1,25-dihydroxyvitamin D_3 (calcitriol), which regulate mineral homeostasis by effects on the kidney, intestine, and bone (Figure 48–3).

Parathyroid Hormone

Parathyroid hormone is a polypeptide that helps to regulate plasma Ca^{2+} by affecting bone resorption/formation, renal Ca^{2+} excretion/reabsorption, and calcitriol synthesis (thus, GI Ca^{2+} absorption).

Figure 48-3 Calcium homeostasis and its regulation by PTH, FGF23, and 1,25-dihydroxyvitamin D_3 . PTH, released from parathyroids (dotted line), has stimulatory effects on bone and kidney, increasing calcium mobilization and reabsorption, decreasing phosphate reabsorption, and stimulating 1 α -hydroxylase activity in kidney mitochondria, leading to the production of 1,25-dihydroxyvitamin D_3 (calcitriol) from 25-hydroxycholecalciferol (Figure 48–6). FGF23, released from bone (dotted line), likewise dampens renal phosphate reabsorption and augments calcium recovery but decreases the production of 1,25-dihydroxyvitamin D_3 by inhibiting 25(OH)1- α -hydroxylase (CYP27B1) and increasing metabolism by inducing 1,25(OH) $_2$ vitamin D_3 24-hydroxylase (CYP24A1). FGF23 also suppresses PTH release by the parathyroid glands. Calcitriol, the biologically active metabolite of vitamin D_3 , increases intestinal calcium and phosphate absorption, and regulates FGF23 synthesis and release and calcium mobilization in bone.

HISTORY

Sir Richard Owen, the curator of the British Museum of Natural History, discovered the parathyroid glands in 1852 while dissecting a rhinoceros that had died in the London Zoo. Credit for discovery of the human parathyroid glands usually is given to Sandstrom, a Swedish medical student who published an anatomical report in 1890. In 1891, von Recklinghausen reported a new bone disease, which he termed *osteitis fibrosa cystica*, which Askanazy subsequently described in a patient with a parathyroid tumor in 1904. The glands were rediscovered a decade later by Gley, who determined the effects of their extirpation with the thyroid. Vassale and Generali then successfully removed only the parathyroids and noted that tetany, convulsions, and death quickly followed unless calcium was given postoperatively. MacCallum and Voegtlin first noted the effect of parathyroidectomy on plasma Ca^{2+} . The relation of low plasma Ca^{2+} concentration to symptoms was quickly appreciated, and a comprehensive picture of parathyroid function began to form. Active glandular extracts alleviated hypocalcemic tetany in parathyroidectomized animals and raised the level of plasma Ca^{2+} in normal animals. For the first time, the relation of clinical abnormalities to parathyroid hyperfunction was appreciated.

Chemistry

Parathyroid hormone is a single polypeptide chain of 84 amino acids with a molecular mass of about 9500 Da. Biological activity is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTHR and hormone activity. Derivatives lacking the first and second residue bind to PTHRs but do not activate the cyclic AMP or IP_3 - Ca^{2+} signaling pathways. The PTH fragment lacking the first six amino acids inhibits PTH action.

Synthesis and Secretion

Parathyroid hormone is synthesized as a 115-amino acid peptide called *preproparathyroid hormone*, which is converted to *proparathyroid hormone* by cleavage of 25 amino-terminal residues in the endoplasmic reticulum. Proparathyroid hormone is converted in the Golgi complex to PTH by cleavage of six amino acids. PTH(1–84) resides within secretory granules until it is discharged into the circulation. PTH(1–84) has a $t_{1/2}$ in plasma of about 4 min; removal by the liver and kidney accounts for about 90% of its clearance. Proteolysis of PTH generates smaller fragments [e.g., a 33- to 36-amino acid N-terminal fragment that is fully active, a larger C-terminal peptide, and PTH(7–84)]. PTH(7–84) and other amino-truncated PTH fragments are normally cleared from the circulation predominantly by the kidneys, whereas intact PTH is also removed by extrarenal mechanisms.

Physiological Functions and Mechanism of Action

The primary function of PTH is to maintain a constant concentration of Ca^{2+} and P_i in the extracellular fluid. The principal processes regulated are renal Ca^{2+} and P_i absorption and mobilization of bone Ca^{2+} (see Figure 48–3). The actions of PTH on its target tissues are mediated by at least two GPCRs that can couple with G_s , G_q , and $\text{G}_{12/13}$ in cell type-specific manners (Garrido et al., 2009). The type I PTHR, which also binds PTHrP, mediates mineral-ion homeostasis and the skeletal actions of PTH. A second PTHR expressed in arterial and cardiac endothelium, brain, pancreas, placenta, and elsewhere binds PTH but not PTHrP. A third putative PTHR, designated the CPTH receptor, interacts with carboxy-terminal PTH fragments that are truncated in the amino-terminal region, contain most of the carboxy terminus, and are inactive at the PTH_1 receptor; CPTH receptors are expressed on osteocytes (Scillitani et al., 2011).

Regulation of Secretion. Plasma Ca^{2+} is the major factor regulating PTH secretion. As the concentration of Ca^{2+} diminishes, PTH secretion increases; hypocalcemia induces parathyroid hypertrophy and hyperplasia. Conversely, if the concentration of Ca^{2+} is high, PTH secretion decreases. Changes in plasma Ca^{2+} regulate PTH secretion by the plasma

membrane-associated CaSR on parathyroid cells. The CaSR is a GPCR that couples with G_q and G_i . Occupancy of the CaSR by Ca^{2+} stimulates the G_q -PLC- IP_3 - Ca^{2+} pathway leading to activation of PKC; this results in inhibition of PTH secretion, an unusual case in which elevation of cellular Ca^{2+} inhibits secretion (another being the granular cells in the juxtaglomerular complex of the kidney, where elevation of cellular Ca^{2+} inhibits renin secretion). Simultaneous activation of the CaSR- G_i pathway by Ca^{2+} reduces cyclic AMP synthesis and lowers the activity of PKA, also a negative signal for PTH secretion. Conversely, reduced occupancy of CaSR by Ca^{2+} reduces signaling through G_i and G_q , thereby promoting PTH secretion. Other agents that increase parathyroid cell cyclic AMP levels, such as β adrenergic receptor agonists and dopamine, also increase PTH secretion, but much less than does hypocalcemia. The active vitamin D metabolite 1,25-dihydroxyvitamin D (*calcitriol*) directly suppresses PTH gene expression. Severe hypermagnesemia or hypomagnesemia can inhibit PTH secretion.

Effects on Bone. Parathyroid hormone exerts both catabolic and anabolic effects on bone. Chronically elevated PTH enhances bone resorption and thereby increases Ca^{2+} delivery to the extracellular fluid, whereas intermittent exposure to PTH promotes anabolic actions. The primary skeletal target cell for PTH is the osteoblast.

Effects on Kidney. In the kidney, PTH enhances the efficiency of Ca^{2+} reabsorption, inhibits tubular reabsorption of phosphate, and stimulates conversion of vitamin D to its biologically active form, 1,25-dihydroxy vitamin D_3 (calcitriol; see Figure 48–3). As a result, filtered Ca^{2+} is avidly retained, and its concentration increases in plasma, whereas phosphate is excreted, and its plasma concentration falls. Newly synthesized 1,25-dihydroxy vitamin D_3 interacts with specific high-affinity receptors in the intestine to increase the efficiency of intestinal Ca^{2+} absorption, thereby contributing to the increase in plasma Ca^{2+} .

Calcitriol Synthesis. The final step in the activation of vitamin D to calcitriol occurs in kidney proximal tubule cells. Three primary regulators govern the enzymatic activity of the 25-hydroxyvitamin D_3 -1 α -hydroxylase that catalyzes this step: P_i , PTH, and Ca^{2+} (see discussion later in this chapter). Reduced circulating or tissue phosphate content rapidly increases calcitriol production, whereas hyperphosphatemia or hypercalcemia suppresses it. PTH powerfully stimulates calcitriol synthesis. Thus, when hypocalcemia causes a rise in PTH concentration, both the PTH-dependent lowering of circulating P_i and a more direct effect of the hormone on the 1 α -hydroxylase lead to increased circulating concentrations of calcitriol.

Integrated Regulation of Extracellular Ca^{2+} and Phosphate by PTH. Even modest reductions of serum Ca^{2+} stimulate PTH secretion. For minute-to-minute regulation of Ca^{2+} , adjustments in renal Ca^{2+} handling suffice to maintain plasma calcium homeostasis. With prolonged hypocalcemia, the renal 1 α -hydroxylase is induced, enhancing the synthesis and release of calcitriol that directly stimulates intestinal Ca^{2+} absorption (see Figure 48–3), and delivery of Ca^{2+} from bone into the extracellular fluid is augmented. With prolonged and severe hypocalcemia, new bone-remodeling units are activated to restore circulating Ca^{2+} concentrations, albeit at the expense of skeletal integrity.

When plasma Ca^{2+} activity rises, PTH secretion is suppressed, and tubular Ca^{2+} reabsorption decreases. The reduction in circulating PTH promotes renal phosphate conservation, and both the decreased PTH and the increased phosphate depress calcitriol production and thereby decrease intestinal Ca^{2+} absorption. Finally, bone remodeling is suppressed. These integrated physiological events ensure a coherent response to positive or negative excursions of plasma Ca^{2+} concentrations.

Fibroblast Growth Factor 23

Fibroblast growth factor 23 is a member of the FGF19 family of endocrine FGFs. Osteocytes and other bone cells, including osteoblasts, and lining cells are the primary source of FGF23. FGF23 is secreted in response to dietary phosphorus load and to changes in serum phosphate and 1,25-dihydroxyvitamin D. Its main function is the promotion of urinary

phosphate excretion and the suppression of active vitamin D production by the kidney. FGF23, unlike PTH, also suppresses intestinal phosphate absorption.

Synthesis and Secretion

Fibroblast growth factor 23 is synthesized as a 251-amino acid peptide. Cleavage of the amino-terminal signal sequence and glycosylation produce the active protein consisting of an amino-terminal core sequence and a shorter carboxy-terminal fragment (Figure 48–4). FGF23 is extensively O-glycosylated, which shields it from proteolysis and enhances secretion. FGF23 possesses a furin cleavage site, ¹⁷⁶RXXR¹⁷⁹. Hydrolysis produces FGF23 fragments that are biologically inactive or act as antagonists. Phosphorylation at Ser¹⁸⁰ inhibits O-glycosylation, thereby making FGF23 more susceptible to protease degradation.

Regulated FGF23 proteolysis may contribute to maintaining serum phosphate levels by generating more of a carboxy terminal cFGF23 peptide (cFGF23) relative to the amount of iFGF23 (intact FGF23). cFGF23 is now thought to inhibit FGF23 action by competitively blocking binding to FGFRs and klotho.

Unlike paracrine FGFs that require heparan sulfate for FGFR activation, FGF23 (and FGF19) bind heparan sulfate with very low affinity, and it is not necessary for signal transduction. FGF23 inhibits renal phosphate transport by activating FGFRs through a mechanism that entails the transmembrane form of α -klotho. *Klotho serves as an essential coreceptor for FGFR activation and transduction of FGF23 signaling.* Cleaved klotho increases FGF23 formation, while FGF23 decreases expression of transmembrane klotho (Smith et al., 2012). FGFRs are receptor TKs consisting of an extracellular domain with immunoglobulin-like loops and an intracellular region that harbors TK domains (Figure 48–4). The amino-terminal portion of FGF23 binds the FGFR, while the carboxy-terminal segment binds to klotho. This ternary complex (FGFR, klotho, and FGF23) then dimerizes, thereby enabling intracellular TK autophosphorylation of FGFR. Intracellular signaling is achieved primarily through ERKs and PLC.

Regulation of Secretion. Fibroblast growth factor 23 is released from bone into the circulation in response to elevations of serum phosphate,

PTH, and 1,25 vitamin D. The sensing mechanism responding to these changes and its control over FGF23 secretion is unknown. Iron deficiency also influences FGF23 levels. FGF23 is normally released by both as iFGF23 and inactive cFGF23 fragments. In healthy individuals, low serum iron is associated with elevated cFGF23 levels, but not with iFGF23. The ratio of iFGF23:cFGF23 varies appreciably in disease states and in inherited disorders of FGF23 metabolism (Wolf and White, 2014).

Physiological Functions and Mechanism of Action

Effects on Kidney. Fibroblast growth factor 23 increases phosphate excretion and lowers vitamin D formation. The phosphaturic action of FGF23 is mediated by FGFR1c and to a lesser degree by FGFR4 (Gattineni et al., 2014). FGF23 and PTH reduce phosphate by mechanisms that involve endocytosis and downregulation of NPT2A and NPT2C, the principal Na-phosphate cotransporters that mediate phosphate retrieval from the tubular fluid. *Notably, although FGF23 and PTH exert parallel inhibitory actions on phosphate excretion, they have opposite effects on vitamin D metabolism. PTH stimulates the formation of the active form of vitamin D, whereas FGF23 reduces vitamin D levels by augmenting its metabolism to inactive forms.*

Exogenous FGF23 administration reduces serum P_i and calcitriol synthesis. Although no clinical agents based on FGF23 have yet been developed, bioactive fragments or FGF23 inhibitors might become useful in counterbalancing the hyperphosphatemic actions of vitamin D therapy. The novel recombinant human IgG monoclonal antibody KRN23, which binds FGF23 and inhibits its activity, can increase P_i reabsorption and serum concentrations of P_i and calcitriol in patients with XLH (Carpenter et al., 2014; Imel et al., 2015).

Soluble klotho, a circulating cleavage product of membrane-associated klotho, when administered to mice increased serum levels of FGF23 and reduced bone mineral content with a concomitant increase in fracture incidence (Smith et al., 2012). These findings suggest that a scavenging antibody directed to the soluble klotho fragment might provide an additional means to reduce FGF23 levels in patients with secondary hyperparathyroidism or CKD-MBD.

Figure 48–4 FGF23-FGFR-Klotho complex. FGF23 binding to the FGFR + klotho complex promotes dimerization of the ternary complex. FGFRs possess three Ig-like domains (I, II, III). Alternative splicing in domain III gives rise to FGFR1/2/3 isoforms. FGFR1c is believed to be the FGF23 receptor. FGF23 requires α -klotho to bind and activate FGFR1. FGF23 consists of a larger N-terminal region and shorter C-terminal segment. Intracellular proteolysis and inactivation of FGF23 occurs at a site separating the two domains. Klotho is a transmembrane protein with two large extracellular KL1 and KL2 domains that can be cleaved by a disintegrin and metalloproteinase 10 and 17 (ADAM10/17). Full-length klotho and the shed extracellular domain of KL have distinct functions. Notably, full-length klotho is coreceptor for FGFR1. Intracellular TK domains on FGFRs mediate downstream signaling, primarily through parallel pathways involving FRS2 α , SGK1, ERK1/2 for FGF23 (Andruxhova et al., 2012), and PLC γ (which activates signaling by Ca^{2+} -activating PKC) (Ornitz and Itoh, 2015).

HISTORY

Prior to the discovery of vitamin D, a high percentage of urban children living in temperate zones developed rickets. Some researchers believed that the disease was due to lack of fresh air and sunshine; others claimed a dietary factor was responsible. Mellanby and Huldschinsky showed both notions to be correct; addition of cod liver oil to the diet or exposure to sunlight prevented or cured the disease. In 1924, it was found that ultraviolet irradiation of animal rations was as efficacious at curing rickets as was irradiation of the animal itself. These observations led to the elucidation of the structures of cholecalciferol and eventually to the discovery that these compounds require further processing in the body to become active. The discovery of metabolic activation is attributable primarily to studies conducted in the laboratories of DeLuca and Kodicek (DeLuca, 1988).

Chemistry and Occurrence

Vitamin D is a hormone rather than a vitamin, and it plays an active role in Ca^{2+} homeostasis. The biological actions of vitamin D are mediated by the VDR, a nuclear receptor. Vitamin D is the name applied to two related fat-soluble substances, vitamin D_3 (cholecalciferol) and vitamin D_2 (ergocalciferol). Recent studies showed clearly that vitamin D_3 has a potency about 10-fold greater than that of vitamin D_2 . This difference is likely attributable to the longer $t_{1/2}$ of vitamin D_3 and lower affinity of vitamin D_2 metabolites for the vitamin D-binding protein (Jones et al., 2014), dispelling the long-held notion that there is no practical difference between vitamin D_2 and vitamin D_3 . The total concentration of serum 25-hydroxyvitamin D ($\text{D}_2 + \text{D}_3$) is now accepted as the clinical parameter for assessing vitamin D status and functional adequacy of vitamin D treatments.

The principal provitamin found in animal tissues is 7-dehydrocholesterol, which is synthesized in the skin. Exposure of the skin to sunlight converts 7-dehydrocholesterol to cholecalciferol (vitamin D_3). Ergosterol, present

only in plants and fungi, is the provitamin for ergocalciferol (vitamin D_2). Vitamin D_2 is the active constituent of a number of commercial vitamin preparations and is in irradiated bread and irradiated milk.

Human Requirements and Units

Although sunlight provides adequate vitamin D supplies in the equatorial belt, in temperate climates insufficient cutaneous solar radiation, especially in winter, may necessitate dietary vitamin D supplementation (Faulschoou et al., 2012). Serum levels of vitamin D vary widely, likely reflecting genetic background, diet, latitude, time spent out of doors, body size, developmental stage, and state of health, as well as plasma levels of vitamin D-binding protein, a specific α globulin. The actions of vitamin D may differ with the expression of components of the synthetic and action pathways of vitamin D. Other factors contributing to the rise of vitamin D deficiency may include diminished consumption of vitamin D-fortified foods owing to concerns about fat intake; reduced intake of dairy products; an increased prevalence and duration of exclusive breastfeeding (human milk is a poor source of vitamin D); and increased use of sunscreens and decreased exposure to sunlight to reduce the risk of skin cancer and prevent premature aging from exposure to ultraviolet radiation. The recommended amount of sunscreen and SPF advised by the World Health Organization may abolish endogenous vitamin D production (Faulschoou et al., 2012). The U.S. Institute of Medicine suggests achieving a serum level for 25-OH vitamin D of 50 nmol/L (20 ng/mL). The most recent recommended daily intakes of vitamin D and calcium are shown in Table 48-1.

Metabolic Activation

Vitamin D requires modification to become biologically active. The primary active metabolite, $1\alpha,25$ -dihydroxy vitamin D (calcitriol), is the product of successive hydroxylations (see Figure 48-5).

25-Hydroxylation of Vitamin D. The initial hydroxylation occurs in the liver to generate 25-OH-cholecalciferol (25-OHD₃, or calcidiol) and 25-OHD₂ (ergocalciferol), respectively. 25-OHD₃ is the major circulating form of vitamin D_3 ; it has a biological $t_{1/2}$ of 19 days, and normal steady-state concentrations are 15–50 ng/mL, whereas 25-OHD₂ has a $t_{1/2}$ of 13 days.

Figure 48-5 Vitamin D metabolism. Vitamin D (cholecalciferol) is formed in the skin by solar ultraviolet irradiation of 7-dehydrocholesterol or provided in the diet or by supplements. Sequential hydroxylation at position 25 (red) in the liver to 25(OH) D_3 (calcidiol) and at position 1 (red) in the kidneys produces biologically active $1\alpha,25(\text{OH})_2\text{D}_3$ (calcitriol). Metabolism of calcidiol and calcitriol by 24-hydroxylase reduces serum levels of $1\alpha,25(\text{OH})_2\text{D}_3$. PTH promotes the formation of $1\alpha,25(\text{OH})_2\text{D}_3$, while FGF23 reduces $1\alpha,25(\text{OH})_2\text{D}_3$ levels by stimulating 24-hydroxylation by CYP24A1 and inhibiting 1 α -hydroxylase (CYP27B1). Elevated calcitriol levels decrease PTH synthesis by parathyroid glands and stimulate FGF23 release from osteocytes.

1 α -Hydroxylation of 25-OHD. After production in the liver, 25-OHD enters the circulation and is carried by vitamin D-binding globulin. Final activation occurs primarily in the *kidney*, where the enzyme 25-hydroxyvitamin D-1 α -hydroxylase (*CYP27B1*) in the proximal tubules converts 25-OHD₃ to *calcitriol*. This process is highly regulated (Figures 48-3 and 48-5). Dietary deficiency of vitamin D, calcium, or phosphate stimulates 1 α -hydroxylation of 25-OHD₃, increasing the formation of biologically active 1,25(OH)₂D₃. In contrast, when Ca²⁺ concentrations are elevated, 25-OHD₃ is inactivated by 24-hydroxylation. Similar reactions occur with 25-OHD₂ (ergocalciferol). Calcitriol controls 1 α -hydroxylase activity by a negative-feedback mechanism that involves a direct action on the kidney, as well as inhibition of PTH secretion. The plasma $t_{1/2}$ of calcitriol is estimated at 3–5 days in humans.

24-Hydroxylation of Calcitriol. The 25(OH) vitamin D-24-hydroxylase enzyme *CYP24A1* catalyzes several steps of 1,25(OH)₂D₃ degradation. *CYP24A1* is upregulated by FGF23 and calcitriol and downregulated by PTH.

Physiological Functions and Mechanism of Action

Calcitriol augments absorption and retention of Ca²⁺ and phosphate and thereby helps to maintain normal concentrations of Ca²⁺ and phosphate in plasma. Calcitriol facilitates absorption of Ca²⁺ and phosphate in the small intestine, interacts with PTH to enhance their mobilization from bone, and decreases their renal excretion. The actions of calcitriol are mediated by the nuclear receptor VDR, a member of the steroid and thyroid hormone nuclear receptor superfamily. Calcitriol binds to cytosolic VDRs within target cells; the VDR-hormone complex translocates to the nucleus and interacts with DNA to modify gene transcription. Calcitriol also exerts rapid, nongenomic effects. These actions also involve the VDR but at an alternative site where calcitriol binds in a planar configuration.

Calcium is absorbed predominantly from the duodenum. In the absence of calcitriol, GI calcium absorption is inefficient and involves passive diffusion via a paracellular pathway. Ca²⁺ absorption is potently augmented by calcitriol. It is likely that calcitriol enhances all three steps involved in intestinal Ca²⁺ absorption (Kellett, 2011):

- entry across mucosal membranes mediated by TRPV6 and Ca(v)1.3 Ca²⁺ channels
- diffusion through the enterocytes
- active extrusion across serosal plasma membranes

Calcitriol upregulates the synthesis of FGF23, calbindin-D_{9K}, calbindin-D_{28K}, and the serosal plasma membrane Ca²⁺-ATPase. Calbindin-D_{9K} enhances the extrusion of Ca²⁺ by the Ca²⁺-ATPase; the precise function of calbindin-D_{28K} is unsettled.

The primary role of calcitriol is to stimulate intestinal absorption of Ca²⁺, which in turn indirectly promotes bone mineralization. Hence, PTH and calcitriol act independently to enhance bone resorption. Osteoblasts, the cells responsible for bone formation, express VDR, and calcitriol induces production of several osteoblast proteins, including osteocalcin, a vitamin K-dependent protein that contains γ -carboxyglutamic acid residues, and IL-1, a lymphokine that promotes bone resorption. Thus, the current view is that calcitriol is a bone-mobilizing hormone but not a bone-forming hormone. In a healthy scenario, osteoblast and osteoclast activities are coupled. Osteoporosis is a disease in which that coupling is disturbed; osteoblast responsiveness to calcitriol is profoundly impaired, osteoclast activity predominates, and bone resorption exceeds formation.

Other Effects of Calcitriol. Effects of calcitriol extend well beyond calcium homeostasis. Receptors for calcitriol are distributed widely throughout the body. Calcitriol affects maturation and differentiation of mononuclear cells and influences cytokine production and immune function. Calcitriol inhibits epidermal proliferation, promotes epidermal differentiation, and is used as a treatment of plaque psoriasis (see Chapter 70).

Calcitonin

Calcitonin is a hypocalcemic hormone whose actions generally oppose those of PTH. The thyroid parafollicular C cells produce and secrete calcitonin.

Calcitonin is the most potent peptide inhibitor of osteoclast-mediated bone resorption and helps to protect the skeleton during periods of “calcium stress,” such as growth, pregnancy, and lactation. Calcitonin acts through the CTR, a GPCR that links to G_s and G_q.

HISTORY

Copp observed in 1962 that perfusion of canine parathyroid and thyroid glands with hypercalcemic blood caused transient hypocalcemia that occurred significantly earlier than that caused by total parathyroidectomy. He concluded that the parathyroid glands secreted a calcium-lowering hormone (calcitonin) in response to hypercalcemia and in this way normalized plasma Ca²⁺ concentrations. The physiological relevance of calcitonin has been challenged vigorously: Calcitonin normally circulates at remarkably low levels; surgical removal of the thyroids has no appreciable effect on calcium metabolism; and conditions associated with profound elevations of serum calcitonin concentration are not accompanied by hypocalcemia (Hirsch and Baruch, 2003). The primary interest in calcitonin arises from its pharmacological use in treating Paget disease and hypercalcemia and in its diagnostic use as a tumor marker for medullary carcinoma of the thyroid.

Regulation of Secretion

Calcitonin is a single-chain peptide of 32 amino acids with a disulfide bridge linking cys1 and cys7. Serum [Ca²⁺] concentrations regulate the biosynthesis and secretion of calcitonin. Calcitonin secretion increases when serum Ca²⁺ is high and decreases when plasma Ca²⁺ is low. Thus, PTH secretion decreases and calcitonin release increases as serum calcium concentrations rise (Figure 48-6). The circulating concentrations of calcitonin are low, normally less than 15 and 10 pg/mL for males and females, respectively. The circulating $t_{1/2}$ of calcitonin is about 10 min. Abnormally elevated levels of calcitonin are characteristic of thyroid C cell hyperplasia and MTC. The calcitonin gene is localized on human chromosome 11p and contains six exons; differential splicing of the exons leads to tissue-specific production of calcitonin, katecalcitonin, and CGRP.

Bone Physiology

The skeleton is the primary structural support for the body and also provides a protected environment for hematopoiesis. It contains both a large mineralized matrix and a highly active cellular compartment.

Bone Mass

Bone mineral density and fracture risk in later years reflect the maximal bone mineral content at skeletal maturity (peak bone mass) and the subsequent rate of bone loss. Major increases in bone mass, accounting for about 60% of final adult levels, occur during adolescence, mainly during years of highest growth velocity. Inheritance accounts for much of the variance in bone acquisition; other factors include circulating estrogen and androgens, physical activity, and dietary calcium. Bone mass peaks during the third decade, remains stable until age 50, and then declines progressively. In women, loss of estrogen at menopause accelerates the rate of bone loss. *Primary regulators of adult bone mass include physical activity, reproductive endocrine status, and calcium intake. Optimal maintenance of BMD requires sufficiency in all three areas, and deficiency of one is not compensated by excessive attention to another.*

Bone Remodeling

Once new bone is laid down, it is subject to a continuous process of breakdown and renewal called *remodeling*, by which bone mass is adjusted throughout adult life. Remodeling is carried out by myriad independent “bone-remodeling units” throughout the skeleton. In response to physical or biochemical signals, recruitment of marrow precursor cells to the bone surface results in their fusion into the characteristic multinucleated

Figure 48-6 Inverse relations between PTH and calcitonin release. As serum calcium falls below its set point of about 1.2 mM, PTH secretion increases as a means to defend calcium homeostasis. Conversely, as calcium levels rise, PTH secretion is inhibited, while release of calcitonin increases. (Replotted from original observations; Imanishi et al., 2002; Torres et al., 1991).

osteoclasts that resorb, or excavate, a cavity into the bone. Osteoclast production is regulated by osteoblast-derived cytokines (e.g., IL-1 and IL-6). One important mechanism is RANK and its natural ligand, RANKL (previously called *osteoclast differentiation factor*). On binding to RANK, RANKL induces osteoclast formation (Figure 48-7). RANKL initiates the activation of mature osteoclasts, as well as the differentiation of osteoclast precursors. Osteoblasts produce OPG, which acts as a decoy ligand that inhibits osteoclast production by competing effectively with RANKL for binding to RANK. Under conditions favoring increased bone resorption, such as estrogen deprivation, OPG is suppressed, RANKL binds to RANK, and osteoclast production increases. When estrogen sufficiency is reestablished, OPG increases and competes effectively with RANKL for binding to RANK.

The resorption phase is followed by invasion of preosteoblasts into the base of the resorption cavity. These cells become osteoblasts and elaborate new bone matrix constituents that help form *osteoid*. Once the newly formed osteoid reaches a thickness of about 20 μ M, mineralization begins. A complete remodeling cycle normally requires about 6 months. Small bone deficits persist on completion of each cycle, reflecting inefficient remodeling dynamics. Consequently, lifelong accumulation of remodeling

deficits underlies the well-documented phenomenon of age-related bone loss, a process that begins shortly after growth stops. *Alterations in remodeling activity represent the final pathway through which diverse stimuli, such as dietary sufficiency, exercise, hormones, and drugs, affect bone balance.*

Disorders of Mineral Homeostasis and Bone

Abnormal Calcium Metabolism

Hypercalcemia

In an outpatient setting, the most common cause of hypercalcemia is primary hyperparathyroidism, which results from hypersecretion of PTH by one or more parathyroid glands. Symptoms and signs of primary hyperparathyroidism include fatigue, exhaustion, weakness, polydipsia, polyuria, joint pain, bone pain, constipation, depression, anorexia, nausea, heartburn, nephrolithiasis, and hematuria. This condition frequently is accompanied by significant hypophosphatemia owing to the effects of PTH in diminishing renal tubular phosphate reabsorption.

Hypercalcemia in hospitalized patients is caused most often by a systemic malignancy, either with or without bony metastasis. PTHrP is a primitive, highly conserved protein that may be abnormally expressed in malignant tissue. PTHrP interacts with the PTHR in target tissues, thereby causing the hypercalcemia and hypophosphatemia seen in humoral hypercalcemia of malignancy (Grill et al., 1998). In some patients with lymphomas, hypercalcemia results from overproduction of 1,25-dihydroxyvitamin D by the tumor cells owing to stimulation of 25(OH) vitamin D-1 α -hydroxylase.

Vitamin D excess may cause hypercalcemia if sufficient 25-OHD is present to stimulate intestinal Ca^{2+} hyperabsorption, leading to hypercalcemia and suppressing PTH and 1,25-dihydroxyvitamin D levels. Measurement of 25-OHD is diagnostic. Occasionally, patients with *hyperthyroidism* show mild hypercalcemia, presumably owing to increased bone turnover. *Immobilization* may lead to hypercalcemia in growing children and young adults but rarely causes hypercalcemia in older individuals unless bone turnover is already increased, as in Paget disease or hyperthyroidism. Hypercalcemia sometimes is noted in adrenocortical deficiency, as in Addison disease, or following removal of a hyperfunctional adrenocortical tumor. Hypercalcemia occurs following renal transplantation owing to persistent hyperfunctioning parathyroid tissue that resulted from the previous renal failure. Serum assays for PTH, PTHrP, and 25-OH- and 1,25-(OH) $_2$ D permit accurate diagnosis in the great majority of cases.

Hypocalcemia

Combined deprivation of Ca^{2+} and vitamin D, as observed with malabsorption states, readily promotes hypocalcemia. When caused by

Figure 48-7 Osteoclast formation. Receptor for activating RANKL, acting on RANK, promotes osteoclast formation and subsequent resorption of bone matrix. OPG, a decoy receptor, binds to RANKL, reducing its interaction with RANK and thereby inhibiting osteoclast differentiation.

malabsorption, hypocalcemia is accompanied by low concentrations of phosphate, total plasma proteins, and magnesium. Mild hypocalcemia (i.e., serum Ca^{2+} in the range of 8–8.5 mg/dL [2–2.1 mM]), is usually asymptomatic. Patients exhibit greater symptoms if the hypocalcemia develops acutely.

Symptoms of hypocalcemia include tetany and related phenomena, such as paresthesias, increased neuromuscular excitability, laryngospasm, muscle cramps, and tonic-clonic convulsions. In chronic *hypoparathyroidism*, ectodermal changes (e.g., consisting of loss of hair, grooved and brittle fingernails, defects of dental enamel, and cataracts) occur. Psychiatric symptoms such as emotional lability, anxiety, depression, and delusions often are present. Hypoparathyroidism is most often a consequence of thyroid or neck surgery but also may be due to genetic or autoimmune disorders. *Pseudohypoparathyroidism* is a family of various hypocalcemic and hyperphosphatemic disorders. Pseudohypoparathyroidism results from resistance to PTH; this resistance is due to mutations in $G_{\alpha s}$ (*GNAS1*), which normally mediates hormone-induced adenyl cyclase activation (Bastepe, 2008). Multiple hormonal abnormalities have been associated with the *GNAS1* mutation, but none is as severe as the deficient response to PTH.

Disturbed Phosphate Metabolism

Dietary inadequacy rarely causes phosphate depletion. Sustained use of antacids, however, can severely limit phosphate absorption and result in clinical phosphate depletion, manifest as malaise, muscle weakness, and osteomalacia (see Chapter 49). *Osteomalacia* is characterized by undermineralized bone matrix and may occur when sustained phosphate depletion is caused by inhibiting its absorption in the GI tract (as with aluminum-containing antacids) or by excess renal excretion owing to PTH action. *Hyperphosphatemia* occurs commonly in CKD. The increased phosphate level reduces the serum Ca^{2+} concentration, which in turn activates the parathyroid gland CaSR, stimulates PTH secretion, and exacerbates the hyperphosphatemia. The CaSR agonist *cinacalcet* suppresses PTH secretion and has been approved as treatment of secondary hyperparathyroidism in adult patients with CKD receiving chronic dialysis therapy, for hypercalcemia secondary to parathyroid cancer, and for primary hyperparathyroidism in patients unable to be managed surgically.

The investigational recombinant human monoclonal antibody KRN23 against FGF23 is extremely effective in correcting the hypophosphatemia associated with XLH, the most common form of hereditary rickets and osteomalacia. Monthly administration provides prolonged restoration of serum phosphate by reducing urinary phosphate excretion without adversely altering serum PTH or calcium levels (Carpenter et al., 2014; Imel et al., 2015). KRN23 was granted orphan drug status for treating XLH or other hypophosphatemic conditions in the E.U. in 2014, but it is not yet approved for use in the U.S.

Disorders of Vitamin D

Hypervitaminosis D

The acute or long-term administration of excessive amounts of vitamin D or enhanced responsiveness to normal amounts of the vitamin leads to derangements in calcium metabolism. In adults, hypervitaminosis D results from overtreatment of hypoparathyroidism and from faddist use of excessive doses. The amount of vitamin D necessary to cause hypervitaminosis varies widely. As a rough approximation, continued daily ingestion of 50,000 units or more may result in poisoning. The initial signs and symptoms of vitamin D toxicity are those associated with hypercalcemia.

Vitamin D Deficiency

Vitamin D deficiency results in inadequate absorption of Ca^{2+} and phosphate. The consequent decrease of plasma Ca^{2+} concentration stimulates PTH secretion, which acts to restore plasma Ca^{2+} at the expense of bone. FGF23 increases as well. Plasma concentrations of phosphate remain subnormal because of the phosphaturic effect of increased circulating PTH and FGF23. In children, the result is failure to mineralize newly formed bone and cartilage matrix, causing the defect in growth known as *rickets*.

In adults, vitamin D deficiency results in osteomalacia, a disease characterized by generalized accumulation of undermineralized bone matrix. Muscle weakness, particularly of large proximal muscles, is typical and may reflect both hypophosphatemia and inadequate vitamin D action on muscle. Gross deformity of bone occurs only in advanced stages of the disease. Circulating 25-OHD concentrations less than 8 ng/mL are highly predictive of osteomalacia.

Metabolic Rickets and Osteomalacia

The disorders of metabolic rickets and osteomalacia are characterized by abnormalities in calcitriol synthesis or response. Variants include the following:

- *Hypophosphatemic vitamin D-resistant rickets*: Usually, this is an X-linked disorder (XLH) of calcium and phosphate metabolism. Patients experience clinical improvement when treated with large doses of vitamin D, usually in combination with inorganic phosphate.
- *Vitamin D-dependent rickets*, also called *VDDR-1* or *PDDR*: This is an autosomal recessive disease caused by an inborn error of vitamin D metabolism involving defective conversion of 25-OHD to calcitriol due to mutations in *CYP1α* (1α-hydroxylase).
- *HVDDR*, also called *vitamin D-dependent rickets type II*: This is an autosomal recessive disorder that is characterized by hypocalcemia, osteomalacia, rickets, and total alopecia. Multiple heterogeneous mutations of the VDR cause this variant.
- *CKD-MBD (renal rickets)*: Refers to the disordered bone morphology that attends CKD. The variant is characterized by abnormalities of bone turnover, mineralization, volume, linear growth, or strength, as well as underlying defects in mineral ion, PTH, or vitamin D metabolism.

Osteoporosis

Osteoporosis is a condition of low bone mass and microarchitectural disruption that results in fractures with minimal trauma. Many women (30%–50%) and men (15%–30%) suffer a fracture related to osteoporosis. Characteristic sites of fracture include vertebral bodies, the distal radius, and the proximal femur, but osteoporotic individuals have generalized skeletal fragility, and fractures at sites such as ribs and long bones also are common. Fracture risk increases exponentially with age, and spine and hip fractures are associated with reduced survival.

Osteoporosis can be categorized as *primary* or *secondary*. *Primary osteoporosis* represents two different conditions: *type I osteoporosis*, characterized by loss of trabecular bone owing to estrogen lack at menopause, and *type II osteoporosis*, characterized by loss of cortical and trabecular bone in men and women due to long-term remodeling inefficiency, dietary inadequacy, and activation of the parathyroid axis with age. *Secondary osteoporosis* is due to systemic illness or chronic use of medications such as glucocorticoids or phenytoin. The most successful approaches to secondary osteoporosis are prompt resolution of the underlying cause and drug discontinuation. Whether primary or secondary, osteoporosis is associated with characteristic disordered bone remodeling, so the same therapies can be used in both conditions.

Paget Disease

Single or multiple sites of disordered bone remodeling characterize Paget disease. It affects up to 2%–3% of the population more than 60 years of age. The primary pathologic abnormality is increased bone resorption followed by exuberant bone formation. However, the newly formed bone is disorganized and of poor quality, resulting in characteristic bowing, stress fractures, and arthritis of joints adjoining the involved bone. The altered bone structure can produce secondary problems, such as deafness, spinal cord compression, high-output cardiac failure, and pain. Malignant degeneration to osteogenic sarcoma is a rare but lethal complication of Paget disease.

Chronic Kidney Disease–Mineral Bone Disease

Bone disease is a frequent consequence of CKD and dialysis treatment. Pathologically, lesions are typical of hyperparathyroidism (osteitis fibrosa),

vitamin D deficiency (osteomalacia), or a mixture of both. The underlying pathophysiology reflects increased serum phosphate and decreased calcium, leading to the loss of bone.

Pharmacological Treatment of Disorders of Mineral Ion Homeostasis and Bone Metabolism

Hypercalcemia

Hypercalcemia can be life threatening. Such patients frequently are severely dehydrated because hypercalcemia compromises renal concentrating mechanisms. Thus, fluid resuscitation with large volumes of isotonic saline must be early and aggressive (6–8 L/d). Agents that augment Ca^{2+} excretion, such as loop diuretics (see Chapter 25), may help to counteract the effect of plasma volume expansion by saline but are contraindicated until volume is repleted.

Corticosteroids administered at high doses (e.g., 40–80 mg/d of prednisone) may be useful when hypercalcemia results from sarcoidosis, lymphoma, or hypervitaminosis D (see Chapter 46). The response to steroid therapy is slow; from 1 to 2 weeks may be required before plasma Ca^{2+} concentration falls. Calcitonin may be useful in managing hypercalcemia. Reduction in Ca^{2+} can be rapid, although “escape” from the hormone commonly occurs within several days. The recommended starting dose is 4 units/kg of body weight administered subcutaneously every 12 h; if there is no response within 1–2 days, the dose may be increased to a maximum of 8 units/kg every 12 h. If the response after 2 more days still is unsatisfactory, the dose may be increased to a maximum of 8 units/kg every 6 h. Calcitonin can lower serum calcium by 1–2 mg/dL.

Intravenous *bisphosphonates* (*pamidronate*, *zoledronate*) have proven very effective in the management of hypercalcemia (see further material for discussion of bisphosphonates). These agents potentially inhibit osteoclastic bone resorption. Pamidronate is given as an intravenous infusion of 60–90 mg over 4–24 h. With pamidronate, resolution of hypercalcemia occurs over several days, and the effect usually persists for several weeks. Zoledronate has largely superseded pamidronate because of its more rapid normalization of serum Ca^{2+} and longer duration of action.

Plicamycin (mithramycin; discontinued in the U.S.) is a cytotoxic anti-biotic that also decreases plasma Ca^{2+} concentrations by inhibiting bone resorption. Reduction in plasma Ca^{2+} concentrations occurs within 24–48 h when a relatively low dose of this agent is given (15–25 $\mu\text{g/kg}$ of body weight) to minimize the high systemic toxicity of the drug; indeed, its toxicity generally precludes its use.

Once the hypercalcemic crisis has resolved, or in patients with milder calcium elevations, long-term therapy is initiated. Parathyroidectomy remains the only definitive treatment of primary hyperparathyroidism. As described further in this chapter, a calcium mimetic that stimulates the CaSR is an effective therapeutic option for hyperparathyroidism. Therapy of hypercalcemia of malignancy ideally is directed at the underlying cancer. When this is not possible, parenteral bisphosphonates often will maintain Ca^{2+} levels within an acceptable range.

Hypocalcemia and Other Therapeutic Uses of Calcium

Calcium is used in the treatment of calcium deficiency states and as a dietary supplement. Hypoparathyroidism is treated primarily with vitamin D and various calcium salts. *Calcium chloride* ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$) contains 27% Ca^{2+} ; it is valuable in the treatment of hypocalcemic tetany and laryngospasm. The salt is given intravenously and *must never be injected* into tissues. Injections of calcium chloride are accompanied by peripheral vasodilation and a cutaneous burning sensation. The usual intravenous preparation is a 10% solution (equivalent to 1.36 mEq Ca^{2+} /mL). The rate of injection should be slow (not more than 1 mL/min) to prevent cardiac arrhythmias from a high concentration of Ca^{2+} . The injection may induce a moderate fall in blood pressure owing to vasodilation.

Calcium gluceptate injection (a 22% solution; 18 mg or 0.9 mEq of Ca^{2+} /mL; not available in the U.S.) is administered intravenously at a dose of

5–20 mL for the treatment of severe hypocalcemic tetany. *Calcium gluconate* injection (a 10% solution; 9.3 mg of Ca^{2+} /mL) given intravenously is the treatment of choice for severe hypocalcemic tetany. Patients with moderate-to-severe hypocalcemia are typically treated by intravenous infusion of calcium gluconate at a dose of 10–15 mg of Ca^{2+} /kg of body weight over 4–6 h. Because the usual 10-mL vial of a 10% solution contains only 93 mg Ca^{2+} , many vials are needed. Treatment with intravenous Ca^{2+} , administered as calcium gluconate (10–30 mL of a 10% solution), also may be lifesaving in patients with extreme hyperkalemia (serum $\text{K}^+ > 7$ mEq/L).

Additional FDA-approved uses of intravenous Ca^{2+} include treatment of black widow spider envenomation and management of magnesium toxicity. The intramuscular route should not be employed because abscess formation at the injection site may result.

For control of milder hypocalcemic symptoms, oral medication suffices, frequently in combination with vitamin D or one of its active metabolites. Calcium carbonate is relatively inexpensive and well tolerated, so it is prescribed most frequently. *Calcium carbonate* and *calcium acetate* are used to restrict phosphate absorption in patients with CKD and oxalate absorption in patients with inflammatory bowel disease.

Vitamin D

The physiology and corresponding mechanism of action of vitamin D was described previously in this chapter.

ADME

Vitamin D is absorbed from the small intestine. Bile is essential for adequate absorption of vitamin D and is also the primary route of vitamin D excretion. Patients who have intestinal bypass surgery or inflammation of the small intestine may fail to absorb vitamin D sufficiently to maintain normal levels; hepatic or biliary dysfunction also may seriously impair vitamin D absorption. Absorbed vitamin D circulates in the blood in association with vitamin D-binding protein. The vitamin disappears from plasma with a $t_{1/2}$ of 20–30 h but is stored in fat depots for prolonged periods.

Therapeutic Uses for Vitamin D

The major therapeutic uses of vitamin D are the following:

- prophylaxis and cure of nutritional rickets
- treatment of metabolic rickets and osteomalacia, particularly in the setting of CKD
- treatment of hypoparathyroidism
- prevention and treatment of osteoporosis
- dietary supplementation

Nutritional Rickets. Nutritional rickets results from inadequate exposure to sunlight or deficiency of dietary vitamin D. The incidence of this condition in the U.S. is now increasing. Infants and children receiving adequate amounts of vitamin D-fortified food do not require additional vitamin D; however, breastfed infants or those fed unfortified formula should receive 400 units of vitamin D daily as a supplement (see Table 48–1) (Wagner et al., 2008), usually administered with vitamin A, for which purpose a number of balanced vitamin A and D preparations are available. *Because the fetus acquires more than 85% of its calcium stores during the third trimester, premature infants are especially susceptible to rickets and may require supplemental vitamin D.* Treatment of fully developed rickets requires a larger dose of vitamin D than that used prophylactically. One thousand units daily will normalize plasma Ca^{2+} and phosphate concentrations in about 10 days, with radiographic evidence of healing in about 3 weeks. However, a larger dose of 3000–4000 units daily often is prescribed for more rapid healing, particularly when severe thoracic rickets compromises respiration.

Treatment of Osteomalacia and CKD-MBD. Osteomalacia, distinguished by undermineralization of bone matrix, occurs commonly during sustained phosphate depletion. Patients with CKD are at risk for developing osteomalacia but also may develop a complex bone disease called CKD-MBD, formerly known as *renal osteodystrophy*. In this setting, bone metabolism is stimulated by an increase in PTH and by a delay in

bone mineralization that is due to decreased renal synthesis of calcitriol. In CKD-MBD, low BMD may be accompanied by high-turnover bone lesions, typically seen in patients with uncontrolled hyperparathyroidism or by low bone remodeling activity seen in patients with adynamic bone disease.

The therapeutic approach to the patient with CKD-MBD depends on its skeletal manifestation. In high-turnover (hyperparathyroid) or mixed high-turnover disease with deficient mineralization, dietary phosphate restriction, generally in combination with a phosphate binder, is recommended. Administration of calcium-containing phosphate binders along with calcitriol may contribute to oversuppression of PTH secretion and likewise result in adynamic bone disease. The increased calcium burden associated with calcium-based phosphate binders likely contributes to the increased incidence of vascular calcification in patients with CKD.

Non-calcium-containing phosphate binders are highly effective alternatives to traditional calcium-based agents. *Sevelamer hydrochloride* is a nonabsorbable polymer that acts as a nonselective anion exchanger. The drug is modestly water soluble, and only trace amounts are absorbed from the GI tract. Sevelamer not only effectively lowers serum phosphate concentration in hemodialysis patients but also binds bile acids, and to a lesser extent low-density lipoprotein cholesterol and fat-soluble vitamins. Side effects of sevelamer hydrochloride include vomiting, nausea, diarrhea, dyspepsia, and metabolic acidosis.

Sevelamer carbonate is equivalent to sevelamer hydrochloride in terms of safety and tolerability, with a lower likelihood of inducing metabolic acidosis. *Lanthanum carbonate* is a poorly permeable trivalent cation that is highly effective in treating the hyperphosphatemia associated with CKD-MBD but is associated with GI side effects.

Most recently, the FDA approved two novel iron-based phosphate binders. *Sucroferric oxyhydroxide* is a polynuclear iron(III)-oxyhydroxide compound that binds phosphate by ligand exchange. The drug exhibits similar phosphate control efficacy as sevelamer with a lower daily pill burden. *Ferric citrate* also exhibits comparable phosphate control efficacy to sevelamer and to calcium acetate. In addition, ferric citrate delivers a significant amount of iron, resulting in increased erythropoietic parameters and the possibility of iron overload with chronic dosing. Diarrhea is a common side effect of both iron-based phosphate binders (Shah et al., 2015).

Niacin and nicotinic acid lower serum phosphate and have been proposed as alternatives to the use of sevelamer. Recent studies suggested that extended-release niacin does not improve cardiovascular outcomes and is associated with greater all-cause mortality. Direct comparison of nicotinic acid and sevelamer in patients with CKD showed that although nicotinic acid reduced hyperphosphatemia, sevelamer exhibited greater efficacy in controlling hyperphosphatemia as well as the $\text{Ca} \times \text{P}$ product (Ahmadi et al., 2012; Kalil et al., 2015).

Hypoparathyroidism. Vitamin D and its analogues are the mainstay of the therapy of hypoparathyroidism. DHT, a reduced form of vitamin D_2 , has a faster onset, shorter duration of action, and greater effect on bone mobilization than does vitamin D and traditionally has been a preferred agent; however, it is no longer available in the U.S. Although most hypoparathyroid patients respond to any form of vitamin D, calcitriol may be preferred for temporary treatment of hypocalcemia while awaiting effects of a slower-acting form of vitamin D.

Prevention and Treatment of Osteoporosis. This is described separately further in the chapter.

Dietary Supplementation. See Table 48–1.

Adverse Effects of Vitamin D Therapy

The primary toxicity associated with calcitriol reflects its potent effect to increase intestinal absorption of Ca^{2+} and phosphate, along with the potential to mobilize osseous Ca^{2+} and phosphate. Hypercalcemia, with or without hyperphosphatemia, commonly complicates calcitriol therapy and may limit its use at doses that effectively suppress PTH secretion. Non-calcemic vitamin D analogues provide alternative interventions, although they do not obviate the need to monitor serum Ca^{2+} and phosphorus

concentrations. Hypervitaminosis D is treated by immediate withdrawal of the vitamin, a low-calcium diet, administration of glucocorticoids, and vigorous fluid support; forced saline diuresis with loop diuretics is also useful. With this regimen, the plasma Ca^{2+} concentration falls to normal, and Ca^{2+} in soft tissue tends to be mobilized. Conspicuous improvement in renal function occurs unless kidney damage has been severe.

Available Vitamin D Analogues

Cholecalciferol (vitamin D_3) and *calcitriol* (1,25-dihydroxycholecalciferol) are available for oral administration or injection. Several derivatives of vitamin D are also used therapeutically.

Doxercalciferol (1 α -hydroxyvitamin D_2), a prodrug that first must be activated by hepatic 25-hydroxylation, is approved for use in treating secondary hyperparathyroidism. DHT is a reduced form of vitamin D_2 . In the liver, DHT is converted to its active form, 25-OH dihydrotachysterol. DHT is effective in mobilizing bone mineral at high doses; it therefore can be used to maintain plasma Ca^{2+} in hypoparathyroidism. DHT is well absorbed from the GI tract and maximally increases serum Ca^{2+} concentration after 2 weeks of daily administration. The hypercalcemic effects typically persist for 2 weeks but can last twice that long. DHT (not marketed in the U.S.) is available for oral administration in doses ranging from 0.2 to 1 mg/d (average 0.6 mg/d).

Ergocalciferol (*calciferol*) is vitamin D_2 . It is available for oral administration. Ergocalciferol is indicated for the prevention of vitamin D deficiency and the treatment of familial hypophosphatemia, hypoparathyroidism, and vitamin D-resistant rickets type II, typically in doses of 50,000–200,000 units/d in conjunction with calcium supplements. *1 α -Hydroxycholecalciferol* (1-OHD $_3$, alfalcidol) is a synthetic vitamin D_3 derivative that is already hydroxylated in the 1 α position and is rapidly hydroxylated by 25-hydroxylase to form 1,25-(OH) $_2\text{D}_3$. It is equivalent to calcitriol in assays for stimulation of intestinal absorption of Ca^{2+} and bone mineralization; it does not require renal activation. It is available in the U.S. for experimental purposes.

Analogues of Calcitriol. Several vitamin D analogues suppress PTH secretion by the parathyroid glands but have less or negligible hypercalcemic activity. They therefore offer a safer and more effective means of controlling secondary hyperparathyroidism.

Calcipotriene (Calcipotriol). Calcipotriol is a synthetic derivative of calcitriol with a modified side chain. Calcipotriol is less than 1% as active as calcitriol in regulating Ca^{2+} metabolism. Calcipotriol has been studied extensively as a treatment of psoriasis and is available for topical use (see Chapter 70).

Paricalcitol. Paricalcitol (1,25-dihydroxy-19-norvitamin D_2) is a synthetic calcitriol derivative that lacks the exocyclic C19 and has a vitamin D_2 rather than vitamin D_3 side chain. It reduces serum PTH levels without producing hypercalcemia or altering serum phosphorus (Mazzaferro et al., 2014). Paricalcitol administered orally or intravenously is FDA-approved for treating secondary hyperparathyroidism in patients with CKD.

Maxacalcitol. Known variously as 1,25-dihydroxy-22-oxavitamin D_3 , OCT, and 22-oxacalcitriol, maxacalcitol differs from calcitriol only in the substitution of C-22 with an O atom. Oxacalcitriol has a low affinity for vitamin D-binding protein; thus, more of the drug circulates in the free (unbound) form and is metabolized more rapidly than calcitriol, with a consequent shorter $t_{1/2}$. Oxacalcitriol is a potent suppressor of PTH gene expression and shows very limited activity on intestine and bone. It is a useful compound in patients with overproduction of PTH in CKD. Oxacalcitriol is not available in the U.S.

Calcitonin

Mechanism of Action

The CTR, a GPCR that couples to multiple G proteins, mediates calcitonin's actions. The hypocalcemic and hypophosphatemic effects of calcitonin are caused predominantly by direct inhibition of osteoclastic bone resorption (Henriksen et al., 2010). The calcitonin peptide family also includes CGRP, the closely related peptide *adrenomedullin*, *intermedin*, and *amylin*. CGRP and adrenomedullin are potent endogenous vasodilators.

Calcitonin is a sensitive and specific marker for the presence of MTC, a neuroendocrine malignancy originating in thyroid parafollicular C cells.

Therapeutic Use

Calcitonin lowers plasma Ca^{2+} and phosphate concentrations in patients with hypercalcemia. Calcitonin is administered through injection or nasal spray. Although calcitonin is effective for up to 6 h in the initial treatment of hypercalcemia, patients become refractory after a few days. This is likely due to receptor downregulation (Henriksen et al., 2010). Use of calcitonin does not substitute for aggressive fluid resuscitation, and the bisphosphonates are the preferred agents. Calcitonin is effective in disorders of increased skeletal remodeling, such as Paget disease, and in some patients with osteoporosis. For Paget disease, calcitonin generally is administered by subcutaneous injection because intranasal delivery is relatively ineffective owing to limited bioavailability. After initial therapy at 100 units/d, the dose typically is reduced to 50 units three times a week. Side effects of calcitonin include nausea, hand swelling, urticaria, and, rarely, intestinal cramping. Hypersensitivity reactions, including anaphylaxis, have also been reported.

Bisphosphonates

Chemistry

Bisphosphonates are analogues of pyrophosphate that contain two phosphonate groups attached to a geminal (central) carbon that replaces the oxygen in pyrophosphate (Figure 48–8). These agents form a three-dimensional structure capable of chelating divalent cations such as Ca^{2+} and have a strong affinity for bone, targeting especially bone surfaces undergoing remodeling. *First-generation bisphosphonates* (medronate, clodronate, and etidronate) contain minimally modified side chains or possess a chlorophenol group (tiludronate) and are the least-potent agents. *Second-generation aminobisphosphonates* (e.g., alendronate and pamidronate) contain a nitrogen group in the side chain and are 10–100 times more potent than first-generation compounds. *Third-generation bisphosphonates* (e.g., risedronate and zoledronate) contain a nitrogen atom within a heterocyclic ring and are up to 10,000 times more potent than first-generation agents (Ebetino et al., 2011).

Mechanism of Action

Bisphosphonates act by direct inhibition of bone resorption. Bisphosphonates concentrate at sites of active remodeling, remain in the matrix until the bone is remodeled, and then are released in the acid environment of the resorption lacunae and induce apoptosis in osteoclasts. Although bisphosphonates prevent hydroxyapatite dissolution, their antiresorptive action is due to direct inhibitory effects on osteoclasts rather than strictly

physiochemical effects (Cremers and Papapoulos, 2011). The antiresorptive activity apparently involves two primary mechanisms: osteoclast apoptosis and inhibition of components of the cholesterol biosynthetic pathway.

ADME

All oral bisphosphonates are poorly absorbed from the intestine. They have remarkably limited bioavailability (<1% [alendronate, risedronate] to 6% [etidronate, tiludronate]), which is further reduced by food and medications containing divalent cations such as calcium supplements, antacids, and iron. Hence, these drugs should be administered with a full glass of water following an overnight fast and at least 30 min before breakfast. Bisphosphonates distribute extensively into bone, undergo negligible hepatic clearance, and are excreted unchanged by the kidneys. Renal excretion of bisphosphonates declines proportionally with kidney function, and they are not recommended for patients with a creatinine clearance of less than 30 mL/min (Cremers and Papapoulos, 2011; Ott, 2015).

Therapeutic Uses

Bisphosphonates are used extensively in conditions characterized by osteoclast-mediated bone resorption, including Paget disease, tumor-associated osteolysis, and hypercalcemia. In particular, much interest is focused on the role of bisphosphonates in the treatment of osteoporosis, including postmenopausal osteoporosis and steroid-induced osteoporosis. Clinical trials showed that treatment is associated with increased BMD and protection against fracture. Bisphosphonates may also have direct antitumor action by inhibiting oncogene activation through their antiangiogenic effects. Randomized clinical trials of bisphosphonates in patients with breast cancer suggested that these agents delay or prevent development of metastases as a component of endocrine adjuvant therapy (Early Breast Cancer Trialists' Collaborative, 2015). Oral bisphosphonates have not been used widely in children or adolescents because of uncertainty of long-term effects of bisphosphonates on the growing skeleton.

Adverse Effects

Oral bisphosphonates can cause heartburn, esophageal irritation, or esophagitis. Other GI side effects include abdominal pain and diarrhea. Symptoms often abate when patients take the medication after an overnight fast, with tap or filtered water (not mineral water), and remain upright. Patients with active upper GI disease should not be given oral bisphosphonates. Initial parenteral infusion of pamidronate may cause skin flushing, flu-like symptoms, muscle and joint aches and pains, nausea and vomiting, abdominal discomfort, and diarrhea (or constipation) but mainly when given in higher concentrations or at faster rates than those recommended. These symptoms are short lived and generally do not recur with subsequent administration.

Zoledronate can cause severe hypocalcemia and has been associated with renal toxicity, deterioration of kidney function, and potential kidney disease. Infusion of zoledronate, 4 mg, should be performed over at least 15 min; patients should have standard laboratory and clinical parameters of kidney function assessed prior to treatment and periodically thereafter to monitor for deterioration in kidney function. Bisphosphonate use also is associated with osteonecrosis of the jaw (a rare event, with an incidence of ~ 2 in 100,000 patient-years in which the precise causal role of bisphosphonates has not been elucidated) as well as stress fractures in the lateral cortex of the femoral shaft (most commonly associated with alendronate and rarely with zoledronate; Reid, 2015).

Available Bisphosphonates

Etidronate sodium is used for treatment of Paget disease and may be used parenterally to treat hypercalcemia (although largely supplanted for this use by amidronate and zoledronate). *Pamidronate* (available in the U.S. only for parenteral administration) is approved for management of hypercalcemia associated with malignancy and Paget disease and for prevention of bone loss in breast cancer and multiple myeloma; it also is effective in other skeletal disorders. For treatment of hypercalcemia, pamidronate may be given as an intravenous infusion of 60–90 mg over 2–24 h.

Several newer bisphosphonates have been approved for treatment of Paget disease. These include *tiludronate*, *alendronate*, and *risedronate*.

Figure 48–8 Pyrophosphate and bisphosphonates. The substituents (R_1 and R_2) on the central carbon of the bisphosphonate parent structure are shown in blue. Examples of a first-generation bisphosphonate (medronate), a second-generation aminobisphosphonate (alendronate), and a third-generation bisphosphonate (zoledronate) are shown.

Tiludronate standard dosing is 400 mg/d orally for 3 months. Tiludronate in recommended doses does not interfere with bone mineralization, unlike etidronate. Zoledronate is approved for treating Paget disease; administered as a single 5-mg infusion, zoledronate decreases bone turnover markers for 6 months with no loss of therapeutic effect. Zoledronate is widely used for prevention of osteoporosis in patients with prostate and breast cancer receiving hormonal therapy. It reduces both vertebral and nonvertebral fractures. A 4-mg formulation is available for intravenous treatment of hypercalcemia of malignancy, multiple myeloma, or bone metastasis resulting from solid tumors. The potent bisphosphonate *ibandronate* is approved for the prevention and treatment of postmenopausal osteoporosis. The recommended oral dose is 2.5 mg daily or 150 mg once monthly.

For patients in whom oral bisphosphonates cause severe esophageal distress, *intravenous* zoledronate and ibandronate offer skeletal protection without causing adverse GI effects. For treatment of osteoporosis, ibandronate (3 mg) is given intravenously every 3 months. Zoledronate is the first bisphosphonate to be approved for once-yearly intravenous treatment of osteoporosis (5 mg annually).

Parathyroid Hormone

Continuous administration of PTH or high-circulating PTH levels achieved in primary hyperparathyroidism causes bone demineralization and osteopenia. However, *intermittent* PTH administration promotes bone growth. Although hypoparathyroidism was the last classic endocrine-deficiency disease to have the missing hormone as an available treatment option, PTH analogues are now available to these patients.

Chemistry

As described previously, PTH is a single-polypeptide chain of 84 amino acids with a molecular mass of about 9500 Da. The classic biological activity of PTH is associated with the N-terminal portion of the peptide; residues 1–27 are required for optimal binding to the PTHR and hormone activity. Currently available PTH analogues include teriparatide, a synthetic human 34-amino acid amino-terminal PTH fragment [hPTH(1–34)]; a full-length replica of endogenous PTH, recombinant human PTH consisting of 84 amino acids [rhPTH(1–84)] (Kim and Keating, 2015); and abaloparatide, a recently approved synthetic 34-amino acid analogue of human PTHrP, hPTHrP(1–34).

Mechanism of Action

The physiological functions and mechanism of action of PTH were described previously in the chapter.

ADME

These agents are peptides and are administered by subcutaneous injection (see *Drugs Available*). Pharmacokinetics and systemic actions of *teriparatide* on mineral metabolism are the same as for PTH. Serum PTH concentrations peak at 30 min after the injection and are undetectable within 3 h, whereas the serum Ca^{2+} concentration peaks at 4–6 h after administration. Teriparatide bioavailability averages 95%. The drug's volume of distribution is approximately 0.1 L/kg. The elimination of teriparatide proceeds by nonspecific enzymatic mechanisms in the liver, followed by renal excretion. Teriparatide systemic clearance averages 62 L/h in women and 94 L/h in men. The elimination $t_{1/2}$ of serum teriparatide is about 1 h when administered subcutaneously versus 5 min when administered intravenously.

Abaloparatide is supplied in an injector pen with 30 daily doses. The peptide is rapidly absorbed (bioavailability = 36%), achieving peak concentrations ~30 min following subcutaneous injection. Elimination half-life is ~1.7 h; clearance is presumed to be by proteolytic hydrolysis, with renal elimination of peptide fragments.

For *rhPTH(1–84)*, dose-proportional increases in serum Ca^{2+} concentration, which peaks at 10–12 h after subcutaneous administration, are exhibited. Bioavailability of rhPTH(1–84) is 53%, and its volume of distribution is 5.3 L. The liver and the kidneys are the major route of rhPTH(1–84) elimination, as for teriparatide. The elimination $t_{1/2}$ of rhPTH(1–84) is ~3 h (Clarke et al., 2014; Kim and Keating, 2015). Overall, the prolonged peak

effects and slower elimination of rhPTH(1–84) compared to teriparatide may explain why teriparatide typically requires multiple injections per day while rhPTH(1–84) requires only single-daily or alternate-day dosing.

Therapeutic Uses

Teriparatide (PTH1-34) and *abaloparatide* (PTHrP(1-34)) are the only anabolic agents currently available that increase new bone formation. They are approved for use in treating severe osteoporosis in patients at a high risk for fracture. In postmenopausal women with osteoporosis, teriparatide increases BMD and reduces the risk of vertebral and nonvertebral fractures. Candidates for treatment with teriparatide and abaloparatide include women who have a history of osteoporotic fracture, who have multiple risk factors for fracture, or who failed or are intolerant of previous osteoporosis therapy. Men with primary or hypogonadal osteoporosis are also candidates for treatment with these agents.

