Endpoint	Method name	Test type
Phototoxicity	3T3 neutral red uptake phototoxicity test	In vitro
	3T3 NRU phototoxicity test: application to UV filter chemicals	In vitro
Preclinical and nonclinical safety studies for drug development	Guidance on nonclinical safety studies for the conduct of human clinical trials and marketing authorization for pharmaceuticals M3(R2) (harmonized guidance can reduce use of animals)	In vivo
	Preclinical safety evaluation of biotechnology-derived pharmaceuticals, ICH S6 (R1)	In vivo
Pyrogenicity	Human whole blood IL-1	In vitro
	Human whole blood IL-6	In vitro
	Human cryopreserved whole blood IL-1	In vitro
	PBMC IL-6	In vitro
	MM6 IL-6	In vitro
	Limulus amebocyte lysate (LAL) test	In vivo/ in vitro
Reproductive and developmental toxicity	Embryonic stem cell test for embryotoxicity	In vitro
	Micromass embryotoxicity assay	Ex vivo
	Whole rat embryotoxicity assay	Ex vivo
	Extended one-generation reproductive toxicity study	In vivo
Skin corrosion	EST-1000 human reconstructed epidermis	In vitro
	Membrane barrier corrosivity test method (Corrositex)	In vitro
	EpiSkin human skin model	In vitro
	EpiDerm human skin model	In vitro
	Rat skin transcutaneous electrical resistance assay	Ex vivo
	SkinEthic human skin model	In vitro
	Vitrolife-Skin human reconstructed epidermis	In vitro
Skin irritation	EpiSkin skin irritation test (with MTT reduction)	In vitro
	EpiDerm skin irritation test (with MTT reduction)	In vitro
	EpiDerm SIT model (EPI-200)	In vitro
	SkinEthic RHE model	In vitro

51.6 Alternatives to animal testing of chemical warfare agents

Greenfield et al. (2014) report that the US Army Medical Research Institute of Chemical Defense (USAMRICD) has been commissioned with a mission to develop medical countermeasures against exposure to chemical warfare agents as well as against agents of biological origin. Over the years, this organization has reduced the number of animals used in its research protocols by 92%. Based on a report by the US House of Representatives Committee on the Armed Services regarding the use of animals in Department of Defense (DOD) military experiments, initiatives to promote alternatives to reduce, refine, and replace (3Rs) were undertaken in 1992. During this time, while adopting the 3Rs, the DOD also added a fourth R, responsibility. This organization developed a unique concept called management by objective program based on science and technology objectives. One such major objective was to develop reduction, refinement, and

replacement strategies for the use of animals in research. The goal was to develop technologies that would incrementally reduce reliance on animal and human subject research and improve the experimental conditions using animals. This further requires introducing a minimum of one improvement per year in experimental protocols using animals.

The scientists at the USAMRICD have taken advantage of emerging computer and biological technologies in the design of molecular modeling software and in the development and maintenance of cell culture models to meet the animal reduction goals. In addition, scientists, where possible, have adopted the use of less sentient animal species.

As an example, computer modelings of the molecular structure of nerve agents, physiological enzymes, and neurotransmitters are used to predict and eventually determine how these chemical compounds interact at the molecular level. A test compound that inhibits acetylcholinesterase (AChE) aging has also been studied via computer modeling to determine the specific molecular events that occur at the peripheral anionic site of AChE, which subsequently prevents a potent AChE inhibitor, such as the nerve agent sarin, from irreversibly binding to the AChE molecule (Khan et al., 2000). With this knowledge the most likely candidates for chemical intervention in the prevention or treatment of nerve agent exposure can be determined. To this end, multiple cell lines or cell cultures are used in research and have led to a reduction of animal usage in research programs on blistering chemical warfare agents. In efforts to evaluate the effects of blister agents, or vesicants, particularly sulfur mustard, and to develop medical countermeasures against such agents, alternatives to animals have proven particularly useful. Several cell line or culture systems, such as peripheral blood lymphocytes, human epidermal keratinocytes, and the HeLa, a human epithelial tumor line, have been adapted and developed by scientists into valuable models for studying vesicant injury. In addition, studies have used a commercial human skin equivalent model and skin biopsies from the Cooperative Human Tissue Network. The USAMRICD also has developed the technology to process and generate a human epidermal model, which possesses typical structural components of human epidermis in vivo to include hemidesmosomes, anchoring filaments, and elements of a true basement membrane. The use of these alternative models has led especially to a decrease in the number of rodents required for these studies.

The USAMRICD also promotes the use of less sentient or less regulated animal species, for example, the use of *Aplysia californica*, a large naked marine mollusk or gastropod with anterior sensory tentacles, commonly referred to as the sea hare or sea slug. This slug possesses large and discrete neural ganglia and its unique neural anatomy that makes these invertebrate animals an excellent and widely used model for neural transmission and neurotoxin research. Murphy and Glanzman (1997) have described "classical conditioning" based on neurological studies in *Aplysia*. It appears to be mediated, in part, by long-term potentiation due to activation of *N*-methyl-D-aspartate-related receptors. In certain sulfur mustard experimental protocols the USAMRICD has used SKH-1 hairless mice as an appropriate substitute for the hairless guinea pig. The main histological feature of skin lesions produced in a SKH-1 hairless mouse following exposure to sulfur mustard is the formation of microblisters at the dermal−epidermal junction. Similar microblisters also occur in sulfur mustard lesions of hairless guinea pigs. Whereas laboratory mice are not subject to the Animal Welfare Act, provisions for their care and use are contained in the Guide for the Care and Use of Laboratory Animals.

51.7 Animal efficacy rule

The animal efficacy pathway was formed shortly after the terror attacks of 2001, which included a harrowing series of incidents in which spores of anthrax were sent through the US Postal Service, killing several people and sickening many more (www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfcfr/CFRSearch.cfm?CFRPart = 314&showFR = 1&subpartNode = 21:5.0.1.1.4.9).

In response to the attacks, legislators and regulators determined that a regulatory process needed to be established to test the safety and effectiveness of so-called medical countermeasures, while taking into account the extremely dangerous nature of the pathogens against which they would need to protect their subjects. The problem, at its most basic level, was testing a drug product in humans which could potentially kill them, the answer to that question was, rather simply, we do not test in humans for efficacy. Instead, the FDA ultimately established the animal efficacy rule, which is an approval pathway through which manufacturers can apply for conditional approval of a medical countermeasure based on efficacy testing in human analogs, such as pigs or chimpanzees, or other appropriately relevant models. Safety testing is still conducted in humans.

Pyridostigmine bromide is the first drug approved under the "animal efficacy rule" that allows use of animal data for evidence of the drug's effectiveness for certain conditions when the drug cannot be ethically or feasibly tested in humans.

The "animal efficacy rule," which became effective on June 30, 2002, is an important component of the FDA's efforts to make medical countermeasures available to treat or prevent the effects of biological and chemical agents. The "animal efficacy rule" enabled the FDA to approve

pyridostigmine bromide to increase survival following soman poisoning despite the impossibility of ethically conducting human studies on the effectiveness of the drug.

The nerve agent soman causes loss of muscle control and death from respiratory failure. Evidence of the effectiveness of pyridostigmine bromide as a pretreatment for exposure to soman was obtained primarily from studies in monkeys and guinea pigs. This evidence shows that administration of the drug before exposure to soman, together with atropine and pralidoxime given after exposure, increases survival. The FDA believes that, based on the animal evidence of effectiveness, pyridostigmine bromide is likely to benefit humans exposed to soman.

The agency's safety assessment is based on long-term use of pyridostigmine bromide, first approved by the FDA in 1955, to treat a neuromuscular disease called myasthenia gravis. The Department of the Army has submitted data from multiple controlled trials and uncontrolled clinical experience demonstrating pyridostigmine bromide is well-tolerated at the doses intended for military use. The dose used for myasthenia gravis is higher than the dose used for pretreatment to protect against soman.

To use this potentially lifesaving drug correctly, military personnel must carefully follow instructions and use the drug only under specific circumstances. For example, if US troops faced the threat of exposure to soman, they would be given instructions to take pyridostigmine bromide every 8 h prior to the anticipated exposure. Soldiers would be warned that the drug is not effective and should not be taken at the time of, or following, exposure to soman.

The troops are to use the drug in conjunction with other protective measures, including chemical protective masks and battle dress garments. Furthermore, effectiveness depends on the rapid use of the antidotes atropine and pralidoxime and discontinuation of pyridostigmine bromide at the first indication of nerve gas exposure. The Department of Defense plans to provide all military personnel with extensive training, prior to deployment, on the proper use of pyridostigmine bromide, as well as other methods used in the prevention and treatment of nerve agent poisoning.

A leaflet that explains the drug's use, benefits, and side effects will be provided to military personnel when the drug is distributed. The leaflet advises that pyridostigmine bromide should not be used by persons who have a history of bowel or bladder obstruction, or sensitivity to certain medicines used during surgery (like physostigmine). Side effects that may occur include stomach cramps, diarrhea, nausea, frequent urination, headaches, dizziness, shortness of breath, worsening of peptic ulcer, blurred vision, and watery eyes.

The approved dose of pyridostigmine bromide for soman pretreatment is one 30-mg tablet every 8 h. The leaflet states that pyridostigmine should be started at least several hours before exposure to soman and emphasizes that it must be discontinued upon exposure to nerve gas, at which point the antidotes atropine and pralidoxime are given.

During the Gulf War, the FDA had allowed distribution of pyridostigmine bromide under its Investigational New Drug provisions because pretreatment with this drug had the potential to help save lives if nerve agents were used.

Johnson & Johnson's Levaquin (levofloxacin), an antibiotic intended to treat pneumonic plague, became the first product to receive FDA (2012a) approval via the Animal Rule. The product received approval based on testing in African green monkeys infected with pneumonic plague. None of the placebo control group survived contact with the virus, while 94% of the Levaquin group survived.

The FDA's (2012b) approval of raxibacumab marks just the second approval under the Animal Rule, but also the first monoclonal antibody. The drug is also notable in that it is intended to treat inhalation anthrax—the pathogen perhaps most responsible for the formation of the animal efficacy rule.

Raxibacumab was tested in one study involving monkeys and three involving rabbits. As with Levaquin, none of the animals in the control groups survived being infected with inhalation anthrax, while 64% of monkeys and 44% of rabbits in one study treated with raxibacumab survived. The FDA also said GSK's studies showed the drug was an improvement over existing antibiotic therapies, according to the animal studies. It is said that the drug is specifically aimed at defending against another bioterrorism-type event. Although antibiotics are approved to prevent and treat anthrax infection, raxibacumab is the first approved agent that acts by neutralizing the toxins produced by *B. anthracis*.

- *Improvements to the Animal Rule*

  Both approvals come as FDA and other government entities are looking into ways to refine the Animal Rule process and the protections it affords to the human subjects it is intended to protect.

  Members of the Alliance for Biosecurity (Gronvall et al., 2007) have made three recommendations for effective implementation of the Animal Rule.
  - First, the Department of Health and Human Services (HHS), the FDA and other US agencies provide strategic direction about how countermeasures may be used. This will aid development and testing.
  - Second, the FDA, along with the National Institute of Allergy and Infectious Diseases (NIAID), should actively develop scientific consensus on animal models for specific disease threats.
  - Third, the FDA should develop a consistent interpretation of the Rule within the agency.

- Aebersold (2012) reviewed the FDA experience with medical countermeasures under the Animal Rule. The author concludes that even though only a few drugs or biologicals have been approved since the Animal Rule became effective, several investigational drugs have been placed in the National Strategic Stockpile for use as medical countermeasures, if needed.
- The FDA has also clarified suggested issues, one of which is an animal model qualification program. The qualification process is limited to animal models used for product approval under the Animal Rule (www.fda.gov/Drugs/DevelopmentApprovalProcess/DrugDevelopmentToolsQualificationProgram/ucm284078.htm). A qualified model may be used for efficacy testing in development programs for multiple investigational drugs for the same targeted disease or condition. Such animal models are considered to be product-independent (i.e., not linked to a specific drug).

The Animal Rule states that the FDA can rely on the evidence from animal studies to provide substantial evidence of the effectiveness of a drug only when all of the following four criteria, quoted below, are met:

a. There is a reasonably well-understood pathophysiological mechanism of the toxicity of the substance and its prevention or substantial reduction by the product;
b. The effect is demonstrated in more than one animal species expected to react with a response predictive for humans, unless the effect is demonstrated in a single animal species that represents a sufficiently well-characterized animal model for predicting the response in humans;
c. The animal study endpoint is clearly related to the desired benefit in humans, generally the enhancement of survival or prevention of major morbidity; and
d. The data or information on the kinetics and pharmacodynamics of the product or other relevant data or information, in animals and humans, allows selection of an effective dose in humans.

The FDA (2003) approved pyridostigmine bromide for combat use by US military personnel to protect them from the lethal effects of the nerve gas soman (www.fda.gov/Drugs/EmergencyPreparedness/BioterrorismandDrugPreparedness/ucm130342.htm).

Sullivan et al. (2009) have reviewed the usefulness of the Animal Rule in the development and regulatory approval process of Ebola virus. Ebola virus infection is a highly lethal disease for which there are no effective therapeutic or preventive treatments. Several vaccines have provided immune protection in laboratory animals, but because outbreaks occur unpredictably and sporadically, vaccine efficacy cannot be proven in human trials, which is required for traditional regulatory approval. The FDA has introduced the "Animal Rule," to allow laboratory animal data to be used to show efficacy when human trials are not logistically feasible. In this review, the authors describe immune correlates of vaccine protection against Ebola virus in animals. This research provides a basis for bridging the gap from basic research to human vaccine responses in support of the licensing of vaccines through the Animal Rule. Table 51.3 lists a few agents approved using the Animal Rule.

51.8 Human-on-a-chip

Hartung and Zurlo (2012) have discussed various alternative approaches for medical countermeasures to biological and chemical terrorism and warfare. One such approach focuses on the development of a human-on-a-chip, as shown in Fig. 51.10. This involves the combination of different three-dimensional (stem) cell-based organ equivalents combined with microfluidics. The prospects of such approaches, their impact on the field of alternative approaches, and necessary complementary activities are discussed. They emphasize the need to adapt quality assurance measures and experiences from validation while executing such newer approaches.

Similarly, scientists at the Edgewood Chemical Biological Center (ECBC) and academic collaborators are performing research on organoids (small swatches of human tissue) on microchips (www.kurzweilai.net/human-on-a-chip). This research focuses on in vitro human organ constructs such as for the heart, liver, lung, and circulatory system, in communication with each

TABLE 51.3 Agents approved using the "Animal Rule."

	Compound	Company	Purpose
1	Abthrax (Raxibacumab)	Glaxo Smith-Kline (GSK)	Anthrax vaccine
2	Cynokit	Orphan Medical Inc/Merck Sante	Cyanide Poisoning
3	Ciprofloxacin	Bayer	Anthrax
4	Levofloxacin	Janssen Pharmaceuticals	Plague (*Yersinia pestis*)
5	Pyridostigmine bromide	US Army	Soman

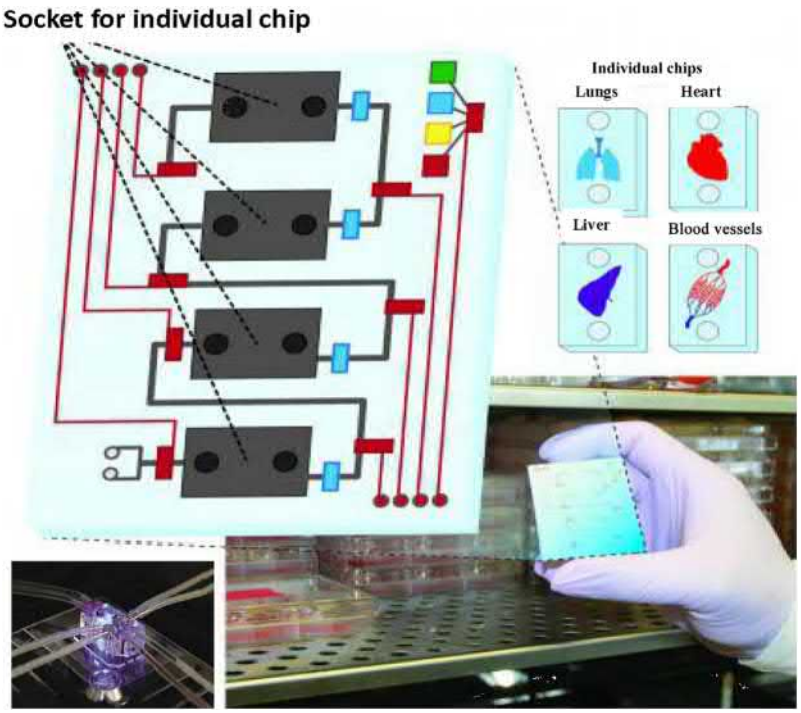

FIGURE 51.10 "Human-on-a-chip" in vitro human organ constructs (for heart, liver, lung, and the circulatory system) in communication with each other used to assess the effectiveness and toxicity of warfare agents that are relevant to humans.

other. The goal is to assess the effectiveness and toxicity of drugs in a way that is relevant to humans and their ability to process these drugs. It is said that "the screening models will be used to assess the efficacy and safety of medical mitigation procedures and countermeasures for the soldier and the nation as a whole."

Each organ-on-a-chip is about the size of a thumb drive and is an "organoid" (a structure that resembles an organ in appearance or function), designed to mimic the properties of an actual human organ. The organoids are created by induced pluripotent stem cells made from adult skin cells. They comprise multiple layers of cells growing on a membrane, connected to each other by microfluidics (tiny microchannels) that copy the function of blood vessels. Their primary purpose is to take the place of animal research. It is proposed that animal tests do not always give the results seen in people. Due to the species-specific differences by which compounds are metabolized, a drug tested on a laboratory rat does not always translate well to a human. In some cases, such as with asthma, no animal testing can mimic the human response. Since human-on-a-chip is made from human cells, it is the next best thing. Human tissue reacts like human tissue.

51.8.1 New predictive models of toxicity

Researchers anticipate that new predictive models of toxicity will result from the more accurate human-on-a-chip testing, saving time and money. This technology is hoped to result in fewer test failures than animal studies. The ECBC houses the only laboratories in the United States that the Chemical Weapons Convention permits to produce chemical warfare agents for testing purposes. It is thought that the ECBC will test the human-on-a-chip against chemical warfare agents to learn more about how the body will respond to agent exposure and explore various treatment options for exposures. For the military, human-on-a-chip research is hoped to save lives.

Labant (2014) points out using in vitro ADME-Tox assays results in more biological data from each experiment. The use of specialized instrumentation such as a single-stage accelerator mass spectrometer (SSAMS) is suggested so trace amounts of metabolites that can be identified and quantitated (Fig. 51.11). Similarly, use of flow cytometry in toxicological testing has truly enhanced the collection of large amounts of data from each experimental units either in vivo or in vitro while reducing animal use (Krishna et al., 1993; Criswell et al., 1998a,b, 2003; Darzynkiewicz et al., 2011; Dertinger et al., 2011; Willjam et al., 1991).

Examples of alternative studies conducted using a variety of warfare agents are briefly listed below. Worek et al. (2007) described the use of highly toxic organophosphorus (OP) warfare nerve agents and underline the necessity for effective medical treatment. Acute OP toxicity is primarily caused by the inhibition of AChE. Reactivators (oximes) of inhibited AChE are a mainstay of treatment. In vitro studies with human tissue have enabled the evaluation of oxime efficacy without animal

FIGURE 51.11 The single-stage accelerator mass spectrometer is a robust and ultrasensitive bioanalytical tool. AMS technology can provide a compound and matrix-independent platform that enables innovative in vitro and in vivo study designs.

experiments and with no need for interspecies extrapolation. Dorandeu et al. (2007) emphasize the use of swine, especially minipigs, based on similarities in a number of interesting biological and physiological characteristics (skin, cardiovascular), as an alternative to other commonly used species such as dogs, macaques, and marmosets. Szinicz et al. (2007) described the development of antidotes against chemical warfare agents as "orphan drugs" given that these poisonings are rare. Computer models are being established to estimate the therapeutic effect of an antidote in various human poisoning scenarios. This approach compensates for the lack of human clinical pharmacodynamic studies given the obvious ethical issues preventing human volunteer studies with these agents. Krishnan et al. (2009) and Reddy et al. (2011a,b) tested a variety of warfare agents in multiple alternative methods including short-term genotoxicity and physiologically based pharmacokinetics modeling of warfare agents, for example, cyclotrimethylenetrinitramine, ethylenediaminedinitrate, diethylenetriaminetrinitrate, and 3-nitro-1,2,4-triazol-5-one.

51.9 Concluding remarks and future directions

Alternatives in animal testing have come a long way in thought and action. Over the years, scientists have continuously improved such methods so that the goals of 3Rs are achieved. For example, the roadmap for the development of alternative (nonanimal) methods for systemic toxicity testing by Basketter et al. (2012) and challenges in developmental neurotoxicity testing in the 21st century versus in vitro opportunities by Smimova et al. (2014) are noteworthy. In recent years, the application of alternatives in testing warfare agents is much appreciated considering the threat of and/or actual terrorist attacks. A variety of such methods have been either validated and/or are being validated. Continued global effort in innovation with reliable assays, instrumentation, and strategies is hoped to produce much anticipated results so one can routinely use such methods in warfare testing and counterterrorism. Regulatory agencies around the globe are working in collaboration with academia and industry, so the stakeholders, the thought, the talk, and the action are on the same page. Meaningful cooperation is sought, as needed, to achieve a common goal of reliable and quality data in our efforts. This kind of collective and collaborative effort and efficient use of resources with funding from multiple bodies, especially the government, will continue to provide impetus in fully achieving the ultimate goal of reducing, refining, and replacing animal use, as applicable, in toxicity and efficacy testing and finding viable alternatives at all times, especially for warfare testing. Going forward, it is believed that with continued innovations in new technologies and instrumentation, ideas and the vision, such as "organ- or organs-on-a-chip" and "human-on-a-chip" as proposed by Lee et al. (2013) and others, would become a reality. Further, with the advancements in science and technology, continued collective efforts are being made by stakeholders in this urgently needed field (PETA, 2019; Mercury News, 2016; Kronman and Moore, 2019). With these advancements, the concerns of excessive use of animals in testing would continue to decrease, yet, quality data be generated with remarkable alternatives.

Chapter 52

Toxicokinetic aspects of nerve agents and vesicants

52.1 Introduction

Despite the long history of chemical warfare agents (CWAs), which were first used in large quantities during World War I, vesicants and nerve agents still represent a commonly perceived threat to military and civilian communities. Therefore, effective medical countermeasures and state-of-the-art medical care are mandatory prerequisites to take the threat of poison attacks seriously. Rising interest in the effective treatment of sulfur mustard, and especially nerve agent poisoning, has led national and governmental authorities to continue programs of medical defense against toxicants. The development and continuous improvement of therapies rely on intensified knowledge of provoked pathophysiological effects, toxicology, and toxicokinetics. The latter is important when understanding the reactivity of poisons in organisms at the molecular level. Awareness of predominant biotransformation and efficient elimination processes is essential for the design of a therapeutic regimen for poisoning. For example, the development of protective scavengers is a current challenge in nerve agent defense research.

The toxicokinetic profile of a CWA in mammalian organisms depends on numerous factors, including the nature of the poison, route of exposure, and differences among species. Sophisticated study design, modern technical and analytical monitoring tools, and reliable data from the literature are indispensable quality criteria that should be met when performing toxicokinetic studies. This chapter is focused on this topic.

We first introduce the reader to typical invasion processes of exogenous poisons. The anatomy of exposed areas of the body is discussed, emphasizing interactions with nerve agents and vesicants invading on similar routes following common absorption principles. Afterward, both classes of CWAs are discussed individually. Organophosphorus (OP) nerve agents are distinguished in terms of their physicochemical properties and toxicity, as well as invasion and distribution processes in vivo, which are relevant to toxicokinetic characteristics. Subsequently, special focus is given to the basics of elimination and biotransformation, describing the phenomena of detoxification and concentration decrease at the molecular level. Enzymatic hydrolysis and binding to proteins and enzymes are discussed in comprehensive detail. A few comments on excretion complete this "journey through the poisoned body." The next several sections of the chapter are dedicated to concentration−time profiles, exemplarily selected for typical routes of nerve agent exposure, followed by short introductions to predictive mathematical toxicokinetic models and to most modern bioanalytical methods that allow poison quantification and identification of biotransformation products.

Vesicants, including sulfur mustard and lewisite, are the subject of the second main part of this chapter. Coherences of invasion and distribution are presented, and the major processes of biotransformation and elimination caused by binding to proteins [and more prominently, to deoxyribonucleic acid (DNA)] are discussed. Finally, we make some comments about current bioanalytical approaches. This chapter provides readers with a comprehensive overview of the toxicokinetics of OP nerve agents and vesicants.

52.2 Overview of the invasion processes of CWAs

Toxicokinetics is a subfield of toxicology that studies how, how fast, and to what extent toxicants are absorbed by, distributed in, biotransformed by, and eliminated from the bodies of living organisms. These processes depend

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00052-0

on multifaceted conditions, such as the species and gender of intoxicated organisms, the physicochemical properties of the toxicant (e.g., hydrophobicity, charge, and molecular weight), their dose and concentration, and their chemical reactivity and stability. Furthermore, the route of exposure is a crucial parameter affecting the effectiveness of incorporation and time for distribution within an organism.

Elaboration of toxicokinetic data of CWAs is essential for designing effective antidotes, improving first aid, and optimizing the therapeutic regimen and medical care. It has to be considered that data obtained from in vitro or in vivo animal studies need careful extrapolation to humans, which at least requires sophisticated mathematical models to consider basic interspecies differences (Langenberg et al., 1997; Sweeney et al., 2006; Levy et al., 2007; Worek et al., 2007).

For controlled toxicological animal studies, the poison is most often administered subcutaneously (s.c.), intravenously (i.v.), or intramuscularly (i.m.), whereas more realistic scenarios of CWA uptake are percutaneous (p.c.) through unprotected skin, by inhalation of aerosols and vapor, or by ingestion (p.o.) of contaminated food and drink. Such exposure events that lead to poison uptake and its distribution in an organism are part of the invasion process, whereas all steps causing a decrease in poison (e.g., elimination by degradation, biotransformation, and excretion) are part of the evasion process. For a better understanding of the pathophysiology and toxicokinetics of CWAs, an overview of the routes of poison incorporation is given in the next section, with a special emphasis on OP nerve agents and vesicants.

52.2.1 Percutaneous uptake by contact with skin

The total skin surface of an adult human is approximately 1.8 m^2, which is very small when compared to the adsorptive surface of the lungs (100 m^2) and the gastrointestinal tract (GIT, 200 m^2; Marquardt et al., 1999). The primary function of the skin is to protect an organism against exogenous compounds present in the external environment. Nevertheless, percutaneous uptake is the predominant route of poisoning by nonvolatile and rather lipophilic agents [e.g., *O*-ethyl *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate (VX)], which exhibits low vapor pressure, thus making respiratory incorporation very unlikely except for the inhalation of aerosols (Czerwinski et al., 2006). In the case of vesicant agents, such as sulfur mustard and lewisite, the skin is both a target organ, susceptible to severe local effects, and a pathway for absorption of the agent, leading to its distribution and subsequent systemic effects. The protective skin architecture is provided by a sophisticated and effective barrier built of two main components: the outer epidermis and the underlying inner dermis.

52.2.1.1 Epidermis

The epidermis is composed of various consecutive complex layers, including the stratum corneum (horny layer), stratum lucidum (clear layer), stratum granulosum (granular layer), and stratum germinativum (germinative layer), which itself is subdivided into two parts: stratum spinosum (spinous or prickle layer) and stratum basale (basal layer) (Marquardt et al., 1999). For a general overview of percutaneous poison uptake, we will now restrict the introduction to the horny and germinative layers, which are in this sense the most significant epidermal strata.

The stratum corneum is the upper stratum of the epidermis. It consists of several avascular, stratified cellular layers of dead keratinocytes characterized by a very low water content (5%−10%), thus making the surface hydrophobic and reducing its permeability for polar compounds. This layer, which exhibits the character of a multilayer lipid membrane, is the major barrier hindering hydrophilic substances from invading an organism. Penetration through the horny layer is most often a passive diffusion-controlled process following Fick's law in a good approximation. Because of their lipophilic nature, liquid nerve agents and vesicants can readily penetrate the horny layer, and absorption of liquids is much more effective than that of their corresponding vapors (Blank et al., 1957). VX and SM were shown to form a reservoir in the skin, enabling continuous delayed release of the poison (Hattersley et al., 2008; Rolland et al., 2013). Accordingly, while in contact with the skin barrier nerve agents might also react with skin proteins, thereby forming adducts and detoxifying the agent, as shown for human callus reacting with VX in vitro (Verstappen et al., 2012). To estimate the capability of nerve agents for skin penetration the octanol:water partition coefficient (listed as dimensionless log *P*; see Table 52.1) can be used, which correlates to the lipophilicity of the agent (Czerwinski et al., 1998, 2006). This parameter can also be used to predict the distribution of OP agents in other tissues and blood (Langenberg et al., 1997; Sweeney et al., 2006).

Skin permeation velocity of toxic substances increases with (1) decreasing molecular weight, (2) increasing lipophilicity, (3) increasing area of contaminated skin, and (4) decreasing thickness of contaminated horny layer. The thickness of the stratum corneum varies depending on the area of the body and species. Heavily strained areas (e.g., the sole of the foot, palm of the hand, and insides of the fingers) are protected by a 400−600-μm horny layer in humans, whereas the arms, legs, and body are covered by a barrier of 8−15 μm in thickness. Since the first

incidents of chemical warfare in World War I, it was observed that skin areas with a very thin horny layer, in particular the axillae and the scrotum, were most susceptible to the effects of sulfur mustard. Effects in these regions, even though they were rarely exposed to the liquid agent, were severe.

Considering the thickness and structural composition of skin (e.g., the diameter and density of hair follicles, as well as the number of cell layers) is essential for choosing appropriate in vitro models for skin penetration. Pig skin, exhibiting a stratum corneum thickness in the ear of 8.6–28 μm, is similar to human abdominal skin (5.5–40 μm), so it offers a good model to study the agent's permeation as recently shown for VX (Vallet et al., 2008). The best model for p.c. in vivo exposure studies is thought to be the pig after inner ear-skin application of the agent (Chilcott et al., 2003). In contrast to persistent VX, the major fraction (98%) of a small amount of liquid sarin, which was applied p.c. to six human subjects, evaporated very rapidly without passing the skin because of its high volatility (Marrs et al., 2007). In the presence of organic carrier solutes, skin penetration may be enhanced, as shown for VX dissolved in isopropanol, thus doubling the permeation velocity for animal and human skin in vitro (Dalton et al., 2006a,b). In contrast, cooling of exposed skin regions was shown to delay entry of the agent into the circulation, thus representing an optional support for the treatment of cutaneous nerve agent poisoning (Mikler et al., 2011). At the least, experimental conditions should also consider that moisture, heat, and abrasions force the transfer and uptake of permeable CWAs (Blank et al., 1957).

The germinative layer, located under the stratum corneum, consists of living keratinocytes that are responsible for the regeneration and proliferation of skin. It exhibits the highest biotransformation activity of all strata toward endogenous and exogenous substances initiating binding to carboxylesterases (CaE or CarbE). Nevertheless, sorption to cutaneous tissue may form a depot, as demonstrated for sarin (Fredriksson, 1958; Satoh and Hosokawa, 2006), which explains the delayed local fasciculation of muscles observed after s.c. administration of nerve agents (Czerwinski et al., 2006).

52.2.1.2 Dermis

The dermis (corium) consists of connective vascularized tissue composed of collagen, elastic and reticular fibers anchoring sweat and sebaceous glands, and hair follicles. Capillaries pervading the dermis and hypodermis (subcutis, located beneath the dermis) allow systemic distribution of toxic compounds once they have passed the epidermis. Therefore, percutaneously incorporated poison may be directly transported by circulation to any compartment of an organism, or it may be temporarily retained within the skin layers. In addition, it might penetrate with first-order kinetics into subcutaneous tissues and muscles, thus creating a poison depot for delayed release (Wolthuis et al., 1981; Chilcott et al., 2005). If nerve agents are kept in fat tissue, degradation by biotransformation appears rather unlikely, thus maintaining an active release system (Sweeney et al., 2006). Correspondingly, Van der Schans et al. (2003) reported that it took more than 3 h to reach a maximum concentration in blood of lipophilic VX after

percutaneous administration of $1 \times LD_{50}$ to hairless guinea pigs (see Section 52.38).

52.2.2 Respiratory uptake by inhalation

52.2.2.1 Airways and absorption

Gaseous poison or aerosols of toxic substances are incorporated following inhalation and contact with the respiratory tract. This appears to be the predominant route of poison intake for volatile G-type nerve agents (e.g., tabun, sarin, and soman) exhibiting relatively high vapor pressure (Table 52.1). However, uptake by inhalation can also be of significance for nonvolatile agents when they are dispersed as an aerosol. The respiratory tract is composed of three main compartments, distinguishable by the areas and organs involved in the breathing process: (1) the extrathoracic or nasopharyngeal compartment, comprising the mouth, nose, and throat (pharynx); (2) the tracheobronchial compartment, containing the voice box (larynx), windpipe (trachea), and right and left bronchi; and (3) the alveolar or pulmonary compartment of the lung, which includes the bronchioles connecting the bronchi with the lobes of the lung and alveoli. The sacs and cavities of the alveoli allow diffusion-controlled oxygen and carbon dioxide exchange in the blood of pulmonary capillaries (blood−air barrier). This diffusion process follows Fick's law, whereupon the diffusion layer exhibits a thickness of 0.4−2.5 μm composed of surfactant and alveolocapillary membranes. The lung of a healthy adult possesses 300−400 million alveoli spread over a surface of approximately 100 m^2 (Marquardt et al., 1999).

Depending on the physicochemical nature of the toxic gas or aerosol, absorption will take place at different areas of the respiratory tract. Apart from the chemical properties, the size of particles and aerosols will also affect the targeted area. Materials with diameters less than 2 μm will reach the alveoli, whereas larger ones (about 20 μm in diameter) are retained in the upper respiratory areas of the throat and bronchi, preventing gas exchange in the lung.

52.2.2.2 Absorption in the upper respiratory tract

In contrast to highly lipophilic compounds, hydrophilic toxicants, characterized by higher water solubility (e.g., hydrogen chloride and fluorine), are primarily adsorbed by the wet mucosa membranes of the throat and trachea in the upper respiratory tract. This is also the primary area for G agent first-order absorption according to higher water solubility (Sweeney et al., 2006; Marrs et al., 2007). Early studies have shown that 80%−90% of inhaled sarin was readily absorbed by humans when exposed to concentrations ranging from 7 to 43 mg min/m^3 (Oberst et al., 1959, 1968). Slightly lower rates (approximately 70%) were obtained for sarin applied to guinea pigs, dogs, and monkeys (Benschop and de Jong, 2001). More aggressive and reactive agents (e.g., vesicants and pulmonary agents) may cause harm by chemical burns, provoking time-delayed inflammation and scarring in these areas. Langenberg et al. (1998b) found significant effects of sulfur mustard in the upper respiratory tract of guinea pigs, caused by a large fraction of inhaled agent.

The nasal system of guinea pigs is more complex than that of other mammalian species, including humans. In those species, the fraction of agent absorbed or deposited in the upper respiratory system may be smaller. Consequently, the middle and lower respiratory systems are likely to be exposed to a larger amount of the agent.

52.2.2.3 Absorption in the middle respiratory tract

Toxic agents with medium water solubility (e.g., chlorine and sulfur dioxide) reach farther into the middle respiratory tract, being absorbed in the bronchi and its junctions. As a result, elevated excretion of mucus, coughing, and bronchoconstriction will lead to heavy dyspnea. The respiratory tube system from the nose to the bronchioles is lined with ciliated epithelium, allowing transportation of the mucous layer produced by cells of the bronchial system from the lung into the oral cavity. This mechanism, which may be supported by coughing, allows the binding and removal of dust particles, thus protecting the alveoli from deterioration. Chemosensory transient receptor potential (TRP) channels play an important role in this context (Dietrich et al., 2017). Chemosensory TRP channels can be activated by a plethora of reactive chemicals including CWAs (Steinritz et al., 2016; Bessac and Jordt, 2010). Especially TRPA1 and TRPV1 channels were found to be essentially involved in airway chemosensation and reflex control (Bessac and Jordt, 2008). However, once the mucus has reached the oral cavity, spontaneous swallowing might transport poison into the digestive tract of the stomach and gut (i.e., the GIT).

It is the middle respiratory tract that apparently is the most significant target in the case of respiratory exposure to sulfur mustard. Local effects, such as the formation of pseudomembranes which result from cellular debris and a fibrin-rich exudate, may both be life-threatening in the acute phase of illness after poisoning and cause long-term disability (White et al., 2016). The systemic absorption from the middle respiratory tract has never been investigated separately. However, findings from Langenberg's guinea pig model (Langenberg et al., 1998b) suggest that the largest part of inhaled sulfur mustard is deposited in that particular area.

52.2.2.4 Absorption in the alveoli

Several toxic compounds, particularly gases of low water solubility or increased lipophilicity (e.g., carbon monoxide, hydrocyanic acid, nitrogen oxides, phosgene, and further inorganic and organic irritants) reach the alveoli and are absorbed by blood. Aggressive and reactive compounds that are inhaled may damage the epithelial cells of the alveoli, causing the liberation of edema fluid, which fatally prolongs the diffusion layer and minimizes the permeability for oxygen and carbon dioxide, finally leading to unconsciousness or death by asphyxia (toxic lung edema). Only very few hints exist for OP-induced lung edema following a yet-unraveled mechanism of action (Lainee et al., 1991; Delaunois et al., 1992; Niven and Roop, 2004). Similarly, in the case of sulfur mustard exposure, the alveoli are only of minor importance in terms of target organ for both local effects and systemic absorption (Langenberg et al., 1998b).

52.2.2.5 Nose-only exposure model for controlled respiratory uptake in animal studies in vivo

To elucidate the velocity of nerve agent absorption via the respiratory tract, which may take seconds to hours, Langenberg et al. (1998a) designed an apparatus that challenged guinea pigs by nose-only exposure with a constant stream of nerve agent vapor in air held for several minutes. As guinea pigs were not ventilated, artificially sublethal doses of soman and sarin (0.4−0.8 LCt_{50}) were applied, thus enabling the affected respiratory frequency and minute volume to be monitored. A typical concentration−time profile detected for C(−)P(+)-soman after administration of C(±)P(±)-soman is characterized by a discontinuous curvature reflecting concentration increase during absorption and concentration decrease by elimination (see the section "Respiratory uptake (nose-only model)," later in this chapter). For more detailed technical data on the nose-only apparatus, see Langenberg et al. (1998a,b) and Benschop and de Jong (2001). The same researchers also used this apparatus in subsequent experiments to investigate the respiratory uptake of vesicant agents, results of which are discussed in Section 52.39.

52.2.3 Gastrointestinal uptake by ingestion

When an animal drinks poisoned liquids or ingests contaminated food, toxicants will be incorporated and directly transferred from the mouth, through the gullet (esophagus), and into the stomach and bowels (intestine) representing the GIT, where transfer into the circulation occurs. The physiological function of the digestive tract includes intake, breakdown, transport, and digestion of food and creation of waste (excrement). Food ingredients, as well as toxicants and their digested (biotransformed) forms, are either absorbed through the walls of the intestine and enter circulation or are eliminated in feces. The surface of the small intestine of an adult human covers more than 200 m^2 and is made up of 4−5 million tiny, fingerlike projections (villi and microvilli) covering the surface of the mucous membrane. In contrast, the resorbing areas of the large intestine (0.5−1 m^2), stomach (0.1−0.2 m^2), rectum (0.04−0.07 m^2), and oral cavity (0.02 m^2) are explicitly smaller due to lack of villi; therefore, they are of minor importance for poison uptake. Uptake by diffusion through lipid layers (hydrophobic molecules) and pores (small hydrophilic molecules) of the intestinal mucosa (following Fick's law) are the most common processes. Nevertheless, facilitated diffusion and active transport, based on affinity binding of the toxicant to carrier molecules, might also occur (Marquardt et al., 1999). The processes of pinocytosis and phagocytosis are unlikely with small CWAs. Following intestinal uptake into the circulation, toxicants are directly transported to the liver, where further biotransformation by cytochrome P450 enzymes may happen. This is of essential relevance for toxification of OP pesticides, including parathion, chlorpyrifos, diazinon, and dimethoate, which are transferred into their more toxic oxon derivatives (Butler and Murray, 1997; Furlong, 2007). The liver and intestine are supposed to play very important roles in the elimination of free soman, as deduced from rabbit studies at high soman dosing (Li et al., 2002).

In contrast, for sarin, it has been shown that the kidney is more important for detoxification than the liver (Little et al., 1986). However, only very limited research efforts have been undertaken to characterize this route of poison uptake for nerve agents (Sim et al., 1971; Sidell and Groff, 1974). Very high lethal oral doses were reported for tabun (rabbit: 16,300 μg/kg; rat: 3700 μg/kg; dog: 200 μg/kg) and sarin (rat: 550 μg/kg), indicating extensive hydrolysis in the GIT (Marrs et al., 2007). Very few investigations of the toxicokinetics of vesicants after ingestion have been conducted. Nevertheless, this route of exposure is supposed to result in significant systemic absorption of an agent. The rationale behind this apparent "blind spot" of toxicokinetic investigation might be the rarity of gastrointestinal exposure during conditions of military operations. Moreover, should a GIT exposure occur, the local, rather than the systemic, effects would be life-threatening. See Section 52.17 for an in-depth discussion. In contrast, ample work has been done with OP pesticides to address the troubling statistics of more than 500,000 deaths per year worldwide caused by accidental and suicidal ingestion (Eddleston et al., 2005, 2008a,b).

52.2.4 Uptake by intravenous injection

Intravenous uptake of CWAs is highly unlikely for realistic exposure scenarios, except perhaps for the contamination of open and bleeding wounds. Nevertheless, numerous scientific studies investigating toxicity and therapeutic treatment of CWAs have made use of this route of administration. The rationale behind this design is to constitute a defined amount of poison in blood, which is immediately systemically distributed by the circulation to the target compartments under conditions of 100% bioavailability. Therefore, i.v. studies are undoubtedly relevant to elaborate systemic toxicity and to characterize the impact on the whole organism. It was shown that sarin was distributed in the central nervous system (CNS) within 20−30 s after i.v. administration to mice (Waser and Streichenberg, 1988). Therefore, poison acts without delayed uptake caused by diffusion or permeation through skin, tissue, and organs, which would increase the extent of degradation and hydrolysis by biotransformation. The latter processes reduce the amount of toxic agents and hamper making a direct correlation to poison concentrations in blood. As demonstrated by Van der Schans et al. (2003) only 2.5% bioavailability was observed in guinea pigs, resulting from a 7-h permeation period after percutaneous administration of VX.

As outlined in previous sections, the amount of incorporated poison and its fraction interacting with target molecules to induce more or less specific toxicological effects may vary drastically, even under controlled conditions of administration. However, monitoring of quantitative concentration−time profiles of the original poison and its biotransformation products is needed to elucidate the kinetic behavior and to unravel pathophysiological mechanisms. Due to the broad range of such essential variations causing a number of uncertainties, many in vivo and in vitro studies have been performed during the last 30 years of sophisticated research on protection against OP compounds (OPCs) and blister agents. The following sections summarize the most important consolidated findings underlining the current status of toxicokinetics of the most prominent CWAs: nerve agents and vesicants.

52.3 Nerve agents

52.3.1 OPCs as nerve agents

For important background information addressing the history, synthesis, basic chemical data, decontamination, toxicity, military use, and political relevance of nerve agents, we refer readers to a number of textbooks, reports, and monographs that go beyond the scope of this toxicokinetic contribution (e.g., Koelle et al., 1963; Franke, 1977; Munro et al., 1999; Augerson, 2000; Committee on Gulf War and Health, 2004; Langford, 2004; Marrs et al., 2007; Richardt and Blum, 2008). Nevertheless, in this section, selected chemical and physicochemical properties are considered that are of importance for understanding the toxicokinetic behavior of OPCs.

Well-known representatives of nerve agents are cyclosarin (*o*-cyclohexyl methylphosphonofluoridate; GF), sarin (isopropyl methylphosphonofluoridate; GB), soman (1,2,2-trimethylpropyl methylphosphonofluoridate; GD), tabun (ethyl dimethylphosphoramidocyanidate; GA), VX (*S*-2-diisopropylaminoethyl *o*-ethyl methylphosphonothioate), and Russian VX [*o*-isobutyl *S*-(*N*,*N*-diethylaminoethyl)methyl phosphonothioate; RVX, VR] (see Table 52.1 and Fig. 52.1). Apart from these substances, a large number of additional OP toxicants with high structural similarity have been seen on experimental and laboratory levels, especially when pesticides for civilian use are included. However, the abovementioned compounds are the most prominent nerve agents in the literature.

This fact is obviously due to political instructions for national security and defense programs that consider historical development, large-scale production, and intended military use and focus on agents that most likely would be relevant chemical threats. Soman, for example, was produced in large amounts during the Cold War by the Soviet Union in particular, thus menacing the Western world. Therefore, toxicokinetic studies on nerve agents are mainly restricted to sarin, soman, and VX. In addition, following United Nations (UN) inspections in Iraq in the 1990s, which revealed the weaponizing of cyclosarin, some studies on the toxicokinetic properties of cyclosarin were also conducted.

52.3.2 Physicochemical properties

If they are present in a highly pure state, all nerve agents are colorless and odorless liquids characterized by different vapor pressures, thus causing either very rapid evaporation with increased inhalational risk (e.g., G-type agents) or relatively high resistance abating p.c. absorption (e.g., V-type agents and cyclosarin; see Table 52.1). Therefore, visual or sensory recognition of these substances by smell or taste is nearly impossible.

52.3.2.1 Water solubility

Water solubility is a crucial parameter affecting the toxicological potency of a compound. Solubility of nonhydrolyzed nerve agents is fundamentally determined by the hydrophobicity and extent of organic substituents. On one hand, hydrophilic compounds exhibiting great water solubility are less effectively absorbed by skin in the absence of organic carrier solutes, but they are easily distributed once they have reached aqueous biological fluids.

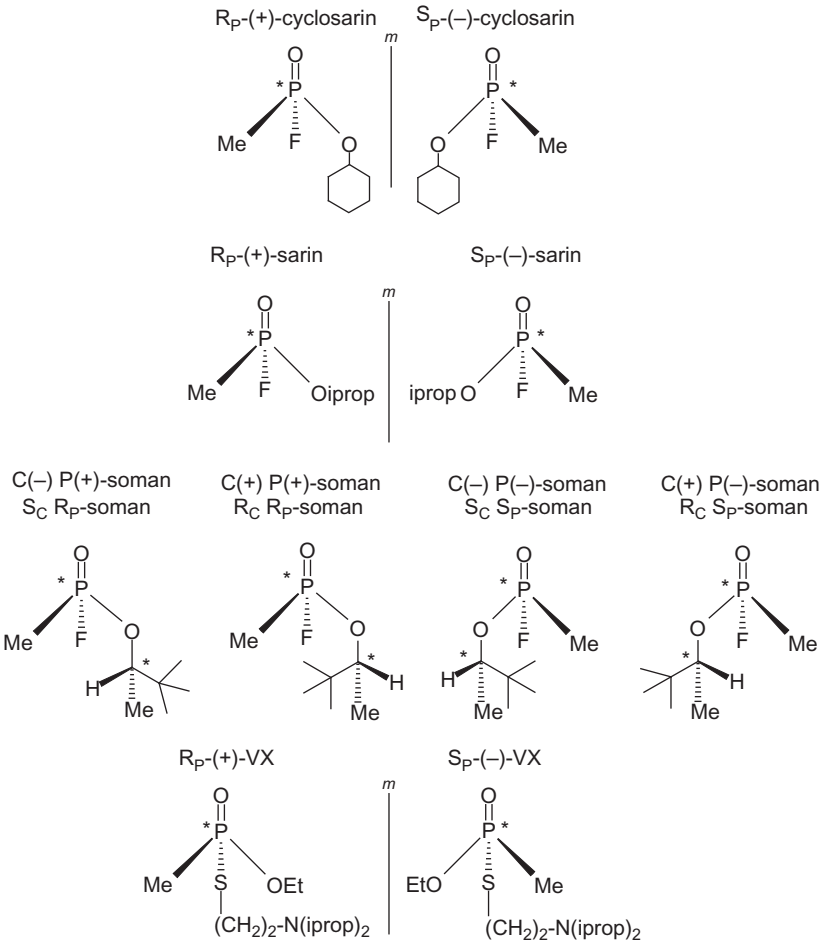

FIGURE 52.1 Structures of stereoisomeric OP nerve agents. Chirality was assigned according to the rules of Cahn, Ingold, and Prelog (Cahn et al., 1966; Prelog and Helmchen, 1982) considering oxygen of the PO bond with minor priority compared to alkoxy substituents (Quin, 2000). Empirically found opticity is, according to Benschop and de Jong (1988), correlated to compounds obtained from stereoselective synthesis (Li et al., 2001). Chirality emerged as a crucial parameter for toxicokinetic properties. S_P-isomers (P(−)-forms) of illustrated G agents (cyclosarin, GF; sarin, GB; soman, GD) are characterized by higher toxicity combined with higher stability against hydrolyzing mammalian wild-type enzymes as their corresponding RP-isomers, P(+)-forms (Table 52.3).

Therefore, skin penetration of less lipophilic sarin (miscible in water) is not favored, whereas nerve agents of significant lipophilicity with low water solubility (VX: 30 g/L; GF: 3.7 g/L; see Table 52.1) penetrate skin and other hydrophobic biological membranes and mucosa unhampered (Winkenwerder, 2002). Nerve agent transfer into blood and its systemic distribution are limited, potentially provoking accumulation in fatty tissue. Nevertheless, noncovalent binding to carrier proteins of circulation (e.g., γ-globulin and albumin) may support systemic transport of not very water-soluble compounds in blood, as would be expected for VX (Vallet et al., 2008), and as commonly known for endogenous fatty acids or exogenous drugs (John and Schlegel, 1999; Li et al., 2007; Weiss et al., 2008). Table 52.1 denotes corresponding measures of solubility in water.

52.3.2.2 Octanol:water partition coefficient

The lipophilicity of nerve agents and their expected partition behavior are characterized by the octanol:water partition coefficient (log *P*). This parameter is often used as an estimate for the tendency of the toxicant to bioaccumulate in an organism. Furthermore, it is helpful to predict the penetration of skin and distribution between tissue and blood (Poulin and Krishnan, 1995; Czerwinski et al., 1998, 2006). The log *P* for the more polar sarin was determined to be 0.30, whereas this measure for lipophilic VX is 2.09, which documents a 50-fold higher lipid solubility. However, this ratio might be slightly different when considering the inconsistency of data from the literature. Table 52.1 summarizes the log *P* values of selected nerve agents.

52.3.2.3 Hydrolysis

In aqueous media, nerve agents undergo nonenzymatic hydrolysis, which is accelerated by very acidic and basic pH values (Franke, 1977). Hydrolysis primarily substitutes the reactive leaving group of the OPC for a hydroxy group, thus making the molecule more soluble (Fig. 52.2). After cleavage of diisopropyl ethyl mercaptoamine (DESH) from the phosphorus atom of VX (Fig. 52.1), the remaining ethyl methylphosphonic acid exhibits a water solubility of 180 g/L, which is six times higher than VX itself (Munro et al., 1999). Depending on pH, the

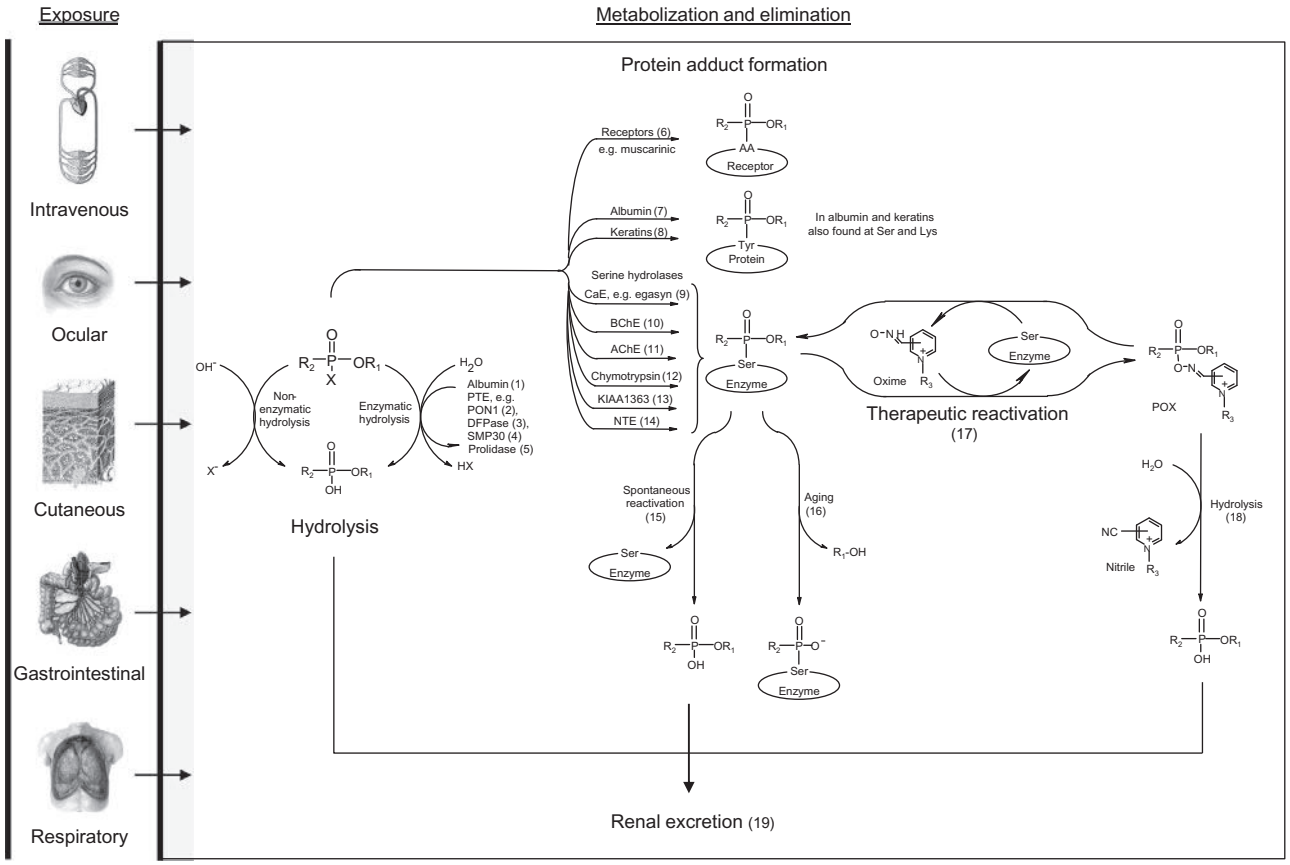

FIGURE 52.2 Elemental steps of toxicokinetics of OP nerve agents in mammalian organisms. OP nerve agents are incorporated following different routes of exposure. Whereas G agents are predominantly taken up by the respiratory tract via inhalation, V agents mainly follow percutaneous invasion. Once the poison has reached the circulation, it is distributed systemically, causing poisoning of the CNS and PNS by inhibition of AChE. Several processes of biotransformation (e.g., enzymatic and nonenzymatic hydrolysis) and elimination (e.g., formation of adducts by binding to proteins and multiple serine esterases, followed by marginal spontaneous reactivation and more prominent aging) reduce the amount of circulating poison. Therapeutic causal intervention by oximes reactivates cholinesterases under liberation of a toxic phosphoryloxime intermediate (POX), which itself undergoes immediate hydrolysis. Hydrolyzed nerve agents emanating from these chemical conversions are excreted by the kidney more prominently than by liver. AA, amino acid; AChE, acetylcholinesterase; BChE, butyrylcholinesterase; CarbE, carboxylesterase; DFPase, diisopropyl fluorophosphatase; KIAA1363, acetyl monoalkylglycerol ether hydrolase; Lys, lysine; NTE, neuropathy target esterase; PON1, paraoxonase 1; POX, phosphoryloxime; PTE, phosphotriesterases; $R_{1/2}$, organic substituents, e.g., methyl, cyclohexyl, isopropyl; Ser, serine; SMP30, senescence marker protein 30; Tyr, tyrosine; X, nucleophilic leaving group; e.g., F, CN, (CH2)2-N(iprop)2. (1) Vilanova and Sogorb (1999); Manoharan and Boopathy (2006); Li et al. (2007); (2) Billecke et al. (2000); Amitai et al. (2006); Furlong (2007); (3) Blum et al. (2006); Nordgren et al. (1984); (4) Kondo et al. (2004); (5) diTargiani et al. (2010); (6) Silveira et al. (1990); (7) Black et al. (1999); Li et al. (2007, 2008); Grigoryan et al. (2009); John et al. (2010); (8) Grigoryan et al. (2009); Schopfer et al. (2010); Verstappen et al. (2012); (9) Maxwell and Brecht (2001); Satoh et al. (2002); Fujikawa et al. (2005); (10) Bartling et al. (2007); Kolarich et al. (2008); (11) Benschop and de Jong (2001); Aurbek et al. (2006); (12) Casida and Quistad (2005); (13) Nomura et al. (2008); (14) Gordon et al. (1983); Costa (2006); (15) Worek et al. (2005); Aurbek et al. (2006); (16) Worek et al. (1998, 2005); Bartling et al. (2007); (17) Sidell and Groff (1974); Kiderlen et al. (2005); Aurbek et al. (2006); Bartling et al. (2007); (18) Kiderlen et al. (2005); (19) Waser and Streichenberg (1988); Shih et al. (1994); Minami et al. (1997).

alkoxy-group of VX might also be cleaved from the phosphorus atom. Hydrolysis of the reactive electronegative leaving group, which is essential for primary toxicity [inhibition of acetylcholinesterase (AChE)], deactivates the molecule, reducing its toxicity dramatically. The major hydrolysis product of sarin is isopropyl methylphosphonic acid (IMPA), which is about 10,000 times less toxic than its precursor when administered orally to rats (Munro et al., 1999). IMPA is also the most prominent biotransformation product of sarin produced in vivo (Little et al., 1986). The dramatically increased rate of hydrolysis under acidic conditions is presumably the most important reason for extraordinarily high lethal dose (LD_{50}) values found in laboratory animals after oral administration of nerve agents (Marrs et al., 2007). Table 52.1 summarizes hydrolysis rates expressed as periods of half-change in aqueous solutions of nerve agents near neutral pH.

52.3.2.4 Chirality

Typical production batches of nerve agents formerly intended for military use are mixtures of enantiomers obtained from nonchiral synthesis (Fig. 52.1). Sarin, cyclosarin, tabun, and VX consist of mixtures of two enantiomers; each of which differs in the chirality at the central phosphorus atom. This enables the rotation of linearly polarized light clockwise [P(+)-enantiomers] or anticlockwise [P(−)-enantiomers; see Fig. 52.1]. In contrast, chirality of soman appears more complex based on two chiral centers, which reside at the phosphorus atom, P(+) and P(−), and additionally in the pinacolyl moiety, C(+) and C(−). Hence, soman occurs in four stereoisomeric conformations as two pairs of diastereomers: P(+)C(+), P(+)C(−), P(−)C(+), and P(−)C(−); (Fig. 52.1). To denominate stereoisomers of nerve agents, the experimentally found rotational direction of light is typically provided, whereas assignments according to the R and S nomenclature are rare. Therefore, Fig. 52.1 summarizes both absolute configurations and related optical activities of the most common nerve agents. Chirality was assigned according to the established rules of Cahn, Ingold, and Prelog (Cahn et al., 1966; Prelog and Helmchen, 1982), considering oxygen of the P═O bond with minor priority to alkoxy substituents (Quin, 2000). Empirically found opticity is, according to Benschop and de Jong (1988), correlated to compounds obtained from stereoselective synthesis (Li et al., 2001).