The *rhPTH(1–84)* is approved for treating hypocalcemia in patients with hypoparathyroidism whose serum Ca^{2+} concentrations cannot be controlled solely by calcium supplementation and active vitamin D treatment. Intermittent rhPTH(1–84) may soon be approved for use in osteoporosis, but its benefits over teriparatide remain to be established.

Adverse Effects

Adverse effects include hypercalcemia; the incidence with abaloparatide is lower than observed with teriparatide (Miller et al., 2016). exacerbation of nephrolithiasis and elevation of serum uric acid levels. Development of osteosarcoma has been a serious concern in patients treated with teriparatide; however, postmarketing surveillance data suggest there is no causal association between teriparatide use and osteosarcoma (Andrews et al., 2012). Nevertheless, teriparatide and abaloparatide carry black box warnings and use should be limited to no more than 2 years and avoided in patients who are at increased baseline risk for osteosarcoma (including those with Paget disease of bone, unexplained elevations of alkaline phosphatase, open epiphyses, or prior radiation therapy involving the skeleton). Orthostatic hypotension may occur shortly after injection of abaloparatide.

Although clinical experience with rhPTH(1–84) is relatively limited to date, the most commonly reported adverse effects in clinical trials included paresthesia, hypo- and hypercalcemia, headache, and nausea. A potential risk of osteosarcoma is based on preclinical data, and the drug should not be used in patients who are at increased baseline risk for osteosarcoma (Kim and Keating, 2015).

Drugs Available

Teriparatide is administered by once-daily subcutaneous injection of 20 mcg into the thigh or abdomen. Abaloparatide is administered at a starting dose of 80 mcg by subcutaneous injection into the periumbilical region of the abdomen. The site of administration should be rotated, but the time at which the injection is made should be the same each day. The starting dose of rhPTH(1–84) is 50 mcg once daily, also administered subcutaneously into the thigh. Serum Ca^{2+} concentrations should be monitored every 3–7 days after initiating treatment or adjusting the dose. Subcutaneous administration of abaloparatide reduced the risk of new vertebral and nonvertebral fractures over a period of 18 months (Miller et al., 2016). Shorter studies demonstrated increased lumbar spine and hip density that were greater than those achieved with teriparatide (Leder et al., 2015). The dose of rhPTH(1–84) may be adjusted to maintain normal serum Ca^{2+} concentrations. The minimum recommended dose of rhPTH(1–84) is 25 µg daily; the dose should not exceed 100 µg daily.

Long-acting formulations of PTH (LA-PTH) currently are in development (Maeda et al., 2013). Such formulations may offer an advantage over teriparatide, which is limited by its short (4- to 6-h) duration of effect on serum Ca^{2+} concentrations. Another agent that consists of the N-terminal biologically active region of PTH linked to a collagen-binding domain exhibits sustained increases in BMD by more than 10% for 1 year in rodents after single-dose administration (Ponnappakkam et al., 2012). The advantages of these LA-PTH formulations over rhPTH(1–84) are not clear at this time.

A novel class of drugs that inhibit the CaSR (*calcilytics*) stimulate the secretion of PTH and decrease renal excretion of Ca^{2+} . The calcilytic *ronacaleret*, investigated for potential treatment of postmenopausal osteoporosis, was less effective than teriparatide, and its development was subsequently halted (Fitzpatrick et al., 2012). The role of calcilytics in the treatment of diseases involving hypocalcemia or hypercalciuria continues to be explored (Nemeth and Shoback, 2013).

Calcium-Sensing Receptor Mimetics

Calcimimetics are drugs that mimic the stimulatory effect of Ca^{2+} on the CaSR to inhibit PTH secretion by the parathyroid glands. *Cinacalcet*, the first and only approved drug in the class currently, offers a pharmacotherapeutic alternative to surgery for the treatment of PTH hypersecretion diseases.

Chemistry

Cinacalcet is available as a hydrochloride (Figure 48–9) and is formulated with one chiral center having an R-absolute configuration; the R-enantiomer is the more potent enantiomer and is primarily responsible for cinacalcet's pharmacodynamic activity.

Mechanism of Action

By enhancing the sensitivity of the CaSR to extracellular Ca^{2+} , calcimimetics lower the concentration of Ca^{2+} at which PTH secretion is suppressed. Inorganic di- and trivalent cations, along with polycations such as aminoglycosides (e.g., streptomycin, gentamicin, and neomycin) and polybasic amino acids (e.g., polylysine) are full agonists and are referred to as *type I calcimimetics*. They are able to activate the CaSR directly with no other cofactors. On the other hand, phenylalkylamine derivatives, including cinacalcet, that are allosteric CaSR modulators require the presence of Ca^{2+} or other full agonists to enhance the sensitivity of activation without altering the maximal response and are designated *type II calcimimetics* (Cianferotti et al., 2015; Filopanti et al., 2013).

ADME

Cinacalcet exhibits first-order absorption, with peak serum concentrations achieved 2–6 h after oral administration. Maximal effects on serum PTH occur 2–4 h after administration. It has an extraordinarily large volume of distribution of 1000 L and is metabolized by multiple hepatic CYPs, including CYPs 3A4, 2D6, and 1A2. Metabolites are eliminated by biliary (15%) and renal excretion (85%). Cinacalcet has an elimination $t_{1/2}$ of 30–40 h.

Therapeutic Uses

Cinacalcet is approved for the treatment of (1) secondary hyperparathyroidism in adults with CKD on dialysis; (2) hypercalcemia in adults with parathyroid carcinoma; and (3) hypercalcemia in adult patients with primary hyperparathyroidism who are not candidates for surgical parathyroidectomy. Treatment with cinacalcet lowers serum PTH levels in patients with normal or reduced kidney function (Nemeth and Shoback, 2013). In patients with secondary hyperparathyroidism on dialysis, treatment with cinacalcet significantly decreases bone turnover and improves bone histology (Behets et al., 2015). Moreover, by lowering serum FGF23 concentrations, cinacalcet treatment decreases the rate of cardiovascular death and major cardiovascular events (Moe et al., 2015).

Adverse Effects

The principal adverse event with cinacalcet is hypocalcemia. Thus, the drug should not be used if the initial serum $[\text{Ca}^{2+}]$ is less than 8.4 mg/dL;

Figure 48–9 Structure of *cinacalcet* (depicted as free base). The compound is a phenyl-propylamine derivative with a 3-trifluoromethyl group (red) and naphthalene moiety (blue).

serum Ca^{2+} and phosphorus concentrations should be measured within 1 week, and PTH should be measured within 4 weeks after initiating therapy and after changing dosage. Seizure threshold is lowered by significant reductions in serum Ca^{2+} , so patients with a history of seizure disorders should be monitored especially closely. Finally, adynamic bone disease may develop if the PTH level is less than 100 pg/mL, and the drug should be discontinued or the dose decreased if the PTH level falls below 150 pg/mL.

Drug Interactions

Drug interactions can be anticipated with drugs that interfere with Ca^{2+} homeostasis or that hinder cinacalcet absorption. Potentially interfering drugs include vitamin D analogues, phosphate binders, bisphosphonates, calcitonin, glucocorticoids, gallium, and cisplatin. Caution is recommended when cinacalcet is coadministered with strong inhibitors of CYP3A4 (e.g., ketoconazole, erythromycin, or itraconazole). Because cinacalcet is a strong inhibitor of CYP2D6, dose adjustment may be required for concomitant medications that are CYP2D6 substrates (e.g., many β adrenergic receptor blockers, flecainide, vinblastine, and most tricyclic antidepressants).

Drugs Available

Cinacalcet is available in 30-, 60-, and 90-mg tablets. The recommended starting dose for treatment of secondary hyperparathyroidism in patients with CKD on dialysis is 30 mg once daily, with a maximum of 180 mg/d. For treatment of parathyroid carcinoma, a starting dose of 30 mg twice daily is recommended, with a maximum of 90 mg four times daily. The starting dose is titrated upward every 2–4 weeks to maintain the PTH level between 150 and 300 pg/mL (secondary hyperparathyroidism) or to normalize serum calcium (parathyroid carcinoma).

Fluoride

Fluoride is discussed because of its effects on dentition and bone and its toxic properties.

Mechanism of Action

Sodium fluoride enhances osteoblast activity and increases bone volume. These effects may be bimodal, with low doses stimulating and higher doses suppressing osteoblasts. However, the apparent effects of fluoride in osteoporosis are slight compared with those achieved with PTH or others. Fluoride can inhibit several enzyme systems and diminish tissue respiration and anaerobic glycolysis.

ADME

Fluoride is obtained from the ingestion of plants and water, with absorption taking place largely in the intestine. A second route of absorption is through the lungs, and inhalation of fluoride present in dusts and gases constitutes the major route of industrial exposure. Fluoride is distributed widely in organs and tissues but is concentrated in bone and teeth, and the skeletal burden is related to intake and age. Bone deposition reflects skeletal turnover; growing bone shows greater deposition than mature bone. The kidneys are the major sites of fluoride excretion. Small amounts of fluoride also appear in sweat, milk, and intestinal secretions.

Therapeutic Use

Because it is concentrated in the bone, the radionuclide ^{18}F has been used in skeletal imaging. Sodium fluoride is a mainstay of therapy for the prevention of dental caries.

Fluoride and Dental Caries. Supplementation of water fluoride content to 1.0 ppm is a safe and practical intervention that substantially reduces the incidence of caries in permanent teeth. There are partial benefits for children who begin drinking fluoridated water at any age; however, optimal benefits are obtained at ages before permanent teeth erupt. Topical application of fluoride solutions by dental personnel appears to be effective on newly erupted teeth and can reduce the incidence of caries by 30%–40%. Dietary fluoride supplements should be considered for children less than 12 years of age whose drinking water contains less than 0.7 ppm fluoride. Adequate incorporation of fluoride into teeth hardens the outer layers of enamel and increases resistance to demineralization. The fluoride salts usually employed in dentifrices are sodium fluoride and

stannous fluoride. Sodium fluoride also is available in a variety of preparations for oral and topical use.

Regulation of the fluoride concentration of community water supplies periodically encounters vocal opposition, including allegations of putative adverse health consequences of fluoridated water. Careful examination of these issues indicates that cancer and all-cause mortalities do not differ significantly between communities with fluoridated and nonfluoridated water.

Acute Poisoning

Acute fluoride poisoning usually results from accidental ingestion of fluoride-containing insecticides or rodenticides. Initial symptoms (salivation, nausea, abdominal pain, vomiting, and diarrhea) are secondary to the local action of fluoride on the intestinal mucosa. Systemic symptoms are varied and severe: increased irritability of the CNS consistent with the Ca^{2+} -binding effect of fluoride and the resulting hypocalcemia; hypotension, presumably owing to central vasomotor depression as well as direct cardiotoxicity; and stimulation and then depression of respiration. Death can result from respiratory paralysis or cardiac failure. The lethal dose of sodium fluoride for humans is about 5 g, although there is considerable variation. Treatment includes the intravenous administration of glucose in saline and gastric lavage with limewater (0.15% calcium hydroxide solution) or other Ca^{2+} salts to precipitate the fluoride. Calcium gluconate is given intravenously for tetany; urine volume is kept high with vigorous fluid resuscitation.

Chronic Poisoning

In humans, the major manifestations of chronic ingestion of excessive fluoride are osteosclerosis and mottled enamel. Osteosclerosis is characterized by increased bone density secondary both to elevated osteoblastic activity and to the replacement of hydroxyapatite by the denser fluoroapatite. The degree of skeletal involvement varies from changes that are barely detectable radiologically to marked cortical thickening of long bones, numerous exostoses scattered throughout the skeleton, and calcification of ligaments, tendons, and muscle attachments. In its severest form, it is a disabling and crippling disease.

Mottled enamel, or dental fluorosis, was first described more than 60 years ago. In very mild mottling, small, opaque, paper-white areas are scattered irregularly over the tooth surface. In severe cases, discrete or confluent, deep brown- to black-stained pits give the tooth a corroded appearance. Mottled enamel results from a partial failure of the enamel-forming ameloblasts to elaborate and lay down enamel. Mottling is one of the first visible signs of excess fluoride intake during childhood. Continuous use of water containing about 1 ppm of fluoride may result in very mild mottling in 10% of children; at 4–6 ppm, the incidence approaches 100%, with a marked increase in severity. Severe dental fluorosis formerly occurred in regions where local water supplies had a very high fluoride content (e.g., Pompeii, Italy, and Pike's Peak, CO). Current regulations in the U.S. require lowering the fluoride content of the water supply or providing an alternative source of acceptable drinking water for affected communities. Sustained consumption of water with a fluoride content of 4 mg/L (4 ppm) is associated with deficits in cortical bone mass and increased rates of bone loss over time.

Integrated Approach to Prevention and Treatment of Osteoporosis

Osteoporosis is a major and growing public health problem in developed nations. Approximately 50% of women and 25% of men more than 50 years of age will experience an osteoporosis-related fracture. Important reductions in fracture risk can be achieved with attention to health (muscle-strengthening exercise; avoiding smoking and excessive alcohol use) and nutrition (i.e., increased dietary calcium or calcium or vitamin D supplements). Pharmacological agents used to manage osteoporosis act by decreasing the rate of bone resorption and thereby slowing the rate of bone loss (antiresorptive therapy) or by promoting bone formation (anabolic therapy). Because bone remodeling is a coupled process, antiresorptive

Figure 48-10 Relative efficacy of different therapeutic interventions on BMD of the lumbar spine. Teriparatide (40 μg) (Neer et al., 2001), PTH (25 μg) + estradiol, alendronate (10 mg), estradiol (0.625 mg/d), raloxifene (120 mg), calcitonin (200 IU). Typical results with placebo treatment underscore the inexorable bone loss without intervention. Some of the indicated treatment interventions involved combination therapy, and absolute comparisons should not be made.

drugs ultimately decrease the rate of bone formation and therefore do not promote substantial gains in BMD. Increases in BMD during the first years of antiresorptive therapy represent a constriction of the remodeling space to a steady-state level, after which BMD reaches a new plateau (Figure 48-10).

Pharmacological treatment of osteoporosis is aimed at restoring bone strength and preventing fractures. Antiresorptive drugs (such as the bisphosphonates, estrogen, the SERM raloxifene, and, to some extent, calcitonin) inhibit osteoclast-mediated bone loss, thereby reducing bone turnover. Although the administration of estrogen to women at menopause is a powerful intervention to preserve bone and protect against fracture, the detrimental effects of HRT have mandated a major reexamination of treatment options (see further and Chapter 44). In addition to antiresorptive agents, the FDA has approved the hPTH(1-34) fragment (teriparatide) and the hPTHrP(1-34) fragment (abaloparatide) for use in treating postmenopausal women with osteoporosis. Teriparatide is also approved for use in increasing bone mass in men with primary or hypogonadal osteoporosis.

Antiresorptive Agents

Bisphosphonates

Bisphosphonates are the most frequently used drugs for the prevention and treatment of osteoporosis. Second- and third-generation oral bisphosphonates, alendronate and risedronate, have sufficient potency to suppress bone resorption at doses that do not inhibit mineralization. Alendronate, risedronate, and ibandronate are used for prevention and treatment of osteoporosis and for the treatment of glucocorticoid-associated osteoporosis.

Denosumab

The ligand of RANK binds to its cognate receptor RANK on the surface of precursor and mature osteoclasts and stimulates these cells to mature and resorb bone. OPG, which competes with RANK for binding to RANKL, is the physiological inhibitor of RANKL. Denosumab is a human monoclonal antibody that binds with high affinity to RANKL, mimicking the effect of OPG and thereby reducing the binding of RANKL to RANK. Denosumab blocks osteoclast formation and activation. It increases BMD and decreases bone turnover markers when given subcutaneously, 60 mg once every 6 months. Osteonecrosis of the jaw and fractures of the femoral shaft have been reported with denosumab use. It is contraindicated in the setting of preexisting hypocalcemia.

Selective Estradiol Receptor Modulators

Considerable work has been undertaken to develop estrogenic compounds with tissue-selective activities. Raloxifene acts as an estrogen agonist on bone and liver, is inactive on the uterus, and acts as an antiestrogen on the breast (see Chapter 44). In postmenopausal women, raloxifene stabilizes and modestly increases BMD and reduces the risk of vertebral compression fracture (Komm and Mirkin, 2014). Raloxifene is approved for both the prevention and the treatment of osteoporosis. Adverse effects of raloxifene include worsening of vasomotor symptoms. The drug is also associated with an increased risk of deep vein thrombosis and pulmonary embolism, so it is contraindicated in adults with a history of venous thromboembolism.

Estrogen

Postmenopausal status or estrogen deficiency at any age significantly increases a patient's risk for osteoporosis and fractures. Likewise, overwhelming evidence supports the positive impact of estrogen replacement on the conservation of bone and protection against osteoporotic fracture after menopause (see Chapter 44). However, the Women's Health Initiative studies indicated that HRT significantly increases risks of heart disease and breast cancer; consequently, HRT is now reserved only for the short-term relief of vasomotor symptoms associated with menopause.

Calcium

The rationale for using supplemental calcium to protect bone varies with time of life. For preteens and adolescents, adequate substrate calcium is required for bone accretion. Higher Ca^{2+} intake during the third decade of life is positively related to the final phase of bone acquisition. There is controversy about the role of calcium during the early years after menopause, when the primary basis for bone loss is estrogen withdrawal. In elderly subjects, supplemental calcium suppresses bone turnover and improves BMD. Patients may increase calcium by dietary means and may choose from many palatable, low-cost calcium preparations. The most frequently prescribed is carbonate, which should be taken with meals to facilitate dissolution and absorption. Traditional dosing of calcium is about 1000 mg/d, nearly the amount present in a quart of milk. Adults more than 50 years of age need 1200 mg of calcium daily. More may be necessary to overcome endogenous intestinal calcium losses, but daily intakes of 2000 mg or more frequently are reported to be constipating.

Vitamin D and Its Analogues

Modest supplementation with vitamin D (400–800 IU/d) may improve intestinal Ca^{2+} absorption, suppress bone remodeling, and improve BMD in individuals with marginal or deficient vitamin D status. Supplemental vitamin D in combination with calcium reduces fracture incidence.

The use of calcitriol to treat osteoporosis is distinct from ensuring vitamin D nutritional adequacy. Here, the rationale is to suppress parathyroid function directly and reduce bone turnover. Higher doses of calcitriol appear to be more likely to improve BMD, but at the risk of developing hypercalciuria and hypercalcemia; therefore, close scrutiny of patients and dose are required. Restriction of dietary calcium may reduce toxicity during calcitriol therapy.

Calcitonin

Calcitonin inhibits osteoclastic bone resorption and modestly increases bone mass in patients with osteoporosis, most prominently in patients

with high intrinsic rates of bone turnover. Calcitonin nasal spray (200 units/d) reduces the incidence of vertebral compression fractures by about 40% in osteoporotic women (Chesnut et al., 2000).

Thiazide Diuretics

Although not strictly antiresorptive, thiazides reduce urinary Ca^{2+} excretion and constrain bone loss in patients with hypercalciuria. Hydrochlorothiazide, 25 mg once or twice daily, may reduce urinary Ca^{2+} excretion substantially. Effective doses of thiazides for reducing urinary Ca^{2+} excretion generally are lower than those necessary for blood pressure control (see Chapters 25 and 28).

Anabolic Agents

Teriparatide

Teriparatide is the only anabolic agent currently available that increases new bone formation. It is FDA-approved for treatment of osteoporosis for up to 2 years in both men and postmenopausal women at high risk for fractures. Teriparatide increases predominantly trabecular bone at the lumbar spine and femoral neck; it has less-significant effects at cortical sites. Teriparatide is approved at the 20-mcg dose, administered once daily by subcutaneous injection in the thigh or abdominal wall. The most common adverse effects associated with teriparatide include injection-site pain, nausea, headaches, leg cramps, and dizziness.

Combination Therapies

Osteoporosis

Because teriparatide stimulates bone formation, whereas bisphosphonates reduce bone resorption, it was predicted that therapy combining the two would enhance the effect on BMD more than treatment with either one alone. However, addition of alendronate to PTH treatment provided no additional benefit for BMD and reduced the anabolic effect of PTH in both women and men. Sequential treatment with PTH(1–84) followed by alendronate increases vertebral BMD to a greater degree than alendronate or estrogen alone.

Paget Disease

Although most patients with Paget disease require no treatment, factors such as severe pain, neural compression, progressive deformity, hypercalcemia, high-output congestive heart failure, and repeated fracture risk are considered indications for treatment. Bisphosphonates and calcitonin decrease the elevated biochemical markers of bone turnover, such as plasma alkaline phosphatase activity and urinary excretion of hydroxyproline. An initial course of bisphosphonate typically is given once daily or once weekly for 6 months. With treatment, most patients experience a decrease in bone pain over several weeks. Such treatment may induce long-lasting remission. If symptoms recur, additional courses of therapy can be effective.

Optimal therapy for Paget disease varies among patients. Bisphosphonates are the standard therapy. Intravenous pamidronate induces long-term remission following a single infusion. Zoledronate exhibits greater response rates and a longer median duration of complete response. Compared with calcitonin, bisphosphonates have the advantage of oral administration, lower cost, lack of antigenicity, and generally fewer side effects.

- Stress-Related Ulcers
- Zollinger-Ellison Syndrome
- Functional Dyspepsia
- Functional Esophageal Disorders

Gastric acid and pepsin in the stomach normally do not produce damage or symptoms of acid-peptic diseases because of intrinsic defense mechanisms. The stomach is protected by a number of factors, collectively referred to as “mucosal defense,” many of which are stimulated by the local generation of PGs and NO. If these defenses are disrupted, a gastric or duodenal ulcer may form. The treatment and prevention of acid-related disorders are accomplished by decreasing gastric acidity and enhancing mucosal defense. The appreciation that an infectious agent, *Helicobacter pylori*, plays a key role in the pathogenesis of acid-peptic diseases revolutionized approaches to prevention and therapy of these common disorders.

Barriers to the reflux of gastric contents into the esophagus comprise the primary esophageal defense. If these protective barriers fail and reflux occurs, dyspepsia or erosive esophagitis may result. Therapies are directed at decreasing gastric acidity, enhancing the tone of the lower esophageal sphincter, and stimulating esophageal motility (see Chapter 50).

Physiology of Gastric Secretion

Gastric acid secretion is a complex and continuous process: Neuronal (ACh, GRP); paracrine (histamine); and endocrine (gastrin) factors regulate the secretion of H^+ by parietal cells (acid-secreting cells) (Figure 49–1). Their specific receptors (M_3 , BB_2 , H_2 , and CCK_2 , respectively) are on the basolateral membrane of parietal cells in the body and fundus of the stomach. Some of these receptors are also present on ECL cells, where they regulate the release of histamine. The H_2 receptor is a GPCR that activates the G_s -adenylyl cyclase-cyclic AMP-PKA pathway (see Chapters 3 and 39). ACh and gastrin signal through GPCRs that couple to the G_q -PLC-IP₃-Ca²⁺ pathway in parietal cells; GRP uses the same signaling pathway to activate gastrin secretion from G cells. In parietal cells, the cyclic AMP and the Ca²⁺-dependent pathways activate H^+ , K^+ -ATPase (the proton pump), which exchanges H^+ and K^+ across the parietal cell membrane. This pump generates the largest ion gradient

known in vertebrates, with an intracellular pH of about 7.3 and an intracanalicular pH of about 0.8.

The important structures for CNS stimulation of gastric acid secretion are the dorsal motor nucleus of the vagal nerve, the hypothalamus, and the solitary tract nucleus. Efferent fibers originating in the dorsal motor nuclei descend to the stomach via the vagus nerve and synapse with ganglion cells of the enteric nervous system. ACh release from postganglionic vagal fibers directly stimulates gastric acid secretion through muscarinic M_3 receptors on the basolateral membrane of parietal cells. The CNS predominantly modulates the activity of the enteric nervous system via ACh, stimulating gastric acid secretion in response to the sight, smell, taste, or anticipation of food (the “cephalic” phase of acid secretion). ACh also indirectly affects parietal cells by increasing the release of histamine from the ECL cells in the fundus of the stomach and of gastrin from G cells in the gastric antrum.

The ECL cells, the source of gastric histamine, are usually in close proximity to parietal cells. Histamine acts as a paracrine mediator, diffusing from its site of release to nearby parietal cells, where it activates H_2 receptors to stimulate gastric acid secretion.

Gastrin, produced by antral G cells, is the most potent inducer of acid secretion. Multiple pathways stimulate gastrin release, including CNS activation, local distention, and chemical components of the gastric contents. In addition to releasing ACh, some vagal fibers to the stomach also release GRP (a peptide of 27 amino acids); GRP activates the BB_2 bombesin receptor on G cells, activating the G_q -PLC-IP₃-Ca²⁺ pathway and causing secretion of gastrin. Gastrin stimulates acid secretion indirectly by inducing the release of histamine by ECL cells; a direct effect on parietal cells also plays a lesser role.

Somatostatin, produced by antral D cells, inhibits gastric acid secretion. Acidification of the gastric luminal pH to less than 3 stimulates somatostatin release, which in turn suppresses gastrin release in a negative-feedback loop. Somatostatin-producing cells are decreased in patients with *H. pylori* infection, and the consequent reduction of somatostatin's inhibitory effect may contribute to excess gastrin production.

Abbreviations

ACh: acetylcholine
cAMP: cyclic adenosine monophosphate
CCK: cholecystokinin
CNS: central nervous system
CYP: cytochrome P450
DU: duodenal ulcer
ECG: electrocardiogram
ECL: enterochromaffin-like cell
ENS: enteric nervous system
GERD: gastroesophageal reflux disease
GI: gastrointestinal
GPCR: G protein–coupled receptor
GRP: gastrin-releasing peptide
GU: gastric ulcer
HIST: histamine
IP₃: inositol 1,4,5-trisphosphate
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
OTC: over the counter
PG: prostaglandin
PK: protein kinase
PLC: phospholipase C
PPI: proton pump inhibitor
SST: somatostatin

Parietal Cell H⁺,K⁺-ATPase

H⁺,K⁺-ATPase is the enzyme responsible for secreting protons into the lumen of the gastric gland (Shin et al., 2009). It is a heterodimeric protein composed of two subunits that are the products of two genes. The *ATP4A* gene encodes the α subunit that contains the catalytic sites of the enzyme and forms the membrane pore, and the *ATP4B* encodes the β subunit of the H⁺,K⁺-ATPase, which contains an N-terminal cytoplasmic domain, a transmembrane domain, and a highly glycosylated extracellular domain. Hydronium ions bind to three active sites present in the α subunit, and secretion involves conformational change that allows the movement of protons. This movement is balanced by the transport of K⁺. The stoichiometry of transport is pH dependent, varying between two H⁺ and two K⁺ per molecule of ATP to one of each under more acidic conditions. Inhibiting the H⁺,K⁺-ATPase (or proton pump) is the mainstay of modern pharmacotherapy for acid-related disorders.

Gastric Defenses Against Acid

The extremely high concentration of H⁺ in the gastric lumen requires robust defense mechanisms to protect the esophagus, stomach, and proximal small intestine (Wallace, 2008). The primary esophageal defense is the gastroesophageal junction—the lower esophageal sphincter in association with the diaphragm and angle of His—which prevents reflux of acidic gastric contents into the esophagus. The stomach protects itself from acid damage by a number of mechanisms that require adequate mucosal blood flow. One key defense is the secretion of a mucous layer that helps to protect gastric epithelial cells by trapping secreted bicarbonate at the cell surface. Gastric mucus is soluble when secreted but quickly forms an insoluble gel that coats the mucosal surface of the stomach, slows ion diffusion, and prevents mucosal damage by macromolecules such as pepsin. Mucus production is stimulated by PGs E₂ and I₂, which also directly inhibit gastric acid secretion by parietal cells. Thus, drugs that inhibit PG formation (e.g., NSAIDs, ethanol) decrease mucus secretion and predispose to the development of acid-peptic disease. The proximal part of the duodenum is protected from gastric acid through the production of bicarbonate, primarily from mucosal Brunner glands.

Figure 49–1 outlines the rationale and pharmacological basis for the therapy of acid-peptic disease. The PPIs are used most commonly, followed by the histamine H₂ receptor antagonists.

Proton Pump Inhibitors

The most potent suppressors of gastric acid secretion are inhibitors of the gastric H⁺,K⁺-ATPase or proton pump (Figure 49–2). These drugs diminish the daily production of acid (basal and stimulated) by 80%–95% (Shin and Sachs, 2008).

Mechanism of Action and Pharmacology

Six PPIs are available for clinical use: *omeprazole* and its S-isomer, *esomeprazole*, *lansoprazole* and its R-enantiomer, *dexlansoprazole*, *rabeprazole*, and *pantoprazole*. All PPIs have equivalent efficacy at comparable doses.

Proton pump inhibitors are prodrugs that require activation in an acid environment. After absorption into the systemic circulation, the prodrug diffuses into the parietal cells of the stomach and accumulates in the acidic secretory canaliculi. Here, it is activated by proton-catalyzed formation of a tetracyclic sulfenamide (see Figure 49–2), trapping the drug so that it cannot diffuse back across the canalicular membrane. The activated form then binds covalently with sulfhydryl groups of cysteines in the H⁺,K⁺-ATPase, irreversibly inactivating the pump molecule. Acid secretion resumes only after new pump molecules are synthesized and inserted into the luminal membrane, providing a prolonged (up to 24- to 48-h) suppression of acid secretion, despite the much shorter plasma *t*_{1/2} of about 0.5–3 h of the parent compounds. Because they block the final step in acid production, the PPIs effectively suppress stimulated acid production, regardless of the physiological stimulus, as well as basal acid production.

The amount of H⁺,K⁺-ATPase increases after fasting; therefore, PPIs should be given before the first meal of the day. In most individuals, once-daily dosing is sufficient to achieve an effective level of acid inhibition, and a second dose, which is occasionally necessary, can be administered before an evening meal. Rebound acid hypersecretion occurs following prolonged treatment with PPIs, and clinical studies suggest that rebound after ceasing treatment can provoke symptoms such as dyspepsia.

To prevent degradation of PPIs by acid in the gastric lumen and improve oral bioavailability, oral dosage forms are supplied in different formulations:

- Enteric-coated pellets within gelatin capsules (*omeprazole*, *dexlansoprazole*, *esomeprazole*, *lansoprazole*, *rabeprazole*)
- Delayed-release tablets (*omeprazole* formulations)
- Delayed-release capsules (*dexlansoprazole*, *esomeprazole* formulations)
- Delayed-release oral suspension packets (*esomeprazole*, *omeprazole*, *pantoprazole*)
- Enteric-coated microgranules in orally disintegrating tablets (*lansoprazole*)
- Enteric-coated tablets (*pantoprazole*, *rabeprazole*, and *omeprazole*)
- Powdered *omeprazole* combined with sodium bicarbonate (capsules and oral suspension)

The delayed-release and enteric-coated tablets dissolve only at alkaline pH, whereas admixture of *omeprazole* with sodium bicarbonate simply neutralizes stomach acid; both strategies substantially improve the oral bioavailability of these acid-labile drugs. Patients for whom the oral route of administration is not available can be treated parenterally with *esomeprazole sodium* or *pantoprazole*.

ADME

Because an acidic pH in the parietal cell acid canaliculi is required for drug activation and food stimulates acid production, these drugs ideally should be given about 30 min before meals. Concurrent administration of food may reduce somewhat the rate of absorption of PPIs, but this effect is not thought to be clinically significant. Once in the small bowel, PPIs are rapidly absorbed, highly protein bound, and extensively metabolized by hepatic CYPs, particularly CYP2C19 and CYP3A4. Asians are more likely

Figure 49-1 Pharmacologist's view of gastric secretion and its regulation: the basis for therapy of acid-peptic disorders. Shown are the interactions among neural input and a variety of enteroendocrine cells: an ECL cell that secretes histamine, a ganglion cell of the ENS, a G cell that secretes gastrin, a parietal cell that secretes acid, and a superficial epithelial cell that secretes mucus and bicarbonate. Physiological pathways, shown in solid black, may be stimulatory (+) or inhibitory (–). 1 and 3 indicate possible inputs from postganglionic cholinergic fibers; 2 shows neural input from the vagus nerve. Physiological agonists and their respective membrane receptors include ACh and its muscarinic (M) and nicotinic (N) receptors; GRP and its receptor, the BB₂ bombesin receptor; gastrin and its receptor, the CCK₂; HIST and the H₂ receptor; and PGE₂ and the EP₃ receptor. A red line with a T bar indicates sites of pharmacological antagonism. A light blue dashed arrow indicates a drug action that mimics or enhances a physiological pathway. Shown in red are drugs used to treat acid-peptic disorders. NSAIDs can induce ulcers via inhibition of cyclooxygenase. Not shown is a physiological pathway that reduces acid secretion: a D cell that secretes SST, which inhibits G-cell release of gastrin.

Figure 49-2 Activation of a PPI from its prodrug form. Omeprazole is converted to a sulfenamide in the acidic secretory canaliculi of the parietal cell. The sulfenamide interacts covalently with sulfhydryl groups in the proton pump, thereby irreversibly inhibiting its activity. Lansoprazole, rabeprazole, and pantoprazole undergo analogous conversions.

912 than Caucasians or African Americans to have the CYP2C19 genotype that correlates with slow metabolism of PPIs (23% vs. 3%, respectively), which may contribute to heightened efficacy or toxicity in this ethnic group (Camilleri, 2012).

Because not all pumps and all parietal cells are active simultaneously, maximal suppression of acid secretion requires several doses of the PPIs. For example, it may take 2–5 days of therapy with once-daily dosing to achieve the about 70% inhibition of proton pumps that is seen at steady state. More frequent initial dosing (e.g., twice daily) will reduce the time to achieve full inhibition but has not been shown to improve patient outcome. The resulting proton pump inhibition is irreversible; thus, acid secretion is suppressed for 24–48 h, or more, until new proton pumps are synthesized and incorporated into the luminal membrane of parietal cells. Chronic renal failure does not lead to drug accumulation with once-a-day dosing of the PPIs. Hepatic disease substantially reduces the clearance of esomeprazole and lansoprazole. Thus, in patients with severe hepatic disease, dose reduction is recommended for esomeprazole and lansoprazole.

Therapeutic Uses and Adverse Effects

Prescription PPIs are primarily used to promote healing of gastric and duodenal ulcers and to treat GERD, including erosive esophagitis, which is either complicated or unresponsive to treatment with H₂ receptor antagonists. They are also used in conjunction with antibiotics for the eradication of *Helicobacter pylori*. PPIs also are the mainstay in the treatment of pathological hypersecretory conditions, including the Zollinger-Ellison syndrome. *Lansoprazole*, *pantoprazole*, and *esomeprazole* are approved for treatment and prevention of recurrence of NSAID-associated gastric ulcers in patients who continue NSAID use. It is not clear if PPIs affect the susceptibility to NSAID-induced damage and bleeding in the small and large intestine. All PPIs are approved for reducing the risk of duodenal ulcer recurrence associated with *H. pylori* infections. Over-the-counter *omeprazole*, *esomeprazole*, and *lansoprazole* are approved for the self-treatment of acid reflux. Therapeutic applications of the PPIs are discussed further in the section Therapeutic Strategies for Specific Acid-Peptic Disorders.

The PPIs generally cause remarkably few adverse effects and have an excellent safety record (Chen et al., 2012; Reimer, 2013). The most common side effects are nausea, abdominal pain, constipation, flatulence, and diarrhea. Subacute myopathy, arthralgias, headaches, interstitial nephritis, and skin rashes also have been reported. PPIs are metabolized by hepatic CYPs and therefore may interfere with the elimination of other drugs cleared by this route. PPIs have been observed to interact with warfarin (*esomeprazole*, *lansoprazole*, *omeprazole*, and *rabeprazole*); diazepam (*esomeprazole* and *omeprazole*); and cyclosporine (*omeprazole* and *rabeprazole*). Among the PPIs, only *omeprazole* inhibits CYP2C19 (thereby decreasing the clearance of disulfiram, phenytoin, and other drugs) and induces the expression of CYP1A2 (thereby increasing the clearance of imipramine, several antipsychotic drugs, tacrine, and theophylline). There is some evidence that PPIs can inhibit conversion of clopidogrel (at the level of CYP2C19) to the active anticoagulating form, but this is controversial (Huang et al., 2012). *Pantoprazole* is less likely to result in this interaction; concurrent use of clopidogrel and PPIs (mainly *pantoprazole*) significantly reduces GI bleeding without increasing adverse cardiac events (see Chapter 32). Another drug interaction is between methotrexate and PPI therapy because PPIs can competitively inhibit methotrexate elimination and thereby increase methotrexate levels.

Chronic treatment with *omeprazole* decreases the absorption of vitamin B₁₂, but the clinical relevance of this effect is not clear. Loss of gastric acidity also may affect the bioavailability of such drugs as ketoconazole, ampicillin esters, and iron salts. Chronic use of PPIs has been reported to be associated with an increased risk of bone fracture and with increased susceptibility to certain infections (e.g., hospital-acquired pneumonia, community-acquired *Clostridium difficile*, spontaneous bacterial peritonitis in patients with ascites). Hypergastrinemia is more frequent and more severe with PPIs than with H₂ receptor antagonists and associated with this is ECL hyperplasia, fundic gland polypsis, and atrophic gastritis. This hypergastrinemia may

predispose to rebound hypersecretion of gastric acid on discontinuation of therapy and also may promote the growth of GI tumors, although the risk appears very low (Song et al., 2014). Recently, there have been associations made between long-term PPI use and increased risk of chronic kidney disease and dementia. These studies are not yet supported by well-controlled prospective trials and the evidence for these significant adverse effects remains very limited (Freedberg et al, 2017).

H₂ Receptor Antagonists

The arrival of selective histamine H₂ receptor antagonists was a landmark in the treatment of acid-peptic disease. Before the availability of the H₂ receptor antagonists, the standard of care was simply acid neutralization in the stomach lumen, generally with inadequate results. The long history of safety and efficacy with the H₂ receptor antagonists led to their availability without a prescription. Increasingly, however, PPIs are replacing the H₂ receptor antagonists in clinical practice.

Mechanism of Action and Pharmacology

The H₂ receptor antagonists inhibit acid production by reversibly competing with histamine for binding to H₂ receptors on the basolateral membrane of parietal cells (Black, 1993). Four different H₂ receptor antagonists, which differ mainly in their pharmacokinetics and propensity to cause drug interactions, are available in the U.S.: *cimetidine*, *ranitidine*, *famotidine*, and *nizatidine*. These drugs are less potent than PPIs but still suppress 24-hour gastric acid secretion by about 70%. Suppression of basal and nocturnal acid secretion is about 70%; because suppression of nocturnal acid secretion is important in the healing of duodenal ulcers, evening dosing of an H₂ receptor antagonist is adequate therapy in most cases. There is little evidence for the use of H₂ receptor antagonists for the treatment of bleeding ulcers, and they are no longer recommended for this purpose. All four H₂ receptor antagonists are available as prescription and over-the-counter formulations for oral administration. Intravenous and intramuscular preparations of cimetidine, ranitidine, and famotidine also are available for use in critically ill patients (Table 49–1)

ADME

The H₂ receptor antagonists are rapidly absorbed after oral administration, with peak serum concentrations within 1–3 h. Absorption may be enhanced by food or decreased by antacids, but these effects probably are unimportant clinically. Therapeutic levels are achieved rapidly after intravenous dosing and are maintained for 4–5 h (*cimetidine*), 6–8 h

TABLE 49–1 ■ INTRAVENOUS DOSES OF H₂ RECEPTOR ANTAGONISTS

	CIMETIDINE	RANITIDINE	FAMOTIDINE
Intermittent bolus	300 mg every 6–8 h	50 mg every 6–8 h	20 mg every 12 h
Continuous infusion	37.5–100 mg/h	6.25–12.5 mg/h	1.7–2.1 mg/h

(*ranitidine*), or 10–12 h (*famotidine*). The $t_{1/2}$ values of these agents after oral administration in adults range from 1 to 3.5 h; cimetidine clearance is faster in children, reducing its $t_{1/2}$ by about 30%. Only a small fraction of these drugs is protein bound. The kidneys excrete these drugs and their metabolites by filtration and renal tubular secretion, and it is important to reduce drug doses in patients with decreased creatinine clearance. Neither hemodialysis nor peritoneal dialysis clears significant amounts of these drugs. Hepatic metabolism accounts for a small fraction of clearance (from < 10% to about 35%), but liver disease per se is generally not an indication for dose adjustment.

Therapeutic Uses and Adverse Effects

The major therapeutic indications for H_2 receptor antagonists are to promote healing of gastric and duodenal ulcers, to treat uncomplicated GERD, and to prevent the occurrence of stress ulcers. For more information about the therapeutic applications of H_2 receptor antagonists, see Therapeutic Strategies for Specific Acid-Peptic Disorders.

The H_2 receptor antagonists generally are well tolerated, with a low (<3%) incidence of adverse effects (Sabesin, 1993). Side effects are minor and include diarrhea, headache, drowsiness, fatigue, muscular pain, and constipation. Less-common side effects include those affecting the CNS (confusion, delirium, hallucinations, slurred speech, and headaches), which occur primarily with intravenous administration of the drugs or in elderly subjects. Several reports have associated H_2 receptor antagonists with various blood disorders, including thrombocytopenia. H_2 receptor antagonists cross the placenta and are excreted in breast milk. Although no major teratogenic risk has been associated with these agents, caution is warranted when they are used in pregnancy.

All agents that inhibit gastric acid secretion may alter the rate of absorption and subsequent bioavailability of the H_2 receptor antagonists (see Antacids section). Drug interactions with H_2 receptor antagonists occur mainly with cimetidine, and its use has decreased markedly. Cimetidine inhibits CYPs (e.g., CYP1A2, CYP2C9, and CYP2D6) and thereby can increase the levels of a variety of drugs that are substrates for these enzymes. Ranitidine also interacts with hepatic CYPs, but with an affinity of only 10% of that of cimetidine. Famotidine and nizatidine are even safer in this regard. Slight increases in blood alcohol concentration may result from concomitant use of H_2 receptor antagonists and alcohol.

Tolerance and Rebound With Acid-Suppressing Medications

Tolerance to the acid-suppressing effects of H_2 receptor antagonists may develop within 3 days of starting treatment and may be resistant to increased doses of the medications (Sandevik et al., 1997). Diminished sensitivity to these drugs may result from the effect of the secondary hypergastrinemia to stimulate histamine release from ECL cells.

Agents That Enhance Mucosal Defense

Misoprostol

Misoprostol (15-deoxy-16-hydroxy-16-methyl-PGE₁) is a synthetic analogue of PGE₁ that is FDA approved to prevent NSAID-induced mucosal injury.

Mechanism of Action and Pharmacology

Prostaglandin E₂ and prostacyclin (PGI₂) are the major PGs synthesized by the gastric mucosa. Contrary to their cyclic AMP-elevating effects on many cells via EP₂ and EP₄ receptors, these prostanoids bind to the EP₃ receptor on parietal cells and stimulate the G_i pathway, thereby decreasing intracellular cyclic AMP and gastric acid secretion. PGE₂ also can prevent gastric injury by cytoprotective effects that include stimulation of mucin and bicarbonate secretion and increased mucosal blood flow. Acid suppression appears to be the most important effect clinically (Wolfe and Sachs, 2000).

Because NSAIDs diminish PG formation by inhibiting cyclooxygenase, synthetic PG analogues offer a logical approach to counteract NSAID-induced damage.

ADME

Misoprostol is rapidly absorbed after oral administration and is rapidly and extensively deesterified to form misoprostol acid, the principal and active metabolite of the drug. A single dose inhibits acid production within 30 min; the therapeutic effect peaks at 60–90 min and lasts for up to 3 h. Food and antacids decrease the rate of misoprostol absorption. The free acid is excreted mainly in the urine, with an elimination $t_{1/2}$ of 20–40 min.

Therapeutic Uses and Adverse Effects

Misoprostol is rarely used because of its side effects (Rostom et al., 2009). The degree of inhibition of gastric acid secretion by misoprostol is directly related to dose; oral doses of 100–200 µg significantly inhibit basal acid secretion (up to 85%–95% inhibition) or food-stimulated acid secretion (up to 75%–85% inhibition). The usual recommended dose for ulcer prophylaxis is 200 µg four times a day.

Diarrhea, with or without abdominal pain and cramps, occurs in up to 30% of patients who take *misoprostol*. Apparently dose related, it typically begins within the first 2 weeks after therapy is initiated and often resolves spontaneously within a week; more severe cases may necessitate drug discontinuation. *Misoprostol can cause clinical exacerbations of inflammatory bowel disease* (see Chapter 51). *Misoprostol is contraindicated for reducing the risk of NSAID-induced ulcer in women of childbearing potential unless the patient is at high risk of complications from gastric ulcers associated with use of the NSAID. It is also completely contraindicated during pregnancy* because it can increase uterine contractility.

Sucralfate

Mechanism of Action and Pharmacology

In the presence of acid-induced damage, pepsin-mediated hydrolysis of mucosal proteins contributes to mucosal erosion and ulcerations. This process can be inhibited by sulfated polysaccharides. *Sucralfate* consists of the octasulfate of sucrose to which Al(OH)₃ has been added. In an acid environment (pH < 4), sucralfate undergoes extensive cross-linking to produce a viscous, sticky polymer that adheres to epithelial cells and ulcer craters for up to 6 h after a single dose. In addition to inhibiting hydrolysis of mucosal proteins by pepsin, *sucralfate* may have other cytoprotective effects, including stimulation of local production of PGs and epidermal growth factor (Szabo, 2014). *Sucralfate* also binds bile salts; thus, some clinicians use *sucralfate* to treat individuals with the syndromes of biliary esophagitis or gastritis (the existence of which is controversial).

Therapeutic Uses and Adverse Effects

The use of *sucralfate* to treat peptic acid disease has diminished in recent years. Nevertheless, because increased gastric pH may be a factor in the development of nosocomial pneumonia in critically ill patients, sucralfate may offer an advantage over PPIs and H_2 receptor antagonists for the prophylaxis of stress ulcers. *Sucralfate* also has been used in conditions associated with mucosal inflammation/ulceration that may not respond to acid suppression, including oral mucositis (radiation and aphthous ulcers) and bile reflux gastropathy. Administered by rectal enema, sucralfate also has been used for radiation proctitis and solitary rectal ulcers. Because it is activated by acid, *sucralfate* should be taken on an empty stomach 1 h before meals. Use of antacids within 30 min of a dose of *sucralfate* should be avoided. The dose of sucralfate is 1 g four times daily (for active duodenal ulcer) or 1 g twice daily (for maintenance therapy). For children, it is given 40–80 mg/kg/d in divided doses every 6 h.

The most common side effect of *sucralfate* is constipation (about 2%). *Sucralfate* should be avoided in patients with renal failure who are at risk for aluminum overload (Marks, 1991). Likewise, aluminum-containing antacids should not be combined with *sucralfate* in these patients. *Sucralfate* forms a viscous layer in the stomach that may inhibit absorption of other drugs, including phenytoin, digoxin, cimetidine, ketocazole, and fluoroquinolone antibiotics. *Sucralfate* therefore should be

taken at least 2 h after the administration of other drugs. The “sticky” nature of the viscous gel produced by *sucralfate* in the stomach also may be responsible for the development of bezoars in some patients.

Antacids

Mechanism of Action and Pharmacology

There are far more effective and persistent agents than antacids, but their price, accessibility, and rapid action make them popular with consumers as OTC medications, and they can be used for the acute treatment of acid reflux (“heartburn”) and esophagitis (see discussion that follows). Many factors, including palatability, determine the effectiveness and choice of antacid. Although sodium bicarbonate effectively neutralizes acid, it is very water soluble and rapidly absorbed from the stomach, and the alkali and sodium loads may pose a risk for patients with cardiac or renal failure. CaCO_3 rapidly and effectively neutralizes gastric H^+ , but the release of CO_2 from bicarbonate- and carbonate-containing antacids can cause belching, nausea, abdominal distention, and flatulence. Calcium also may induce rebound acid secretion, necessitating more frequent administration. Combinations of Mg^{2+} (rapidly reacting) and Al^{3+} (slowly reacting) hydroxides provide a relatively balanced and sustained neutralizing capacity and are preferred by most experts. Magaldrate, a hydroxymagnesium aluminate complex, is converted rapidly in gastric acid to $\text{Mg}(\text{OH})_2$ and $\text{Al}(\text{OH})_3$, which are absorbed poorly and thus provide a sustained antacid effect. Although fixed combinations of Mg^{2+} and Al^{3+} theoretically counteract the adverse effects of each other on the bowel (Al^{3+} can relax gastric smooth muscle, producing delayed gastric emptying and constipation; Mg^{2+} exerts the opposite effects), such balance is not always achieved in practice. Simethicone, a surfactant that may decrease foaming and hence esophageal reflux, is included in many antacid preparations. However, other fixed combinations, particularly those with aspirin, that are marketed for “acid indigestion” are potentially unsafe in patients predisposed to gastroduodenal ulcers and should not be used.

Therapeutic Uses and Adverse Effects

Antacids are given orally 1 and 3 h after meals and at bedtime. For severe symptoms or uncontrolled reflux, antacids can be given as often as every 30–60 min. In general, antacids should be administered in suspension form because this probably has greater neutralizing capacity than powder or tablet dosage forms. Antacids are cleared from the empty stomach in about 30 min. However, the presence of food is sufficient to elevate gastric pH to about 5 for about 1 h and to prolong the neutralizing effects of antacids for about 2–3 h.

Antacids vary in the extent to which they are absorbed and hence in their systemic effects. In general, most antacids can elevate urinary pH by about 1 pH unit. Antacids that contain Al^{3+} , Ca^{2+} , or Mg^{2+} are absorbed less completely than are those that contain NaHCO_3 . With renal insufficiency, absorbed Al^{3+} can contribute to osteoporosis, encephalopathy, and proximal myopathy. About 15% of orally administered Ca^{2+} is absorbed, causing transient hypercalcemia. The hypercalcemia from as little as 3–4 g of CaCO_3 per day can be problematic in patients with uremia. In the past, when large doses of NaHCO_3 and CaCO_3 were administered commonly with milk or cream for the management of peptic ulcer, the *milk-alkali syndrome* (alkalosis, hypercalcemia, and renal insufficiency) occurred frequently. Today, this syndrome is rare and generally results from the chronic ingestion of large quantities of Ca^{2+} (five to forty 500-mg tablets per day of calcium carbonate) taken with milk.

By altering gastric and urinary pH, antacids may affect a number of drugs (e.g., thyroid hormones, allopurinol, and imidazole antifungals, by altering rates of dissolution and absorption, bioavailability, and renal elimination). Al^{3+} and Mg^{2+} antacids also are notable for their propensity to chelate other drugs present in the GI tract and thereby decrease their absorption. Most interactions can be avoided by taking antacids 2 h before or after ingestion of other drugs.

Other Acid Suppressants and Cytoprotectants

The M_1 muscarinic receptor antagonists *pirenzepine* and *telenzepine* (see Chapter 9) can reduce basal acid production by 40%–50%. The ACh receptor on the parietal cell itself is of the M_3 subtype, and these drugs are

believed to suppress neural stimulation of acid production via actions on M_1 receptors of intramural ganglia (see Figure 49–1). Because of their relatively poor efficacy, significant and undesirable anticholinergic side effects, and risk of blood disorders (pirenzepine), they rarely are used today.

Rebamipide is used for ulcer therapy in parts of India and Asia. Its cytoprotective effects are exerted by increasing PG generation in gastric mucosa and by scavenging reactive oxygen species. Ecabet, which appears to increase the formation of PGE_2 and PGI_2 , also is used for ulcer therapy, mostly in Japan. Carbenoxolone, a derivative of glycyrrhizic acid found in licorice root, has been used with modest success for ulcer therapy in Europe. Unfortunately, carbenoxolone inhibits the type I isozyme of 11β -hydroxysteroid dehydrogenase, which protects the mineralocorticoid receptor from activation by cortisol in the distal nephron; it therefore causes hypokalemia and hypertension due to excessive mineralocorticoid receptor activation (see Chapter 46). Bismuth compounds (see Chapter 50) are frequently prescribed in combination with antibiotics to eradicate *H. pylori* and prevent ulcer recurrence. Bismuth compounds bind to the base of the ulcer, promote mucin and bicarbonate production, and have significant antibacterial effects.

Therapeutic Strategies for Specific Acid-Peptic Disorders

Gastroesophageal Reflux Disease

Although most cases of acid reflux or gastroesophageal regurgitation follow a relatively benign course, these symptoms, often referred to as non-erosive reflux disease, can still be troubling (Boeckxstaens et al., 2014). More severe GERD is erosive esophagitis, characterized by endoscopically visible mucosal damage. This can lead to stricture formation and Barrett metaplasia (replacement of squamous by intestinal columnar epithelium), which is associated with a small but significant risk of adenocarcinoma. The goals of GERD therapy are complete resolution of symptoms and healing of esophagitis (Altan et al., 2012). PPIs clearly are more effective than H_2 receptor antagonists in achieving these goals (see Figure 49–3).

In general, the optimal dose for each patient is determined based on symptom control. Strictures associated with GERD also respond better to PPIs than to H_2 receptor antagonists. One of the complications of GERD, Barrett esophagus, appears to be more refractory to therapy because neither acid suppression nor antireflux surgery has been shown convincingly to produce regression of metaplasia.

Regimens for the treatment of GERD with PPIs and histamine H_2 receptor antagonists are listed in Table 49–2. Although some patients with

Figure 49–3 Comparative success of therapy with PPIs and H_2 antagonists. Data show the effects of a PPI (given once daily) and an H_2 receptor antagonist (given twice daily) in elevating gastric pH to the target ranges (i.e., pH 3 for duodenal ulcer, pH 4 for GERD, and pH 5 for antibiotic eradication of *H. pylori*).

TABLE 49-2 ■ ANTISECRETORY DRUG REGIMENS FOR TREATMENT OF GERD

DRUG	ADULT DOSAGE	PEDIATRIC DOSAGE
H₂ receptor antagonists^a		
Cimetidine	400 mg 4 times daily or 800 mg twice daily for 12 weeks	20–40 mg/kg/d divided every 6 h for 8–12 weeks
Famotidine	20 mg twice daily for up to 12 weeks	0.5 mg/kg/d at bedtime or divided every 12 h (infants < 3 months) ^b
Nizatidine	150 mg twice daily	<12 years: 10 mg/kg/d ^c divided every 12 h >12 years: 150 mg twice daily
Ranitidine	150 mg twice daily	5–10 mg/kg/d divided, every 8–12 h
Proton pump inhibitors		
Esomeprazole magnesium	20–40 mg daily for 4–8 weeks	2.5–20 mg daily ^d up to 8 weeks
Esomeprazole sodium	20–40 mg daily (IV) ^e	IV ^{d,e} : 0.5 mg/kg daily (infants > 1 month). Children: 10 mg daily (<55 kg); 20 mg daily (>55 kg)
Esomeprazole strontium	24.65 or 49.3 mg daily for 4–8 weeks	
Dexlansoprazole	30 mg daily for 4 weeks (nonerosive GERD); erosive GERD: 60 mg daily up to 6 months, then 30 mg daily up to 6 months (maintenance therapy)	Safety/efficacy not established
Lansoprazole	15 mg (nonerosive GERD) or 30 mg (erosive GERD) daily up to 8 weeks	15–30 mg daily ^d for up to 12 weeks
Omeprazole	20 mg daily	5–20 mg daily ^d
Pantoprazole	40 mg daily (erosive GERD)	20–40 mg daily ^d for up to 8 weeks
Rabeprazole	20 mg daily (erosive GERD)	Children 1–11 years old: 5–10 mg daily up to 12 weeks Adolescents: 20 mg daily up to 8 weeks

^aNot for erosive disease.^bFor children and adolescents, individualize treatment duration and dose based on clinical response or pH determination (gastric or esophageal) and endoscopy. For infants, employ conservative measures (e.g., thickened feedings) and limit therapy to 8 weeks.^cIndicates off-label use.^dVaries by weight.^eUsed when oral PPI cannot be given; short-term use only.

mild GERD symptoms may be managed by nocturnal doses of H₂ receptor antagonists, twice-daily dosing usually is required. Antacids are insufficient and are recommended only for the patient with mild, infrequent episodes of acute acid reflux. In general, prokinetic agents (see Chapter 50) are not particularly useful for GERD, either alone or in combination with acid-suppressant medications. There is reasonable evidence that PPIs, and, to a lesser extent, H₂ receptor antagonists, are safe and effective for the treatment of GERD in children (Tighe et al., 2014).

Severe Symptoms and Nocturnal Acid Breakthrough

In patients with severe symptoms or extraintestinal manifestations of GERD, twice-daily dosing with a PPI may be needed. However, it is difficult, if not impossible, to render patients achlorhydric, and two-thirds or more of subjects will continue to make acid, particularly at night. This phenomenon, called *nocturnal acid breakthrough*, has been invoked as a cause of refractory symptoms in some patients with GERD. However, decreases in gastric pH at night while on therapy generally are not associated with acid reflux into the esophagus, and the rationale for suppressing nocturnal acid secretion remains to be established. Patients with continuing symptoms on twice-daily PPIs are often treated by adding an H₂ receptor antagonist at night. Although this can further suppress acid production, the effect is short lived, probably due to the development of tolerance (Fackler et al., 2002).

Therapy for Extraintestinal Manifestations of GERD

Acid reflux has been implicated in a variety of atypical symptoms, including noncardiac chest pain, asthma, laryngitis, chronic cough, and other ear, nose, and throat conditions. PPIs (at higher doses) have been used with some success in certain patients with these disorders.

GERD and Pregnancy

Acid reflux is estimated to occur in 30%–50% of pregnancies, with an incidence approaching 80% in some populations (Richter, 2003). In the vast majority of cases, GERD ends soon after delivery and thus does not represent an exacerbation of a preexisting condition. Because of its high prevalence and the fact that it can contribute to the nausea of pregnancy, treatment often is required. Treatment choice in this setting is complicated by the paucity of safety data about use during pregnancy for the most commonly used drugs. In general, most drugs used to treat GERD fall in FDA category B, with the exception of *omeprazole* (FDA category C; see Appendix I for information on these categories). Mild cases of GERD during pregnancy should be treated conservatively; antacids or sucralfate are considered the first-line drugs. If symptoms persist, H₂ receptor antagonists can be used, with ranitidine having the most established track record in this setting. PPIs are reserved for women with intractable symptoms or complicated reflux disease. In these situations, omeprazole, lansoprazole, and pantoprazole are considered the safest choices (Ali and Egan, 2007).

Pediatric GERD

Reflux disease in infants and children is increasing at an alarming rate (Vandenplas, 2014). Children over 10 years can be diagnosed and treated similarly to adults, but infants and very young children require careful diagnosis to rule out cow's milk allergy or eosinophilic esophagitis. Many nonpharmacologic approaches can be used to alleviate some of the very troubling symptoms of this condition, which may not be due to acid reflux. If acid reduction is indicated, PPIs are more effective than H₂ receptor antagonists; however, the therapeutic efficacy of PPIs in newborns and infants is low, and there is an increased risk of adverse effects,

Peptic Ulcer Disease

Peptic ulcer disease is best viewed as an imbalance between mucosal defense factors (bicarbonate, mucin, PG, NO, and other peptides and growth factors) and injurious factors (acid and pepsin) (Hunt et al., 2015; Wallace, 2008). On average, patients with *duodenal ulcers* produce more acid than do control subjects, particularly at night (basal secretion). Although patients with *gastric ulcers* have normal or even diminished acid production, ulcers rarely, if ever, occur in the complete absence of acid. Presumably, weakened mucosal defense and reduced bicarbonate production contribute to the injury from the relatively lower levels of acid in these patients. *Helicobacter pylori* and exogenous agents such as NSAIDs interact in complex ways to cause an ulcer. Up to 60% of peptic ulcers are associated with *H. pylori* infection of the stomach. This infection may lead to impaired production of somatostatin by D cells and, in time, cause decreased inhibition of gastrin production, resulting in increased acid production and reduced duodenal bicarbonate production. Table 49–3 summarizes current recommendations for drug therapy of gastroduodenal ulcers.

The PPIs relieve symptoms of duodenal ulcers and promote healing more rapidly than do H₂ receptor antagonists, although both classes of drugs are effective in this setting (see Figure 49–3). A peptic ulcer represents a chronic disease, and recurrence within 1 year is expected in the majority of patients who do not receive prophylactic acid suppression. With the appreciation that *H. pylori* plays a major etiopathogenic role in the majority of peptic ulcers, prevention of relapse is focused on eliminating this organism from the stomach. Intravenous *esomeprazole* (80 mg IV over 30 min, followed by 8 mg/h continuous infusion for a total of 72 h, then 40 mg orally or another single daily dose oral PPI, for an appropriate duration; off-label use) and *pantoprazole* (off-label use) are the preferred therapy in patients with acute bleeding ulcers (Laine and Jensen, 2012; Wong and Sung, 2013). The theoretical benefit of maximal acid suppression in this setting is to accelerate healing of the underlying ulcer. In addition, a higher gastric pH enhances clot formation and retards clot dissolution.

The NSAIDs also are frequently associated with peptic ulcers and bleeding. The effects of these drugs are mediated systemically; in the stomach, NSAIDs suppress mucosal PG synthesis (particularly PGE₂ and PGI₂) and thereby reduce mucus production and cytoprotection (see Figure 49–1). Thus, minimizing NSAID use is an important adjunct to gastroduodenal ulcer therapy.

Treatment of Helicobacter pylori Infection

Helicobacter pylori, a gram-negative rod, has been associated with gastritis and the subsequent development of gastric and duodenal ulcers, gastric adenocarcinoma, and gastric B-cell lymphoma (Suerbaum and Michetti, 2002). Because of the critical role of *H. pylori* in the pathogenesis of peptic ulcers, eradicating this infection is standard care in patients with gastric or duodenal ulcers (Malfertheiner et al., 2013). Provided that patients are not taking NSAIDs, this strategy almost completely eliminates the risk of ulcer recurrence. Eradication of *H. pylori* also is indicated in the treatment of mucosa-associated lymphoid tissue lymphomas of the stomach, which can regress significantly after such treatment. *Helicobacter pylori* eradication is also indicated for treatment of chronic atrophic gastritis and presence of intestinal metaplasia/dysplasia (with positive *H. pylori* biopsies).

Five important considerations influence the selection of an eradication regimen (Table 49–4) (Chey and Wong, 2007; Malfertheiner et al., 2012):

- Single-antibiotic regimens are ineffective in eradicating *H. pylori* infection and lead to microbial resistance. Combination therapy with two or three antibiotics (plus acid-suppressive therapy) is associated with the highest rate of *H. pylori* eradication.
- A PPI significantly enhances the effectiveness of *H. pylori* antibiotic regimens containing amoxicillin and clarithromycin (see Figure 49–3).
- A regimen of 10–14 days of treatment appears to be better than shorter treatment regimens.
- Poor patient compliance is linked to the medication-related side effects experienced by as many as half of patients taking triple-agent regimens and to the inconvenience of three- or four-drug regimens administered several times per day. Packaging that combines the daily doses into one convenient unit is available and may improve patient compliance.

TABLE 49–3 ■ REGIMENS FOR TREATING GASTRODUODENAL ULCERS IN ADULTS ^a		
DRUG	ACTIVE ULCER	MAINTENANCE THERAPY
Proton pump inhibitors ^b		
Esomeprazole magnesium	NSAID risk reduction: 20 or 40 mg daily for up to 6 months	
Esomeprazole strontium	NSAID risk reduction: 24.65 or 49.3 mg daily for up to 6 months	
Lansoprazole	15 mg (DU) daily for 4 weeks 15 mg (NSAID risk reduction) daily for up to 12 weeks 30 mg (GU including NSAID associated) daily for up to 8 weeks	15 mg daily 30 mg daily ^c
Omeprazole	20 mg (DU) daily for 4–8 weeks 40 mg (GU) daily for 4–8 weeks	20 mg daily ^c
Pantoprazole	20 mg (NSAID risk reduction) daily ^c 40 mg (GU) daily ^c	20 mg daily ^c
Rabeprazole	20 mg (DU for up to 4 weeks; GU ^c) daily	
Prostaglandin analogue		
Misoprostol	200 µg four times daily (NSAID-associated ulcer prevention) ^d	

^aThere is little evidence for the use of H₂ receptor antagonists for the treatment of bleeding ulcers.
^bDeslansoprazole is not labeled for the treatment of active ulcers.
^cOff-label use.
^dOnly misoprostol 800 µg/d has been directly shown to reduce the risk of ulcer complications such as perforation, hemorrhage, or obstruction. (Rostom A, Moayyedi P, Hunt R. Canadian Association of Gastroenterology Consensus Group. Canadian consensus guidelines on long-term nonsteroidal anti-inflammatory drug therapy and the need for gastroprotection: benefits versus risks. *Aliment Pharmacol Ther*, 2009; 29:481–496.)