It is well known that chirality of OP nerve agents causes significantly differing toxicological properties determining poison elimination by hydrolysis and kinetics of enzyme inhibition (Benschop and de Jong, 1988). Therefore, special attention should be paid to the corresponding stereoisomers when elaborating toxicokinetics. A number of studies took care of these conformational differences by administration of pure stereoisomers (Benschop and de Jong, 2001) or by enantioselective detection and quantification of poison molecules (Spruit et al., 2001; Li et al., 2003a,b; Van der Schans et al., 2003; Reiter et al., 2007, 2008, 2011; Yeung et al., 2007; Tenberken et al., 2010). Different techniques were established to produce pure (or at least enriched) enantiomers of nerve agents, for example, (1) synthesis by use of chiral adducts subjected to reactions of defined stereochemical outcome; (2) fractional crystallization, chromatographic separation, and isolation of mixed enantiomers; (3) stereoselective binding to serine esterases (e.g., α-chymotrypsin); and (4) stereoselective enzymatic hydrolysis by phosphorylphosphatases (chemoenzymatic preparation; Benschop and de Jong, 2001; Li et al., 2001).

Stereoselective enzymatic degradation of nerve agents is also a current issue in developing both novel noncorrosive decontamination systems and new therapeutics using recombinant mutated enzymes optimized for fast and exhaustive hydrolysis of most toxic isomers (Tsugawa et al., 2000; Li et al., 2001; Ghanem and Raushel, 2005; Furlong, 2007; Blum and Richardt, 2008).

52.3.3 Toxicity

OPCs, especially nerve agents, represent a class of highly reactive compounds undergoing nucleophilic substitution of their leaving group [e.g., F, CN, S-$(CH_2)_2$-N(iprop)$_2$; Fig. 52.1] by nearly irreversible coupling to nucleophiles (e.g., strongly polarized hydroxyl groups in amino acid side chains or OH functions in aqueous media; Fig. 52.2). Toxic effects are mainly due to derivatized enzymes which were subjected to this reaction.

Although most toxicological studies were performed as animal studies, some data about humans exist, which were obtained from military volunteers exposed to nonlethal doses of sarin (NRC, 1982, 1985), accidentally intoxicated industrial workers (Duffy et al., 1979), and poisoned civilians affected by terrorist attacks in Tokyo in 1995, Matsumoto in 1994, and Osaka (Morita et al., 1995; Okumura et al., 1996; Tsuchihashi et al., 1998). For detailed data on these events, see the reports of the Committee on Health Effects Associated with Exposures During the Gulf War (2000).

52.3.4 Inhibition of AChE

Phosphorylation of the OH moiety of serine residue, being part of the catalytic triad in the esteratic center of AChE, represents pathophysiologically the most important reaction, resulting in enzyme deactivation. Inhibition of AChE was proved to be the predominant major reaction in vivo, which causes death within minutes in mammals, insects, and other species depending on acetylcholine (ACh)-mediated signal transduction. Maxwell et al. (2006) found compelling arguments that inhibition of AChE by nerve agents is the primary mechanism of OP toxicity. They correlated the median LD_{50} of highly toxic nerve agents determined from rats after s.c. administration with the corresponding bimolecular rate constants of AChE inhibition determined in vitro, using a probit model for interpreting the mathematical relationship.

AChE is present in the nervous system, where it is most important for toxic effects, and on the surface of red blood cells (RBCs), where its biological function is still unknown. Inactivation of AChE hinders the degradation of the neurotransmitter ACh in the synaptic cleft, which is of major importance for regulation of presynaptic and especially postsynaptic effects. Rising ACh concentrations cause permanent overstimulation of muscarinic (subtypes m1−m5) and nicotinic receptors of effector cells, leading to cholinergic crisis and, ultimately, death. Clinical

symptoms of poison-induced AChE inhibition include (1) muscarinic effects (e.g., miosis, bradycardia, increased secretion of urine, saliva, tears and sweat, bronchoconstriction, and increased gastrointestinal motility); as well as (2) nicotinic effects (e.g., muscular weakness, twitching and tremors, elevated blood pressure, and tachycardia); and (3) central effects (e.g., headache, impaired memory and alertness, anxiety, insomnia, and, most important, respiratory depression and paralysis). Death is caused by respiratory failure, as elicited by flaccid paralysis of respiratory muscles, and bronchoconstriction, together with increased bronchial secretion and central respiratory depression (Costa, 2006). Liquids or vapors from these agents can cause death within minutes after exposure. Table 52.2 summarizes the LD_{50} values for different species and routes of administration for the most

TABLE 52.2 Acute lethality of OP nerve agents.

common nerve agents. The relative lethality of these substances, determined in animal studies, is as follows, listed in descending order: VX, soman, cyclosarin, and tabun (Sidell and Borak, 1992).

Local irritations do not occur except by fasciculation of underlying muscles after percutaneous uptake or miosis caused by excessive stimulation of muscarinic receptors on the papillary sphincter muscles, resulting from ocular exposure (Sidell and Borak, 1992; Dabisch et al., 2008). However, clinical symptoms related to massive restraints in motoric and respiratory abilities require the reduction of AChE activity by more than 70%, as deduced by Thiermann et al. (2005) from murine diaphragm experiments. Accordingly, acute cholinergic syndromes in humans were not observed until the RBC AChE activity was inhibited by 75%–80% (Sidell and Borak, 1992). Clinical symptoms may depend on the gender of the animal, as recently documented for the extent of miosis after vapor exposure to soman, cyclosarin, and VX (Dabisch et al., 2008). Male rats were approximately three times less sensitive than female rats, whereas miniature pigs show the reverse effect. This phenomenon refers to different activities of ocular AChE and butyrylcholinesterase (BChE; Dabisch et al., 2008).

52.3.5 Additional targets with potential clinical relevance

As binding to proteins other than AChE reduces the amount of free OP poison, these alternative targets are to be considered when discussing toxicokinetic behavior. Albumin (Black et al., 1997a,b; Li et al., 2007, 2008; Williams et al., 2007; John et al., 2010), receptor/channel complexes (Pope, 1999), muscarinic and nicotinic ACh receptors (Bakry et al., 1988; Silveira et al., 1990), and other secondary serine hydrolase targets were shown to be chemically modified by OPCs; changing their functionality into potential pathophysiological situations by affecting noncholinergic mechanisms (Duysen et al., 2001; Casida and Quistad, 2005). In general, chemical modification of any protein and enzyme requires very high OPC concentrations that are far beyond the lethal dose of nerve agents, thus being of only minor relevance for acute poisoning scenarios (Pope, 1999). In contrast, elaboration of toxicity of the much-less-toxic OP pesticides is more and more focused on these additional targets; investigating, for example, genetic susceptibility, developmental toxicity and neurotoxicity, delayed neurotoxicity, and organophosphate-induced delayed polyneuropathy (OPIDP), a distal sensorimotor axonopathy (Costa, 2006; Balali-Mood and Balali-Mood, 2008). OPIDP is associated with OP-inhibited enzyme neuropathy target esterase (NTE), which undergoes an essential aging process of phosphylated NTE (elimination of an organic substituent from the central phosphorus atom, as shown in Fig. 52.2; Costa, 2006). However, Gordon et al. (1983) demonstrated that, despite NTE inhibitory potency of the nerve agents tabun, soman, and VX, no OPIDP was induced. Nerve agent concentrations inhibiting half of the NTE activity were about three orders of magnitude higher (micromolar range) than for AChE (nanomolar range).

Using microarray technology, Gao et al. (2013) performed a toxicogenomic study on neural cells that had been exposed to VX. A huge number of affected gene expressions relevant in numerous physiological and pathophysiological processes were identified, indicating a broad variety of targets for potential harm. Specific long-term changes in the brain were also observed after exposure to nerve agents (Zhu et al., 2010; Spradling et al., 2011; Oswal et al., 2013). In addition, epigenetic changes were found in cell culture models after paraquat exposure (Song et al., 2011). The aerotoxic syndrome in humans is discussed as possibly being associated with the incorporation of OP tri-O-cresyl-phosphate (TOCP) as an additive in jet hydraulic and engine fluids (Carletti et al., 2013). However, the mechanism causing signs and symptoms is still unknown.

52.3.6 Elemental steps of nerve agent toxicokinetics

Although toxicological characterizations in terms of mean acute lethal doses for different species are available for all nerve agents, detailed and extensive toxicokinetic data are rare in literature for most of them, with the exception of soman and sarin (Benschop and de Jong, 2001). For VX, and in particular GF, only a very limited extent of data is available (Van der Schans et al., 2003; Reiter et al., 2007).

52.3.6.1 Invasion

Supplementary to the more common discussion on invasion processes given in the introductory overview (see Section 52.2), we now present some recent findings on skin penetration models. Nerve agents are readily absorbed through the skin, eyes, lungs, and GIT. Depending on individual vapor pressures of nerve agents, different routes of poison uptake are preferred. G agents (such as sarin, soman, and tabun) are very volatile, limiting percutaneous uptake due to significant evaporation from the skin (approximately 98% for sarin). In contrast, VX exhibits high persistency due to its vapor pressure being 3000 times lower than that of sarin (Marrs et al., 2007; see Table 52.1). Therefore, percutaneous uptake is most prominent for V agents, characterized by an absorption rate of at least 600 $\mu g/cm^2/h$, as shown for VX after

inner ear-skin droplet application of 2 LD_{50} (Fig. 52.2; Chilcott et al., 2005). Nevertheless, VX penetration through skin is characterized in vitro by a significant lag time of at least 1 h and a moderate penetration rate of about 1%−2% per hour (Vallet et al., 2008). These data are in accordance with early studies on human subjects demonstrating that, 3 h after percutaneous exposure of VX, only 0.4%−0.6% was incorporated (Vallet et al., 2008). In vitro studies using guinea pig and human skin, as well as dermatomed, abdominal skin from domestic pigs, revealed significant differences in VX permeability. The highest permeability was observed for the skin of the guinea pig, whereas no significant differences in penetration kinetics were found for human skin and skin taken from a pig's flank (Dalton et al., 2006a,b). Therefore, pig skin may serve as an appropriate in vitro model for human skin (Vallet et al., 2008), as already established in pharmaceutical research using Franz-type diffusion cells (Franz, 1975; Simonsen and Fullerton, 2006). To predict in vivo human VX absorption via skin, full-thickness human abdominal skin has also been demonstrated to be appropriate (Vallet et al., 2008).

52.3.6.2 Distribution

Once nerve agents have penetrated the blood, systemic distribution, including crossing of the blood−brain barrier (BBB), causes toxicity within the CNS and peripheral nervous system (PNS). In mouse and rat studies, it has been shown that within 1 min after sublethal single-dose i.v. administration of sarin, the nerve agent was present in many other compartments (e.g., the diaphragm, heart, lung, and brain) and in much higher concentrations in the plasma, liver, and kidney (Little et al., 1986; Waser and Streichenberg, 1988). Similar results were observed for VX (Chilcott et al., 2005) and soman, which was also found in cerebrospinal fluid with 100% bioavailability after i.v. bolus injection into pigs (Göransson-Nyberg et al., 1998; Augerson, 2000). For a mathematical description, Langenberg et al. (1997) calculated related tissue/blood partition coefficients for the distribution of soman in guinea pigs, revealing a measure of approximately 2 for liver and 1.1 for kidney; whereas the values for the lung and brain were calculated as 0.5. Sarin present in the brain did not severely inhibit AChE activity in the cortex (60%), striatum (40%), and hippocampus (56%) within 24 h (Whalley and Shih, 1989). In contrast, soman has caused more severe inhibition in these three areas (83%−99%), lowering the synaptosomal sodium-dependent, high-affinity choline uptake (SDHACU) within the first 4 h in the hippocampus; whereas from 2 to 24 h after exposure, SDHACU increased in the striatum (Whalley and Shih, 1989). The differences are thought to be due to different aging rates and different AChE-inhibiting potencies. However, the brainstem and midbrain were influenced by neither sarin nor soman. It is assumed that active sites of the brain are affected primarily due to increased metabolic action, vasodilation, and increased blood flow in these regions (Scremin and Jenden, 1996). In contrast, 50% inhibition of AChE activity in brain was associated with death or serious signs of toxicity in mice after subcutaneous exposure (Duysen et al., 2001).

The presence of sarin, soman, and VX in the brain demonstrates the necessity for antidotes, especially AChE reactivators, to be capable of passing the BBB, representing a current scientific challenge (Lorke et al., 2008; Okuno et al., 2008).

Concentrations of sarin found in different tissues were decreased by 85% within 15 min after exposure (Committee on Gulf War and Health, 2004). Apart from active sarin, its inactivated biotransformation product, IMPA, was found in these tissues in a predominant ratio, indicating rapid in vivo biotransformation. This finding is discussed in the next section. Soman was mainly accumulated in the lung after s.c. challenge of rats (Shih et al., 1994) and disappeared from blood and liver 2 min after i.p. administration of $0.75 \times LD_{50}$ to mice (Nordgren et al., 1984). In contrast, VX is more persistent in vivo than sarin or soman, causing delayed systemic distribution after s.c or p.c. administration. This provoked maximum concentrations of VX in blood several hours after p.c. exposure in guinea pigs (Van der Schans et al., 2003).

As outlined in Section 52.13, the toxicological mechanism of action of nerve agents is based on the chemical reactivity of the nucleophilic leaving group. Therefore, biotransformation in terms of degradation by hydrolysis and binding to proteins determines bioavailability and elimination processes, regulating toxicity.

52.3.6.3 Biotransformation and elimination

Enzymes from plasma and tissue are mainly responsible for hydrolysis of OPCs producing derivatives of phosphoric and phosphonic acids characterized by high water solubility and nearly no toxicity. In vivo studies in mice have shown that, within 1 min after injection, 50% of sarin was rapidly biotransformed, generating both free hydrolyzed IMPA and bound IMPA attached to esterases by phosphorylation as predominant in plasma (Little et al., 1986). In contrast, V-type agents are more stable against enzymatic hydrolysis, but may undergo additional biotransformation pathways, including oxidation of nitrogen, sulfur, or both (Van der Schans et al., 2003). Due to the slow reaction velocity of nonenzymatic hydrolysis, this process is of minor importance for elimination kinetics of nerve agents under physiological conditions near neutral pH. As listed in Table 52.1, periods of half-life for nerve agent hydrolysis range from

approximately 9 h for tabun to 6 weeks for VX. In contrast, the velocity of enzymatic hydrolysis in blood is much faster, defining the rate-determining step for poison elimination.

52.3.7 Enzymatic hydrolysis

Enzymes that hydrolyze OPCs cleave the reactive leaving group of OPCs (e.g., F or CN) from the central phosphorus atom, initiating nucleophilic substitution by a hydroxyl group. Hydrolyzing enzyme activity is present in plasma, and to a much higher extent in kidney and liver, enabling the removal of toxicants from the circulation (Sweeney et al., 2006). Early studies using an isolated hydrolyzing rat liver enzyme demonstrated degradation efficacy for nerve agents in the following order: sarin, soman, and then tabun (Little et al., 1989).

Biotransformation products deactivated by hydrolysis are nearly nontoxic and easily eliminated from the organism via renal excretion (Munro et al., 1999). Despite this capability to hydrolyze OPCs, the original physiological functions and substrates of different enzymes vary significantly, not allowing assignment to a specific class of enzymes (Fig. 52.2). The following section presents the most important enzyme systems relevant for nerve agent biotransformation.

52.3.7.1 Phosphotriesterases

Based on historical development, different (and sometimes inconsistent) nomenclatures were used to assign enzymes that lead to the degradation of OPs. Meanwhile, the International Union of Biochemistry has introduced systematic rules and numbering to classify the relevant enzymes in the following way: hydrolases (group 3), which cleave ester links (group 3.1), that may represent carboxylester hydrolases (group 3.1.1) or phosphoric triester hydrolases, phosphotriesterase (PTE) (group 3.1.8). The latter group contains aryldialkylphosphatase (EC 3.1.8.1) and diisopropyl fluorophosphatase (EC 3.1.8.2; Vilanova and Sogorb, 1999). As these enzymes catalyze substrate cleavage without self-inhibition, they are representatives of A-esterases.

- Paraoxonase 01 (PON1): Paraoxonase (PON1, EC 3.1.8.1; formerly EC 3.1.1.2) is a calcium-dependent, liver-expressed P450 PTE belonging to the class of A-esterases with broad substrate specificity toward various lactones and esters, which is present in liver and plasma associated with high-density lipoprotein particles (Vilanova and Sogorb, 1999). P450 isozymes and variants are well known for their dual role in OP biotransformation. On one hand, they bioactivate less toxic phosphorothioates to their highly toxic oxon derivatives via monooxygenase activity. On the other hand, they hydrolyze and detoxify OP insecticides, such as paraoxon, chlorpyrifos, and diazinon by dearylation, as well as nerve agents (e.g., sarin and soman) by defluorination (Davies et al., 1996; Kiderlen et al., 2005; Furlong, 2007; Fig. 52.2). The original physiological function of PON1 is involved in inactivation of toxic products produced by lipid oxidation (Dragonov and Du, 2004). In addition, PON1 hydrolyzes OPCs, such as sarin, cyclosarin, tabun, and soman, thus accomplishing enzymatic protection against nerve agents in circulation (Billecke et al., 2000; Amitai et al., 2006; Fig. 52.2). Levels and genetic variability of PON1 influence sensitivity to these specific substrates caused by Glu/Arg point mutation at position 192 of the human wild-type enzyme (Billecke et al., 2000; Dragonov and Du, 2004). The Glu^{192} mutant is about three times more active than the Arg^{192} variant (Dragonov and Du, 2004). Despite these differentiations, rather low catalytic activity of recombinant human PON1 expressed in HEK cells occurred as a moderate stereoselective process characterized by preferred cleavage of the less toxic P(+)C(+)-enantiomer of soman (k_{cat} 1030 min^{-1}), which happens twice as fast as for the other three stereoisomers (Yeung et al., 2007, 2008; see Table 52.3). Nordgren et al. (1984) used an enzyme isolated from swine kidney, which they called "phosphoryl phosphatase," to incubate purified enantiomers of soman in vitro. Whereas the less toxic P(+)-isomers (R_PS_C- and R_PR_C-soman) were hydrolyzed very rapidly ($\tau_{1/2} = 2$ min under experimental conditions), both highly toxic P(−) forms (S_PS_C- and S_PR_C-soman) showed much higher stability ($\tau_{1/2}$ 60−120 min). It appears likely that the predominant enzyme isolated was PON1. No stereoselective effects in the catalytic PON1 mediated hydrolysis of cyclosarin and soman using recombinant mammalian material from *Escheria coli* were detected by Amitai et al. (2006). No (+)-cyclosarin was detected in hemolyzed blood samples taken from swine after i.v. administration of racemic (±)-cyclosarin, whereas the (−)-cyclosarin enantiomer was present for at least 20 min after exposure (Reiter et al., 2007). These authors suppose that this phenomenon was due to rapid enzymatic and nonenzymatic hydrolysis in blood in vivo, but they do not discuss the potential role of PON1 explicitly. Yeung et al. (2007) conclude that variations in catalytic efficiency of hPON1 toward soman enantiomers are due to differing Michaelis−Menten constants (K_M), characterizing the stability of the enzyme−substrate complex. Consequently, site-directed mutagenesis of recombinant enzymes could cause reduction of K_M for the more toxic enantiomers, improving its hydrolyzing capacity. A 10- to 100-fold increase in catalytic activity of wild-type hPON1 is

TABLE 52.3 Catalytic constants for hydrolysis of nerve agents and rate constants of esterase inhibition.

	Inhibition rate constant, k_i (M^{-1} min^{-1})								k_{cat} (min^{-1})
	Bovine	Electric eel	Human	Minipig	Pig	Equine	Human	Rat plasma	hr wt
	AChE	AchE	AChE	AChE	AChE	BChE	BChE	CarbE	PON1
Soman									
C(±)P(±)-soman	5×10^7 [a]	1.5×10^8 [a]	9.2×10^7 [b,c]			1.29×10^7 [d]	2.8×10^8 [b]	0.51×10^7 [d]	7,500 [e,f]

VR									
(±)-VR			4.60×10^8 [l,c]	1.95×10^8 [l]	1.88×10^8 [l]				
CVX									
(±)-CVX			3.06×10^8 [m,c]		1.46×10^8 [m]				

Rate constants for inhibition of most prominent serine esterases by nerve agents differ significantly depending on the nature of enzyme, its originating species, and stereoisomers of the agent. It appears obvious that for the depicted G agents and VX, the P(−)-isomers are much more effective inhibitors than their corresponding P(+)-forms. In contrast, hydrolysis of the latter isomers happens faster than that of the toxic P(−)-variants. Hydrolytic stability is determined by PON1 activity characterized by its catalytic constant k_{cat} (last column). Both properties (inhibition and hydrolysis) cause higher toxicity for P(−)-agents in vivo selectively (Table 52.4). AChE, acetylcholinesterase; BChE, butyrylcholinesterase; CarbE, carboxylesterase; CVX, Chinese VX; hr wt, human recombinant wild type; k_{cat}, catalytic constant for hydrolysis; PON1, paraoxonase 1; VR, Russian VX.

expected to allow effective protection against incorporated nerve agents (Amitai et al., 2006; Rochu et al., 2007; Masson and Rochu, 2009). Masson and Rochu provided Chapter 70, Pyridinium oximes in the treatment of poisoning with organophosphorus compounds, of the previous edition. Following a directed evolution process, Goldsmith et al. (2012) succeeded in producing a recombinant variant with more than 340-fold increased catalytic activity. In addition, stereoselectivity was reversed to preferred hydrolysis of the more toxic $S_P(-)$-isomer of cyclosarin. Recently, the aforementioned PON1 mutant was successfully tested against $2*LD_{50}$ cyclosarin in a guinea pig model. Prophylactic administration of the enzyme prevented death, as well as signs and symptoms of GF poisoning (Worek et al., 2014a). In addition, this enzyme showed a catalytic activity against a broad spectrum of alkyl methylfluorophosphonates. Engineering efficient recombinant human PON1 is a current challenge in medical defense research, intending to yield an effective and biocompatible therapeutic applicable for a wide range of nerve agents exhibiting sufficient activity toward all relevant isomers (Amitai et al., 2006; Valiyaveettil et al., 2011; Kirby et al., 2013). Fig. 52.2 displays its role in biotransformation and elimination.

- Senescence Marker Protein-30 (SMP30): The human senescence marker protein-30 (SMP30 or regucalcin, primary Swiss-Prot accession No. Q15493) is expressed by hepatocytes and plays a role in regulation of plasma membrane Ca^{2+}-pumping activity, with the potential to rescue cells from high calcium level-induced apoptosis (Kondo et al., 2004). The expression of this liver enzyme decreases with aging. SMP30 was originally identified in rat liver and exhibits a 65% amino acid similarity to PON1 in rat species, but does not show catalytic PON1 activity toward the hydrolysis of paraoxon (Billecke et al., 1999). In contrast, mouse and rat SMP30 hydrolyze diisopropylfluorophosphate (DFP), an OPC related to nerve agents (Kondo et al., 2004). It may be speculated that this enzyme is also involved in nerve agent biotransformation in liver. This assumption is supported by the findings of Little et al. (1989), who observed hydrolysis of sarin, soman, and tabun by an enzyme derived from rat liver homogenate. Recombinant human material might also represent a valuable countermeasure for nerve agents and was expressed in *E. coli* as a properly folded and active protein (Choi et al., 2010).
- Prolidase: Prolidase is a Mn^{2+}-dependent enzyme of 54 kDa that was purified from fibroblast cells, erythrocytes, kidney, and liver (EC 3.4.13.9) and exhibits a primary catalytic activity toward peptide-bond cleavage of dipeptides containing a C-terminal proline or hydroxyproline residue. In addition, it was found to hydrolyze G-type nerve agents tabun, sarin, soman, and cyclosarin by liberating the respective leaving groups in vitro with K_M values in the millimolar range. Unfortunately, recombinant human material expressed in *E. coli* exhibited a stereoselective preference for less toxic S_P-isomers; thus, it may not degrade the poison efficiently (diTargiani et al., 2010). This enzyme will affect the toxicokinetics of nerve agents and may represent an additional bioscavenger candidate when activity can be enhanced and stereoselectivity reversed.
- Diisopropyl Fluorophosphatase (DFPase): Some enzymes were isolated, but not unambiguously identified, from swine kidney, which exhibit DFP-cleaving activity and were denominated diisopropyl fluorophosphatase (DFPase) in older swine (Nordgren et al., 1984). This DFPase belongs to the class of A-esterases acting on DFP, tabun, and organofluorophosphates (e.g., cyclosarin, sarin, and soman). Nowadays, most recent studies define DFPase (EC 3.1.8.2, formerly assigned as EC 3.8.2.1) as a calcium-dependent PTE identified in squid *Loligo vulgaris* exhibiting unique structural properties (Blum et al., 2006). This squid-type DFPase has not yet been identified in mammalian organisms.

52.3.7.2 Nonmammalian enzymes

Several other enzymes from bacteria [e.g., PTEs or OPH, from *Pseudomonas diminuta* or *Flavobacterium* sp., OP acid anhydrolase (OPAA), from *Alteromonas* sp. and prolidases from *Pyroscoccus furiosus*, or squid (DFPase)] are also known to detoxify nerve agents, and it is of interesting relevance for novel noncorrosive decontamination approaches (Blum and Richardt, 2008; Theriot et al., 2011). So far it does not play a role in the toxicokinetics of OPCs in humans (Amitai et al., 2006; Rochu et al., 2007; Masson and Rochu, 2009) but has shown benefit in animal studies. Wille et al. (2016) reported on the PTE mutant C23AL that was administered [intraosseous (i.o.) and i.v.] to guinea pigs poisoned with VX. Animals challenged with the nerve agent (2 LD_{50}) and subsequently treated with PTE survived despite substantial inhibition of AChE in erythrocytes, brain, and diaphragm (Wille et al., 2016). In contrast, promising studies were performed in rodents demonstrating a protective effect of OPH (Wales and Reeves, 2012). However, potential application as detoxifying antidotes remains a future challenge (Ashani et al., 2016; Goldsmith et al., 2016). Promising new strategic approaches on systematic testing of enzyme mutants were presented by Bigley et al. (2019) documenting effective improvement of catalytic activity toward V-type agent hydrolysis. Current review articles on this aspect are provided by Goldsmith and Ashani (2018) and Masson and Lushchekina (2016).

52.3.8 Nonproteinaceous scavengers and hydrolyzing compounds

Scavenging and hydrolysis of OP nerve agents in vivo is a major challenge in therapeutic treatment of poisoning. Compounds that enable degradation of poison to nontoxic products in the body help to minimize the toxic impact of nerve agents. In contrast to bioscavengers like PON1 or BChE, small molecules are much less immunogenic and might be of higher stability and longer half-life, representing more favorable properties for antidotal treatment. Following this idea, structures of modified β-cyclodextrins (β-CD) are currently optimized for improved hydrolysis of G- and V-type nerve agents (Estour et al., 2013). In vitro studies indicate reversible binding to β-CD as noninclusion (interaction with the outer surface) and as inclusion complexes (interaction inside the hydrophobic cavity) initiating hydrolysis that might occur with enantioselective preference (Müller et al., 2013). Recently, a β-cyclodextrin derivative bearing a pyridinium oximate in 6-position of one glucose unit was synthesized and shown to possess a promising detoxification potential against a variety of alkyl methylfluorophosphonates in vitro (Bierwisch et al., 2014; Kranawetvogl et al., 2015). Recent studies showed that the nerve agent-degrading effect of glucose functionalized with oximate and hydroxamic acid is a result of stoichiometric binding but not of a catalytic process (Bierwisch et al., 2016). Prophylactic i.v. injection of the β-cyclodextrin derivative prevented systemic toxicity in cyclosarin ($\sim 2LD_{50}$) poisoned guinea pigs and preserved brain AChE activity (Worek et al., 2014b). Such compounds will seriously affect toxicokinetic behavior of poisons and support the elimination process. In addition, derivatives of calixarenes were also tested but need much more improvement of efficacy (Schneider et al., 2016; Ede et al., 2018).

52.3.9 Formation of protein adducts

Besides direct enzymatic hydrolysis of nerve agent substrates, numerous additional proteins are present in organisms that allow covalent binding to OPCs, contributing to detoxification of the poison load (Fig. 52.2). Serine esterases are especially predominant targets of nerve agents mostly undergoing irreversible adduct formation. Nevertheless, more than 75% of serine hydrolases (B-esterases) present in plasma and tissues are essentially unknown with respect to their interaction with OPCs (Casida and Quistad, 2005).

52.3.9.1 Carboxylesterase

Ubiquitous glycosylated carboxylesterases (CarbE, EC 3.1.1.1), formerly named *ali-esterases*, are B-esterases belonging to the multigene enzyme superfamily of α/β hydrolases (Hosokawaand Satoh, 2006; Satoh and Hosokawa, 2006). In principle, this class of isozymes plays a major role in pharmacokinetics by hydrolytic biotransformation of exogenous ester-drugs and ester-prodrugs. However, their physiological function remains unclear (Satoh and Hosokawa, 2006).

Carboxylesterases are very important serine esterases in plasma of nonhuman species that bind nerve agents with broad specificity, representing the major determinant for in vivo detoxification, especially in mice and rats (Maxwell and Brecht, 1991; Fig. 52.2). Apart from catalytic CarbE activity in plasma, it is also found in several tissues and organs, including the brain, lung, kidney, and liver, thus indicating that poison decrease was not only in the circulation (Satoh et al., 2002). Microsomal liver carboxylesterase 1, which is also referred to as *egasyn*, is loosely associated with a β-glucuronidase (BG) complex (Fujikawa et al., 2005). Organophosphate-inhibited egasyn causes cleavage of this complex, releasing elevated quantities of BG into circulation. Thus, BG plasma activity may serve as a sensitive biomarker for OP poisoning (Inayat-Hussain et al., 2007).

Interaction of CarbE with nerve agents follows a kinetic of first order characterized by inhibition of CarbE at the active site serine residue described by a bimolecular rate constant, k_i (Maxwell and Brecht, 2001). For noncharged nerve agents (e.g., sarin and soman), the k_i of rat serum CarbE was found to be greater than $10^6\ M^{-1}\ min^{-1}$, whereas cationic substrates (e.g., VX) are converted with poor reactivity ($k_i < 10^4\ M^{-1}\ min^{-1}$). This specificity is explained by the electrostatic characteristics of the large active site containing only a few cation-Π bonding and anionic residues (Maxwell and Brecht, 2001; Satoh and Hosokawa, 2006).

Covalent binding of OPCs to CarbE is considered an irreversible reaction of 1:1 stoichiometry, resulting in adducts that do not age (Maxwell and Brecht, 2001). In contrast, spontaneous pH-dependent reactivation liberates the enzyme, making it accessible for additional detoxification (though only to a very limited extent). At physiological pH in vitro, spontaneous reactivation (specified by the rate constant k_r) is a poison-dependent process showing significantly different velocities depending on the size of the inhibitor (steric demand). Whereas reactivation of VX- and sarin-inhibited rat serum CarbE was faster (k_r $4.2 \times 10^{-3}\ min^{-1}$ and $3.8 \times 10^{-3}\ min^{-1}$), reactivation for soman and VR was about 10 times slower (k_r $0.44 \times 10^{-3}\ min^{-1}$ and $0.52 \times 10^{-3}\ min^{-1}$; Maxwell and Brecht, 2001). Meanwhile, Hemmert et al. (2011) produced a recombinant variant of human CarbE1 that spontaneously dephosphorylates 33,000-fold faster than the wild type after inhibition with sarin, soman, and cyclosarin. This effect was achieved by implementing a pair of histidine

and glutamic acid residues proximal to the catalytic triad without changing the high-affinity binding. In addition to these differences, CarbE exhibits stereoselective properties. Nordgren et al. (1984) demonstrated that CaE from swine liver binds to the less toxic P(+)C(+)-enantiomer of soman (R_CR_P) most efficiently, whereas conversion of highly toxic P(−)C(+)-soman (R_CS_P) happens much more slowly (Table 52.3). This fact indicates that degradation of incorporated nerve agents is primarily targeted to less toxic enantiomers, minimizing the protective effect of CaE. In contrast to G agents, no prominent enantiomeric selectivity was evident for sequestration of VX after p.c. administration (Van der Schans et al., 2003).

Consequently, striking species-dependent differences in LD_{50} values of OPCs are mainly due to variable concentrations of endogenous CarbE acting as a bioscavenger in blood (Tables 52.2 and 52.3). Whereas mice and rats exhibit high CarbE activities, activity in rabbits and guinea pigs appears moderate. In contrast, dogs and primates, as well as humans, possess only little or no CarbE (Benschop and de Jong, 2001). These relations are obvious from s.c. soman LD_{50} values obtained from mice and guinea pigs after inhibition of CarbE (10.2 and 12.2 μg/kg), which were very similar to those obtained for dogs and primates without inhibition (9.1 and 13.0 μg/kg; Maxwell and Brecht, 1991). In contrast, the corresponding soman s.c. LD_{50} values for untreated CarbE are much higher for mice (113 μg/kg) and guinea pigs (28.2 μg/kg; Maxwell and Brecht, 1991). For these reasons, guinea pigs are most often used for in vivo toxicity and toxicokinetic studies intending to examine a small laboratory animal model predictive for humans. Missing CarbE activity in humans hinders efficient detoxification in vivo, thus keeping the toxic effect of nerve agents (Due et al., 1993). Consequently, the value of CarbE as a bioscavenger for effective clearance of OP poison from the circulation has led to therapeutic concepts that were applied successfully to rodents and nonhuman primates (Maxwell and Brecht, 2001). Feasibility for human organisms has yet to be demonstrated.

52.3.9.2 Acetyl monoalkylglycerol ether hydrolase

KIAA1363 (primary Swiss-Prot accession No. Q6PIU2) is a human serine hydrolase derived from acetyl monoalkylglycerol ether hydrolase (AcMAGE, EC 3.1.1.) present in the brain, lung, heart, and kidney, which is involved in tumor cell invasiveness and lipid metabolism, but can also detoxify OPCs by hydrolysis of the reactive leaving group following transient binding to the active site serine residue (Nomura et al., 2008; Fig. 52.2). This capability has been demonstrated for the pesticide chlorpyrifos and its more toxic oxon derivative. Activity toward nerve agent hydrolysis is expected, but it has not been shown so far.

52.3.9.3 Acetylcholinesterase

AChE (EC 3.1.1.7) from vertebrates is deduced from a single gene (Massoulie, 2002) expressing identical enzyme primary structures on the surface of RBCs, in synapses and different organs. Inhibition of this serine-esterase causes the most prominent pathophysiological effects, determining the severity of poisoning. Covalent binding to AChE can also be considered a step in poison elimination (Fig. 52.2), which reduces the amount of incorporated poison, though only to a small extent.

AChE activity in whole blood differs significantly among mammalian species, which makes it relevant for toxicokinetic consideration. Humans exhibit a very high AChE activity in blood (651 mU/μmol hemoglobin, Hb) in contrast to smaller values for miniature pigs (297 mU/μmol Hb) and pigs (190 mU/μmol Hb; Worek et al., 2008). The bimolecular rate constants (k_i) for nerve agent-induced inhibition of AChE vary among different species. Table 52.3 gives an overview of corresponding inhibition kinetics. The k_i for inhibition of human AChE by VX, for example, is about twice as high as for pig AChE (Aurbek et al., 2006). These differences must be considered when assessing interspecies toxicokinetic data.

Nerve agents show enantioselective inhibition kinetics when reacting with AChE. Chirality at the central phosphorus atom plays the predominant role, affecting higher rates of inhibition for the P(−)-isomers (S_P) than for the P(+)-forms (RP; Nordgren et al., 1984). Benschop and de Jong (2001) made great efforts to look at this stereoselectivity topic, and they determined the corresponding inhibition rate constants (k_i) for electric eel AChE in vitro (Table 52.3). Both P(−)-diastereomers of soman (S_PS_C- and S_PR_C-soman) exhibit very high k_i values ranging from $1.8-2.8 \times 10^8\ M^{-1}\ min^{-1}$, which documents their high toxicity. In contrast, the less toxic P(+)-diastereomers (R_PR_C- and R_PS_C-soman) are characterized by k_i values that are 100,000 times smaller ($<5 \times 10^3\ M^{-1}\ min^{-1}$; Benschop and de Jong, 2001). Similar results were obtained for sarin enantiomers, which differ by a factor of 5000, revealing a k_i of $1.4 \times 10^7\ M^{-1}\ min^{-1}$ for the S_P-(−)-form (Table 52.3). VX enantiomers exhibit the smallest differences, because the k_i of the more toxic S_P-(−)-VX ($4 \times 10^8\ M^{-1}\ min^{-1}$) is 200 times higher than for the RP-(+)-enantiomer (Table 52.3; Benschop and de Jong, 2001). These k_i data correspond to the order of experimentally determined LD_{50} values in mice, not considering the impact of hydrolyzing enzymes in vivo which also exhibit stereoselective kinetics for hydrolysis (Table 52.4; Benschop and de Jong, 2001).

TABLE 52.4 Acute lethality in mice caused by stereoisomers of OP nerve agents.

Nerve agent	LD_{50} (μg/kg)
Stereoisomers	**Mouse**
Soman	
C(±)P(±)-soman	156 (s.c.)[a]
C(+)P(+)-soman	<5000 (s.c.)[b]
C(−)P(+)-soman	<5000 (s.c.)[b]
C(+)P(−)-soman	99 (s.c.)[a]
C(−)P(−)-soman	38 (s.c.)[a]
Sarin	
(±)-sarin	83 (i.v.)[b]
(+)-sarin	
(−)-sarin	41 (i.v.)[b]
VX	
(±)-VX	20.1 (i.v.)[b]
(+)-VX	165 (i.v.)[b]
(−)-VX	12.6 (i.v.)[b]

Higher rate constants of P(−)-isomers for inhibition of AChE in combination with their minor susceptibility to enzymatic hydrolysis by mammalian PTEs cause eminently different lethal doses in vivo.
[a]*Benschop et al. (1984)*.
[b]*Benschop and de Jong (2001)*.

AChE on the surface of RBCs shows a turnover rate of about 1% per day, enabling complete exchange within approximately 100 days after exposure (Sidell and Borak, 1992). In contrast, regeneration of synaptic AChE is assumed to be faster, reaching 7%−10% turnover rates, an estimation determined by animal experiments (Grubić et al., 1981; Brank et al., 1998; Eddleston et al., 2008b). Both are of importance for therapeutic monitoring of poisoning, as well as for verification of exposure following bioanalytical methods.

- Spontaneous Reactivation of AChE: Although inhibition of AChE is mainly discussed as an irreversible reaction, detailed kinetic investigations consider the process of spontaneous reactivation re-releasing an active enzyme and a hydrolyzed detoxified agent (Fig. 52.2). Rate constants for spontaneous reactivation (k_s) of human AChE adducts are very small, as measured for some sarin analogs (0.01−0.052 h^{-1}), whereas the k_s for sarin, cyclosarin, and VX was too small to provoke an experimentally detectable effect (Bartling et al., 2007). Sidell and Groff (1974) demonstrated that spontaneous reactivation of RBC AChE inhibited by VX happens much faster than for sarin, which is in accordance with recent human k_s data on V agents VX 0.021 h^{-1}, VR 0.039 h^{-1}, and Chinese VX (CVX) 0.171 h^{-1} (Aurbek et al., 2006). Following point mutations in recombinant human AChE spontaneous reactivation rates for VX, VR, and CVX could be increased up to 110-fold (Trovaslet-Leroy et al., 2011). However, the toxicokinetic relevance of spontaneous reactivation is obvious from the liberation of free esterase accessible for reinhibition with 1:1 stoichiometry.
- Aging of AChE: The cleavage of an organic substituent from the phosphorus atom, which is bound to the side chain of an amino acid residue from a protein, is described by the aging process (Fig. 52.2). Promoted by specific ionic interactions of neighboring amino acid residues in AChE (and BChE), the remaining P-OH function will undergo deprotonation, leaving a negatively charged phosphorus moiety (Fig. 52.2). Chandar and Ganguly (2013) investigated the aging process of soman-inhibited AChE in silico by density functional theory (DFT) and found that dealkylation of the pinacolyl-group and migration of the methyl-group take place simultaneously, catalyzed by histidine 440 and tryptophan 84 residues located in the catalytic triad and catalytic anionic subsite, respectively. Whereas esterase adducts of sarin and soman age by cleaving alkoxy moieties from the central phosphorus atom, tabun loses its dimethylamine moiety (P−N scission) instead of its ethoxy group (Elhanany et al., 2001). These aged enzyme adducts are not accessible for reactivation by common antidotal oximes, limiting the success of therapeutic treatment of poisoning with OPCs. The soman−AChE adduct is known for very rapid aging ($\tau_{1/2} \approx 2$ min), causing severe problems in clinical treatment (Worek et al., 2005). Aging half-lives of phosphylated AChE and phosphylated BChE depend on the nature of the inhibiting OPC. Whereas GF-inhibited AChE exhibits a half-life of 8.7 h, the corresponding BChE derivative ages much more rapidly (2.2 h; Worek et al., 1998). The order of $\tau_{1/2}$ for aging of human AChE−nerve agent adducts was found to be, in ascending order, soman (2 min), sarin (3 h), cyclosarin (7 h), tabun (19 h), and VX (36.5 h; Worek et al., 2005). V agent-inhibited RBC-AChE ages very slowly in humans, allowing therapeutic intervention with oximes for a longer period lasting several days (Sidell and Groff, 1974; Thiermann et al., 2007).

52.3.9.4 Butyrylcholinesterase

BChE (EC 3.1.1.8), formerly named *pseudocholinesterase*, is synthesized in the liver and present in blood (5 μg/mL), the synapse of neuromuscular junctions, and glia

cells and axons of white matter in the brain in numerous allelic variants (Massoulie, 2002). Although BChE has long been considered a nonfunctional vestigial analog of AChE, recent findings point out a possibly more prominent role; especially in mice, where the total amount of BChE in the body is 10 times as high as AChE (Duysen et al., 2001). Correspondingly, it was observed that the activity of BChE in human whole blood was significantly higher than that of AChE (Worek et al., 2008). This led to speculation that BChE may play a backup role for insufficient AChE activity in neurotransmission as deduced from the physiology of AChE knockout mice (Duysen et al., 2001) and may serve as a safeguard against diffusion of ACh into the bloodstream (Massoulie, 2002). However, mandatory experimental evidence is still missing.

Highly glycosylated BChE is a prominent target of OPCs, acting as a protective biological stoichiometric scavenger averting damage to neuronal AChE (Kolarich et al., 2008). However, common nerve agents may exhibit significantly differing inhibition rate constants (k_i); for AChE and BChE, they are approximately in the range of 10^7–10^9 M^{-1} min^{-1} (Bartling et al., 2007). Table 52.3 shows a comparison of the inhibitory potency of nerve agents against AChE and BChE. In vivo studies in humans suggest that VX preferentially inhibits RBC AChE much more effectively than BChE, resulting in 70% and 20% inhibition, respectively (Sidell and Groff, 1974). In addition to agent-dependent k_i values, there is a striking stereoselective dependency in BChE inhibition. The more toxic soman P(−)-enantiomers (S_P) inhibit with preference when compared to their corresponding P(+)-forms (RP; Table 52.3; Nordgren et al., 1984). However, differences are not as pronounced as for AChE, but point out effective detoxification properties of endogenous BChE.

Interestingly, no clinical features result from inhibited BChE in vivo (Eddleston et al., 2008b). The status of plasma BChE activity is, despite all concerns, a commonly recommended measure to monitor the progress of chemical injury (Eddleston et al., 2008a).

In contrast to all studies on VX toxicokinetics and toxicodynamics published so far, Dorandeu et al. (2008) reported an unexpected and not-yet-clarified phenomenon that emerged after i.v. administration of VX to isoflurane-anesthetized and ventilated swine without oxime therapy. Time-resolved measurement of esterase activities during the experimental period of poison application revealed very fast rebound of BChE activity (from 70% inhibition to 30% within 1 h), while retaining nearly complete inhibition of whole-blood cholinesterase. Design and control experiments allowed the following explanations to be excluded: (1) spontaneous reactivation, which should happen much more slowly; (2) induced hypoalbuminemia liberating albumin as scavenger competing with BChE; and (3) stimulated release of hydrolyzing enzymes like PON1. More probably, this observation is explained by an increased biosynthesis of BChE in the liver, an elevated release of BChE from other organs (e.g., heart, lung, or pancreas), or both. Future studies will possibly shed more light on this curious and interesting phenomenon.

As total replacement of BChE by synthesis in the liver happens within a couple of weeks, this rather long period allows experimental verification of OP poisoning, even when blood samples from poisoned humans are collected with significant delay to the time of exposure (Sidell and Borak, 1992). Therefore, detection of BChE adducts by means of modern mass spectrometric methods is the state-of-the-art technique for proving exposure to OP nerve agents (Carol-Visser et al., 2008; Noort et al., 2006; John et al., 2008). Apart from that specific serine residue that is phosphylated by organophosphorus pesticides and nerve agents, Schopfer and Lockridge (2019) identified additional amino acids being phosphylated after in vitro incubation of BChE with clorpyrifos oxon including 10 tyrosine, 14 lysine, two histidine, and two threonine residues. Whether these modifications are of relevance for the enzymatic activity remains unclear.

The relevant enzyme adducts at the serine residue of the esteratic center may undergo the previously described consecutive reactions: spontaneous reactivation and aging. Jiang et al. (2013) demonstrated that human BChE can be inhibited by both enantiomers of tabun, resulting in stereospecific aging processes showing deamination for S_P-tabun and O-dealkylation for R_P-tabun. In general, aging of BChE nerve agent adducts occurs with highly different agent-dependent periods of half-change ($\tau_{1/2}$) as determined in vitro by Worek et al. (2005). Whereas the soman adduct typically exhibits by far the shortest $\tau_{1/2}$ (less than 1 min), cyclosarin appears much more stable ($\tau_{1/2}$ 2.2 h), followed by tabun ($\tau_{1/2}$ 7 h) and sarin ($\tau_{1/2}$ 12 h). The adduct of VX was the most stable BChE derivative characterized by a $\tau_{1/2}$ of 77 h. Spontaneous reactivation by simple hydrolysis of the serine−phosphorus bond was observed for cyclosarin, with a half-life of 20 h and much longer times for VX (63 h) and sarin (63 h; Worek et al., 2005). These data demonstrate that inhibition of wild-type BChE is nearly irreversible, lowering the amount of incorporated toxic OPCs significantly in a stoichiometric manner. Therefore, protection against nerve agent doses of up to $5.5 \times LD_{50}$ (soman and VX) was achieved with exogenous BChE from different species applied prophylactically i.m. to the guinea pig, rhesus monkey, and cynomolgus (Lenz et al., 2007). It is supposed that a dose of 200 mg BChE/70 kg will be sufficiently protective in humans against $2 \times LD_{50}$ of soman (Saxena et al., 2008). Based on this valuable protective capacity, current efforts are under investigation to use BChE from recombinant

(e.g., transgenic plants or milk of transgenic animals) or natural sources for therapeutic/prophylactic treatment of nerve agent poisoning (Chilukuri et al., 2005; Lockridge et al., 2005; Huang et al., 2007; Lenz et al., 2007, 2010; Geyer et al., 2010; Saxena et al., 2011; Mumford et al., 2013). The plasma half-life of recombinant preparations is significantly prolonged by fusion to albumin (Huang et al., 2008) or pegylation (attachment of polyethyleneglycol; Chilukuri et al., 2005; Sun et al., 2013), or by polysialylation (Ilyushin et al., 2013). In addition, enhanced rapid spontaneous reactivation will deblock the enzyme, thus being accessible for subsequent binding to another OP molecule. This strategy is followed by site-directed mutagenesis of BChE, leading to a 10^5-fold increase in dephosphorylating activity (Casida and Quistad, 2005). Accordingly, substitution of histidine 117 by glycine in engineered human BChE generated a significant amount of OP hydrolase activity (Nachon et al., 2011). Feasibility for the human body still has to be shown.

52.3.9.5 Albumin

Although albumin is present in blood in high concentrations (0.6 mM; 41 g/L; 50%−60% of total plasma protein), it does not represent an effective scavenger for nerve agent detoxification in vivo, hampered by its slow reaction velocity (Li et al., 2008). Nevertheless, sarin and soman bind to albumin at active site tyrosine residue 411, as shown in neat buffered solution and crude human plasma. This inhibits the enzymatic acylamidase and esterase activity of albumin (Black et al., 1999; Li et al., 2007, 2008; Fig. 52.2). Besides tyrosine 411, additional amino acid residues capable of phosphorylation by nerve agents and pesticides were described by John et al. (2010) after matrix-assisted laser desorption/ionization (MALDI)−mass spectrometry (MS) as well as by Schopfer and Lockridge (2019) and Fu et al. (2019) using liquid chromatography-tandem mass spectrometry (LC MS/MS) analysis. Albumin also exhibits slight hydrolyzing catalytic activity against OPCs (Vilanova and Sogorb, 1999). Concerning enantio-selectivity in phosphorylation of albumin by soman, contradictory results have been presented in recent studies. Li et al. (2008) did not find any enantiomeric preference, and Yeung et al. (2008) demonstrated that human serum albumin preferentially binds to the less toxic C(±)P(+)-enantiomer. However, the albumin adduct is very stable in terms of spontaneous reactivation, exhibiting extended periods of half-life (6.5 days at 25°C, pH 8.0 and 20 days at 22°C, pH 7.4); in addition, it does not show any aging phenomena (Li et al., 2007, 2008; John et al., 2010). Derivatized albumin serves as a biomarker for nerve agent exposure detectable by modern mass spectrometric techniques (Black et al., 1999; Peeples et al., 2005; Li et al., 2007, 2008; Williams et al., 2007). Recently, a novel class of disulfide adducts was presented that is produced from albumin in the presence of V-type nerve agents and pesticides containing a thiol-leaving group (John et al., 2018a,b; Kranawetvogl et al., 2016, 2017, 2018a,b). The thiol-containing leaving group undergoes disulfide formation with the Cys^{34} residue of albumin which—in the native structure—is the only free, nondisulfide bridged cysteine residue within that protein. Whether these chemical modifications effect any changes in the 3D structure or functionality of albumin remains unclear, but the derivatized Cys^{34} residue can be used for bioanalytical detection and thus for verification of poisoning. The adducted albumin is proteolyzed by pronase producing the dipeptide Cys^{34}Pro that is modified at the cysteine side chain containing the disulfide-linked leaving group (John et al., 2018a,b; Kranawetvogl et al., 2016, 2017, 2018a,b).

52.3.9.6 Keratins

Keratins are the most abundant proteins in the stratum corneum, exhibiting molecular weights of about 50−100 kDa. Formation of intermediate filaments assembled from bundles of keratin monomers cause durability and insolubility in water, representing the protective barrier of the body. Verstappen et al. (2012) found that VX and OP pesticides covalently bind to tyrosine residues in human keratins when exposed in vitro. MS/MS analysis revealed phosphorylation in keratin 1, 6, and 10, results that are very similar to a report from Schopfer et al. (2010) documenting phosphorylation of tyrosine induced by in vitro incubation of chlorpyrifos-oxon with human keratin 1, 2, 9, and 10. No distinct binding motifs or consensus sequences have been identified so far that explain preferred phosphorylation at specific tyrosine residues (Schopfer et al., 2010). In addition, adducts were also found at lysine residues in keratin 1 and 10. Corresponding phosphoamidate bonds showed unexpected stability (Grigoryan et al., 2009). Such binding processes might contribute to general skin absorption phenomena as observed after cutaneous exposure to VX (Chilcott et al., 2005). No pathophysiological consequences are obvious at present. These phosphorylation reactions minimize the total amount of toxic nerve agents penetrating into circulation, representing a kind of natural scavenging barrier.

52.3.9.7 Ubiquitin

Ubiquitin is a small endogenous and ubiquitous protein (approximately 8600 Da) with a nearly globular confirmation (Welchman et al., 2005). In vivo, it appears either as free (extracellular space, for example, plasma, urine, cerebrospinal fluid) or anchored molecules covalently bound to any target protein (intracellular space). Such conjugates often contain multiple ubiquitin molecules connected to

long chains (poly-ubiquitinylation). The kind and extent of ubiquitin chains are crucial parameters that determine the fate of the protein with respect to proteasomal degradation. Chain prolongation requires one of seven free lysine residues to react with the C-terminal glycine of another ubiquitin molecule. Therefore, the presence of free, chemically unaltered ε-amino side chains is essential for correct biological function.

Recently, adducts of ubiquitin produced in vitro with VX, VR, and CVX were identified by different mass spectrometric methods, documenting that phosphorylation untypically occurred in at least six of the seven lysine residues selectively (Schmidt et al., 2014). An additional adduct at a tyrosine residue was also found, but to a much lesser extent. Intramolecular cyclization between the derivatized lysine and adjacent glutamic acid residues was detected. Such a reaction has never been described before for any other phosphylated protein but has been shown meanwhile for additional proteins including aprotinin, casein alpha S1, human serum albumin, BChE and tubulin alpha 1A (Schopfer and Lockridge, 2019). Cyclization will dramatically change the tertiary structure of ubiquitin and presumably of other proteins. All these chemical and structural changes after reaction with V agents will surely affect biological function. It is not clear whether phosphylated ubiquitin is produced in in vivo poisoning scenarios or whether it is relevant to any pathophysiological situation.

52.3.9.8 Additional proteins

By means of modern, highly selective, and high-resolving mass spectrometry coupled to effective chromatographic separation, a number of mammalian proteins were shown to form covalent adducts in vitro. These targets include, for example, α_2-glycoprotein 1, human transferrin, kinesin 3C motor domain 5, bovine tubulin α and β, actin α skeletal muscle, chymotrypsinogen, mouse transferrin, ATP synthase, adenine nucleotide translocase I, aprotinin, casein alpha S1, and porcine pepsin (Grigoryan et al., 2009; Schopfer et al., 2010; Schopfer and Lockridge, 2019). Nerve agents were found to phosphorylate tyrosine, serine, threonine, and lysine residues predominantly. However, no correlation to any specific disease or evidence for any pathophysiological consequence has been reported. Nevertheless, numerous signs and symptoms in OP poisoning suggest that AChE inhibition is not the only reason behind the entire clinical picture.

Besides diverse nucleophilic side chains of amino acids from a number of endogenous proteins, OP nerve agents also form adducts with other small, nucleophilic molecules relevant for toxicokinetic analysis. Gäb et al. (2010, 2011) demonstrated that sarin, soman, and cyclosarin react with phosphate anions. Such ions are present in vivo or in typical phosphate buffers used for dilution of biological fluids or as solvents for kinetic measurements. G-type nerve agents (Gäb et al., 2011) and VX (Creasy et al., 2012) produce very stable pyrophosphate-like adducts fast enough to compete with sample hydrolysis in aqueous media. Similar reactivity was found for amino alcohol buffers like tris(hydroxymethyl)aminomethane (TRIS), and *N*-tris(hydroxymethyl)methyl-2-aminoethanesulfonic acid (TES), generating *O*-bound esters of methyl-*O*-alkyl phosphonates derived from sarin, soman, and cyclosarin (Gäb et al., 2010). These reactions might be relevant when planning and performing any kind of quantitative and kinetic analysis of G-type nerve agents.

52.3.10 Muscarinic receptors

It has been shown that tabun, sarin, soman, and VX bind to the muscarinic receptor subtype m_2, leading to the assumption that the ACh binding site is deactivated, causing potential additional vulnerability (Fig. 52.2; Silveira et al., 1990). Despite the high affinity of nerve agents, pathophysiological effects seem to be of only minor relevance compared to AChE inhibition. However, binding to receptors will lower the concentration of toxic and reactive OPCs.

52.3.11 Excretion

Sarin and its corresponding nontoxic hydrolysis products (IMPA and additional methylphosphonic acids) are predominantly eliminated via the kidneys, so those organs play a more important role in detoxification than the liver (Little et al., 1986; Waser and Streichenberg, 1988). Urinary excretion happens very rapidly, as demonstrated for single-dose s.c. applications of sarin, cyclosarin, and soman to rats (Shih et al., 1994). The terminal elimination half-life was found to be 3.7 ± 0.1 h for sarin and 9.9 ± 0.8 h for cyclosarin. Soman showed a biphasic elimination, with terminal half-lives of about 18.5 and 3.6 h (Shih et al., 1994). Maximum peak levels of sarin biotransformation products in urine were detected 10−18 h after exposure (Minami et al., 1997) and, after 2 days, hydrolyzed sarin products had been excreted nearly quantitatively (Shih et al., 1994). Even at 5 days, postexposure soman product recovery was only 62% (Shih et al., 1994). Excretion of soman from blood, liver, and kidneys following chemical and enzymatic hydrolysis is considered a first-order elimination process (Sweeney et al., 2006).

52.3.12 Concentration−time profiles of nerve agents in blood after various routes of administration

Extensive toxicokinetic studies in animal models using rats, marmosets, and guinea pigs were performed for sarin

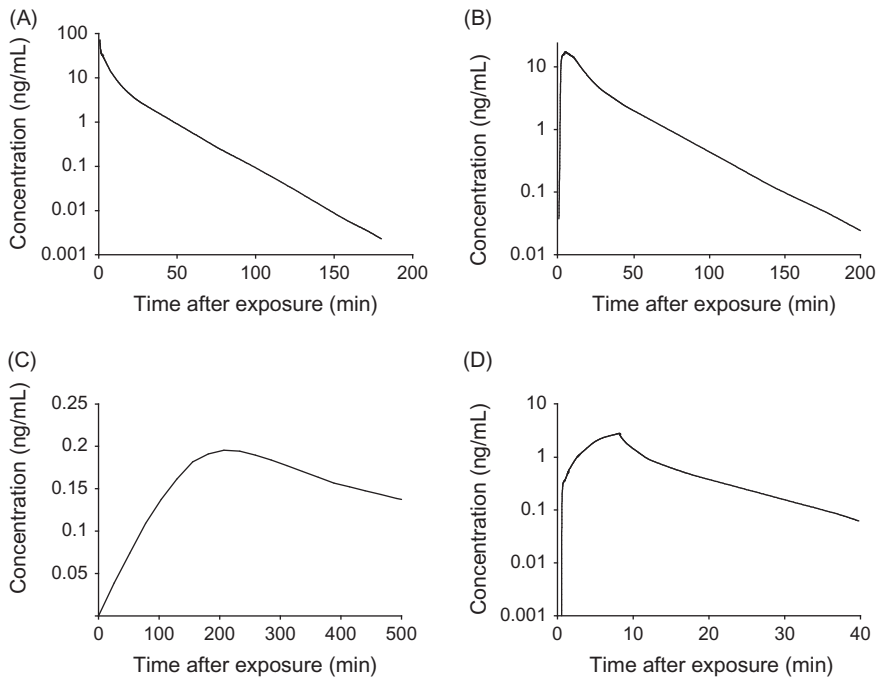

FIGURE 52.3 Concentration−time profiles of highly toxic C(−)P(−) soman and (±) VX in guinea pig blood after administration of nerve agents via different routes of exposure. Guinea pigs were challenged with C(±)P(±)-soman (A, B, D) or (±) − VX (C). (A) Intravenous, $6 \times LD_{50}$ (165 μg/kg); (B) subcutaneous bolus, $6 \times LD_{50}$ (148 μg/kg); (C) percutaneous bolus, $1 \times LD_{50}$ (125 μg/kg); (D) nose-only for soman vapor in air at $0.8 \times LCt50$ (48 mg/m^3 for 8 min). Nerve agents were applied to anesthetized, atropinized, and mechanically ventilated animals. Data fits are according to basic studies presented by Benschop and de Jong (2001; A, B, D) and by Van der Schans et al. (2003; C).

and most often for soman, thereby considering individual concentration−time profiles of different enantiomers (Benschop and de Jong, 2001). The resulting concentration curvatures reflect the combination of toxicokinetic factors of distribution and elimination by hydrolysis and protein binding, as described previously in detail. The next section will briefly summarize the most prominent findings about stereoselectivity and related blood concentration−time profiles. In contrast to many OP pesticides, detailed toxicokinetic data on oral uptake of nerve agents is not available. Therefore, we restrict this section to i.v., s.c., p.c., and respiratory exposure. For more detail, a concise and extensive overview is given by Benschop and de Jong (2001).