TABLE 49-4 ■ THERAPY OF *HELICOBACTER PYLORI* INFECTION

Triple therapy × 10–14 days: PPI + clarithromycin 500 mg + amoxicillin 1 g twice a day (metronidazole 500 mg twice a day can be substituted for amoxicillin)

Quadruple therapy × 10–14 days: PPI + metronidazole 250 mg + bismuth subsalicylate 525 mg + tetracycline 500 mg four times daily

or

Sequential therapy: PPI + amoxicillin 1 g twice a day for 5 days followed by PPI + clarithromycin 500 mg and tinidazole/metronidazole 500 mg twice a day for 5 days;

or

PPI + amoxicillin 1 g twice a day + levofloxacin 250 or 500 mg twice a day for 10 days

PPI daily dosages:

Omeprazole: 20 mg twice a day (triple therapy); 40 mg daily (dual therapy)

Lansoprazole: 30 mg twice a day (triple therapy); 30 mg three times daily for 14 days (dual therapy with amoxicillin)

Rabeprazole: 20 mg twice a day for 7 days

Pantoprazole: 40 mg twice a day^a

Esomeprazole magnesium: 40 mg daily (triple therapy)

Esomeprazole strontium: 49.3 mg daily (triple therapy)

^aOff-label use.

Data from Chey and Wong, 2007.

- The emergence of resistance to clarithromycin and metronidazole increasingly is recognized as an important factor in the failure to eradicate *H. pylori*. In the presence of in vitro evidence of resistance to metronidazole, amoxicillin should be used instead. In areas with a high frequency of resistance to clarithromycin and metronidazole, a 14-day quadruple-drug regimen (three antibiotics combined with a PPI) generally is effective therapy.

NSAID-Related Ulcers

Chronic NSAID users have a 2%–4% risk of developing a symptomatic ulcer, GI bleeding, or perforation. Ideally, NSAIDs should be discontinued in patients with an ulcer if at all possible. Healing of ulcers despite continued NSAID use is possible with the use of acid-suppressant agents, usually at higher doses and for a considerably longer duration than standard regimens (e.g., ≥ 8 weeks). PPIs are superior to H₂ receptor antagonists and misoprostol in promoting the healing of active ulcers and in preventing recurrence of gastric and duodenal ulcers in the setting of continued NSAID administration (Lanas and Hunt, 2006; Rostom et al., 2009). The FDA has approved fixed-dose combinations of NSAIDs with a PPI or H₂ antagonist; these combinations are intended to lower the risk of ulcers in patients who regularly use NSAIDs for arthritic pain.

Stress-Related Ulcers

Stress ulcers are ulcers of the stomach or duodenum that occur in the context of a profound illness or trauma requiring intensive care (Bardou et al., 2015). The etiology of stress-related ulcers differs somewhat from that of other peptic ulcers, involving acid and mucosal ischemia. Because of limitations on the oral administration of drugs in many patients with stress-related ulcers, intravenous H₂ receptor antagonists have been used extensively to reduce the incidence of GI hemorrhage due to stress ulcers. Now that intravenous preparations of PPIs are available, they are appropriate to consider. However, there is some concern over the risk of pneumonia

secondary to gastric colonization by bacteria in an alkaline milieu. In this setting, sucralfate appears to provide reasonable prophylaxis against bleeding without increasing the risk of aspiration pneumonia.

Zollinger-Ellison Syndrome

Patients with Zollinger-Ellison syndrome develop pancreatic or duodenal gastrinomas that stimulate the secretion of very large amounts of acid, sometimes in the setting of multiple endocrine neoplasia, type I (Krampitz and Norton, 2013). This can lead to severe gastroduodenal ulceration and other consequences of uncontrolled hyperchlorhydria. PPIs are the drugs of choice, usually given at about twice the routine dosage for peptic ulcers (omeprazole 60 mg daily, esomeprazole 80 mg daily, lansoprazole 60 mg daily, rabeprazole 60 mg daily, or pantoprazole 120 mg daily); some patients need two to three times these doses to control acid secretion. However, once control of acid secretion has been achieved, dose reduction is usually possible. PPIs are well tolerated and safe even at very high doses. If PPIs are unable to control gastric acid secretion, the long-acting somatostatin analogue *octreotide* (off-label indication) can be given to inhibit secretion of gastrin. This is not a first-line agent due to unpredictable response rates and the side effects of the treatment.

Functional Dyspepsia

The term *functional dyspepsia* refers to ulcer-like symptoms in patients who lack overt gastroduodenal ulceration (Tack and Talley, 2013). Functional dyspepsia can be subdivided into postprandial distress syndrome and epigastric pain syndrome, based on the presence of symptoms related to meals. It is defined as the presence of one or more of the following: postprandial fullness, early satiation, epigastric pain or burning, and no evidence of structural disease. It may be associated with gastritis (with or without *H. pylori*) or with NSAID use, but the pathogenesis of this syndrome remains controversial.

The PPIs appear to be moderately effective in the treatment of patients with functional dyspepsia (Vanheel and Tack, 2014). In general, twice-daily PPIs are no better than once-daily PPIs. The dosing is as for GERD (Table 49-2). H₂ receptor antagonists are only marginally effective for the treatment of functional dyspepsia. Because central mechanisms may contribute to functional dyspepsia either through visceral hypersensitivity or other mechanisms, tricyclic antidepressants such as amitriptyline or desipramine (10 to 25 mg at night) (see Chapter 15) can be considered in patients with functional dyspepsia whose symptoms persist despite PPI therapy for 8 weeks. Prokinetic agents such as metoclopramide (see Chapter 50) are not considered for functional dyspepsia because of their side-effect profile. The novel gastroprokinetic agent *acotiamide* is being investigated for use in postprandial distress syndrome, and 5HT_{1A} serotonin receptor agonists that relax the fundus (see Chapter 13) are being tested in patients with postprandial distress syndrome with early satiation. Antacids are not generally helpful for the treatment of functional dyspepsia.

Functional Esophageal Disorders

Functional esophageal disorders are disorders that cause esophageal symptoms and that are diagnosed on the basis of negative results on standard esophageal tests, thereby excluding structural disorders, motility disorders like achalasia, and GERD (Amarasinghe and Sifrim, 2014). There are four of these fairly common disorders: (1) functional heartburn, (2) functional chest pain, (3) functional dysphagia, and (4) globus. PPI therapy (off-label use) as outlined previously is routinely used for the initial treatment of functional heartburn, functional chest pain, and globus. As in functional dyspepsia, central mechanisms contribute to these disorders and similar approaches follow for the treatment of functional heartburn and functional chest pain if PPI therapy is ineffective, including the use of tricyclic antidepressants or selective serotonin reuptake inhibitors. For the treatment of globus, gabapentin or pregabalin is used.

- Other Drugs

ANTINAUSEANTS AND ANTIEMETICS

- Nausea and Vomiting

MISCELLANEOUS GI DISORDERS

- Cystic Fibrosis, Chronic Pancreatitis, and Steatorrhea
- Gallstones and Primary Biliary Cirrhosis
- Flatulence
- Short-Bowel Syndrome

Gastrointestinal Motility

The GI tract is in a continuous contractile, absorptive, and secretory state. The control of this state is complex, with contributions by the muscle and epithelium, the enteric nervous system (ENS), the autonomic nervous system (ANS), and local and circulating hormones. Of these, perhaps the most important regulator of physiological gut function is the ENS (Figure 50–1) (Furness, 2006; Furness, 2012; Grundy et al., 2006).

The ENS is an extensive collection of nerves and glial cells that constitutes the third division of the ANS. It is the only part of the ANS truly capable of autonomous function if separated from the CNS. The ENS lies within the wall of the GI tract and is organized into two connected networks of neurons, nerve fibers, and glial cells: the *myenteric* (Auerbach) *plexus*, found between the circular and longitudinal muscle layers, and the *submucosal* (Meissner) *plexus*, located in the submucosa (Furness, 2012; Sharkey, 2015). The former is largely responsible for motor control, whereas the latter regulates secretion, fluid transport, and blood flow.

To prevent the unwanted translocation of toxins, antigen commensal bacteria, and other potentially pathogenic components of the luminal contents, an elaborate “intestinal barrier” has developed. This consists of a physical barrier, an immune barrier, and a secretory barrier, which includes the secretion of antimicrobial peptides, mucus, and fluid. The secretory and immune components of the intestinal barrier are regulated by ENS and ANS neural mechanisms that integrate the control of these components of barrier function with digestive processes in the gut (Mayer et al., 2014; Sharkey and Savidge, 2014).

Generation and Regulation of GI Motor Activity

The ENS is responsible for the largely autonomous nature of most GI activity. This activity is organized into relatively distinct programs that respond to input from the local environment of the gut, as well as the ANS-CNS. Each program consists of a series of complex, but coordinated, patterns

of secretion and movement that show regional and temporal variation (Deloof et al., 2012). The *fasting program* of motor activity in the gut is called the MMC (*migrating myoelectric complex* when referring to electrical activity and *migrating motor complex* when referring to the accompanying contractions) and consists of a series of four phasic activities: I, quiescence; II, increasing frequencies of action potentials and smooth muscle contractions; III, peak contractile activity; and IV, declining activity toward a renewal of phase I. Phase II of the MMC is associated with the release of the peptide hormone *motilin*. Motilin agonists stimulate motility in the proximal gut. The most characteristic, phase III, consists of clusters of rhythmic contractions that occupy short segments of the intestine for a period of 6–10 min before proceeding caudally (toward the anus). One MMC cycle (i.e., all four phases) takes about 80–110 min. The MMC occurs in the fasting state, helping to sweep debris caudad in the gut and limiting the overgrowth of commensal luminal bacteria. The MMC is interrupted by the fed program in intermittently feeding animals such as humans. The *fed program* consists of high-frequency (12–15/min) contractions that either are propagated for short segments (*propulsive*) or are irregular and not propagated (*mixing*).

Peristalsis is a series of reflex responses to a bolus in the lumen of a given segment of the intestine; the *ascending excitatory reflex* results in contraction of the circular muscle on the oral side of the bolus, whereas the *descending inhibitory reflex* results in relaxation on the anal side. The net pressure gradient moves the bolus caudad. Motor neurons receive input from ascending and descending interneurons (which constitute the relay and programming systems), which are of two broad types, *excitatory* and *inhibitory*. The primary neurotransmitter of the *excitatory motor neurons* is ACh. The principal neurotransmitter in the *inhibitory motor neurons* is NO, although important contributions may also be made by ATP, VIP, and PACAP. Enterochromaffin cells, the major population of enteroendocrine cells, scattered throughout the epithelium of the intestine, release serotonin (5HT) to initiate many gut reflexes by acting locally on enteric neurons (Gershon and Tack, 2007). Excessive release of 5HT in the gut

ACh: acetylcholine
ANS: autonomic nervous system
AQP: aquaporin
CA: carbonic anhydrase
CCK: cholecystokinin
CFTR: cystic fibrosis transmembrane conductance regulator
CTZ: chemoreceptor trigger zone
CYP: cytochrome P450
DOR: delta opioid receptor
DRA: downregulated in adenoma
ECG: electrocardiogram
ENaC: epithelial sodium channel
ENS: enteric nervous system
FDA: U.S. Food and Drug Administration
GC: guanyl cyclase
GERD: gastroesophageal reflux disease
GI: gastrointestinal
GLP: glucagon-like peptide
GPCR: G protein-coupled receptor
HERG: human ether-a-go-go related gene
HIV: human immunodeficiency virus
5HT: serotonin, 5-hydroxytryptamine
IBS: irritable bowel syndrome
KOR: kappa opioid receptor
MOR: mu opioid receptor
NEP: neutral endopeptidase
NHE: Na⁺-H⁺ exchanger
NK: neurokinin
NO: nitric oxide
NSAID: nonsteroidal anti-inflammatory drug
OTC: over the counter
PACAP: pituitary adenylyl cyclase-activating peptide
PAF: platelet-activating factor
PEG: polyethylene glycol
QT: ECG interval
SERT: serotonin transporter
SGLT: sodium-glucose cotransporter
SLC: solute carrier transporter
SSRI: selective serotonin reuptake inhibitor
SST: somatostatin
STN: solitary tract nucleus
TJ: tight junction
TMEM: transmembrane protein
USP: U.S. Pharmacopeia
VIP: vasoactive intestinal peptide

wall (e.g., by chemotherapeutic agents) leads to vomiting by actions of 5HT on vagal nerve endings in the proximal small intestine. Compounds targeting the 5HT system are important modulators of motility, secretion, and emesis.

Other cell types are also important in the regulation of GI motility, including interstitial cells of Cajal and various enteroendocrine cell populations. Interstitial cells of Cajal, which are distributed in networks within the gut wall, are responsible for setting the electrical rhythm and the pace of contractions in various regions of the gut (Huizinga and Chen, 2014). These cells also modulate excitatory and inhibitory neuronal communication to the smooth muscle. Enteroendocrine cell populations release locally acting hormones, such as *ghrelin*, *CCK*, *motilin*, and *GLP-1*, all of

which can influence GI motility, before (e.g., ghrelin) or after meals (e.g., CCK and GLP-1) (Psichas et al., 2015).

Excitation Contraction Coupling in GI Smooth Muscle

Control of tension in GI smooth muscle is dependent on the intracellular Ca²⁺ concentration (Sanders et al., 2012). There are basically two types of excitation-contraction coupling in these cells. *Ionotropic receptors* can mediate changes in membrane potential, which in turn activate voltage-gated Ca²⁺ channels to trigger an influx of Ca²⁺ (electromechanical coupling); *metabotropic receptors* activate various signal transduction pathways to release Ca²⁺ from intracellular stores (pharmacomechanical coupling). Inhibitory receptors act via PKA and PKG and lead to hyperpolarization, decreased cytosolic [Ca²⁺], and reduced interaction of actin and myosin. As an example, NO may induce relaxation via activation of the guanylyl cyclase-cyclic GMP pathway and cause the opening of several types of K⁺ channels.

Functional and Motility Disorders of the Bowel

Gastrointestinal motility disorders are a heterogeneous group of conditions (Drossman, 2006; Faure et al., 2012). Common motility disorders include achalasia of the esophagus (impaired relaxation of the lower esophageal sphincter associated with defective esophageal peristalsis that results in dysphagia and regurgitation), gastroparesis (delayed gastric emptying), GERD (chronic reflux of gastric contents into the esophagus due to an increased frequency of transient lower esophageal sphincter relaxations, ineffective esophageal peristalsis, or gastric dysmotility); intestinal pseudoobstruction (myopathic and neuropathic forms of intestinal dysmotility); constipation; Hirschsprung disease; anorectal dysfunction; and others. These disorders can be congenital, idiopathic, or secondary to systemic diseases (e.g., diabetes mellitus or scleroderma). Motility disorders also traditionally include the functional GI conditions, such as IBS, functional dyspepsia, and noncardiac chest pain. These are brain-gut disorders that are characterized by the presence of increased pain from the gut associated with GI motor abnormalities and other symptoms. For most of these disorders, treatment remains empirical and symptom based, reflecting limited understanding of the pathophysiology involved in most cases.

Prokinetic Agents and Other Stimulants of GI Motility

Prokinetic agents are medications that enhance coordinated GI motility and transit of material in the GI tract (Acosta and Camilleri, 2015; Altan et al., 2012; Corsetti and Tack, 2014; Tack and Zaninotto, 2015). These agents appear to enhance the release of excitatory neurotransmitter at the nerve-muscle junction without interfering with the normal physiological pattern and rhythm of motility. By contrast, activation of muscarinic receptors with the older cholinomimetic agents (see Chapter 9) or acetylcholinesterase inhibitors (see Chapter 10) enhances contractions in a relatively uncoordinated fashion that produces little or no net propulsive motor activity.

Dopamine Receptor Antagonists

Dopamine is present in significant amounts in the GI tract and has several inhibitory effects on motility, including reduction of lower esophageal sphincter and intragastric pressures. These effects, which result from suppression of ACh release from myenteric motor neurons, are mediated by D₂ dopaminergic receptors. Dopamine receptor antagonists are effective as prokinetic agents; they have the additional advantage of relieving nausea and vomiting by antagonism of dopamine receptors in the CTZ of the brainstem. Examples are *metoclopramide* and *domperidone* (Acosta and Camilleri, 2015; Reddymasu et al., 2007).

Figure 50-1 The neuronal network that initiates and generates the peristaltic response. Mucosal stimulation leads to release of serotonin by enterochromaffin cells (8), which excites the intrinsic primary afferent neurons (1), which then communicate with ascending (2) and descending (3) interneurons in the local reflex pathways. The reflex results in contraction at the oral end via the excitatory motor neuron (6) and aboral relaxation via the inhibitory motor neuron (5). The migratory myoelectric complex (see text) is shown here as being conducted by a different chain of interneurons (4). Another intrinsic primary afferent neuron with its cell body in the submucosa also is shown (7). MP, myenteric plexus; CM, circular muscle; LM, longitudinal muscle; SM, submucosa; Muc, mucosa. (Adapted with permission from Kunze WA, Furness JB. The enteric nervous system and regulation of intestinal motility. *Annu Rev Physiol*, 1999, 61:117–142. Permission conveyed via Copyright Clearance Center, Inc.)

Metoclopramide

Mechanism of Action and Pharmacology. *Metoclopramide* and other substituted benzamides are derivatives of *para*-aminobenzoic acid and are structurally related to procainamide. The mechanisms of action of *metoclopramide* are complex and involve 5HT₄ receptor agonism, vagal and central 5HT₃ antagonism, and possible sensitization of muscarinic receptors on smooth muscle, in addition to dopamine receptor antagonism. Administration of *metoclopramide* results in coordinated contractions that enhance transit. Its effects are confined largely to the upper digestive tract, where it increases lower esophageal sphincter tone and stimulates antral and small intestinal contractions. *Metoclopramide* has no clinically significant effects on large-bowel motility (Acosta and Camilleri, 2015).

ADME. *Metoclopramide* is absorbed rapidly after oral ingestion, undergoes sulfation and glucuronide conjugation by the liver, and is excreted principally in the urine, with a $t_{1/2}$ of 4–6 h. Peak concentrations occur within 1 h after a single oral dose; the duration of action is 1–2 h.

Therapeutic Uses and Adverse Effects. *Metoclopramide* is indicated in patients with gastroparesis, in whom the drug may cause moderate improvements of gastric emptying. *Metoclopramide* injection is used as an adjunctive measure in medical or diagnostic procedures such as upper endoscopy or contrast radiography of the GI tract (single IV dose of 10 mg). Its greatest utility lies in its ability to ameliorate the nausea and vomiting that often accompany GI dysmotility syndromes. *Metoclopramide* is available in oral dosage forms (tablets and solution) and as a parenteral preparation for intravenous or intramuscular administration. The initial regimen is 10 mg orally, 30 min before each meal and at

bedtime. The onset of action is within 30–60 min. In patients with severe nausea, an initial dose of 10 mg can be given intramuscularly (onset of action 10–15 min) or intravenously (onset of action 1–3 min). For prevention of chemotherapy-induced emesis, *metoclopramide* can be given as an infusion of 1–2 mg/kg administered over at least 15 min, beginning 30 min before the chemotherapy is begun and repeated as needed every 2 h for two doses, then every 3 h for three doses. Because of adverse effects related to drug exposure, the recommended duration of use is less than 12 weeks. *Metoclopramide* has a very limited use for the treatment of GERD in children because of significant safety concerns (see discussion that follows) and limited efficacy.

The major side effects of *metoclopramide* include extrapyramidal effects. Dystonias, usually occurring acutely after intravenous administration, and Parkinsonian-like symptoms that may occur several weeks after initiation of therapy generally respond to treatment with anticholinergic or antihistaminic drugs and reverse on discontinuation of *metoclopramide*. Tardive dyskinesia also can occur with chronic treatment and may be irreversible. Extrapyramidal effects appear to occur more commonly in children and young adults and at higher doses. *Metoclopramide* also can cause galactorrhea by blocking the inhibitory effect of dopamine on prolactin release (seen infrequently in clinical practice). Methemoglobinemia has been reported occasionally in premature and full-term neonates receiving *metoclopramide*.

Domperidone

Mechanism of Action and Pharmacology. In contrast to *metoclopramide*, *domperidone* predominantly antagonizes the D₂ receptor without major involvement of other receptors, but otherwise its mechanism of action is similar (Reddymasu et al., 2007).

ADME. *Domperidone* is rapidly absorbed, yielding peak concentrations in 30 min. The drug undergoes metabolism via hepatic CYP3A4, N-dealkylation, and hydroxylation; it has a $t_{1/2}$ of 7 h. It is excreted in the feces (~two-thirds) and urine (~one-third).

Therapeutic Uses and Adverse Effects. Domperidone is available for use in the U.S. only through an expanded access to investigational drugs with the FDA, but it is readily available in many other countries. It has modest prokinetic activity in doses of 10 mg three times a day. Although it does not readily cross the blood-brain barrier to cause extrapyramidal side effects, domperidone exerts effects in the parts of the CNS that lack this barrier, such as those regulating emesis, temperature, and prolactin release. Domperidone does not appear to have any significant effects on lower GI motility. Like metoclopramide, it has limited efficacy in children. There is an increased risk of serious ventricular arrhythmias, including sudden cardiac death, in association with domperidone use, especially in older persons (>60 years) and at doses above 30 mg/d. Like metoclopramide, it can also elevate prolactin levels, presenting as galactorrhea, gynecomastia, amenorrhea, or impotence.

Serotonin Receptor Agonists

Serotonin (5HT) plays an important role in the normal motor and secretory function of the gut (see Chapter 13) (Gershon and Tack, 2007). Indeed, more than 90% of the total 5HT in the body exists in the GI tract. The enterochromaffin cell produces most of this 5HT and rapidly releases it in response to chemical and mechanical stimulation (e.g., food boluses; chemotherapeutic agents such as cisplatin; certain microbial toxins; adrenergic, cholinergic, and purinergic receptor agonists). 5HT triggers the *peristaltic reflex* (see Figure 50–1) by stimulating intrinsic sensory neurons in the myenteric plexus (via 5HT_{1p} and 5HT₄ receptors), as well as extrinsic vagal and spinal sensory neurons (via 5HT₃ receptors). In addition, stimulation of submucosal intrinsic afferent neurons activates secretomotor reflexes, resulting in epithelial secretion.

The 5HT receptors occur on other neurons in the ENS, where they can be either stimulatory (5HT₃ and 5HT₄) or inhibitory (5HT_{1A}). In addition, serotonin stimulates the release of other neurotransmitters. Thus, 5HT₁ stimulation of the gastric fundus results in release of NO and reduction in smooth muscle tone. 5HT₄ stimulation of excitatory motor neurons enhances ACh release at the neuromuscular junction, and both 5HT₃ and 5HT₄ receptors facilitate interneuronal signaling. Developmentally, 5HT acts as a *neurotrophic factor* for enteric neurons via the 5HT_{2B} and 5HT₄ receptors. Reuptake of serotonin by enteric neurons and epithelium is mediated by the same transporter (SERT) as 5HT reuptake by serotonergic neurons in the CNS. This reuptake also is blocked by SSRIs (see Figure 15–1), which explains the common side effect of diarrhea that accompanies the use of these agents (Gershon, 2013).

Modulation of the multiple, complex, and sometimes-opposing effects of 5HT on gut motor function has become a major target for drug development. The availability of serotonergic prokinetic drugs has in recent years been restricted because of serious adverse cardiac events (Tack et al., 2012). In the U.S., tegaserod is only available as an emergency investigational new drug, and cisapride is available only via a limited-access protocol. A novel 5HT₄ agonist, prucalopride, is approved in Europe and Canada for symptomatic treatment of chronic constipation in women in whom laxatives fail to provide adequate relief.

Cisapride

Mechanism of Action and Pharmacology. Cisapride is a 5HT₄ agonist that stimulates adenylyl cyclase activity in neurons. It also has weak 5HT₃ antagonistic properties and may directly stimulate smooth muscle.

Cisapride was a commonly used prokinetic agent; however, it no longer is generally available in the U.S. because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. These arrhythmias result from a prolonged QT interval through an interaction with pore-forming subunits of the *HERG* K⁺ channel (see Chapter 30).

ADME. Cisapride is metabolized in the liver by CYP3A4 (see Chapter 6). It has an onset of action of 30–60 min and a $t_{1/2}$ of 6–12 h.

Therapeutic Uses and Adverse Effects. Cisapride is available only through an investigational, limited-access program for patients with GERD, gastroparesis, intestinal pseudoobstruction, refractory severe chronic constipation, and neonatal enteral feeding intolerance who have failed all standard therapeutic modalities and who have undergone a thorough diagnostic evaluation, including an ECG. It has modest prokinetic activity in doses of 5–10 mg four times a day before meals. Cisapride is contraindicated in patients with a history of prolonged QT interval, renal failure, ventricular arrhythmias, ischemic heart disease, congestive heart failure, respiratory failure, uncorrected electrolyte abnormalities, or concomitant medications known to prolong the QT interval.

Prucalopride

Mechanism of Action and Pharmacology. Prucalopride is a specific 5HT₄ receptor agonist (Figure 50–2) that facilitates cholinergic neurotransmission. It acts throughout the length of the intestine, increasing oral-cecal transit and colonic transit without affecting gastric emptying in healthy volunteers.

ADME. Prucalopride has a time to peak action of 2–3 h and a $t_{1/2}$ of 24 h. It is primarily excreted in the urine as the unchanged drug.

Therapeutic Uses and Adverse Effects. Given in doses of 1–4 mg orally, once daily, the drug improved bowel habits; significantly increased the number of spontaneous, complete bowel movements; reduced the severity of symptoms; and improved quality of life in patients with severe chronic constipation. Prucalopride is approved for use in women with chronic constipation in whom laxatives fail to provide adequate relief. Nausea, diarrhea, abdominal pain, and headaches are common adverse effects. Cardiovascular risks do not seem to be elevated, but patients should be monitored (Diederer et al., 2015).

Motilin and Macrolide Antibiotics

Mechanism of Action and Pharmacology

Motilin, a 22-amino acid peptide hormone secreted by enteroendocrine M cells and by some enterochromaffin cells of the upper small bowel, is a potent contractile agent of the upper GI tract. Motilin levels fluctuate in association with the MMC and appear to be responsible for the amplification, if not the actual induction, of phase III activity. In addition, motilin receptors are GPCRs found on smooth muscle cells and enteric neurons.

The effects of motilin can be mimicked by erythromycin, a property shared to varying extents by other macrolide antibiotics (e.g., azithromycin, clarithromycin, etc.; see Chapter 59). In addition to its motilin-like effects, which are most pronounced at higher doses (250–500 mg), erythromycin at lower doses (e.g., 40–80 mg) also may act by other poorly defined mechanisms that may involve cholinergic facilitation. Erythromycin has multiple effects on upper GI motility, increasing lower esophageal pressure

 5HT	LIGAND	SPECIFICITY
	Alosetron	5HT ₃ antagonist
	Metoclopramide	5HT ₄ agonist; 5HT ₃ antagonist; D ₂ antagonist
	Prucalopride	5HT ₄ agonist
	Tegaserod	5HT ₄ partial agonist

Figure 50–2 Serotonergic agents modulating GI motility.

and stimulating gastric and small-bowel contractility. By contrast, it has little or no effect on colonic motility. At doses higher than 3 mg/kg, it can produce a spastic type of contraction in the small bowel, resulting in cramps, impairment of transit, and vomiting.

ADME

Erythromycin is metabolized by demethylation in the liver by CYP3A4. The time to peak action is about 0.5–2.5 h (ethylsuccinate), and it has a $t_{1/2}$ of 2 h. It is primarily excreted in the feces.

Therapeutic Uses and Adverse Effects

Erythromycin is used as a prokinetic agent in patients with diabetic gastroparesis, where it can improve gastric emptying in the short term. *Erythromycin*-stimulated gastric contractions can be intense and result in “dumping” of relatively undigested food into the small bowel. This potential disadvantage can be exploited clinically to clear the stomach of undigestible residue such as bezoars. Rapid development of tolerance (~28 days) to *erythromycin*, possibly by downregulation of the motilin receptor, and antibiotic effects (undesirable in this context) limit the use of this drug as a prokinetic agent. A standard dose of *erythromycin* for gastric stimulation is 1.5–3 mg/kg intravenous infusion every 6 h in a hospital setting or 125 mg orally every 12 h (Acosta and Camilleri, 2015). For small-bowel stimulation, a smaller dose (e.g., 3 mg/kg IV every 8 h) may be more useful; higher doses may actually retard the motility. Tachyphylaxis to *erythromycin* and potential side effects limit its use in the management of gastroparesis. Concerns about GI toxicity, ototoxicity, pseudomembranous colitis, and the induction of resistant strains of bacteria, QT prolongation, and sudden death, particularly when used in patients taking medications that inhibit CYP3A4, limit the use of *erythromycin* to acute situations or in circumstances where patients are resistant to other medications.

Other macrolides (e.g., *azithromycin* and *clarithromycin*) accelerate gastric emptying, but because there are no clinical trials compared to other medications or placebo indicating any benefit, their additional cost, potential for risk, and antibiotic resistance would preclude consideration for their use in motility disorders.

Miscellaneous Agents for Stimulating Motility

The hormone CCK is released from the intestine in response to meals and delays gastric emptying, causes contraction of the gallbladder, stimulates pancreatic enzyme secretion, increases intestinal motility, and promotes satiety. The C-terminal octapeptide of CCK, *sinicalide*, is useful for stimulating the gallbladder or pancreas and for accelerating barium transit through the small bowel for diagnostic testing of these organs. It is given by intravenous injection or infusion and has an onset of action of 5–15 min.

Currently, there are a number of agents under evaluation that stimulate motility whose mechanisms of action are based on well-established

neurohumoral mechanisms (Camilleri, 2014). These include a novel *motilin receptor agonist* (camicinal), a *ghrelin receptor agonist* (relamorelin), and novel *5HT₄ agonists* (velusetrag and naronapride).

Agents That Suppress Motility

Smooth muscle relaxants such as organic nitrates, type 5 phosphodiesterase inhibitors, and Ca^{2+} channel antagonists produce temporary, if partial, relief of symptoms in motility disorders such as achalasia, in which the lower esophageal sphincter fails to relax, resulting in severe difficulty in swallowing (Pandolfino and Gawron, 2015). Preparations of botulinum toxin (onabotulinumtoxinA), injected directly into the lower esophageal sphincter via an endoscope, in doses of 80–100 units, inhibit ACh release from nerve endings and can produce partial paralysis of the sphincter muscle, with significant improvements in symptoms and esophageal clearance (Zhao and Pasricha, 2003). Other GI conditions in which botulinum toxin A has been used include gastroparesis, sphincter of Oddi dysfunction, and anal fissures, although currently there are no strong trial data to support its efficacy.

Laxatives, Cathartics, and Therapy for Constipation

Overview of GI Water and Electrolyte Flux

Water normally accounts for 70%–85% of total stool weight. Net stool fluid content reflects a balance between luminal input (ingestion of fluids and lumenally directed secretion of water and electrolytes) and output (absorption) along the length of the GI tract. The daily challenge for the gut is to extract water, minerals, and nutrients from the luminal contents, leaving behind a manageable pool of fluid for proper expulsion of waste material via the process of defecation.

Normally, about 8–9 L of fluid enter the small intestine daily from exogenous and endogenous sources (Figure 50–3). Net absorption of the water occurs in the small intestine in response to osmotic gradients that result from the uptake and secretion of ions and the absorption of nutrients (mainly sugars and amino acids), with only about 1–1.5 L crossing the ileocecal valve. The colon then extracts most of the remaining fluid, leaving about 100 mL of fecal water daily. Under normal circumstances, these quantities are within the range of the total absorptive capacity of the small bowel (~16 L) and colon (4–5 L). Neurohumoral mechanisms, pathogens, and drugs can alter secretion and absorption of fluid by the intestinal epithelium (Figure 50–4). Altered motility also contributes in a general way to this process. With decreased motility and excess fluid removal, feces can become inspissated and impacted, leading to constipation. When the capacity of the colon to absorb fluid is exceeded, diarrhea occurs.

Figure 50–3 Typical volume and composition of fluid that traverses the small and large intestines daily. Of the 9 L of fluid typically presented to the small intestine each day, 2 L are from the diet and 7 L are from secretions (salivary, gastric, pancreatic, and biliary). The absorptive capacity of the colon is 4–5 L per day.

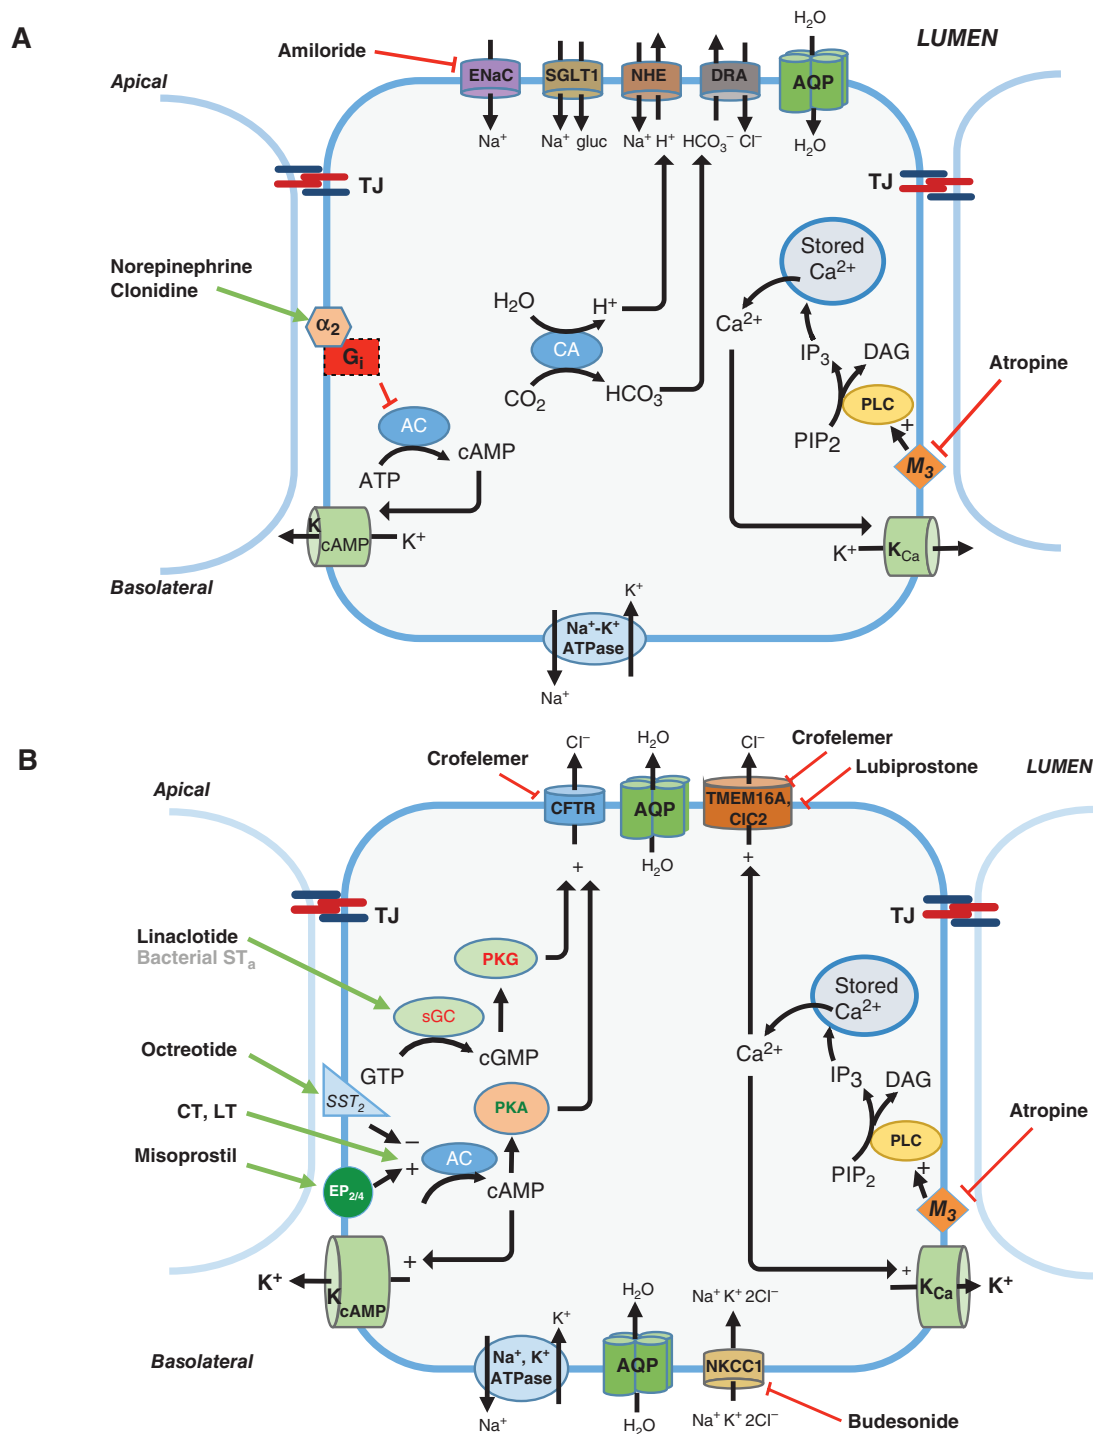

Figure 50-4 Mechanism of action of drugs that alter intestinal epithelial secretion and absorption. **A.** Agents affecting intestinal epithelial secretion. Secretion is driven in secretory enterocytes by the Na⁺ gradient established by the Na⁺-K⁺-ATPase. This Na⁺ gradient drives the symporter NKCC1 (SLC12A2), which allows for the accumulation of Cl⁻ in the cell. Regulation of chloride channels in the apical (luminal) membrane drives Cl⁻ secretion. Vectorial movement of chloride drives the secretion of water through the paracellular route and through AQP water channels. Chloride secretion is rapidly regulated through phosphorylation of CFTR by the cyclic nucleotide-dependent protein kinases, PKA and PKG. Thus, drugs that stimulate adenyl cyclase (i.e., misoprostil, acting through prostanoide EP₂ or EP₄ receptors) or GC (linaclootide) will stimulate Cl⁻ and water secretion. Several bacterial toxins cause water efflux and diarrhea by these mechanisms: cholera toxin (CT) and heat-labile *Escherichia coli* toxin (LT) stimulate cyclic AMP synthesis in the enterocyte by ADP-ribosylating G_q, blocking its GTPase activity and leading to constitutive activation of adenyl cyclase; the heat-stable enterotoxins (e.g., ST_a) stimulate the membrane-bound form of guanylyl cyclase. Drugs that inhibit adenyl cyclase (e.g., octreotide, acting at SST₂ receptors) inhibit secretion. Calcium-dependent chloride channels (TMEM 16A, ClC₂) are regulated by increases in cytosolic Ca²⁺, such as that induced by activation of muscarinic M₃ receptors that atropine blocks. Increases in cytosolic cyclic AMP and Ca²⁺ also regulate cyclic AMP-dependent and Ca²⁺-dependent K⁺ channels; this regulation is essential in maintaining the Na⁺ gradient necessary to facilitate secretion. Apical chloride channels (CFTR, TMEM 16A) can also be inhibited by drugs such as lubiprostone and crofelermer. Drugs such as budesonide inhibit NKCC1 function and thereby reduce secretion. **B.** Agents affecting intestinal epithelial absorption. Absorption is also driven by Na⁺-K⁺-ATPase in absorptive enterocytes, which creates the Na⁺ gradient that facilitates Na⁺ absorption through ENaC or through coupled transporters such as the Na⁺-glucose cotransporter SGLT1 (SLC5A1) and members of the NHE family. ENaC is blocked by amiloride and similar compounds. NHE and the bicarbonate-Cl⁻ exchanger, DRA, depend on the action of carbonic anhydrase (CA), which generates H⁺ and HCO₃⁻ from water and CO₂ in the cytosol. Water enters the cell through apical AQPs. As in secretion, regulation of K⁺ channels by cyclic AMP and Ca²⁺ is essential. Thus, drugs that act on α₂ adrenergic receptors (e.g., clonidine) will reduce adenyl cyclase activity and lower enterocyte cyclic AMP levels, thereby reducing absorption.

Constipation: General Principles of Pathophysiology and Treatment

Patients use the term *constipation* not only for decreased frequency, but also for difficulty in initiation or passage of firm or small-volume feces or a feeling of incomplete evacuation.

Constipation has many reversible or secondary causes, including lack of dietary fiber, drugs, hormonal disturbances, neurogenic disorders, and systemic illnesses. In most cases of chronic constipation, no specific cause is found. Up to 60% of patients presenting with constipation have normal colonic transit. These patients either have IBS or define constipation in terms other than stool frequency. In the rest, attempts usually are made to categorize the underlying pathophysiology either as a disorder of delayed colonic transit because of an underlying defect in colonic motility or, less commonly, as an isolated disorder of defecation or evacuation (outlet disorder) due to dysfunction of the neuromuscular apparatus of the rectoanal region.

Colonic motility is responsible for mixing luminal contents to promote absorption of water and moving them from proximal to distal segments by means of propulsive contractions (Dinning et al., 2009). Mixing in the colon is accomplished in a way similar to that in the small bowel: by short- or long-duration, stationary (nonpropulsive) contractions. In any given patient, the predominant factor often is not obvious. Consequently, the pharmacological approach to constipation remains empirical and is usually based on nonspecific principles.

Constipation generally may be corrected by adherence to a fiber-rich (20–35 g daily) diet, adequate fluid intake, appropriate bowel habits and training, and avoidance of constipating drugs (Emmanuel et al., 2009; Lacy et al., 2014; Menees et al., 2012). Constipation related to medications can be corrected by use of alternative drugs where possible or adjustment of dosage. If nonpharmacological measures alone are inadequate, they may be supplemented with bulk-forming agents or osmotic laxatives.

When stimulant laxatives are used, they should be administered at the lowest effective dosage and for the shortest period of time to avoid abuse. In addition to perpetuating dependence on drugs, the laxative habit may lead to excessive loss of water and electrolytes; secondary aldosteronism may occur if volume depletion is prominent. Steatorrhea, protein-losing enteropathy with hypoalbuminemia, and osteomalacia due to excessive loss of calcium in the stool have been reported. Laxatives frequently are employed before surgical, radiological, and endoscopic procedures where an empty colon is desirable. The terms *laxatives*, *cathartics*, *purgatives*, *aperients*, and *evacuants* often are used interchangeably. There is a distinction, however, between *laxation* (the evacuation of formed fecal material from the rectum) and *catharsis* (the evacuation of unformed, usually watery, fecal material from the entire colon). Most of the commonly used agents promote laxation, but some are actually cathartics that act as laxatives at low doses.

Laxatives relieve constipation and promote evacuation of the bowel via the following:

- enhancing retention of intraluminal fluid by hydrophilic or osmotic mechanisms;
- decreasing net absorption of fluid by effects on small- and large-bowel fluid and electrolyte transport; and
- altering motility by inhibiting segmenting (nonpropulsive) contractions or stimulating propulsive contractions.

Laxatives can be classified based on their actions (Table 50–1) or by the pattern of effects produced by the usual clinical dosage (Table 50–2), with some overlap between classifications.

A variety of laxatives, both osmotic agents and stimulants, increases the activity of NO synthase and the biosynthesis of PAF (see Chapter 37) in the gut. PAF is a phospholipid pro-inflammatory mediator that stimulates colonic secretion and GI motility (Izzo et al., 1998). NO also may stimulate intestinal secretion and inhibit segmenting contractions in the colon, thereby promoting laxation. Agents that reduce the expression of NO synthase or its activity can prevent the laxative effects of castor oil, cascara, magnesium sulfate, and bisacodyl (but not senna).

TABLE 50–1 ■ CLASSIFICATION OF LAXATIVES

1. Luminally active agents Hydrophilic colloids; bulk-forming agents (bran, psyllium, etc.) Osmotic agents (nonabsorbable inorganic salts or sugars) Stool-wetting agents (surfactants) and emollients (docusate, mineral oil)
2. Nonspecific stimulants or irritants (with effects on fluid secretion and motility) Diphenylmethanes (bisacodyl) Anthraquinones (senna and cascara) Castor oil
3. Prokinetic agents (acting primarily on motility) 5HT ₄ receptor agonists Dopamine receptor antagonists Motilides (erythromycin)

Dietary Fiber and Supplements

Bulk, softness, and hydration of feces depend on the fiber content of the diet. Fiber is that part of food that resists enzymatic digestion and reaches the colon largely unchanged. Colonic bacteria ferment fiber to varying degrees, depending on its chemical nature and water solubility. Fermentation of fiber has two important effects: (1) It produces short-chain fatty acids that are trophic for colonic epithelium; (2) it increases bacterial mass. Although fermentation of fiber generally decreases stool water, short-chain fatty acids may have a prokinetic effect, and increased bacterial mass may contribute to increased stool volume. However, fiber that is not fermented can attract water and increase stool bulk. The net effect on bowel movement therefore varies with different compositions of dietary fiber (Table 50–3). In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

Bran, the residue left when flour is made from cereal grains, contains more than 40% dietary fiber. Wheat bran, with its high lignin content, is most effective at increasing stool weight (a dose of 1–3 g up to three times a day). Fruits and vegetables contain more *pectins* and *hemicelluloses*, which are more readily fermentable and produce less effect on stool transit. *Psyllium husk*, derived from the seed of the plantago herb (*Plantago ovata*; known as ispaghula or isabgol in many parts of the world), is a component of many commercial products for constipation. Psyllium husk contains

TABLE 50–2 ■ CLASSIFICATION AND COMPARISON OF REPRESENTATIVE LAXATIVES

LAXATIVE EFFECT AND LATENCY IN USUAL CLINICAL DOSAGE		
SOFTENING OF FECES, 1–3 DAYS	SOFT OR SEMIFLUID STOOL, 6–8 H	WATERY EVACUATION, 1–3 H
Bulk-forming laxatives Bran Psyllium preparations Methylcellulose Calcium polycarbophil	Stimulant laxatives Diphenylmethane derivatives Bisacodyl	Osmotic laxatives^a Magnesium sulfate Milk of magnesia Magnesium citrate
Surfactant/osmotic laxatives Docusates Poloxamers Lactulose	Anthraquinone derivatives Senna Cascara sagrada	Castor oil

^aEmployed in high dosage for rapid cathartic effect and in lower dosage for laxative effect.

TABLE 50-3 ■ PROPERTIES OF DIFFERENT DIETARY FIBERS

TYPE OF FIBER	WATER SOLUBILITY	% FERMENTED
Nonpolysaccharides		
Lignin	Poor	0
Cellulose	Poor	15
Noncellulose polysaccharides		
Hemicellulose	Good	56–87
Mucilages and gums	Good	85–95
Pectins	Good	90–95

In general, insoluble, poorly fermentable fibers, such as lignin, are most effective in increasing stool bulk and transit.

a hydrophilic mucilloid that undergoes significant fermentation in the colon, leading to an increase in colonic bacterial mass; the usual dose is 2.5–4 g (1–3 teaspoons full in 250 mL of fruit juice), titrated upward until the desired goal is reached. A variety of semisynthetic celluloses—such as methylcellulose (~2 g three times a day) and the hydrophilic resin calcium polycarbophil (1–2 g/d), a polymer of acrylic acid resin—also are available. These poorly fermentable compounds absorb water and increase fecal bulk. Malt soup extract, an extract of malt from barley grains that contains small amounts of polymeric carbohydrates, proteins, electrolytes, and vitamins, is another orally administered bulk-forming agent. The onset of action of these bulk-forming laxatives is generally between 12 and 72 h. Bloating is the most common side effect of soluble fiber products (perhaps due to colonic fermentation), but it usually decreases with time (Lacy et al., 2014).

Osmotically Active Agents

Polyethylene Glycol–Electrolyte Solutions. Long-chain PEGs (MW ~ 3350 Da) are poorly absorbed and retain water via their high osmotic nature (Paré and Fedorak, 2014). When used in high volume, aqueous solutions of PEGs with electrolytes produce an effective catharsis and have replaced oral sodium phosphates as the most widely used preparations for colonic cleansing prior to radiological, surgical, and endoscopic procedures.

Usually, 240 mL of this solution is taken every 10 min until 4 L is consumed or the rectal effluent is clear. To avoid net transfer of ions across the intestinal wall, these preparations contain an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride. The osmotic activity of the PEG molecules retains the added water, and the electrolyte concentration ensures little or no net ionic shifts. A powder form of PEG 3350 is now available as an OTC product for the treatment of occasional constipation and for the treatment of more chronic constipation; the PEG preparation is suitable because it has such a benign side-effect profile. The usual dose is 8.5–34 g of powder per day in 8 oz of water, with an expected onset of action of 1–4 days. These laxatives may cause nausea, cramping, and bloating.

Saline Laxatives. Laxatives containing magnesium cations or phosphate anions commonly are called *saline laxatives*: magnesium sulfate, magnesium hydroxide, magnesium citrate, and sodium phosphate. Their cathartic action is believed to result from osmotic water retention, which then stimulates peristalsis. Other mechanisms may contribute, including the production of inflammatory mediators.

Magnesium-containing laxatives may stimulate the release of CCK, which leads to intraluminal fluid and electrolyte accumulation and to increased intestinal motility. For every additional milliequivalent of Mg²⁺ in the intestinal lumen, fecal weight increases by about 7 g. The usual dose of Mg²⁺ salts contains 40–120 mEq of Mg²⁺ and produces 300–600 mL of stool within 0.5–6 h. The most common side effects of these laxatives is urgency to defecate and watery stools.

Phosphate salts are better absorbed than Mg²⁺-based agents and therefore need to be given in larger doses to induce catharsis. However, because

of the risks of acute phosphate nephropathy, oral phosphates are not recommended for the treatment of constipation and should be completely avoided in patients at risk (the elderly, patients with known bowel pathology or renal dysfunction, and patients on angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and NSAIDs).

The Mg²⁺-containing preparations must be used with caution or avoided in patients with renal insufficiency, cardiac disease, or preexisting electrolyte abnormalities and in patients on diuretic therapy.

Nondigestible Sugars and Alcohols. *Lactulose* is a synthetic disaccharide of galactose and fructose that resists intestinal disaccharidase activity. This and other nonabsorbable sugars such as *sorbitol* and *mannitol* are hydrolyzed in the colon to short-chain fatty acids, which stimulate colonic propulsive motility by osmotically drawing water into the lumen. Sorbitol and lactulose are equally efficacious in the treatment of constipation caused by opioids and vincristine, of constipation in the elderly, and of idiopathic chronic constipation. They are available as 70% solutions, which are given in doses of 15–30 mL at night, with increases as needed up to 60 mL/d in divided doses. Effects may not be seen for 24 to 48 h after dosing begins. Abdominal discomfort or distention and flatulence are relatively common but usually subside with continued administration.

Lactulose also is used to treat hepatic encephalopathy. Patients with severe liver disease have an impaired capacity to detoxify ammonia coming from the colon, where it is produced by bacterial metabolism of fecal urea. The drop in luminal pH that accompanies hydrolysis to short-chain fatty acids in the colon results in “trapping” of the ammonia by its conversion to the polar ammonium ion. Combined with the increases in colonic transit, this therapy significantly lowers circulating ammonia levels. The therapeutic goal in this condition is to give sufficient amounts of lactulose (usually 20–30 g three to four times per day) to produce two to three soft stools a day with a pH of 5–5.5.

Stool-Wetting Agents and Emollients

Docusate. Docusate salts are anionic surfactants that lower the surface tension of the stool to allow mixing of aqueous and fatty substances, softening the stool, and permitting easier defecation. These agents also stimulate intestinal fluid and electrolyte secretion (possibly by increasing mucosal cyclic AMP) and alter intestinal mucosal permeability. Docusate sodium (dioctyl sodium sulfosuccinate, 100 mg twice per day) and docusate calcium (dioctyl calcium sulfosuccinate, 240 mg per day) are well tolerated but have marginal efficacy in most cases of constipation.

Mineral Oil. Mineral oil is a mixture of aliphatic hydrocarbons obtained from petrolatum. The oil is indigestible and absorbed only to a limited extent. When mineral oil is taken orally for 2–3 days, it penetrates and softens the stool and may interfere with resorption of water. The side effects of mineral oil preclude its regular use and include interference with absorption of fat-soluble substances (such as vitamins), elicitation of foreign-body reactions in the intestinal mucosa and other tissues, and leakage of oil past the anal sphincter. Rare complications such as lipid pneumonitis due to aspiration also can occur, so “heavy” mineral oil should not be taken at bedtime and “light” (topical) mineral oil should never be administered orally.

Stimulant (Irritant) Laxatives

Stimulant laxatives have direct effects on enterocytes, enteric neurons, and GI smooth muscle and probably induce limited low-grade inflammation in the small and large bowel to promote accumulation of water and electrolytes and stimulate intestinal motility (Lacy et al., 2014; Paré and Fedorak, 2014). This group includes *diphenylmethane derivatives*, *anthraquinones*, and *ricinoleic acid*.

Diphenylmethane Derivatives. *Bisacodyl.* Bisacodyl is marketed as enteric-coated and regular tablets and as a suppository for rectal administration. The usual oral daily dose of bisacodyl is 10–30 mg for adults and 5–10 mg for children ages 6–12 years old. The drug requires hydrolysis by endogenous esterases in the bowel for activation, so the laxative effects after an oral dose usually are produced in 6–10 h. Suppositories (10 mg) work within 15–60 min. Due to the possibility of developing an atonic nonfunctioning colon, bisacodyl should not be used for more than

10 consecutive days. Bisacodyl is mainly excreted in the stool; about 5% is absorbed and excreted in the urine as a glucuronide. Overdosage can lead to catharsis and fluid and electrolyte deficits. The diphenylmethanes can damage the mucosa and initiate an inflammatory response in the small bowel and colon, and they can also cause colonic ischemia.

Sodium Picosulfate. Sodium picosulfate is a diphenylmethane derivative that is hydrolyzed by colonic bacteria to its active form and acts locally only in the colon. Effective doses of the diphenylmethane derivatives vary as much as 4- to 8-fold in individual patients. This agent is only used for bowel cleansing prior to colonoscopy. Significant adverse reactions include hypermagnesemia and reduced glomerular filtration rate. Caution should be exercised in patients with cardiac arrhythmias and those with renal impairment. *Phenolphthalein*, once among the most popular components of laxatives, has been withdrawn from the market in the U.S. because of potential carcinogenicity. *Oxyphenisatin* was withdrawn due to hepatotoxicity.

Anthraquinone Laxatives. These derivatives of plants such as aloe, cascara, and senna share a tricyclic anthracene nucleus modified with hydroxyl, methyl, or carboxyl groups to form monoanthrones, such as rhein and frangula. For medicinal use, monoanthrones (oral mucosal irritants) are converted to more innocuous dimeric (dianthrones) or glycoside forms. This process is reversed by bacterial action in the colon to generate the active forms.

Senna. Senna is obtained from the dried leaflets on pods of *Cassia acutifolia* or *Cassia angustifolia* and contains the rhein dianthrone glycosides sennoside A and B. The 15–30 mg is given as a single dose or a divided dose twice daily; it has an onset of action of 6–12 h. Chronic use of senna may lead to melanosis coli, and adverse effects include nausea and vomiting and abdominal cramping.

Cascara sagrada. Cascara sagrada is obtained from the bark of the buckthorn tree and contains the glycosides barbaloin and chrysaloin. The synthetic monoanthrone danthron was withdrawn from the U.S. market because of concerns over possible carcinogenicity.

The FDA has categorized aloe and cascara sagrada products sold as laxatives as not generally recognized as safe and effective for OTC use because of a lack of scientific information about potential carcinogenicity. These ingredients may still be sold OTC in the U.S., but legally they cannot be labeled for use as laxatives. This judgment is medically prudent but may provoke a wistfulness among Joyceans, who recall that cascara sagrada, the *sacred bark*, worked well for Leopold Bloom, in Dublin, on the morning of June 16, 1904:

Midway, his last resistance yielding, he allowed his bowels to ease themselves quietly as he read, reading still patiently that slight constipation of yesterday quite gone. Hope its not too big to bring on piles again. No, just right. So. Ah! Costive one tabloid of cascara sagrada. Life might be so. (*Ulysses*, James Joyce, 1922)

Castor Oil. A bane of childhood since the time of the ancient Egyptians, castor oil is derived from the bean of the castor plant, *Ricinus communis*. The castor bean is the source of an extremely toxic protein, ricin, as well as the oil (chiefly of the triglyceride of ricinoleic acid). The triglyceride is hydrolyzed in the small bowel by the action of lipases into glycerol and the active agent, *ricinoleic acid*, which acts primarily in the small intestine to stimulate secretion of fluid and electrolytes and speed intestinal transit. When taken on an empty stomach, as little as 4 mL of castor oil may produce a laxative effect within 1–3 h; however, the usual dose for a cathartic effect is 15–60 mL for adults. Because of its unpleasant taste and its potential toxic effects on intestinal epithelium and enteric neurons, castor oil is not recommended now.

Enemas and Suppositories. Enemas are employed either by themselves or as adjuncts to bowel preparation regimens to empty the distal colon or rectum of retained solid material. Bowel distention by any means will produce an evacuation reflex in most people, and almost any form of enema, including normal saline solution, can achieve this. Specialized enemas contain additional substances that are either osmotically active or irritant;

however, their safety and efficacy have not been studied. Repeated enemas with hypotonic solutions can cause hyponatremia; repeated enemas with sodium phosphate-containing solution can cause hypocalcemia.

Glycerin. Glycerin is absorbed when given orally but acts as a hygroscopic agent and lubricant when given rectally. The resultant water retention stimulates peristalsis and usually produces a bowel movement in less than an hour. Glycerin is for rectal use only and is given in a single daily dose as a 2- or 3-g rectal suppository or as 5–15 mL of an 80% solution in enema form. Rectal glycerin may cause local discomfort, burning, or hyperemia and (minimal) bleeding. *CEO-TWO* suppositories contain sodium bicarbonate and potassium bitartrate and make use of rectal distention to initiate laxation. When administered rectally, the suppository produces CO₂, which initiates a bowel movement in 5–30 min.

Prokinetic and Secretory Agents for Constipation

The term *prokinetic* is reserved for agents that enhance GI transit via interaction with specific receptors involved in the regulation of motility (Acosta and Camilleri, 2015; Altan et al., 2012; Corsetti and Tack, 2014; Tack and Zaninotto, 2015).

The potent 5HT₄ receptor agonist *prucalopride* (1–4 mg per day) may be useful for the treatment of chronic constipation. *Misoprostol*, a synthetic prostaglandin analogue, is primarily used for protection against gastric ulcers resulting from the use of NSAIDs and for the medical termination of pregnancy (see Chapters 37, 44, and 49). Prostaglandins can stimulate colonic contractions, particularly in the descending colon; this may account not only for the diarrhea that limits the usefulness of misoprostol as a gastroprotectant, but also for misoprostol's utility in patients with intractable constipation. Doses of 200 µg daily or every other day can be effective when used with PEG. Misoprostol should not be used in women who could become pregnant because it induces labor. It can also increase menstrual bleeding. *Colchicine*, a microtubule formation inhibitor used for gout (see Chapter 38), also has been shown to be effective in constipation (1 mg per day), but its toxicity limits widespread use.

Three recently introduced secretory agents, *lubiprostone*, *linaclotide*, and *plecanatide*, with novel mechanisms of action restricted to the gut lumen, have demonstrated effectiveness in the treatment of chronic constipation in adults.

Lubiprostone. Mechanism of Action and Pharmacology. Lubiprostone is a prostanoid activator of Cl[−] channels. The drug appears to bind to the EP₄ receptor for PGE₂, a GPCR that couples to G_s, activating adenylyl cyclase and leading to enhanced apical Cl[−] conductance. The drug promotes the secretion of a chloride-rich fluid, thereby improving stool consistency and promoting increased frequency by reflexly activating motility (Wilson and Schey, 2015).

Therapeutic Uses and Adverse Effects. A dose of 8 µg twice daily was found to be effective in constipation-predominant IBS, although higher doses (24 µg twice daily) are given for chronic constipation and opioid-induced constipation (see discussion that follows). The drug is poorly bioavailable, acting only in the lumen of the bowel. Side effects of lubiprostone include nausea (in up to 30% of patients), headache, diarrhea, allergic reactions, and dyspnea.

Linaclotide. Mechanism of Action and Pharmacology. Another class of secretory agent is linaclotide, a 14-amino acid peptide agonist of the membrane-spanning GC-C. In the intestinal epithelium, GC-C is activated physiologically by guanylin and uroguanylin, pathologically by heat-stable bacterial toxins that cause diarrhea, and pharmacologically by linaclotide. Activation of GC-C results in increased synthesis of cyclic GMP, resulting in enhanced chloride and bicarbonate secretion into the intestinal lumen, leading in turn to water secretion and enhanced motility. Some cellular cyclic GMP may be exported and may reduce visceral pain by an action on primary afferent nerves innervating the GI tract (Yu and Rao, 2014).

Therapeutic Uses and Adverse Effects. This compound is approved in the treatment of constipation-predominant IBS and chronic constipation in adults at doses of 290 and 145 µg daily, respectively. Common side effects include diarrhea (which can be serious), gas, abdominal pain, and headaches. Linaclotide is contraindicated in children under 6 years old and is not recommended for older children.

Plecanatide. Mechanism of Action and Pharmacology. Plecanatide is a 16-amino acid peptide related to uroguanylin; it has essentially the same mechanism of action as linaclotide.

Therapeutic Uses and Adverse Effects. This agent is approved for the treatment of chronic idiopathic constipation in adults at a dose of 3 mg daily, with or without food. The most common adverse reaction is diarrhea (5%; severe in 0.6%). Plecanatide is contraindicated in children less than 6 years old and not advised in older children up to 18 years of age.

Opioid-Induced Constipation

Opioid analgesics can cause severe constipation. Laxatives and dietary strategies are frequently ineffective in the management of opioid-induced constipation. In addition to *lubiprostone*, a promising alternative strategy is the prevention of opioid-induced constipation with peripherally acting MOR antagonists that specifically target the underlying reason for this condition, without limiting centrally produced analgesia and limiting the symptoms of opioid withdrawal (Nelson and Camilleri, 2016).

Methylnaltrexone

Mechanism of Action and Pharmacology. The peripherally restricted MOR antagonist methylnaltrexone is approved for the treatment of opioid-induced constipation. The efficacy of this compound has been shown in randomized placebo-controlled trials (Nelson and Camilleri, 2016).

ADME. In patients who respond to the drug, its onset of action is 30–60 min. It is excreted largely unchanged in the urine and feces, but does undergo some hepatic metabolism including sulfation. The time to peak plasma concentration is 30 min and the $t_{1/2}$ is about 8 h.

Therapeutic Uses and Adverse Effects. *Methylnaltrexone* is given as a subcutaneous injection (12 mg per day) in adults with chronic noncancer pain after discontinuing other laxatives. In advanced illness (palliative care), dosing varies according to body weight (0.15 mg/kg), with dosing every other day to a maximum of daily injection if required. When administered repeatedly every other day for 2 weeks, bowel movements occurred in about 50% of patients, compared with 8%–15% of patients receiving placebo. Abdominal pain, flatulence, and nausea frequently accompany this treatment. Serious diarrhea sometimes occurs that requires discontinuing therapy. Patients with known or suspected GI obstruction are at increased risk of perforation. Opioid withdrawal may be precipitated in patients with a compromised blood-brain barrier.

Naldemedine

Mechanism of Action and Pharmacology. Naldemedine is a peripherally-restricted opioid antagonist. It is a derivative of naltrexone made more polar and larger in mass with the addition of a side-chain. It is also a substrate for the Pgp efflux transporter. These two properties limit its access to the CNS.

ADME. Following oral administration in the fasted state, naldemedine is rapidly absorbed, reaching peak concentrations in ~45 min. Food prolongs the time to peak (to ~2.5 h) but does not reduce the overall extent of absorption. Naldemedine is metabolized by hepatic CYP3A and is excreted in both the urine (57%) and feces (35%); its $t_{1/2}$ is 11 h.

Therapeutic Uses and Adverse Effects. Naldemedine is approved for the treatment of opioid-induced constipation in adult patients with chronic noncancer pain; dose, 0.2 mg/d, orally. Common adverse reactions are abdominal pain, diarrhea, nausea, vomiting, and gastroenteritis. Naldemedine is contraindicated in patients with known or suspected obstruction of the GI tract. Opioid withdrawal may be precipitated with the use of this compound.