52.3.12.1 Intravenous uptake

Direct poison injection into the circulation allows immediate distribution in an organism, but also enables undelayed elimination provoked by plasma components. To illustrate these impacts, we introduce some fundamental results obtained for some G agents, as depicted in Fig. 52.3A (Benschop and de Jong, 2001).

As soon as 0.3 min after i.v. administration of C(±)P(±)-soman to rats, guinea pigs, and marmosets (3−6 LD_{50}), the less toxic C(+)P(+)-enantiomer degrades to nondetectable concentration, whereas its diastereomer C(−)P(+)-soman is detectable for a few minutes longer. This rapid decrease in P(+)-enantiomers is caused by fast enantioselective catalytic hydrolysis (Table 52.3). In contrast, the highly toxic P(−)-diastereomers are detected for up to 1 h or longer, showing a steep initial concentration decrease caused by systemic distribution, protein binding, and hydrolysis, followed by a more moderate concentration decline during the later elimination phase (Fig. 52.3A). CarbE is expected to be the most important scavenger in laboratory animals, being essential for nerve agent elimination and causing high species-dependent variations in LD_{50} values (listed in descending order, rat, guinea pig, and marmoset), which correlate to individual CarbE concentrations (Table 52.2). Resulting concentration curvatures were fitted best by a three-exponential equation (Benschop and de Jong, 2001). Fig. 52.3A gives a representative example of the concentration−time profile of C(−)P(−)-soman in guinea pigs. Corresponding experiments, performed with (±)-sarin applied to guinea pigs, demonstrated that initial distribution of (−)-sarin happened an order of magnitude faster than P(−)-soman, whereas elimination was one order of magnitude slower (Benschop and de Jong, 2001). The reasons for these differences are not clarified yet, but they are expected to be due to different kinetics of hydrolysis and protein binding, causing higher persistence of (−)-sarin.

Similar results of stereospecific kinetics were also observed for tabun after i.v. challenge in swine, showing a shorter terminal half-life elimination for the less toxic (+)-tabun (Tenberken et al., 2010). In accordance, the (−)-cyclosarin enantiomer could be detected for at least 20 min after i.v. administration of racemic cyclosarin to swine, whereas the (+)-isomer could not be detected in any sample even though the first blood draw was done about 2 min after poisoning (Reiter et al., 2007).

Monitoring the concentration−time profile of VX after i.v. challenge in swine, Reiter et al. (2011) also measured the concentration of its toxic hydrolysis product EA-2192 (*S*-[2(diisopropylamino)ethyl]methylphosphonothioic acid) by means of liquid chromatography-tandem MS (LC-MS/MS). This biotransformation was also observed in heparinized rat plasma in vitro, showing a notable stability, and should be considered for therapy of OP poisoning by VX.

52.3.12.2 Subcutaneous uptake

Subcutaneous exposure is often used as a substitute for respiratory exposure due to experimental difficulties in performing controlled inhalational poisoning (Benschop and de Jong, 2001). For example, we will note a typical study illustrating the s.c. behavior of soman (Fig. 52.3B). A C(±)P(±)-soman bolus injection in the scruff of a guinea pig neck resulted in a discontinuous C(−)P(−)-soman concentration−time profile following a monoexponential equation for the absorption phase and a biexponential fit for the distribution phase (Fig. 52.3B; Benschop and de Jong, 2001). The steep initial concentration increase in blood indicated rapid penetration through capillary walls. Maximum concentration was not reached until 7 min after soman injection, yielding an absorption half-life of about 3.5 min. Despite some certain diastereomer-specific differences [decreased bioavailability of C(+)P(−)-soman], both P(−)-forms exhibited comparable kinetic behavior. Bioavailability was found to be 70%−80% when comparing the corresponding area under the curve (AUC) to that of i.v. injection. Very similar to the i.v. characteristics mentioned previously, the toxic, more stable P(−)-isomers were detectable in blood for more than 3 h after exposure, whereas the less toxic P(+)-forms of soman could not be determined at any time. This is attributed to the high-hydrolyzing catalytic activity of PTEs in blood, skin, and other affected tissue (Table 52.3).

52.3.12.3 Percutaneous uptake

(±)-VX dissolved in isopropanol (1 LD_{50}) was applied p.c. to hairless guinea pigs (Fig. 52.3C; Van der Schans et al., 2003). Typically for p.c. exposure, concentration in blood increased very slowly, reaching its maximum between 3 and 4 h after challenge, followed by a slight decrease within the next 4 h. Despite that longer period of monitoring, the illustrated concentration−time profile only reflects the distribution and early elimination phases. This slow release is due to the formation of a depot under and in the skin, as well as to reduced hydrolytic degradation of VX in vivo. No prominent effects of stereoselective toxicokinetics were observed; therefore, the depicted curvature reflects the racemic mixture of analytes. Bioavailability of VX at 7 h was found to be very small compared to i.v. data (not exceeding 3%). The long-lasting elimination phase demonstrated high VX persistence in the organism, resulting in threatening concentrations with acute toxicological relevance for a longer period. Such information is important for therapeutic treatment, pointing out the necessity of long-time oxime infusion.

52.3.12.4 Respiratory uptake (nose-only model)

As pointed out in Section 52.6, respiratory uptake is the most likely route of exposure for G agents, causing 70%−80% absorption in the upper respiratory tract. The sophisticated exposure model of the nose-only design applied to guinea pigs challenged the laboratory animals free of potential distortions derived from simultaneous ocular or p.c. uptake, as occurs in vapor chambers (Langenberg et al., 1998a).

The toxicokinetics caused by administration of C(±)P(±)-soman to guinea pigs documented a discontinuous process of monoexponential function for the absorption phase followed by a biexponential fit for distribution and elimination (Fig. 52.3D). C(−)P(−)-soman was detected in blood as early as 30 s after challenge, and a short-term maximum was reached immediately after terminating the 8-min exposure period (Fig. 52.3D; Benschop and de Jong, 2001). Nevertheless, some depot formation might also occur when applying higher doses, causing maximum levels after completion of exposure. The concentration curvature of C(+)P(−)-soman showed a similar profile, but with consistently smaller concentrations, which is due to a higher degree of enzymatic hydrolysis (Table 52.3). In contrast, less toxic C(−)P(+)-soman was detected in very small concentrations during the exposure phase exclusively, whereas C(+)P(+)-soman was not detected at all. Curvatures for S_P-(−)-sarin appeared to be very similar in terms of time for first appearance in blood and for reaching maximum concentration.

These selected representative examples indicate that concentration−time profiles are variable despite common underlying basic chemical reactions of hydrolysis and adduct formation. Despite improving medical treatment of nerve agent poisoning, the concurrence of numerous physiological and pathophysiological parameters should be understood. Therefore, establishment of a descriptive and predictive model is important for medical defense of OPCs.

52.3.13 Mathematical simulation for prediction of nerve agent toxicokinetics

As is obvious from the huge number of parameters affecting toxicokinetic behavior (e.g., route of administration, nature of OPCs, hydrolyzing and bioscavenging enzymes,

proteins, and distinct compartments for distribution and species specificities), mathematical modeling of this complex situation is a big challenge. Based on numerous experimental data on soman toxicokinetics, Sweeney et al. (2006) introduced a model described by mathematical algorithms that allows the prediction of concentration−time profiles evoked by i.v., s.c., or inhalational soman uptake (≥1 LD_{50}) in common laboratory animals (i.e., rat, guinea pig, and marmoset). This physiologically based pharmacokinetic model (PB/PK) benefits from the combination of relevant pharmacokinetic basics and soman-specific experiences, realizing both an excellent degree of confidence for theoretical and laboratory data, as well as extrapolation to other species. This concept is a further development of an initial model from the same working group introduced by Langenberg et al. (1997). A more detailed description of these models would go beyond the scope of this chapter. Readers are referred to the sources in the reference list at the end of the chapter.

52.3.14 Bioanalytical techniques relevant to toxicokinetics

Elaboration of nerve agent toxicokinetics requires sophisticated analytical tools to detect and, if possible, quantify the free toxicants, as well as adducts with proteins and enzymes. Analysis of OP nerve agents has been performed by capillary electrophoresis (CE), biosensors, MALDI-MS, desorption electrospray ionization MS (DESI MS), ion mobility time-of-flight MS (IM-TOF MS), nuclear magnetic resonance (NMR) spectroscopy, liquid chromatography-ultraviolet (LC-UV), gas chromatography (GC), and many more techniques (Hooijschuur et al., 2002; John et al., 2008).

52.3.14.1 Determination of nerve agents

In contrast to those rather unusual methods, GC coupled to diverse detection systems [e.g., flame ionization detector (FID), nitrogen−phosphorus detector (NPD), flame photometric detector or mass spectrometer, as well as LC methods] represent the most common techniques for OP determination, especially for biological samples. These methods offer high resolution, sufficient limits of detection, good reproducibility, and robust hardware devices. For more detailed information, readers are referred to other review articles (e.g., Hooijschuur et al., 2002; John et al., 2008).

Analysis becomes much more complex when stereoisomers are quantified separately (Fig. 52.1). Enantiomers cause identical detector responses in NPD, FID, or MS. Therefore, chiral separation systems are required to overcome these detector limitations. Despite enormous progress in separation media and detector systems within the last two decades, the number of reports on chiral analysis of nerve agents valuable for toxicokinetic studies is still very small. Chiral separations make use of special chromatographic columns modified with chiral ligands.

Isomers of soman were separated by GC on a Chirasil-L-Val column, but lacked baseline separation (Benschop et al., 1981, 1985; Li et al., 2003a,b). In contrast, (+)-sarin and (−)-sarin could be completely separated by the same column (Benschop and de Jong, 2001). Another study presented a modified method using a Chiraldex gamma-cyclodextrin trifluoroacetyl GC-column coupled to an electron impact (EI)-MS, which enabled sufficient baseline separation of all four stereoisomers of soman (Smith and Schlager, 1996; Yeung et al., 2008).

Apart from the Chirasil-L-Val method, sarin enantiomers were also separated by a two-dimensional GC technique on chiral Cyclodex B material prior to NPD monitoring (Spruit et al., 2000, 2001). Additional GC-based approaches allowed baseline separation of cyclosarin enantiomers on a GAMMA DEX column monitored by EI-MS (Reiter et al., 2007), separation of VX stereoisomers on hydrodex-β-TBDAc (β-cyclodextrin; Reiter et al., 2008), and separation of tabun enantiomers on BetaDex 225 coupled to APCI-MS (Tenberken et al., 2010). VX enantiomers were also chromatographed on a Chiracel OD column by LC coupled to an electrochemical detector, yielding a lower limit of quantification of about 10 ng/mL blood (Van der Schans et al., 2003). Another LC method coupled with MS/MS detection for VX made use of CHIRALCEL OD-H and CHIRAL AGP columns (Reiter et al., 2008).

52.3.14.2 Detection of enzyme and protein adducts of nerve agents

In contrast to the measurement of free agents, the qualitative detection of protein adducts is a very novel approach that came about by overwhelming technical progress in bioanalytical mass spectrometry. Electrospray ionization (ESI) and MALDI as soft ionization methods for mass spectrometric detection are highly valuable for the detection of biomacromolecules like DNA, peptides, and proteins (Schulz-Knappe et al., 2001; John et al., 2004, 2005). Therefore, these technologies are also favorable for the analysis of proteins interacting with nerve agents. Consequently, a number of approaches have been published that identify and characterize these adducts. Typically, protein and enzyme adducts are first isolated from complex biological matrices (e.g., blood) using affinity chromatographic methods; subsequently, they are subjected to enzymatic cleavage by adding selected proteases. The resulting internal peptide cleavage products containing the derivatized phosphylated) residues are chromatographically separated and analyzed by modern

TABLE 52.5 Physicochemical properties of most common vesicant agents.

mass spectrometry. Using sophisticated MALDI-MS techniques, this general procedure allowed the identification of albumin adducts (Li et al., 2007, 2008; John et al., 2010), as well as the adducts of BChE and their aged products (Jiang et al., 2013). LC-ESI MS was applied to analyze adducts of albumin (Peeples et al., 2005; Williams et al., 2007), BChE (Noort et al., 2006; Tsuge and Seto, 2006; John et al., 2015), CarbE (Peeples et al., 2005), keratins, tubulin, actin, and transferrin (Grigoryan et al., 2009; Schopfer and Lockridge, 2019). For a more detailed description, see John et al. (2008), Schopfer and Lockridge (2012), and Black and Read (2013).

For diagnostic detection of BChE adducts of common G- and V-type nerve agents, enhanced sample throughput was achieved by automated processes in 96-well plate format, extracting plasma by immunomagnetic separation (Knaack et al., 2012). An alternative method, based on the principle of a sandwich enzyme-linked immunosorbent assay (ELISA), was presented by Wang et al. (2011) to determine OP adducts in complete BChE. Modern mass spectrometry-based methods were successfully applied to prove a case of fatal sarin poisoning in the violent conflict in the Syrian Arab Republic in 2015 (John et al., 2018a,b).

This summary underlines the great importance of modern analytical techniques to unraveling pathophysiological situations at the molecular level and to supporting toxicokinetic studies by discovering the most relevant protein-binding elimination processes.

52.4 Vesicants

52.4.1 Sulfur mustard

52.4.1.1 Overview of sulfur mustard

Sulfur mustard is a blistering or vesicating agent that primarily incurs damage on organs that come into immediate contact with either its liquid or vaporous form. Even low-dose dermal and respiratory exposure to the agent results in systemic absorption of sulfur mustard, which subsequently may cause additional systemic damage (Kehe and Szinicz, 2005; Steinritz et al., 2016).

Unfortunately, sulfur mustard has been used in acts of chemical warfare throughout the 20th century, from World War I to the attacks of Saddam Hussein's former Iraqi regime against Iran and even Kurdish civilians or the repetitive use of sulfur mustard in the Syria crisis starting in 2013. The simplicity of the agent and its synthesis combined with its devastating medical, psychological, and socioeconomic effects, along with the fact that no causative therapy has yet been established, may convince future aggressors (both state and nonstate parties) to use this agent in their attacks. This, in turn, necessitates medical research efforts, including toxicodynamic and toxicokinetic studies, to develop countermeasures against the effects of sulfur mustard. Table 52.5 displays the basic physicochemical properties for sulfur mustard, which constitute the fundamental reason behind many of its toxicokinetic properties. Data for lewisite, another vesicant agent described Section 52.44.2, are also shown in this table.

52.4.1.2 Toxicity of sulfur mustard

Fig. 52.4 depicts the basic chemical mechanism by which sulfur mustard incurs its primary damage to biological molecules, which results in subsequent damage to cells, tissues, and organs. Sulfur mustard forms an intermediate sulfonium ion that further transforms into a carbenium ion, a strong electrophile capable of reacting with nucleophile targets, primarily in DNA and RNA. Examples include the N7 in guanine (61%; Ludlum et al., 1994), the N3 in adenine (6.6%), and the O6 in guanine (0.1% for chloroethylthioethene) (Ludlum et al., 1986). Even though the latter is considerably less frequent, it is of significant concern, as the repair enzyme (O6-alkylguanine-DNA-alkyltransferase) is not capable of reversing this reaction. Therefore, DNA mutation due to mispairing may occur

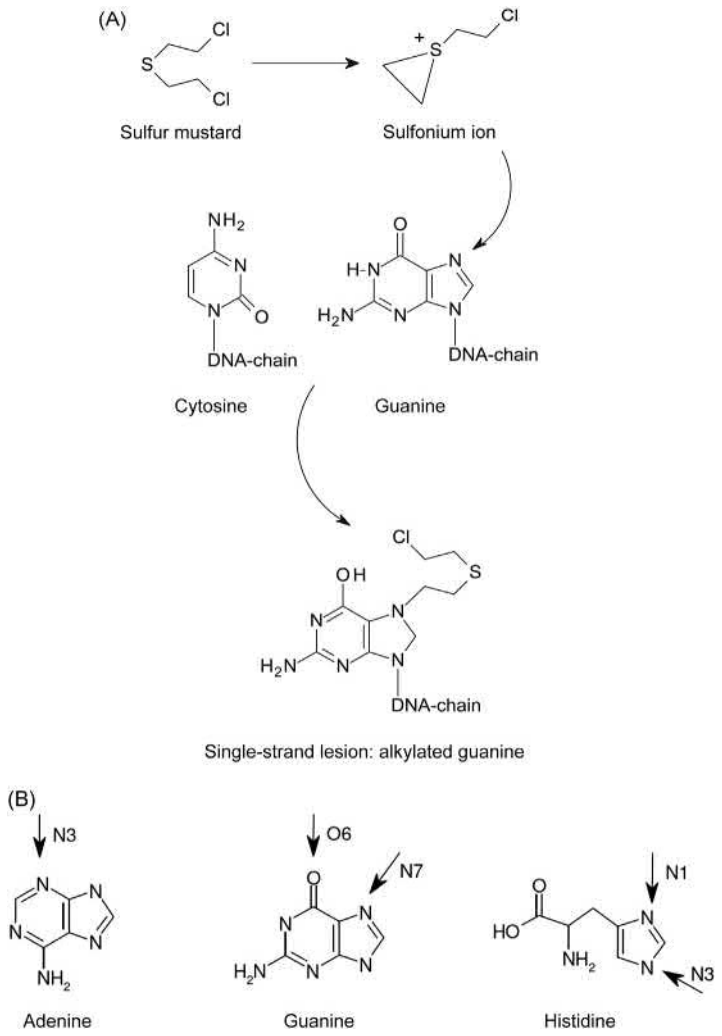

FIGURE 52.4 Sulfur mustard, its structure, mechanism of action, and targets of adduct formation. (A) Mechanism of reaction of sulfur mustard and nucleotide guanine. (B) Sites of alkylation by sulfur mustard. Arrows mark identified targets in nucleotides and amino acid histidine.

during DNA replication, which is proposed to be the origin of subsequent cancer formation (Ludlum et al., 1986). Because of its bifunctional character, sulfur mustard also forms interstrand DNA cross-links, in particular from one guanine to another (17%). It is estimated that a 100-μM concentration of sulfur mustard accounts for 0.28 cross-links per 10,000 DNA bases (Shahin et al., 2001). Remarkably, adipose tissue seems more sensitive to sulfur mustard in means of DNA adduct formation. Here, cross-links were more abundant compared with in nonadipose tissue (Wang et al., 2015). Moreover, more recent studies, that investigated sulfur mustard DNA adduct formation in both cell cultures and animal experiments, revealed a dose-dependency regarding the formation of N7-HETEG, N3-HETEA, O6-HETEG, and Bis-G (Yue et al., 2014). Furthermore, cross-links between N7 in guanine and glutathione (GSH) were described by Batal et al. in murine organs (skin, brain, and lung) after percutaneous in vivo exposure of mice to sulfur mustard (Batal et al., 2015). GSH adducts were found in quantities similar to the Bis-G product (Batal et al., 2015). Membrane-bound proteins and enzymes may undergo alkylation in the presence of sulfur mustard (Kehe and Szinicz, 2005). Recently it was shown that chemosensing TRPA1 channels are targeted by sulfur mustard and that TRPA1 activation contributes to cytotoxicity (Stenger et al., 2015). The exact activation mechanism is still not fully understood. Covalent modification of intracellular cysteine residues, but also interaction between sulfur mustard and extracellular or transmembrane parts, may occur (Stenger et al., 2017) Fig. 52.4 depicts targets of alkylation in both DNA bases and amino acids. As sulfur mustard-induced DNA damage has the most significant impact on the cell's short- and long-term survivability, it is DNA alkylation that produces the most significant toxic effects, whereas effects from protein alkylation are usually visible only in the presence of high concentrations of sulfur mustard (Peters, 1947; Lodhi et al., 2001). As systemic

concentrations will always be several orders of magnitude below local concentrations at the site of immediate contact, the systemic toxic effects of sulfur mustard are also most likely to result from DNA alkylation. DNA alkylation produces the most evident effects in proliferating cells; tissues with rapidly proliferating cells, such as bone marrow, suffer the most obvious damage. Toxic effects are similar to side effects from alkylating antineoplastic drugs (Dacre and Goldman, 1996). [Actually, the first antineoplastic drug was developed from a structural analog of nitrogen mustard—see Goodman et al. (1984).] Those effects include nausea, vomiting, fever, fatigue, apathy, and loss of appetite. Bone marrow toxicity results in an initial leukocytosis, which is soon followed by leukopenia, thrombopenia, eosinopenia, and subsequent anemia (Dacre and Goldman, 1996).

Specific toxic effects of sulfur mustard have also been reported in the CNS and may range from agitation to seizures (Balali-Mood and Navaeian, 1986). In addition to these acute CNS symptoms, long-term neurological and neuropsychological complications of sulfur mustard and lewisite were also reported (Isono et al., 2018).

Sulfur mustard-induced DNA alkylation is regarded as exclusively causal for toxicity. However, it was demonstrated that sulfur mustard is able to provoke immediate behavior responses along with fast changes in the electrical field potential (EFP) of neurons in the insect species *Blaptica dubia*, suggesting that lesions of DNA are probably not the only effect of alkylating compounds (Popp et al., 2018).

52.4.1.3 Invasion

Significant amounts of sulfur mustard may be absorbed from skin that has been in direct contact with sulfur mustard. Vapors of sulfur mustard may also be absorbed through the respiratory system.

In theory, there are two additional pathways for systemic uptake of sulfur mustard: the surface of the eyes and the gastrointestinal system. They have, however, never been investigated for the following reasons: gastrointestinal exposure to sulfur mustard is a rare phenomenon and may only occur in cases of sabotage (deliberate food poisoning) or a considerable lack of basic chemical defense measures (i.e., food consumption in a contaminated area). The local effects of exposing the gastrointestinal system to sulfur mustard are severe and life-threatening; they include strong abdominal pain, bloody diarrhea and vomiting, and rupture of stomach or duodenum. Subsequent peritonitis is often fatal (Dacre and Goldman, 1996). In comparison to life-threatening local effects of gastrointestinal exposure, any related systemic effect would be of secondary importance.

As opposed to the rarity of gastrointestinal exposure, ocular exposure is frequent among the victims of sulfur mustard attack, and local symptoms of varying severity are likely to occur whenever the individual was not protected by a respirator (gas mask) at the time of attack (Solberg et al., 1997). As the eye is a very sensitive organ, ocular symptoms are often among the first signs of sulfur mustard exposure. Due to the close proximity of a large number of capillary vessels and the fact that the eye constitutes a relatively weak barrier, xenobiotic substances are often rapidly absorbed (Lama, 2005). As the surface of the eye is small in comparison to the skin and the respiratory tract, the total amount of sulfur mustard that may be absorbed from the eye's surface is low. Self-protective effects of the eye, such as blepharospasm and pronounced lacrimation, may further reduce the amount of an agent that may be absorbed through this pathway. The local effects of exposure appear very severe and are a primary reason for concern in victims of sulfur mustard exposure. Whereas blepharospasm and lid edema cause transitory loss of vision—already resulting in immense distress for victims—heavy exposure may result in permanently opaque cornea and blindness. In general, early effects in the eyes are treatable with therapy and have a relatively good outcome after several weeks. In comparison, any systemic effects from transocular absorption alone would be of only minor concern. It has to be emphasized that isolated ocular exposure on the battlefield or due to terrorist attacks utilizing sulfur mustard is exceedingly unlikely. Ocular exposure would inevitably be accompanied by cutaneous and respiratory exposure. The specific rate of absorption (i.e., the amount absorbed through a given surface over a specified time) may be lower, particularly in the case of initially intact skin. However, the larger surface of the skin (and possibly the respiratory tract) would result in an amount that constitutes the major fraction of sulfur mustard absorbed, which would subsequently determine the occurrence and severity of systemic effects. Research regarding the absorption of sulfur mustard has focused on two major pathways, which are described in further detail in the subsequent sections.

52.4.1.3.1 Percutaneous absorption

Penetration rates of liquid sulfur mustard were determined in vitro (71−294 $\mu g/cm^2/h$) on human skin with a Franz-type glass diffusion cell and correspond very well to in vivo data derived from human skin (60−240 $\mu g/cm^2/h$; Chilcott et al., 2000). Significant effort has been dedicated to confirm the validity of animal models by comparing data derived from these models with findings from in vitro human skin experiments. Chilcott et al. (2001) investigated absorption in in vitro models of pig-ear and heat-separated human skin. Absorption was determined at 411 ± 175 $\mu g/cm^2/h$ for pig-ear skin and 157 ± 66 $\mu g/cm^2/h$ for human skin, respectively. These data were considered to agree with earlier in vivo findings, even

though the authors cautioned that data on effectiveness of decontaminants were completely disparate between human and pig-ear skin. Logan et al. (1999) determined that sulfur mustard exposure through skin of the hairless guinea pig was 120 $\mu g/cm^2/h$.

Occlusion of the skin (i.e., covering the skin with a material that is impenetrable to air and moisture) can result in a dramatic increase in p.c. absorption. For example, in a study by Chilcott et al. (2002) using in vitro models of human skin, absorption rates in unoccluded controls ($4.41 \pm 1.90\ \mu g/cm^2/h$) increased to $538 \pm 193\ \mu g/cm^2/h$ under occluded conditions.

In contrast, Karvaly et al. (2008) showed that a commercially available barrier cream and a perfluoropolyether oil applied prior to exposure reduced p.c. uptake of sulfur mustard. In particular, perfluoropolyether oil was highly effective, preventing sulfur mustard exposure for a period of 20 min. A petroleum jelly ointment, however, had no protective effect, even when applied prior to exposure.

Benson et al. (2011) percutaneously exposed guinea pigs to ^{14}C-labeled sulfur mustard vapors ($525\ mg/m^3$) for 12 min, applied to three skin areas totaling $19.8\ cm^2$. A total of $29.8 \pm 5.31\ \mu g$ sulfur mustard per animal was absorbed, 90% of which remained in the skin. This result agrees with an in vitro study by Hattersley et al. (2008) using human skin samples, which confirmed that a depot of sulfur mustard existed for at least 24 h following dermal exposure, and estimated concentrations in skin are at least 20 times above the acutely toxic concentration.

Regarding airtight vapor cups frequently used for percutaneous sulfur mustard exposure studies, Dalton et al. (2006b) validated this approach and showed that equilibrium concentrations developed within 2 min after sealing the cups and were not significantly different from calculated saturated vapor concentration ($1{,}363\ mg/m^3$) when cups were placed on inert control surfaces. However, when cups were placed on samples of pig skin, percutaneous uptake of sulfur mustard lowered actual vapor concentrations to values significantly below saturation (i.e., to $592 \pm 246\ mg/m^3$ on a $10.15\ cm^2$ skin surface and $740 \pm 224\ mg/m^3$ on a $2.54\ cm^2$ skin surface). The authors validated the assumption that saturated vapor concentration could be used to calculate concentration−time products for percutaneous absorption studies, but they cautioned that, depending on the size of the reservoir and the skin surface, decreasing vapor concentrations had to be taken into account.

52.4.1.3.2 Respiratory absorption

Langenberg et al. (1998b) conducted inhalation exposure experiments in hairless guinea pigs. LCt_{50} was determined at $800\ mg\ min/m^3$. Following application of 1 LCt_{50} over 5 min, no unchanged sulfur mustard in blood was found (with a limit of detection of 5 pg/mL). Low concentrations (0.7 adducts per 10^7 nucleotides) of N7-guanine adducts of sulfur mustard were found in the lung. The concentration of N7-guanine adducts was also determined from various tissues along the respiratory tract. In fact, concentrations found were much larger, peaking at approximately 90 adducts per 10^7 nucleotides in the larynx and trachea. The concentration in the carina was lower (approximately 50 per 10^7 nucleotides), but it was still substantially higher than the abovementioned value in the lungs. The authors concluded that most of the sulfur mustard inhaled reacts in the upper airways rather than being absorbed. In animals with complex nasal systems (such as guinea pigs), only very minor fractions would reach the lung. However, they also pointed out that, in humans (along with other species with a less complex nasal system), the proportion of sulfur mustard reaching the lung may be larger.

Following inhalation of $3 \times LCt_{50}$ ($300\ mg/m^3$ over a period of 8 min), sulfur mustard was found in blood. Its peak concentration during the inhalation period was found to be approximately 5 ng/mL. This concentration soon declined. A mean value of 2 ng/mL was found even after 4 h. A mathematical model explaining the data during the distribution and elimination phase could not be developed. These findings were further complicated by the fact that in 2 of 12 animals, no sulfur mustard was found in any of the samples. No sulfur mustard was detected in any of the animals at 15 and 20 min (7 and 12 min postexposure, respectively), before reappearing in most of the animals at the abovementioned concentration of 2 ng/mL. The latter finding may possibly be explained by the hypothesis that the early peak in sulfur mustard concentration is due to direct inhalation (afterward, concentration declines to levels below the limit of detection), whereas the second, long-term increase in sulfur mustard concentration may be attributed to sulfur mustard absorbed from depots in the upper airways. Fig. 52.5 depicts the concentration over time, following the respiratory exposure to $3 \times LCt_{50}$ of sulfur mustard. For comparison, concentration over time after i.v. application is also depicted. The authors concluded that toxicity from sulfur mustard inhalation was due to its local, rather than its systemic, effects.

Benson et al. (2011) presented a respiratory exposure study using ^{14}C-labeled sulfur mustard. Anesthetized rats with transorally placed tracheal catheters were exposed to $250\ mg\ ^{14}C$ sulfur mustard vapor/m^3 for 10 min. A total of $18.1 \pm 3\ \mu g$ sulfur mustard per animal was absorbed. Within 2 h postexposure, inhaled sulfur mustard was distributed and more than 70% were deposited in the carcass and pelt.

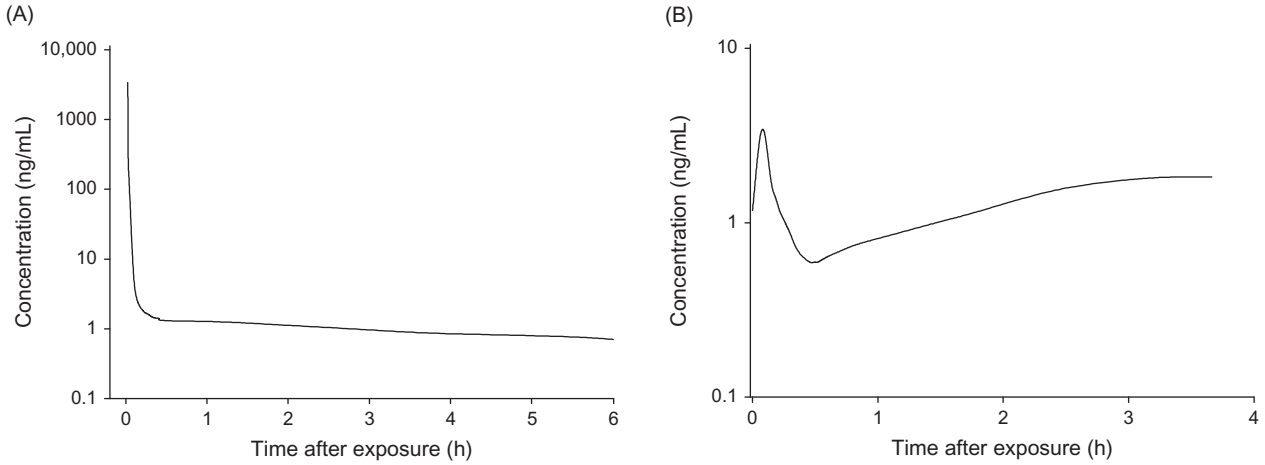

FIGURE 52.5 Concentration over time, following i.v. and respiratory exposure to sulfur mustard in the guinea pig. (A) Decline of sulfur mustard exposure after i.v. injection. (B) Concentration over time after respiratory exposure: initial increase in the inhalation phase, followed by a decline and a secondary increase; concentration of approximately 2 ng/mL is sustained for 4 h.

52.4.1.4 Distribution

Sulfur mustard is a strongly lipophilic substance that may accumulate in fatty tissues and has been detected at autopsy in a patient who died 7 days postexposure. Detailed data, as published by Drasch et al. (1987), are displayed in Table 52.6. This case report observation was affirmed by animal experiments using rats (Xu et al., 2017).

Obviously, these findings confirm the theoretical assumption that the lipophilic properties of sulfur mustard result in a distribution, primarily in lipophilic tissues. High concentrations found in the brain may also explain why the CNS is one of the organs exhibiting systemic effects of sulfur mustard poisoning, even though it is not a site of rapidly proliferating cells.

It should be noted that some authors have questioned the findings by Drasch et al., considering the absolute concentrations excessively high and therefore unlikely. However, as high-dose sulfur mustard poisoning is a rare event, it is nearly impossible to verify or falsify the data. One might argue that the amounts of sulfur mustard described may not even permit short-term survival. However, if most of an agent entered the organism via p. c. absorption, there is a possibility that large amounts of the agent actually had been absorbed and formed a depot without resulting in instant death, but ultimately leading to death 7 days later. Whether or not the absolute values are accurate, they at least give an impression of the distribution of sulfur mustard within an organism that correlates with the agent's lipophilic properties.

More recent in vitro experiments using human skin have confirmed the presence of unhydrolyzed sulfur mustard in the lipophilic stratum corneum and the upper epidermis. At 24 h post-exposure, the distribution ratio between epidermis and dermis has been determined to be 62%–38%. Chilcott et al. (2000) also suggested that efforts to remove or neutralize the agent from these deposits might have a clinical benefit for the patient.

These findings suggest that, despite the presumably brief half-life calculated (see Section 52.44.1.7), sulfur

TABLE 52.6 Content of sulfur mustard in the tissues of a deceased victim.

Tissue/organ	Concentration (mg/kg)

Source: Data are according to Drasch, G., Kretschmer, G., Kauert, L., 1987. Concentration of mustard gas [bis(2-chloroethyl)sulfide] in the tissues of a victim of a vesicant exposure. J. Forensic Sci. 32, 1788–1793.

mustard may be present in an organism for a significantly longer period of time, necessitating measures for medical personnel providing therapy and an awareness for the possibility of secondary blister formation, even 30 days post-exposure (Balali-Mood and Hefazi, 2005), as well as efforts to remove these deposits. In particular, the use of laser debridement (Graham et al., 2008) and mechanical dermabrasion (Rice, 2008) has been recommended to facilitate the healing process after dermal exposure to sulfur mustard. The effects may be partly attributed to the removal of epidermal depots of sulfur mustard.

As mentioned previously, Benson et al. (2011) confirmed that 90% of percutaneously absorbed sulfur mustard was deposited in skin, whereas more than 70% of absorbed sulfur mustard was distributed to the carcass and pelt after respiratory exposure. The distribution of sulfur mustard is highly dependent on the original route of exposure. It was confirmed that a considerable amount of sulfur mustard was still present in deep lipophilic compartments even after the end of exposure.

52.4.1.5 Biotransformation

While the previously discussed findings demonstrate the stability of sulfur mustard in lipophilic tissues, the agent is rapidly hydrolyzed whenever situated in an aqueous compartment (Vycudilik, 1987). Thiodiglycol (TDG) is the primary hydrolysis product, in which the chlorine atoms have been replaced by hydroxyl groups. Karvaly et al. (2008) used subcutaneous microdialysis to monitor TDG in rats exposed to sulfur mustard. Peak concentrations of 7.2−21.7 nmol/L TDG were found, following percutaneous exposure to 2 μM sulfur mustard.

TDG may undergo oxidation to TDG sulfoxide, which is conjugated with glutathione to form 1,1′-sulfonylbis [2-*S*-(*N*-acetylcysteinyl)ethane]. Following the β-lyase pathway, the 1,1-sulphonylbis[2-(methylsulfinyl)ethane] and 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl]ethane can be formed (Black and Read, 1995). Fig. 52.6 summarizes the pathways of sulfur mustard biotransformation. No sulfo- or glucuronyl-conjugates were detected in urine after i.v. administration of sulfur mustard (Maisonneuve et al., 1993).

Halme et al. (2011) presented a method for the efficient stable isotope dilution LC-HESI-MS/MS method for verification of β-lyase biotransformation products in human urine after sulfur mustard exposure. The β-lyase products 1,1′-sulfonylbis-[2-(methylsulfinyl)ethane] (SBMSE) and 1-methylsulfinyl-2-[2-(methylthio) ethylsulfonyl]ethane (MSMTESE) were successfully detected at a concentration of 4 ng/mL, whereas the limit of quantification was established at 10 and 11 ng/mL for SBMSE and MSMTESE, respectively.

Within cells, sulfur mustard forms adducts with DNA, primarily those described above. Adducts can also be formed with nucleophilic sites of amino acids and proteins. Byrne et al. (1996) demonstrated that sulfur mustard, with two highly reactive groups, was able to form protein cross-links between cysteine residues and assumed that protein cross-link formation may actually contribute to sulfur mustard toxicity. Contrary to DNA adducts, there is no specific mechanism to reverse protein adduct formation. For this reason, there is a strong forensic interest in the detection of protein adducts of sulfur mustard, as these may provide evidence of sulfur mustard exposure for prolonged periods after an incident.

Capacio et al. (2008) developed a method to detect sulfur mustard adducts in plasma proteins by hydrolyzation (which produced TDG) and subsequent derivatization of TDG, followed by GS/MS analysis. The method was successfully applied to determine sulfur mustard adducts in rat plasma, following respiratory exposure to sulfur mustard.

A number of adducts to amino acid residues have been identified (Noort et al., 1996; Black et al., 1997a,b; John et al., 2019; Siegert et al., 2019). Several histidine, glutamic acid, aspartic acid, cysteine, methionine, tryptophan, and valine residues were found to be alkylated. While N1 and N3 histidine adducts were found to be most abundant, it was the alkylated *N*-terminal valine adducts of hemoglobin that were most useful for subsequent quantification. See Section 52.4.6.2 for analytical details.

Noort et al. (2008) investigated the persistence of sulfur mustard adducts to albumin and hemoglobin in rats. The albumin adduct (*S*-2-hydroxyethylthioethyl)-Cys-Pro-Tyr was detectable up to 7 days after exposure, while the adduct to the *N*-terminal valine in hemoglobin was still detected after 28 days. The decrease in the adduct concentration corresponded with the albumin half-life and the lifetime of the rat erythrocyte, respectively. The respective adduct of human serum albumin was detected for at least 29 days after exposure in three cases of accidental human poisoning with sulfur mustard vapor (Steinritz et al., 2016).

Following two simultaneous cases of accidental human exposure to sulfur mustard, Smith et al. (2008) investigated the concentration of cysteine-34 adduct to albumin and adducts to glutamic and aspartic acids of plasma proteins. In the case of a more severely exposed patient who required hospitalization, both adducts were detected over a 42-day period, although they decreased by approximately 75% toward the end of that time. In a second patient who had developed a single, small blister, the albumin adduct was found during a 6-day period post-exposure. John et al. (2019) reported on four cases of human poisoning as a result of a mortar attack in the

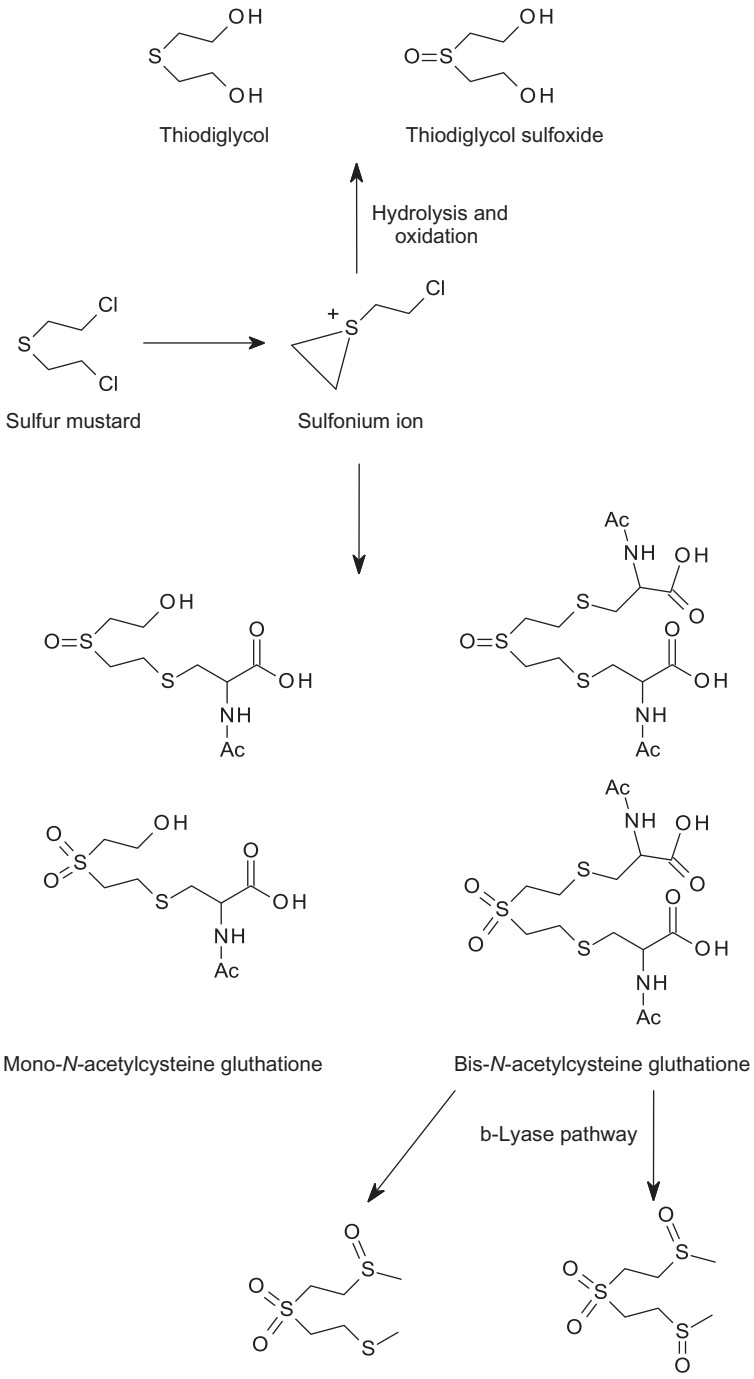

FIGURE 52.6 Biotransformation of sulfur mustard.

Middle East. Exposure to sulfur mustard was proven by detection of diverse albumin adducts even though blood drawing from poisoned persons was done 15 days after exposure (John et al., 2019).

Recently, local adduct formation after cutaneous exposure to sulfur mustard has been a focus of investigation in an effort not only to establish new forensic methods, but also to better understand vesication, the most evident symptom of sulfur mustard exposure via the skin. Adducts of sulfur mustard to cytokeratin types I and II, actin stratifin, and galectin-7 were successfully identified by Mol et al. (2008) in sulfur mustard-exposed human epidermal keratinocytes. Sulfur mustard adducts to actin, annexin A2, and keratin 9 were also found in HaCaT cells (immortalized keratinocytes) by Sayer et al. (2009).

52.4.1.6 Elimination

Following i.v. application of ^{14}C-labeled sulfur mustard in rats, 80% of the radioactivity administered was

excreted via the renal pathway. Fecal excretion amounted to less than 3% (Maisonneuve et al., 1993). A study by Benson et al. (2011) in rats and guinea pigs, following respiratory and percutaneous exposure to ^{14}C-labeled sulfur mustard, confirmed predominantly renal excretion. Biotransformation products excreted in urine after accidental human exposure included TDG, TDG sulfoxide, and the bis-mercapturate of mustard sulfone (Barr et al., 2008). When comparing the concentrations of TDG and its sulfoxide, the latter was found in concentrations twice as high. When p.c. exposing weanling pigs to sulfur mustard, Graham et al. (2000) found peak levels of TDG either in the samples drawn after 6–8 h or in other cases after 24–48 h. Findings were considered to be in agreement with earlier data from rodent species and cases of accidental human exposure.

It is worth noting that background levels of TDG and TDG sulfoxide have been found in the urine of healthy individuals never exposed to sulfur mustard. For this reason, their validity as unambiguous markers for sulfur mustard exposure has been questioned. Black and Read (1995) suggested the determination of β-lyase pathway biotransformation products, which in the urine of exposed patients were found at concentrations similar to those of TDG sulfoxide, but were not found in unexposed individuals.

52.4.2 Lewisite

52.4.2.1 Overview of lewisite

Lewisite (2-chlorvinyldichlorarsin) is another vesicant. It was first synthesized and described by the Belgian priest and chemist Julius Arthur Nieuwland (Nieuwland, 1904). Unlike sulfur mustard, there has never been a documented use of this substance in armed conflict. During World War I, the American military chemist Winford Lee Lewis suggested and initiated its development into a chemical weapon, but due to the 1918 armistice in Europe, it was not used on the battlefield (Vilensky and Redman, 2003).

Lewisite remains a concern because its physical properties (in particular a melting point of −18°C; see Table 52.5) might facilitate its use in cold climates. A belligerent party willing to use chemical weapons might decide that lewisite would provide a "unique" capability to wage chemical warfare even in winter or in mountainous regions. Large stockpiles of the agent were abandoned by the Imperial Japanese Army during its retreat from China in the latter stages of World War II, creating a chemical hazard that persists decades after the war (Hanaoka et al., 2006). Table 52.5 summarizes the physicochemical properties of lewisite.

52.4.2.2 Toxicity of lewisite

The dominant element in lewisite structure is arsenic, which is able to react with sulfhydryl groups of various enzymes, disabling the enzyme in the process (Goldman and Dacre, 1989). Fig. 52.7 depicts the structure of lewisite and its toxic mechanism.

Lipoic acid is particularly susceptible to this reaction and one of the most evident consequences is the inhibition of the enzyme pyruvate dehydrogenase (PDH), rapidly disabling the cell's metabolism of glucose and fatty acids. The resulting energy deficiency may lead to swift, necrotic cell death. In comparison to sulfur mustard, the latency period (from exposure to first signs and symptoms) is significantly shorter, and lewisite injuries have been described as extremely painful from an early stage. This may be explained by activation of TRPA1 channels by lewisite. Moreover, it is a much more lethal agent and has a large systemic toxicity; 0.5 mL of the agent may produce systemic effects, whereas 2 mL (approximately 3.6 g) can be fatal (Marrs et al., 1996).

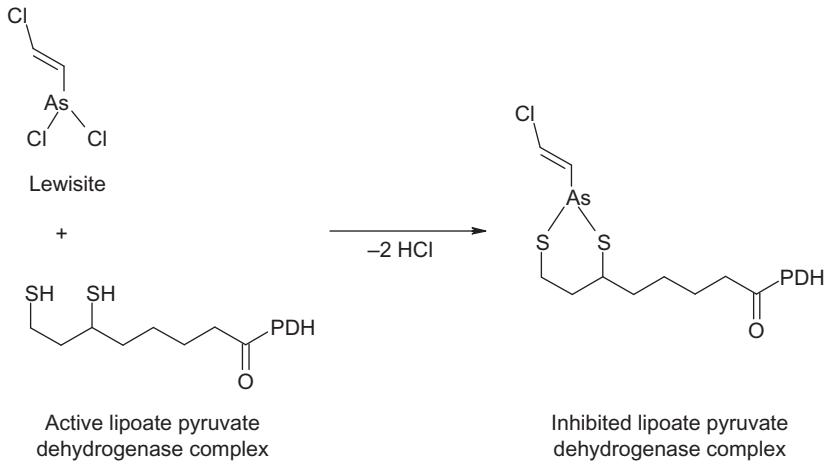

FIGURE 52.7 The structure and mechanism of action of lewisite. Lewisite forms covalent bonds with lipoic acid, inactivating the enzyme PDH.

52.4.2.3 Invasion

52.4.2.3.1 Percutaneous absorption

Precise data [i.e., a diffusion coefficient expressing the p.c. absorption of lewisite (amount absorbed per area and time)] is not available. However, Inns and Rice (1993) conducted p.c. toxicity studies in rabbits and determined the LD_{50} to be 5.3 mg/kg (3.5−8.5 mg/kg, 95% confidence interval). The exposed area was 2 cm^2, and exposure lasted for 6 h.

Inns et al. (1990) had also determined the LD_{50} of i.v. lewisite administration to be 1.8 mg/kg (1.6−2.1 mg/kg 95% confidence interval). It can be concluded that by exposing 2 cm^2 of rabbit skin to a dose of 5.3 mg/kg for 6 h, a dose producing the equivalent effect of 1.8 mg/kg is absorbed. No further calculations that might exaggerate the reliability of available data shall be conducted here.

King et al. (1992) conducted lewisite absorption studies on isolated perfused porcine skin flaps, using lewisite concentrations from 0.07 to 5.0 mg/mL. Blister formation was observed, and at higher lewisite concentrations, there was a pronounced increase of lactate dehydrogenase in blister fluid, a sign of necrotic cell death. Cellular glucose utilization was decreased at the same time, underscoring the detrimental effect of lewisite on cellular energy metabolism. At the highest concentration of 5 mg/mL of lewisite, arsenic was detected in venous blood from the perfused skin preparation. At this concentration, systemic uptake of lewisite or its degradation products and toxic effects resulting thereof are to be expected.

52.4.2.3.2 Respiratory absorption

The LCt_{50} of lewisite in humans has been estimated at 1500 mg min/m^3 (ATSDR, 2007), although no experimental data have been cited. Considering its pronounced local effects, lethality can at least partly be attributed to local effects of lewisite on the respiratory tract.

52.4.2.4 Distribution

High distribution volumes per kilogram indicate extensive distribution in tissues, due to the lipophilicity of the substance. In a rabbit model, more than sevenfold more of the substance was found in some tissues (e.g., the liver, lung, and kidneys) compared to blood concentrations. That ratio was maintained over the sampling period, that is, for at least 96 h (Snider et al., 1990).

52.4.2.5 Biotransformation

Once incorporated, unbound lewisite is quickly hydrolyzed. Its predominant biotransformation product is 2-chlorovinylarsonous acid (CVAA; Fig. 52.8). Analytical methods to confirm lewisite exposure have focused on the detection and quantification of CVAA, at least in the past. However, Noort et al. (2002) also pointed out that, due to the high affinity of arsenic toward sulfhydryl groups, adducts of lewisite/CVAA and cysteine residues of proteins are formed. In an in vitro study, incubating 14C-labeled lewisite with human blood samples, 90% of lewisite was found in erythrocytes, whereas 25%−50% of

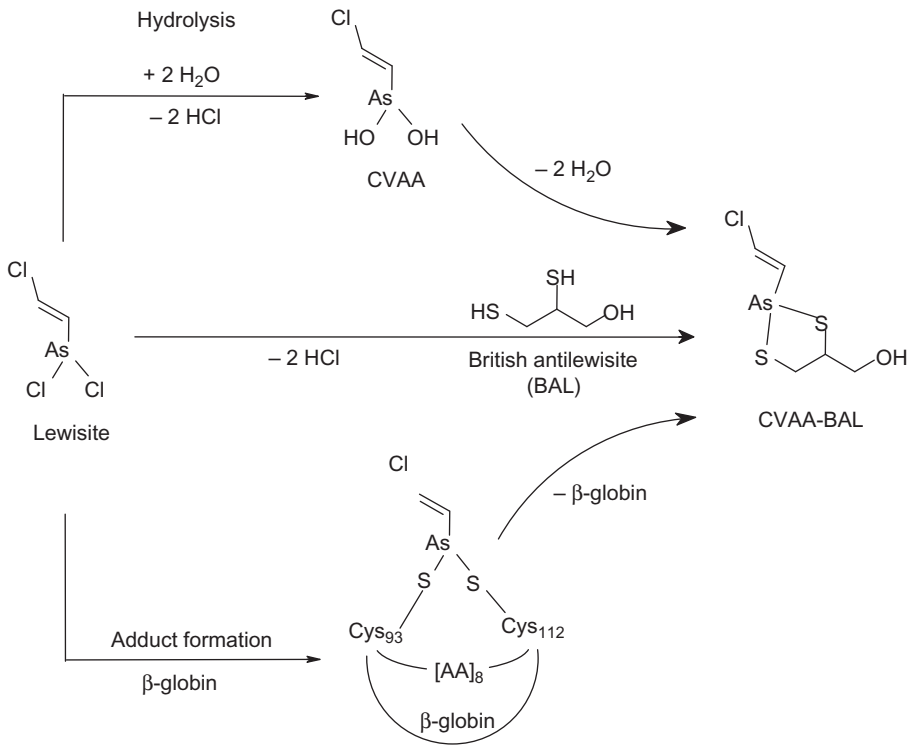

FIGURE 52.8 Lewisite biotransformation, adduct formation, and its reversal.

arsenic was bound to globin. From these protein adducts, CVAA can be released to form an adduct with the antidote British antilewisite (BAL; Fidder et al., 2000). The authors were also able to identify a specific protein adduct of lewisite formed with cysteine residues 93 and 112 of β-globin. See Section 52.46.2 for analytical details. Fig. 52.8 summarizes the biotransformation and reversal of adduct formation by BAL.

52.4.2.6 Elimination

Snider et al. (1990) determined the elimination of lewisite from rabbits after p.c. injection. The half-life was determined, ranging from 55–75 h. A clearance of 120 mL/h/kg was found. These findings only describe the overall elimination of arsenic from the organism following a lewisite exposure.

In vivo, unbound CVAA is quickly excreted via the renal pathway and cannot be detected in urine samples taken later than 12 h postexposure. The biological half-life of protein adducts is much longer: in blood samples taken 10 days postexposure and treated with BAL, Fidder et al. (2000) were still able to release 10% of the CVAA-BAL concentration found on day 1. Protein adducts of CVAA play an important role in the verification of potential lewisite exposure.

52.4.2.7 Bioanalytical techniques for quantification of vesicants

52.4.2.7.1 Determination of vesicants and direct biotransformation products

When Drasch et al. (1987) determined the concentration of sulfur mustard in tissues of a deceased victim, they had to employ a combination of dichloromethane extraction and a thin-layer chromatography cleanup on silica plates, followed by derivatization with gold chloride and quantification by electrothermal atom absorption spectroscopy.

Vycudilik (1985) had already used gas chromatography-mass spectrometry (GC-MS) to confirm the presence of sulfur mustard in urine samples. Sodium chloride was added to the sample to facilitate extraction and slow down hydrolysis in the aqueous sample, and then the analyte was extracted with diethylether. The solvent was evaporated and the residue dissolved in methylene chloride. After purification—by shaking the sample solution for 1 h with silicagel—the solvent was again evaporated. The residue was again dissolved in methylene chloride and used for chromatography.

To detect TDG, TDG sulfoxide, and their acid-labile esters, Black and Read (1991) used $TiCl_3$ reduction, converting these products into single analyte TDG. TDG was then converted to its bis(pentafluorobenzoyl) derivative and quantified by GC-MS using negative ion chemical ionization. TDG sulfoxide could also be extracted directly using solid-phase extraction, followed by a Florisil cleanup. Derivatization and quantification were conducted as described previously. $TiCl_3$ was also used by Daly and O'Hehir (2007) to reduce the β-lyase pathway biotransformation product 1,1-sulfonylbis[2-(methylsulfinyl)ethane] to 1,1′-sulfonylbis[2-(methylthio)ethane] (SBMTE). This was followed by automated solid-phase extraction and LC-positive ion-ESI–tandem mass spectrometry.

Li et al. (2013) presented an ultrahigh-performance LC-tandem mass spectrometry (UPLC-MS/MS) method for simultaneous quantification of seven plasma biotransformation products of sulfur mustard. Limits of quantification ranged from 0.01 to 5.0 μg/L. The main products found in rat plasma were bis-β-chloroethyl sulfoxide (SMO), TDG, TDG sulfoxide (TDGO), 1,1′-sulfonylbis-[2-*S*-(*N*-acetylcysteinyl) ethane] (SBSNAE), 1,1′-sulfonylbis-[2-(methylsulfinyl)ethane] (SBMSE), and 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl]ethane (MSMTESE).

Methods to detect lewisite exposure have been focused on its main biotransformation product, CVAA. Initial methods were developed for environmental samples (Bossle et al., 1989). Methods for CVAA quantification in serum were described by Fowler et al. (1991), as well as Jakubowski et al. (1993). CVAA was derivatized with 1,2-ethanedithiol and quantified using GC-MS. Logan et al. (1996) employed a similar method to detect CVAA in the urine of guinea pigs exposed to lewisite.

52.4.2.7.2 Detection of DNA and protein adducts of vesicants

Adducts of sulfur mustard can be hydrolyzed to release TDG. Lawrence et al. (2008) used this procedure, followed by extraction, derivatization, and GC-negative ion chemical ionization–mass spectrometry. A number of methods have been developed to directly detect and quantify the adducts of sulfur mustard. The most prevalent DNA adduct, *N*7-(2-hydroxyethylthioethyl)-guanine, was directly detected and quantified by Fidder et al. (1994, 1996a), using electrospray LC-tandem MS with multiple reaction monitoring. A more recent work on DNA-adduct quantification was presented by Zubel et al. (2019). Benschop et al. (1997) used an immunoslotblot assay to detect this adduct in blood samples from Iranian patients, in order to verify their exposure that had occurred during the Iran–Iraq War in the 1980s.

Initial efforts by Noort et al. (1996, 1997) to detect the protein adducts of sulfur mustard focused on the 4-(2-hydroxyethylthioethyl)-l-aspartate, 5-(2-hydroxyethylthioethyl)-l-glutamate, cysteine and *N*-terminal valine adduct, and two histidine adducts, *N*1- and *N*3-(2-hydroxyethylthioethyl)-l-histidine. Acidic hydrolysis and pronase digestion were used to release these adducts from globin. Pronase is a mixture of proteinases isolated from the

extracellular fluid of *Streptomyces griseus*. Adducts were derivatized with 9-fluorenylmethyl chloroformate, followed by identification and quantification, using GC-MS.

Even though they constitute only 1%−2% of alkylated amino acids, the *N*-terminal valine adducts were useful for subsequent quantification efforts. *N*-alkylated *N*-terminal valine could be selectively cleaved, using pentafluorophenyl isothiocyanate as a reagent in a modified Edman procedure. The product of this reaction, pentafluorophenyl thiohydantoin, was derivatized with heptafluorobutyric anhydride and quantified by negative ion GC-MS/MS. This method was sensitive enough to confirm an in vivo exposure of guinea pigs 48 h after i.v. administration of 0.5 mg/kg, that is, 6% of the LD_{50} (Fidder et al., 1996b). Recently, an improved method to detect the *N*-terminal valine adduct was presented by Nie et al. (2011) with a lowered limit of detection for identification of the adduct after a 20 nmol/L in vitro sulfur mustard exposure of human blood.