Naloxegol

Mechanism of Action and Pharmacology. *Naloxegol* is composed of the MOR antagonist naloxone conjugated to a PEG polymer. This limits blood-brain barrier permeability because it is a substrate for the P-glycoprotein efflux transporter, so it behaves as a peripherally restricted MOR antagonist. It is approved for the treatment of opioid-induced constipation. Randomized placebo-controlled trials have demonstrated the efficacy of this compound (Nelson and Camilleri, 2016).

ADME. The drug is given orally on an empty stomach and is rapidly absorbed. The time to peak plasma concentration is about 2 h with a secondary peak occurring 0.4–3 h after the first. Naloxegol is metabolized primarily by hepatic CYP3A; metabolites are excreted in the feces (68%) and urine (16%). The plasma $t_{1/2}$ is variable, 6–11 h.

Therapeutic Uses and Adverse Effects. *Naloxegol* is approved for opioid-induced constipation in adults, given orally 12.5 or 25 mg once per day after discontinuing other laxatives. Diarrhea, abdominal pain, flatulence, and nausea and vomiting are the major adverse reactions. Precautions are the same as for *methylnaltrexone*: Patients with known or suspected GI obstruction are at increased risk of perforation, and opioid withdrawal may be precipitated in patients with a compromised blood-brain barrier.

Naloxone and Oxycodone

Mechanism of Action and Pharmacology. A fixed-ratio (2:1 of oxycodone:naloxone) combination drug is given orally to relieve opioid-induced constipation when opioid pain relief is still required. The *naloxone* displaces oxycodone from the MOR in the GI tract without limiting the degree of central analgesia (Nelson and Camilleri, 2016). This combination drug carries with it the risks inherent with all opioids, including addiction and respiratory depression. Full details of this agent are given in Chapter 20.

Therapeutic Uses and Adverse Effects. Naloxone-oxycodone is approved in Canada and other countries for opioid-induced constipation in adults, but currently not for this purpose in the U.S. This oral medication dosing is for pain control and is individualized. A single dose of 40 mg oxycodone/20 mg naloxone every 12 h should not be exceeded. Adverse GI reactions include nausea and vomiting, constipation, and diarrhea.

Other Agents for Opioid-induced Constipation. In clinical trials, the MOR antagonist *alvimopan* (see separate discussion in the following material) increased spontaneous bowel movements and improved other symptoms of opioid-induced constipation without compromising analgesia. *Alvimopan* is approved for use in the U.S. for postoperative bowel recovery. However, due to significant cardiovascular adverse events, this drug is not FDA-approved for opioid-induced constipation, and further phase III trials are under way. In addition, the 5HT₄ agonist *prucalopride* and the GC-C agonist *linaclotide* (see previous discussion) are in clinical trials for this condition, as are other novel peripherally active MOR antagonists.

Postoperative Ileus

Postoperative ileus refers to the intolerance to oral intake and nonmechanical obstruction of the bowel that occurs after abdominal and nonabdominal surgery. The pathogenesis is complex and is a combination of activation of neural inhibitory reflexes involving sympathetic nerves, enteric MOR, and the activation of local inflammatory mechanisms that reduce smooth muscle contractility (Bragg et al., 2015). The condition is exacerbated by opioids, which are the mainstay of postoperative analgesia. Prokinetic agents typically do not have much effect in this condition, but a new therapeutic agent has been introduced to reduce GI recovery time after surgery.

Alvimopan

Mechanism of Action and Pharmacology. *Alvimopan* is an orally active, peripherally restricted MOR antagonist that is approved to accelerate the time to upper and lower GI recovery following partial large- or small-bowel resection surgery with primary anastomosis (Curran et al., 2008).

ADME. The drug is hydrolyzed by the gut flora to the active amide. The active metabolite is further metabolized by hepatic glucuronidases. The peak plasma concentration of the active metabolite occurs in about 36 h. The drug's $t_{1/2}$ is 10–18 h; the drug is excreted in the urine and feces.

Therapeutic Uses and Adverse Effects. The drug is given 30 min to 5 h prior to surgery (12 mg) and then twice daily for up to a maximum of 7 days or until discharge, not to exceed 15 doses total. Adverse effects include hypokalemia, dyspepsia, and anemia. Because of the risk of myocardial infarctions, this drug is only available through a restricted-access program in the U.S.

Antidiarrheal Agents

Diarrhea: General Principles and Approach to Treatment

Diarrhea (Greek and Latin: *dia*, “through,” and *rheia*, “to flow or run”) does not require any definition to people who suffer from “the too rapid evacuation of too fluid stools.” Scientists usually define diarrhea as excessive fluid weight, with 200 g per day representing the upper limit of normal stool water weight for healthy adults in the Western world. Because stool weight is largely determined by stool water, most cases of diarrhea result from disorders of intestinal water and electrolyte transport.

An appreciation and knowledge of the underlying causative processes in diarrhea facilitates effective treatment (Thiagarajah et al., 2015). From a mechanistic perspective, diarrhea can be caused by an increased osmotic load within the intestine (resulting in retention of water within the lumen); excessive secretion of electrolytes and water into the intestinal lumen; exudation of protein and fluid from the mucosa; and altered intestinal motility resulting in rapid transit (and decreased fluid absorption). In most instances, multiple processes are affected simultaneously, leading to a net increase in stool volume and weight accompanied by increases in fractional water content.

Many patients with sudden onset of diarrhea have a *benign*, self-limited illness requiring no treatment or evaluation. *Acute diarrhea* is frequently due to infection with bacteria, viruses, or protozoa. In more severe cases of diarrhea and in infants and small children, dehydration and electrolyte imbalances are the principal risk. *Oral rehydration therapy* therefore is a cornerstone for patients with acute illnesses resulting in significant diarrhea. This therapy exploits the fact that nutrient-linked cotransport of water and electrolytes remains intact in the small bowel in most cases of acute diarrhea. Na^+ absorption links to glucose uptake by the enterocyte; this is followed by movement of water in the same direction. A balanced mixture of glucose and electrolytes in volumes matched to losses therefore can prevent dehydration. This can be provided by many commercial premixed formulas using glucose-electrolyte or rice-based physiological solutions.

Pharmacotherapy of diarrhea in adults should be reserved for patients with significant or persistent symptoms (Menees et al., 2012). Nonspecific antidiarrheal agents typically do not address the underlying pathophysiology responsible for the diarrhea. Many of these agents act by decreasing intestinal motility and should be avoided in acute diarrheal illnesses caused by invasive organisms. In such cases, these agents may mask the clinical picture, delay clearance of organisms, and increase the risk of systemic invasion by the infectious organisms.

Empiric Antibiotic Therapy

The use of empiric antibiotic therapy for acute diarrhea (therapy given in the absence of diagnostic evaluation) must be carefully balanced with the risks. In patients with suspected or proven enterohemorrhagic *Escherichia coli*, antibiotics should be avoided because of the risk of hemolytic uremic syndrome. Similarly, in patients with suspected *Clostridium difficile*, other antibiotics should be discontinued if possible. Treatment of traveler's diarrhea, bacterial diarrhea, and those with more severe conditions is appropriate under some conditions, based on the severity of diarrhea and the duration of the symptoms (Steffen et al., 2015). The first-line therapy for acute (most commonly, traveler's) diarrhea in adults is oral *fluoroquinolone* antibiotics (see Chapter 56 for specific drug details): *ciprofloxacin* (500 mg twice daily for up to 3 days), *norfloxacin* (400 mg twice daily for up to 3 days), *ofloxacin* (200 mg twice daily for up to 3 days), or *levofloxacin* (500 mg daily for up to 3 days). *Azithromycin* (500 mg per day for 1–3 days, or a maximum of 1000-mg single dose) and *rifaximin* (200 mg three times per day for up to 3 days) are alternative therapeutic agents. Trimethoprim/sulfamethoxazole is also FDA-approved for this use (1 double-strength tab [160/8000 mg] twice daily for 5 days). In children, the treatment of traveler's diarrhea remains controversial. *Azithromycin* (10 mg/kg to a maximum of 500-mg single dose) is the preferred treatment of children with traveler's diarrhea.

Bismuth Subsalicylate

Mechanism of Action and Pharmacology. Bismuth compounds are used to treat a variety of GI disorders, although their mechanism of action remains poorly understood (Menees et al., 2012). Bismuth subsalicylate is a popular OTC preparation that consists of trivalent bismuth and salicylate suspended in a mixture of magnesium aluminum silicate clay. In the low pH of the stomach, the bismuth subsalicylate reacts with hydrochloric acid to form bismuth oxychloride and salicylic acid.

Bismuth is thought to have antisecretory, anti-inflammatory, and antimicrobial effects. Bismuth also relieves nausea and abdominal cramps. The clay in bismuth subsalicylate and generic formulations may have some additional benefits in diarrhea, but this is not clear. Bismuth subsalicylate is used for the prevention and treatment of traveler's diarrhea, but it also is effective in other forms of episodic diarrhea and in acute gastroenteritis.

Therapeutic Uses and Adverse Effects. A recommended dose of the bismuth subsalicylate (30 mL of regular-strength liquid or 2 tablets) contains approximately equal amounts of bismuth and salicylate (262 mg each). For control of indigestion, nausea, or diarrhea, the dose is repeated every 30–60 min, as needed, up to eight times a day. Dark stools (sometimes mistaken for melena) and black staining of the tongue in association with bismuth compounds are caused by bismuth sulfide formed in a reaction between the drug and bacterial sulfides in the GI tract. Although 99% of the bismuth passes unaltered and unabsorbed into the feces, the salicylate is absorbed in the stomach and small intestine. Thus, the product carries the same warning regarding Reye syndrome as other salicylates and may also cause CNS side effects, hearing loss, and tinnitus.

Probiotics

The GI tract contains a vast and complex commensal microflora necessary for health. Alterations in the balance or composition of the microflora are responsible for antibiotic-associated diarrhea and possibly other disease conditions (see Chapter 51). Probiotic preparations containing a variety of bacterial strains have shown some degree of benefit in acute diarrheal conditions, antibiotic-associated diarrhea, and infectious diarrhea (Menees et al., 2012). In clinical trials, preparations containing *Lactobacillus* GG and *Saccharomyces boulardii* have been found to be effective for these conditions.

Antimotility and Antisecretory Agents

Opioids. Opioids continue to be widely used in the treatment of diarrhea. They act by several different mechanisms, mediated principally through either MORs or DORs on enteric nerves, epithelial cells, and muscle (see Chapter 20). These mechanisms include effects on intestinal motility (MOR), intestinal secretion (DOR), or absorption (MOR and DOR). Commonly used antidiarrheals such as *diphenoxylate*, *difenoxin*, and *loperamide* act principally via peripheral MOR and are preferred over opioids that penetrate the CNS.

Loperamide. **Mechanism of Action and Pharmacology.** *Loperamide*, a compound with MOR activity, is an orally active antidiarrheal agent (Hanauer, 2008; Menees et al., 2012). The drug is 40–50 times more potent than morphine as an antidiarrheal agent and penetrates the CNS poorly. It increases small intestinal and mouth-to-cecum transit times. *Loperamide* also increases anal sphincter tone. In addition, *loperamide* has antisecretory activity against cholera toxin and some forms of *E. coli* toxin, presumably by acting on G_i -linked receptors to counter the stimulation of adenylyl cyclase activity by the toxins.

ADME. *Loperamide* is available OTC in capsule, solution, and chewable tablet forms. It acts quickly after an oral dose, with peak plasma levels achieved within 3–5 h. It has a $t_{1/2}$ of about 11 h and undergoes extensive hepatic metabolism.

Therapeutic Uses and Adverse Effects. The usual adult dose is 4 mg initially followed by 2 mg after each subsequent loose stool, up to 16 mg per day. If clinical improvement in acute diarrhea does not occur within 48 h, *loperamide* should be discontinued. Recommended maximum daily doses for children are 3 mg for ages 2–5 years, 4 mg for ages 6–8 years, and 6 mg for ages 8–12 years. *Loperamide* is not recommended for use in children younger than 2 years. *Loperamide* is effective against traveler's diarrhea,

used alone or in combination with antibiotics. It is used as adjunct treatment in many forms of chronic diarrheal disease (initially as for acute diarrhea, but with typical divided daily doses of 4–8 mg per day), with few adverse effects. *Loperamide* lacks significant abuse potential and is more effective in treating diarrhea than diphenoxylate. Overdosage, however, can result in constipation, CNS depression (especially in children), and paralytic ileus. In patients with active inflammatory bowel disease involving the colon (see Chapter 51), *loperamide* should be used with great caution, if at all, to avoid development of toxic megacolon.

Diphenoxylate and Difenoxin. Mechanism of Action and Pharmacology. *Diphenoxylate* and its active metabolite *difenoxin* (diphenoxylate acid) are related structurally to meperidine. As antidiarrheal agents, *diphenoxylate* and *difenoxin* are somewhat more potent than morphine (Menees et al., 2012). Both drugs are listed as schedule V controlled substances by the Drug Enforcement Agency, and both are coformulated with atropine to discourage habituation.

ADME. Both compounds are extensively absorbed after oral administration, with peak levels achieved within 1–2 h. *Diphenoxylate* is rapidly deesterified to *difenoxin*, which is eliminated with a $t_{1/2}$ of about 12 h.

Therapeutic Uses and Adverse Effects. Both drugs are indicated for the treatment of diarrhea. The usual dosage for adults is 2 tablets initially (*diphenoxylate* or *difenoxin*), then 1 tablet every 3–4 h, not to exceed 20 mg/d (*diphenoxylate*) or 8 mg/d (*difenoxin*). Acute diarrhea usually improves in 48 h if the medication is effective. If chronic diarrhea does not improve within 10 days at the maximum daily dose, then these agents are not likely to be effective. *Diphenoxylate* is also sold as an oral solution (2.5 mg per 5 mL), which is recommended if used cautiously in children. For children, the initial dose is 0.3–0.4 mg/kg/d in four divided doses to a maximum of 10 mg per day. Once symptoms are controlled, dosing should be reduced; if no effect is seen in 48 h, the drug is unlikely to be effective. Both drugs can produce CNS effects when used in higher doses (40–60 mg per day) and thus have a potential for abuse or addiction. They are available in preparations containing small doses of atropine (considered subtherapeutic) to discourage abuse and deliberate overdosage: 25 µg of atropine sulfate per tablet with either 2.5 mg *diphenoxylate* hydrochloride or 1 mg of *difenoxin* hydrochloride. With excessive use or overdose, constipation and (in inflammatory conditions of the colon) toxic megacolon may develop. In high doses, these drugs cause CNS effects as well as anticholinergic effects from the atropine (nausea, dry mouth, blurred vision, etc.) (see Chapter 9).

Other Opioids. Opioids used for diarrhea include codeine (in doses of 30 mg given three or four times daily) and opium-containing compounds. *Paregoric* (camphorated opium tincture) contains the equivalent of 2 mg of morphine per 5 mL (0.4 mg/mL); *deodorized tincture of opium*, which is 25 times stronger, contains the equivalent of 50 mg of morphine per 5 mL (10 mg/mL). The two tinctures sometimes are confused in prescribing and dispensing, resulting in dangerous overdoses. The antidiarrheal dose of opium tincture for adults is 0.6 mL (equivalent to 6 mg morphine) four times daily; the adult dose of *paregoric* is 5–10 mL (equivalent to 2–4 mg morphine) one to four times daily. *Paregoric* is used in children at a dose of 0.25–0.5 mL/kg (equivalent to 0.1–0.2 mg morphine/kg) one to four times daily.

Enkephalins. Enkephalins are endogenous opioids that are important enteric neurotransmitters; they can inhibit intestinal secretion without affecting motility. *Racecadotril* is an example.

Mechanism of Action and Pharmacology. *Racecadotril* (acetorphan), a prodrug, is rapidly converted in the body to thiorphan, a dipeptide inhibitor of enkephalinase (an NEP; EC 3.4.24.11) that does not penetrate into the CNS. By inhibiting peripheral enkephalin degradation, thiorphan potentiates the effects of endogenous enkephalins on the MOR in the GI tract to produce an antidiarrheal effect predominantly as an antisecretory agent (Thiagarajah et al., 2015). In addition to enkephalins, substrates of NEP include neuropeptide Y, atrial and brain natriuretic peptides, substance P, and neurotensins, among others (Erdős and Skidgel, 1989). Thus, inhibition of enkephalinase activity could elevate the levels of these messengers as well, complicating interpretation of *racecadotril*'s effects on physiological systems.

Therapeutic Uses and Adverse Effects. *Racecadotril* is indicated for acute diarrhea. It is given orally as a 100 mg initial dose, which is repeated every 8 h as needed until diarrhea stops, for up to 7 days maximum. In children, it is given with oral rehydration solution according to body weight (1.5 mg/kg every 8 h), until symptoms improve or for a maximum of 7 days. This drug is available in many countries, but not the U.S., and is efficacious and safe in children with acute diarrhea. It produces less constipation than *loperamide* and has minimal other adverse effects (headache, itching).

α_2 Adrenergic Receptor Agonists

Mechanism of Action and Pharmacology. The α_2 adrenergic receptor agonists such as *clonidine* can interact with specific receptors on enteric neurons and enterocytes, thereby stimulating absorption and inhibiting secretion of fluid and electrolytes and increasing intestinal transit time. These agents may have a role for use by diabetics with chronic diarrhea.

Therapeutic Uses and Adverse Effects. Oral *clonidine* (beginning at 0.6 mg three times daily) has been used in diabetic patients with chronic diarrhea; the use of a topical preparation may result in plasma levels of the drug that are more steady. *Clonidine* also may be useful in patients with diarrhea caused by opiate withdrawal. Side effects such as hypotension, depression, and perceived fatigue may be dose limiting in susceptible patients (see Chapter 12 for details of the pharmacology of *clonidine*).

Ocreotide and Somatostatin

Mechanism of Action and Pharmacology. *Ocreotide* (see Chapter 43) is an octapeptide analogue of SST that is effective in inhibiting the severe secretory diarrhea brought about by hormone-secreting tumors of the pancreas and the GI tract. *Ocreotide* inhibits secretion of 5HT and various GI peptides. Its greatest utility may be in the “dumping syndrome” seen in some patients after gastric surgery and pyloroplasty, in whom *octreotide* inhibits the release of hormones (triggered by rapid passage of food into the small intestine) that are responsible for distressing local and systemic effects. *Ocreotide* is widely available; SST is available in some countries, but not the U.S.

ADME. *Ocreotide* has a $t_{1/2}$ of 1–2 h and is administered either subcutaneously or intravenously as a bolus dose. The time to peak is 0.4 h after subcutaneous injection and 1 h after intramuscular injection. It is metabolized in the liver and excreted in the urine. SST has a plasma $t_{1/2}$ of 1–2 min.

Therapeutic Uses and Adverse Effects. Standard initial therapy with *octreotide* is 50–100 µg, given subcutaneously two or three times a day, with titration to a maximum dose of 500 µg three times daily, based on clinical and biochemical responses. A long-acting preparation of *octreotide* acetate enclosed in biodegradable microspheres is available for use in the treatment of diarrhea associated with carcinoid tumors and VIP-secreting tumors, as well as in the treatment of acromegaly (see Chapter 42). This preparation is injected intramuscularly once per month in a dose of 20 mg. Side effects of *octreotide* depend on the duration of therapy: Transient nausea, bloating, or pain at sites of injection may occur in the short term, and gallstone formation and hypo- or hyperglycemia may happen in the long term. However, there are also numerous other side effects, including cardiovascular, endocrine, and CNS.

Variceal Bleeding. SST and *octreotide* are effective in reducing hepatic blood flow, hepatic venous wedge pressure, and azygos blood flow. These agents constrict the splanchnic arterioles by a direct action on vascular smooth muscle and by inhibiting the release of peptides contributing to the hyperdynamic circulatory syndrome of portal hypertension. *Ocreotide* also may act through the ANS. For patients with variceal bleeding, therapy with *octreotide* usually is initiated while the patient is waiting for endoscopy (a 50-µg bolus dose followed by 50 µg hourly for 2–5 days) (Bhutta and Garcia-Tsao, 2015). Because of its short $t_{1/2}$ (1–2 min), SST can be given only by intravenous infusion (a 250-µg bolus dose followed by 250 µg hourly for 2–5 days). Higher doses (up to 500 µg/h) are more efficacious and can be used for patients who continue to bleed on the lower dose.

Intestinal Dysmotility. *Octreotide* has complex and apparently conflicting effects on GI motility, including inhibition of antral motor activity and colonic tone. However, *octreotide* also can rapidly induce phase III activity of the migrating motor complex in the small bowel to produce longer and faster contractions than those occurring spontaneously. Its use has been shown to result in improvement in selected patients with scleroderma and small-bowel dysfunction.

Pancreatitis. Both SST and *octreotide* inhibit pancreatic secretion and have been used for the prophylaxis and treatment of acute pancreatitis (Li et al., 2011). The rationale for their use is to rest the pancreas so inflammation by the continuing production of proteolytic enzymes is not aggravated, to reduce intraductal pressures, and to ameliorate pain. However, clinical trials have demonstrated that neither agent is effective in the treatment of acute pancreatitis, although *octreotide* confers some benefit when given prophylactically to prevent postendoscopic retrograde cholangiopancreatography pancreatitis.

Telotristat Ethyl

Mechanism of Action and Pharmacology. This drug reduces diarrhea associated with carcinoid tumors by inhibiting tryptophan hydroxylase, the rate-limiting enzyme of 5HT biosynthesis. 5HT secretion stimulates fluid secretion and motility in the GI tract.

ADME. Telotristat ethyl is absorbed after oral administration and converted to the active agent Telotristat by the action of carboxylesterases. Peak plasma levels of Telotristat occur 1–3 h after ingestion. Clearance occurs with a $t_{1/2}$ of 5 h; elimination is via the feces.

Therapeutic Uses and Adverse Effects. Telotristat is given in combination with somatostatin analog therapy for the treatment of diarrhea in carcinoid syndrome. A dose of 250 mg three times/d may be given to adult patients who are not adequately controlled by somatostatin analog therapy alone. The main adverse effects are constipation, nausea, headache, increased gamma glutamyl transferase levels, depression, peripheral edema, flatulence, reduced appetite and, pyrexia.

Berberine

Berberine is a plant alkaloid that has complex pharmacological actions that include antimicrobial effects, stimulation of bile flow, inhibition of ventricular tachyarrhythmias, and possible antineoplastic activity. It is used most commonly to treat bacterial diarrhea and cholera but is also apparently effective against intestinal parasites (Menees et al., 2012). The antidiarrheal effects in part may be related to its antimicrobial activity, as well as its ability to inhibit smooth muscle contraction and delay intestinal transit by antagonizing the effects of ACh (by competitive and noncompetitive mechanisms) and blocking the entry of Ca^{2+} into cells. In addition, it inhibits intestinal secretion. Berberine is not FDA-approved for use in the U.S.

Bulk-Forming and Hydroscopic Agents

Hydrophilic and poorly fermentable colloids or polymers such as *carboxymethylcellulose* and calcium polycarboxophil absorb water and increase stool bulk (calcium polycarboxophil absorbs 60 times its weight in water). They usually are used for constipation but are sometimes useful in acute episodic diarrhea and in mild chronic diarrhea in patients with IBS. Some of these agents also may bind bacterial toxins and bile salts.

Another bulk-forming agent is *dextranomer and hyaluronic acid*. Dextranomer microspheres are a network of dextran-sucrose beads with exposed hydroxy groups. When this complex is applied to an exudative wound surface, the exudate is drawn by capillary forces generated by the swelling of the beads. The sodium hyaluronate provides viscosity and facilitates injection of the dextranomer. This agent is licensed (as a device) for the treatment of fecal incontinence in adults. It is given as four time 1-mL submucosal injection in the anal canal, which can be repeated after at least 4 weeks if the first treatment is inadequate. The major adverse effects include injection area pain and bleeding.

Bile Acid Sequestrants

Cholestyramine, *colestipol*, and *colesevelam* effectively bind bile acids and some bacterial toxins (Menees et al., 2012). *Cholestyramine* is useful in the treatment of bile salt–induced diarrhea, as in patients with resection

of the distal ileum or after cholecystectomy. In these patients, excessive concentrations of bile salts reach the colon and stimulate water and electrolyte secretion. Patients with extensive ileal resection (usually > 100 cm) eventually develop net bile salt depletion, which can produce steatorrhea because of inadequate micellar formation required for fat absorption. In such patients, the use of *cholestyramine* aggravates the diarrhea. In patients having bile salt–induced diarrhea, *cholestyramine* and *colesevelam* can be given as an off-label use at a dose of 4–12 g of the dried resin per day. If successful, the dose may be titrated down to achieve the desired stool frequency. The use of these agents is limited by GI side effects, including bloating, flatulence, abdominal discomfort, and constipation.

Crofelemer

Mechanism of Action and Pharmacology. Crofelemer is a purified oligomeric proanthocyanidin from “dragon’s blood,” the reddish latex-like sap of a South American euphorbia. This botanic extract is used for the treatment of diarrhea associated with antiretroviral therapy for HIV/AIDS (Crutchley et al., 2010). It is not approved for infectious or other diarrheas. This drug has minimal systemic absorption and works by inhibiting the cyclic AMP–stimulated CFTR Cl^- channel and Ca^{2+} -activated chloride ion channels on the luminal aspect of the enterocyte, thereby reducing the water loss associated with chloride secretion into the lumen.

Therapeutic Uses and Adverse Effects. This drug is given orally (125 mg twice daily) to adults. Infectious diarrhea must be ruled out before treatment. The main adverse effects include upper respiratory tract infections, cough, flatulence, nausea, joint and back pain, and some other GI conditions.

Irritable Bowel Syndrome

Irritable bowel syndrome affects up to 15% of the population in the U.S. and most other Western countries. Patients may complain of a variety of symptoms, the most characteristic of which is recurrent abdominal pain associated with altered bowel movements. IBS appears to result from a varying combination of disturbances in visceral motor and sensory function, often associated with significant affective disorders (Khan and Chang, 2010; Mayer et al., 2014). The disturbances in bowel function can be either constipation or diarrhea or both at different times. Considerable evidence suggests a specific enhancement of visceral (as opposed to somatic) sensitivity to noxious, as well as physiological, stimuli in this syndrome (Dekel et al., 2013; Mayer et al., 2014).

Many patients can be managed with dietary restrictions, notably by avoiding fermentable oligo-di-monosaccharides and polyols, lactose, or gluten, and fiber supplementation; many cannot. Treatment of bowel symptoms (either diarrhea or constipation) is predominantly symptomatic and nonspecific, using the agents discussed previously. An important role for serotonin in IBS has been suggested based on its involvement in sensitization of nociceptor neurons in inflammatory conditions and its role in the control of motility and secretion (Dekel et al., 2013). This has led to the development of specific receptor modulators for the treatment of IBS, such as the 5HT₃ antagonist *alosetron* and the 5HT₄ agonist *prucalopride* (see Figure 50–2).

An effective class of agents for IBS has been the tricyclic antidepressants (see Chapter 15), which can have neuromodulatory and analgesic properties independent of their antidepressant effect (Dekel et al., 2013). Tricyclic antidepressants have a proven track record in the management of chronic “functional” visceral pain in adults (off-label use). *Amitriptyline*, *nortriptyline*, *imipramine*, or *desimipramine* can be used at lower doses than those used to treat depression. Starting doses of 10–25 mg *amitriptyline*, *nortriptyline*, or *imipramine* or 12.5–25 mg *desimipramine* at bedtime, should be given for 3–4 weeks because of their delayed onset of action; doses can be increased if tolerated and the patient is responsive to treatment. Although changes in mood usually do not occur at these doses, there may be some diminution of anxiety and restoration of sleep patterns. SSRIs (see Chapters 13 and 15) have fewer side effects and have been advocated particularly for patients with functional constipation because SSRIs can increase bowel movements

and even cause diarrhea. However, they probably are not as effective as tricyclic antidepressants in the management of visceral pain. Antidepressant use in children is not strongly supported by clinical trials. α_2 Adrenergic agonists, such as clonidine (see Chapter 12), also can increase visceral compliance and reduce distention-induced pain.

Alosetron

Mechanism of Action and Pharmacology

The 5HT₃ receptor participates in sensitization of spinal sensory neurons, vagal signaling of nausea, and peristaltic reflexes. The clinical effect of 5HT₃ antagonism is a general reduction in GI contractility with decreased colonic transit, along with an increase in fluid absorption. *Alosetron*, a potent antagonist of the 5HT₃ receptor, was initially withdrawn from the U.S. market because of an unusually high incidence of ischemic colitis (up to 3 per 1000 patients), leading to surgery and even death in a small number of cases. Nevertheless, the FDA has reapproved this drug under a limited distribution system for women with severe diarrhea-predominant IBS (Camilleri, 2013). The manufacturer requires a prescription program that includes physician certification and an elaborate patient education and consent protocol before dispensing.

ADME

Alosetron is rapidly absorbed from the GI tract; its duration of action (~10 h) is longer than expected from its $t_{1/2}$ of 1.5 h. It is metabolized by hepatic CYPs and is excreted in the urine and feces.

Therapeutic Uses and Adverse Effects

The drug should be started at 1 mg/d divided into two doses for the first 4 weeks and, if tolerated, advanced to a maximum of 1 mg twice daily if necessary. If the response is inadequate after 4 weeks of 1 mg twice-daily dosing, treatment should be discontinued. The most serious adverse reactions are constipation and ischemic colitis, and therapy must be discontinued immediately in patients who develop those symptoms. Other adverse reactions include nausea and vomiting, GI discomfort and pain, diarrhea, flatulence, hemorrhoids, and others.

Additional 5HT₃ antagonists currently available in the U.S. are approved for nausea and vomiting (see further in this chapter and Chapter 13).

Eluxadoline

Mechanism of Action and Pharmacology

Eluxadoline is a mixed MOR agonist, DOR antagonist, and κ -opioid receptor agonist. It acts locally to reduce abdominal pain and diarrhea without producing constipation in patients with IBS. This opioid drug is FDA approved for the treatment of diarrhea-predominant IBS in adults (Hornby, 2015).

ADME

Eluxadoline's time to peak C_p is 1.5–2 h; its $t_{1/2}$ is 3.7–6 h. The route of *eluxadoline's* metabolism is not well established; the drug and its metabolic products are excreted in the feces.

Therapeutic Uses and Adverse Effects

In patients with diarrhea-predominant IBS with a gallbladder, the therapeutic dose is 100 mg twice daily with food; the dose may be decreased to 75 mg twice daily in patients unable to tolerate the 100-mg dose. In patients without a gallbladder, *eluxadoline* is dosed at 75 mg twice daily to reduce the risk of sphincter of Oddi spasm and the potential complication of pancreatitis. Patients with known or suspected biliary duct obstruction, sphincter of Oddi disease or dysfunction, or a history of pancreatitis or structural diseases of the pancreas, should not be given *eluxadoline*. There are also risks from constipation, and the drug should be discontinued if severe constipation occurs. There is some potential for addiction. The major adverse reactions to the drug are constipation, nausea, and abdominal pain.

Rifaximin

Mechanism of Action and Pharmacology

Antibiotics should not be used routinely in patients with IBS, but the FDA has approved the bacterial RNA synthesis inhibitor *rifaximin* for diarrhea-predominant IBS (Saadi and McCallum, 2013).

ADME

Rifaximin is well absorbed, with a time to peak less than 1 h. Its $t_{1/2}$ is 6 h; it is cleared by the action of hepatic CYP3A; metabolites are excreted in the feces.

Therapeutic Uses and Adverse Effects

In patients with diarrhea-predominant IBS, the therapeutic dose is 550 mg three times daily for 2 weeks. This regimen may be re-treated twice if symptoms recur. Adverse reactions include nausea, peripheral edema, dizziness, fatigue, and the development of ascites and elevation in serum alanine aminotransferase. If diarrhea worsens after treatment with *rifaximin*, then an evaluation for development of a severe infectious diarrhea, *C. difficile* enterocolitis, should be performed.

Antispasmodics

Anticholinergic agents (“spasmolytics” or “antispasmodics”) often are used in patients with IBS. The most common agents of this class available in the U.S. are nonspecific antagonists of the muscarinic receptor (see Chapter 9) and include the tertiary amines *dicyclomine* and *hyoscyamine* and the quaternary ammonium compounds *glycopyrrolate* and *methscopolamine* (off-label use). The advantage of the last two compounds is that they have a limited propensity to cross the blood-brain barrier and hence a lower risk for neurological side effects such as light-headedness, drowsiness, or nervousness. These agents typically are given on either an as-needed basis or before meals to prevent the pain and fecal urgency that occur in some patients with IBS.

Dicyclomine is given in 20-mg doses orally every 6 h, increasing to 40 mg every 6 h unless limited by side effects. *Hyoscyamine* is available as sublingual tablets, orally disintegrating tablets, immediate-release oral capsules, tablets, elixir, and drops (all administered as 0.125–0.25 mg every 4 h as needed) and extended-release forms for oral use (0.25–0.375 mg every 12 h, or 0.375 mg every 8 h, as needed), and as an injection for intramuscular, intravenous, or subcutaneous use (0.25–0.5 mg every 4 h as needed). *Glycopyrrolate* is rarely used but is available as immediate-release tablets, as an oral solution, and as an injectable; the oral dose is 1–2 mg two or three times daily, not to exceed 6 mg/d. *Methscopolamine* is provided as 2.5-mg and 5-mg tablets; the dose is 2.5 mg a half hour before meals and 2.5–5 mg at bedtime.

Other Drugs

Cimetropium and *acotiamide* are muscarinic antagonists that are effective in patients with IBS but are not available in the U.S. *Acotiamide* appears to be a promising agent for the treatment of postprandial distress syndrome, one of two major forms of functional dyspepsia (Zala et al., 2015). *Otilonium* bromide is a quaternary ammonium salt with antimuscarinic effects that also appears to block Ca²⁺ channels and neurokinin NK₂ receptors; it is not available in the U.S. *Mebeverine* hydrochloride, a derivative of hydroxybenzamide, appears to have a direct effect on the smooth muscle cell, blocking K⁺, Na⁺, and Ca²⁺ channels. *Mebeverine* is used outside the U.S. as an antispasmodic agent. It is given orally, 100–135 mg three times daily or 200 mg twice daily, before meals.

Antinauseants and Antiemetics

Nausea and Vomiting

Emesis and the sensation of *nausea* that frequently accompanies it are generally viewed as components of a protective reflex that serve to rid the stomach and intestine of toxic substances (*emesis*) and prevent their further ingestion (*nausea* serves as an unconditioned aversive stimulus for learning and memory) (Horn, 2008; Hornby, 2001). *Vomiting* is a complex process that appears to be coordinated by a central emesis center in the lateral reticular formation of the midbrainstem adjacent to both the CTZ in the area postrema on the floor of the fourth ventricle and the STN. The lack of a blood-brain barrier at the CTZ permits monitoring of blood and cerebrospinal fluid constantly for toxic substances and

Figure 50-5 Pharmacologist's view of emetic stimuli. Many signaling pathways lead from the periphery to the emetic center. Stimulants of these pathways are noted in *italics*. These pathways involve specific neurotransmitters and their receptors (**bold type**). Receptors are shown for dopamine (D_2), ACh (muscarinic, M), histamine (H_1), cannabinoids (CB_1), substance P (NK_1), and $5HT_3$. Some of these receptors also may mediate signaling in the emetic center.

relaying information to the emesis center to trigger nausea and vomiting. The emesis center also receives information from the gut, principally by the vagus nerve (via the STN) and also by splanchnic afferents via the spinal cord. Two other important inputs to the emesis center come from the cerebral cortex (particularly in anticipatory nausea or vomiting) and the vestibular apparatus (in motion sickness). The CTZ has high concentrations of receptors for serotonin ($5HT_3$), dopamine (D_2), ACh (muscarinic M_1), neurokinin (NK_1), cannabinoid (CB_1), and opioids. The STN is rich in receptors for enkephalin, histamine, and ACh and also expresses $5HT_3$ receptors. Myriad neurotransmitter agonists for these receptors are involved in nausea and vomiting (Figure 50-5). Antiemetics generally are classified according to the predominant receptor on which they are proposed to act (Table 50-4). For treatment and prevention of the nausea and emesis associated with cancer chemotherapy, several antiemetic agents from different pharmacological classes may be used in combination (Table 50-5).

Nausea is distinct from emesis and is a frequent side effect of medications as well as a common feature of diseases that range from CNS disorders to GI disorders and infection. The brain centers involved in the sensation of nausea are located in higher brain regions than the emetic centers and include the insular, anterior cingulate, orbitofrontal, somatosensory, and prefrontal cortices. Most drugs used to treat emesis are relatively poor at preventing nausea (Andrews and Sanger, 2014).

5HT₃ Receptor Antagonists

Mechanism of Action and Pharmacology. The $5HT_3$ antagonists are the most effective drugs for the treatment of chemotherapy-induced and postoperative nausea and vomiting in adults and children (Andrews and Sanger, 2014; Kovac, 2013; Navari, 2013). However, they are less effective at suppressing acute nausea than they are at suppressing acute vomiting, and they are ineffective at reducing instances of delayed (24 h later) nausea and vomiting and anticipatory nausea and vomiting.

Ondansetron is the prototypical drug in this class. Other agents in this class include the first-generation antagonists *granisetron*, *dolasetron* (not available in Canada), and *tropisetron* (not available in the U.S.) and the second-generation antagonist *palonosetron*. Palonosetron has higher

TABLE 50-4 ■ GENERAL CLASSIFICATION OF ANTIEMETIC AGENTS

ANTIEMETIC CLASS	EXAMPLES	MOST EFFECTIVE AGAINST
$5HT_3$ receptor antagonists ^a	Ondansetron	Cytotoxic drug-induced emesis
Centrally acting dopamine receptor antagonists	Metoclopramide ^b Promethazine ^c	
Cannabinoid receptor agonists	Dronabinol nabilone	
Neurokinin receptor antagonists	Aprepitant	Cytotoxic drug-induced emesis (delayed vomiting)
Histamine H_1 antagonists	Cyclizine	Vestibular emesis (motion sickness)
Muscarinic receptor antagonists	Hyoscine (scopolamine)	

^aThe most effective agents for chemotherapy-induced nausea and vomiting are the $5HT_3$ antagonists and metoclopramide. In addition to their use as single agents, they are often combined with other drugs to improve efficacy and reduce incidence of side effects. See Table 50-5.

^bAlso has some peripheral activity at $5HT_3$ receptors.

^cAlso has some antihistaminic and anticholinergic activity.

receptor affinity, a longer $t_{1/2}$, and demonstrated superiority over first-generation antagonists (Navari, 2014).

The $5HT_3$ receptors are present in several critical sites involved in emesis, including vagal afferents, the STN (which receives signals from vagal afferents), and the area postrema itself (see Figure 50-5). Serotonin is released by the enterochromaffin cells of the small intestine in response to chemotherapeutic agents and stimulates vagal afferents (via $5HT_3$ receptors) to initiate the vomiting reflex. The highest concentrations of $5HT_3$ receptors in the

TABLE 50-5 ■ ANTIEMETIC AGENTS IN CANCER CHEMOTHERAPY^a**Low risk of emesis:**

- Prechemotherapy
- Dexamethasone
 - Metoclopramide ± diphenhydramine
 - Prochlorperazine ± lorazepam
- Postchemotherapy (delayed emesis)
- None

Moderate risk of emesis:

- Prechemotherapy
- 5HT₃ antagonist + dexamethasone
 - 5HT₃ antagonist + dexamethasone + NK₁ antagonist
- Postchemotherapy (delayed emesis)
- Aprepitant (days 2 and 3)
 - Dexamethasone or 5HT₃ antagonist (days 2–3 or 4)
 - Aprepitant (days 2–3, if used prechemo) ± dexamethasone (days 2–4) ± lorazepam (days 2–4)

High risk of emesis:

- Prechemotherapy
- 5HT₃ antagonist + dexamethasone + NK₁ antagonist ± lorazepam
 - 5HT₃ antagonist/NK₁ antagonist + dexamethasone
- Postchemotherapy (delayed emesis)
- Dexamethasone + aprepitant
 - Dexamethasone (days 2–4) + aprepitant (days 2 and 3) ± lorazepam (days 2–4)

^aSpecific recommendations and doses are tailored to the patient and the chemotherapeutic regimen. For updated information, see the National Cancer Institute website (see Cancer Topics: Nausea and Vomiting). Some patients profit from cannabinoids (dronabinol, nabilone) with or without a phenothiazine or dexamethasone.

CNS are found in the STN and CTZ, and antagonists of 5HT₃ receptors also may suppress nausea and vomiting by acting at these sites.

ADME. These agents are absorbed well from the GI tract and have a rapid onset of action. *Ondansetron* is extensively metabolized in the liver by CYP1A2, CYP2D6, and CYP3A4, followed by glucuronide or sulfate conjugation. The $t_{1/2}$ is 3–6 h. Patients with hepatic dysfunction have reduced plasma clearance, and some adjustment in the dosage is advisable. *Granisetron* also is metabolized predominantly by the liver by the CYP3A family and has a $t_{1/2}$ of 6–9 h, depending on the route of administration. *Dolasetron* is converted rapidly by plasma carbonyl reductase to its active metabolite, hydrodolasetron. A portion of this compound then undergoes subsequent biotransformation by CYP2D6 and CYP3A4 in the liver, while about one-third of it is excreted unchanged in the urine. The $t_{1/2}$ of the active metabolite hydrodolasetron is 6–8 h. *Palonosetron* is metabolized principally by CYP2D6; the metabolized and the unchanged

forms are excreted in the urine in roughly equal proportions. The $t_{1/2}$ after intravenous injection is about 40 h in adults. The antiemetic effects of these drugs persist long after they disappear from the circulation, suggesting their continuing interaction at the receptor level; these drugs can be administered effectively just once a day.

Therapeutic Uses and Adverse Effects. These agents are most effective in treating chemotherapy-induced nausea and in treating nausea secondary to upper abdominal irradiation. They also are effective against hyperemesis of pregnancy and, to a lesser degree, postoperative nausea, but not against motion sickness. Unlike other agents in this class, *palonosetron* may be helpful in delayed emesis, perhaps reflecting its long $t_{1/2}$. These agents are available as tablets, oral solution, and intravenous preparations for injection. *Palonosetron*, in combination with the NK₁ receptor antagonist *netupitant* (see further discussion), is FDA approved for the treatment of acute and delayed nausea and vomiting. This combination is highly effective when combined with the corticosteroid *dexamethasone* (see further discussion). For patients on cancer chemotherapy, these drugs can be given in a single intravenous dose (Table 50–6) infused over 15 min, beginning 30 min before chemotherapy, or in two or three divided doses, with the first usually given 30 min before and subsequent doses at various intervals after chemotherapy. The drugs also can be used intramuscularly (*ondansetron* only) or orally. *Granisetron* is available as a transdermal formulation that is applied 24–48 h before chemotherapy and worn for up to 7 days.

In general, these drugs are very well tolerated, with the most common adverse effects being constipation or diarrhea, headache, and lightheadedness. Electrocardiogram interval changes (QT prolongation) are a feature of the first-generation antagonists; the injectable form of *dolasetron* is contraindicated for prophylactic therapy for chemotherapy-induced nausea and vomiting. The oral form is associated with a lower risk, but risk is still present. *Palonosetron* does not appear to increase QT intervals (Gonullu et al., 2012). These drugs have also been associated with serotonin syndrome and should be used cautiously if patients are taking other medications, such as SSRIs, that could increase 5HT levels.

Dopamine Receptor Antagonists

Mechanism of Action and Pharmacology. The principal mechanism of action of dopamine receptor antagonists is D₂ receptor antagonism at the CTZ, reducing excitatory neurotransmitter release (Andrews and Sanger, 2014; Kovac, 2013).

Phenothiazines. *Prochlorperazine*, and to a lesser extent *chlorpromazine* (see Chapter 16), are among the most commonly used “general-purpose” antinauseants and antiemetics in adults and children. These drugs are not uniformly effective in cancer chemotherapy-induced emesis, but they possess antihistaminic and anticholinergic activities that are of value in other forms of nausea and vomiting, such as motion sickness and that of GI origin. These drugs are available as tablets, injectables, or suppositories. Typical dosing of *prochlorperazine* is 5–10 mg orally every 6–8 h, 5–10 mg intramuscularly, or 2.5 mg to 10 mg intravenously every 3–4 h (maximum 40 mg/d), or 25 mg rectally every 12 h. The main adverse effects are extrapyramidal reactions, including dystonia, cardiac effects, and hypotension. These drugs are contraindicated due to increased mortality in elderly patients with dementia-related psychosis.

TABLE 50-6 ■ 5HT₃ ANTAGONISTS IN CHEMOTHERAPY-INDUCED NAUSEA/EMESIS

DRUG	CHEMICAL NATURE	RECEPTOR INTERACTIONS	$t_{1/2}$	ADULT DOSE (IV)
Ondansetron	Carbazole derivative	5HT ₃ antagonist, weak 5HT ₄ antagonist	3.9 h	0.15 mg/kg
Granisetron	Indazole	5HT ₃ antagonist	9–11.6 h	10 µg/kg
Dolasetron (not approved in the U.S.)	Indole moiety	5HT ₃ antagonist	7–9 h	1.8 mg/kg
Palonosetron	Isoquinoline	5HT ₃ antagonist; highest affinity for 5HT ₃ receptor in class	40 h	0.25 mg

Benzamides. The prokinetic benzamide agents (see previous discussion) are moderately useful antiemetics, but are no longer the drugs of choice for acute chemotherapy-induced nausea and vomiting due to their lack of efficacy and side-effect profile. However, the antiemetic actions add to their value in the treatment of GI motor disturbances, and metoclopramide is a useful treatment of delayed emesis.

Trimethobenzamide is given for gastroenteritis and postoperative nausea and vomiting (orally at doses of 300 mg every 6 h or 200 mg IM).

Olanzapine. Olanzapine is an atypical (second-generation) antipsychotic that is a dopamine (D_{1-4}) and $5HT_2$ receptor antagonist (see Chapter 16). It is an effective agent for the prevention of chemotherapy-associated delayed nausea or vomiting (off-label use; used in combination with a corticosteroid and $5HT_3$ antagonist) (Fonte et al., 2015). It is also gaining attention for the treatment of refractory non-chemotherapy-induced nausea and vomiting. It is given orally, 10 mg once daily for 3 to 5 days, beginning on day 1 of chemotherapy or 5 mg once daily for 2 days before chemotherapy, followed by 10 mg once daily (beginning on the day of chemotherapy) for 3 to 8 days. The adverse reactions are extensive and include many CNS, cardiovascular, and metabolic side effects that are described in Chapter 16.

Antihistamines

Histamine H_1 antagonists are primarily useful for motion sickness and postoperative emesis. They act on vestibular afferents and within the brainstem. *Cyclizine*, *meclizine*, *promethazine*, and *diphenhydramine* are examples of this class of agents. *Cyclizine* has additional anticholinergic effects that may be useful for patients with abdominal cancer. Sedation is always a common side effect of these drugs. For a detailed discussion of these drugs, see Chapter 39.

Anticholinergic Agents

The most commonly used muscarinic receptor antagonist for motion sickness is *scopolamine* (hyoscine), which can be injected as the hydrobromide, but usually is administered as the free base in the form of a transdermal patch (1.5 mg every 3 days). Its principal utility is in the prevention and treatment of motion sickness, with some activity in postoperative nausea and vomiting. In general, however, anticholinergic agents have no role in chemotherapy-induced nausea. The principle side effects are dry mouth, visual disturbances, and drowsiness.

Neurokinin Receptor Antagonists

Mechanism of Action and Pharmacology. The nausea and vomiting associated with emetogenic chemotherapy (see Chapter 65) has two components: an acute phase that universally is experienced (within 24 h after chemotherapy) and a delayed phase that affects only some patients (on days 2–5). $5HT_3$ receptor antagonists are not very effective against delayed emesis. However, antagonists of the NK_1 receptors, the receptors for the neuropeptide substance P, such as *aprepitant* (and its parenteral formulation *fosaprepitant*), have antiemetic effects in delayed nausea and improve the efficacy of standard antiemetic regimens in patients receiving multiple cycles of chemotherapy (Aapro et al., 2015). A new, highly selective NK_1 antagonist, *rolapitant*, with an exceptionally long plasma $t_{1/2}$ (180 h) was FDA approved in September 2015 for prevention of chemotherapy-induced delayed emesis.

Aprepitant. The NK_1 antagonist *aprepitant* is typically given with a $5HT_3$ antagonist and dexamethasone.

ADME. After absorption, *aprepitant* is bound extensively to plasma proteins (>95%); it is metabolized primarily by hepatic CYP3A4 and is excreted in the stools; its $t_{1/2}$ is 9–13 h. *Aprepitant* has the potential to interact with other substrates of CYP3A4, requiring adjustment of other drugs, including dexamethasone, methylprednisolone (whose dose may need to be reduced by 50%), and warfarin.

Therapeutic Uses and Adverse Effects. *Aprepitant* is contraindicated in patients on cisapride or pimozone, in whom life-threatening QT prolongation has been reported. *Aprepitant* is supplied in 40-, 80-, and 125-mg capsules and is administered for 3 days in conjunction with highly emetogenic chemotherapy, along with a $5HT_3$ antagonist and

a corticosteroid. The injectable form, *fosaprepitant*, in a dose of 115 mg, may be substituted for the first dose of *aprepitant* at the start of the 3-day regimen. The recommended adult dosage of *aprepitant* is 125 mg administered 1 h before chemotherapy on day 1, followed by 80 mg once daily in the morning on days 2 and 3 of the treatment regimen.

Rolapitant. *Rolapitant* is a potent NK_1 receptor antagonist that is administered with a $5HT_3$ antagonist and dexamethasone to help prevent delayed phase chemotherapy-induced nausea and vomiting.

ADME. After a single oral dose of 180 mg, *rolapitant* is well absorbed with peak C_p at 4 h and $t_{1/2}$ at about 180 h. *Rolapitant* is metabolized primarily by CYP3A4 to form an active metabolite, M19 (C4-pyrrolidine-hydroxylated *rolapitant*). M19 has a $t_{1/2}$ of about 158 h. *Rolapitant* is eliminated mainly via the hepatic/biliary route.

Therapeutic Uses and Adverse Effects. A single 180-mg dose is administered orally 1–2 h prior to chemotherapy (together with $5HT_3$ antagonist and dexamethasone). The adverse effects include neutropenia, hiccups, decreased appetite, and dizziness. *Rolapitant* is a moderate inhibitor of CYP2D6 and of the Pgp and BCRP transporters. *Rolapitant* is contraindicated in patients receiving drugs that are CYP2D6 substrates, such as thioridazine or pimozone. A significant increase in plasma concentrations of thioridazine may result in QT prolongation and torsades de pointes.

Netupitant and Palonosetron Combination. A combination NK_1 receptor antagonist plus $5HT_3$ receptor antagonist (*netupitant* and *palonosetron*) was recently approved (Abramovitz and Gaertner, 2016).

ADME. This combination is well absorbed; the drugs have a similar time to peak C_p (5 h) and very long half-lives (*netupitant*, ~ 80 h; *palonosetron*, ~ 48 h). They are excreted in the feces and urine. *Netupitant* is extensively metabolized by CYP3A4 (major) and CYP2C9 and CYP2D6 (minor) to active metabolites. *Palonosetron* is about 50% metabolized in the liver to inactive metabolites.

Therapeutic Uses and Adverse Effects. A single capsule is administered orally about 1 h prior to chemotherapy (together with dexamethasone, at doses varying according to the type of chemotherapy). The adverse effects are the same as for the $5HT_3$ antagonists (see previous discussion).

Cannabinoids

Dronabinol. **Mechanism of Action and Pharmacology.** *Dronabinol* (Δ -9-tetrahydrocannabinol) is a naturally occurring cannabinoid that can be synthesized chemically or extracted from the marijuana plant, *Cannabis sativa*. The mechanism of the antiemetic action of *dronabinol* is related to stimulation of the CB_1 subtype of cannabinoid receptors on neurons in and around the CTZ and emetic center (see Figure 50–5) (Sharkey et al., 2014).

ADME. *Dronabinol* is a highly lipid-soluble compound that is absorbed readily after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2–4 h. It undergoes extensive first-pass metabolism with limited systemic bioavailability after single doses (only 10%–20%). The principal active metabolite is 11-OH- Δ -9-tetrahydrocannabinol. These metabolites are excreted primarily via the biliary-fecal route, with only 10%–15% excreted in the urine. Both *dronabinol* and its metabolites are highly bound (>95%) to plasma proteins. Because of its large volume of distribution, a single dose of *dronabinol* can result in detectable levels of metabolites for several weeks.

Therapeutic Uses and Adverse Effects. *Dronabinol* is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. It also can stimulate appetite and has been used in patients with AIDS and anorexia. As an antiemetic agent, it is administered at an initial dose of 5 mg/m² given 1–3 h before chemotherapy and then every 2–4 h afterward for a total of four to six doses. If this is inadequate, incremental increases can be made up to a maximum of 15 mg/m² per dose. For other indications, the usual starting dose is 2.5 mg twice a day; this can be titrated up to a maximum of 20 mg per day.

Dronabinol has complex effects on the CNS, including a prominent central sympathomimetic activity. This can lead to palpitations, tachycardia, vasodilation, hypotension, and conjunctival injection (bloodshot eyes). Patient supervision is necessary because marijuana-like “highs” (e.g., euphoria, somnolence, detachment, dizziness, anxiety, nervousness, panic, etc.) can occur, as can more disturbing effects such as paranoid reactions and abnormalities of thinking. After abrupt withdrawal of dronabinol, an abstinence syndrome (irritability, insomnia, and restlessness) can occur. Because of its high affinity for plasma proteins, dronabinol can displace other plasma protein-bound drugs, whose doses may have to be adjusted as a consequence. Dronabinol should be prescribed with great caution to persons with a history of substance abuse (alcohol, drugs) because it also may be abused by these patients.

Nabilone. *Mechanism of Action and Pharmacology.* Nabilone is a synthetic cannabinoid with a mode of action similar to that of dronabinol.

ADME. Nabilone is a highly lipid-soluble compound that is rapidly absorbed after oral administration; its onset of action occurs within an hour, and peak levels are achieved within 2 h. The $t_{1/2}$ is about 2 h for the parent compound and 35 h for metabolites. The metabolites are excreted primarily via the biliary-fecal route (60%), with only about 25% excreted in the urine.

Therapeutic Uses and Adverse Effects. Nabilone is a useful prophylactic agent in patients receiving cancer chemotherapy when other antiemetic medications are not effective. A dose (1–2 mg) can be given the night before chemotherapy; usual dosing starts 1–3 h before treatment and then every 8–12 h during the course of chemotherapy and for 2 days following its cessation. The adverse effects are largely the same as for dronabinol, with significant CNS actions in more than 10% of patients. Cardiovascular, GI, and other side effects are also common and, together with the CNS actions, limit the usefulness of this agent.

Glucocorticoids and Anti-inflammatory Agents

Glucocorticoids such as dexamethasone can be useful adjuncts (see Table 50–5) in the treatment of nausea in patients with widespread cancer, possibly by suppressing peritumoral inflammation and prostaglandin production. A similar mechanism has been invoked to explain beneficial effects of NSAIDs in the nausea and vomiting induced by systemic irradiation (Chu et al., 2014). For a detailed discussion of these drugs, see Chapters 38 and 46.

Benzodiazepines

Benzodiazepines, such as *lorazepam* and *alprazolam*, by themselves are not very effective antiemetics, but their sedative, amnesic, and antianxiety effects can be helpful in reducing the anticipatory component of nausea and vomiting in patients. For a detailed discussion of these drugs, see Chapter 19.

Phosphorated Carbohydrate Solutions

Aqueous OTC solutions of *glucose*, *fructose*, and *orthophosphoric* are available to relieve nausea. These solutions are given orally (15–30 mL, adults; 5–10 mL, children; repeated every 15 min until the symptoms alleviate. No more than five doses may be taken). Their mechanisms of action are unclear.

Doxylamine Succinate and Pyridoxine

Mechanism of Action and Pharmacology. Nausea commonly occurs in the early stages of pregnancy. This may or may not be accompanied by vomiting. The management of this condition depends of the severity of symptoms, which usually resolve by midpregnancy regardless of their severity. *Pyridoxine* (vitamin B₆) improves mild-to-moderate nausea and its efficacy is improved when it is combined with the histamine H₁ antagonist *doxylamine* (Fantasia, 2014). Considering the caveats associated with the use of antinausea medications during early pregnancy, readers may wish to review the history of this drug combination; see the work of Slaughter et al., 2014.

ADME. *Doxylamine* is metabolized in the liver by N-dealkylation. It has a $t_{1/2}$ of 10–12 h and is excreted in the urine. *Pyridoxine* is well absorbed and has a $t_{1/2}$ of 2–3 weeks.

Therapeutic Uses and Adverse Effects. This drug-vitamin combination is given for the treatment of nausea and vomiting of pregnancy. Initially, 2 delayed-release tablets (a total of *doxylamine* 20 mg and *pyridoxine* 20 mg) are taken at bedtime. The dose may be increased to 4 tablets per day as needed for more severe nausea (1 tablet in the morning, 1 tablet in the afternoon, 2 tablets at bedtime). The major side effects of this drug include drowsiness, dry mouth, light-headedness, and constipation.

Miscellaneous GI Disorders

Cystic Fibrosis, Chronic Pancreatitis, and Steatorrhea

Pancreatic Enzymes

Chronic pancreatitis is a debilitating syndrome that results in symptoms from loss of glandular function (exocrine and endocrine) and inflammation (pain). The goals of pharmacological therapy are prevention of malabsorption and palliation of pain (Trang et al., 2014). *Cystic fibrosis* is a genetic disorder that affects exocrine secretion. Exocrine pancreatic insufficiency occurs in the majority of patients with more severe forms of cystic fibrosis. Pharmacological therapy is used to treat these patients (Somaraju and Solis-Moya, 2014).

Enzyme Formulations. Pancreatic enzymes (lipase, amylase, and proteases) are secreted together; hence, lipase can be used to titrate the doses of pancreatic enzyme supplements, which are typically prescribed on the basis of the lipase content. Only *pancrelipase* is licensed for sale in the U.S. Pancrelipase products, of which there are six on the market, differ in their content of lipase, protease, and amylase and thus may not be interchangeable.

Replacement Therapy for Malabsorption. Fat malabsorption (*steatorrhea*) and protein maldigestion occur when the pancreas loses more than 90% of its ability to produce digestive enzymes. This occurs in chronic pancreatitis, following pancreatectomy, or in cystic fibrosis. The resultant diarrhea and malabsorption can be managed well if 90,000 USP units of pancreatic lipase are delivered to the duodenum during a 4-h period with and after meals. Alternatively, one can titrate the dosage to the fat content of the diet, with about 8000 USP units of lipase activity required for each 17 g of dietary fat. Available preparations of pancreatic enzymes contain 3000–40,000 USP units of lipase, 10,000–136,000 USP units of protease, and 15,000–218,000 USP units of amylase. In adults and children over 4 years, the initial dose of lipase is 500 USP units/kg/meal, increasing up to 2500 USP units/kg/meal. Children younger than 4 have increased needs for lipase, and initial doses are higher. There are also special dosing regimens for breastfeeding infants. In all cases, lipase dosing should not exceed maximum recommendations and generally should not exceed 2500 USP units/kg/meal or 10,000 USP unit/kg/d.

Enzymes for Pain. Pain is the other cardinal symptom of chronic pancreatitis. The rationale for its treatment with pancreatic enzymes is based on the principle of negative-feedback inhibition of the pancreas by the presence of duodenal proteases. The release of CCK, the principal secretagogue for pancreatic enzymes, is triggered by CCK-releasing monitor peptide in the duodenum, which normally is denatured by pancreatic trypsin. In chronic pancreatitis, trypsin insufficiency leads to persistent activation of this peptide and an increased release of CCK, which is thought to cause pancreatic pain because of continuous stimulation of pancreatic enzyme output and increased intraductal pressure. Delivery of active proteases to the duodenum (which can be done reliably only with uncoated preparations) therefore is important for the interruption of this loop. Although enzymatic therapy has become firmly entrenched for the treatment of painful pancreatitis, the evidence supporting this practice is equivocal at best.

Adverse Effects. Despite the fact that the enzymes are not absorbed and are excreted in feces, there are adverse effects, which include headache and abdominal pain; however, pancreatic enzyme preparations are tolerated extremely well by patients. Hyperuricosuria in patients with cystic fibrosis can occur, and malabsorption of folate and iron has been reported.

Gallstones and Primary Biliary Cirrhosis

Bile Acids

Bile acids and their conjugates are synthesized from cholesterol in the liver. Bile acids induce bile flow, feedback-inhibit cholesterol synthesis, promote intestinal excretion of cholesterol, and facilitate the emulsification and absorption of lipids and fat-soluble vitamins. After secretion into the biliary tract, bile acids are largely (95%) reabsorbed in the intestine, returned to the liver, and then again secreted in bile (enterohepatic circulation). Cholic acid, chenodeoxycholic acid, and deoxycholic acid constitute 95% of bile acids; lithocholic acid and ursodeoxycholic acid are minor constituents. The bile acids exist largely as glycine and taurine conjugates, the salts of which are called bile salts.

Traditional therapy for gallstones involves oral litholysis with *ursodeoxycholic acid* (ursodiol), but there is now evidence that inhibiting cholesterol synthesis (with statins) or intestinal cholesterol absorption (with ezetimibe) may have some beneficial effects to reduce gallstone formation (Portincasa et al., 2012). As for the treatment of gallstones, treatments for primary biliary cirrhosis also involve the use of *ursodeoxycholic acid*. New therapies are being developed that include *obeticholic acid*, a semisynthetic analogue of *chenodeoxycholic acid*, an endogenous ligand of the farnesoid X receptor (a nuclear receptor important for regulating bile acid and cholesterol metabolism), and treatment with fibrates, peroxisome proliferator-activated receptor alpha agonists. Another promising therapy includes combining *ursodeoxycholic acid* with the steroid budesonide (see Chapter 46) for the treatment of early-stage primary biliary cirrhosis (Tabibian and Lindor, 2015).

Ursodeoxycholic acid (ursodiol) (Figure 50–6) is a hydrophilic, dehydroxylated bile acid that is formed by epimerization of the bile acid chenodeoxycholic acid (chenodiol) in the gut by intestinal bacteria. Ursodiol is given for the prevention and treatment of gallstones and for the treatment of primary biliary cirrhosis (Portincasa et al., 2012; Tabibian and Lindor, 2015). When administered orally, litholytic bile acids such as chenodiol and ursodiol alter relative concentrations of bile acids, decrease biliary lipid secretion, and reduce the cholesterol content of the bile so that it is less lithogenic. *Ursodiol* also may have cytoprotective effects on hepatocytes and effects on the immune system that account for some of its beneficial effects in cholestatic liver diseases. For gallstone treatment, it is given orally 8–10 mg/kg/d in divided doses, for gallstone prevention 300 mg twice daily, and for primary biliary cirrhosis 13–15 mg/kg/d in two to four divided doses with food. Adverse effects at these doses are generally uncommon, but include headache, GI disturbances, and nausea. At higher-than-recommended doses, there may be serious adverse effects of *ursodiol*. Dissolution of gallstones by chenodiol is reserved for patients who are at increased surgical risk and have radiolucent stones.

Flatulence

“Gas” is a common but relatively vague GI complaint, used in reference not only to flatulence and eructation but also bloating or fullness. OTC and herbal preparations are popular. *Simethicone*, a mixture of siloxane polymers stabilized with silicon dioxide, is an inert nontoxic, insoluble liquid. Because of its capacity to collapse bubbles by forming a thin layer on their surface, it is an effective antifoaming agent; whether this accomplishes a therapeutic effect in the GI tract is not clear. Simethicone is available in chewable tablets, liquid-filled capsules, suspensions, and orally disintegrating strips, either by itself or in combination with other OTC medications, including antacids and other digestants. The usual dosage in adults is 40–125 mg four times daily after meals; the pediatric

Figure 50–6 Major bile acids in adults.

dose is 20–50 mg four times daily after meals and at bedtime, depending on the age of the child. Activated charcoal may be used alone or in combination with simethicone but has not been shown conclusively to have much benefit. An α -galactosidase OTC preparation is available to reduce gas from baked beans.

Short-Bowel Syndrome

Short-bowel syndrome is a malabsorption disorder caused by removal of the small intestine or rarely because of a congenital bowel abnormality. Short-bowel syndrome requires total *parenteral nutrition*, and treatments are aimed at reducing the need for this, including supplemented specialized diets and implementing a therapy based on physiologic principles of the actions of gut hormones.