Noort et al. (1999) again used pronase to digest human serum albumin that had been incubated with sulfur mustard. The cleavage product after proteolysis, *S*-[2-[(hydroxyethyl)thio]ethyl]-Cys-Pro-Phe, was analyzed by micro LC-tandem mass spectroscopy. Depending on the protease applied for albumin-adduct enzymatic cleavage different biomarkers can be detected including the above mentioned tripeptide but also the alkylated dipeptide (Cys-Pro) (Gandor et al., 2015; John et al., 2016a,b) or a pepsin-mediated hexapeptide and dodecapeptide (John et al., 2019).

Carol-Visser et al. (2008) developed a method for online pepsin digestion-liquid chromatography-tandem mass spectrometry configuration for rapid analysis of protein adducts of CWAs and demonstrated the detection of specific adducts of sulfur mustard in human serum albumin (along with sarin adducts to human butyryl cholinesterase).

Yeo et al. (2008) presented a verification method for the detection of albumin adducts of sulfur mustard by pronase digestion, followed by LC-MS-MS/MRM analysis. A blood concentration of 50 nM sulfur mustard resulted in formation of adducts that were successfully detected. Adducts of nitrogen mustards could also be detected after exposure to 100 nM HN-2 or 200 nM of HN-1 or HN-3, respectively. A more recent approach made use of proteinase K for proteolysis of the albumin adduct allowing quantification of sulfur and nitrogen mustard adducts (Pantazides et al., 2019).

Incubation of lewisite−protein adducts with BAL is capable of transferring its product 2-CVAA into a BAL-CVAA derivative. This derivative can be quantified using GC-MS. The method is able to detect a 1-nM lewisite exposure of human blood in vitro (Fidder et al., 2000).

A specific β-globin adduct to Cys93 and Cys112 was identified by the use of electrospray tandem mass spectrometry, as well as by chemical transformation with the cysteine-selective reagent vinylpyridine and derivatization by *S*-carbamylation (Fidder et al., 2000). No method for quantification of this adduct was described. As of mid-2008, no specific adducts other than the abovementioned ones have been described in literature.

Despite 90 years of research into the effects of vesicant agents and on medical countermeasures, only very limited data on toxicokinetics are available. However, technological advances in analytical chemistry have contributed to a better understanding of toxicokinetic properties of both sulfur mustard and lewisite, particularly in the last two decades. Knowledge gaps exist, but research efforts continue. The Chemical Weapons Convention (CWC) constitutes enormous progress in efforts to completely rule out future incidents of chemical warfare, and the risk of chemical weapons being used by state parties is probably lower than in any decade since 1910. On the other hand, there is a worldwide asymmetric threat, and the risk of terrorist attacks using chemical weapons cannot be ruled out. Defense experts, including medical chemical defense researchers, will be concerned about these issues for the foreseeable future. It is to be hoped that more comprehensive knowledge on both toxicodynamics and toxicokinetics will contribute to the development of more effective, and possibly causative, therapies of vesicant poisoning. At the same time, the capability to unanimously prove vesicant exposure, even long after the incident, certainly increases the possibility that any use of these CWAs will ultimately be detected and sanctioned. State-of-the-art analytical methods may play an important role in deterring and preventing acts of chemical warfare.

52.5 Concluding remarks and future directions

Measurement of toxicokinetic profiles is primarily motivated to improve the in-depth understanding of the poison's fate in an organism, and thus of pathophysiological consequences. Both are important to optimize antidote treatment and therapy regimens for poisoned humans that intend to boost poison elimination and reverse toxic effects; or at least minimize harm by causal and symptomatic approaches. As outlined in this chapter, the fate of poison is regulated by multifactorial processes characterized by degradation and enzymatic biotransformation, as well as elimination by protein or DNA binding. With respect to state-of-the-art techniques and study design, only a few animal models are being investigated comprehensively for nerve agents, whereas almost no data on sulfur mustard and lewisite are available in the literature.

To make matters worse, almost no human toxicity or toxicokinetic data for CWAs are available due to ethical reasons, hindering specific and tailored medical approaches. Therefore, data are to be obtained from animal studies requiring extrapolation of relevant characteristics to human conditions. As is obvious from the tabular compilations on acute lethal doses of nerve agents in different laboratory animals and different routes of exposure (Table 52.2), especially under consideration of stereoisomeric differences (Table 52.4) and underlying kinetic characteristics in terms of rate constants for serine esterase inhibition and catalytic constants for PTE-mediated hydrolysis (Table 52.3), such data remain incomplete. In addition, interspecies and intraspecies variations are enormous, limiting comparability and transferability of experimental results. There is only a limited amount of data considering specific differences between lethal and sublethal exposure scenarios. Data on tissue distribution in animals are rare and correlation to humans is not clarified conclusively to explain, for example, the larger persistence of nerve agents in the human body. This lack of information indicates future demands of medical defense research. There is also a rising need for combined toxicokinetic and pharmacokinetic data obtained from poisoned organisms under therapeutic treatment. This will help to find the most valuable reactivators of OP-inhibited cholinesterases, which differ dramatically in efficacy in a poison- and species-dependent manner. Taken together, results of future studies should (1) support the development of mathematical models to describe and predict poison and antidote behavior in vivo in humans; (2) unravel novel targets of poison on the molecular or compartmental level, which are useful as biomarkers or to identify additional pathophysiological situations; and (3) establish novel bioanalytical methods and techniques, which allow very low quantification limits and sufficient selectivity for stereoisomers in various tissues and compartments. Whereas a number of studies have been performed using commonly known nerve agents, there remains much more demand for further work with respect to vesicants.

Chapter 53

Toxicokinetics and toxicodynamics of DFP

Miguel Sogorb, Jorge Estevez and Eugenio Vilanova
University Miguel Hernandez of Elche, Elche, Spain

53.1 Introduction

53.1.1 DFP synonyms and scientific publications

Diisopropylfluorophosphate (DFP) is an organophosphorus compound (OP) which is mentioned in the literature using several synonyms (Table 53.1). Soon after its discovery, it was demonstrated to be a very potent cholinesterase inhibitor and toxic compound. However, it has not been used as a pesticide, a chemical warfare agent, or a plasticizer. DFP is commercially available from chemical suppliers and has been extensively used in toxicology and biological research. In April 2014, a search of the PubMed database yielded 3514 results and 4049 in September 2019 looking for all the different synonyms (including the acronym "DFP") in titles and abstracts.

In other searches, using only one of the four MeSH terms (isofluorate, DFP, diisopropylphosphofluoridate, or diisopropylphosphorofluoridate), 3298 results were found. Therefore, the PubMed databases use these four terms as synonyms and the same references are found with each search. They represent most but not all publications involving DFP. A search using the synonyms in (All Fields) gave up to 4726 documents, but the search in (Title and Abstract) was preferred for restricting results to publications in which the compound has a relevant role.

A search updated on September 7, 2019, using all synonyms (including "DFP") and looking at titles and abstracts provided 4049 entries, of which 312 were published after April 2014 (date reported in previous edition of this book). Following manual review, 94 were identified as studies actually using DFP.

It should be noted that with the abbreviation "DFP," many nonrelated publications are found (i.e., "bacterial DFP-flavoproteins"; DFP-10917 a deoxycytidine analog; database fingerprint; deferiprone, a hydroxypyridinone-derived iron chelator; delayed facial palsy; and other). Unfortunately, there is not an established tradition of indicating the CAS number for a unique reference of the chemicals in scientific publications and standard chemical nomenclature is not always used. Therefore, the use of the acronym "DFP" for a publication search gives many irrelevant publications. If the word "DFP" is not included in the search, then results were 2768 detected documents, with 112 published after 2014. Within these 112, 102 had relevant use of the compound for toxicological or biological studies. Combining the initial 94 and the above112 yielded 70 in common and a combined total of 130 new publications from April 2014 to September 7, 2019 (Table 53.2).

Statistics of the distribution of publications over time are shown in Fig. 53.1. The highest rate of publications was during the period 1970−2000. The first publication registered in PubMed was in 1946, while its synthesis was done in the 1930s and the first patent issued in 1938 but published in 1948. Details of the history of DFP are described below.

53.1.2 Research field of the use of DFP

DFP has been used extensively for several reasons:

1. It was one of the first synthesized anticholinesterase OPs. On the basis of a report by Lange (1930), a high yield preparation of DFP was described by Saunders and Stacey (Cambridge, UK) in 1948. A US patent was filed in 1949 and it was proposed as a chemical warfare agent. It was previously synthesized by Schrader (1937) and a patent filed in 1938 but not published until 1951.
2. Since the 1960s, DFP has been commercially available through suppliers of laboratory chemical reagents. DFP with ^{3}H or ^{32}P radioisotopes has been reported in publications since the 1960s (Johnson, 1969a).
3. Other fluorophosphates were synthesized and produced as chemical warfare agents (sarin and soman).

However, DFP is less toxic than the G-series nerve agents and is therefore easier to handle.

4. DFP is an appropriate model compound for toxicological studies and developing prophylaxis and therapeutic strategies and understanding the mechanisms involved in toxicity of OPs. DFP is able to bind to many proteins with serine, tyrosine, and other residues, and therefore is an inhibitor of proteases and other esterases other than cholinesterases. This capacity has triggered interest in using it for toxicological, pharmacological, and biomedical research, as indicated in Table 53.3.

A detailed examination of the 130 articles identified and published during the aforementioned 5-year period produced a tentative distribution of the topics (Table 53.4). More than half (61%) were dedicated to studies related to cholinesterase inhibition in vitro and in vivo, kinetic and molecular mechanisms of inhibition, interaction of OPs, and development and mechanistic studies of reactivators (oximes and others) for therapy and prophylaxis against intoxications of OPs. A large number dealt with in vivo studies as a model of neuroinflammation, status epilepticus, and related therapeutic research (25%). Studies of hydrolysis, biodegradation, and stability were also a significant portion (19%). About 12% dealt with binding to proteases and other proteins, and in some cases, the inhibition by DFP was used as evidence of it being a serine-containing protein. It should be noted that the actual number of papers using DFP for protease inhibition is much higher because when DFP is applied only as a methodological procedure for inhibiting proteases it is not usually mentioned in the abstract or title.

DFP is an inhibitor of the so-called neuropathy target esterase (NTE), and is a critical model compound used to demonstrate the role of aging in the capacity of OP to be an inducer of delayed neuropathy (Clothier and Johnson, 1979a,b) in the usual avian model of OP-induced delayed neuropathy. DFP has been used recently to demonstrate the delayed effects of neuroinflammation in rat (Li et al., 2015) and mouse (Ebrahimi et al., 2018) models.

In brief, there are many studies in which DFP is used either as a model OP compound of toxicity due to binding to esterases (cholinesterases, NTE, and others), as a tool for understanding some biological and toxicological processes, and for developing and studying therapeutic drugs. More than 4000 papers mention DFP, of which 3000 do so in the title or abstract. For 5 years, the individual revision of 130 articles with DFP in the title and abstract indicated that most uses have been for studies related to its properties of cholinesterase inhibition, including kinetic mechanistic studies in vitro and in vivo, with a high proportion using it as a model compound of neuroinflammation and for

Indicated results of searches including or not the acronym "DFP," looking in [All Fields] or only in [Title/Abstract] and documents published during 5 years since those reported in the first edition of this book (obtained April 2014 until September 2019).
[a] *"All Synonyms" means the list of synonyms described in Table 53.1*
[b] *Considered "relevant" all the studies actually working or using diisopropylfluorophosphate (DFP) for toxicological or biological studies. Rejected those using "DFP" as an acronym/abbreviation for other substances or other purposes as well as those only using DFP for chemical studies no related with toxicology or biological research.*

simulation neurotoxicity of warfare nerve agents, and also for biodegradation studies and applications to characterization and binding to proteases and other proteins. Some of these aspects are discussed further in the following sections.

53.2 Physicochemical properties and chemical identification of DFP

53.2.1 Chemical structure, identity, and analogy with other nerve agents

DFP, is an O,O′-dialkylfluorophosphate (CAS #55-91-4) synthesized in the 1930s by procedures patented looking either for insecticides, mold control, warfare agents, or fluorine compounds for dental protection. However, it has not been used as a warfare agent. It is classified and labeled in the EU Regulation (CE 1272/2008) following the global harmonized system (GHS) as H300 (*Fatal in contact with skin*) + H310 (*Fatal if swallowed*) + H330 (*Fatal if inhaled*), and with the Precautionary Statements as follows: P260 (*Do not breathe dust/fume/gas/mist/vapors/spray*) and P264 (*Wash hands thoroughly after handling*).

DFP is named and referred to using other synonyms (Table 53.1), although most commonly it is called DFP or diisopropylphosphorofluoridate. Isofluorophate is used as its heading in some databases. Similar to a warfare nerve agent, DFP contains the oxon group (P═O) of the oxophosphates, and therefore does not need the toxic activating reaction needed by the thiophosphates (P═S).

The two organic substitutions with isopropyl groups are bonded to the phosphorus atom through an oxygen atom (alkoxy groups), being a third substitution of the acidic group fluorine (F) which is the most labile group against possible reaction of nucleophilic substitution and considered the "leaving group" or "X-group" (Fig. 53.2). Therefore, DFP may be considered as F-containing oxo-organophosphate, the expression of "phosphate" indicating the two O-substitutions through oxygen atoms.

Other well-known G-nerve agents also contain fluoride (i.e., sarin, soman, and cyclosarin) while tabun contains −CN as a leaving group (Fig. 53.3). However, sarin and soman have one substitution by a P−O bond and another a P−C, so they are usually labeled as phosphonates. Phosphoramidate compounds have also been synthesized with a nonsubstituted amido group (P-NH_2,

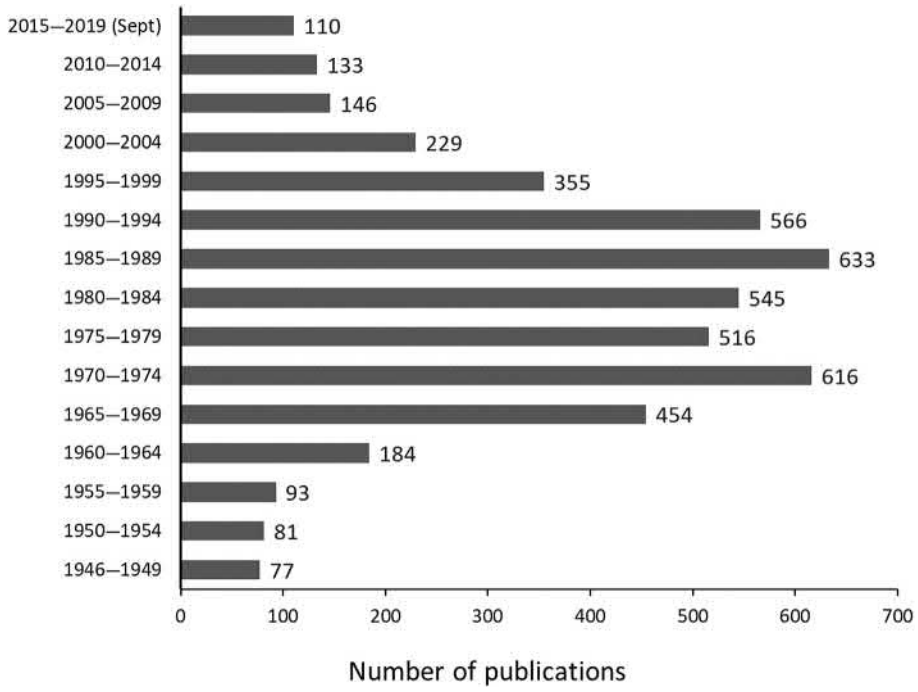

FIGURE 53.1 Evaluation of publications in PubMed containing DFP synonyms in all fields. Data updated September 7th, 2019. Indicated publications in periods of 5 years.

i.e., methamidophos), or mono- (P-NH-R) or disubstituted (P-N-[R_1,R_2]) groups. An example is mipafox (N,N′-diisopropylphosphorodiamidoflouridate).

Mipafox was developed for insecticidal use, but was withdrawn for that application due to its potential for causing delayed neuropathy. It is currently used as a selective inhibitor of NTE (Tormo et al., 1993; Vicedo et al., 1993). DFP has a common property with mipafox for inhibiting NTE (Estevez et al., 2013) and inducing delayed neuropathy.

53.2.2 Physicochemical properties

Table 53.5 shows some basic physicochemical properties of DFP, some nerve agents and mipafox. DFP is a liquid (mp = 82°C) with a clear or slightly yellow color. Dialkyl fluorophosphates was described as producing a pleasant odor by a researcher who inhaled fumes in the process of synthesis and became intoxicated after a few minutes. Melting and boiling points are in the same range as for other nerve agents. The vapor pressure is 0.570 mmHg, which is higher than tabun but lower than sarin. Vapor pressure may be a criterion for assessing the risk of inhalation exposure when handling the pure liquid compound in the laboratory. It is low when compared with other liquids like water (25 mmHg) or organic solvents (i.e., 28 mmHg toluene, 151 mmHg *n*-hexane). Therefore, handling a small amount in the laboratory for experimental studies is viable if the appropriate protective measures are used.

53.3 History of DFP synthesis and its relationship with the development of warfare nerve agents

DFP is used in research to understand the mechanism of toxicity and for studying the therapy and prophylaxis of chemical warfare OP agents due to its relatively low toxicity when compared to the G-series nerve agents [tabun (GA), sarin (GB), soman (GD), or cyclosarin (GF)].

A history of monofluorophosphates has been reported by Peter Meirs (http://www.fluoride-history.de). Inorganic fluorophosphates (sodium monofluorophosphate) and organic aryl or alkyl substitutions were the subjects of filing patents of methods of synthesis looking for substances intended as either insecticides or warfare chemicals.

Willy Lange described the synthesis of some fluorophosphates, difluorophosphoric acid, and patented the synthesis of aryl fluorosulfonates and proposed their use as insecticides (Lange, 1930). It has been described that, in 1932, Gerda von Krueher, one of Lange's students, was involved in fluorophosphates research in laboratory work for her PhD thesis. By heating silver monofluorophosphate with methyl or ethyl iodide, she prepared dialkyl monofluorophosphates. She described that initially the fumes had a pleasant odor but, within a few minutes, she and her colleagues began to suffer pressure in the larynx, difficulty breathing, disturbances of consciousness, blurred vision, and painful sensitivity to light. After several hours, these symptoms resolved. von Krueher described the effects as not being due to the acidic effects but from the small

TABLE 53.3 Type of studies, for which DFP have been used.

Role of DFP and type of studies	Description
Kinetic inhibition and reactivation	Inhibition of cholinesterases in vitro and in vivo, for studying the kinetic and molecular mechanisms of inhibition and interaction of OPs, including development and mechanistic studies of reactivators (oximes and others) for therapy and prophylaxis against intoxications of OPs
Neurotoxicity OP insecticides and warfare agents	Model compound of neurotoxicity and pharmacology related to cholinesterase inhibition. Used as a model OP counterpart similar to chemical warfare G-agents. Model for experimental in vivo studies of neuroinflammation, epilepticus status, and other related clinical status for experimental studying in the development of proposed therapies
Protease inhibitor and phosphorylable proteins	As a tool as irreversible serine of inhibitor in studies in biological processes. Used as evidence that a protease is a serine protease. This is usually done checking also inhibition with PMSF (phenyl methane sulfonyl fluoride)
	Detection of phosphorylable sites in proteins and binding to protein in serine or in tyrosine residues on esterases, proteases, and other proteins
Esterase inhibitor, biological process	In studies related to biological processes when esterases or other DFP-binding proteins were thought to be involved. Coagulation and thrombin and prothrombin inhibition; role of lysozyme; in some cardiovascular process; skin sensitization process; neurodevelopment; neurobehavioral alterations; others
Therapy	In ophthalmological studies related to glaucoma and other disease in which AChE inhibitors have been proposed as therapeutic strategies, i.e.: Alzheimer disease, Parkinson disease, glaucoma
Labeling, cell biology	Use for labeling in study and clinical diagnosis of the turnover and life span of some human cells: erythrocytes, platelets, leukocytes, granulocytes
Delayed neuropathy	In the detection of the target of the organophosphorus-induced neuropathy (OPIDN), and the so-called neuropathy target esterase (NTE) and in the understanding of the molecular mechanism of induction including the role of the so-called "aging" reaction as a mechanism in delayed neuropathy
Other	Other biological and biotechnological applications

No specific statistics were performed for the different types of studies showed in this table. See Table 53.1 for specific statistics based on more recent studies.

TABLE 53.4 Identified published papers during a period of 5 years using DFP for toxicology or biological research.

Classification by issues		Number
1. Model of OP toxicity neurotoxicity related with inhibition of cholinesterases and other esterases		
1.1 Inhibition, kinetic cholinesterases	12 (9%)	
1.2 Oximes, reactivation, protection	8 (6%)	
1.3 Model for in vivo studies of neuroinflammation, status epilepticus, and related therapies	32 (25%)	
1.4 Other neurotoxicity, development and/or in vitro	10 (8%)	
1.5 Intended as model nerve agent (Gulf War illness)	15 (12%)	
1.6 Model of delayed neuropathy, NTE	2 (1.5%)	
Total group 1		79 (61%)
2. OP hydrolysis—biodegradation, stability		25(19%)
3. Proteases, inhibition or characterization of serine-proteases and binding to other serine proteins		15 (12%)
4. Alzheimer disease and other CNS diseases		4 (3%)
5. Other and model of analytical detection		7 (5%)
Total:		130

Based on information obtained from PubMed database of publications since April 2014 (as reported in the last edition of this book) until a systemic bibliographic search on 7 September 2019 (total selected: 130 publications mentioned in Table 53.2).

amount of esters. Other homologs were prepared as di-*n*-propyl and di-*n*-butyl esters. Lange considered that these compounds might be useful for pest control and offered them to the I.G. Farben Industry but the company had no interest at that time. Later, in 1935, at I.G. Farben, Gerhard Schrader, Han Kükenthal, and Otto Bayer (director of research at Farben) patented alkylsulfonates as insecticides (Schrader et al., 1935), claiming that they were more effective than the aryl analogs proposed by Lange in 1930. They also patented dialkylaminophosphorofluorides for insecticide applications (Schrader and Bayer, 1935).

In 1937, Schrader and Kükenthal prepared several compounds and tested them for insecticidal activity. They observed that the most effective were the di-esters with an acidic group of Cl, F, SCN, VNO, and others (Schrader, 1937). The highly toxic compound with the CN group, a *O*-ethyl and a *N*-dimethyl substitution was developed and is now known as tabun. Schrader also described other more effective methods to synthesize esters of fluorophosphoric acid than those described by Lange and Krueger, and synthesized other homologs, among them DFP. A patent was filed in 1938 but kept secret and not published until 1951. This patent does not cover sarin and sarin-type compounds.

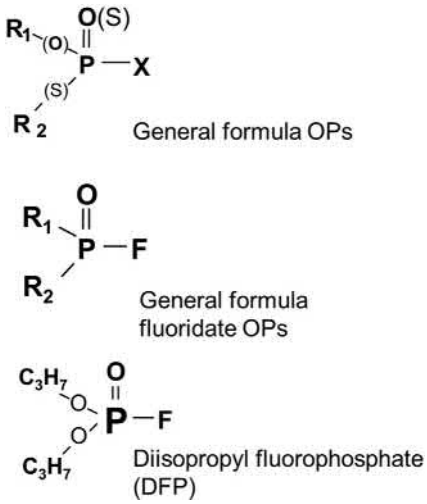

FIGURE 53.2 **General structure of organophosphorus compounds and fluorophosphates.** R is an alkyl or aryl group. X is the so called "leaving group."

Bernard Charles Saunders (UK, University of Cambridge) studied the 1932 report of Lange, prepared several new monofluorophosphoric esters, and tested them for possible use as warfare agents. It was reported to the government in 1941 (Saunders, 1957) and a patent for the synthesis of esters of fluorophosphoric acid was filed in 1943 (McCombie et al., 1944). The method was based on treatment of the corresponding chloro compound with a metallic fluoride such as NaF.

Willy Lange emigrated to the United States, worked for Procter and Gamble, and at the University of Cincinnati. In a work supported by the Ozark Chemical Company in 1943, Lange filed a patent for preparing anhydrous monofluorophosphoric acid and claimed that it would allow it to be used for the synthesis of esters for use as insecticides (Lange and Livingston, 1943). Another related patent was registered in 1944 also claiming the application reacting with alcohol for preparing the corresponding dialkyl esters (Lange, 1946).

In 1944, Hardy and Kosolapoff from the Monsanto Chemical Company patented the production of dialkylfluorophosphates as DFP by a procedure based on the reaction of alcohol with PCl3 producing dialkylphosphite,

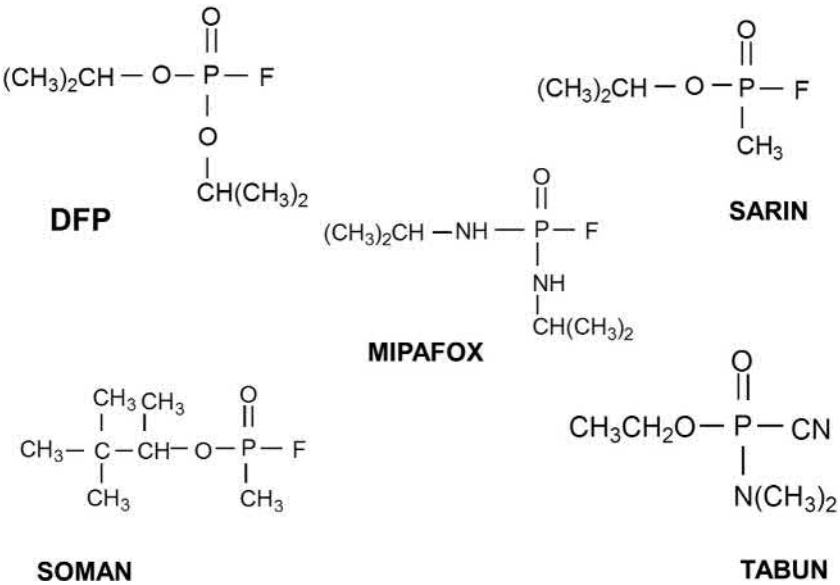

FIGURE 53.3 DFP structure and fluoro and cyano organophosphate analogs.

then chlorinating and finally fluorinating with NaF (Hardy and Kosolapoff, 1944).

In 1945, the capacity of inhibiting cholinesterase by DFP was reported by Mackworth (personal communication; Mazur and Bodansky, 1946; Michel and Krop, 1951). The publication of Mazur and Bodansky demonstrated that the inhibition was irreversible and involved binding of the enzyme. DFP and other alkyl fluorophosphate esters were the first compounds reported to be "irreversible" inhibitors. Michel and Krop (1951) reported the quantitative potency of inhibition for cholinesterases (inhibitory properties of DFP on cholinesterases).

In 1947, Lange and Livingstone (Monsanto) published a series of reports about fluorophosphoric acids and their derivatives (Lange and Livingston, 1947). They reported that, "It has recently been shown that the esters of monofluorophosphoric acid, H2P03F, which were previously known to be highly toxic, have a probable usefulness in the treatment of glaucoma and myasthenia gravis, the diisopropyl ester being especially suited for this purpose. Unpublished observations by the senior author also showed that the esters possess insecticidal properties and may act as fumigants" (Lange and Livingston, 1947).

In 1948, a preparation of DFP was described by Saunders and Stacey of Cambridge, UK (Saunders and Stacey, 1948), and a US patent was filed (McCombie et al., 1949). In 1949, another patent was filed for production of mono- and dialkyl fluorophosphates. These were produced by treating alkyl polyphosphates with HF and then named dialkoxy phosphoryl monofluoride (Lange, 1949). The monoesters were purported to have a low toxicity in mammals but did show fungicidal properties. In the same time-period, preparation of DFP by other complicated methods was published, and the effects of DFP on the nervous system and as a potential treatment of human diseases were studied. Further efforts on the application of fluorophosphoric acid and its salts were focused in their application for the prevention of dental disease, that is, as an additive in toothpaste.

B.C. Saunders synthesized DFP and labeled it PF-3. It appears that he based his research on the previous study by Lange and Gerda von Krueger, who synthesized the series of mono-*o*-alkyl fluorophosphoric acid with C1, C2, C3, C4 alkyl groups. However, it was less effective than the G-series agents (sarin, tabun, and soman).

DFP may be synthesized by reactions similar to that used for other OPs. For example, by reacting the alcohol (isopropyl alcohol) with phosphorus trichloride (PCl_3) to form diisopropyl phosphite, and then chlorinating, the chlorine-substituted fluorine was patented by Hardy and Kosolapoff (1944). Therefore, the process of the synthesis of DFP is closely related to the development of the

synthesis of organophosphates for nerve agents, insecticides, and other fluorine compounds for dental application.

DFP has been commercially available since the 1970s from chemical suppliers, such as Sigma. Radiolabeled as [^{3}H]DFP and [^{32}P]DFP it has been used for labeling proteins and for toxicokinetic studies. Therefore, it has been available and used either for understanding its toxicity or for its use as a tool for toxicological or pharmacological research activities.

53.4 Toxicokinetic and biotransformation of DFP and studies on DFPase

53.4.1 Absorption, distribution, and toxicokinetic studies

Radiolabeled [^{3}H]DFP has been used for studying its absorption and biodisposition by inhalation in guinea pigs (Scimeca and Martin, 1988) and mice (Scimeca et al., 1985), and by intravenous administration in mice (Martin, 1985). Skin penetration has been studied in pigs and human skin in vitro (Vallet et al., 2007).

53.4.1.1 Distribution after exposure by inhalation

The tissue disposition of radiolabeled [^{3}H]DFP and its metabolites was studied in guinea pigs after inhalation exposure from 5 min to 24 h after treatment (Scimeca and Martin, 1988). [^{3}H]DFP was rapidly distributed in all tissues. The product of hydrolysis, the metabolite diisopropyl phosphoric acid (DIP), was detected covalently bound to the tissue biphasic curve, with an initial phase representing a very rapid decrease in tissue concentrations, followed by a slower phase of tissue clearance for bound [^{3}H]DFP and free [^{3}H]DIP.