Teduglutide

Mechanism of Action and Pharmacology. The gut hormone GLP-2 is secreted by L cells of the ileum and colon and is the only intestinotrophic gut peptide. Among other actions, it enhances growth of the intestinal mucosa through the release of mediators, including insulin-like growth factor 1. *Teduglutide* is a 33-amino acid GLP-2 analogue recently approved for the treatment of short-bowel syndrome (Jeppesen, 2015).

ADME. The drug has a $t_{1/2}$ of 1–2 h and is excreted in the urine. It is catabolized by dipeptidyl peptidase 4, but more slowly than the native peptide because of the substituted amino acid structure.

Therapeutic Uses and Adverse Effects. *Teduglutide* is administered subcutaneously once daily (0.05 mg/kg) to help improve intestinal absorption of nutrients and thereby reduce the need for parenteral support. Common side effects include abdominal pain, nausea, headache, and flu-like symptoms. There is also the potential for *teduglutide* to cause cancer of the bowel; therefore, it is not recommended for patients with active malignancies.

Acknowledgment: Laurence L. Brunton, Pankaj Jay Pasricha, and John L. Wallace contributed to this chapter in earlier editions of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: Antisecretory Agents and Gastroprotectives

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Prokinetic Agents (agents acting through specific receptors to regulate GI motility)		
<i>MOR antagonist</i> Alvimopan	<ul style="list-style-type: none"> Postoperative ileus 	<ul style="list-style-type: none"> Myocardial infarction Hypokalemia Dyspepsia
<i>5HT₄ receptor agonists</i> Cisapride Prucalopride	<ul style="list-style-type: none"> Gastroesophageal reflux disease Gastroparesis Intestinal pseudoobstruction Severe constipation Neonatal feeding intolerance 	<ul style="list-style-type: none"> Serious cardiac risks Headache Diarrhea
<i>D₂ receptor antagonist</i> Domperidone Metoclopramide (also 5HT ₃ receptor antagonist, 5HT ₄ receptor agonist)	<ul style="list-style-type: none"> Gastroparesis Prevention of nausea and vomiting 	<ul style="list-style-type: none"> Serious cardiac risks, especially in older persons Limited pediatric use Tardive dyskinesia Limited pediatric use Short-term use only
Motilin receptors Erythromycin (stimulate motilin receptors on GI smooth muscle cells)	<ul style="list-style-type: none"> Gastroparesis 	<ul style="list-style-type: none"> Short-term use only Ototoxicity Pseudomembranous colitis Cardiac risks
<i>CCK peptide analogue</i> Sincalide (C-terminal octapeptide of CCK)	<ul style="list-style-type: none"> Intravenous injection Gallbladder contraction Pancreatic secretion Intestinal motility Accelerates barium transit through small bowel for diagnostic testing 	<ul style="list-style-type: none"> Nausea, vomiting, diarrhea Sweating Light-headed Headache May cause serious allergic reactions
Laxatives		
Dietary Fiber		
Psyllium Methylcellulose	<ul style="list-style-type: none"> Increase fecal bulk 	<ul style="list-style-type: none"> Bloating

SUPPORTIVE THERAPY IN IBD

PEDIATRIC IBD

THERAPY OF IBD DURING PREGNANCY

Inflammatory Bowel Disease

Inflammatory bowel disease is a spectrum of remitting and relapsing, chronic, inflammatory intestinal conditions. IBD causes significant GI symptoms that include diarrhea, abdominal pain, bleeding, anemia, and weight loss. IBD conventionally is divided into two major subtypes: *ulcerative colitis* and *Crohn disease*.

Ulcerative colitis is characterized by confluent mucosal inflammation of the colon starting at the anal verge and extending proximally for a variable extent (e.g., proctitis, left-sided colitis, or pancolitis) (Ordas et al., 2012). *Crohn disease*, by contrast, is characterized by transmural inflammation of any part of the GI tract but most commonly the area adjacent to the ileocecal valve (Sartor, 2006). The inflammation in Crohn disease is not necessarily confluent, frequently leaving “skip areas” of relatively normal mucosa. The transmural nature of the inflammation may lead to fibrosis and strictures or fistula formation. IBD is often associated with extraintestinal manifestations involving the joints, skin, or eyes (Ott and Scholmerich, 2013). Primary sclerosing cholangitis is a serious but infrequent complication of ulcerative colitis in which inflammation and fibrostenosis occurs in the intra- and extrahepatic biliary tree (Williamson and Chapman, 2014). Chronic, severe IBD is associated with an increased risk for the development of colorectal cancer (Beaugerie and Itzkowitz, 2015).

Pathogenesis of IBD

A summary of proposed pathogenic events and potential sites of therapeutic intervention is shown in Figure 51–1. Both diseases are associated with an aberrant immune response to the commensal microbiota of the gut in genetically susceptible individuals (Sartor, 2006). Recent evidence of dysbiosis of the microbiome in IBD supports this theory (Bellaguarda and Chang, 2015). Nevertheless, Crohn disease and ulcerative colitis result from distinct pathogenic mechanisms at the level of mucosal immune activation (Xavier and Podolsky, 2007). Histologically, the transmural lesions in *Crohn disease* exhibit marked infiltration of lymphocytes and macrophages, granuloma formation, and submucosal fibrosis, whereas the superficial lesions in *ulcerative colitis* have lymphocytic and neutrophilic infiltrates.

Our understanding of the pathogenesis of both Crohn disease and ulcerative colitis has increased dramatically in recent years (Kaser et al., 2010). Within the diseased bowel in *Crohn disease*, the cytokine profile includes increased levels of IL-12, IL-23, IFN- γ , and TNF- α , findings characteristic of T_H1 -mediated inflammatory processes. In contrast,

the inflammatory response in *ulcerative colitis* resembles aspects of that mediated by the T_H2 pathway. Understanding of the inflammatory processes has evolved with the description of regulatory T cells and pro-inflammatory T_H17 cells, a novel T-cell population that expresses IL-23 receptor as a surface marker and produces, among others, the pro-inflammatory cytokines IL-17, IL-21, IL-22, and IL-26. T_H17 cells seem to play a prominent role in intestinal inflammation, particularly in *Crohn disease*.

Medical therapy for IBD is problematic. Because of the multifactorial nature of disease etiology, current therapy for IBD seeks to dampen the generalized inflammatory response. Regrettably, no agent can reliably accomplish this, and the response of an individual patient to a given drug may be limited and unpredictable. Recently, mucosal healing has become an important therapeutic aim, as opposed to simply the relief of symptoms (Florholmen, 2015). Specific goals of pharmacotherapy in IBD include controlling acute exacerbations of the disease, maintaining remission, and treating specific complications, such as fistulas (D’Haens et al., 2014). The major therapeutic options are considered in the following material.

Classifications of Drugs to Treat IBD

Mesalamine-Based Therapy

First-line therapy for mild-to-moderate ulcerative colitis generally involves 5-ASA (Bressler et al., 2015). 5-ASA-based treatments have largely been abandoned in maintenance of remission Crohn disease (Sandborn et al., 2007) due to the fact that their anti-inflammatory effects are targeted topically to the mucosa, with limited effects on deeper inflammation, which has implications for long-term outcomes. The archetype for this class of medications is *sulfasalazine*, which consists of 5-ASA linked to *sulfapyridine* by an *azo* bond (Figure 51–2).

Mechanism of Action, Pharmacological Properties, and Therapeutic Uses

Sulfasalazine is an oral prodrug that effectively delivers 5-ASA to the distal GI tract (Figure 51–3). The *azo* linkage in *sulfasalazine* prevents absorption in the stomach and small intestine, and the individual components are not liberated until colonic bacterial *azoreductases* cleave the bond for local effect (Peppercorn and Goldman, 1972). 5-ASA is the therapeutic moiety, with little, if any, contribution by *sulfapyridine*, a *sulfonamide* antibiotic. Although 5-ASA is a salicylate and can block COX, its mode of action does not appear to involve this activity; indeed, traditional NSAIDs

Abbreviations

APC: antigen-presenting cell
5-ASA: 5-aminosalicylic acid, mesalamine
COX: cyclooxygenase
FDA: Food and Drug Administration
GI: gastrointestinal
HGPRT: hypoxanthine-guanine phosphoribosyl transferase
HPA: hypothalamic-pituitary-adrenal (axis)
IBD: inflammatory bowel disease
IFN: interferon
IL: interleukin
6-MMP: 6-methyl-mercaptopurine
NSAID: nonsteroidal anti-inflammatory drug
PPAR-γ: peroxisome proliferator-activated receptor gamma
TGF: transforming growth factor
T_H: T helper (lymphocyte)
TNF-α: tumor necrosis factor alpha
TPMT: thiopurine methyltransferase
XO: xanthine oxidase

may exacerbate IBD and are strongly contraindicated. Many potential sites of action (effects on immune function and inflammation) have been demonstrated in vitro for *sulfasalazine* and *mesalamine* (Perrotta et al., 2015), including inhibition of the production of IL-1 and TNF-α, inhibition of the lipoxygenase pathway, scavenging of free radicals and oxidants, the inhibition of PPAR-γ, and inhibition of NF-κB, a transcription factor pivotal to production of inflammatory mediators. However, specific mechanisms of action underlying the efficacy of *sulfasalazine*/5-ASA in IBD have not been identified.

To preserve the therapeutic effect of 5-ASA without the adverse effects of *sulfapyridine*, several second-generation 5-ASA compounds have been developed. They are divided into two groups: *prodrugs* and *coated drugs*. Prodrugs contain the same azo bond as *sulfasalazine* but replace the linked *sulfapyridine* with either another 5-ASA (*olsalazine*) or an inert compound (*balsalazide*) (Jain et al., 2006). The alternative approaches employ *mesalamine* directly, using either a delayed-release formulation or a pH-sensitive coating. *Delayed-release mesalamine* releases drug throughout the GI tract, whereas *pH-sensitive mesalamine* is released in the small intestine and colon. These different distributions of drug delivery have potential therapeutic implications (Figure 51–4).

Oral *sulfasalazine* is effective in patients with mild or moderately active ulcerative colitis, with response rates of 60%–80%. The usual dose is 4 g/d in four divided doses with food; to avoid adverse effects, the dose is increased gradually from an initial dose of 500 mg twice a day. Doses as high as 6 g/d can be used but cause an increased incidence of side effects. For patients with severe colitis, *sulfasalazine* is of less-certain value, even though it is often added as an adjunct to systemic glucocorticoids. The drug plays a useful role in preventing relapses once remission has been achieved. Because they lack the dose-related side effects of *sulfapyridine*, the delayed- and pH-dependent formulations can be used to deliver *mesalamine* with improved safety and tolerability. The doses of *mesalamine* used to treat active disease are 2.4–4.8 g/d for up to 8 weeks, and current practice is to administer 5-ASA as a once-daily dose, which is as effective as a multiple daily dosing regimen (Feagan and Macdonald, 2012).

Topical preparations of *mesalamine* suspended in a wax matrix suppository or in a suspension enema are effective in active proctitis and distal ulcerative colitis, respectively. They appear to be superior to topical hydrocortisone in this setting, with response rates of 75%–90%. *Mesalamine* enemas (4 g/60 mL) should be used at bedtime and retained for at least 8 h; the suppository (500 and 1000 mg) should be used two to three times a day with the objective of retaining it for at least 3 h. Response to

local therapy with *mesalamine* may occur within 7–14 days; however, the usual course of therapy is from 8 to 16 weeks for induction of remission. Once remission has occurred, lower doses can be considered for maintenance, although increasingly the dose used for induction is continued for maintenance.

ADME

The pharmacokinetics of 5-ASA-based drugs are well described (Sandborn and Hanauer, 2003). About 20%–30% of orally administered *sulfasalazine* (*mesalamine* prodrug) is absorbed in the small intestine. Much of this is taken up by the liver and excreted unmetabolized in the bile; the rest (~10%) is excreted unchanged in the urine. The remaining 70% reaches the colon, where, if cleaved completely by bacterial enzymes, it generates 400 mg *mesalamine* for every gram of the parent compound. Thereafter, the individual components of *sulfasalazine* follow different metabolic pathways. *Sulfapyridine* is absorbed rapidly from the colon and undergoes extensive hepatic metabolism, including acetylation and hydroxylation, and conjugation with glucuronic acid, prior to excretion in the urine. The acetylation phenotype of the patient determines plasma levels of *sulfapyridine* and the probability of side effects; rapid acetylators have lower systemic levels of the drug and fewer adverse effects. Only 25% of *mesalamine* is absorbed from the colon, and most of the drug is excreted in the stool. The small amount that is absorbed is acetylated in the intestinal mucosal wall and liver and then excreted in the urine. Intraluminal concentrations of *mesalamine* therefore are very high (~1500 µg/mL).

The pH-sensitive coatings limit gastric and small intestinal absorption of *mesalamine*. The pharmacokinetics of delayed-release formulations differ somewhat. The ethylcellulose-coated microgranules are released in the upper GI tract as discrete prolonged-release units of *mesalamine*. Acetylated *mesalamine* can be detected in the circulation within an hour after ingestion, indicating some rapid absorption, although some intact microgranules can later be detected in the colon. Because the delayed-release drug is released in the small bowel, a greater fraction of the 5-ASA in the delayed-release formulations is absorbed systemically compared with the other 5-ASA preparations.

Adverse Effects

Side effects of *sulfasalazine* occur in 10%–45% of patients with ulcerative colitis and are related primarily to the sulfa moiety. Some are dose related, including headache, nausea, and fatigue; these can be minimized by giving the medication with meals or by decreasing the dose. Allergic reactions include rash, fever, Stevens-Johnson syndrome, hepatitis, pneumonitis, hemolytic anemia, and bone marrow suppression. *Sulfasalazine* reversibly decreases the number and motility of sperm but does not impair female fertility. *Sulfasalazine* inhibits intestinal folate absorption and is usually administered with folate. *Mesalamine* formulations generally are well tolerated. Headache, dyspepsia, and skin rash are the most common side effects. Diarrhea appears to be particularly common with *olsalazine* (occurring in 10%–20% of patients). Nephrotoxicity, although rare, is a more serious concern. *Mesalamine* has been associated with interstitial nephritis; renal function should be monitored in all patients receiving these drugs.

Both *sulfasalazine* and its metabolites cross the placenta but have not been shown to harm the fetus. The newer formulations also appear to be safe in pregnancy, but there have been some safety concerns about dibutyl phthalate, an inactive ingredient in the coating of some formulations, in the context of pregnancy.

Glucocorticoids

The glucocorticoids cortisone, dexamethasone, prednisolone, and triamcinolone are all FDA approved for the treatment of IBD.

Mechanism of Action, Pharmacological Properties, and Therapeutic Uses

The effects of glucocorticoids on the inflammatory response are numerous (see Chapters 42 and 46). Glucocorticoids are indicated for

Figure 51-1 Proposed pathogenesis of IBD and target sites for pharmacological intervention. Shown are the interactions among bacterial antigens in the intestinal lumen and immune cells in the intestinal wall. If the epithelial barrier is impaired, bacterial antigens can gain access to APCs such as dendritic cells in the lamina propria. These cells then present the antigen(s) to CD4⁺ lymphocytes and also secrete cytokines such as IL-12 and IL-18, thereby inducing the differentiation of T_H1 cells in Crohn disease (or, under the control of IL-4, T_H2 cells in ulcerative colitis). The balance of pro-inflammatory and anti-inflammatory events is also governed by regulatory T_H17 and T_{Reg} cells, both of which serve to limit immune and inflammatory responses in the GI tract. TGF-β and IL-6 are important cytokines that drive the expansion of the regulatory T-cell subsets. The T_H1 cells produce a characteristic array of cytokines, including IFN-γ and TNF-α, which in turn activate macrophages. Macrophages positively regulate T_H1 cells by secreting additional cytokines, including IFN-γ and TNF-α. Recruitment of a variety of leukocytes is mediated by activation of resident immune cells, including neutrophils. Cell adhesion molecules such as integrins are important in the infiltration of leukocytes, and novel biological therapeutic strategies aimed at blocking leukocyte recruitment are effective at reducing inflammation. General immunosuppressants (e.g., glucocorticoids, thioguanine derivatives, methotrexate, and cyclosporine) affect multiple sites of inflammation. More site-specific interventions involve intestinal bacteria (antibiotics, prebiotics, and probiotics) and therapy directed at TNF-α, IL-12/23, or integrins.

moderate-to-severe IBD. Patients with IBD segregate into three general groups with respect to their response to glucocorticoids:

- *Glucocorticoid-responsive patients* improve clinically within 1–2 weeks and remain in remission as the steroids are tapered and then discontinued.
- *Glucocorticoid-dependent patients* respond to glucocorticoids but then experience a relapse of symptoms as the steroid dose is tapered or discontinued.
- *Glucocorticoid-unresponsive* or “steroid-resistant” patients do not improve even with prolonged high-dose steroids.

Glucocorticoids induce a reduction in the inflammatory response and symptomatic remission in most patients with Crohn disease, with improvement generally occurring within 5 days of initiating treatment; however, some patients require treatment for several weeks before

remission occurs. Glucocorticoids sometimes are used for prolonged periods to control symptoms in corticosteroid-dependent patients, as these patients will often experience a recurrence of their disease as the glucocorticoid is withdrawn. A proportion of patients with IBD are steroid resistant, and the failure to respond to steroids with prolonged remission (i.e., a disease relapse) should prompt consideration of adjunctive and alternative therapies, including immunosuppressive agents and biological therapies (Manz et al., 2012). Glucocorticoids are not a safe or practical means to maintain remission in either ulcerative colitis or Crohn disease due to the high rate of adverse events associated with their prolonged use. The most commonly used glucocorticoid in Crohn disease is *prednisone*, given orally or intravenously. For more severe cases, glucocorticoids such as *methylprednisolone* or *hydrocortisone* are given intravenously.

Sulfasalazine

Olsalazine

Balsalazide

Figure 51-2 Sulfasalazine and related agents. The red N atoms indicate the diazo linkage that is cleaved to generate the active moiety.

The enteric-release form of the synthetic steroid, *budesonide*, is used for ileocecal Crohn disease. Its putative action is the delivery of therapeutic quantities of steroid to a specific portion of inflamed gut while minimizing systemic side effects, owing to its local release and extensive first-pass hepatic metabolism to inactive derivatives such that systemic levels remain low. Generally, however, oral *budesonide* is considered less effective than conventional glucocorticoids. *Budesonide* is FDA-approved for use in the short-term maintenance of remission (up to 3 months), although recent studies have suggested it is not more effective than placebo for this indication (Kuenzig et al., 2014).

Glucocorticoid enemas are useful mainly in patients whose disease is limited to the rectum and left colon. *Betamethasone* and *budesonide* are available as retention enemas. Patients with distal disease usually respond within 3–7 days. Absorption, although less than with oral preparations, is still substantial (up to 50%–75%). *Hydrocortisone* also can be given once or twice daily as a 10% foam suspension that delivers 80 mg *hydrocortisone* per application; this formulation can be useful in patients with very short areas of distal proctitis and difficulty retaining enemas.

ADME

Prednisone is the most commonly administered glucocorticoid and is used for the induction of remission of moderate-to-severe Crohn disease in patients who do not respond to 5-ASA drugs (Benchimol et al., 2008).

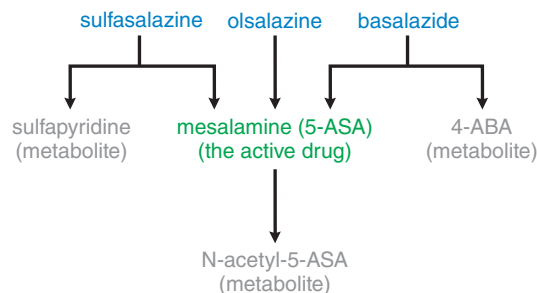

Figure 51-3 Metabolic fates of the different oral formulations of 5-ASA. Chemical structures are in Figure 51-2. 4-ABA, 4-aminobenzoyl- β -alanine.

It is sometimes given as a first-line therapeutic to induce remission. *Prednisone* is most often administered orally but can be administered intravenously when patients present with severe, acute flares of disease. Initial doses in IBD are 40–60 mg of *prednisone* or equivalent per day; higher doses are generally no more effective. Most patients respond within 10–14 days, at which point the dose is reduced by 5 mg per week (tapered) over several weeks to months. *Prednisone* is absorbed at a rate of 50%–90%; 65%–90% of the absorbed drug is protein bound in the serum. It is metabolized to the active compound, *prednisolone*, in the liver. The $t_{1/2}$ for *prednisone* about 3.5 h, with metabolized drug excreted in the urine. Because of the complex nature of the mechanism of action of glucocorticoids, numerous drug interactions have been reported.

Budesonide for the treatment of IBD is administered orally at a dose of 9 mg/d for up to 8 weeks (Kane et al., 2002). There is usually no therapeutic benefit of continuing treatment beyond 3 months. The bioavailability of orally administered *budesonide* is limited (9%–21%) by its high first-pass metabolism. The time to peak serum concentration is 7–19 h when given in capsule form. The $t_{1/2}$ is about 2–3.6 h. Excretion of metabolites is renal (60%) and fecal.

Adverse Effects

The significant adverse events associated with conventional glucocorticoids such as *prednisone* limit their long-term use. These are numerous, but among the more common are skin and soft tissue manifestations, including skin thinning and the development of Cushingoid features (weight redistribution and weight gain). Other side effects include cardiovascular events and psychiatric and cognitive effects. Conventional glucocorticoids can suppress the HPA axis, which can result in adrenal insufficiency when the drug is withdrawn abruptly. This effect necessitates the tapering of dose rather than quick withdrawal of the drug. The mechanisms underlying these and other adverse effects of conventional glucocorticoids are detailed in Chapter 46. *Budesonide* has a similar profile of adverse events, but with lower incidence due its extensive first-pass hepatic metabolism.

Immunomodulatory Agents

Several drugs developed for cancer chemotherapy or as immunosuppressive agents in organ transplants are also used for treatment of IBD.

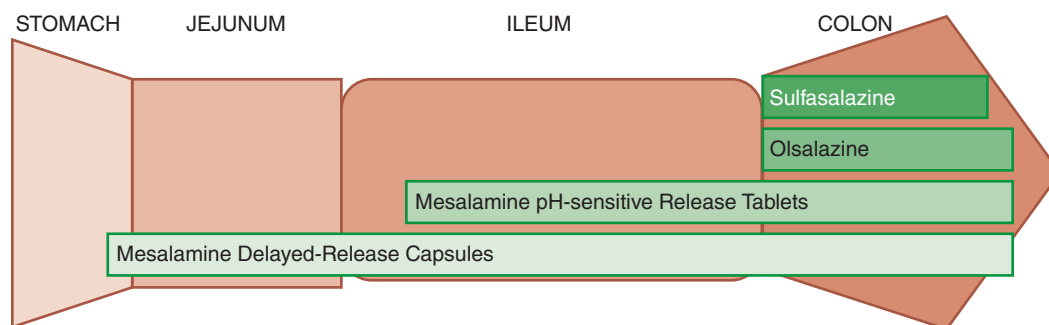

Figure 51-4 Sites of release of mesalamine (5-ASA) in the GI tract from different oral formulations.

Clinical experience has defined specific roles for each of these agents as mainstays in the pharmacotherapy of IBD. However, their potential for serious adverse effects mandates a careful assessment of risks and benefits in each patient.

Thiopurine Derivatives

The cytotoxic thiopurine derivatives *mercaptopurine* and *azathioprine* (see Chapters 35 and 66) are used off label to treat patients with severe IBD or those who are steroid resistant or steroid dependent (Coskun et al., 2016). These thiopurines impair purine biosynthesis and inhibit cell proliferation. Both are prodrugs: Azathioprine is converted to 6-mercaptopurine, which is subsequently metabolized to 6-thioguanine nucleotides, the putative active moieties (Figure 51–5).

Therapeutic Uses. These drugs are generally used interchangeably with appropriate dose adjustments, typically *azathioprine* (1.5–2.5 mg/kg) or *mercaptopurine* (1.5–2.0 mg/kg) in both Crohn disease and ulcerative colitis as an adjunct to glucocorticoids and biologics (Nielsen et al., 2001). They help maintain remission in both diseases; they also may prevent or delay recurrence of Crohn disease after surgical resection. Finally, they are used to treat fistulas in Crohn disease. The clinical response to *azathioprine* or *mercaptopurine* may take weeks to months, such that other drugs with a more rapid onset of action (e.g., *mesalamine*, glucocorticoids, or biologics) are preferred in the acute setting.

In general, physicians who treat IBD believe that the long-term risks of *azathioprine-mercaptopurine* are lower than those of steroids. Thus, these purines are used in glucocorticoid-unresponsive or glucocorticoid-dependent disease and in patients who have had recurrent flares of disease requiring repeated courses of steroids. In addition, patients who have not responded adequately to *mesalamine* but are not acutely ill may benefit by conversion from glucocorticoids to immunomodulatory drugs. Immunomodulators therefore may be viewed as steroid-sparing agents.

ADME. Favorable responses to *azathioprine-mercaptopurine* are seen in up to two-thirds of patients. *Mercaptopurine* has three metabolic fates (Figure 51–5):

- conversion by XO to 6-thiouric acid;
- metabolism by TPMT to 6-MMP; and
- conversion by HGPRT to 6-thioguanine nucleotides and other metabolites.

The relative activities of these different pathways may explain, in part, individual variations in efficacy and adverse effects.

The plasma $t_{1/2}$ of *mercaptopurine* is limited by its relatively rapid (i.e., within 1–2 h) uptake into erythrocytes and other tissues. Following this uptake, differences in TPMT activity determine the drug's fate. Approximately 80% of the U.S. population has what is considered “normal” metabolism, whereas 1 in 300 individuals have minimal TPMT activity. In the latter setting, *mercaptopurine* metabolism is shifted away from 6-MMP and driven toward 6-thioguanine nucleotides, which can severely suppress the bone marrow. About 10% of people have intermediate TPMT activity;

Figure 51–5 Metabolism of *azathioprine* and *6-mercaptopurine*. The activities of these enzymes vary among humans because genetic polymorphisms are expressed differentially, explaining responses and side effects when *azathioprine-mercaptopurine* therapy is employed.

given a similar dose, these individuals will tend to have higher 6-thioguanine levels than the normal metabolizers. Finally, about 10% of the population are rapid metabolizers. In these individuals, *mercaptopurine* is shunted away from 6-thioguanine nucleotides toward 6-MMP, which has been associated with abnormal liver function tests. In addition, relative to normal metabolizers, the 6-thioguanine levels of these rapid metabolizers are lower for an equivalent oral dose, possibly reducing therapeutic response. Pharmacogenetic typing can guide therapy (see Chapter 7).

Xanthine oxidase in the small intestine and liver converts *mercaptopurine* to thiouric acid, which has no therapeutic activity. Inhibition of XO by allopurinol diverts *mercaptopurine* to more active metabolites, such as 6-thioguanine, increasing both immunomodulatory and potential toxic effects. Thus, patients on *mercaptopurine* should be warned about potentially serious interactions with medications used to treat gout or hyperuricemia, and the dose should be decreased to 25% of the standard dose in subjects who are already taking allopurinol.

Adverse Effects. Adverse effects of *azathioprine-mercaptopurine* can be either *idiosyncratic* or *dose related*. Adverse effects occur at any time after initiation of treatment and can affect up to 10% of patients. One of the most serious idiosyncratic reactions is pancreatitis, which affects about 5% of patients treated with these drugs. Fever, rash, and arthralgias are seen occasionally; nausea and vomiting are somewhat more frequent. The major dose-related adverse effect is bone marrow suppression, and blood counts should be monitored closely when therapy is initiated and at less-frequent intervals during maintenance therapy. Elevations in liver function tests also may be dose related. The serious adverse effect of cholestatic hepatitis is relatively rare. Thiopurines given in the setting of cancer chemotherapy or organ transplants have been associated with an increased incidence of malignancy, particularly non-Hodgkin lymphoma.

Methotrexate

Methotrexate is a folic acid analogue that inhibits *dihydrofolate reductase*, thereby blocking DNA synthesis and causing cell death (Coskun et al., 2016). The anti-inflammatory effects of *methotrexate* may involve mechanisms in addition to inhibition of dihydrofolate reductase. These include inhibition of purine metabolism, inhibition of T-cell activation and production of cytokines and intercellular adhesion molecules, and inhibition of IL-1 β receptor binding.

Therapeutic Uses. *Methotrexate* is reserved for patients whose IBD is either steroid resistant or steroid dependent. In Crohn disease, it is used for maintenance of remission and as an adjunct to biologics to boost efficacy and reduce formation of antidrug antibodies (Patel et al., 2014). *Methotrexate* (15–25 mg/week) is generally administered parenterally. The choice of parenteral administration reflects the unpredictable intestinal absorption at higher doses of *methotrexate* and in the presence of intestinal disease. A dose of 25 mg weekly is often used for induction of the remission of the inflammatory response, with 15 mg given once weekly for maintenance of remission. *Methotrexate* is sometimes used in combination with anti-TNF- α antibody therapy (see discussion that follows).

ADME. *Methotrexate* is administered intramuscularly or subcutaneously for induction and maintenance of remission of Crohn disease. After administration, approximately 50% is bound to serum proteins. *Methotrexate* can cross the blood-brain barrier but occurs at much lower levels in cerebrospinal fluid than in serum. It has a $t_{1/2}$ of about 3–10 h at doses used for the treatment of Crohn disease (see Appendix II). Approximately 90% of administered *methotrexate* appears unaltered in the urine, likely as a result of active tubular secretion.

Adverse Effects. Drugs that inhibit renal excretion of MTX may increase treatment-related toxicity. These include NSAIDs, phenytoin, ciprofloxacin, penicillin-type drugs, probenecid, amiodarone, and proton pump inhibitors. *Methotrexate*, at the doses used for the treatment of Crohn disease, is generally well tolerated. When toxicity occurs, it manifests as nausea, loose stool, stomatitis, punctate cutaneous eruption, CNS symptoms (including headache, fatigue, and impaired ability to concentrate),

alopecia, fever (drug related or due to infection), and hematologic abnormalities, particularly macrocytosis.

Cyclosporine

Cyclosporine is an inhibitor of calcineurin and a potent immunomodulator used most frequently after organ transplantation (see Chapter 35). It is effective in specific clinical settings in IBD, but the high frequency of significant adverse effects limits its use as a first-line medication.

Therapeutic Uses. Between 50% and 80% of these severely ill patients with IBD improve significantly (generally within 7 days) in response to intravenous *cyclosporine* (2–4 mg/kg per day), sometimes avoiding emergent colectomy. Careful monitoring of *cyclosporine* levels is necessary to maintain a therapeutic level between 300 and 400 ng/mL of whole blood. Oral *cyclosporine* is less effective as maintenance therapy in Crohn disease, perhaps because of its limited intestinal absorption. In this setting, long-term therapy with formulations of *cyclosporine* that have increased oral bioavailability may be more effective. *Cyclosporine* can be used to treat fistulous complications of Crohn disease. A significant rapid response to intravenous *cyclosporine* has been observed; however, frequent relapses accompany oral *cyclosporine* therapy, and other medical strategies are required to maintain fistula closure. Thus, calcineurin inhibitors generally are used to treat specific problems over the short-term while providing a bridge to longer-term therapy.

ADME. *Cyclosporine* given orally is erratically and incompletely absorbed by the intestine. Following absorption, 90%–98% is bound to serum lipoproteins. Depending on the formulation, the $t_{1/2}$ is biphasic, with the terminal phase being about 9–18 h.

Adverse Effects. The significant adverse effects associated with the use of *cyclosporine* limit its use to specific types of severe IBD. These side effects most often include increased susceptibility to infections, renal insufficiency, hypertension, seizures, and peripheral neuropathy. Significant drug interactions have been reported.

Other immunosuppressants that are being evaluated in IBD include the calcineurin inhibitor *tacrolimus* (FK506) and the inhibitors of inosine monophosphate dehydrogenase, *mycophenolate mofetil* and *mycophenolate*, to which lymphocytes are especially susceptible (see Chapter 35).

Biological Therapies for IBD

Anti-TNF- α Monoclonal Antibodies

Infliximab, *adalimumab*, and *certolizumab pegol* are monoclonal immunoglobulins that have been developed for the treatment of chronic inflammatory diseases. *Infliximab* is a chimeric antibody (25% mouse, 75% human), whereas *adalimumab* is a fully humanized antibody. *Certolizumab pegol* is a humanized fragment antigen binding that is “pegylated” (i.e., bound to a polyethylene glycol polymer to increase serum half-life of the parent compound). These drugs bind to and neutralize both soluble and membrane-bound TNF- α , one of the principal cytokines mediating the T_H1 immune response characteristic of Crohn disease (see Figure 51–1), thereby preventing its binding to p55 and p75 receptors. Chapters 34 and 35 present more detailed and mechanistic view of Ab production and the use of Abs to regulate immune function.

Therapeutic Uses and ADME—Crohn Disease. Monoclonal anti-TNF- α antibodies are used for moderate-to-severe Crohn disease, including fistulizing disease that is resistant to other therapies (Peyrin-Biroulet et al., 2008). The antibody preparations are used for both the induction and the maintenance of remission in adults and children. Anti-TNF- α antibodies used in the treatment of Crohn disease are administered parenterally. *Infliximab* is given intravenously at an initial dose of 5 mg/kg, with subsequent doses of 5 mg/kg at weeks 2 and 6, followed by maintenance doses of 5 mg/kg every 8 weeks. The $t_{1/2}$ is about 8–10 days, although the clearance rate increases in patients who develop anti-infliximab antibodies. *Adalimumab* is given subcutaneously at an initial dose of 160 mg, with subsequent doses of 80 mg at week 2 and maintenance doses of 40 mg every second week starting on week 4. Bioavailability following a 40-mg

dose is about 64%; the $t_{1/2}$ is about 2 weeks. *Certolizumab pegol* is given at an induction dose of 400 mg subcutaneously at weeks 0, 2, and 4, and then every 4 weeks for maintenance of response. Bioavailability when given subcutaneously is about 80%; the $t_{1/2}$ is about 2 weeks. The clearance of monoclonal anti-TNF- α antibodies is not well understood but is likely due to proteolytic degradation. The polyethylene glycol moiety of *certolizumab pegol* is cleared by urinary excretion.

Adverse Effects. Both acute (fever, chills, urticaria, or even anaphylaxis) and subacute (serum sickness–like) reactions may develop after infliximab infusion. Antibodies to infliximab can decrease its clinical efficacy (Lichtenstein, 2013). Strategies to minimize the development of these antibodies (e.g., treatment with glucocorticoids or other immunosuppressives) may be critical to preserving infliximab efficacy but may increase the chance of infection. Because *adalimumab* and *certolizumab* are humanized antibodies, there is less chance for the development of an immune response against them. *Infliximab* therapy is associated with increased incidence of respiratory infections; of particular concern is potential reactivation of tuberculosis or development of opportunistic infections with subsequent dissemination. The FDA recommends that candidates for *infliximab* therapy be tested for latent tuberculosis with purified protein derivative; patients testing positive should be treated prophylactically with isoniazid. *Infliximab* is contraindicated in patients with severe congestive heart failure. There is concern about a possible increased incidence of non-Hodgkin lymphoma, but a causal role has not been established.

Although *infliximab* was designed specifically to target TNF- α , it may have more complex actions. *Infliximab* binds membrane-bound TNF- α and may cause lysis of these cells by antibody-dependent or cell-mediated cytotoxicity. Thus, *infliximab* may deplete specific populations of subepithelial inflammatory cells. These effects, together with its mean terminal plasma $t_{1/2}$ of 8–10 days, may explain the prolonged clinical effects of *infliximab*. *Infliximab* (5 mg/kg infused IV at intervals of every 6–8 weeks) decreases the frequency of acute flares in approximately two-thirds of patients with moderate-to-severe Crohn disease and also facilitates the closing of enterocutaneous fistulas associated with Crohn disease. Emerging evidence also supports its efficacy in maintaining remission and in preventing recurrence of fistulas. The combination of *infliximab* and *azathioprine* is more effective than *infliximab* alone in induction of remission and mucosal healing in steroid-resistant patients.

Other Monoclonal Antibodies for the Treatment of Crohn Disease

Vedolizumab is a humanized, monoclonal antibody that binds to and inhibits the α_4 -integrin subunit and therefore blocks binding of $\alpha_4\beta_1$ and $\alpha_4\beta_7$ on lymphocytes to *addressin* (also known as mucosal vascular addressin cell adhesion molecule, MADCAM 1) on venular endothelial cells, thus preventing lymphocyte recruitment to the intestinal mucosa (Jovani and Danese, 2013). It is approved for use in the treatment of moderate-to-severe Crohn disease and ulcerative colitis. *Vedolizumab* is generally given at a dose of 300 mg at 0, 2, and 6 weeks, with maintenance doses given every 8 weeks thereafter. The main side effects are headache, hypersensitivity reactions, arthralgia, nasopharyngitis, and fatigue. Anti-TNF- α drugs may enhance the adverse effects of *vedolizumab*.

Ustekinumab is a monoclonal antibody that targets the p40 subunit common to the pro-inflammatory cytokines IL-12 and IL-23, thus preventing activation of IL-12 β 1 and IL-23 receptors on lymphocytes (Teng et al., 2015). Originally developed for the treatment of psoriasis, it shows efficacy in the induction and maintenance of remission in Crohn disease. Trials indicate effective induction and maintenance of remission at a dose of 6 mg/kg (Khanna et al., 2015). During the initial trials of *ustekinumab* for Crohn disease, side effects included headache, arthralgia, infection, nausea, and nasopharyngitis.

Therapeutic Uses and ADME—Ulcerative Colitis. Unlike Crohn disease, ulcerative colitis can be cured with surgery (colectomy). Thus, the cost and potential adverse events associated with monoclonal antibody

therapy need to be balanced with the effectiveness of the drug at preventing the need for colonic resection. Biologics are well established in their use in ulcerative colitis, particularly in those patients for whom primary therapy with glucocorticoids, 5-ASA, or immunomodulators has failed. *Infliximab*, *adalimumab*, and *golimumab* have become mainstays in the treatment of ulcerative colitis, and *vedolizumab* is also now available. Large controlled clinical trials have demonstrated that anti-TNF- α agents significantly reduce the severity of the inflammation that characterizes ulcerative colitis. Similarly, *vedolizumab* is now indicated and approved for the treatment of moderate-to-severe ulcerative colitis. The administration, dosing, metabolism, and adverse events are similar for the use of these drugs in ulcerative colitis and Crohn disease.

Manipulating the Intestinal Microbiome to Treat IBD

Antibiotics and Probiotics

A balance normally exists in the GI tract among the mucosal epithelium, the normal gut flora, and the immune response (Biteen et al., 2016; Schreiner et al., 2015). Dysbiosis of the intestinal microbiome is now considered a key factor in the development of IBD (Dalal and Chang, 2014). Thus, certain bacterial strains may be either pro- (e.g., *Bacteroides*) or anti-inflammatory (e.g., *Lactobacillus*), prompting attempts to manipulate the colonic flora in patients with IBD. Traditionally, antibiotics have been used most prominently in Crohn disease.

Antibiotics can be used as:

- adjunctive treatment along with other medications for active IBD in severe cases where there is concern about coexisting sepsis
- treatment of perforating or fistulizing complications of Crohn disease
- prophylaxis for recurrence in postoperative Crohn disease

Metronidazole, *ciprofloxacin*, *amoxicillin-clavulanate*, and *piperacillin-tazobactam* are the antibiotics used most frequently. Crohn disease–related complications that may benefit from antibiotic therapy include intra-abdominal abscess and inflammatory masses, perianal disease (including fistulas and perirectal abscesses), small-bowel bacterial overgrowth secondary to partial small-bowel obstruction, secondary infections with organisms such as *Clostridium difficile*, and postoperative complications.

More recently, *probiotics* have been used to treat specific clinical situations in IBD. Probiotics are mixtures of putatively beneficial lyophilized bacteria given orally. Several studies have provided evidence for beneficial effects of probiotics in ulcerative colitis and pouchitis (Sokol, 2014). However, the utility of probiotics as a primary therapy for IBD remains unclear.

Fecal Transplant as Therapy in IBD

The recognition that the etiology of IBD involves dysbiosis of the intestinal microbiome has raised interest in methods to reestablish normal microflora in patients. Fecal transplant involves the instillation of a preparation of feces from a healthy donor into the colon, either by enema or during colonoscopy. This has proven to be an effective therapy for antibiotic-resistant *C. difficile* infection. Several clinical trials have assessed the efficacy of fecal transplant in Crohn disease and ulcerative colitis, with varying results (Hansen and Sartor, 2015).

Supportive Therapy in IBD

Analgesic, anticholinergic, and antidiarrheal agents play supportive roles in reducing symptoms and improving quality of life. Oral iron, folate, and

vitamin B₁₂ should be administered as indicated. *Loperamide* or *diphenoxylate* (see Chapter 50) can be used to reduce the frequency of bowel movements and relieve rectal urgency in patients with mild disease in selected circumstances; these agents are contraindicated in patients with severe disease because they may predispose to the development of toxic megacolon. *Cholestyramine* can be used to treat bile salt–induced colonic secretion in patients who have undergone limited ileocolic resections. Anticholinergic agents (dicyclomine hydrochloride, etc.; Chapter 10) are used to reduce abdominal cramps, pain, and rectal urgency. As with the antidiarrheal agents, they are contraindicated in severe disease or when obstruction is suspected.

Pediatric IBD

Children and adolescents remain the fastest-growing group of patients with IBD. On average, children present with more severe disease than do adults. In addition, while many children present with the classical symptoms of IBD, approximately 22% of children present with additional symptoms, such as growth failure, perianal disease, or other extraintestinal manifestations as the primary symptom, thus complicating diagnosis.

The drugs used for treating pediatric IBD are the same as those used for the treatment of these diseases in adults. Exclusive enteral nutrition is an effective alternative to 5-ASA compounds, glucocorticoids, immunosuppressants, and biologics. Indeed, 8–12 weeks of liquid formula as the sole source of calories is as effective as glucocorticoids in relieving symptoms and has the advantage of supporting growth (Rosen et al., 2015). In terms of drug therapy, a child's immunization status should be considered before commencing immunosuppressive therapy (glucocorticoids, *azathioprine-methotrexate*, anti-TNF- α drugs). Children should be tested for latent tuberculosis, particularly prior to treatment with anti-TNF- α drugs. During treatment, children may receive inactivated vaccines, but it is not recommended that they be given live vaccines.

Antibiotics have recently been shown to have some utility in treating mild-to-moderate pediatric Crohn disease. In particular, *ciprofloxacin*, *metronidazole*, and *rifaximin* were demonstrably effective in small clinical trials (Serban, 2015). Their role in the treatment of ulcerative colitis has yet to be established.

Therapy of IBD During Pregnancy

Inflammatory bowel disease is a chronic disease that affects women in their reproductive years. In general, decreased disease activity increases fertility and improves pregnancy outcomes. At the same time, limiting medication during pregnancy is always desired but sometimes conflicts with the goal of controlling the disease. The use of medical therapies to treat IBD during pregnancy and lactation has been reviewed (Nielsen et al., 2014), although studies that thoroughly investigated the use of medications to treat IBD in pregnancy are limited (Damas et al., 2015). *Mesalamine* and *glucocorticoids* are FDA category B drugs (see Appendix I) that are used frequently in pregnancy and generally are considered safe, whereas *methotrexate* is absolutely contraindicated in pregnant patients. There does not appear to be an increase in adverse outcomes in pregnant patients maintained on thiopurine-based immunosuppressives. Anti-TNF- α drugs, particularly *infliximab* and *adalimumab*, have been assessed for their safety for use during pregnancy and have been found to have low risk for adverse events (Khan et al., 2014).

Acknowledgment: Laurence L. Brunton, Syed Jafri, Joseph H. Sellin, Pankaj Jay Pasricha, and John L. Wallace contributed to this chapter in earlier editions of this book. We have retained some of their text in the current edition.

Drug Facts for Your Personal Formulary: *Drugs for the Treatment of Inflammatory Bowel Diseases*

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Mesalamine-Based Drugs		
Mesalamine (5-ASA)	<ul style="list-style-type: none"> Induction and maintenance of remission in mild-to-moderate ulcerative colitis Used in combination with glucocorticoids for severe ulcerative colitis 	<ul style="list-style-type: none"> Effects are primarily topical with limited effects on deeper tissue inflammation Following oral administration, jejunum is primary site of absorption, so utility in more distal disease is limited Can be delivered as a suppository for rectal disease
Sulfasalazine	<ul style="list-style-type: none"> Induction and maintenance of remission in mild-to-moderate ulcerative colitis Used in combination with glucocorticoids for severe ulcerative colitis 	<ul style="list-style-type: none"> Prodrug, delivers 5-ASA to more distal GI regions following metabolism by colonic bacteria Sulfapyridine is also released; may cause adverse effects in patients sensitive to sulfa drugs
Olsalazine	<ul style="list-style-type: none"> Induction and maintenance of remission in mild-to-moderate ulcerative colitis Used in combination with glucocorticoids for severe ulcerative colitis 	<ul style="list-style-type: none"> Prodrug with two azo-linked 5-ASA molecules Eliminates the side effects associated with the sulfapyridine moiety of sulfasalazine
Balsalazide	<ul style="list-style-type: none"> Induction and maintenance of remission in mild-to-moderate ulcerative colitis Used in combination with glucocorticoids for severe ulcerative colitis 	<ul style="list-style-type: none"> Prodrug with a 5-ASA molecule linked to an inert, unabsorbable second moiety Eliminates the side effects associated with the sulfapyridine moiety of sulfasalazine
Glucocorticoids: Minimize duration of use. Taper dose prior to stopping to minimize disease relapse and avoid adrenal insufficiency that follows rapid glucocorticoid withdrawal after prolonged therapy has suppressed the HPA axis.		
Prednisone	<ul style="list-style-type: none"> Induction of remission in moderate-to-severe Crohn disease and ulcerative colitis 	<ul style="list-style-type: none"> Hepatic metabolism to active moiety, prednisolone Not used for maintenance therapy due to serious adverse effects
Methylprednisolone	<ul style="list-style-type: none"> Induction of remission in moderate-to-severe Crohn disease and ulcerative colitis 	<ul style="list-style-type: none"> Can be administered orally, intravenously, or intramuscularly to patients who respond poorly to oral prednisone Preferred over hydrocortisone, which has higher incidence of Na⁺ retention and K⁺ wasting
Hydrocortisone	<ul style="list-style-type: none"> Induction of remission in moderate-to-severe Crohn disease and ulcerative colitis 	<ul style="list-style-type: none"> Administered intravenously to patients who respond poorly to oral prednisone
Budesonide	<ul style="list-style-type: none"> Induction of remission in mild-to-moderate Crohn disease and ulcerative colitis, particularly in distal disease Not effective for long-term maintenance of clinical remission 	<ul style="list-style-type: none"> Prominent first-pass metabolism reduces side effects that can result from maintenance of higher systemic levels
Immunomodulatory Agents		
6-Mercaptopurine	<ul style="list-style-type: none"> Used as an adjunct to glucocorticoids and biologics in the treatment of moderate-to-severe Crohn disease and ulcerative colitis Effective in maintenance of remission 	<ul style="list-style-type: none"> Slow-acting drug; maximum therapeutic benefit may take months to achieve Other metabolites also have anti-inflammatory activity Fourfold increased risk of lymphoma in patients with IBD treated with thiopurines
Azathioprine	<ul style="list-style-type: none"> Used as an adjunct to glucocorticoids and biologics in the treatment of moderate-to-severe Crohn disease and ulcerative colitis Effective in maintenance of remission 	<ul style="list-style-type: none"> Prodrug metabolized nonenzymatically in blood to active form, 6-mercaptopurine Other metabolites also have anti-inflammatory activity Fourfold increased risk of lymphoma in patients with IBD treated with thiopurines
Methotrexate	<ul style="list-style-type: none"> Maintenance of remission in Crohn disease, particularly steroid-resistant or steroid-dependent disease Often used in combination with biologic agents 	<ul style="list-style-type: none"> Folic acid analogue that has anti-inflammatory activity of unclear mechanism Administered parenterally Cleared unaltered by the kidney, so inhibition of renal excretion mechanisms may lead to drug toxicity
Cyclosporine	<ul style="list-style-type: none"> Used to treat specific cases of severe Crohn disease, including fistulizing disease Not useful for maintenance of remission 	<ul style="list-style-type: none"> Erratic and incomplete absorption means blood levels must be monitored Significant adverse events profile
Tacrolimus (FK506)	<ul style="list-style-type: none"> Useful for the treatment of refractory Crohn disease 	<ul style="list-style-type: none"> Immunomodulator with similar mechanism as cyclosporine but with better oral absorption

Biologics: Anti-TNF- α		
Infliximab	<ul style="list-style-type: none"> Induction or maintenance of remission in moderate-to-severe Crohn disease or ulcerative colitis in patients who have not responded well to other therapies 	<ul style="list-style-type: none"> Partly humanized, chimeric anti-TNF-α monoclonal antibody Usually administered by intravenous infusion Patients may develop antibodies against the drug
Adalimumab	<ul style="list-style-type: none"> Induction or maintenance of remission in moderate-to-severe Crohn disease or ulcerative colitis in patients who have not responded well to other therapies 	<ul style="list-style-type: none"> Fully humanized anti-TNF-α monoclonal antibody; reduced incidence of antidrug antibodies Administered subcutaneously Useful for patients for whom infliximab has lost efficacy or has caused adverse reactions
Certolizumab pegol	<ul style="list-style-type: none"> Induction or maintenance of remission in moderate-to-severe Crohn disease in patients who have not responded well to other therapies 	<ul style="list-style-type: none"> Humanized anti-TNF-α monoclonal antibody bound to PEG to increase plasma $t_{1/2}$ Administered subcutaneously Useful for patients for whom infliximab has lost efficacy or caused adverse reactions May be a better option in pregnant women due to less drug crossing placental barrier
Biologics: Other		
Vedolizumab	<ul style="list-style-type: none"> Induction or maintenance of remission in moderate-to-severe Crohn disease or ulcerative colitis in patients who have not responded to other therapies 	<ul style="list-style-type: none"> Humanized anti-$\alpha_4\beta_7$ monoclonal antibody Given by intravenous infusion May cause hypersensitivity reactions
Ustekinumab	<ul style="list-style-type: none"> Induction or maintenance of remission in moderate-to-severe Crohn disease in patients who have not responded to other therapies 	<ul style="list-style-type: none"> Humanized monoclonal antibody against p40 subunit of IL-12 and IL-23 Administered subcutaneously Long-term safety profile has not yet been established
Antibiotics		
Metronidazole	<ul style="list-style-type: none"> Used as adjunctive therapy in mild-to-moderate Crohn disease Sometimes used in conjunction with ciprofloxacin Used in pediatric IBD 	<ul style="list-style-type: none"> Modest therapeutic benefit in Crohn disease Little to no benefit in ulcerative colitis
Ciprofloxacin	<ul style="list-style-type: none"> Used as adjunctive therapy in mild-to-moderate Crohn disease Sometimes used in conjunction with metronidazole Used in pediatric IBD 	<ul style="list-style-type: none"> Modest therapeutic benefit in Crohn disease Little to no benefit in ulcerative colitis
Rifaximin	<ul style="list-style-type: none"> Used as adjunctive therapy in mild-to-moderate Crohn disease Used in pediatric Crohn disease 	<ul style="list-style-type: none"> Less experience with this drug compared to metronidazole or ciprofloxacin
Probiotics		
Various types and formulations	<ul style="list-style-type: none"> Some utility in ulcerative colitis and pouchitis, but few clinical trials 	<ul style="list-style-type: none"> Effects are transient; long-term colonic colonization rarely occurs Watch for progress on fecal transplant therapy

General Principles of Antimicrobial Therapy

Tawanda Gumbo

ANTIMICROBIAL CHEMOTHERAPY: CLASSES AND ACTIONS

THE PHARMACOKINETIC BASIS OF ANTIMICROBIAL THERAPY

- Penetration of Antimicrobial Agents Into Anatomic Compartments
- Pharmacokinetic Compartments
- Population Pharmacokinetics and Variability in Drug Response

IMPACT OF SUSCEPTIBILITY TESTING ON SUCCESS OF ANTIMICROBIAL AGENTS

- Bacteria
- Fungi
- Viruses
- Parasites

BASIS FOR SELECTION OF DOSE AND DOSING SCHEDULE

TYPES AND GOALS OF ANTIMICROBIAL THERAPY

- Prophylactic Therapy
- Empirical Therapy in the Symptomatic Patient

- Definitive Therapy With Known Pathogen
- Posttreatment Suppressive Therapy

MECHANISMS OF RESISTANCE TO ANTIMICROBIAL AGENTS

- Resistance Due to Reduced Entry of Drug Into Pathogen
- Resistance Due to Drug Efflux
- Resistance Due to Destruction of Antibiotic
- Resistance Due to Altered Target Structure
- Incorporation of Drug
- Resistance Due to Enhanced Excision of Incorporated Drug
- Heteroresistance and Viral Quasi-Species

EVOLUTIONARY BASIS OF RESISTANCE EMERGENCE

- Development of Resistance via Mutation Selection
- Hypermutable Phenotypes
- Resistance by External Acquisition of Genetic Elements
- Horizontal Gene Transfer

Antimicrobial Chemotherapy: Classes and Actions

The *germ theory* of disease, based on the work of Louis Pasteur and Robert Koch, was a revolution in the human understanding of nature that linked specific microorganisms to specific diseases. The germ theory developed considerably in the 20th century, with identification and characterization of many microbial pathogens and their pathogenic mechanisms and the introduction of antimicrobial drugs. With the use of these drugs came issues of appropriate regimens, drug resistance, drug interactions, and toxicity.

This chapter reviews the general classes of antimicrobial drugs, their mechanisms of action, mechanisms of resistance, and patterns of kill by different classes of the drugs. Chapters 53 through 64 present the pharmacological properties and uses of individual classes of antimicrobials.

Microorganisms of medical importance fall into four categories: *bacteria*, *viruses*, *fungi*, and *parasites*. The first broad classification of antibiotics follows this classification closely, so that we have antibacterial, antiviral, antifungal, and antiparasitic agents. However, there are many antibiotics that work against more than one category of microbes, especially those that target evolutionarily conserved pathways. Within each of these major categories, drugs are further categorized by their biochemical properties.

Antimicrobial molecules should be viewed as ligands whose receptors are microbial proteins. The term *pharmacophore*, introduced by Ehrlich, defines that active chemical moiety of the drug that binds to the microbial receptor. The microbial proteins targeted by the antibiotic are essential components of biochemical reactions in the microbes, and interference with these physiological pathways kills the microorganisms. The biochemical processes commonly inhibited include cell

wall synthesis in bacteria and fungi, cell membrane synthesis, synthesis of 30S and 50S ribosomal subunits, nucleic acid metabolism, function of topoisomerases, viral proteases, viral integrases, viral envelope entry/fusion proteins, folate synthesis in parasites, and parasitic chemical detoxification processes. Recently, *antisense antibiotics* have been developed; these work by inhibiting gene expression in bacteria in a sequence-specific manner. Furthermore, *interferon*-based products work by inducing specific antiviral activities of the infected human cells.

Classification of an antibiotic is based on the following:

- class and spectrum of microorganisms it kills
- biochemical pathway it interferes with
- chemical structure of its pharmacophore

Because antimicrobial agents are ligands that bind to their targets to produce effects, the relationship between drug concentration and effect on a population of organisms is modeled using the standard Hill-type curve for receptor and agonist (Chapters 2 and 3), characterized by three parameters:

- IC_{50} (also termed EC_{50}), the inhibitory concentration that is 50% effective, a measure of the antimicrobial agent's potency
- E_{max} , a measure of the maximal effect
- H , the slope of the curve, or Hill factor

In antimicrobial therapy, the relationship is often expressed as an inhibitory sigmoid E_{max} model (Figure 52–1), to take into account the *control bacterial population without treatment* (E_{con}) as a fourth parameter (Equation 52–1 and Figure 52–1), where E is *effect as measured by microbial burden*.

$$E = E_{con} - E_{max} \times [IC]^H / ([IC]^H + [IC_{50}]^H) \quad (\text{Equation 52–1})$$

Abbreviations

ABC:	ATP binding cassette
AUC:	area under the C_p -time curve
CCR5:	chemokine receptor type 5
CD4:	T-helper cells
CFU:	colony-forming unit
CMV:	cytomegalovirus
CNS:	central nervous system
C_p :	plasma concentration
C_{pmax} :	peak concentration
CSF:	cerebrospinal fluid
DHFR:	dihydrofolate reductase
DHPS:	dihydropteroate synthase
E:	effect
EC:	effective concentration
ELF:	epithelial lining fluid
E_{max} :	maximal effect
H:	the slope of the curve or Hill factor
HIV:	human immunodeficiency virus
IC:	inhibitory concentration
MALDI-TOF MS:	matrix-assisted laser desorption/ionization time-of-flight mass spectrometry
mdr1:	multidrug resistance gene
MEC:	minimum effective concentration
MIC:	minimum inhibitory concentration
PAE:	post antibiotic effect
PCR:	polymerase chain reaction
PK/PD:	pharmacokinetics-pharmacodynamics
rpoB:	RNA polymerase

The Pharmacokinetic Basis of Antimicrobial Therapy

Penetration of Antimicrobial Agents Into Anatomic Compartments

In many infections, the pathogen causes disease not in the whole body, but in specific organs. Within an infected organ only specific pathological compartments may be infected. Antibiotics are often administered orally or parenterally, far away from these sites of infection. Therefore, in choosing an antimicrobial agent for therapy, a crucial consideration is whether the drug can penetrate to the site of infection.

For example, the antibiotic levofloxacin achieves a skin tissue/peak plasma concentration C_{pmax} ratio of 1.4, ELF/ (C_p) ratio of 2.8, and urine/ (C_p) ratio of 67 (Chow et al., 2002; Conte et al., 2006; Wagenlehner et al., 2006). The two most important factors in predicting successful clinical and microbiological outcomes using levofloxacin in the patients are the site of infection and achieving a C_{pmax} level of 12 times the MIC ($C_{pmax}/MIC \geq 12$). The failure rate of therapy is 0% in patients with urinary tract infections, 3% in patients with pulmonary infections, and 16% in patients with skin and soft tissue infections (Preston et al., 1998). Clearly, the poorer the penetration into the anatomical compartment, the higher the likelihood of failure.

The penetration of a drug into an anatomical compartment depends on the *physical barriers* that the molecule must traverse, the *chemical properties of the drug*, and the *presence of multidrug transporters*. The physical barriers are usually due to layers of epithelial and endothelial cells and the type of junctions formed between these cells. As discussed in Chapters 2 and 5, penetration across this physical barrier generally correlates the hydrophilicity or hydrophobicity of the drug. Hydrophobic molecules concentrate in the bilipid cell membrane bilayer, whereas

Figure 52-1 Inhibitory sigmoid E_{max} curve.

hydrophilic molecules tend to concentrate in the blood, the cytosol, and other aqueous compartments. Thus, the greater its lipophilicity, the greater the likelihood that an antimicrobial agent will cross physical barriers erected by layers of cells. Conversely, *the more charged a molecule is, and the larger it is, the poorer its penetration across membranes and other physical barriers* (see Figure 2-3).

Another barrier is due to *membrane transporters*, which actively export drugs from the cellular or tissue compartment back into the blood (Figure 5-4). A well-known example is the *P-glycoprotein*. *P-glycoprotein exports structurally unrelated amphiphilic and lipophilic molecules of 3–4 kDa, reducing their effective penetration*. Examples of antimicrobial agents that are P-glycoprotein substrates include HIV protease inhibitors, the antiparasitic agent ivermectin, the antibacterial agent telithromycin, and the antifungal agent itraconazole.

CNS

The CNS is guarded by the blood-brain barrier. The movement of antibiotics across the blood-brain barrier is restricted by tight junctions that connect endothelial cells of cerebral microvessels to one another in the brain parenchyma, as well as by protein transporters (Daneman and Prat, 2015). Antimicrobial agents that are polar at physiological pH generally penetrate poorly; some, such as *penicillin G*, are actively transported out of the CSF and achieve CSF concentrations of only 0.5%–5% of the C_p . However, the integrity of the blood-brain barrier is diminished during active bacterial infection; tight junctions in cerebral capillaries open, leading to a marked increase in the penetration of even polar drugs. As the infection is eradicated and the inflammatory reaction subsides, penetration diminishes to normal. Because this may occur while viable microorganisms persist in the CSF, drug dosage should not be reduced as the patient improves.

Eye

Drug penetration into the eye is especially pertinent in the treatment of endophthalmitis and infections of the retina. There is generally poor penetration of drug from plasma to this compartment, so that the standard therapy is direct instillation of antibiotics into the ocular cavity (see Chapter 69). In patients with pulmonary infections such as pneumonia, drugs must penetrate into the ELF, where the pathogens are found (Kiem and Schentag, 2008).

Pericardium

Drug penetration into the pericardium is governed by physical barriers and also likely by some form of active transport. In patients treated for tuberculous pericarditis with the regimen of isoniazid, rifampin, pyrazinamide, and ethambutol, simultaneous blood and pericardial fluid concentrations were measured over 24 h (Shenje et al., 2015). Rifampin concentrations in pericardial fluid were only 20% those in plasma due to poor penetration as well as active clearance, while ethambutol C_{pmax} was 55% due to poor penetration. On the other hand, isoniazid and pyrazinamide concentrations in pericardial fluid and blood were equivalent. Do not assume that different drugs penetrate equally to the compartment of concern.

Biofilms

Compartments requiring special drug penetration are endocardial vegetations and the biofilm formed by bacteria and fungi on prosthetic devices such as artificial heart valves, long-dwelling intravascular catheters, artificial hips, and devices for internal fixation of bone fractures. Bacterial and fungal biofilms are colonies of slowly growing cells enclosed within an exopolymer matrix. The exopolysaccharide is negatively charged and can bind positively charged antibiotics and restrict their access to the intended target. To be effective against infections in these compartments, antibiotics have to be able to penetrate the biofilm and endothelial barriers (Sun et al., 2013).

Pharmacokinetic Compartments

Once an antibiotic has penetrated to the site of infection, it may be subjected to processes of elimination and distribution that differ from those in the blood. Sites where the concentration-time profiles differ from each other are considered separate pharmacokinetic compartments; thus, the human body is viewed as *multicompartmental*. The concentration of antibiotic within each compartment is assumed to be homogeneous. If two compartments have similar concentration profiles, then they may be considered a single compartment. Antibiotic concentrations can be analyzed using any number of such compartments, with the best number of compartments chosen based on the least number of compartments that can adequately explain the findings. The model is also defined as *open* or *not open*; an open model is one in which the drug is eliminated out of the body from the compartment (e.g., kidneys). The kinetic order of the process must also be specified (Chapter 2): A *first-order process* is directly correlated to concentration of drug D, or $[D]^1$, as opposed to *zero order*, which is independent of $[D]$ and reflects a process that is saturated at ambient levels of D (such as the elimination of ethanol; Chapter 23).

Consider a patient with pneumonia, with the pathogen in the lung ELF. The patient ingests an antibiotic that is absorbed via the GI tract (g) into blood or the central compartment (*compartment 1*) as a first-order input. In this process, the transfer constant from the GI tract to central compartment is termed the *absorption constant* and is designated k_a . The antibiotic in the central compartment is then delivered to the lungs, where it penetrates into the ELF (*compartment 2*). However, it also penetrates into other tissues of the body peripheral to the site of infection, termed the *peripheral compartment* (*compartment 3*). Thus, we have four compartments (including g, a specific compartment, the GI tract, from the set of initial absorption compartments in Figure 52-2), each with its own concentration-time profile. The penetration of drug from compartment 1 to 2 is based on the penetration factors discussed previously and is defined by the transfer constant k_{12} . However, the drug also redistributes from

compartment 2 back to 1, defined by transfer constant k_{21} . A similar process between the blood and peripheral tissues leads to transfer constants k_{13} and k_{31} . The drug may also be lost from the body (i.e., open system) via the lungs and other peripheral tissues (e.g., kidneys or liver) at a rate proportional to the concentration.

Antibiotic concentrations within each compartment change with time (the changes are described using standard differential equations). If X is the amount of antibiotic in a compartment, SCL the drug clearance, and V_c the volume of the central compartment, then equations for *absorption compartment* (Equation 52-2), *central compartment* (Equation 52-3), *site of infection* or compartment 2 (Equation 52-4), and *peripheral compartment* (Equation 52-5) are as follows:

$$dX_g/dt = -K_a \cdot X_g \quad (\text{Equation 52-2})$$

$$dX_1/dt = K_a \cdot X_g - [(SCL/V_c) + K_{12} + K_{13}] \cdot X_1 + K_{21} \cdot X_2 + K_{31} \cdot X_3 \quad (\text{Equation 52-3})$$

$$dX_2/dt = K_{12} \cdot X_1 - K_{21} \cdot X_2 \quad (\text{Equation 52-4})$$

$$dX_3/dt = K_{13} \cdot X_1 - K_{31} \cdot X_3 \quad (\text{Equation 52-5})$$

Such models have been used in conjunction with population pharmacokinetics to describe and model a plethora of antimicrobials used to treat bacteria, fungi, viruses, and parasites (Hope et al., 2007; Tarning et al., 2008; Wilkins et al., 2008). Semimechanistic models have been applied to relate pathogen response to drug concentrations within these pharmacokinetic compartments in preclinical disease models and in patients (Gumbo et al., 2006; Jumbe et al., 2003; Talal et al., 2006). These models can be made more complex and more predictive by adding parameters describing the effect of inoculum, delay in microbial effect, or splitting the drug-resistant population to smaller subpopulations based on a molecular mechanism of resistance (Bulitta et al., 2009).

Population Pharmacokinetics and Variability in Drug Response

When multiple patients are treated with the same dose of a drug, each patient will achieve unique pharmacokinetic parameters. This is termed *between-patient variability*. Even when the same dose is administered to the same patient on two separate occasions, the patient may achieve a different concentration-time profile of the drug between the two occasions.

Figure 52-2 Diagrammatic depiction of a multicompartment model. K_a , absorption constant; V_c , central compartment volume; V_L , volume of lung compartment; V_p , peripheral compartment volume.

This is termed *interoccasion or within-patient variability*. The variability is reflected at the level of the compartmental pharmacokinetic parameters in Equations 52–2 to 52–5, such as k_a , k_{12} , k_{21} , SCL , V_d , and so on. Even when a recommended dose is administered, the drug may fail to reach a therapeutic concentration in some patients, purely because of the between-patient variability.

An important example of the consequences of between-patient variability involves antituberculosis drugs: In patients who are adherent to therapy, subtherapeutic concentrations of isoniazid, rifampin, pyrazinamide, and ethambutol account for more than 90% of therapy failure, slower sterilizing effect, and acquired drug resistance (Chigutsa et al., 2015; Pasipanodya et al., 2013). The same has been seen with antileishmania drugs and antifungal agents (Andes et al., 2011; Dorlo et al., 2014). In other patients, the drug may reach high and toxic concentrations because of the between-patient variability. Such variability could be due to genetic variability, weight, height, age, and comorbid conditions such as renal and liver dysfunction. An important driver of variability is the widespread problem of overweight and obesity, which increases the clearance and can alter the volume of distribution of many antibiotics. This emerging problem is prompting changes in dosing strategies.

Drug interactions are another important source of variability with potentially dangerous consequences. These interactions usually occur when one drug inhibits or induces uptake or clearance mechanisms affecting another drug (see Chapters 5 and 6).

The common practice of using an “average” value of data, or “naïve pooling,” has implications of smoothing out data and failing to recognize subgroups of patients at risk for therapeutic failure or increased toxicity of antibiotic. Knowledge of covariates associated with pharmacokinetic variability leads to better dose adjustments, switching therapy from one antibiotic to another, or changing concomitant medications.

Impact of Susceptibility Testing on Success of Antimicrobial Agents

The microbiology laboratory plays a central role in the decision to choose a particular antimicrobial agent over others. First, identification and isolation of the culprit organism takes place when the patients' specimens are sent to the microbiology laboratory. Once the microbial species causing the disease has been identified, a rational choice of the class of antibiotics likely to work in the patient can be made. The microbiology laboratory then plays a second role, which is to perform susceptibility testing.

Millions of individuals across the globe become infected by many different isolates of the same species of pathogen. Evolutionary processes cause each isolate to be slightly different from the next, so that each may have a unique susceptibility to antimicrobial agents. As the microorganisms divide within the patient, they may undergo further evolution between the time of infection and the time of diagnosis. Therefore, one observes a distribution of concentrations of antimicrobial agents that can kill the pathogens. Often, this distribution is Gaussian, with a skew that depends on where the patient lives. Such factors will affect the shape of the inhibitory sigmoid E_{max} model described by Equation 52–1.

With changes in susceptibility, the sigmoid E_{max} curve shifts in one of two basic ways. The first is a shift to the right, an increase in IC_{50} (Figure 52–3A), meaning that much higher concentrations of antimicrobials than before are now needed to show specific effect. *Susceptibility tests for bacteria, fungi, parasites, and viruses have been developed to determine whether these shifts have occurred at a sufficient magnitude to warrant higher doses of drug to achieve particular effect.* The change in IC_{50} may become so large that it is not possible to overcome the concentration deficit by increasing the antimicrobial dose without causing toxicity to the patient. At that stage, the organism is now “resistant” to the particular antibiotic.

A second possible change in the curve is decrease in E_{max} (Figure 52–3B), such that increasing the dose of the antimicrobial agent beyond a certain point will achieve no further effect; that is, changes in the microbe are such that eradication of the microbe by the particular drug can never be achieved. This occurs because the available target proteins have been reduced or the

Figure 52–3 Changes in sigmoid E_{max} model with increases in drug resistance. An increase in resistance may show changes in IC_{50} : In A, the IC_{50} increases from 70 (orange line) to 100 (green line) to 140 (blue line). An increase in resistance may also show a decrease in E_{max} : In B, efficacy decreases from full response (orange line) to 70% (green line).

microbe has developed an alternative pathway to overcome the biochemical inhibition. For example, maraviroc is an allosteric, noncompetitive antagonist that binds to the CCR5 receptor of patient's CD4 cells to deny HIV entry into the cell. Viral resistance occurs by a mechanism that involves HIV adapting to use of the maraviroc-bound CCR5, which results in decrease of E_{max} in phenotypic susceptibility assays (Hirsch et al., 2008).

Bacteria

For bacteria, dilution tests employ antibiotics in serially diluted concentrations on solid agar or in broth medium that contains a culture of the test microorganism. The lowest concentration of the agent that prevents visible growth after 18–24 h of incubation is known as the *minimum inhibitory concentration (MIC)*.

Recently, nucleic acid amplification–based reactions of specific bacterial genes have been used in the clinic for rapid diagnosis of drug resistance. The genes targeted are those encoding known drug resistance proteins or processes. For example, rifampin resistance in *Mycobacterium tuberculosis* has been difficult to ascertain in a timely fashion: The bacteria take 2 to 3 weeks to grow in order to identify them as a cause of disease, and then a similar amount of time is needed to form some version of the broth dilution tests. Small PCR reactors at points of care can purify and concentrate a patient's fluid sample, perform nucleic acid amplification of a target gene, identify mutations, and provide a result in less than 2 h. In other bacteria, MALDI-TOF MS is being used for identification of resistance to drugs such as vancomycin in *Staphylococcus aureus* and is being extended to many other compounds and bacterial species.

Fungi

For fungi that are yeasts (i.e., *Candida*), susceptibility testing methods are similar to those used for bacteria. However, the definitions of MIC differ

based on drug and the type of yeast, so there are cutoff points of 50% decrease in turbidity compared to controls at 24 h, 80% at 48 h, or total clearance of the turbidity. Susceptibility tests and MICs for triazoles have been extensively shown to correlate with clinical outcomes.

Standardized tests for echinocandin antifungals and amphotericin B-based compounds are available. Susceptibility tests for molds have also been developed, especially for *Aspergillus* species. Different terminology from MICs is required when evaluating echinocandins against molds because the fungal burden cannot be readily measured, given that hyphae will break up into unpredictable numbers of discrete fungi when under antifungal pressure. Furthermore, echinocandins often do not completely inhibit mold growth, but instead cause damage reflected by morphological changes in hyphae. Thus, the *minimum effective concentration* (MEC) for echinocandins is the lowest drug concentration at which short, stubby, and highly branched hyphae are observed on microscopic examination.

Viruses

In HIV phenotypic assays, the patient's HIV-RNA is extracted from plasma, and genes for targets of antiretroviral drugs such as reverse transcriptase and protease are amplified. The genes are then inserted into a standard HIV vector that lacks an alogous gene sequences to produce a recombinant virus, which is coinoculated with a drug of interest in a mammalian cell viability assay (Hanna and D'Aquila, 2001; Petropoulos et al., 2000). Growth is compared to a standardized wild-type control virus.

Genotypic tests are now a standard part of HIV care in many parts of the world. The simplest tests measure presence of mutations associated with loss of susceptibility to a drug, that is, that the organism is "resistant" to the drug and the drug should not be used to treat that patient.

Parasites

Susceptibility testing for parasites, especially those that cause malaria, has been performed in the laboratory. The tests are similar to the broth tests for bacteria, fungi, and viruses. *Plasmodium* species in the patient's blood are cultured *ex vivo* in the presence of different dilutions of anti-malarial drug. A sigmoid E_{max} curve for effect versus drug concentration is used to identify IC_{50} and E_{max} . These susceptibility tests are usually field tests at sentinel sites that are used to determine if there is drug resistance in a particular area. In general, susceptibility tests for parasitic infections are not standardized. These tests are primarily used in the research setting and not for individualization of therapy.

Basis for Selection of Dose and Dosing Schedule

Although susceptibility testing in the laboratory is central to decision making, it does not completely predict patient response. In susceptibility tests, the drug concentration is constant; by contrast, in patients the drug concentration is dynamic and ever changing. Antibiotics are prescribed at a certain schedule (e.g., three times a day) so that there is a periodicity in the fluctuations of drug at the site of infection, and the microbe is exposed to a particular shape of the concentration-time curve. Harry Eagle performed studies on penicillin and discovered that the shape of the concentration-time profile was an important determinant of the efficacy of the antibiotic. This important observation was forgotten until William Craig and colleagues rediscovered it and performed systematic studies on several classes of antibiotics, initiating the era of antimicrobial PK/PD (Ambrose et al., 2007; Craig, 2007). These findings have now been extended to combination therapy and to microbes that require long treatment durations, such as *Mycobacterium tuberculosis* and HIV.

There are three precepts to follow in antimicrobial therapy:

First, apply knowledge of the susceptibility (either MIC or IC_{50}) of the organism to the antimicrobial agent and index drug exposure to MIC.

As an example, the pyrazinamide MIC is an important determinant of *M. tuberculosis* response and microbial measures of cure (Chigutsa et al., 2015). In fact, microbial response is driven by the ratio of the AUC to the MIC.

Similarly, in the treatment of candidemia, the rate of response is driven by the ratio dose/MIC (Rodríguez-Tudela et al., 2007). This is not a surprise because the IC_{50} shifts to the right with decrease in susceptibility (Figure 52-3A).

Second, use the optimal dose of the antibiotic for the patient, that is, the dose that achieves IC_{80} to IC_{90} exposures at the site of infection.

Dose by itself is a poor measure of drug exposure. Rather, actual drug concentration achieved at the site of infection is the important measure. The shape of the relationship between non-protein-bound antibiotic concentration (exposure) versus microbial kill is the inhibitory sigmoid E_{max} curve of Figure 52-1. Maximal kill is actually on an asymptote, so that non-protein-bound antimicrobial exposures associated with 80%–90% of E_{max} are termed *optimal* concentrations. This exposure can often be easily identified in preclinical models and directly applied to patient populations, provided interspecies differences in protein binding and pharmacokinetic variability are taken into account.

Third, use a dosing schedule that maximizes the antimicrobial effect; recognize that optimal microbial kill by the antibiotic may be best achieved by maximizing certain shapes of the concentration-time curve.

As an example, consider an antibiotic with a serum $t_{1/2}$ of 3 h that is being used to treat a bloodstream infection by a pathogen with an MIC of 0.5 mg/L; the antibiotic is administered with a dosing interval of 24 h (that is, a once-daily schedule). Figure 52-4A depicts the concentration-time curve of the antibiotic, with definitions of C_{Pmax} , AUC, and the fraction of the dosing interval for which the drug concentration remains above the

Figure 52-4 Effect of different dose schedules on shape of the concentration-time curve. The same total dose of a drug was administered as a single dose (panel A) and in three equal portions every 8 h (panel B). The total AUC for the fractionated dose in B is determined by adding AUC_{0-8h} , AUC_{8-16h} , and AUC_{16-24h} , which totals to the same AUC_{0-24h} in A. The time that the drug concentration exceeds MIC in B is also determined by adding $T_1 > MIC$, $T_2 > MIC$, and $T_3 > MIC$, which results in a fraction greater than that for A.

MIC ($T > \text{MIC}$), as shown. The AUC is a measure of the total concentration of drug and is calculated by taking an integral between two time points, 0–24 h (AUC_{0-24}) in this case.

Now, if one were to change the dosing schedule of the same antibiotic amount by splitting it into three equal doses administered at 0, 8, and 16 h, the shape of the concentration-time curve changes to that shown in Figure 52–4B. Because the same cumulative dose has been given for the dosing interval of 24 h, the AUC_{0-24} will be similar whether it was given once a day or three times a day. For the same pathogen, therefore, the change in dose schedule does not change the $\text{AUC}_{0-24}/\text{MIC}$. However, the C_{pmax} will decrease by a third when the total dose is split into thirds and administered more frequently (Figure 52–4B). Thus, when a dose is fractionated and administered more frequently, the $C_{\text{pmax}}/\text{MIC}$ ratio decreases. In contrast, the time that the drug concentration persists above MIC ($T > \text{MIC}$) will increase with the more frequent dosing schedule, despite the same cumulative dose being administered. Which of the three indices (AUC/MIC , $C_{\text{pmax}}/\text{MIC}$, or $T > \text{MIC}$) is the most important to the outcome being assessed (i.e., microbial kill)? A common approach to the answer is to determine which of these patterns best approximates a perfect inhibitory sigmoid E_{max} curve (based on various statistical assessments of goodness of fit) in Equation 52–1.

Some classes of antimicrobial agents kill best when concentration persists above MIC for longer durations of the dosing interval. Indeed, increasing the drug concentration beyond four to six times the MIC does not increase microbial kill for such antibiotics. Two good examples are β -lactam antibiotics (e.g., penicillin) and the antifungal agent 5-fluorocytosine (Ambrose et al., 2007; Andes and van Ogtrop, 2000). There are usually good biochemical explanations for this pattern; the clinical implication, however, is that a drug optimized by $T > \text{MIC}$ should be dosed more frequently, or if possible should have its $t_{1/2}$ prolonged by other drugs, so that drug concentrations persist above MIC (or EC_{95}) as long as possible. Thus, the effectiveness of penicillin is enhanced when it is given as a continuous infusion. Some antibiotics, such as ceftriaxone ($t_{1/2} = 8$ h), have a long half-lives, such that infrequent dosing several times a day still optimizes $T > \text{MIC}$. On the other hand, HIV protease inhibitors are often “boosted” with ritonavir. This “boosting” inhibits the metabolism of the protease inhibitors by CYPs 3A4 and 2D6, thereby prolonging time above EC_{95} .

Conversely, the peak concentration is what matters for other antimicrobial agents. Persistence of concentration above the MIC has less relevance for these drugs, meaning that these drugs can be dosed more intermittently. Aminoglycosides are a prime example of this class; aminoglycosides are highly effective when given once a day. These $C_{\text{pmax}}/\text{MIC}$ -linked drugs can often be administered less frequently due to their long duration of PAE, with effectiveness continuing long after antibiotic concentrations decline below the MIC.

Rifampin is such a drug (Gumbo et al., 2007a). The entry of rifampin into *M. tuberculosis* increases with increased concentration in the bacillus microenvironment, likely because of a saturable transport process. Once inside the bacteria, the drug’s macrocyclic ring binds the β subunit of

DNA-dependent RNA polymerase (*rpoB*) to form a stable drug-enzyme complex within 10 min, a process not enhanced by longer incubation of drug and enzyme and only slowly reversed. The PAE of the rifampin is long and concentration dependent (Gumbo et al., 2007a).

There is a third group of drugs for which it is the cumulative dose that matters, and for which the daily dosing schedule has no effect on efficacy. Thus, it is more ratio of the total concentration (AUC) to MIC that matters and not the time that concentration persists above a certain threshold. Antibacterial agents such as daptomycin fall into this class (Louie et al., 2001). These agents also have a good PAE. The $\text{AUC}/\text{IC}_{50}$ explains why tenofovir and emtricitabine (nucleoside analogue reverse transcriptase inhibitors) have been combined into one pill, administered once a day for the treatment of AIDS.

The shape of the concentration-time curve that optimizes resistance suppression is often different from that which optimizes microbial kill. In many instances, the drug exposure associated with resistance suppression is much higher than that for optimal kill. Ideally, this higher exposure should be achieved by each dose in patients for optimal effect, rather than the EC_{80} as discussed previously. However, this is often precluded by drug toxicity at higher dosages. Second, although the relationship between kill and exposure is based on the inhibitory sigmoid E_{max} model, experimental work with preclinical models demonstrated that this model does not apply to resistance suppression (Gumbo et al., 2007b; Tam et al., 2007).

To summarize:

- The optimal dose should be designed to achieve a high probability of exceeding the EC_{80} microbial PK/PD index, or an index associated with suppression of resistance, given the population pharmacokinetic variability and the MIC distribution of clinical microbe isolates.
- The dose schedule is chosen according to whether efficacy is driven by AUC/MIC (or $\text{AUC}/\text{EC}_{95}$), $C_{\text{pmax}}/\text{MIC}$, or $T > \text{MIC}$. Duration of therapy is then chosen based on best-available evidence.

Types and Goals of Antimicrobial Therapy

A useful way to organize the types and goals of antimicrobial therapy is to consider where along the disease progression timetable therapy is initiated (Figure 52–5); therapy can be prophylactic, preemptive, empiric, definitive, or suppressive.

Prophylactic Therapy

Prophylaxis involves treating patients who are not yet infected or have not yet developed disease. The goal of prophylaxis is to prevent infection in some patients or to prevent development of a potentially dangerous disease in those who already have evidence of infection. The main principle behind prophylaxis is targeted therapy.

An important recent advance has been the understanding of the roles of the human microbiome in health. The biome is a critical defense against dangerous infections and important in uptake of vaccines. So extensive is

Figure 52–5 Antimicrobial therapy–disease progression timeline.

the putative preventive role of the microbiome that the list of conditions when it is disrupted is long, but includes common conditions such as allergies, autism, cancer, antibiotic-associated colitis, diabetes, and obesity. Thus, in routine prophylaxis there is need to preserve the native biome as much as possible. Thus, consider the following:

- Consider narrow-spectrum antibiotics targeted at the most important (potential surgical site) infectious organisms and do not target all possible bacteria.
- Limit the duration of prophylaxis to be as short as the time in which maximum contamination is expected (e.g., during incisions and the surgical procedure) and do not prolong beyond this time.
- Apply PK/PD thinking, as described previously.

Prophylaxis in Immunosuppressed Patients

Prophylaxis is used in immunosuppressed patients such as those with HIV-AIDS or are posttransplantation and on antirejection medications. The efficacy of prophylaxis in these patients is based on excellent evidence (Centers for Disease Control and Prevention et al., 2000; DHHS Panel, 2015). In these groups of patients, specific antiparasitic, antibacterial, antiviral, and antifungal therapy is administered based on the well-defined pattern of pathogens that are major causes of morbidity during immunosuppression. A risk-benefit analysis determines choice and duration of prophylaxis. Prophylaxis of opportunistic infections in patients with AIDS is started when the CD4 count falls below 200 cells/mm³, and is discontinued when the CD4 count climbs above 200 cells/mm³. In post-transplant patients, prophylaxis depends on time since the transplant procedure, which is related to intensity of use and type of immunosuppressive therapy. Prophylaxis should be discontinued in patients who are doing well at certain benchmarks, such as 1 year posttransplant. Infections for which prophylaxis is given include *Pneumocystis jiroveci*, *Mycobacterium avium-intracellulare*, *Toxoplasma gondii*, *Candida* species, *Aspergillus* species, *Cytomegalovirus*, and other Herpesviridae. In general, the prophylactic dose is lower than when the same drug is used for acute treatment.

Chemoprophylaxis for Surgical Procedures

Wound infection results when a critical number of bacteria are present in the wound at the time of closure, and chemoprophylaxis can be used to prevent wound infections after surgical procedures. Antimicrobial agents directed against the invading microorganisms may reduce the number of viable bacteria below the critical level and thus prevent infection. Because *S. aureus* is consistently the most common organism causing surgical site infections, programs have been developed to decolonize the patient of this organism prior to cardiac and orthopedic surgery. Approaches to decrease surgical site infections involve screening by culturing the patient's nares and other colonization sites before surgery and decolonizing any *S. aureus* with intranasal mupirocin twice daily and chlorhexidine-gluconate baths daily for up to 5 days before the surgery, followed by the usual perioperative systemic antibiotics (Schweizer et al., 2015).

The systemic antibiotic used is chosen based on the pathogen most likely to contaminate the incision, which in turn depends on the site where surgery is being performed (Bratzler et al., 2013). The most common pathogens infecting incision sites after clean surgery are staphylococci, specifically *S. aureus* and coagulase-negative staphylococci. In clean contaminated surgery over the abdomen and pelvis, the same organisms remain important, but *Enterococcus* species and gram-negative rods are also common. The perioperative antimicrobial dose should be administered intravenously within 60 min prior to the surgical incision, so that concentrations are above the MIC of the organism at time of incision. The frequency of redosing during the procedure is based on the half-life of the drug in order to have adequate antibiotic concentrations above the MIC until closure of the surgical incision. This is especially important for those β -lactam antibiotics that have short half-lives; these should be redosed at intervals of two times the half-life. It is recommended that the duration of prophylaxis be shorter than 24 h postoperation and in many instances be just a single dose.

The types of surgical procedures for which systemic antibiotic prophylaxis is required has recently been expanded (Table 52-1) (Bratzler et al., 2013). The guidelines, based on consensus of opinion leaders, also suggest

that the same principles for adults apply to children. However, note that the pharmacokinetics of the antibiotics may differ in children.

Prophylaxis in Patients at Risk of Infective Endocarditis

Patients at the highest risk for infective endocarditis for which prophylaxis is recommended fall into four groups (Wilson et al., 2007):

- those with a prosthetic material used for heart valve repair or replacement;
- patients having had previous infective endocarditis;
- patients with congenital heart disease such as unrepaired cyanotic heart disease, or within 6 months of repair of the heart disease with prosthetic material, or those with residual defects adjacent to prosthetic material; and
- postcardiac transplant patients with heart valve defects.

Chemoprophylaxis is reasonable when these patients undergo dental procedures if there is manipulation of gingival tissue or the periapical region of teeth or perforation of oral mucosa, but not for other dental procedures. Recommended therapy is a single dose of oral amoxicillin 30 min to 1 h before the procedure; intravenous ampicillin or ceftriaxone in those unable to take oral medication; or macrolide or clindamycin for patients allergic to β -lactam agents. Therapy may be administered no more than 2 h after the procedure for patients who failed to receive the prophylaxis prior to the procedure (Wilson et al., 2007).

Prophylaxis for Procedures on Infected Tissues

Prophylaxis is also reasonable for procedures that will involve infected skin and soft tissues as well as infected respiratory tract, but not in routine genitourinary and GI tract procedures. If the organism causing the infection is known, then the prophylactic antibiotic for patients undergoing these procedures should be tailored toward that organism.

Postexposure Prophylaxis

Postexposure prophylaxis may be used to protect healthy persons from acquisition of or invasion by specific microorganisms to which they are exposed. Successful examples of this practice include rifampin administration to prevent meningococcal meningitis in people who are in close contact with a case, prevention of gonorrhea or syphilis after contact with an infected person, and macrolides after contact with confirmed cases of pertussis.

For HIV, there is now clear evidence to use antiretroviral therapy as part of prophylaxis in four situations: (1) immediate antiretroviral therapy for the partner in a serodiscordant couple; (2) preexposure prophylaxis for all population groups at substantial risk of HIV infection; (3) prevention of mother-to-child transmission; and (4) postexposure prophylaxis, which is after accidental exposure to HIV in body fluids. It is recommended that at least three drugs be administered for at least 28 days.

For influenza, the neuraminidase inhibitor oseltamivir is recommended for prevention of influenza A and B in healthy adults and children with close contact of laboratory-confirmed cases (Hayden and Pavia, 2006). Finally, mother-to-child transmission of syphilis is also an important public health problem for which specific chemotherapeutic regimens have been devised, based on locality. Prophylactic therapy for syphilis during pregnancy is effective in reducing neonatal death and infant neurological, auditory, and bone malformations.

Preemptive Therapy

Preemptive therapy is used as a substitute for universal prophylaxis and as early targeted therapy in high-risk patients who already have a laboratory or other test indicating that an asymptomatic patient is infected. The principle is that delivery of therapy prior to development of symptoms aborts impending disease, and the therapy is for a short and defined duration. This has been applied in the clinic to therapy for CMV after both hematopoietic stem cell transplants and after solid-organ transplantation (Gerna et al., 2008). When rapid turnaround tests (e.g., PCR based) are available, the preemptive strategy is now more preferable than universal prophylaxis for CMV.

Empirical Therapy in the Symptomatic Patient

Should a symptomatic patient be treated immediately? *The reflex action to associate fever with treatable infections and prescribe antimicrobial therapy without further evaluation is irrational and potentially dangerous.*

TABLE 52-1 ■ PROPHYLACTIC ANTIMICROBIALS FOR SURGERY

ANATOMICAL REGION	TYPE OF PROCEDURE	RECOMMENDED ANTIBIOTICS
Head and neck	Neurosurgery: craniotomy and cerebrospinal fluid shunting	Cefazolin
	Clean contaminated cancer surgery	Cefazolin + metronidazole Cefuroxime + metronidazole Ampicillin-sulbactam
Thoracic/cardiac	Coronary artery bypass, cardiac device insertion	Cefazolin, cefuroxime
	Lobectomy, pneumonectomy, lung resection, thoracotomy	Cefazolin, ampicillin-sulbactam
	Transplantation of heart and lung	Cefazolin
Abdomen		
Gastroduodenal	Procedures that enter GI lumen or no GI entry but high-risk patients	Cefazolin
Biliary tract	Open procedure	Cefazolin, ampicillin-sulbactam, cefoxitin, ceftriaxone, cefotetan
Laparoscopy	High-risk procedures	Cefazolin, ampicillin-sulbactam, cefoxitin, ceftriaxone, cefotetan
Appendix	Appendectomy for appendicitis	Cefazolin + metronidazole, cefoxitin, cefotetan
Hernia	Hernia repair	Cefazolin
Colorectal	All	Cefazolin + metronidazole, ampicillin-sulbactam, cefoxitin, ceftriaxone, cefotetan, ceftriaxone + metronidazole ertapenem
Pancreas	Pancreas and pancreas-kidney transplantation	Cefazolin + fluconazole
Pelvis/gynecological		
Uterus	Hysterectomy	Cefazolin, ampicillin-sulbactam, cefoxitin, cefotetan
	Cesarean section	Cefazolin
Urologic	Lower tract instrumentation with risk factors for infection	Fluoroquinolone, trimethoprim-sulfamethoxazole, cefazolin
	Clean: with or without entry into urinary tract	Cefazolin
	Involving implanted prosthesis	Cefazolin + aminoglycoside, cefazolin, ampicillin-sulbactam
	Clean contaminated	Cefazolin + metronidazole, cefoxitin
Orthopedic	Spinal procedures, hip fracture repair, joint replacement	Cefazolin

The first consideration in selecting an antimicrobial is to determine if the drug is indicated. The diagnosis may be masked if therapy is started and appropriate cultures are not obtained. Antimicrobial agents are potentially toxic and may promote selection of resistant microorganisms. For some diseases, the risk in waiting a few days is low, and these patients can wait for microbiological evidence of infection without empirical treatment. If the risks of waiting are high, based either on the patient's immune status or other known risk factors, then initiation of optimal empirical antimicrobial therapy should rely on the clinical presentation and clinical experience. In addition, simple and rapid laboratory techniques are available for the examination of infected tissues.

The most valuable and time-tested method for immediate identification of bacteria is examination of the infected secretion or body fluid with Gram stain. In malaria-endemic areas, or in travelers returning from such an area, a simple thick-and-thin blood smear may mean the difference between a patient's survival on appropriate therapy or death while on the wrong therapy for a presumed bacterial infection. On the other hand, neutropenic patients with fever have high risks of mortality, and when febrile, they are presumed to have either a bacterial or a fungal infection. Thus, a broad-spectrum combination of antibacterial and antifungal agents that cover common infections encountered in granulocytopenic

patients is given. Performance of cultures is still mandatory with a view to modify antimicrobial therapy with culture results.

Definitive Therapy With Known Pathogen

Once a pathogen has been identified and susceptibility results are available, therapy should be streamlined to a narrow targeted antibiotic. *Monotherapy is preferred* to decrease the risk of antimicrobial toxicity and selection of antimicrobial-resistant pathogens. Proper antimicrobial doses and dose schedules are crucial to maximizing efficacy and minimizing toxicity. In addition, the duration of therapy should be as short as is necessary. Unnecessarily prolonged therapies lead to the emergence of resistance.

Combination therapy is an exception, rather than a rule. Once a pathogen has been isolated, there should be no reason to use multiple antibiotics, except when evidence overwhelmingly suggests otherwise. Using two antimicrobial agents where one suffices leads to increased toxicity and unnecessary damage to the patient's protective fungal and bacterial flora. There are special circumstances where evidence favors combination therapy:

- preventing resistance to monotherapy;
- accelerating the rapidity of microbial kill;

- enhancing therapeutic efficacy by use of synergistic interactions or enhancing kill by a drug based on a mutation generated by resistance to another drug;
- reducing toxicity (i.e., when sufficient efficacy of a single antibacterial agent can be achieved only at doses that are toxic to the patient and a second drug is coadministered to permit lowering the dose of the first drug)

Clinical situations for which combination therapy is advised include antiretroviral therapy for AIDS; antiviral therapy for hepatitis B and C; the treatment of tuberculosis, *M. avium-intracellulare*, and leprosy; fixed-dose combinations of antimalarial drugs; the treatment of *Cryptococcus neoformans* with flucytosine and amphotericin B; during empirical therapy for patients with febrile neutropenia; and for advanced AIDS with fever. The combination of a sulfonamide and an inhibitor of DHFR, such as trimethoprim, is synergistic owing to the inhibition of sequential steps in microbial folate synthesis; a fixed combination of sulfamethoxazole and trimethoprim is active against organisms that may be resistant to sulfonamides alone.

Posttreatment Suppressive Therapy

In some patients, the infection is controlled but not completely eradicated by the initial round of antimicrobial treatment, and the immunological or anatomical defect that led to the original infection is still present. In such patients, therapy is continued at a lower dose. This is common in patients with AIDS and patients posttransplant. The goal is more as secondary prophylaxis. Nevertheless, risks of toxicity from the long durations of therapy are still real. In this group of patients, the suppressive therapy is eventually discontinued if the patient's immune system improves.

Mechanisms of Resistance to Antimicrobial Agents

Antimicrobial agents were viewed as miracle cures when first introduced into clinical practice. However, as became evident soon after the discovery of penicillin, resistance develops and dims the luster of the miracle. This serious development is ever present with each new antimicrobial agent and threatens the end of the antimicrobial era. Today, every major class of antibiotic is associated with the emergence of significant resistance. *Two major factors are associated with emergence of antibiotic resistance: evolution and clinical/environmental practices.* When a microbial species is subjected to an existential threat, chemical or otherwise, that pressure will select for random mutations in the species' genome that permit survival. Pathogens will evolve to develop resistance to the chemical warfare to which we subject them. This evolution is greatly assisted by poor therapeutic practices by healthcare workers and the indiscriminant use of antibiotics in agriculture and animal husbandry.

Antimicrobial resistance can develop at any one or more of steps in the processes by which a drug reaches and combines with its target. Thus, resistance development may develop due to

- reduced entry of antibiotic into pathogen
- enhanced export of antibiotic by efflux pumps
- release of microbial enzymes that alter or destroy the antibiotic
- alteration of target proteins
- development of alternative pathways to those inhibited by the antibiotic

Mechanisms by which such resistance develops can include acquisition of genetic elements that code for the resistant mechanism, mutations that develop under antibiotic pressure, or constitutive induction.

Resistance Due to Reduced Entry of Drug Into Pathogen

The outer membrane of gram-negative bacteria is a semipermeable barrier that excludes large polar molecules from entering the cell. Small polar molecules, including many antibiotics, enter the cell through protein channels called *porins*. Absence of, mutation in, or loss of a favored porin

channel can slow the rate of drug entry into a cell or prevent entry altogether, effectively reducing drug concentration at the target site. If the target is intracellular and the drug requires active transport across the cell membrane, a mutation or phenotypic change that slows or abolishes this transport mechanism can confer resistance. For example, *Trypanosoma brucei* is treated with suramin and pentamidine during early stages, but with melarsoprol and eflornithine when CNS disease (sleeping sickness) is present. Melarsoprol is actively taken up by the trypanosome P2 transporter. When the parasite lacks the P2 transporter or has a mutant form, resistance to melarsoprol and cross resistance to pentamidine occur due to reduced drug uptake (Ouellette, 2001).

Resistance Due to Drug Efflux

Microorganisms can overexpress efflux pumps and then expel antibiotics to which the microbes would otherwise be susceptible. There are five major systems of efflux pumps that are relevant to antimicrobial agents:

- The multidrug and toxin extruder
- The major facilitator superfamily transporters
- The small multidrug resistance system
- The resistance nodulation division exporters
- ABC transporters

Efflux pumps are a prominent mechanism of resistance for parasites, bacteria, and fungi. One of the tragic consequences of resistance emergence has been the development of drug resistance by *Plasmodium falciparum*. Drug resistance to most antimalarial drugs, specifically chloroquine, quinine, mefloquine, halofantrine, lumefantrine, and the artemether-lumefantrine combination is mediated by an ABC transporter encoded by *P. falciparum* multidrug resistance gene 1 (*Pfmdr1*) (Happi et al., 2009). Point mutations in the *Pfmdr1* gene lead to drug resistance and failure of chemotherapy.

Drug efflux sometimes works in tandem with chromosomal resistance, as is seen in *Streptococcus pneumoniae* and *M. tuberculosis*. In these situations, induction of efflux pumps occurs early, which increases the MIC only modestly. However, this MIC increase may suffice to allow further microbial replication, a continuation of mutation, and the development of resistance via more robust chromosomal mutations (Gumbo et al., 2007b; Jumbe et al., 2006; Schmalstieg et al., 2012).

Resistance Due to Destruction of Antibiotic

Drug inactivation is a common mechanism of drug resistance. Bacterial resistance to aminoglycosides and to β -lactam antibiotics usually is due to production of an aminoglycoside-modifying enzyme or β -lactamase.

Resistance Due to Altered Target Structure

A common consequence of either single- or multiple-point mutations is a change in amino acid composition and conformation of an antimicrobial's target protein. This change can lead to reduced affinity of drug for its target or of a prodrug for the enzyme that activates the prodrug. Such alterations may be due to mutation of the natural target (e.g., fluoroquinolone resistance), target modification (e.g., ribosomal protection type of resistance to macrolides and tetracyclines), or acquisition of a resistant form of the native, susceptible target (e.g., staphylococcal methicillin resistance caused by production of a low-affinity penicillin-binding protein) (Hooper, 2002; Lim and Strynadka, 2002; Nakajima, 1999). In HIV resistance, mutations associated with reduced affinity are encountered for protease inhibitors, integrase inhibitors, fusion inhibitors, and nonnucleoside reverse transcriptase inhibitors (Nijhuis et al., 2009). Similarly, benzimidazoles are used against myriad worms and protozoa and work by binding to the parasite's tubulin; point mutations in the β -tubulin gene lead to modification of the tubulin and drug resistance (Ouellette, 2001).

Incorporation of Drug

An uncommon situation occurs when an organism not only becomes resistant to an antimicrobial agent but also subsequently starts requiring

it for growth. Enterococcus, which easily develops vancomycin resistance, can, after prolonged exposure to the antibiotic, develop vancomycin-requiring strains. In 1955, shortly after introduction of streptomycin for tuberculosis, Hashimoto isolated a streptomycin-dependent mutant of *M. tuberculosis*; it grows in the presence of the antibiotic but goes into dormancy in the absence of the streptomycin.

Resistance Due to Enhanced Excision of Incorporated Drug

Nucleoside reverse transcriptase inhibitors such as zidovudine are 2'-deoxyribonucleoside analogues that are converted to their 5'-triphosphate form and compete with natural nucleotides. These drugs are incorporated into the viral DNA chain and cause chain termination. When resistance emerges via mutations in the reverse transcriptase gene, phosphorolytic excision of the incorporated chain-terminating nucleoside analogue is enhanced (Arion et al., 1998).

Heteroresistance and Viral Quasi-Species

Heteroresistance occurs when a subset of the total microbial population is resistant, despite the total population being considered susceptible on testing (Falagas et al., 2008; Rinder, 2001). A subclone that has alterations in genes associated with drug resistance is expected to reflect the normal mutation rates (occurrence in 1 in 10^6 to 10^5 colonies). In bacteria, heteroresistance has been described especially for vancomycin in *S. aureus* and *Enterococcus faecium*; colistin in *Acinetobacter baumannii-calcoaceticus*; rifampin, isoniazid, and streptomycin in *M. tuberculosis*; and penicillin in *S. pneumoniae* (Falagas et al., 2008; Rinder, 2001). Increased therapeutic failures and mortality have been reported in patients with heteroresistant staphylococci and *M. tuberculosis* (Falagas et al., 2008; Hofmann-Thiel et al., 2009). For fungi, heteroresistance leading to clinical failure has been described for fluconazole in *C. neoformans* and *Candida albicans* (Marr et al., 2001; Mondon et al., 1999).

Viral replication is more error prone than replication in bacteria and fungi. Viral evolution under drug and immune pressure occurs relatively easily, commonly resulting in variants or quasi-species that may contain drug-resistant subpopulations. This is not often termed heteroresistance, but the principle is the same: A virus may be considered susceptible to a drug because either phenotypic or genotypic tests reveal "lack" of resistance, even though there is a resistant subpopulation just below the limit of assay detection. These minority quasi-species that are resistant to antiretroviral agents have been associated with failure of antiretroviral therapy (Metzner et al., 2009).

Evolutionary Basis of Resistance Emergence

Development of Resistance via Mutation Selection

Mutations are random events that confer a survival advantage when drug is present. Mutation and antibiotic selection of resistant mutants are the molecular basis for resistance for many bacteria, viruses, and fungi. Mutations may occur in the gene encoding the following:

- the target protein, altering its structure so that it no longer binds the drug
- a protein involved in drug transport
- a protein important for drug activation or inactivation
- in a regulatory gene or promoter affecting expression of the target, a transport protein, or an inactivating enzyme

In some instances, a single-step mutation results in a high degree of resistance. In *M. tuberculosis* *katG*, Ser315 mutations cause resistance to isoniazid; the M814V mutation in the reverse transcriptase gene of HIV-1 causes resistance to lamivudine; and *C. albicans* *fkp1* Ser645 mutations cause resistance to echinocandins.

In other circumstances, however, it is the sequential acquisition of multiple mutations that leads to clinically significant resistance. For example, the combination of pyrimethamine (an inhibitor of DHFR) and sulfadoxine (an inhibitor of DHPS) blocks the folate biosynthetic pathway in

P. falciparum. Clinically meaningful resistance occurs only when there is a single-point mutation in the *DHPS* gene accompanied by at least a double mutation in the *DHFR* gene.

Hypermutable Phenotypes

Genetic continuity is accomplished principally by the replicative and repair activities of DNA polymerases and postreplicative repair systems. The development of a defect in one of these repair mechanisms leads to a high degree of mutations in many genes; such isolates are termed *mutator (Mut) phenotypes* and may include mutations in genes causing antibiotic resistance (Giraud et al., 2002). This second-order selection of hypermutable (mutator) alleles based on alterations in DNA repair genes has been implicated in the emergence of multidrug-resistant strains of *M. tuberculosis* Beijing genotype (Rad et al., 2003).

Resistance by External Acquisition of Genetic Elements

As described, drug resistance may be acquired by mutation and selection, with passage of the trait *vertically* to daughter cells, provided the mutation is not lethal, does not appreciably alter virulence, and does not affect replication by the progeny. Drug resistance more commonly is acquired by *horizontal transfer* of resistance determinants from a donor cell, often of another bacterial species, by *transduction*, *transformation*, or *conjugation*. Resistance acquired by horizontal transfer can disseminate rapidly and widely either by clonal spread of the resistant strain or by subsequent transfers to other susceptible recipient strains. Horizontal transfer of resistance offers several advantages over mutation selection. Lethal mutation of an essential gene is avoided; the level of resistance often is higher than that produced by mutation, which tends to yield incremental changes. The gene, which still can be transmitted vertically, can be mobilized and rapidly amplified within a population by transfer to susceptible cells, and the resistance gene can be eliminated when it no longer offers a selective advantage.

Horizontal Gene Transfer

Horizontal transfer of resistance genes is greatly facilitated by mobile genetic elements. Mobile genetic elements include plasmids and transducing phages. Other mobile elements—*transposable elements*, *integrations*, and *gene cassettes*—also participate. *Transposable elements* are of three general types: *insertion sequences*, *transposons*, and *transposable phages*. Only insertion sequences and transposons are important for resistance. There are numerous modes of horizontal resistance transfer:

- *Insertion sequences* are short segments of DNA encoding enzymatic functions (e.g., transposase and resolvase) for site-specific recombination with inverted repeat sequences at either end. They can copy themselves and insert themselves into a chromosome or a plasmid. Insertion sequences do not encode resistance, but they function as sites for integration of other resistance-encoding elements (e.g., plasmids or transposons).
- *Transposons* are insertion sequences, mobile elements that excise and integrate in the bacterial genomic or plasmid DNA (i.e., from plasmid to plasmid, from plasmid to chromosome, or from chromosome to plasmid). Basically, a resistance gene can "hitchhike" with a transferable element out of the host and into a recipient.
- *Integrations* are not formally mobile and do not copy themselves, but they encode an integrase and provide a specific site into which mobile gene cassettes integrate.
- *Gene cassettes* encode resistance determinants, usually lacking a promoter, with a downstream repeat sequence. The integrase recognizes this repeat sequence and directs insertion of the cassette into position behind a strong promoter that is present on the integron. Integrons may be located within transposons or in plasmids and therefore may be mobilizable or located on the chromosome.
- *Transduction* is the acquisition of bacterial DNA from a phage (a virus that propagates in bacteria) that has incorporated DNA from a previous host bacterium within its outer protein coat. If the DNA includes a

Resistance Transfer in Action

A startling example of how the transfer mechanisms spread resistance is the recent description of the plasmid-mediated colistin resistance gene (*mcr-1*), which confers resistance to one of the last-resort antibiotics for multidrug-resistant gram-negative bacteria (Liu et al., 2016). Colistin is used in agriculture and animal husbandry. *Escherichia coli* strains carrying this gene were found in pigs, then in pork, and then in patients. The plasmid carrying *mcr-1* was mobilized by conjugation to *E. coli* at a frequency of 10^{-1} to 10^{-3} cells per recipient and could be spread and maintained in other gram-negative rods of clinical significance. The resistant bacteria were initially identified in China, but within months isolates were also identified in North America, South America, Europe, East Asia, and Africa and in other organisms, such as *Salmonella typhimurium*. The gene has now been demonstrated in gut microbiota of healthy individuals, suggesting integration in the human gut and the capacity to spread to organisms in the human microbiome.

gene for drug resistance, the newly infected bacterial cell may acquire resistance. Transduction is particularly important in the transfer of antibiotic resistance among strains of *S. aureus*.

- **Transformation** is the uptake and incorporation into the host genome by homologous recombination of free DNA released into the environment by other bacterial cells. Transformation is the molecular basis of penicillin resistance in pneumococci and *Neisseria*.
- **Conjugation** is gene transfer by direct cell-to-cell contact through a sex pilus or bridge, allowing the transfer of multiple resistance genes in a single event. The transferable genetic material consists of two different sets of plasmid-encoded genes on the same or different plasmids: one encoding the actual resistance, and another encoding genes necessary for bacterial conjugation. Conjugation with genetic exchange between nonpathogenic and pathogenic microorganisms probably occurs in the GI tract. The efficiency of transfer is low; however, antibiotics can exert a powerful selective pressure to allow emergence of the resistant strain. Genetic transfer by conjugation is common among gram-negative bacilli, and resistance is conferred on a susceptible cell as a single event. Enterococci also contain a broad range of host-range conjugative plasmids that are involved in the transfer and spread of resistance genes among gram-positive organisms.

TREATING THE MOSQUITO RATHER THAN THE HUMAN

Global Impact of Malaria

Malaria remains among the top five causes of death among children younger than 5 years, affects about a quarter of a billion people, and causes almost 900,000 deaths annually (GBD_2013_Collaborators, 2015). Malarial transmission occurs in regions of Africa, Latin and South America, Asia, the Middle East, the South Pacific, and the Caribbean (Figure 53–1). This disease is caused by infection with protozoan parasites of the genus *Plasmodium*. Five *Plasmodium* spp. are known to infect humans: *P. falciparum*, *P. vivax*, *P. ovale*, *P. malariae*, and *P. knowlesi*. *Plasmodium falciparum* and *P. vivax* cause most malarial infections worldwide. *Plasmodium falciparum* accounts for the majority of the burden of malaria in sub-Saharan Africa and is associated with the most severe disease. *Plasmodium vivax* accounts for half of the malaria burden in South and East Asia and more than 80% of the malarial infections in the Americas and has been underappreciated as a cause of severe malaria (Baird, 2013).

Over the past half-century, malaria parasites worldwide—primarily *P. falciparum* and *P. vivax*—have become increasingly resistant to anti-malarial drugs, including chloroquine (Djimde et al., 2001; Warhurst, 2001); mefloquine (White et al., 2014); quinine (White et al., 2014); sulfadoxine/pyrimethamine (Artimovich et al., 2015; Plowe et al., 1995; Sibley et al., 2001); and atovaquone (Garcia-Bustos et al., 2013; Kessl et al., 2007). In response, new, multiprong international public-private partnerships as well as other funding agencies and sources have emerged to create new pipelines that advance drug candidates from discovery to clinical development (Hemingway et al., 2016; Wells et al., 2010, 2015).

Biology of Malarial Infection

Malarial infection is initiated when a female anopheline mosquito injects *Plasmodium* sporozoites during a blood meal (Miller et al., 1998). After entering the dermis, sporozoites enter the bloodstream and, within minutes, arrive at the liver, where they infect individual hepatocytes via cell surface receptor-mediated events (Sinnis et al., 2013). This process initiates the *asymptomatic prepatent period*, or *exoerythrocytic stage* of infection, which typically lasts about 1 week.

During this period, the parasite undergoes asexual replication within hepatocytes, resulting in production of liver-stage *schizonts*. When an infected hepatocyte ruptures, tens of thousands of *merozoites* are released

into the bloodstream and infect red blood cells. After the initial exoerythrocytic stage, *P. falciparum* and *P. malariae* are no longer found in the liver. *Plasmodium vivax* and *P. ovale*, however, can maintain a quiescent hepatocyte infection as a dormant form of the parasite known as the *hypnozoite* and can reinitiate symptomatic disease long after the initial symptoms of malaria are recognized and treated. Erythrocytic forms cannot reestablish infection of hepatocytes. Transmission of human-infecting malarial parasites is maintained in human populations by the persistence of hypnozoites (several months to a few years for *P. vivax* and *P. ovale*), by antigenic variation in *P. falciparum* (probably months), and by the putative antigen variation in *P. malariae* (for as long as several decades).

The *asexual erythrocytic stages* of malarial parasites are responsible for the clinical manifestations of malaria. This part of the *Plasmodium* life cycle is initiated by merozoite recognition of red blood cells and mediated by cell surface receptors that facilitate invasion of red blood cells.

Once inside a red blood cell, the merozoite develops into a ring form, which becomes a hemoglobin-metabolizing trophozoite (feeding stage) that matures into an asexually dividing blood-stage *schizont*. Schizont rupture at the end of the growth-and-division cycle releases 8–32 merozoites that invade new red blood cells. The erythrocytic replication cycle lasts for 24 h (for *P. knowlesi*), 48 h (for *P. falciparum*, *P. vivax*, and *P. ovale*), and 72 h (for *P. malariae*). Although most invading merozoites develop into schizonts, a small proportion becomes *gametocytes*, the form of the parasite infective to mosquitoes. Gametocytes are ingested by the mosquito during an infectious blood meal; on reaching the midgut of the mosquito, the gametocytes transform into gametes that fertilize to become zygotes. Zygotes mature into ookinets that invade the mosquito midgut wall and transform into oocysts. Numerous rounds of asexual replication occur in the oocyst to generate sporozoites over 10–14 days. Fully developed sporozoites rupture from oocysts and invade the mosquito salivary glands, from which they can initiate a new infection during subsequent mosquito blood meals (Figure 53–2). Thus, the infection cycles from mosquito to human to mosquito.

Plasmodium falciparum has a family of binding proteins that recognize a variety of host cell molecules that this parasite species uses to invade all stages of erythrocytes (Lim et al., 2015; Weiss et al., 2016); high parasitemia may result from this mechanism. In contrast, *P. vivax* selectively binds to the Duffy chemokine receptor protein as well as reticulocyte-specific proteins (Chitnis et al., 2008; Paul et al., 2015). *Plasmodium falciparum* assembles cytoadherence proteins (e.g., PfEMP1) (Weiss et al., 2016), encoded by a highly variable family of *var* genes into structures called

knobs that are presented on the erythrocyte surface (Hviid et al., 2015; Ukaegbu et al., 2015). Knobs allow the *P. falciparum*-parasitized erythrocyte to bind to postcapillary vascular endothelium to avoid spleen-mediated clearance and allow the parasite to grow in a low-O₂, high-CO₂ microenvironment.

Clinical Manifestations of Malaria

The cardinal signs and symptoms of malaria are high, spiking fevers (with or without periodicity), chills, headaches, myalgias, malaise, and GI symptoms (White et al., 2014). Severe headache, a characteristic early symptom in malaria caused by all *Plasmodium* spp., often heralds the onset of disease, even before fever and chills. *Plasmodium falciparum* causes the most severe disease and may lead to organ failure and death. Placental malaria, of particular danger for primigravidae, is due to *P. falciparum* adherence to CSA in the placenta. This often leads to severe complications, including miscarriage. When treated early, symptoms of malarial infection usually improve within 24–48 h. New insights into malaria clinical presentations indicate that—in the endemic setting where nonsterilizing clinical immunity is the rule, not the exception—the cardinal symptoms of malaria may be atypical or absent (Chen et al., 2016).

Acute illness due to *P. vivax* infection may appear severe due to high fever and prostration. Indeed, the pyrogenic threshold of this parasite (i.e., “blood stage” parasite burden associated with fever) is lower than that of *P. falciparum*. Nonetheless, *P. vivax* malaria generally has a low mortality rate. *Plasmodium vivax* malaria is characterized by relapses caused by the reactivation of latent tissue forms. Clinical manifestations of relapse are the same as those of primary infection. In recent years, severe *P. vivax* malaria from Oceania (Papua New Guinea, Indonesia) and India possess important similarities to severe malaria caused by *P. falciparum*. These include neurological symptoms (diminished consciousness, seizure) and pulmonary edema. Rare but life-threatening complications can occur, including splenic rupture, acute lung injury, and profound anemia.

Plasmodium ovale causes a clinical syndrome similar to that of *P. vivax* but may be milder with lower levels of parasitemia. It shares with *P. vivax* the ability to form the hypnozoite (dormant liver stage) that may relapse after months to 2 years later. *Plasmodium ovale* is more common in sub-Saharan Africa and some islands in Oceania.

Plasmodium malariae generally causes an indolent infection with very low levels of parasitemia and often does not produce clinical symptoms. This parasite can be found in all malaria-endemic areas but is most common in sub-Saharan Africa and the southwest Pacific. Interestingly, *P. malariae* prevalence increases during the dry season and can be found as a coinfection with *P. falciparum*. An uncommon but potentially fatal complication of *P. malariae* is a glomerulonephritis syndrome that does not respond to antimalarial treatment.

Plasmodium knowlesi infection is often misdiagnosed as *P. malariae* by light microscopy. This infection is distinguished by a shorter erythrocytic cycle (24 h compared with 72 h for *P. malariae*) and higher levels of parasitemia. Like *P. malariae*, *P. knowlesi* is generally sensitive to chloroquine, but patients presenting with advanced disease nonetheless may progress to death despite adequate drug dosing.

Asymptomatic *P. falciparum* and *P. vivax* infections are common in endemic regions and represent important potential reservoirs for malaria transmission. Although different studies are not entirely consistent in the definition of *asymptomatic*, generally this state implies a lack of fever, headache, and other systemic complaints, within a defined time period prior to a positive test for malaria parasitemia. Migration of asymptomatic individuals to areas where malaria is not present but vector mosquitoes are (i.e., anophelism without malaria) is an important mechanism for the introduction or reintroduction of malaria, in addition to facilitating the spread of drug-resistant isolates. Novel approaches to preventing transmission from asymptomatic reservoirs—whether through new drugs or vaccines—will be essential for future malaria control, elimination, and eradication strategies.

Classification of Antimalarial Agents

The various stages of the malarial parasite life cycle in humans differ in their drug sensitivity. Thus, antimalarial drugs can be classified based on their activities during this life cycle as well as by their intended use for either chemoprophylaxis or treatment. The spectrum of antimalarial drug activity leads to several generalizations.

The first relates to chemoprophylaxis: *Because no antimalarial drug kills sporozoites, it is not truly possible to prevent infection; drugs can only prevent the development of symptomatic malaria caused by the asexual erythrocytic forms, either in the bloodstream or as produced within and released by hepatocytes prior to erythrocyte invasion.*

The second relates to the treatment of an established infection: *No single antimalarial is effective against all hepatic and intraerythrocytic stages of the life cycle that may coexist in the same patient. Complete elimination of the parasite infection, therefore, may require more than one drug.*

The patterns of clinically useful antimalarial agents fall into three general categories (Table 53–1):

1. Agents (artemisinins, chloroquine, mefloquine, quinine and quinidine, pyrimethamine, sulfadoxine, and tetracycline) that are not reliably effective against primary or latent liver stages. Instead, their action is directed against the asexual blood stages responsible for disease. These drugs will treat, or prevent, clinically symptomatic malaria.
2. Drugs (typified by atovaquone and proguanil) that target not only the asexual erythrocytic forms but also the primary liver stages of *P. falciparum*. This additional activity shortens to several days the required period for postexposure chemoprophylaxis.
3. Primaquine, an eight-amino quinoline that is effective against primary and latent liver stages as well as gametocytes. Primaquine is used most commonly to eradicate the intrahepatic hypnozoites of *P. vivax* and *P. ovale* that are responsible for relapsing infections. Tafenoquine, an eight-amino quinolone, is a long half-life analogue of primaquine, has a similar spectrum of action as primaquine, and is in advanced clinical trials (Llanos-Cuentas et al., 2014).

Aside from their antiparasitic activity, the utility of antimalarials for chemoprophylaxis or therapy depends on their pharmacokinetics and

A. Eastern Hemisphere

Figure 53-1 *Malaria-endemic countries. A. Eastern Hemisphere; B. Western Hemisphere.* A country is shaded orange even if malaria is endemic in just a portion of that country. Large regions not shown on the maps (e.g., Scandinavia, Russia, Canada, U.S.A., Tasmania, New Zealand) are non-endemic for malaria. (Reproduced from Centers for Disease Control and Prevention. <https://wwwnc.cdc.gov/travel/yellowbook/2018/infectious-diseases-related-to-travel/malaria>; accessed July 29, 2017). In areas of endemic malaria, the disease is largely chloroquine-resistant. For up-to-date information, consult the online CDC Malaria Map (https://www.cdc.gov/malaria/travelers/about_maps.html) and the CDC's Malaria Information and Prophylaxis, by Country (http://www.cdc.gov/malaria/travelers/country_table/a.html).

B. Western Hemisphere

Figure 53-1 (Continued)

safety. Quinine and primaquine, which have significant toxicity and relatively short half-lives, generally are reserved for the treatment of established infection and are not used for chemoprophylaxis in a healthy traveler. By contrast, chloroquine, which is relatively free from toxicity and has a long $t_{1/2}$, is convenient for chemoprophylactic dosing (in those few areas still reporting chloroquine-sensitive malaria).

Specific Antimalarial Agents

For ease of reference, detailed information on the antimalarial drugs appears next in alphabetical order by drug name.

Artemisinin and Its Derivatives

Artemisinin and its three major semisynthetic derivatives in clinical use, dihydroartemisinin, artemether, and artesunate, are potent and fast-acting antimalarials. They are optimized for the treatment of severe *P. falciparum*

malaria and are also effective against the asexual erythrocytic stages of *P. vivax*. Increasingly, the standard treatment of malaria employs *artemisinin-based combination therapies* (ACTs) to increase treatment efficacy and reduce selection pressure for the emergence of drug resistance. Recent reports of *P. falciparum* artemisinin “resistance” do not indicate true resistance but reflect delayed parasite clearance time on the order of hours (Ashley et al., 2014; Huang et al., 2015); mutations in the *P. falciparum* gene *Pfk13* encoding the kelch13 propeller protein have been associated with these delayed parasite clearance times, although the mechanism by which the kelch13 propeller protein mediates delayed parasite clearance remains unknown. True resistance to artemisinin has not been reported, and no infection from this parasite has been reported to survive ACT due to delayed clearance times (van Schalkwyk et al., 2015). The clinical significance of *P. falciparum* artemisinin “resistance/delayed clearance” remains unclear (Fairhurst, 2015), but this mutation potential could threaten the future utility of this drug class. Moreover, in the presence of mutations that confer resistance to partner drugs (e.g., the ACT partner

Figure 53–2 Life cycle of malaria parasites.

drug piperazine), clinically significant ACT failure is substantial, with recrudescence rates reported to exceed 50% (Amaratunga et al., 2016; Spring et al., 2015). Resistance of non-*P. falciparum* malaria parasites to artemisinin class drugs has not been reported.

Artemisinins cause a significant reduction of the parasite burden, with a 4-log₁₀ reduction in the parasite population for each 48-h cycle of intraerythrocytic invasion, replication, and egress. Only three to four cycles (6–8 days) of treatment are required to remove all the parasites from the blood. In addition, artemisinins possess some gametocytocidal activity, leading to a decrease in malarial parasite transmission.

Mechanism of Action

The activity of artemisinin and derivatives seems to result from cleavage of the drug's peroxide bridge by reduced heme-iron, produced inside the highly acidic digestive vacuole of the parasite as it digests hemoglobin. The site of action of the putatively toxic heme-adducts is unclear. In addition, activated artemisinin might in turn generate free radicals that alkylate and oxidize macromolecules in the parasite.

ADME

The semisynthetic artemisinins have been formulated for oral (dihydroartemisinin, artesunate, and artemether); intramuscular (artesunate and artemether); intravenous (artesunate); and rectal (artesunate) routes. Bioavailability after oral dosing typically is 30% or less. Peak serum levels occur rapidly with artemisinins and in 2–6 h with intramuscular artemether. Both artesunate and artemether have modest levels of plasma protein binding, ranging from 43% to 82%. These derivatives are extensively metabolized and converted to dihydroartemisinin, which has a plasma $t_{1/2}$ of 1–2 h. Drug bioavailability via rectal administration is highly variable among individual patients. With repeated dosing, artemisinin and artesunate induce their own CYP-mediated metabolism, primarily via CYPs 2B6 and 3A4, which may enhance clearance by as much as 5-fold.

Therapeutic Uses

Given their rapid and potent activity against even multidrug-resistant parasites, the artemisinins are valuable for the treatment of severe *P. falciparum* malaria. The artemisinins generally are not used alone because of their limited ability to eradicate infection completely. Artemisinins are highly effective for the first-line treatment of malaria when combined with other antimalarials. Artemisinins should not be used for chemoprophylaxis because of their short $t_{1/2}$ values.

Toxicity and Contraindications

In pregnant rats and rabbits, artemisinins can cause increased embryo lethality or malformations early postconception. Preclinical toxicity studies have identified the brain (and brainstem), liver, and bone marrow as the principal target organs. However, no systematic neurological changes have been attributed to treatment in patients 5 years of age or older. Patients may develop dose-related and reversible decreases in reticulocyte and neutrophil counts and increases in transaminase levels. About 1 in 3000 patients develops an allergic reaction. Although studies of artemisinin treatment during the first trimester have found no evidence of adverse effects on fetal development, it is recommended that ACTs not be used during the first trimester of pregnancy or for the treatment of children 5 kg or less.

ACT Partner Drugs

Partner drugs for ACT are chosen for potency and $t_{1/2}$ that substantially exceeds that of the artemisinin partner. The primary ACT regimens that are well tolerated in adults and children 5 kg or more are artemether-lumefantrine, artesunate-amodiaquine, and dihydroartemisinin-piperazine. In the U.S., artemether-lumefantrine is probably the drug of choice for all malaria cases if oral drug treatment is appropriate. Pyronaridine remains in clinical trials and is not licensed.

- **Lumefantrine** shares structural similarities with the arylamino alcohol drugs mefloquine and halofantrine and is formulated with artemether. This combination is highly effective for the treatment of uncomplicated malaria and is the most widely used first-line antimalarial across Africa. The pharmacokinetic properties of lumefantrine include a large apparent volume of distribution and a terminal elimination $t_{1/2}$ of 4–5 days. Administration with a high-fat meal is recommended because it significantly increases absorption. A sweetened dispersible formulation of artemether-lumefantrine has been approved for treatment of children.
- **Amodiaquine** is a congener of chloroquine that is no longer recommended in the U.S. for chemoprophylaxis of *P. falciparum* malaria because of toxicities (hepatic and agranulocytosis) generally associated with its prophylactic use. Amodiaquine is rapidly converted by hepatic CYPs into monodesethyl-amodiaquine. This metabolite, which retains substantial antimalarial activity, has a plasma $t_{1/2}$ of 9–18 days and reaches a peak concentration of about 500 nM 2 h after oral administration of the recommended dose. By contrast, amodiaquine has a $t_{1/2}$ of about 3 h, attaining a peak concentration of about 25 nM within 30 min of oral administration. Clearance rates of amodiaquine vary widely among individuals (78–943 mL/min/kg).
- **Piperaquine** is a potent and well-tolerated bisquinoline compound structurally related to chloroquine. Piperaquine has a large volume of

TABLE 53-1 ■ SUSCEPTIBILITY TO DRUGS OF MALARIAL PARASITES AT VARIOUS DEVELOPMENTAL STAGES

—, no activity; +/-, low to moderate activity; +, clinically important activity.

distribution and reduced rates of excretion after multiple doses. It is rapidly absorbed, with a T_{\max} (time to reach the highest concentration) of 2 h after a single dose. Piperaquine has the longest plasma $t_{1/2}$ (5 weeks) of all ACT partner drugs, a factor that could contribute to reducing rates of reinfection following treatment. Reduced efficacy of piperaquine in combination with dihydroartemisinin in Cambodia has been reported, primarily associated with mutations that led to piperaquine resistance but also in the *Pfk13* gene associated with delayed parasite clearance time (Amaratunga et al., 2016; Spring et al., 2015).

- **Pyronaridine**, an antimalarial structurally related to amodiaquine, is well tolerated and potent against both *P. falciparum* and *P. vivax*. Pyronaridine leads to fever resolution in 1–2 days and parasite clearance in 2–3 days. This drug, tested in clinical trials as a partner with artemisinin class drugs, has not yet been licensed.

Atovaquone

A fixed combination of *atovaquone* with *proguanil hydrochloride* is available in the U.S. for malaria chemoprophylaxis and for the treatment of uncomplicated *P. falciparum* malaria in adults and children.

Mechanism of Action, Selective Toxicity, Antimalarial Action, and Resistance

Atovaquone is a lipophilic analogue of ubiquinone (coenzyme Q), the electron acceptor for the parasite's cytb_c complex. Cytbc_c, situated on the inner mitochondrial membrane, supplies oxidized ubiquinone for dihydroorotate dehydrogenase, an essential enzyme in pyrimidine biosynthesis in the parasite. In addition, cytb_c is part of the respiratory chain and transports H⁺ into the intramembranous space of mitochondria. By binding at the Q_o site of cytb_c1, atovaquone inhibits electron transport, collapses the mitochondrial membrane potential, and inhibits regeneration of ubiquinone. The selective toxicity of atovaquone for the *Plasmodium* genus and not the human host may stem from structural differences in the amino terminal regions of plasmodial and human cytochrome b (Capper et al., 2015).

The drug is highly active against *P. falciparum* asexual blood-stage parasites and the liver stages of *P. falciparum*, but not against *P. vivax* liver-stage hypnozoites. Synergy between proguanil and atovaquone results from the ability of nonmetabolized proguanil to enhance the mitochondrial toxicity of atovaquone. Resistance to atovaquone alone in *P. falciparum* develops easily and is conferred by single, nonsynonymous nucleotide polymorphisms in the cytochrome b gene located in the mitochondrial genome. Addition of proguanil markedly reduces the frequency of appearance of atovaquone resistance. However, once atovaquone resistance is present, the synergy of the partner drug proguanil diminishes.

ADME

Atovaquone absorption is slow and variable after an oral dose; absorption improves when the drug is taken with a fatty meal. More than 99% of the drug is bound to plasma protein; CSF levels are less than 1% of those in plasma. Profiles of drug concentration versus time often show a double peak, the first at 1–8 h, the second 1–4 days after a single dose; this pattern suggests enterohepatic circulation. Humans do not metabolize atovaquone significantly. The drug is excreted in bile, and more than 94% of the drug is recovered unchanged in feces. Atovaquone has a reported elimination $t_{1/2}$ from plasma of 2–3 days in adults and 1–2 days in children.

Therapeutic Uses

A tablet containing a fixed dose of 250 mg atovaquone and 100 mg proguanil hydrochloride, taken orally, is highly effective and safe in a 3-day regimen for treating mild-to-moderate attacks of chloroquine- or sulfadoxine-pyrimethamine-resistant *P. falciparum* malaria. The same regimen followed by a primaquine course is effective in treatment of *P. vivax* malaria. Atovaquone-proguanil is a standard agent for malaria chemoprophylaxis. Experience in prevention of non-*P. falciparum* malaria is limited. *Plasmodium vivax* infection may occur after drug discontinuation, indicating imperfect activity against exoerythrocytic stages of this parasite.

Toxicity

Atovaquone may cause side effects (abdominal pain, nausea, vomiting, diarrhea, headache, rash) that require cessation of therapy. Vomiting and diarrhea may decrease drug absorption, resulting in therapeutic failure. However, readministration of this drug within an hour of vomiting may still be effective in patients with *P. falciparum* malaria. Atovaquone occasionally causes transient elevations of serum transaminase or amylase.

Precautions and Contraindications

Although atovaquone is generally considered to be safe, it needs further evaluation in children weighing less than 11 kg, pregnant women, and lactating mothers. Atovaquone may compete with certain drugs for binding to plasma proteins. Therapy with rifampin reduces plasma levels of atovaquone substantially; the mechanism of this effect is not clear. Coadministration with tetracycline is associated with a 40% reduction in plasma concentration of atovaquone.

Diaminopyrimidines

Sulfadoxine-pyrimethamine was a primary treatment of uncomplicated *P. falciparum* malaria, especially against chloroquine-resistant strains. Due to widespread resistance, it is no longer recommended for the treatment of uncomplicated malaria.

Antimalarial Action and Resistance

Pyrimethamine is a slow-acting blood *schizonticide* with antimalarial effects in vivo resulting from inhibition of *folate biosynthesis* in *Plasmodium*, similar to proguanil. The efficacy of pyrimethamine against hepatic forms of *P. falciparum* is less than that of proguanil. At therapeutic doses, pyrimethamine fails to eradicate *P. vivax* hypnozoites or gametocytes of any *Plasmodium* species. The drug increases the number of circulating *P. falciparum* mature infecting gametocytes, likely leading to increased transmission to mosquitoes during the period of treatment.

Synergy of pyrimethamine and the sulfonamides or sulfones results from inhibition of two metabolic steps in folate biosynthesis in the parasite:

- the utilization of *p*-aminobenzoic acid for the synthesis of dihydropteroic acid, which is catalyzed by dihydropteroate synthase and inhibited by sulfonamides; and
- the reduction of dihydrofolate to tetrahydrofolate, which is catalyzed by dihydrofolate reductase and inhibited by pyrimethamine (see Figure 56–2).

Dietary *p*-aminobenzoic acid or folate may affect the therapeutic response to antifolates. Resistance to pyrimethamine has developed in regions of prolonged or extensive drug use and can be attributed to mutations in dihydrofolate reductase that decrease the binding affinity of pyrimethamine.

ADME

Oral pyrimethamine is slowly but completely absorbed, reaching peak plasma levels in 2–6 h. The compound is significantly distributed in the tissues and is about 90% bound to plasma proteins. Pyrimethamine is slowly eliminated from plasma, with a $t_{1/2}$ of 85–100 h. Concentrations that are suppressive for responsive *Plasmodium* strains remain in the blood for about 2 weeks. Pyrimethamine also enters the milk of nursing mothers.

Therapeutic Uses

Due to increasing drug resistance, pyrimethamine-sulfadoxine is no longer recommended for the treatment of uncomplicated malaria or for chemoprophylaxis. However, for those living in malaria-endemic areas, some still recommend it for the intermittent preventive treatment of malaria in pregnancy.

Toxicity, Precautions, and Contraindications

Antimalarial doses of pyrimethamine alone cause minimal toxicity except for occasional skin rashes and reduced hematopoiesis. Excessive doses can produce a megaloblastic anemia, resembling that of folate deficiency, which responds readily to drug withdrawal or treatment with folic acid. At high doses, pyrimethamine is teratogenic in animals, and in humans the related combination, trimethoprim-sulfamethoxazole, may cause birth defects.

Sulfonamides or sulfones, rather than pyrimethamine, usually account for the toxicity associated with coadministration of these antifolate drugs. The combination of pyrimethamine and sulfadoxine causes severe and even fatal cutaneous reactions, such as erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. It has also been associated with serum sickness-type reactions, urticaria, exfoliative dermatitis, and hepatitis. Pyrimethamine-sulfadoxine is contraindicated for individuals with previous reactions to sulfonamides, for lactating mothers, and for infants less than 2 months of age. Administration of pyrimethamine with dapsone, a drug combination unavailable in the U.S., has occasionally been associated with agranulocytosis.

Proguanil

The antimalarial activity of proguanil (chloroguanide) is ascribed to cycloguanil, a cyclic triazine metabolite (structurally related to pyrimethamine) and selective inhibitor of the bifunctional plasmodial dihydrofolate reductase–thymidylate synthetase that is crucial for parasite *de novo* purine and pyrimidine synthesis.

Antimalarial Action and Resistance

In drug-sensitive *P. falciparum* malaria, proguanil exerts activity against both the primary liver stages and the asexual red blood cell stages, thus adequately controlling the acute attack and usually eradicating the infection. Proguanil is also active against acute *P. vivax* malaria, but because the latent tissue stages of *P. vivax* are unaffected, relapses may occur after the drug is withdrawn. Proguanil treatment does not destroy gametocytes, but oocytes in the gut of the mosquito can fail to develop normally.

Cycloguanil selectively inhibits the bifunctional dihydrofolate reductase–thymidylate synthetase of sensitive plasmodia, causing inhibition of DNA synthesis and depletion of folate cofactors. A series of amino acid changes near the dihydrofolate reductase-binding site have been identified that cause resistance to cycloguanil, pyrimethamine, or both. The presence of *Plasmodium* dihydrofolate reductase is not required for the intrinsic antimalarial activity of proguanil or chlorproguanil; however, the molecular basis for this alternative activity is unknown. Proguanil accentuates the mitochondrial membrane-potential-collapsing action of atovaquone against *P. falciparum* but displays no such activity by itself. In contrast to cycloguanil, resistance to the parent drug, proguanil, either alone or in combination with atovaquone, is not well documented.

ADME

Proguanil is slowly but adequately absorbed from the GI tract. After a single oral dose, peak plasma concentrations are attained within 5 h. The mean plasma elimination $t_{1/2}$ is about 180–200 h or longer. The drug's activation and metabolism involve the CYP2C subfamily; about 3% of whites are deficient in this oxidation phenotype, contrasted with about 20% of Asians and Kenyans. Proguanil is oxidized to two major metabolites, the active cycloguanil and an inactive 4-chlorophenyl biguanide. On a daily dosage regimen of 200 mg-daily, plasma levels of cycloguanil in extensive metabolizers exceed the therapeutic range, whereas cycloguanil levels in poor metabolizers do not. Proguanil itself does not accumulate appreciably in tissues during long-term administration, except in red blood cells, where its concentration is about three times that in plasma. In humans, 40%–60% of the absorbed proguanil is excreted in urine, either as the parent drug or as the active metabolite.

Therapeutic Uses

Proguanil as a single agent is not available in the U.S. but has been prescribed as chemoprophylaxis in England and Europe for individuals traveling to malarious areas in Africa. Strains of *P. falciparum* resistant to proguanil emerge rapidly in areas where the drug is used exclusively, but breakthrough infections may also result from deficient conversion of proguanil to its active antimalarial metabolite. Proguanil is effective and tolerated well in combination with atovaquone, once daily for 3 days, to treat drug-resistant strains of *P. falciparum* or *P. vivax* (see section on atovaquone). *P. falciparum* readily develops clinical resistance to monotherapy with either proguanil or atovaquone; however, resistance to the combination is uncommon unless the strain is initially resistant to atovaquone.

Toxicity and Side Effects

In chemoprophylactic doses of 200–300 mg daily, proguanil causes relatively few adverse effects, except occasional nausea and diarrhea. Large doses (≥ 1 g daily) may cause vomiting, abdominal pain, diarrhea, hematuria, and the transient appearance of epithelial cells and casts in the urine. Doses as high as 700 mg twice daily have been taken for more than 2 weeks without serious toxicity. Proguanil is safe for use during pregnancy. It is remarkably safe when used in conjunction with other antimalarial drugs.

Quinolines and Related Compounds

Quinine is the chief alkaloid of cinchona, the powdered bark of the South American cinchona tree. Quinine and its many derivatives have been the mainstay of malarial treatment for four centuries. Structure-

activity analysis of the cinchona alkaloids provided the basis for the discovery of more recent antimalarials, such as mefloquine.

Antimalarial Action

Asexual malarial parasites flourish in host erythrocytes by digesting hemoglobin; this generates free radicals and iron-bound heme as highly reactive by-products. Heme is sequestered as an insoluble, chemically inert malarial pigment termed *hemozoin*. Quinolines interfere with heme sequestration. Failure to inactivate heme and drug-heme complexes is thought to kill the parasites via oxidative damage to membranes or other critical biomolecules.

Chloroquine and Hydroxychloroquine

Chloroquine, a weak base, concentrates in the highly acidic digestive vacuoles of susceptible *Plasmodium*, where it binds to heme and disrupts its sequestration. Hydroxychloroquine, in which one of the *N*-ethyl substituents of chloroquine is β -hydroxylated, is essentially equivalent to chloroquine against *P. falciparum* malaria.

Resistance. Resistance of erythrocytic asexual forms of *P. falciparum* to antimalarial quinolines, especially chloroquine, now is widespread (Figure 53-1). Chloroquine resistance results from mutations in the polymorphic gene *pfprt* gene that encodes a putative transporter that resides in the membrane of the acidic digestive vacuole, the site of hemoglobin degradation and chloroquine action. In addition to PfCRT, the P-glycoprotein transporter encoded by *pfmdr1*, and other transporters, including *P. falciparum* multidrug resistance-associated protein (PfMRP), may play a modulatory role in chloroquine resistance.

ADME. Chloroquine is well absorbed from the GI tract and rapidly from intramuscular and subcutaneous sites. This drug extensively sequesters in tissues, particularly liver, spleen, kidney, lung, and, to a lesser extent, brain and spinal cord. Chloroquine binds moderately (60%) to plasma proteins. The actions of hepatic CYPs produce two active metabolites, desethylchloroquine and bisdesethylchloroquine. Renal clearance of chloroquine is about half of its total systemic clearance. Unchanged chloroquine and desethylchloroquine account for more than 50% and 25% of the urinary drug products, respectively, and their renal excretion is increased by urine acidification. To avoid potentially lethal toxicity, parenteral chloroquine is given either slowly by constant intravenous infusion or in small divided doses by the subcutaneous or intramuscular route. Chloroquine is safer when given orally because the rates of absorption and distribution are more closely matched. Peak plasma levels are achieved in about 3–5 h. The $t_{1/2}$ of chloroquine increases from a few days to weeks as plasma levels decline. The terminal $t_{1/2}$ ranges from 30 to 60 days, and traces of the drug can be found in the urine for years after a therapeutic regimen.

Therapeutic Uses. Chloroquine is highly effective against the erythrocytic forms of *P. vivax*, *P. ovale*, *P. malariae*, *P. knowlesi*, and chloroquine-sensitive strains of *P. falciparum*. For infections caused by *P. ovale* and *P. malariae*, it remains the agent of choice for chemoprophylaxis and treatment. For *P. falciparum*, ACTs have largely replaced chloroquine.

The utility of chloroquine has declined across most malaria-endemic regions of the world because of the spread of chloroquine-resistant *P. falciparum*. Except in areas where resistant strains of *P. vivax*

are reported, chloroquine is effective in chemoprophylaxis or treatment of acute attacks of malaria caused by *P. vivax*, *P. ovale*, and *P. malariae*. Chloroquine has no activity against primary or latent liver stages of the parasite. To prevent relapses in *P. vivax* and *P. ovale* infections, primaquine can be given either with chloroquine or used after a patient leaves an endemic area. Chloroquine rapidly controls the clinical symptoms and parasitemia of acute malarial attacks. Most patients become completely afebrile within 24–48 h after receiving therapeutic doses. If patients fail to respond during the second day of chloroquine therapy, resistant strains should be suspected and therapy instituted with quinine plus tetracycline or doxycycline or with atovaquone-proguanil, artemether-lumefantrine, or mefloquine if the others are not available. In comatose children, chloroquine is well absorbed and effective when given through a nasogastric tube. Tables 53-2 and 53-3 provide information about recommended chemoprophylactic and therapeutic dosage regimens involving chloroquine. Chloroquine and its analogues are also used to treat certain nonmalarial conditions, including hepatic amebiasis.

Toxicity and Side Effects. Taken in proper doses and for recommended total durations, chloroquine is safe, but its safety margin is narrow; a single dose of 30 mg/kg may be fatal. Acute chloroquine toxicity is encountered most frequently when therapeutic or high doses are administered too rapidly by parenteral routes. Cardiovascular effects include hypotension, vasodilation, suppressed myocardial function, cardiac arrhythmias, and eventual cardiac arrest. Confusion, convulsions, and coma may also result from overdose. Chloroquine doses of more than 5 g given parenterally usually are fatal. Prompt treatment with mechanical ventilation, epinephrine, and diazepam may be lifesaving.

Doses of chloroquine used for oral therapy of the acute malarial attack may cause GI upset, headache, visual disturbances, and urticaria. Pruritus also occurs most commonly among dark-skinned persons. Prolonged treatment with suppressive doses occasionally causes side effects such as headache, blurring of vision, diplopia, confusion, convulsions, lichenoid skin eruptions, bleaching of hair, widening of the QRS interval, and T-wave abnormalities. These complications usually disappear soon after the drug is withheld. Rare instances of hemolysis and blood dyscrasias have been reported. Chloroquine may cause discoloration of nail beds and mucous membranes. This drug has also been reported to interfere with the immunogenicity of certain vaccines. Irreversible retinopathy and ototoxicity can result from high daily doses (>250 mg) of chloroquine or hydroxychloroquine leading to cumulative total doses of more than 1 g/kg. Retinopathy presumably is related to drug accumulation in melanin-containing tissues and can be avoided if the daily dose is 250 mg or less. Prolonged therapy with high doses of chloroquine or hydroxychloroquine also can cause toxic myopathy, cardiopathy, and peripheral neuropathy. These reactions improve if the drug is withdrawn promptly. Rarely, neuropsychiatric disturbances, including suicide, may be related to overdose.

Precautions and Contraindications. Chloroquine is not recommended for treating individuals with epilepsy or myasthenia gravis and should be used cautiously, if at all, in the presence of advanced liver disease or severe GI, neurological, or blood disorders. The dose should be reduced in renal failure. In rare cases, chloroquine can cause hemolysis in patients with G6PD deficiency. Chloroquine should not be prescribed for patients with psoriasis or other exfoliative skin conditions. It should not be used to treat malaria in patients with porphyria cutanea tarda; however, it can be used in lower doses for treatment of manifestations of this form of porphyria.

Chloroquine inhibits CYP2D6 and thus can interact with a variety of different drugs. It attenuates the efficacy of the yellow fever vaccine when administered at the same time. It should not be given with mefloquine because of increased risk of seizures. Chloroquine opposes the action of anticonvulsants and increases the risk of ventricular arrhythmias when coadministered with amiodarone or halofantrine. By increasing plasma levels of digoxin and cyclosporine, chloroquine can increase the risk of toxicity from these agents. Patients receiving long-term, high-dose

TABLE 53-2 ■ CHEMOPROPHYLAXIS FOR PREVENTION OF MALARIA IN NONIMMUNE INDIVIDUALS

DRUG (USAGE)	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone/proguanil (Prophylaxis in all areas)	Adult tablets contain 250 mg atovaquone and 100 mg proguanil hydrochloride; 1 adult tablet orally, daily	Pediatric tablets (62.5 mg atovaquone/25 mg proguanil HCl) 5–8 kg: 1/2 ped tab/day >8–10 kg: 3/4 ped tab/day >10–20 kg: 1 ped tab/day >20–30 kg: 2 ped tab/day >30–40 kg: 3 ped tab/day >40 kg: 1 adult tab daily	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 7 days after leaving such areas. Contraindicated in persons with severe renal impairment (creatinine clearance < 30 mL/min). Take with food or a milky drink. Not recommended for prophylaxis for children weighing less than 5 kg, pregnant women, and women breastfeeding infants weighing less than 5 kg.
Chloroquine phosphate (Prophylaxis in areas with chloroquine-sensitive malaria)	300 mg base (500 mg salt) orally, once/week	5 mg/kg base (8.3 mg/kg salt) orally, once/week, up to maximum adult dose (300 mg base)	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas. May exacerbate psoriasis.
Doxycycline (Prophylaxis in all areas)	100 mg orally, daily	≥8 years of age: 2 mg/kg up to adult dose of 100 mg/d	Begin 1–2 days before travel to malarious areas. Take daily at the same time each day while in the malarious area and for 4 weeks after leaving such areas. Contraindicated in children less than 8 years of age and pregnant women.
Hydroxychloroquine sulfate (Alternative to chloroquine for prophylaxis in areas with chloroquine-sensitive malaria)	310 mg base (400 mg salt) orally, once/week	5 mg/kg base (6.5 mg/kg salt) orally, once/week, up to maximum adult dose (310 mg base)	Begin 1–2 weeks before travel to malarious areas. Take weekly on the same day of the week while in the malarious area and for 4 weeks after leaving such areas.
Mefloquine (Prophylaxis in areas with mefloquine-sensitive malaria)	228 mg base (250 mg salt) orally, once/week	≤9 kg: 4.6 mg/kg base (5 mg/kg salt) orally, once/week >9–19 kg: 1/4 tab weekly >19–30 kg: 1/2 tab weekly >31–45 kg: 3/4 tab weekly ≥45 kg: 1 tablet weekly	Begin 1–2 weeks before travel to malarious areas. Take weekly on same day of the week while in malarious area and for 4 weeks after leaving such areas. Contraindicated in persons allergic to mefloquine or related compounds (e.g., quinine, quinidine) and in persons with active depression, recent history of depression, generalized anxiety disorder, psychosis, schizophrenia, other major psychiatric disorders, or seizures. Use with caution in persons with psychiatric disturbances or a previous history of depression. Not recommended for persons with cardiac conduction abnormalities.
Primaquine (Prophylaxis for short-duration travel to areas with principally <i>P. vivax</i>)	30 mg base (52.6 mg salt) orally, daily	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, daily	Begin 1–2 days before travel to malarious areas. Take daily at same time each day while in malarious area and for 7 days after leaving such areas. Contraindicated in persons with G6PD ^a deficiency and during pregnancy and lactation (unless the infant being breastfed has documented normal G6PD level).
Primaquine (For presumptive antirelapse therapy [terminal prophylaxis] to decrease the risk of relapses (<i>P. vivax</i> , <i>P. ovale</i>))	30 mg base (52.6 mg salt) orally, once/day for 14 days after departure from the malarious area.	0.5 mg/kg base (0.8 mg/kg salt) up to adult dose orally, once/day for 14 days after departure from the malarious area	Indicated for persons who have had prolonged exposure to <i>P. vivax</i> and <i>P. ovale</i> or both. Contraindicated in persons with G6PD ^a deficiency and during pregnancy and lactation (unless the infant being breastfed has documented normal G6PD level).

ped, pediatric; tab, tablet.

These regimens are based on published recommendations of the U.S. CDC. These recommendations may change over time. Up-to-date information should be obtained from <https://wwwnc.cdc.gov/travel>. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the last, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

^aAll persons who take primaquine should have a documented normal G6PD level before starting the medication.

therapy should undergo ophthalmological and neurological evaluations every 3–6 months.

Quinine and Quinidine

Oral quinine is FDA-approved for the treatment of uncomplicated *P. falciparum* malaria. Quinidine, a stereoisomer of quinine, is more potent as an antimalarial and more toxic than quinine.

Antimalarial Action and Resistance. Quinine acts against asexual erythrocytic forms and has no significant effect on hepatic forms of malarial parasites. This drug is more toxic and less effective than chloroquine against malarial parasites susceptible to both drugs. Compared to artemisinin class therapy, quinine produces poorer clinical outcomes. However, quinine, along with its stereoisomer quinidine, is especially

TABLE 53-3 ■ AGENTS FOR PRESUMPTIVE SELF-TREATMENT OF MALARIA^a

DRUG	ADULT DOSE	PEDIATRIC DOSE	COMMENTS
Atovaquone-Proguanil			
Adult tablet: 250 mg atovaquone and 100 mg proguanil.	4 adult tablets, orally as a single daily dose for 3 consecutive days	Daily dose to be taken for 3 consecutive days:	Contraindicated in people with severe renal impairment (creatinine clearance < 30 mL/min).
Pediatric tablet: 62.5 mg atovaquone and 25 mg proguanil.		5–8 kg: 2 pediatric tabs 9–10 kg: 3 pediatric tablets 11–20 kg: 1 adult tablet 21–30 kg: 2 adult tablets 31–40 kg: 3 adult tablets >41 kg: 4 adult tablets	Not recommended for people on atovaquone-proguanil prophylaxis. Not recommended for children weighing <5 kg, pregnant women, and women breastfeeding infants weighing < 5 kg.
DRUG	DOSE		COMMENTS
Artemether-Lumefantrine			
A tablet contains 20 mg artemether and 120 mg lumefantrine.	A 3-day treatment schedule with a total of 6 oral doses is recommended for both adult and pediatric patients <i>based on weight</i> . The patient should receive the initial dose, followed by the second dose 8 h later, then 1 dose twice daily for the following 2 days. 5 to < 15 kg: 1 tablet per dose 15 to < 25 kg: 2 tablets per dose 25 to < 35 kg: 3 tablets per dose ≥35 kg: 4 tablets per dose		Not for people on mefloquine prophylaxis. Not recommended for children weighing < 5 kg, pregnant women, and women breastfeeding infants weighing < 5 kg.

^aIf used for presumptive self-treatment, medical care should be sought as soon as possible.

Source: Modified from www.cdc.gov/travel; accessed May 26, 2016.

valuable for the parenteral treatment of severe illness owing to drug-resistant strains of *P. falciparum*. Because of its toxicity and short $t_{1/2}$, quinine is generally not used for chemoprophylaxis. The antimalarial mechanism of quinine is presumably similar to that of chloroquine. The basis of *P. falciparum* resistance to quinine is complex. Patterns of *P. falciparum* resistance to quinine correlate in some strains with resistance to chloroquine yet in others correlate more closely with resistance to mefloquine and halofantrine. A number of transporter genes may confer resistance to quinine.

Action on Skeletal Muscle. Quinine not only increases the tension response to a single maximal stimulus delivered to muscle directly or through nerves, but also increases the refractory period of muscle so that the response to tetanic stimulation is diminished. The excitability of the motor end-plate region decreases so that responses to repetitive nerve stimulation and to acetylcholine are reduced. Quinine can antagonize the actions of physostigmine on skeletal muscle. Quinine may also produce alarming respiratory distress and dysphagia in patients with myasthenia gravis.

ADME. Quinine is readily absorbed when given orally or intramuscularly. Oral absorption occurs mainly from the upper small intestine and is more than 80% complete, even in patients with marked diarrhea. After an oral dose, plasma levels reach a maximum in 3–8 h and, after distributing into an apparent volume of about 1.5 L/kg, decline with a $t_{1/2}$ of about 11 h. The pharmacokinetics of quinine may change with severe malarial infection: The apparent volume of distribution and the systemic clearance of quinine decrease, such that the average elimination $t_{1/2}$ increases to 18 h. The high levels of plasma α_1 -acid glycoprotein produced in severe malaria may prevent toxicity by binding quinine and thereby reducing the free fraction of drug. Concentrations of quinine are lower in erythrocytes (33%–40%) and CSF (2%–5%) than in plasma, and the drug readily reaches fetal tissues. The cinchona alkaloids are metabolized extensively, especially by hepatic CYP3A4; thus, only about

20% of an administered dose is excreted in an unaltered form in the urine. The major metabolite of quinine, 3-hydroxyquinine, retains some antimalarial activity and can accumulate and possibly cause toxicity in patients with renal failure. Renal excretion of quinine itself is more rapid when the urine is acidic.

Therapeutic Uses. Quinine and quinidine have long been treatments of choice for drug-resistant and severe *P. falciparum* malaria. However, the advent of oral and intravenous artemisinin therapy has changed this situation. Standard of care for severe illness, and only until artemisinin therapy can be started, is the prompt use of loading doses of intravenous quinine (or quinidine, where intravenous quinine is not available) can be lifesaving. Oral medication to maintain therapeutic concentrations is then given as soon as tolerated and is continued for 5–7 days. Especially for treatment of infections with multidrug-resistant strains of *P. falciparum*, slower-acting blood schizonticides such as tetracyclines or clindamycin are given concurrently to enhance quinine efficacy. Formulations of quinine and quinidine and specific regimens for their use in the treatment of *P. falciparum* malaria are shown in the Drug Facts table.

The therapeutic range for “free” quinine is 0.2 and 2.0 mg/L. Regimens needed to achieve this target vary based on patient age, severity of illness, and the responsiveness of *P. falciparum* to the drug. Dosage regimens for quinidine are similar to those for quinine, although quinidine binds less to plasma proteins and has a larger apparent volume of distribution, greater systemic clearance, and shorter terminal elimination $t_{1/2}$ than quinine. The CDC recommends a dose of quinidine of 10 mg salt/kg initially, followed by 0.02 mg salt/kg/min.

Nocturnal Leg Cramps. It is commonly believed that night cramps are relieved by quinine (200–300 mg) taken at bedtime. The FDA has required drug manufacturers to stop marketing over-the-counter quinine products for nocturnal leg cramps, stating that data supporting safety and efficacy of quinine for this indication were inadequate and that risks outweighed the potential benefits.

Toxicity and Side Effects. The fatal oral dose of quinine for adults is about 2–8 g. Quinine is associated with a triad of dose-related toxicities when given at full therapeutic or excessive doses: cinchonism, hypoglycemia, and hypotension. Mild forms of cinchonism (consisting of tinnitus, high-tone deafness, visual disturbances, headache, dysphoria, nausea, vomiting, and postural hypotension) occur frequently and disappear soon after the drug is withdrawn. Hypoglycemia is also common and can be life threatening if not treated promptly with intravenous glucose. Hypotension is rare and most often is associated with excessively rapid intravenous infusions of quinine or quinidine. Prolonged medication or high single doses also may produce GI, cardiovascular, and skin manifestations. GI symptoms (nausea, vomiting, abdominal pain, and diarrhea) result from the local irritant action of quinine, but the nausea and emesis also have a central basis. Cutaneous manifestations may include flushing, sweating, rash, and angioedema, especially of the face. Quinine and quinidine, even at therapeutic doses, may cause hyperinsulinemia and severe hypoglycemia through their powerful stimulatory effect on pancreatic beta cells.

Quinine rarely causes cardiac complications unless therapeutic plasma concentrations are exceeded. QTc prolongation is mild and does not appear to be affected by concurrent mefloquine treatment. Acute overdosage also may cause serious and even fatal cardiac dysrhythmias, such as sinus arrest, junctional rhythms, atrioventricular block, and ventricular tachycardia and fibrillation. Quinidine is even more cardiotoxic than quinine. Cardiac monitoring of patients on intravenous quinidine is advisable where possible.

Severe hemolysis can result from hypersensitivity to these cinchona alkaloids. Hemoglobinuria and asthma from quinine may occur more rarely. “Blackwater fever”—the triad of massive hemolysis, hemoglobinemia, and hemoglobinuria leading to anuria, renal failure, and in some instances death—is a rare hypersensitivity reaction to quinine therapy that can occur during treatment of malaria. Quinine occasionally may cause milder hemolysis, especially in people with G6PD deficiency. Thrombotic thrombocytopenic purpura also is rare but can occur even in response to ingestion of tonic water, which has about 4% the therapeutic oral dose per 12 oz (“cocktail purpura”). Other rare adverse effects include hypoprothrombinemia, leukopenia, and agranulocytosis.

Research in model systems indicated that quinine can inhibit a number of transport proteins, including Tat2p, which transports tryptophan, the precursor of 5HT. Quinine also competitively inhibits the rate-limiting step in 5HT biosynthesis, tryptophan hydroxylase (Islahudin et al., 2014; Khozoe et al., 2009). Whether these data relate to adverse effects of quinine in humans remains to be determined.

Precautions, Contraindications, and Drug Interactions. Quinine must be used with considerable caution, if at all, in patients who manifest hypersensitivity. Quinine should be discontinued immediately if evidence of hemolysis appears. This drug should be avoided in patients with tinnitus or optic neuritis. In patients with cardiac dysrhythmias, the administration of quinine requires the same precautions as for quinidine. Quinine appears to be safe in pregnancy and is used commonly for the treatment of pregnancy-associated malaria. However, glucose levels must be monitored because of the increased risk of hypoglycemia.

Quinine and quinidine are highly irritating and should not be given subcutaneously. Concentrated solutions may cause abscesses when injected intramuscularly or thrombophlebitis when infused intravenously. Antacids that contain aluminum can delay absorption of quinine from the GI tract. Quinine and quinidine can delay the absorption and elevate plasma levels of cardiac glycosides and warfarin and related anticoagulants. The action of quinine at neuromuscular junctions enhances the effect of neuromuscular blocking agents and opposes the action of acetylcholinesterase inhibitors. Prochlorperazine can amplify quinine’s cardiotoxicity, as can halofantrine. The renal clearance of quinine can be decreased by cimetidine and increased by urine acidification and by rifampin.

Mefloquine

Mefloquine emerged from the Walter Reed Malaria Research Program as safe and effective against drug-resistant strains of *P. falciparum*.

Mechanisms of Action and Resistance. Mefloquine is a highly effective blood schizonticide. Mefloquine associates with intraerythrocytic hemozoin, suggesting similarities to the mode of action of chloroquine. However, increased *pfmdr1* copy numbers are associated with both reduced parasite susceptibility to mefloquine and increased PfMDR1-mediated solute import into the digestive vacuole of intraerythrocytic parasites, suggesting that the drug’s target resides outside this vacuolar compartment. The (–)-enantiomer is associated with adverse CNS effects; the (+)-enantiomer retains antimalarial activity with fewer side effects. Mefloquine can be paired with artesunate to reduce the selection pressure for resistance. This combination has proved efficacious for the treatment of *P. falciparum* malaria, even in regions with high prevalence of mefloquine-resistant parasites.

ADME. Mefloquine is taken orally because parenteral preparations cause severe local reactions. The drug is absorbed rapidly but with marked variability. Probably owing to extensive enterogastric and enterohepatic circulation, plasma levels of mefloquine rise in a biphasic manner to their peak in about 17 h. Mefloquine has a variable and long $t_{1/2}$, 13–24 days, reflecting its high lipophilicity, extensive tissue distribution, and extensive binding (about 98%) to plasma proteins. The slow elimination of mefloquine fosters the emergence of drug-resistant parasites. Mefloquine is extensively metabolized in the liver by CYP3A4; this CYP can be inhibited by ketoconazole and induced by rifampicin. Excretion of mefloquine is mainly by the fecal route; about 10% of mefloquine appears unchanged in the urine.

Therapeutic Uses. Mefloquine should be reserved for the prevention and treatment of malaria caused by drug-resistant *P. falciparum* and *P. vivax*; it is no longer considered first-line treatment of malaria. The drug is especially useful as a chemoprophylactic agent for travelers spending weeks to years in areas where these infections are endemic (see Table 53–2). In areas where malaria is due to multiply drug-resistant strains of *P. falciparum*, mefloquine is more effective when used in combination with an artemisinin compound.

Toxicity and Side Effects. At chemoprophylactic dosages, while oral mefloquine is generally well tolerated, the U.S. FDA has added a “black box” warning to mefloquine labeling, noting the drug’s potential to cause severe, possibly permanent, neurological and psychiatric adverse effects. Vivid dreams are common; significant neuropsychiatric signs and symptoms can occur in 10% or more of people receiving treatment doses; serious adverse events (psychosis, seizures) are rare. Short-term adverse effects of treatment include nausea, vomiting, and dizziness. Dividing the dose improves tolerance. The full dose should be repeated if vomiting occurs within the first hour. After treatment of malaria with mefloquine, CNS toxicity can be as high as 0.5%; symptoms include seizures, confusion or decreased sensorium, acute psychosis, and disabling vertigo. Such symptoms are reversible on drug discontinuation. Mild-to-moderate toxicities (e.g., disturbed sleep, dysphoria, headache, GI disturbances, and dizziness) occur even at prophylactic dosages. Adverse effects usually manifest after the first to third doses and often abate even with continued treatment. Cardiac abnormalities, hemolysis, and agranulocytosis are rare.

Contraindications and Drug Interactions. At very high doses, mefloquine is teratogenic in rodents. Studies have suggested an increased rate of stillbirths with mefloquine use, especially during the first trimester. Pregnancy should be avoided for 3 months after mefloquine use because of the prolonged $t_{1/2}$ of this agent. This drug is contraindicated for patients with a history of seizures, depression, bipolar disorder and other severe neuropsychiatric conditions, or adverse reactions to quinoline antimalarials. Although this drug can be taken safely 12 h after a last dose of quinine, taking quinine shortly after mefloquine can be hazardous because the latter is eliminated so slowly. Treatment with or after halofantrine or within 2 months of prior mefloquine administration is contraindicated. Controlled studies suggest that mefloquine does not impair performance in persons who tolerate the drug; nonetheless, some advise against the use of mefloquine for patients in occupations that require focused concentration, dexterity, and cognitive function.

Primaquine

Primaquine, in contrast to other antimalarials, acts on exoerythrocytic tissue stages of *Plasmodium* spp. in the liver to prevent and cure relapsing malaria. Patients should be screened for G6PD deficiency prior to therapy with this drug.

Antimalarial Action and Parasite Resistance. The mechanism of action of the 8-aminoquinolines has not been elucidated. Primaquine acts against primary and latent hepatic stages of *Plasmodium* spp. and prevents relapses in *P. vivax* and *P. ovale* infections. This drug and other 8-aminoquinolines also display gametocytocidal activity against *P. falciparum* and other *Plasmodium* species. However, primaquine is inactive against asexual blood-stage parasites.

ADME. Absorption of primaquine from the GI tract approaches 100%. Peak plasma concentration occurs within 3 h and then falls with a variable $t_{1/2}$ averaging 7 h. Primaquine is metabolized rapidly; only a small fraction of a dose is excreted as the parent drug. Importantly, primaquine induces CYP1A2. The major metabolite, carboxyprimaquine, is inactive.

Therapeutic Uses. Primaquine is used primarily for terminal chemoprophylaxis and radical cure of *P. vivax* and *P. ovale* (relapsing) infections because of its high activity against the latent tissue forms (hypnozoites) of these *Plasmodium* species. The compound is given together with a blood schizonticide, usually chloroquine, to eradicate erythrocytic stages of these plasmodia and reduce the possibility of emerging drug resistance. For terminal chemoprophylaxis, primaquine regimens should be initiated shortly before or immediately after a subject leaves an endemic area (see Table 53–2). Radical cure of *P. vivax* or *P. ovale* malaria can be achieved if the drug is given either during an asymptomatic latent period of presumed infection or during an acute attack. Simultaneous administration of a schizonticidal drug plus primaquine is more effective than sequential treatment in promoting a radical cure. Limited studies demonstrated efficacy in prevention of *P. falciparum* and *P. vivax* malaria when primaquine was taken as chemoprophylaxis. Primaquine is generally well tolerated when taken for up to 1 year.

Toxicity and Side Effects. Primaquine has few side effects when given in the usual therapeutic doses. Primaquine can cause mild-to-moderate abdominal distress in some individuals. Taking the drug at mealtime often alleviates these symptoms. Mild anemia, cyanosis (methemoglobinemia), and leukocytosis are less common. High doses (60–240 mg daily) worsen the abdominal symptoms. Methemoglobinemia can occur even with usual doses of primaquine and can be severe in individuals with congenital deficiency of NADH methemoglobin reductase (NADH-cytochrome b5 reductase [diaphorase 1]). Chloroquine and dapsone may synergize with primaquine to produce methemoglobinemia in these patients. Granulocytopenia and agranulocytosis are rare complications of therapy and usually are associated with overdosage. Other rare adverse reactions are hypertension, arrhythmias, and symptoms referable to the CNS.

Therapeutic or higher doses of primaquine may cause acute hemolysis and hemolytic anemia in humans with G6PD deficiency. Primaquine is the prototype of more than 50 drugs, including antimalarial tafenoquine and sulfonamides, that causes hemolysis in G6PD-deficient individuals.

Precautions and Contraindications. G6PD deficiency should be ruled out prior to administration of primaquine. Primaquine has been used cautiously in subjects with the A form of G6PD deficiency, although benefits of treatment may not necessarily outweigh the risks but should not be used in patients with more severe deficiency. If a daily dose of more than 30 mg primaquine base (>15 mg in potentially sensitive patients) is given, then

blood counts should be followed carefully. Patients should be counseled to look for dark or blood-colored urine, which would indicate hemolysis. Primaquine should not be given to pregnant women; in treating lactating mothers, primaquine should be prescribed only after ascertaining that the breastfeeding infant has a normal G6PD level. Primaquine is contraindicated for acutely ill patients suffering from systemic disease characterized by a tendency to granulocytopenia (e.g., active forms of rheumatoid arthritis and lupus erythematosus). Primaquine should not be given to patients receiving drugs capable of causing hemolysis or depressing the myeloid elements of the bone marrow.

Tafenoquine

As a derivative of primaquine, tafenoquine presumably has the same mechanism of action as primaquine; its reported toxicities and side effects are the same, particularly with relation to G6PD deficiency. Absorption after dosing is nearly complete but delayed over about 12 h in healthy volunteers (Charles et al., 2007). The main differences between primaquine and tafenoquine relate to ADME. There are no reported detectable QTc effects with tafenoquine. This agent has not been tested in pregnant women or children.

ADME. After oral administration (no parenteral formulation is available) tafenoquine is slowly absorbed, with maximum plasma concentrations occurring about 12 h after dosing in fasting healthy subjects; absorption and elimination are first order (Brueckner et al., 1998). The elimination $t_{1/2}$ of tafenoquine is about 14 days (Brueckner et al., 1998; Charles et al., 2007). The drug has a large volume of distribution and low clearance. In vivo metabolism of the parent drug and resultant metabolites is not well understood. Mild GI side effects include heartburn, gas, vomiting, and diarrhea. Methemoglobinemia, hemolytic anemia, thrombocytopenia, or changes in white blood cell counts or electrocardiograms are not observed in healthy fasting subjects without G6PD deficiency (Brueckner et al., 1998; Charles et al., 2007).

Therapeutic Uses, Toxicity, Side Effects, Precautions, and Contraindications. These are largely considered to be those of primaquine, but potentially exacerbated because of the long elimination half-life.

Sulfonamides and Sulfones

The sulfonamides and sulfones are slow-acting blood schizonticides and are more active against *P. falciparum* than *P. vivax*.

Mechanism of Action

Sulfonamides are *p*-aminobenzoic acid analogues that competitively inhibit *Plasmodium* dihydropteroate synthase. These agents are combined with an inhibitor of parasite dihydrofolate reductase to enhance their antimalarial action. See Figure 56–2 and neighboring text for details of these agents.

Drug Resistance

Sulfadoxine resistance is conferred by several point mutations in the dihydropteroate synthase gene. These sulfadoxine resistance mutations, when combined with mutations of dihydrofolate reductase and conferring pyrimethamine resistance, greatly increase the likelihood of sulfadoxine-pyrimethamine treatment failure. Sulfadoxine-pyrimethamine, given intermittently during the second and third trimesters of pregnancy, is a routine component of antenatal care throughout Africa. Intermittent preventive treatment strategies may also benefit infants. Generally, one can anticipate that, in the absence of novel antifolates effective against existing drug-resistant strains, the use of these antimalarials for either prevention or treatment will continue to decline.

Tetracyclines and Clindamycin

Tetracycline and doxycycline are useful in malaria treatment, as is clindamycin. These agents are slow-acting blood schizonticides that can be used alone for short-term chemoprophylaxis in areas with chloroquine- and mefloquine-resistant malaria (only doxycycline is recommended for malaria chemoprophylaxis).

These antibiotics act via a delayed-death mechanism resulting from their inhibition of protein translation in the parasite apicoplast

(an organelle evolutionarily derived from plant chloroplasts). This effect on malarial parasites manifests as death of the progeny of drug-treated parasites, resulting in slow onset of antimalarial activity. Their relatively slow mode of action makes these drugs ineffective as single agents for malaria treatment. Dosage regimens for tetracyclines and clindamycin are listed in the Drug Facts table. Because of their adverse effects on bones and teeth, tetracyclines should not be given to pregnant women or to children younger than 8 years. For details of these agents, see Chapter 59.

Principles and Guidelines for Chemoprophylaxis and Chemotherapy of Malaria

Pharmacological prevention of malaria poses a difficult challenge because *P. falciparum*, which causes nearly all the deaths from human malaria, has become progressively more resistant to available antimalarial drugs. Oral artemether-lumefantrine is likely appropriate as first-line antimalarial treatment of uncomplicated malaria. Chloroquine remains effective against malaria caused by *P. ovale*, *P. malariae*, *P. knowlesi*, most strains of *P. vivax*, and chloroquine-sensitive strains of *P. falciparum* found in some geographic areas. However, chloroquine-resistant strains of *P. falciparum* are now the rule, not the exception, in most malaria-endemic regions (see Figure 53-1). Extensive geographic overlap also exists between chloroquine resistance and resistance to pyrimethamine-sulfadoxine. Multidrug-resistant *P. falciparum* malaria is especially prevalent and severe in Southeast Asia and Oceania. These infections may not respond adequately even to mefloquine or quinine. The following section presents an overview of the chemoprophylaxis and chemotherapy of malaria. Current CDC recommendations for drugs and dosing regimens for the chemoprophylaxis and treatment of malaria in nonimmune individuals are shown in Tables 53-2 and 53-3.

Drugs should not replace simple, inexpensive measures for malaria prevention. Individuals visiting malarious areas should take appropriate steps to prevent mosquito bites. One such measure is to avoid exposure to mosquitoes at dusk and dawn, usually the times of maximal feeding. Others include using insect repellents containing at least 30% DEET and sleeping in well-screened rooms or under bed nets impregnated with a pyrethrin insecticide such as permethrin.

Malaria Chemoprophylaxis

Regimens for malaria chemoprophylaxis include primarily three drugs: *atovaquone-proguanil* and *doxycycline*, which can both be used in all areas; and *mefloquine*, which can be used in areas with mefloquine-sensitive malaria. Other available options are chloroquine or hydroxychloroquine (but their use is restricted to the few areas with chloroquine-sensitive malaria) and primaquine (for short-duration travel to areas with principally *P. vivax*). In general, dosing should be started before exposure, ideally before the traveler leaves home (see Table 53-2).

In those few areas where chloroquine-sensitive strains of *P. falciparum* are found, chloroquine is still suitable for chemoprophylaxis. In areas where chloroquine-resistant malaria is endemic, mefloquine and atovaquone-proguanil are the regimens of choice for chemoprophylaxis. For chemoprophylaxis in long-term travelers, chloroquine is safe at the doses used, but some recommend yearly retinal examinations, and there is a finite dose limit for which chemoprophylaxis with chloroquine is recommended because of ocular toxicity. Mefloquine and doxycycline are well tolerated. Mefloquine is the best-documented drug for malaria prophylaxis in long-term travelers and, if well tolerated, can be used for prolonged periods. Atovaquone-proguanil has been studied for prophylactic use up to 20 weeks but probably is acceptable for years based on experience with the individual components.

Self-Treatment of Presumptive Malaria for Travelers

The CDC provides travelers' guidelines for self-treatment of presumptive malaria with appropriate drugs (atovaquone-proguanil, artemether-lumefantrine; as described in Table 53-3) when professional care is not available within 24 h. In such cases, medical care should be sought immediately after treatment. These recommendations may change over

time and with specific locations. Consult the CDC Yellow Book (<https://wwwnc.cdc.gov/travel/page/yellowbook-home-2014>).

Diagnosis and Treatment of Malaria

The diagnosis of malaria must be considered for patients presenting with acute febrile illness after returning from a malaria-endemic region. An organized, rational approach to diagnosis, parasite identification, and appropriate treatment is crucial. Guidelines for treatment of malaria in the U.S. are provided by the CDC and are shown Figure 53-3, with details of the available agents summarized in Table 53-3. More information is available online (<http://www.cdc.gov/malaria/resources/pdf/treatmenttable.pdf>) and from the CDC Malaria Hotline (770-488-7788 and 770-488-7100).

Children and pregnant women are the most susceptible to severe malaria. The treatment of children generally is the same as for adults (pediatric dose should never exceed adult dose) (see the Drug Facts table). However, tetracyclines should not be given to children less than 8 years of age except in an emergency, and atovaquone-proguanil as treatment has been approved only for children weighing more than 5 kg.

Chemoprophylaxis and Treatment During Pregnancy

Chemoprophylaxis during pregnancy is complex, and women should evaluate with expert medical staff the benefits and risks of different strategies with regard to their particular situations. Severe malaria during pregnancy should be treated with intravenous antimalarial treatment according to the general guidelines for severe malaria, taking into account the drugs that should be avoided during pregnancy. In lactating mothers, treatment with most compounds is acceptable, although chloroquine and hydroxychloroquine are the preferred agents. The use of atovaquone-proguanil is not recommended unless breastfeeding infants weigh more than 5 kg. Also, the breastfeeding infant should be shown to have a normal G6PD level before receiving primaquine.

Treating the Mosquito Rather Than the Human

Recent technological developments seem likely to revolutionize mosquito control and mosquito susceptibility to malarial parasites. Isaacs et al. (2011) engineered resistance to infection by *P. falciparum* in mosquitoes by having the mosquitoes express single-chain antibodies that targeted antigens on the parasite's surface and inhibited the parasite's capacity to invade the midgut and salivary glands of the mosquito, effects that would reduce or eliminate the capacity of the mosquito to infect humans in the course of a blood meal.

The development of gene editing using CRISPR/cas9 (see Chapter 3) has opened up a new avenue for high-efficiency expression of resistance genes for treating the spread and prevalence of malaria. Gantz and Bier (2015) have described a "mutagenic chain reaction" based on CRISPR/cas9 that can spread a mutation from one chromosome to its homologous chromosome, converting heterozygous mutations to homozygosity in most germline and somatic cells in *Drosophila*. This gene drive system works in mosquitoes as well (Gantz et al., 2015), introducing antiplasmodium effector genes into the germline and thence into the progeny with very high frequency. Other CRISPR/cas9 endonuclease constructs have driven genes in the malarial vector *Anopheles gambiae*, targeting female reproduction and holding the promise of reducing the mosquito population in malarious areas to levels that will not support transmission of the disease (Hammond et al., 2016).

It seems likely that this gene editing-gene drive technology will be applicable to other vector-borne diseases. As Hammond et al. (2016) noted, "The success of gene drive technology for vector control will depend on the choice of suitable promoters to effectively drive homing during ... gametogenesis, the phenotype of the disrupted genes, the robustness of the nuclease during homing and the ability of the target population to generate compensatory mutations". CRISPR/cas9 gene drives have not yet been released into the wild. Indeed, the use of these techniques in the field must be approached with caution and must await a full understanding of the ecological consequences and the ethical and regulatory issues.

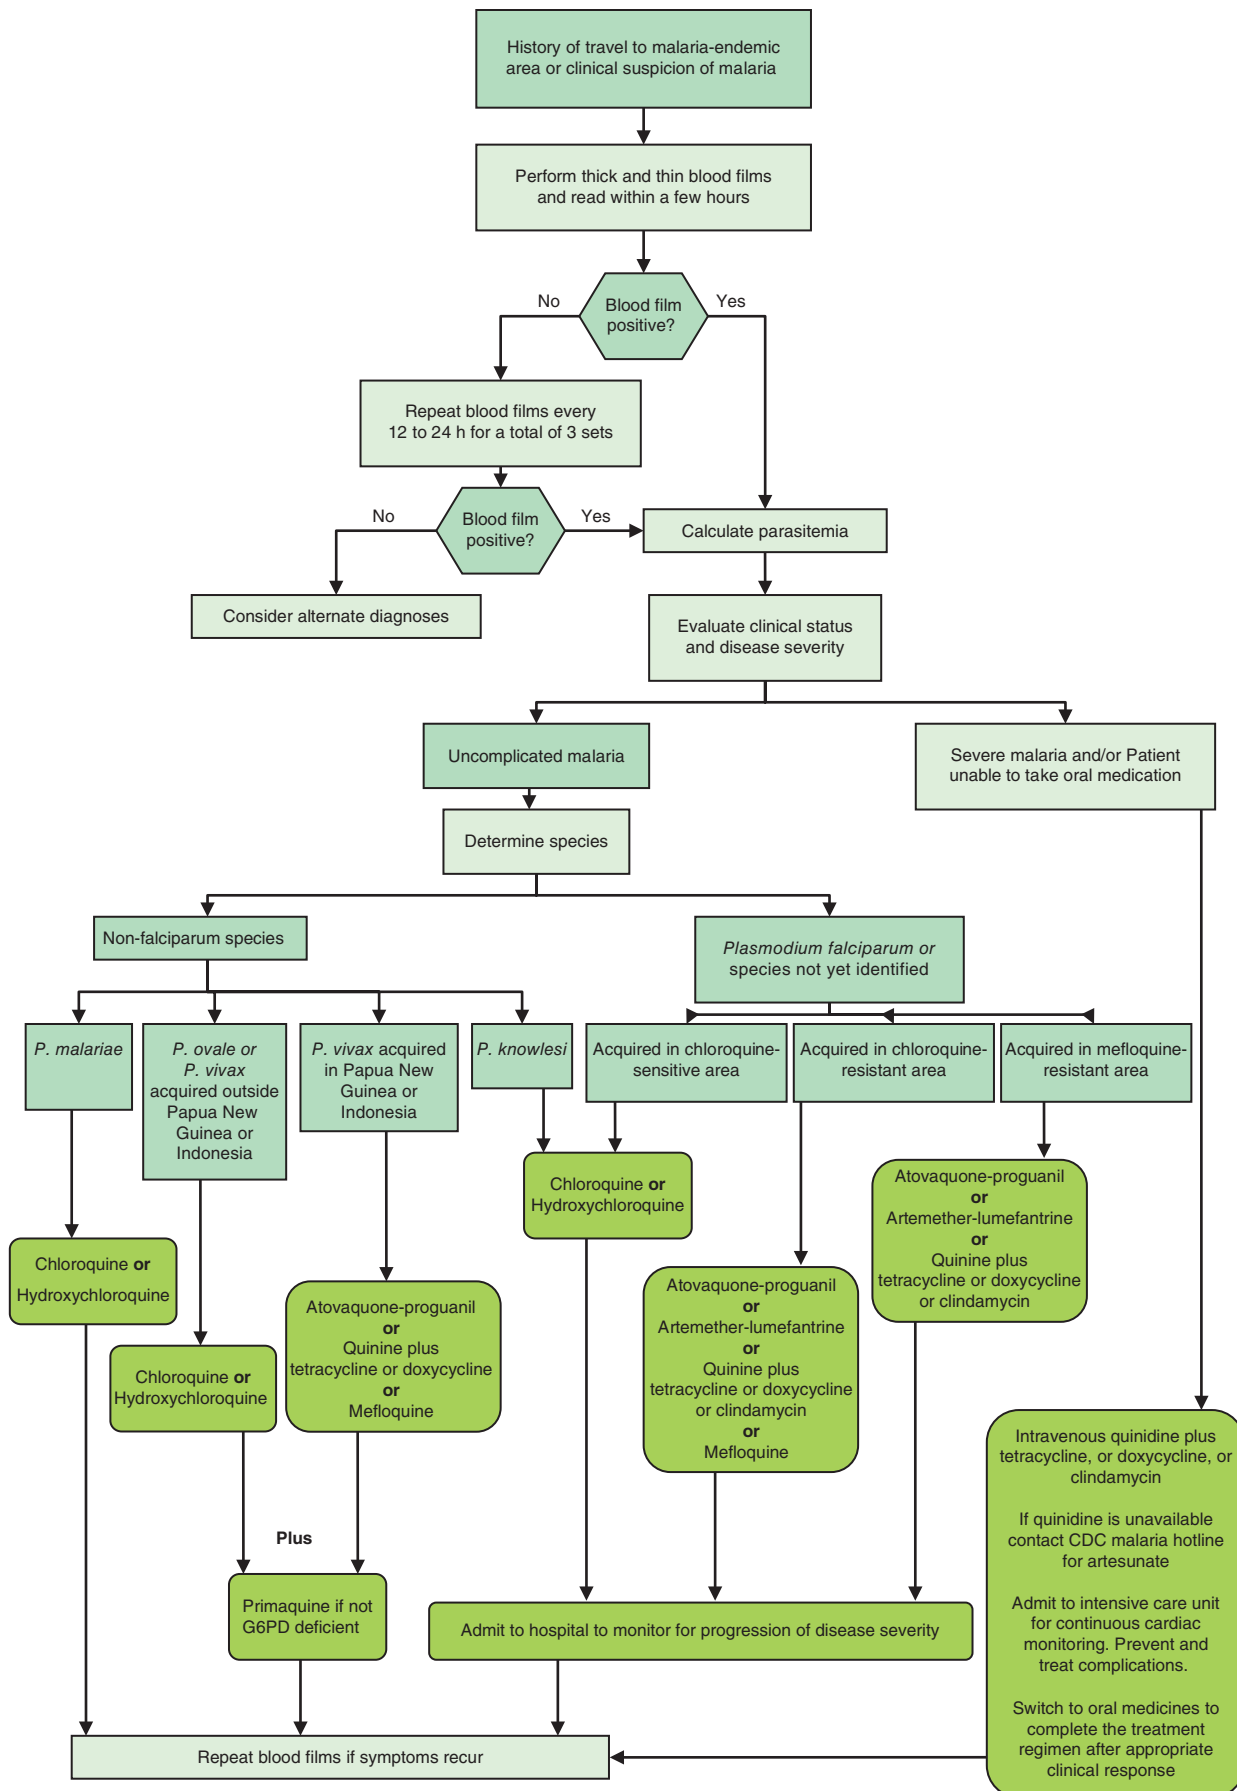

Figure 53–3 Decision algorithm for the treatment of malaria. Atovaquone-proguanil, mefloquine, artemether-lumefantrine, tetracycline, and doxycycline are not indicated during pregnancy (pregnancy category C). Tetracycline and doxycycline are not indicated in children younger than 8 years. (Modified from Centers for Disease Control and Prevention. Malaria. n.d. <http://www.cdc.gov/malaria/resources/pdf/algorithm.pdf>. Accessed May 24, 2016.)

Drug Facts for Your Personal Formulary: *Regimens for Malaria Treatment*

Drug Indication	Adult Dosage	Pediatric Dosage ^a	Potential Adverse Effects	Comments
Artemether-lumefantrine <i>P. falciparum</i> from chloroquine-resistant or unknown areas	Tablet: 20 mg artemether, lumefantrine. Dose: 4 tablets. Day 1: 2 doses separated by 8 h; thereafter twice daily × 2 days	Wgt (kg) Tablets/dose 5–15 1 15–25 2 25–<35 3 >35 4 Use same 3-day schedule as adults	Adults: headache, anorexia, dizziness, asthenia, arthralgia, myalgia Children: fever, cough, vomiting, loss of appetite, headache	Take with food or whole milk. If patient vomits within 30 min, repeat dose. Contraindicated in pregnancy.
Artesunate (IV; available from CDC) Severe malaria; see CDC guidelines.	U.S. treatment IND (CDC): 4 equal doses of artesunate (2.4 mg/kg each) over a 3-day period followed by oral treatment with atovaquone-proguanil, doxycycline, clindamycin, or mefloquine (to avoid emergence of resistance)		See Artemether	See Artemether CDC guidelines
Atovaquone-proguanil <i>P. falciparum</i> from chloroquine-resistant areas <i>P. vivax</i>	Adult tablet 250 mg atovaquone/100 mg proguanil 4 Adult tablets orally per day × 3 days	Pediatric tablet = 62.5 mg atovaquone/25 mg proguanil 5–8 kg: 2 ped tab orally/d × 3 d >8–10 kg: 3 ped tab daily × 3 d >10–20 kg: 1 adult tab daily × 3 d >20–30 kg: 2 adult tab daily × 3 d >30–40 kg: 3 adult tab daily × 3 d >40 kg: 4 adult tab daily × 3 d	Abdominal pain, nausea, vomiting, diarrhea, headache, rash, mild reversible elevations in liver aminotransferase levels	Not indicated for use in pregnant women due to limited data. Contraindicated if hypersensitivity to atovaquone or proguanil; severe renal impairment (creatinine clearance < 30 mL/min). Should be taken with food to increase absorption of atovaquone.
Chloroquine phosphate <i>P. falciparum</i> from chloroquine-sensitive areas <i>P. vivax</i> from chloroquine-sensitive areas All <i>P. ovale</i> All <i>P. malariae</i> All <i>P. knowlesi</i>	600 mg base (1000 mg salt) orally immediately, followed by 300 mg base (500 mg salt) orally at 6, 24, and 48 h Total dose: 1500 mg base (2500 mg salt)	10 mg base/kg orally immediately, followed by 5 mg base/kg orally at 6, 24, and 48 h Total dose: 25 mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus	Safe in children and pregnant women. Give for chemoprophylaxis (500 mg salt orally every week) in pregnant women with chloroquine-sensitive <i>P. vivax</i> . Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines. Use with caution in those with impaired liver function since the drug is concentrated in the liver.
Clindamycin (oral or IV) <i>P. falciparum</i> from chloroquine-resistant areas <i>P. vivax</i> from chloroquine-resistant areas	Oral: 20 mg base/kg/d orally divided 3 times daily × 7 d IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (as above) as soon as patient can take oral meds; duration = 7 d	Oral: 20 mg base/kg/d orally divided 3 times daily × 7 d IV: 10 mg base/kg loading dose IV followed by 5 mg base/kg IV every 8 h; switch to oral clindamycin (oral dose as above) as soon as patient can take oral medication; treatment course = 7 d	Diarrhea, nausea, rash	Always use in combination with quinine-quinidine. Safe in children and pregnant women.
Doxycycline (oral or IV) <i>P. falciparum</i> and <i>P. vivax</i> from chloroquine-resistant areas	Oral: 100 mg orally twice daily × 7 d. IV: 100 mg IV every 12 h and then switch to oral doxycycline (as above) as soon as patient can take oral medication; treatment course = 7 d.	Oral: 2.2 mg/kg orally every 12 h × 7 d. IV: Only if patient is not able to take oral medication; for children < 45 kg, give 2.2 mg/kg IV every 12 h and then switch to oral doxycycline (dose as above) as soon as patient can take oral medication; for children > 45 kg, use same dosing as for adults; duration = 7 d.	Nausea, vomiting, diarrhea, abdominal pain, dizziness, photosensitivity, headache, esophagitis, odynophagia. Rarely hepatotoxicity, pancreatitis, and benign intracranial hypertension seen with tetracycline class of drugs.	Always use in combination with quinine or quinidine. Contraindicated in children < 8 y, pregnant women, and persons with known hypersensitivity to tetracyclines. Food, milk, and Ca ²⁺ antacids decrease absorption and decrease GI disturbances. To prevent esophagitis, take tetracyclines with large amounts of fluids (patients should not lie down for 1 h after taking the drugs). Barbiturates, carbamazepine, or phenytoin may cause reduction in C _p of doxycycline.

Drug Facts for Your Personal Formulary: Regimens for Malaria Treatment (continued)

Drug Indication	Adult Dosage	Pediatric Dosage ^a	Potential Adverse Effects	Comments
Hydroxychloroquine (oral) Secondary alternative for treatment of <i>P. falciparum</i> and <i>P. vivax</i> from chloroquine-sensitive areas All <i>P. ovale</i> All <i>P. malariae</i>	620 mg base (= 800 mg salt) orally immediately, followed by 310 mg base (= 400 mg salt) orally at 6, 24, and 48 h Total dose: 1550 mg base (= 2000 mg salt)	10 mg base/kg orally immediately, followed by 5 mg base/kg orally at 6, 24, and 48 h Total dose: 25 mg base/kg	Nausea, vomiting, rash, headache, dizziness, urticaria, abdominal pain, pruritus ^b	Safe in children and pregnant women. Contraindicated if retinal or visual field change; hypersensitivity to 4-aminoquinolines. Use with caution in those with impaired liver function.
Mefloquine^c <i>P. falciparum</i> from chloroquine-resistant areas, except Thailand-Burmese and Thailand-Cambodian border regions <i>P. vivax</i> from chloroquine-resistant areas	684 mg base (= 750 mg salt) orally as initial dose, followed by 456 mg base (= 500 mg salt) orally given 6–12 h after initial dose Total dose = 1250 mg salt	13.7 mg base/kg (= 15 mg salt/kg) orally as initial dose, followed by 9.1 mg base/kg (= 10 mg salt/kg) orally given 6–12 h after initial dose Total dose = 25 mg salt/kg	Nausea, vomiting, diarrhea, abdominal pain; dizziness, headache, somnolence, sleep disorders; myalgia, mild skin rash, and fatigue; moderate-to-severe neuropsychiatric reactions; ECG changes (sinus arrhythmia, sinus bradycardia, 1° AV block, QTc prolongation, and abnormal T waves.	Contraindicated if hypersensitive to the drug or to related compounds; cardiac conduction abnormalities; psychiatric disorders; and seizure disorders. Do not administer if patient has received related drugs (chloroquine, quinine, quinidine) less than 12 h ago
Primaquine phosphate Radical cure of <i>P. vivax</i> and <i>P. ovale</i> (to eliminate hypnozoites)	30 mg base orally per day × 14 d	0.5 mg base/kg orally per day × 14 d	GI disturbances, methemoglobinemia (self-limited), hemolysis in persons with G6PD deficiency	Must screen for G6PD deficiency prior to use. Contraindicated in persons with G6PD deficiency; pregnant women. Should be taken with food to minimize GI adverse effects.
Quinine sulfate (oral) <i>P. falciparum</i> from chloroquine-resistant areas <i>P. vivax</i> from chloroquine-resistant areas	542 mg base (650 mg salt) ^d orally 3 times daily × 3 d (infections acquired outside Southeast Asia) to 7 d (infections acquired in Southeast Asia)	8.3 mg base/kg (10 mg salt/kg) orally 3 times daily × 3 d (infections acquired outside Southeast Asia) to 7 d (infections acquired in Southeast Asia)	Cinchonism, ^e sinus arrhythmia, junctional rhythms, atrioventricular block, prolonged QT interval, ventricular tachycardia, ventricular fibrillation (these are rare and more commonly seen with quinidine), hypoglycemia	Combine with tetracycline, doxycycline, or clindamycin, except for <i>P. vivax</i> infections in children < 8 y or pregnant women. Contraindicated in hypersensitivity, including history of blackwater fever, thrombocytopenic purpura, or thrombocytopenia associated with quinine or quinidine use; many cardiac conduction defects and arrhythmias ^f ; myasthenia gravis; optic neuritis.
Quinidine gluconate (intravenous) Severe malaria (all species, independently of chloroquine resistance) Patient unable to take oral medication Parasitemia > 10%	6.25 mg base/kg (= 10 mg salt/kg) loading dose IV over 1–2 h, then 0.0125 mg base/kg/min (0.02 mg salt/kg/min) continuous infusion for at least 24 h Note alternative regimen ^g	Same as adult	Cinchonism, tachycardia, prolongation of QRS and QTc intervals, flattening of T wave (effects are often transient). Ventricular arrhythmias, hypotension, hypoglycemia	Combine with tetracycline, doxycycline, or clindamycin. Contraindicated in hypersensitivity; history of blackwater fever including history of blackwater fever, thrombocytopenic purpura or thrombocytopenia associated with quinine or quinidine use; many cardiac conduction defects and arrhythmias ^h ; myasthenia gravis; optic neuritis.

Drug Facts for Your Personal Formulary: Regimens for Malaria Treatment (continued)

Drug Indication	Adult Dosage	Pediatric Dosage ^a	Potential Adverse Effects	Comments
Tetracycline (oral or IV) <i>P. falciparum</i> and <i>P. vivax</i> from chloroquine-resistant areas (with quinine/ quinidine)	Oral: 250 mg 4 times daily × 7 d IV: dosage same as for oral	25 mg/kg/d orally, divided, 4x daily × 7 d IV: dosage same as for oral	See doxycycline	See doxycycline.

These regimens are based on published recommendations of the U.S. CDC. Although current at the time of writing, these recommendations may change over time. Up-to-date information should be obtained from the CDC website at <https://wwwnc.cdc.gov/travel>. Recommendations and available treatment differ among countries in the industrialized world, developing world, and malaria-endemic regions; in the last, some antimalarial treatments may be available without prescription, but the most effective drugs usually are controlled by governmental agencies.

^aPediatric dosage should never exceed adult dosage.

^bExtrapolated from chloroquine literature.

^cMefloquine should not be used to treat *P. falciparum* infections acquired in the following areas: borders of Thailand with Burma (Myanmar) and Cambodia, western provinces of Cambodia, eastern states of Burma (Myanmar), border between Burma and China, Laos along borders of Laos and Burma (and adjacent parts of Thailand-Cambodia border), and southern Vietnam due to resistant strains.

^dQuinine sulfate capsule manufactured in the U.S. is in a 324-mg dose; therefore, 2 capsules should be sufficient for adult dosing.

^eNausea, vomiting, headache, tinnitus, deafness, dizziness, and visual disturbances.

^fRefer to quinine sulfate, package insert (Mutual Pharmaceutical Inc., Philadelphia, PA, Rev. 08, November 2009).

^gAlternative dosing hypoglycemia optic neuritis regimen for quinidine gluconate (IV): 15 mg base/kg (24 mg salt/kg) loading dose IV infused over 4 h, followed by 7.5 mg base/kg (= 12 mg salt/kg) infused over 4 h every 8 h, starting 8 h after the loading dose (see package insert); once parasite density < 1% and patient can take oral medication, complete treatment with oral quinine, dose as above. Quinidine or quinine course = 7 d in Southeast Asia (3 d in Africa or South America).

^hRefer to quinidine gluconate, package insert (Eli Lilly Co., Indianapolis, IN, February 2002).

Chapter 54

Chemotherapy of Protozoal Infections: Amebiasis, Giardiasis, Trichomoniasis, Trypanosomiasis, Leishmaniasis, and Other Protozoal Infections

Dawn M. Wetzel and Margaret A. Phillips

PROTOZOAL INFECTIONS OF HUMANS

- Amebiasis
- Giardiasis
- Trichomoniasis
- Toxoplasmosis
- Cryptosporidiosis
- Trypanosomiasis
- Leishmaniasis
- Other Protozoal Infections

ANTIPROTOZOAL DRUGS

- Amphotericin B

- Eflornithine
- 8-Hydroxyquinolines
- Melarsoprol
- Metronidazole and Tinidazole
- Miltefosine
- Nifurtimox and Benznidazole
- Nitazoxanide
- Paromomycin
- Pentamidine
- Sodium Stibogluconate
- Suramin

Humans host a wide variety of protozoal parasites that can be transmitted by insect vectors, directly from other mammalian reservoirs, or from one person to another. The immune system plays a crucial role in protecting against the pathological consequences of many protozoal infections. Thus, opportunistic infections with protozoa are prominent in infants, individuals with cancer, transplant recipients, those receiving immunosuppressive drugs or extensive antibiotic therapy, and persons with advanced HIV infection. Because effective vaccines are unavailable, chemotherapy has been the only practical way to both treat infected individuals and reduce transmission. Satisfactory agents for treating important protozoal infections such as African trypanosomiasis (sleeping sickness) and chronic Chagas disease still are lacking. Many effective antiprotozoal drugs are toxic at therapeutic doses; this problem is exacerbated by increasing drug resistance. For a list of drugs and doses used to treat these diseases see Drugs for Parasitic Infections (2013).

Protozoal Infections of Humans

Amebiasis

Amebiasis affects about 10% of the world's population, causing invasive disease in about 50 million people and death in about 100,000 of these annually (Stanley, 2003). Amebiasis is seen most commonly among individuals living in poverty, crowded conditions, and areas with poor sanitation (Petri 2014). Three morphologically identical but genetically distinct species of *Entamoeba*—*E. histolytica*, *E. dispar*, and *E. moshkovskii*—exist (Petri, 2014). In addition, *Entamoeba bangladeshi* was recently discovered in diarrheal samples and may be pathogenic (Royer et al., 2012). However, the major species that definitely requires treatment is *E. histolytica*, the third-leading cause of mortality by parasitic infection.

Humans are the only known hosts for these protozoa, which are transmitted by the fecal-oral route. Ingested *E. histolytica* cysts survive acid gastric contents and transform into *trophozoites* that reside in the large intestine (Petri, 2014). The outcome of *E. histolytica* infection is variable. Many individuals remain asymptomatic but excrete the infectious cyst form, making them a source for further infections. In other individuals,

E. histolytica trophozoites invade into the colonic mucosa with resulting colitis and bloody diarrhea (amebic dysentery). In a small proportion of patients, *E. histolytica* trophozoites invade through the colonic mucosa, reach the portal circulation, and travel to the liver, where they establish an amebic liver abscess (Haque et al., 2003). Both host and parasite factors influence the course and severity of the disease (Marie and Petri, 2014).

The cornerstone of therapy for amebiasis is metronidazole or its analogue tinidazole (Haque et al., 2003; Petri, 2014; Stanley, 2003). Because metronidazole is so well absorbed in the gut, levels may not be therapeutic in the colonic lumen. The drug is also less effective against cysts. Therefore, patients with amebic colitis or amebic liver abscess should receive a luminal agent in addition to metronidazole to eradicate any *E. histolytica* trophozoites residing within the gut lumen. Luminal agents are also used to treat asymptomatic individuals found to be infected with *E. histolytica*. The nonabsorbed aminoglycoside *paromomycin* and the 8-hydroxyquinoline compound *iodoquinol* are effective luminal agents (Haque et al., 2003). In addition, *nitazoxanide*, which is approved in the U.S. for treatment of cryptosporidiosis and giardiasis, has activity against *E. histolytica* (Adagu et al., 2002).

Giardiasis

Giardiasis, caused by the flagellated protozoan *Giardia intestinalis*, is prevalent worldwide and is the most commonly reported intestinal protozoal infection in the U.S. Infection results from ingestion of the cyst form of the parasite, which is found in fecally contaminated water or food. Cysts shed from animals or infected humans can contaminate recreational and drinking water supplies (Fletcher et al., 2012). Human-to-human transmission is common among children in day-care centers, institutionalized individuals, and male homosexuals (Escobedo, Almirall, et al., 2014). Infection with *Giardia* results in one of three syndromes:

- an asymptomatic carrier state
- acute self-limited diarrhea
- chronic diarrhea, characterized by signs of malabsorption (steatorrhea) and weight loss

Abbreviations

ADME: absorption, distribution, metabolism, excretion
CDC: Centers for Disease Control and Prevention
CNS: central nervous system
CSF: cerebrospinal fluid
DFMO: α -D,L-difluoromethylornithine
FDA: Food and Drug Administration
GI: gastrointestinal
HAART: highly active antiretroviral therapy
HIV: human immunodeficiency virus
IND: investigational new drug
NADH: reduced (hydrogenated) nicotinamide adenine dinucleotide
NECT: nifurtimox-eflornithine combination therapy
PCP: *Pneumocystis carini*
PCR: polymerase chain reaction
PFOR: pyruvate-ferredoxin oxidoreductase
PJP: *Pneumocystis jiroveci*
WHO: World Health Organization

Chemotherapy with a 5- to 7-day course of *metronidazole* usually is successful, although sometimes therapy may have to be repeated or prolonged (Escobedo, Hanevik, et al., 2014). A single dose of *tinidazole* may be superior to metronidazole. *Paromomycin* can be used to treat pregnant women to avoid any possible mutagenic effects of the other drugs (Hill and Nash, 2014). *Nitazoxanide* is also approved for the treatment of giardiasis in adults and immune-competent children less than 12 years of age (Drugs for Parasitic Infections, 2013).

Trichomoniasis

Trichomoniasis is caused by the flagellated protozoan *Trichomonas vaginalis* (Meites, 2013). This organism inhabits the human genitourinary tract, where it causes vaginitis in women and, uncommonly, urethritis in men. Trichomoniasis is the most common nonviral sexually transmitted disease. Infection with this organism is associated with an increased risk of acquiring HIV (Kissinger, 2015). Only *trophozoite* forms of *T. vaginalis* have been identified in infected secretions. Metronidazole remains the drug of choice for treating trichomoniasis (Secor et al., 2014). Tinidazole, another nitroimidazole, appears to be better tolerated than metronidazole and has been used successfully to treat metronidazole-resistant *T. vaginalis* (Schwebke, 2014).

Toxoplasmosis

Toxoplasmosis is a zoonotic infection caused by the obligate intracellular protozoan *Toxoplasma gondii*. Although cats and other feline species are the natural hosts, tissue cysts (*bradyzoites*) have been recovered from all mammalian species examined. Common routes of infection in humans are as follows:

- ingestion of undercooked meat containing tissue cysts;
- ingestion of contaminated vegetable matter containing infective oocysts;
- direct oral contact with feces of cats shedding oocysts; or
- transplacental fetal infection with *tachyzoites* from acutely infected mothers (Woodhall et al., 2014).

The acute illness is usually self-limiting, and treatment rarely is required. However, individuals who are immunocompromised, such as patients with AIDS, are at risk of developing toxoplasmic encephalitis from reactivation of tissue cysts deposited in the brain (Jones et al., 2014). Clinical manifestations of congenital toxoplasmosis vary, but chorioretinitis,

which may present decades after exposure, is the most common finding (Kieffer and Wallon, 2013).

The primary treatment of toxoplasmic encephalitis consists of the antifolates *pyrimethamine* and *sulfadiazine* along with *folinic acid* (*leucovorin*) (Woodhall et al., 2014). Therapy must be discontinued in about 40% of cases because of toxicity, primarily due to the sulfa compound (Yan et al., 2013). Pyrimethamine-clindamycin appears to have comparable efficacy to pyrimethamine-sulfadiazine for treating toxoplasmosis in immunocompromised patients, but this combination also causes substantial toxicity (Rajapakse et al., 2013). Alternative regimens combining azithromycin, clarithromycin, atovaquone, or dapsone with either trimethoprim-sulfamethoxazole or pyrimethamine are not only less toxic but also less effective (Rajapakse et al., 2013). *Spiramycin*, which concentrates in placental tissue, is used for the treatment of acute acquired toxoplasmosis in early pregnancy to prevent transmission to the fetus (Kieffer and Wallon, 2013). Spiramycin is available through the investigational new drug process at the U.S. FDA. If fetal infection occurs, the combination of pyrimethamine, sulfadiazine, and folinic acid is administered to the mother (only after the first 12–14 weeks of pregnancy) and to the newborn postnatally for 1 year (Contopoulos-Ioannidis and Montoya, 2012; Kieffer and Wallon, 2013).

Cryptosporidiosis

Cryptosporidia are coccidian protozoan parasites that cause diarrhea. *Cryptosporidium parvum* and the newly named *Cryptosporidium hominis* appear to account for almost all infections in humans (Checkley et al., 2015). Infectious oocysts in feces may be spread either by direct human-to-human contact or by contaminated water supplies. Groups at risk include travelers, children in day care, male homosexuals, animal handlers, and veterinary or healthcare personnel. After ingestion, the mature oocyte is digested, releasing *sporozoites* that invade host epithelial cells (Wilhelm and Yarovinsky, 2014). In most individuals, infection is self-limited. However, in patients with AIDS and other immunocompromised individuals, the severity of diarrhea may require hospitalization (Marcos and Gotuzzo, 2013).

Nitazoxanide has shown activity in treating cryptosporidiosis in immunocompetent children and adults (Wright, 2012). Its efficacy in children and adults with HIV/AIDS or other immunocompromising conditions is not clearly established (Cabada and White, 2010). The most effective therapy for cryptosporidiosis in immunocompromised patients is restoration of immune function (e.g., through HAART in patients with AIDS) (White, 2014).

Trypanosomiasis

African trypanosomiasis, or “sleeping sickness,” is caused by subspecies of the hemoflagellate *Trypanosoma brucei* that are transmitted by bloodsucking tsetse flies of the genus *Glossina* (Kennedy, 2013). Largely restricted to sub-Saharan Africa, the infection causes serious human illness and also threatens livestock (*nagana*), leading to protein malnutrition. In humans, the infection is fatal unless treated. Sleeping sickness is found in 36 countries in Africa, but the caseload has dropped significantly due to renewed control efforts, and fewer than 10,000 cases were reported in 2013 (WHO, 2015a).

The parasite is entirely extracellular, and early human infection is characterized by the finding of replicating parasites in the bloodstream or lymph without CNS involvement (stage 1); stage 2 disease is characterized by CNS involvement (Kennedy, 2013). Symptoms of early-stage disease include febrile illness, lymphadenopathy, splenomegaly, and occasional myocarditis that result from systemic dissemination of the parasites. There are two types of African trypanosomiasis: The East African (Rhodesian; *T. brucei rhodesiense*) variety produces a progressive and rapidly fatal form of disease marked by early involvement of the CNS and frequent terminal cardiac failure; the West African type (Gambian; *T. brucei gambiense*) causes illness characterized by later involvement of the CNS and a more long-term course that progresses to the classical symptoms of sleeping sickness over months to years. Neurological symptoms include confusion,

sensory deficits, psychiatric signs, disruption of the sleep cycle, and eventual progression into coma and death.

Standard therapy for early-stage disease is *pentamidine* for *T. brucei gambiense* and *suramin* for *T. brucei rhodesiense* (Barrett et al., 2007; Kennedy, 2013). Both compounds are given parenterally over long periods and are not effective against late-stage disease. The CNS phase was traditionally treated with melarsoprol (available from the CDC), a highly toxic agent that causes a fatal reactive encephalopathy in 2%–10% of treated patients.

Eflornithine (available from the CDC), an inhibitor of ornithine decarboxylase, a key enzyme in polyamine metabolism, is the only agent for the treatment of late-stage disease. It has efficacy against both early and late stages of human *T. brucei gambiense* infection; however, it is thought to be ineffective as monotherapy for infections of *T. brucei rhodesiense*. Notably, eflornithine has significantly fewer side effects than melarsoprol and is more effective than melarsoprol for treatment of late-stage Gambian trypanosomiasis. *NECT* (nifurtimox-eflornithine combination) allows shorter exposure to eflornithine with good efficacy and a reduction in adverse events; it has become the treatment of choice for late-stage *T. brucei gambiense* (Lutje et al., 2013; Yun et al., 2010). However, NECT is difficult to administer in a rural setting, and the lack of an alternative to melarsoprol to treat *T. brucei rhodesiense* is concerning. Two new orally available agents are currently in clinical trials, fexinidazole and SCYX-7158, which offer the potential for improved treatment of the disease if they successfully make it to registration (Eperon et al., 2014).

American trypanosomiasis, or *Chagas disease*, is a zoonotic infection caused by *Trypanosoma cruzi* (Bern et al., 2011; Chatelain, 2015; Messenger et al., 2015). The World Health Organization estimates that Chagas affects about 6–7 million worldwide. The spread of Chagas disease is primarily confined to Latin America, but due to immigration, a number of cases are now seen outside that region. Bloodsucking triatomid bugs infesting poor rural dwellings most commonly transmit this infection to young children; transplacental transmission may also occur. Within the Western Hemisphere, the United States has the seventh-highest caseload (300,000 identified cases), representing a significant public health concern because the parasite can also be transmitted by blood transfusion and organ transplantation (Bern et al., 2011; Hotez et al., 2013; Malik et al., 2015). Most cases in the U.S. arise through immigration, but the parasite and its vector are endemic in the southern half of the U.S. (Bern et al., 2011), and transmission within the U.S. can occur, as highlighted by five recent case reports from Texas (Garcia et al., 2015).

While the blood supply is now being monitored, lack of awareness of the disease can lead to nonoptimal care of those infected (Hotez et al., 2013). The clinical outcome of an infected patient can vary widely from asymptomatic to severe disease; whether genetic differences in *T. cruzi* isolates contribute to outcome is not firmly established (Kaplinski et al., 2015). The chronic form of the disease in adults is a major cause of cardiomyopathy, megaesophagus, megacolon, and death. Chagas heart disease is typically managed in accordance with American College of Cardiology/American Heart Association guidelines for treatment of heart failure, although whether doses of angiotensin-converting enzyme inhibitors and β adrenergic blockers should be adjusted downward is debated (Botoni et al., 2013; Malik et al., 2015; Ribeiro et al., 2012). Atypical clinical presentations and higher morbidity have been observed in immunosuppressed or compromised patients.

Two nitroheterocyclic drugs, *nifurtimox* and *benznidazole* (both available from the CDC), are used to treat this infection, although neither is approved by the U.S. FDA. Both agents suppress parasitemia and can cure the acute phase of Chagas disease. Treatment of intermediate- and late-stage disease is likely also beneficial, although the usefulness of treating at these stages is still debated. Both nifurtimox and benznidazole are toxic and must be taken for long periods. Increased awareness among physicians, better drugs, and better diagnostic methods are badly needed to help combat this disease.

Leishmaniasis

Leishmaniasis is a complex vector-borne zoonosis caused by about 20 different species of intramacrophage protozoa of the genus *Leishmania*. Small mammals and canines generally serve as reservoirs for these pathogens,

which can be transmitted to humans by the bites of female phlebotomine sandflies (WHO, 2015b).

Various forms of leishmaniasis affect people in southern Europe and many tropical and subtropical regions throughout the world. Flagellated extracellular free *promastigotes*, regurgitated by feeding flies, enter the host, where they attach to and become phagocytized by tissue macrophages. These transform into *amastigotes*, which reside and multiply within phagolysosomes until the cell bursts. Released amastigotes then propagate the infection by invading more macrophages. Amastigotes taken up by feeding sandflies transform back into promastigotes, thereby completing the transformation cycle. The particular localized or systemic disease syndrome caused by *Leishmania* depends on the species or subspecies of infecting parasite, the distribution of infected macrophages, and especially the host's immune response.

In increasing order of systemic involvement and clinical severity, major syndromes of human leishmaniasis are classified into *cutaneous*, *mucocutaneous*, *diffuse cutaneous*, and *visceral (kala azar)* forms (WHO, 2015b). The disease syndrome manifested depends on the species of infecting parasite, the distribution of infected macrophages, and the host immune response (Podinovskaia and Descoteaux, 2015). As such, leishmaniasis is increasingly recognized as an AIDS-associated opportunistic infection (van Griensven et al., 2014). Cutaneous forms of leishmaniasis generally are self-limiting, with cures occurring 3–18 months after infection, but can leave disfiguring scars (Monge-Maillo and Lopez-Velez, 2013). Mucocutaneous, diffuse cutaneous, and visceral leishmaniasis do not resolve without therapy. Visceral disease caused by *Leishmania donovani* is fatal unless treated (Sundar and Chakravarty, 2015).

The classic therapy for all species of *Leishmania* is with *pentavalent antimony compounds* such as sodium stibogluconate (sodium antimony gluconate); resistance is widespread, particularly in India (Sundar and Chakravarty, 2015). Recently, treatment of leishmaniasis has undergone major changes owing to the success of the first orally active agent, *miltefosine*, which has been FDA-approved for cutaneous, mucocutaneous, and visceral disease (Miltefosine [Impavido] for Leishmaniasis, 2014). Miltefosine also appears to have promise for treating dogs, an important animal reservoir of the disease (Alvar et al., 2006). However, its teratogenic effects limit its utility in women of childbearing age (Sindermann and Engel, 2006). As an alternative, *liposomal amphotericin B* is a highly effective agent for visceral leishmaniasis (Magill, 2014) and is now recommended therapy in the U.S. in a recently released treatment guideline (Aronson et al., 2016). In addition, paromomycin has been used with some success as a parenteral agent for visceral disease, and topical formulations of paromomycin have also been used for cutaneous disease (Monge-Maillo and Lopez-Velez, 2013).

Other Protozoal Infections

Just a few of the many less-common protozoal infections of humans are highlighted in this section.

Babesiosis

Babesiosis, caused by either *Babesia microti* or *B. divergens*, is a tick-borne zoonosis that superficially resembles malaria in that the parasites invade erythrocytes and produce a febrile illness, hemolysis, and hemoglobinuria. Although this infection usually is mild and self-limiting, it can be severe or even fatal in asplenic or severely immunocompromised individuals. Therapy is with a combination of *clindamycin* and *quinine* for severe disease or the combination of *azithromycin* and *atovaquone* for mild or moderate infections (Gelfand and Vannier, 2014; Vannier et al., 2015).

Balantidiasis

Balantidiasis, caused by the ciliated protozoan *Balantidium coli*, is an infection of the large intestine that may be confused with amebiasis. However, unlike amebiasis, this infection usually responds to *tetracycline* therapy (Schuster and Ramirez-Avila, 2008; Suh et al., 2014).

Other Coccidia

Cyclospora cayentanensis (Szumowski and Troemel, 2015) causes self-limited diarrhea in normal hosts and can cause prolonged diarrhea in immunocompromised individuals. *Cystoisospora belli*, formerly known

as *Isospora belli*, causes diarrhea in patients with AIDS. Both *Cyclospora* and *Cystoisospora* respond to trimethoprim-sulfamethoxazole (Legua and Seas, 2013; Suh et al., 2014).

Microsporidia

Microsporidia are spore-forming, unicellular, eukaryotic organisms that were once thought to be parasites but are now classified as fungi (Field and Milner, 2015). As such, they are discussed in Chapter 61 (on antifungal agents).

Antiprotozoal Drugs

For ease of reference, the myriad agents used to treat nonmalarial protozoal diseases are presented alphabetically.

Amphotericin B

The pharmacology, formulation, and toxicology of amphotericin B are presented in Chapter 61.

Antiprotozoal Effects

Amphotericin B is a highly effective antileishmanial agent that cures more than 90% of the cases of visceral leishmaniasis and is the drug of choice for antimonial-resistant cases (Mohamed-Ahmed et al., 2012). It is the recommended agent for visceral leishmaniasis in the U.S. (Aronson et al., 2016). Amphotericin B is also therapy for cutaneous or mucosal leishmaniasis and is effective for treating immunocompromised patients (van Griensven et al., 2014). Lipid preparations of the drug have reduced toxicity, but the cost of the drug and the difficulty of administration remain a problem in endemic regions (Bern et al., 2006).

Mechanism of Action

Amphotericin's activity against *Leishmania* is similar to its antifungal effects (see Chapter 61). Amphotericin complexes with ergosterol precursors in the cell membrane, forming pores that allow ions to enter the cell. *Leishmania* has similar sterol composition to fungi, and amphotericin binds fungal sterols preferentially over host cholesterol (Moen et al., 2009).

Therapeutic Uses

Typical regimens of 10–20 mg/kg total dose given in divided doses over 10–20 days by intravenous infusion have yielded cure rates of more than 95%. In the U.S., the FDA recommends 3 mg/kg intravenously on days 1–5, 14, and 21 for a total dose of 21 mg/kg to treat visceral leishmaniasis or 3 mg/kg/d for 7–10 days to treat cutaneous disease. Shorter courses of the drug for treatment of visceral leishmaniasis have demonstrated good efficacy and provide a potential cost-saving alternative, although only a limited number of patients have been tested (Monge-Maillou and Lopez-Velez, 2013). In addition, combining antileishmanial drugs may be effective; further studies are needed for such regimens (Sundar and Chakravarty, 2013).

Eflornithine

Eflornithine (DFMO) is an irreversible catalytic (suicide) inhibitor of ornithine decarboxylase, the enzyme that catalyzes the first and rate-limiting step in the biosynthesis of polyamines (putrescine, spermidine, and spermine) that are required for cell division and for normal cell differentiation (Jacobs et al., 2011). In trypanosomes, spermidine is required for the synthesis of trypanothione, a conjugate of spermidine and glutathione that replaces many of the functions of glutathione in the parasite. Eflornithine is transported into the cell via an amino acid transporter (*Tb* AAT6) (Vincent et al., 2010).

Eflornithine in combination with nifurtimox (NECT) is currently the drug of choice for treatment of late-stage West African (Gambian) trypanosomiasis caused by *T. brucei gambiense* (Jacobs et al., 2011). It is thought to be less effective against East African trypanosomiasis and thus is not recommended for this application. Eflornithine is no longer available for systemic use in the U.S. but is available for treatment of Gambian trypanosomiasis by special request from the CDC. NECT is safer and more efficacious than melarsoprol for late-stage gambiense sleeping sickness.

Antitrypanosomal Effects

Eflornithine is a cytostatic agent that has multiple biochemical effects on trypanosomes, all of which are a consequence of polyamine depletion (Jacobs et al., 2011). The parasite and human enzymes are equally susceptible to inhibition by eflornithine; however, the mammalian enzyme is turned over rapidly, whereas the parasite enzyme is stable, and this difference likely plays a role in the selective toxicity.

ADME

Eflornithine is given by intravenous infusion. The drug does not bind to plasma proteins but is well distributed and penetrates into the CSF, where estimated concentrations of at least 50 μM must be reached for parasite clearance (Burri and Brun, 2003). The mean $t_{1/2}$ is 3–4 h, and renal clearance after intravenous administration is rapid (2 mL/min/kg), with more than 80% of the drug cleared by the kidney largely in unchanged form (Sanderson et al., 2008).

Therapeutic Uses

Eflornithine in combination with nifurtimox (NECT) is used for the treatment of late-stage West African trypanosomiasis caused by *T. brucei gambiense*. The combination is logistically easier to administer and better tolerated than eflornithine alone. Importantly, compared to eflornithine alone, NECT achieves a higher cure rate (96.5% vs. 91.5%). Dosing is as follows: 200 mg/kg IV every 12 h by 2-h infusion for 7 days plus nifurtimox (orally at 15 mg/kg/d in three divided doses [every 8 h]) for 10 days (Priotto et al., 2009).

Toxicity and Side Effects

Eflornithine causes adverse reactions that are generally reversible on withdrawal of the drug. Abdominal pain and headache are the predominant complaints, followed by reactions at the injection sites. Tissue infections and pneumonia are also observed. The most severe reactions for eflornithine alone were reported to include fever peaks (6%), seizures (4%), and diarrhea (2%) (Balasegaram et al., 2009; Priotto et al., 2008). For NECT, severe adverse events were reduced compared to eflornithine alone (14% vs. 29%), and treatment-related deaths were also fewer (0.7% vs. 2%) (Priotto et al., 2009). The case fatality rate for eflornithine (0.7%–1.2%) and for NECT (0.2%) is significantly lower than for melarsoprol (4.9%), and overall either eflornithine alone or NECT is superior to melarsoprol with respect to both safety and efficacy. Reversible hearing loss can occur after prolonged therapy with oral doses. Therapeutic doses of eflornithine are large and require coadministration of substantial volumes of intravenous fluid. This poses significant practical limitations in remote settings and can cause fluid overload in susceptible patients.

8-Hydroxyquinolines

The halogenated 8-hydroxyquinolines iodoquinol (diiodohydroxyquin) and clioquinol (iodochlorhydroxyquin) can be used as luminal agents to eliminate intestinal colonization with *E. histolytica* and combined with metronidazole to treat amebic colitis or amebic liver abscess. Because of its superior adverse-event profile, paromomycin is preferred as the luminal agent for amebiasis. However, iodoquinol, the safer of the two 8-hydroxyquinolones, is available for use in the U.S. and is a reasonable alternative. When used at appropriate doses (never to exceed 2 g/d) for short periods of time (not greater than 20 days in adults), adverse effects are unusual (Haque et al., 2003). However, using these drugs at high doses for long periods carries significant risk. The most important toxic reaction, ascribed primarily to clioquinol, is subacute myelo-optic

neuropathy (Meade, 1975). Administering iodoquinol in high doses to children with chronic diarrhea is associated with optic atrophy and permanent vision loss (Escobedo et al., 2009). Peripheral neuropathy is a less-severe manifestation of neurotoxicity from these drugs (Haque et al., 2003). For adults, the recommended dose of iodoquinol is 650 mg orally three times daily for 20 days, whereas children receive 30–40 mg/kg body weight orally, divided three times a day (not to exceed 1.95 g/d) for 20 days (Drugs for Parasitic Infections, 2013).

Melarsoprol

Despite the fact that it causes an often-fatal encephalopathy in 2%–10% of the patients treated with it, melarsoprol is the only drug for the treatment of late (CNS) stages of East African trypanosomiasis caused by *T. brucei rhodesiense* (Kennedy, 2013). Although melarsoprol is also effective against late-stage West African trypanosomiasis caused by *T. brucei gambiense*, NECT has become the first-line treatment of this disease.

Melarsoprol is supplied as a 3.6% (w/v) solution in propylene glycol for intravenous administration. It is available in the U.S. only from the CDC.

Mechanism of Action; Antiprotozoal Effects

Melarsoprol is metabolized to melarsen oxide, the active drug (Barrett et al., 2007). Arsenoxides react avidly and reversibly with vicinal sulphydryl groups and thereby inactivate many enzymes. Melarsoprol reacts with trypanothione, the spermidine-glutathione adduct that substitutes for glutathione in these parasites. Binding of melarsoprol to trypanothione results in a melarsen oxide–trypanothione adduct that inhibits trypanothione reductase. Treatment failure owing to resistance of trypanosomes to melarsoprol has risen sharply, and some of the resistant strains are an order of magnitude less sensitive to the drug. Resistance to melarsoprol arises due to transport defects linked to the aquaglyceroporin pore-forming protein (Munday et al., 2015).

ADME

Melarsoprol is always administered by slow intravenous injection, with care to avoid leakage into the surrounding tissues because the drug is intensely irritating. Melarsoprol is a prodrug and is metabolized rapidly (<30 min) to melarsen oxide, the active form of the drug (Barrett et al., 2007). Bioassays show that the active metabolite has a terminal $t_{1/2}$ of 43 h. A small but therapeutically significant amount of the drug enters the CSF and clears trypanosomes infecting the CNS.

Therapeutic Uses

Melarsoprol is the only effective drug available for treatment of the late meningoencephalitic stage of East African (Rhodesian) trypanosomiasis, which is nearly 100% fatal if untreated (Kennedy, 2013). The drug is also effective in the early hemolymphatic stage of these infections, but because of its toxicity, it is reserved for therapy of late-stage infections. Patients infected with *T. brucei rhodesiense* who relapse after a course of melarsoprol usually respond to a second course of the drug. In contrast, patients infected with *T. brucei gambiense* who are not cured with melarsoprol rarely benefit from repeated treatment with this drug. Such patients often respond well to eflornithine.

Dosing is 2.2 mg/kg/d IV for 10 days for both *T. brucei gambiense* (Pepin and Mpia, 2006) and *T. brucei rhodesiense* (Kuepfer et al., 2012).

Encephalopathy develops more frequently in patients with *T. brucei rhodesiense* compared to *T. brucei gambiense*. Concurrent administration of prednisolone is frequently employed throughout the treatment course to reduce the prevalence of encephalopathy.

Toxicity and Side Effects

Treatment with melarsoprol is associated with significant toxicity and morbidity (Barrett et al., 2007; Kennedy, 2013). A febrile reaction often occurs soon after drug injection, especially if parasitemia is high. The most serious complications involve the nervous system. A reactive encephalopathy occurs 9–11 days after treatment starts in about 5%–10% of patients, leading to death in about half of these. Peripheral neuropathy occurs in about 10% of patients receiving melarsoprol. Hypertension and myocardial damage are not uncommon, although shock is rare. Albuminuria occurs frequently, and evidence of renal or hepatic damage may necessitate modification of treatment. Vomiting and abdominal colic also are common, but their incidence can be reduced by injecting melarsoprol slowly into the supine, fasting patient.

Precautions and Contraindications

Melarsoprol should be given only to patients under hospital supervision. Initiation of therapy during a febrile episode has been associated with an increased incidence of reactive encephalopathy. Administration of melarsoprol to leprosy patients may precipitate erythema nodosum. Use of the drug is contraindicated during epidemics of influenza. Severe hemolytic reactions have been reported in patients with deficiency of glucose-6-phosphate dehydrogenase. The drug may be used in pregnancy.

Metronidazole and Tinidazole

Metronidazole is active in vitro against a wide variety of anaerobic protozoal parasites and anaerobic bacteria. Other clinically effective 5-nitroimidazoles closely related in structure and activity to metronidazole include tinidazole, secnidazole, and ornidazole. Among these, only tinidazole is available in the U.S. Metronidazole is clinically effective in trichomoniasis, amebiasis, and giardiasis. Metronidazole manifests antibacterial activity against all anaerobic cocci; anaerobic gram-negative bacilli, including *Bacteroides* spp.; anaerobic spore-forming, gram-positive bacilli such as *Clostridium*; and microaerophilic bacteria such as *Helicobacter* and *Campylobacter* spp. Nonsporulating gram-positive bacilli often are resistant, as are aerobic and facultatively anaerobic bacteria (Lofmark et al., 2010). Please refer to Chapter 59 on protein synthesis inhibitors for additional details about the use of metronidazole in bacterial infections.

Mechanism of Action

Metronidazole is a prodrug requiring reductive activation of the nitro group by susceptible organisms. Unlike their aerobic counterparts, anaerobic and microaerophilic pathogens (e.g., the amitochondriate protozoa *T. vaginalis*, *E. histolytica*, and *G. lamblia* and various anaerobic bacteria) contain electron transport components that have a sufficiently negative redox potential to donate electrons to metronidazole. The single-electron transfer forms a highly reactive nitro radical anion that kills susceptible organisms by radical-mediated mechanisms that target DNA. Metronidazole is catalytically recycled; loss of the active metabolite's electron regenerates the parent compound. Increasing levels of O_2 inhibit metronidazole-induced cytotoxicity because O_2 competes with metronidazole for electrons. Thus, O_2 can both decrease reductive activation of metronidazole and increase recycling of the activated drug. Anaerobic or microaerophilic organisms susceptible to metronidazole derive energy from the oxidative fermentation of ketoacids such as pyruvate. Pyruvate decarboxylation, catalyzed by PFOR, produces electrons that reduce ferredoxin, which in turn catalytically donates its electrons to biological electron acceptors or to metronidazole (Lamp et al., 1999).

Resistance

Clinical resistance to metronidazole is well documented for *T. vaginalis*, *G. lamblia*, and a variety of anaerobic and microaerophilic bacteria.

Resistance correlates with impaired oxygen-scavenging capabilities, leading to higher local O_2 concentrations, decreased activation of metronidazole, and futile recycling of the activated drug. Other resistant strains have lowered levels of PFOR and ferredoxin, perhaps explaining why they may still respond to higher doses of metronidazole (Townson et al., 1994).

ADME

Preparations of metronidazole are available for oral, intravenous, intravaginal, and topical administration. The drug usually is absorbed completely and promptly after oral intake and distributed to a volume approximating total body water; less than 20% of the drug is bound to plasma proteins. A linear relationship between dose and plasma concentration pertains for doses of 200–2000 mg. Repeated doses every 6–8 h result in some drug accumulation. The $t_{1/2}$ of metronidazole in plasma is about 8 h. With the exception of the placenta, metronidazole penetrates well into body tissues and fluids, including vaginal secretions, seminal fluid, saliva, breast milk, and CSF. After an oral dose, more than 75% of labeled metronidazole is eliminated in the urine, largely as metabolites formed by the liver from oxidation of the drug's side chains, a hydroxy derivative and an acid; about 10% is recovered as unchanged drug.

Two principal metabolites result. The hydroxy metabolite has a longer $t_{1/2}$ (~12 h) and has about 50% of the antitrichomonal activity of metronidazole. Formation of glucuronides also is observed. Small quantities of reduced metabolites are formed by the gut flora. The urine of some patients may be reddish brown owing to the presence of unidentified pigments derived from the drug. Oxidative metabolism of metronidazole is induced by phenobarbital, prednisone, rifampin, and possibly ethanol and is inhibited by cimetidine (Lamp et al., 1999; Martinez and Caumes, 2001).

Therapeutic Uses

Trichomoniasis. Metronidazole cures genital infections with *T. vaginalis* in more than 90% of cases. The preferred treatment regimen is 2 g metronidazole as a single oral dose for both males and females. Tinidazole, which has a longer $t_{1/2}$ than metronidazole, is also used at a 2-g single dose and appears to provide equivalent or better responses (Drugs for Parasitic Infections, 2013). When repeated courses or higher doses of the drug are required, it is recommended that intervals of 4–6 weeks elapse between courses. Leukocyte counts should occur before, during, and after each course. Treatment failures owing to the presence of metronidazole-resistant strains of *T. vaginalis* are becoming increasingly common. Most of these cases can be treated successfully by giving a second 2-g dose to both patient and sexual partner. In addition to oral therapy, the use of a 500- to 1000-mg vaginal suppository may be beneficial in refractory cases (Muzny and Schwabke, 2013).

Amebiasis. Metronidazole is the agent of choice for the treatment of all symptomatic forms of amebiasis, including amebic colitis and amebic liver abscess. The recommended dose is 500–750 mg metronidazole taken orally three times daily for 7–10 days (McCarthy et al., 2014) or, for children, 35–50 mg/kg/d given in three divided doses for 7–10 days (Drugs for Parasitic Infections, 2013). Amebic liver abscess has been treated successfully by short courses of metronidazole or tinidazole. *Entamoeba histolytica* persists in most patients who recover from acute amebiasis after metronidazole therapy, so it is recommended that all such individuals also be treated with a luminal amebicide.

Giardiasis. Tinidazole is approved for the treatment of giardiasis as a single 2-g dose and is appropriate first-line therapy (Hill and Nash, 2014). Although metronidazole has never been FDA-approved for treatment of giardiasis in the U.S., there are many years of experience with its use (Drugs for Parasitic Infections, 2013; Pasupuleti et al., 2014).

Toxicities and Contraindications

Common side effects are headache, nausea, dry mouth, and a metallic taste. Vomiting, diarrhea, and abdominal distress are experienced occasionally. Dysuria, cystitis, and a sense of pelvic pressure have been reported. Dizziness, vertigo, and, very rarely, encephalopathy, convulsions, incoordination, and ataxia are neurotoxic effects that warrant drug discontinuation.

Metronidazole also should be withdrawn if numbness or paresthesias of the extremities occur. Reversal of serious sensory neuropathies may be slow or incomplete.

Urticaria, flushing, and pruritus indicate drug sensitivity and can require withdrawal of metronidazole (Lofmark et al., 2010). Metronidazole is a rare cause of Stevens-Johnson syndrome, which may be more common among individuals receiving high doses of metronidazole and concurrent therapy with the antihelminthic mebendazole (Chen et al., 2003).

Drug Interactions

Metronidazole has a disulfiram-like effect, and some patients experience abdominal distress, vomiting, flushing, or headache if they drink alcoholic beverages during or within 3 days of therapy (Jang and Harris, 2007). Metronidazole and disulfiram or any disulfiram-like drug should not be taken together because confusional and psychotic states may occur. Metronidazole should be used cautiously in patients with active disease of the CNS because of potential neurotoxicity. The drug also may precipitate CNS signs of lithium toxicity in patients receiving high doses of lithium. Metronidazole can prolong the prothrombin time of patients receiving therapy with warfarin anticoagulants. The dosage of metronidazole should be reduced in patients with severe hepatic disease. Metronidazole use during the first trimester of pregnancy generally is not advised (Drugs for Parasitic Infections, 2013; Lofmark et al., 2010).

Miltefosine

Miltefosine is an alkylphosphocholine analogue developed originally as an anticancer agent. Its antiprotozoal activity was discovered in the 1980s as it was being evaluated for cancer chemotherapy. In 2002, it was approved in India as the first orally active treatment available for visceral leishmaniasis. It is highly curative against visceral leishmaniasis and also is effective against the cutaneous forms of the disease (Magill, 2014). Its main drawback is its teratogenicity; consequently, it must not be used in pregnant women (Miltefosine [Impavido] for Leishmaniasis, 2014).

Antiprotozoal Effects

Miltefosine is the first orally available therapy for leishmaniasis. It is a safe and effective treatment of visceral leishmaniasis and has shown greater than 90% efficacy against some species of cutaneous leishmaniasis, although significant strain variation has been noted in clinical trials (Sundar and Chakravarty, 2015). The mechanism of action of miltefosine is not understood. Studies suggest that the drug may alter ether-lipid metabolism, cell signaling, or glycosylphosphatidylinositol anchor biosynthesis (Dorlo et al., 2012). A transporter for miltefosine has been cloned by functional rescue of a laboratory-generated resistant strain of *L. donovani*. The transporter is a P-type ATPase that belongs to the aminophospholipid translocase subfamily. The basis for the drug resistance appears to be a point mutation in this transporter that leads to decreased drug uptake and thereby confers drug resistance (Perez-Victoria et al., 2003; Sundar and Chakravarty, 2015).

ADME

Miltefosine is well absorbed orally and distributed throughout the human body. Detailed pharmacokinetic data are lacking, with the exception that miltefosine has a long $t_{1/2}$ (1–4 weeks). Plasma concentrations are proportional to the dose (Miltefosine [Impavido] for Leishmaniasis, 2014; Sundar and Chakravarty, 2015).

Therapeutic Uses

In the U.S., the recommended dose for oral miltefosine for both visceral and cutaneous disease for adults over 45 kg is 150 mg/kg/d for 28 days, given in three divided doses, and for patients weighing 30–45 kg

is 100 mg/kg/d, given in two divided doses (Aronson et al., 2016; Miltefosine (Impavido) for Leishmaniasis, 2014). The compound cannot be given intravenously because it has hemolytic activity (Dorlo et al., 2012).

Toxicity and Side Effects

Vomiting and diarrhea are reported as frequent side effects, in up to 60% of patients. Elevations in hepatic transaminases and serum creatinine also have been reported. These effects are typically mild and reversible. Because of its teratogenic potential, miltefosine is contraindicated in pregnant women. In fact, guidelines for miltefosine use in the U.S. state that adequate contraception must be used during treatment and for 5 months after therapy is complete (Milttefosine (Impavido) for Leishmaniasis, 2014).

Nifurtimox and Benznidazole

Nifurtimox and benznidazole are used to treat American trypanosomiasis caused by *T. cruzi*, while nifurtimox is also used in combination with eflornithine for treatment of *T. brucei* (see previous discussion). Nifurtimox, a nitrofurantoin analogue, and benznidazole, a nitroimidazole analogue, can be obtained in the U.S. from the CDC.

Antiprotozoal Effects and Mechanisms of Action

Nifurtimox and benznidazole are trypanocidal against both the trypomastigote and amastigote forms of *T. cruzi* (Barrett et al., 2007; Kennedy, 2013). Nifurtimox also has activity against *T. brucei* and can be curative against both early- and late-stage disease (see previous discussion of NECT). The trypanocidal effects of nifurtimox and benznidazole derive from their activation by an NADH-dependent mitochondrial nitroreductase to nitro radical anions that are thought to account for the trypanocidal effects (Wilkinson et al., 2011). The generated nitro anion radicals form covalent attachments to macromolecules, leading to cellular damage that includes lipid peroxidation and membrane injury, enzyme inactivation, and damage to DNA. Reduced nitroreductase expression through single-allele gene knockout experiments or through drug selection leads to drug resistance (Wilkinson et al., 2011).

ADME

Nifurtimox is well absorbed after oral administration, with peak plasma levels observed after about 3.5 h. Less than 0.5% of the dose is excreted in urine (Paulos et al., 1989). The elimination $t_{1/2}$ is about 3 h. Nifurtimox undergoes rapid biotransformation, probably via a presystemic first-pass effect, and high concentrations of several unidentified metabolites are found. Nifurtimox crosses the blood-brain barrier in mice (Jeganathan et al., 2011).

Benznidazole is absorbed rapidly and reaches peak plasma levels within 3 h; the terminal elimination half-life is 12 h (Raaflaub and Ziegler, 1979). Recent population studies have suggested that, in adults, a dose of 2.5 mg/kg/24 h maintains the trough concentration above the therapeutic range of 3–6 mg/L, indicating that the current recommended dose of 2.5 mg/kg/12 h may be higher than needed (Soy et al., 2015). In children, drug levels were found to be lower than in adults, with excellent efficacy nonetheless (Altchek et al., 2014).

Therapeutic Uses

Nifurtimox and benznidazole are employed in the treatment of American trypanosomiasis (Chagas disease) caused by *T. cruzi* (Bern et al., 2011; Chatelain, 2015; Malik et al., 2015; Ribeiro et al., 2012). Nifurtimox is also used in combination with eflornithine (NECT) for treatment of African sleeping sickness (see eflornithine section for discussion). Because of toxicity concerns, benznidazole is the preferred treatment of Chagas disease. Both drugs markedly reduce the parasitemia, morbidity, and mortality of acute Chagas disease, with parasitological cures obtained in more than 80% of these cases, although the clinical response of the acute illness to drug therapy varies with geographic region (Messenger et al., 2015). In the chronic form of the disease, parasitological cures are still possible, although the drug is less effective than in the acute stage. In a recent study of chronic Chagas patients, 94% of patients who completed treatment with 150 mg benznidazole

twice daily for 60 days remained PCR negative until completion of the study at the 10-month follow-up (Molina, et al., 2014; Molina, et al., 2014). The current recommendations are that patients less than 50 years of age with either acute- or recent chronic-phase disease, without advanced cardiomyopathy, should be treated. In patients more than 50 years of age, the benefits of treatment are complicated by lowered drug tolerability. Therapy is strongly encouraged for patients who will receive immunosuppressive therapy or who are HIV positive. Therapy with nifurtimox or benznidazole should start promptly after exposure for persons at risk of *T. cruzi* infection from laboratory accidents or from blood transfusions.

Both drugs are given orally with doses recommended as described (Drugs for Parasitic Infections, 2013). For nifurtimox, adults (>17 years) with acute infection should receive 8–10 mg/kg/d in three to four divided doses for 90 days; children 1–10 years old should receive 15–20 mg/kg/d in three to four divided doses for 90 days; for individuals 11–16 years old, the daily dose is 12.5–15 mg/kg given according to the same schedule.

For benznidazole, the recommended treatment for adults (>13 years) is 5–7 mg/kg/d in two divided doses for 60 days, with children up to 12 years receiving 10–15 mg/kg/d in two divided doses for 60 days. However, some studies have suggested that total doses exceeding 300 mg/d are less well tolerated (Salvador et al., 2014). If gastric upset and weight loss occur during treatment, dosage should be reduced. The ingestion of alcohol should be avoided. Nifurtimox is used in combination with eflornithine in treating late-stage *T. brucei gambiense* sleeping sickness.

Toxicity and Side Effects

Side effects are common and range from hypersensitivity reactions (e.g., dermatitis, fever, icterus, pulmonary infiltrates, and anaphylaxis) to dose- and age-dependent complications referable to the GI tract and both the peripheral nervous system and CNS (Ribeiro et al., 2012). Nausea and vomiting are common, as are myalgia and weakness. For benznidazole, the most common adverse event (occurring in 30% of patients in the first week of treatment) is urticarial dermatitis, which can be treated with antihistamines or corticosteroids. However, treatment often has to be discontinued in patients with this reaction. Bone marrow suppression can occur early during therapy, so blood cell counts should be measured every 2–3 weeks, and treatment stopped if suppression is observed. Peripheral neuropathy and GI symptoms are especially common after prolonged treatment; the latter complication may lead to weight loss and preclude further therapy. Benznidazole should be given with food to minimize GI effects. Because of the seriousness of Chagas disease and the lack of superior drugs, there are few absolute contraindications to the use of these drugs.

Nitazoxanide

Nitazoxanide (N-[nitrothiazolyl] salicylamide) is an oral synthetic broad-spectrum antiparasitic agent (see Chapter 55). Nitazoxanide is FDA-approved for the treatment of cryptosporidiosis and giardiasis in adults and immunocompetent children (Wright, 2012).

Antimicrobial Effects

Nitazoxanide and its active metabolite, tizoxanide (desacetyl-nitazoxanide), inhibit the growth of sporozoites and oocytes of *C. parvum* and inhibit the growth of the trophozoites of *G. intestinalis*, *E. histolytica*, and *T. vaginalis* in vitro (Wright, 2012). Nitazoxanide also has activity against intestinal helminthes (van den Enden, 2009).

Mechanism of Action

Nitazoxanide interferes with the PFOR enzyme-dependent electron-transfer reaction, which is essential to anaerobic metabolism in protozoan and bacterial species (Raether and Hanel, 2003).

ADME

Following oral administration, nitazoxanide is hydrolyzed rapidly to its active metabolite, tizoxanide, which undergoes conjugation to tizoxanide glucuronide. Bioavailability after an oral dose is excellent, and maximum

plasma concentrations of the metabolites occur 1–4 h following administration. Tizoxanide is more than 99.9% bound to plasma proteins. Tizoxanide is excreted in the urine, bile, and feces; tizoxanide glucuronide is excreted in the urine and bile (Raether and Hanel 2003).

Therapeutic Uses

In the U.S., nitazoxanide is approved for the treatment of *G. intestinalis* infection (therapeutic efficacy of 85%–90%) (Hill and Nash, 2014) and for the treatment of diarrhea caused by *Cryptosporidia* (therapeutic efficacy, 56%–88%) in adults and children more than 1 year of age (Flynn, 2012). The efficacy of nitazoxanide in immunocompromised patients with *Cryptosporidia* infection has not been clearly established (Wright, 2012).

Nitazoxanide has been used as a single agent to treat mixed infections with intestinal parasites (protozoa and helminths). Effective parasite clearance after nitazoxanide treatment was shown for *G. intestinalis*, *E. histolytica*, *Blastocystis hominis*, *C. parvum*, *C. cayetanensis*, *I. belli*, *Hymenolepis nana*, *Trichuris trichiura*, *Ascaris lumbricoides*, and *Enterobius vermicularis*, although more than one course of therapy was required in some cases. Nitazoxanide also has been used to treat infections with *G. intestinalis* resistant to metronidazole and albendazole (Wright, 2012).

Dosing

To treat cryptosporidiosis, for children ages 12–47 months, the recommended dose is 100 mg nitazoxanide every 12 h for 3 days; for children ages 4–11 years, the dose is 200 mg nitazoxanide every 12 h for 3 days (Drugs for Parasitic Infections, 2013; Flynn, 2012). A 500-mg tablet, suitable for adult dosing every 12 h for 3 days, is available (McCarthy et al., 2014).

Toxicity and Side Effects

Adverse effects are rare with nitazoxanide. A greenish tint to the urine can be seen. Nitazoxanide is a pregnancy category B agent, based on animal teratogenicity and fertility studies (Anderson and Curran, 2007).

Paromomycin

Paromomycin (aminosidine) is an aminoglycoside of the neomycin/kanamycin family (see Chapter 58) that is used as an oral agent to treat *E. histolytica* infection, cryptosporidiosis, and giardiasis. Topical formulations have been used to treat trichomoniasis and cutaneous leishmaniasis; parenteral administration has been used to treat visceral leishmaniasis, both alone and in combination with antimony compounds (Sundar and Chakravarty, 2015). However, only oral paromomycin is available in the U.S. (McCarthy et al., 2014).

Mechanism of Action; ADME

Paromomycin shares the same mechanism of action as neomycin and kanamycin (binding to the 30S ribosomal subunit) and has the same spectrum of antibacterial activity. The drug is not absorbed from the GI tract; thus, the actions of an oral dose are confined to the GI tract, with 100% of the oral dose recovered in the feces (Mishra et al., 2007).

Antimicrobial Effects

Amebiasis. Paromomycin is the drug of choice for treating intestinal colonization with *E. histolytica* and is used in combination with metronidazole to treat amebic colitis and amebic liver abscess. Adverse effects are rare with oral usage but include abdominal pain and cramping, epigastric pain, nausea and vomiting, steatorrhea, and diarrhea. Rarely, rash and headache have been reported. Dosing for adults and children is 25–35 mg/kg/d in three divided oral doses (Drugs for Parasitic Infections, 2013).

Giardiasis. Paromomycin has been advocated as a treatment of giardiasis when metronidazole is contraindicated. It is used in pregnant women and for metronidazole-resistant isolates (Wright et al., 2003).

Pentamidine

Pentamidine is a positively charged aromatic diamine. It is a broad-spectrum agent with activity against several species of pathogenic protozoa

and some fungi. Pentamidine as the di-isethionate salt is marketed for injection or as an aerosol (De et al., 1986; Rex and Stevens, 2014).

Antiprotozoal and Antifungal Effects

Pentamidine is used for the treatment of early-stage *T. brucei gambiense* infection but is ineffective in the treatment of late-stage disease and has reduced efficacy against *T. brucei rhodesiense* (Barrett et al., 2007; Kennedy, 2013). Pentamidine is an alternative agent for the treatment of cutaneous leishmaniasis (Monge-Maillo and Lopez-Velez, 2013). Pentamidine is an alternative agent for the treatment and prophylaxis of pneumonia caused by *Pneumocystis jiroveci* (PJP), formerly known as *Pneumocystis carinii* (PCP) (Castro, 1998). See Chapter 61, on antifungal agents, for additional details.

Diminazene (not available in the U.S.) is a related diamidine that is used as an inexpensive alternative to pentamidine for the treatment of early African trypanosomiasis and has been used outside the U.S. for the treatment of early-stage *T. brucei gambiense* in periods of pentamidine shortage (Munday et al., 2015).

Mechanism of Action and Resistance

The mechanism of action of the diamidines is unknown. The compounds display multiple effects on any given parasite and act by disparate mechanisms in different parasites. Multiple transporters contribute to pentamidine uptake. However, recently, it has been shown that a single high-affinity transporter from the aquaglyceroporin gene family (TbAQP2) is responsible for cross-resistance between pentamidine and melarsoprol and represents the major route for the uptake of pentamidine (Munday et al., 2015).

ADME

Pentamidine isethionate is fairly well absorbed from parenteral sites of administration. Following a single intravenous dose, the drug disappears from plasma with an apparent $t_{1/2}$ of several minutes to a few hours; maximum plasma concentrations after intramuscular injection occur at 1 h. The $t_{1/2}$ of elimination is long (weeks to months); the drug is 70% bound to plasma proteins (Bronner et al., 1995). This highly charged compound is poorly absorbed orally and does not cross the blood-brain barrier, explaining its ineffectiveness against late-stage trypanosomiasis.

Therapeutic Uses

African Trypanosomiasis. Pentamidine isethionate is used for the treatment of early-stage *T. brucei gambiense* and is given by intramuscular or intravenous injection in doses of 4 mg/kg daily for 7 days.

Leishmaniasis. Pentamidine can be used in doses of 2–3 mg/kg IV or IM daily or every second day for 4–7 doses to treat cutaneous leishmaniasis (Drugs for Parasitic Infections, 2013). This compound provides an alternative to antimonials, lipid formulations of amphotericin B, or miltefosine, but it is overall the least well tolerated (Monge-Maillo and Lopez-Velez, 2013).

Toxicity and Side Effects. Approximately 50% of individuals receiving the drug at recommended doses show some adverse effect (Barrett et al., 2007). Intravenous administration of pentamidine may be associated with hypotension, tachycardia, and headache. These effects can be ameliorated by slowing the infusion rate. Hypoglycemia, which can be life threatening, may occur at any time during pentamidine treatment. Careful monitoring of blood sugar is key. Paradoxically, pancreatitis, hyperglycemia, and the development of insulin-dependent diabetes have been seen in some patients. Pentamidine is nephrotoxic (~25% of treated patients show signs of renal dysfunction), and if the serum creatinine concentration rises, it may be necessary to withhold the drug temporarily or change to an alternative agent (Rex and Stevens, 2014). Other adverse effects include skin rashes, thrombophlebitis, anemia, neutropenia, and elevation of hepatic

enzymes (Salamone and Cunha, 1988). Intramuscular administration of pentamidine is associated with the development of sterile abscesses at the injection site, which can become infected secondarily; most authorities recommend intravenous administration (Cheung et al., 1993).

Sodium Stibogluconate

Antimonials were introduced in 1945 and have been used for therapy of leishmaniasis and other protozoal infections. The first trivalent antimonial compound used to treat cutaneous leishmaniasis and kala azar was antimony potassium tartrate (tartar emetic), which was both toxic and difficult to administer. Tartar emetic and other trivalent arsenicals eventually were replaced by pentavalent antimonial derivatives of phenylstibonic acid. An early member of this family of compounds was sodium stibogluconate (sodium antimony gluconate), a pentavalent antimonial compound that has been the mainstay of the treatment of leishmaniasis. Increasing resistance to antimonials has reduced their efficacy (WHO, 2015c). In the U.S., sodium stibogluconate can be obtained from the CDC (Aronson et al., 2016).

Mechanism of Action

The pentavalent antimonials act as prodrugs that are reduced to the more toxic Sb^{3+} species that kill amastigotes within the phagolysosomes of macrophages. Following reduction, the drugs seem to interfere with the trypanothione redox system. Sb^{3+} induces a rapid efflux of trypanothione and glutathione from the cells and also inhibits trypanothione reductase, thereby causing a significant loss of thiol reduction potential in the cells (Frezard et al., 2009).

ADME

The drug is given intravenously or intramuscularly; it is not active orally. The agent is absorbed rapidly and distributed in an apparent volume of about 0.22 L/kg. Elimination occurs in two phases, the first with a $t_{1/2}$ of about 2 h, the second with a much longer half-time (33–76 h). The prolonged terminal elimination phase may reflect conversion of the Sb^{5+} to the more toxic Sb^{3+} that is concentrated in and only slowly released from tissues. The drug is eliminated in the urine (Frezard et al., 2009).

Therapeutic Uses

Sodium stibogluconate is given parenterally. The standard course is 20 mg/kg/d for 20 days for cutaneous disease and for 28 days for visceral leishmaniasis (Drugs for Parasitic Infections, 2013; McCarthy et al., 2014). Increased resistance has greatly compromised the effectiveness of antimonials, and sodium stibogluconate is now obsolete in India. Previously, liposomal amphotericin B was the recommended alternative, but now the orally effective compound miltefosine is likely to see much wider use (Sundar and Chakravarty, 2015). Intraleisional treatment has also been advocated as a safer, alternative method for treating cutaneous disease (Monge-Maillo and Lopez-Velez, 2013). Patients who respond show clinical improvement within 1–2 weeks of initiating therapy. The drug may be given on alternate days or for longer intervals if unfavorable reactions occur in especially debilitated individuals (Sundar and Chakravarty, 2015). Patients infected with HIV often relapse after therapy (Magill, 2014).

Toxicity and Side Effects

In general, regimens of sodium stibogluconate are tolerated; toxic reactions usually are reversible, and most subside despite continued therapy. Adverse effects include chemical pancreatitis in nearly all patients; elevation of serum hepatic transaminase levels; bone marrow suppression, manifested by decreased red cell, white cell, and platelet counts; muscle and joint pain; weakness and malaise; headache; nausea and abdominal pain; and skin rashes. Reversible polyneuropathy has been reported. Hemolytic anemia and renal damage are rare manifestations of antimonial toxicity, as are shock and sudden death (Frezard et al., 2009).

Suramin

Research into the trypanocidal activity of the dyes *trypan red*, *trypan blue*, and *afridol violet* led to the introduction of suramin into therapy in 1920.

Today, the drug is used primarily for treatment of African trypanosomiasis; it has no clinical utility against American trypanosomiasis.

Suramin sodium is a water-soluble trypanocide; solutions deteriorate quickly in air, and only freshly prepared solutions should be used. In the U.S., suramin is available only from the CDC.

Antiparasitic Effects

Suramin is a relatively slow-acting trypanocide (>6 h in vitro) with high clinical activity against both *T. brucei gambiense* and *T. brucei rhodesiense*. Its mechanism of action is unknown, although a recent study has suggested a role for lysosomal function in suramin action (Alsford et al., 2012). This same study also found that the invariant surface glycoprotein (ISG75) family mediates suramin uptake into the parasite. Selective toxicity is likely to result from selective uptake by the parasite. Suramin inhibits many trypanosomal and mammalian enzymes and receptors. No consensus for the mechanism of action has emerged, and the lack of any significant field resistance points to multiple potential targets.

ADME

Because it is not absorbed after oral intake, suramin is given intravenously to avoid local inflammation and necrosis associated with subcutaneous or intramuscular injections (Kaur et al., 2002). After its administration, the drug displays complex pharmacokinetics with marked interindividual variability. The drug is 99.7% serum protein bound and has a terminal elimination $t_{1/2}$ of 41–78 days. Suramin is not appreciably metabolized; renal clearance accounts for elimination of about 80% of the compound from the body. Very little suramin penetrates the CSF, consistent with its polar character and lack of efficacy once the CNS has been invaded by trypanosomes.

Therapeutic Uses

Suramin is the first-line therapy for early-stage *T. brucei rhodesiense* infection (Barrett et al., 2007; Kennedy, 2013; McGeary et al., 2008). It is also active against *T. brucei gambiense* but is only used as a second-line treatment if pentamidine fails or is otherwise contraindicated. Because only small amounts of the drug enter the brain, suramin is used only for the treatment of early-stage African trypanosomiasis (before CNS involvement). Treatment of active African trypanosomiasis should not be started until 24 h after diagnostic lumbar puncture to ensure no CNS involvement, and caution is required if the patient has onchocerciasis (river blindness) because of the potential for eliciting a Mazzotti reaction (i.e., pruritic rash, fever, malaise, lymph node swelling, eosinophilia, arthralgias, tachycardia, hypotension, and possibly permanent blindness). Suramin is given by slow intravenous injection as a 10% aqueous solution. The normal single dose for adults with *T. brucei rhodesiense* infection is 1 g. It is advisable to employ a test dose of 100 mg initially to detect sensitivity, after which the normal dose is given intravenously (e.g., on days 1, 3, 5, 14, and 21). The pediatric test dose is 2 mg/kg followed by a dose of 20 mg/kg, given according to the same schedule as adults. Patients in poor condition should be treated with lower doses during the first week. Patients who relapse after suramin therapy should be treated with melarsoprol.

Toxicity and Side Effects

The most serious immediate reaction, consisting of nausea, vomiting, shock, and loss of consciousness, is rare (~1 in 2000 patients) (Kaur et al., 2002). Malaise, nausea, and fatigue are also common immediate reactions. The most common problem encountered after several doses of suramin is renal toxicity, manifested by albuminuria, and delayed neurological complications, including headache, metallic taste, paresthesias, and peripheral neuropathy. These complications usually disappear spontaneously despite continued therapy. Other, less-prevalent reactions include vomiting, diarrhea, stomatitis, chills, abdominal pain, and edema. Patients receiving suramin should be followed closely. Therapy should not be continued in patients who show intolerance to initial doses, and the drug should be employed with great caution in individuals with renal insufficiency.

Drug Facts for Your Personal Formulary: Antiparasitic Agents: Protozoal Infections Other Than Malaria

Drugs	Therapeutic Uses	Clinical Pharmacology and Tips
Amebiasis		
Metronidazole	• Amoebic colitis and liver abscess	<ul style="list-style-type: none"> • Always administer with luminal agent • Orally administered: > 80% bioavailable • Common side effects: headache and metallic taste • Can have disulfiram-like effect
Tinidazole	• Amoebic colitis and liver abscess	• Always administer with luminal agent
Paromomycin	• Luminal agent (eradicates <i>E. histolytica</i> from gut)	<ul style="list-style-type: none"> • Drug of choice due to side effects of 8-hydroxyquinolones • Side effects of paromomycin: GI (nausea/vomiting/diarrhea)
Iodoquinol	• Luminal agent	• Use less than 2 g/d for less than 20 days to avoid neurotoxicity
Giardiasis		
Metronidazole	• Giardiasis	<ul style="list-style-type: none"> • 5-day course • Not FDA-approved for indication, but years of experience
Tinidazole	• Giardiasis	• Single dose sufficient
Paromomycin	• Giardiasis	• Used in pregnancy