After 4 h, the higher proportion of radioactivity in all the tissues was in the bound form of [^{3}H]DIP. Bound [^{3}H]DIP levels did not follow a biphasic clearance curve and declined at a slower rate than [3H]DFP and free [^{3}H]DIP tissue levels. After 5 min, the greatest accumulation of bound [^{3}H]DIP occurred in the liver (nearly 20% of the total body burden), with a noticeably small amount in the brain (0.1%). Total cholinesterase activity in the brain and red blood cells was inhibited by about 90%, with plasma pseudo- and true cholinesterase activity inhibited by 99% and 97%, respectively.

53.4.1.2 Distribution after intravenous administration

Intravenous administration of [^{3}H]-DFP was studied in mice and the disposition of [3H]DFP in selected tissues and cholinesterase activity and recovery were studied (Martin, 1985). After 1 min [^{3}H]DFP had penetrated the tissues and was irreversibly bound. The tissue concentrations decreased quickly and after 2 h all concentrations were below 50 pg/mg tissue. Most radioactivity was bound to tissue as [^{3}H]DIP but decreased with time in all tissues except liver, kidney, and fat, which reached a maximum at 30 min before declining. Only in the liver and kidney did appreciable quantities of [^{3}H]DIP remain after 3 days.

[^{3}H]DFP was rapidly hydrolyzed to free [^{3}H]DIP, which was found in all tissues within 1 min of [3H]DFP administration. [^{3}H]DIP concentrations were equivalent to or exceeded those of [^{3}H]DFP in all tissues, except the brain.

Cholinesterase inhibition in plasma, diaphragm, and brain following DFP treatment (1 mg/kg, iv) was temporarily correlated with the concentrations of bound [^{3}H]DIP in these same tissues between 1 h and 3 days. Cholinesterase inhibition in the brain and diaphragm did not correlate well with bound [^{3}H]DIP, suggesting there is binding to sites other than cholinesterase.

DFP treatment (1 mg/kg) induced motor hypoactivity up to 6 h after i.v. administration with a time course that did not correlate with free [^{3}H]DFP, bound [^{3}H]DIP concentrations in the brain, or with cholinesterase inhibition in the brain, which suggested that another noncholinesterase interaction was responsible.

Other older studies have been reported on its distribution in oxygenated blood and atrial tissue (Schuh, 1970), excretion in cats (Hansen et al., 1968a), and distribution and metabolism in the guinea pig (Hansen et al., 1968b).

In short, DFP is rapidly distributed, bound to tissues in the form of bound diisopropryl phosphoryl group to proteins, then it is released as a metabolite DIP, and, finally, it is excreted mainly in the urine. There is evidence that a high proportion of binding is to other sites than cholinesterases. Moreover, the time course of CNS effects suggests that other noncholinesterase interactions are involved in DFP neurotoxicity.

53.4.1.3 Skin penetration

Percutaneous penetration of [^{3}H]DFP was tested in vitro with human and pig skin. In the test using intact skin, the absorbed dose after 24 h post-depot was 15.6% ± 1% in pig skin and 9.4% ± 1.5 % in human skin, with a ratio of 1.7 pig/human. Penetration rates between 0.5 and 4 h were 3.22% and 1.63% dose/h, with a ratio of 1.7 for pig/human skin. Similar behavior was observed using split-thickness skin.

The radioactivity quantified in the receptor fluid corresponds to not only intact DFP, but also to its metabolites, both tritiated. In preliminary findings, it was also found that at 24 h post-exposure, more than 99% of DFP reaching the receptor fluid was hydrolyzed into the skin. It was

not specified if this was due to degradation by phosphotriesterases, by binding and dephosphorylation to proteins/esterases, or by spontaneous degradation.

53.4.1.4 Physiologically based pharmacokinetic/pharmacodynamic studies

Two studies with physiologically based pharmacokinetic and pharmacodynamic (PBPK/PD) models have been reported (Chen et al., 2009; Gearhart et al., 1990). Gearhart et al. (1990) developed a model for mammals in which the following factors were considered: (1) DFP tissue/blood partition coefficients, (2) rates of DFP hydrolysis by esterases, and (3) DFP-esterase bimolecular inhibition rate constants determined in rat tissue homogenates. Other model parameters were scaled for rats and mice using standard allometric relationships. These DFP-specific parameter values were used to simulate in vivo pharmacokinetic data from mice and rats. DFP concentrations in mouse plasma and brain were successfully simulated with data of a single i.v. injection reported by Martin (1985) as well as AChE inhibition and its reactivation. Effects of repeated, subcutaneous DFP dosing on AChE activity in rat plasma and brain (Michalek et al., 1982; Traina and Serpietri, 1984) were also well simulated, but the return of brain AChE activity to basal levels after cessation of repeated dosing was not well described. The model returned brain AChE activity to the original level, while in the laboratory studies brain AChE never returned to basal levels, even after 35 days. These data suggest modulation of AChE synthesis with prolonged DFP exposure. This study demonstrated the possibility of using a model based on mammalian physiology and biochemistry to simulate in vivo data on DFP pharmacokinetics and AChE inhibition. Scaling of the model between rats and mice was also successful.

Another study developed a model in the mouse and rat (Chen et al., 2009) with the following steps: (1) the influence of the variability of the rate constants for synthesis [K(syn)] and degradation [K(deg)] of AChE, and regeneration [K(reg)] and aging [K(age)] of inhibited AChE on the variability of AChE activity in venous blood and brain was first calculated by a global sensitivity analysis, (2) the mouse PBPK/PD model was calibrated by optimizing the values of K(syn), K(deg), K(reg) and K(age), (3) scale-up of DFP-induced AChE activity was performed from mouse to rat. Validation of the rat model was performed by comparing the time course of venous blood and brain AChE activities from a Monte Carlo analysis to those obtained in vivo. Sensitivity analysis on the verified models showed that K(reg) and K(syn) were the most influential factors of AChE activity at shorter and longer durations, respectively, after DFP challenge, and (4) scale-up of AChE dynamics from mouse to rat successfully evidenced by significant overlapping between the predicted 95th percentile confidence intervals and the experimental data. These approaches hold promise for predictive simulation of organophosphate-mediated AChE inhibition in humans. In vitro toxicokinetic studies for understanding the molecular mechanism of elimination of cyclosarin have been used and DFP applied as a simulant for comparison (Reiter et al., 2014)

53.4.2 Biotransformation of DFP: phosphotriesterases, paraoxonase, DFPPase

DFP is a phosphoric triester and consequently it is not subjected to bioactivation through desulfuration, as in the case of thiophosphates such as chlorpyrifos, malathion, and other OP compounds used as insecticides. DFP can be enzymatically hydrolyzed by the enzymes phosphotriesterases or phosphoric triester hydrolases according to the nomenclature of the International Union of Biochemistry and Molecular Biology (Table 53.6). The hydrolysis of DFP releases the fluoride ion and the acidic moiety of DFP, DIP. This hydrolysis must be considered as a detoxification reaction (Sogorb and Vilanova, 2010).

There are two types of phosphotriesterases, the aryldialkylphosphatase (EC 3.1.8.1) and the diisopropylfluorophosphatase (EC 3.1.8.2). The group EC 3.1.8.1 includes paraoxonases, while the group EC 3.1.8.2 includes the enzymes dialkylfluorophosphatases (also known as DFPases). The enzymes belonging to both families are metal-dependent (calcium in the case of paraoxonases and magnesium in the case of DFPases) and are inhibited by chelating agents (Vilanova and Sogorb, 1999). All these enzymes also contain active centers with discrete binding pockets to accommodate the three ester moieties (Bigley and Raushel, 2013). Although there are mechanistic differences among different phosphotriesterases, in all cases the divalent metal is needed for activation of phosphoryl oxygen that is further attacked by a hydroxide group, causing hydrolysis and the release of the leaving group (fluoride in the case of DFP) (Bigley and Raushel, 2013).

Paraoxonases are expressed mainly in mammals, display a broad range of substrate specificity, and are able to hydrolyze P−F bonds. Consequently, they may also hydrolyze DFP and other analogous warfare agents. DFPases are enzymes with a specific capability to break the P−F bonds and they possess a higher efficacy than paraoxonases for the hydrolysis of DFP and related compounds. However, DFPases are not expressed in mammals. The usual biological source for studying DFPases is the squid (*Loligo vulgaris*) (Wymore et al., 2014; Katsemi et al., 2005; Scharff et al., 2001; Hartleib and Rüterjans, 2001).

DFPases are highly specific for hydrolysis of P−F bonds in DFP. These enzymes can enhance the hydrolysis

EC 3.1.8.2. diisopropyl-fluorophosphatase (DFPase)

Reaction: diisopropyl fluorophosphate + H_2O = diisopropyl phosphate + fluoride

Other name(s): DFPase; tabunase; somanase; organophosphorus acid anhydrolase; organophosphate acid anhydrase; OPA anhydrase; diisopropylphosphofluoridase; dialkylfluorophosphatase; diisopropyl phosphorofluoridate hydrolase; isopropylphosphorofluoridase; diisopropylfluorophosphonate dehalogenase

Systematic name: diisopropyl-fluorophosphate fluorohydrolase

Comments: Acts on phosphorus anhydride bonds (such as phosphorus-halide and phosphorus-cyanide) in organophosphorus compounds (including "nerve gases"). Inhibited by chelating agents; requires divalent cations. Related to EC 3.1.8.1 aryldialkylphosphatase. Previously listed as EC 3.8.2.1

of DFP and analogous warfare agents. As a result, these enzymes can be used either for the deactivation of chemical warfare agents or as prophylactic and therapeutic agents against exposures to these chemicals (Sogorb et al., 2004). However, since DFPases are not expressed in humans, the hydrolysis of DFP by paraoxonases, despite the low specificity, is the only defense against this compound in mammals based on enzymatic hydrolysis. This book contains other chapters dealing with phosphotriesterases (both DFPases and paraoxonases) and readers are referred to those chapters for more detailed information.

Theoretical analysis using the current available computational approaches has been performed to understand the differences among paraoxonase PON1 and DFPase for the preference of substrates (Zhang et al., 2018), as well as specifying technologies for degradation or chemical warfare and the remediation process (Soares et al., 2018).

53.4.2.1 Detoxification of DFP by binding to proteins

In the distribution studies described above, it was observed that after administration of radiolabeled DFP, most radioactivity is bound-DIP and later it is released as free DIP. It is then excreted mainly via the urine. This suggests that, in mammals, binding to a protein by phosphorylation is the main mechanism of withdrawal and detoxification. Catalytically active imine-based covalent binding has been proposed using DFP as a simulant for the detoxification of nerve agents (Royuela et al., 2019).

The mechanism involved in binding to proteins also explains the mechanism involved in toxicity. In Chapter 54, Physiologically based pharmacokinetic modeling of chemical warfare agents, examples of binding to protein are described either as a detoxificating mechanism (i.e., binding to albumin) or binding to the

target esterases causing toxicological consequences (i.e., acetylcholinesterase (AChE) and NTE).

53.4.2.2 The role of albumin in the detoxification of DFP

Albumins exhibit esterase-like activities for carboxylesters (Means and Bender, 1975; Tildon and Ogilvie, 1972; Kokubo et al., 1982). These esterase activities were based in the reversible acylation of a tyrosine residue of the sequence Arg-Tyr-Thr-Arg (position 410 in bovine serum albumin and 411 in human serum albumin) (Peters, 1996a). However, it has also been suggested that this activity, at least in human serum albumin, is the result of the irreversible acetylation of 82 different amino acid residues rather than reversible acylations (Lockridge et al., 2008).

Serum albumin also displays other esterase activities against carbamates, such as carbaryl (Sogorb et al., 2007; 2004) based on the Tyr-411 residue as the main target of the active center. The Tyr was also proposed as a target of phosphorylation of OP compounds, such as phosphoramidates (Sogorb et al., 1998), azamethaphos, chlorfenvinphos, chlorpyrifos−oxon, diazoxon, dichlorvos, malaoxon, pirimiphos-methyl (Carter et al., 2007; Tarhoni et al., 2008), diazoxon, and paraoxon (Sogorb et al., 2008). It is also necessary to add DFP to this list. It is demonstrated that 1 h of in vitro exposure of rat and human serum albumin to 19 μM DFP causes the binding of 0.011 or 0.039 moles DFP/mole of albumin, respectively (Tarhoni et al., 2008). In addition, this binding is prevented by exposure to most of the above-listed OP compounds (Carter et al., 2007; Tarhoni et al., 2008), which suggests that DFP and others are in competition for the same amino acid residue. Other analogous structures to DFP, such as soman, sarin, cyclosarin, and tabun, have been shown to bind to albumin via phosphorylation (Williams et al., 2007; Li et al., 2008; Read et al., 2010).

Mass spectrometry assays have allowed the confirmation of tyrosine-411 as the target amino acid for binding of DFP and analogous nerve agents as well as other OP compounds (Li et al., 2007, 2008). However, other target amino acids for phosphorylation of albumin have also been suggested, specifically four additional Tyr, two Ser (Ding et al., 2008), and several Lys (Grigoryan et al., 2009).

The binding of DFP to albumin, despite the fact it can be considered an enzymatic reaction or a scavenging process with an undetermined number of target amino acids, causes the release of the fluoride ion and generates an adduct between albumin and the diisopropyl moiety. The immediate consequence is that a molecule of DFP is removed from the media and cannot reach the nervous system, where it would cause inhibition of esterases, thereby triggering the neurotoxic effects. Thus, this binding is a detoxification mechanism.

The detoxification of DFP through binding to albumin might seem irrelevant due to its low efficacy in comparison with the detoxification capability of DFPase and paraoxonase. However, the efficacy of this process is based on the high concentration of albumin circulating in the blood (40 mg/mL or 600 μM) (Peters, 1996b), that is, higher than the systemic DFP concentrations compatible with the survival of the individual, and not in a high turnover of the phosphorylated albumin residues. Indeed, the binding of paraoxon to albumin has proved to be responsible for the detoxification of physiologically relevant paraoxon concentrations in mammals (Sogorb et al., 2008). The possibility of applying copper activation of albumin for hydrolysis of OPs has been proposed (Monroy-Noyola et al., 2018).

All the above considerations allow the prediction that the binding of DFP to albumin, in addition to forming adducts with the capability to act as a biomarker of exposure, might be playing a relevant role in the detoxification of DFP, especially considering that paraoxonases are not very efficient in the hydrolysis of OPs with a fluoride leaving group (Sogorb et al., 2004, 2010). DFPases are not expressed in mammals and paraoxonases exhibit a double genetic polymorphism in certain individuals who are more susceptible since they express low amounts of paraoxonase with very low specific activity.

53.5 Acute toxicity of DFP and interaction with AChE

53.5.1 In vitro studies on cholinesterase inhibition

Soon after DFP was discovered, it was demonstrated that it has the capacity to irreversibly inhibit AChE. Mazur and Bodansky (1946) reported in a personal communication that Mackworths had observed inactivation of horse serum cholinesterase by DFP and presented evidence that DFP in very high dilutions *irreversibly inactivates* the cholinesterase of brain, red blood cells, and serum in rabbit, monkey, and man, measuring cholinesterase activity by the liberated CO_2 as a consequence of the acetic acid formation in a bicarbonate−carbonic acid buffer in a classical methodology with Warburg vessels, as had been previously described by Ammon (1930).

Therefore, it was concluded that DFP and the other alkyl fluorophosphate esters were the first compounds reported to be “irreversible” inhibitors of cholinesterases. In contrast with another anticholinesterase drug, physostigmine, withdrawal of the compound by dialysis did not recover the activity.

Michel and Krop (1951) using DFP containing radiophosphorus of high specific activity, demonstrated that the inhibition of cholinesterase by DFP is associated with the binding of DFP phosphorus by the enzyme.

One of the earliest published reports with a systematic study of the inhibitory properties of DFP was that of Koelle and Gilman (1946). This study gave the pharmacological basis of a potential application, as cholinesterase inhibitor, for example, for glaucoma. Comparative inhibition in several species and the differences among brain, red cells, and serum were studied. Differences in the substrate specificity between brain/red cell (so-called "specific") and serum (then called "unspecific") were also noted.

In vitro log pI_{50} was reported to be 6.5 for serum BuChE and 4.2, 4.5, and 4.8 for AChE from rat erythrocyte, brain, and muscle, respectively, with similar values in dogs. In vivo studies after intramuscular injection in rats, dogs, and monkeys were performed and inhibition toxic effects and AChE regenerations was evaluated. Levels in the range of 0.05−1 mg/kg showed significant inhibition of serum ChE and doses of 1−5 mg/kg caused total inhibition of erythrocyte cholinesterase. Human exposure to a dose of 0.5−2 mg/60 kg caused marked inhibition of serum BuChE, without any inhibition of erythrocyte AChE and/or toxic symptoms.

In a study with mipafox, a sarin analog, compared with theoretical studies, it was demonstrated why some compounds, such as mipafox, are refractory to reactivation including when no aging reaction of AChE is occurring (Mangas et al., 2016)

53.5.2 Experimental animal studies on cholinesterase inhibition and acute toxicity

A number of studies have shown AChE inhibition, including gender difference (Table 53.7; Tuovinen et al., 1997) and effects on the different AChE forms in mice, rats, and chickens (Sung and Ruff, 1987; Michalek et al., 1981; Cisson et al., 1981).

Several routes of acute exposure have been tested, including oral, intramuscular, subcutaneous, intravenous, and intraperitoneal. LD_{50} doses are expressed in terms of mg/kg body weight and are shown in Table 53.8.

The main observed effects are those expected from cholinesterase inhibition:

- Respiratory stimulation, cyanosis, and dyspnea;
- Gastrointestinal tract hypermotility, diarrhea, and hypersalivation;
- Behavioral changes, such as tremors, convulsions, seizures, coma, muscle weakness, and alterations in sleep time and righting reflex;
- Alterations in peripheral nerves with neuromuscular blockage and flaccid paralysis, as well as ataxia;
- Fasciculations.

Other data of I_{50} for chicken brain AChE are shown in the section of delayed neuropathy later in this chapter for comparing AChE with other esterases.

53.5.3 Studies in man

The acute toxicity of DFP can be well correlated with a rapid and high degree of AChE inhibition. Table 53.9 shows the I_{50} for 45 min reported for human cholinesterases for DFP in comparison with other nerve agents. There is a correlation between AChE inhibition and acute toxicity.

There is very little reported information about accidental acute toxicity in humans. It has been noted that intramuscular and oral doses in the range of 0.07–0.1 mg/kg body weight can produce 50% depression of erythrocyte cholinesterase and moderate clinical symptoms (Grob and Harvey, 1957; Table 53.10).

Other studies of administration of DFP to man in the range of 0.07–0.5 mg/kg were reported with moderate ChE inhibition and some moderate alterations (Grob and Lilienthal, 1947).

53.6 DFP in studies on neurotoxicity and therapy with reactivators

53.6.1 Neuropharmacological studies of the cholinergic system

DFP is used in studies of neurotoxicity and neuropharmacology. In most studies, DFP is used as a model compound causing depression of cholinesterase activity and an increased level of acetylcholine (ACh). Studies include examples of rats surviving status epilepticus induced by DFP (Deshpande et al., 2010), a comparison of strains of rats in their susceptibility to neurotoxicity (Gordon and MacPhail, 1993), age-related differences in the rate recovery of cholinesterase and receptors (Michałek et al., 1990), inhibition of the motor system (Chemnitius et al.,1989), and alterations in energy homeostasis in skeletal muscles (Gupta et al., 1986) and brain (Gupta et al., 2001a,b).

Pharmacological effects and interactions have been the subject of many publications in which DFP is used to induce cholinergic effects and the modulation, agonist, or antagonist of drugs. Examples include: (1) alteration of cannabinoid signaling and its relationship with cholinergic toxicity (Nallapaneni et al., 2008); (2) role of opioid receptors in development of tolerance to DFP toxicity (Tien et al., 2005); (3) preventive effect of galantamine (Saghafi et al., 2013); (4) alteration in the patterns of GFAP upregulation (Liu et al., 2012); (5) alteration of the muscarinic receptor density and their regional adaptation (Yamada et al., 1983a,b), and (6) genetic and sex

TABLE 53.9 Comparison of human cholinesterases inhibition by DFP [I_{50}(45 min)] in comparison with other nerve agents and their LD_{50} for acute toxicity.

differences in the development of tolerance (Russell et al., 1983). The alteration of electrophysiology, nerve conduction, and action potential has been described since the early toxicological studies with DFP (Toman et al., 1947; Couteaux et al., 1946) for which the use of the squid giant axon is a frequent model system (Hoskin and Prusch, 1983).

53.6.2 Neurobehavior and neurodevelopment

DFP has been used as a model compound for studying neurobehavioral alteration related to the increased cholinergic effect caused by AChE inhibition. In some studies, these alterations are compared with those caused by other OPs and have also been related to oxidative stress (Dettbarn et al., 2006; Gupta and Milatovic, 2012; Milatovic et al., 2006, 2014; López-Granero et al., 2013; Gupta and Milatovic, 2014).

Chronic persistent alterations in spatial learning and memory have been described after exposure to DFP (Terry et al., 2012). Zebrafish is also a suggested model for testing developmental effects Faria et al., 2018).

Long-term changes in behavior, such as anxiety, have been reported in adult mice exposed to DFP during the preweanling period (Kofman and Ben-Bashat, 2006). The relationship between behavioral changes and decreased brain cholinesterase activity has been described since the 1950s in studies following intracerebral injections (White, 1956). Since then, many studies have been performed with DFP and other OPs on neurobehavioral effects. Some of the neurobehavioral studies have been related to studies on development by exposure during the prenatal and neonatal periods (Gupta et al., 1985; Das Gupta et al., 1988; Slotkin, 2006; Bushnell and Moser, 2006).

The alteration of circadian patterns (Raslear et al., 1986) and the involvement of nitric oxide in mitotoxicity in muscle and brain hyperactivity induced by DFP have been investigated (Gupta et al., 2001, 2002a; Zaja-Milatovic et al., 2009).

53.6.3 Therapy against anticholinesterase toxicity

Therapy against cholinergic symptoms continues to be a topic of interest for many researchers. DFP has been used extensively as a model compound for inducing cholinesterase inhibition, as well as other nervous system proteins. Studies into the kinetic mechanism of action with oximes and other therapies continue to be an issue of current research. In experimental studies, some of the compounds tested against DFP include bipyridinium oximes (Theirmann et al., 2009), tubocurarine (Barstad, 1956), meptazinol (Galli and Mazri, 1988), 2-PAM (Tuovinen et al., 1996), and quaternary ammonium compounds (Funke et al., 1955).

In silico approaches are introducing new perspectives and capacities for predicting, development, and understanding the mechanism of oxime and other reactivators. For this, DFP has been a relevant tool (Berberich et al., 2016).

53.6.4 DFP in other biological studies

During the 1950s–60s, DFP (isofluorate) was used in ophthalmological studies, including esotropia. Its potential therapeutic application in glaucoma and myasthenia gravis was described in 1947 (Quilliam, 1947) and other studies were published during the 1950s and 1960s in relation to ocular pressure (Zekman and Snydacker, 1953) and retinal detachment (Weekers and Lavergne, 1955).

During the 1960–70s, studies on the mechanism of coagulation were performed using DFP as an agent for blocking endogenous thrombin (Baskova et al., 1970). The interaction of DFP with human blood-coagulating factors has been studied, including factors VII (Osterud et al., 1979), V, and Va (Bartlett et al., 1978), and the Hageman factor (factor XII) (Becker, 1960).

The interaction of the anticholinesterase effect of DFP, with cardiovascular and respiratory reflexes and cardiac failure was also the subject of several studies (Heymans and Pannier, 1946; Wolthuis and Meeter, 1968). During the 1970s, a methodology was developed and applied based on labeling proteins with [^{32}P]DFP for studying the turnover, life-span, and survival of human blood cells (Matsuda, 1969). These approaches have also been applied to studying the kinetics of platelets (Ginnsburg and Aster,1973; Ebbe et al., 1966, 1970; Leeksma, 1963), the survival of erythrocytes (Derelanko, 1987; Cline and Berlin, 1963: Hjort and Paputchis, 1960; Saito and Sakai, 1977; Manunta and Cancedda, 1975), and the kinetics of granulocytes and neutrophils (Vorob'eva, 1976; Nowotny et al., 1978; Dresch et al., 1971).

53.7 Interaction of DFP with other esterases

53.7.1 Serine proteases and albumin: role of tyrosine residues

Serine proteases are proteins containing a serine residue in their active catalytic center acting in a molecular mechanism similar to esterases. Therefore, they are susceptible to phosphorylation by OPs in general and DFP in particular. This has been the basis for DFP use in biochemical studies for blocking serine-containing esterases, and thereby stabilizing proteins and avoiding proteolysis in tissue homogenates. Moreover, DFP has been used as a tool for specific studies either for understanding the mode of action of proteases or for biological studies, for testing the role of proteases in some biological processes. DFP-inhibited chymotrypsin and chymotrypsinogen were studied using P^{31} NMR (Reeck et al., 1977). DFP induced inactivation of bovine trypsinogen and chymotrypsinogen (Morgan et al., 1972). The subtilisin serine protease has been analyzed by NMR (Chen et al., 2008). The involvement of DFP-sensitive proteasomes in the control of oocyte maturation has been evaluated (Takahashi et al., 1994). The evidence of the role of tryptophan residue in the interaction of DFP with alpha-chymotrypsin has been reported (Wooton and Hess, 1960). The effects on sulfhydryl proteases have also been demonstrated (Heinicke and Mori, 1959).

Human serum albumin has been demonstrated to show arylacylamidase activity that is sensitive to DFP (Manoharan and Boopathy, 2006). A tyrosine residue has been characterized as a target of the binding of DFP to albumin (Means and Wu, 1979). Evidence has been reported that the tyrosine residue 411 is responsible for *p*-nitrophenyl acetate catalytic hydrolysis (Tildon and Ogilvie, 1972) and that it has a critical role in the detoxification of OPs such as paraoxon and diazoxon, and carbamates such as carbaryl (Sogorb et al., 1998, 2004, 2007, 2008). Therefore, albumin has been suggested as a biomarker of OP nerve agent exposure (Read et al., 2010; Lockridge et al., 2008).

53.7.2 Inhibition of soluble PVases of peripheral nerve by DFP

In the peripheral nerves, soluble carboxylesterases measured with the substrate phenylvalerate (PV) were found to have a high sensitivity to DFP. Tissue preparations were preincubated with DFP at nanomolar concentrations (up to 10 nM) for different inhibition times (up to 120 min; Fig. 53.4) and with DFP at nanomolar concentrations (up to 1000 nM) for 30 min of fixed inhibition time (Fig. 53.5). Inhibition data were analyzed with model

equations of one, two, and three sensitive (exponential) components, with or without resistant components. The best model according to an F test in both experiments was a model composed of two sensitive enzymatic components and one resistant to DFP. Around 84% of PVase activity was highly sensitive to DFP with I_{50} (30 min) of 0.8−1.2 nM and around 16% was resistant (Table 53.11). The number of enzymatic components and proportions are similar to the results obtained in inhibition experiments with mipafox, PMSF, paraoxon, and S9B (Estévez et al., 2004, 2010, 2011, 2012).

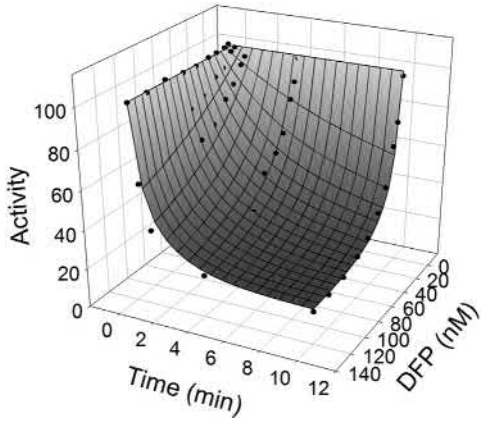

FIGURE 53.4 Inhibition kinetic of esterases by DFP. Example of a 3D representation of the inhibition kinetic of soluble peripheral nerve phenyl valerate esterase activity (PVase) by DFP. Inhibitory surface obtained by fitting the 3D model equation to the data corresponding to DFP inhibition. The surface reflects the result of the best model according to the F test. It corresponds to a model with two sensitive enzymatic components plus other resistant.

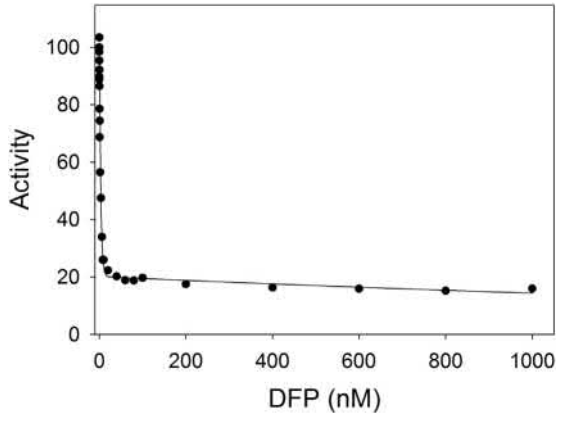

FIGURE 53.5 Fixed time inhibition. DFP 30-min fixed-time inhibition curve of soluble peripheral nerve phenyl valerate esterase activity (PVase). The curve was fitted to the best model according to the F test (two exponential and a resistant component). Each point represents the mean of three replicates (SD < 5%).

53.7.3 DFP- and OP-induced delayed neuropathy and neuropathy target esterase

53.7.3.1 Phosphorylation site identified by radiolabeled DFP

Organophosphorus-induced neuropathy is a neurodegenerative syndrome induced by some OPs (Johnson, 1982). An epidemiological outbreak was first described as a consequence of an adulterated alcoholic drink during the US Prohibition (Smith and Elvove,1930; Smith et al.,1930) and an episode in Morocco in 1959 by consumption of a lubricant oil (Travers, 1962) for which tri-*o*-cresyl phosphate was identified as the causative agent. It was demonstrated that neither AChE nor BuChE inhibition were involved as a mechanism for inducing this syndrome (Aldridge and Barnes,1961). Adult hens were shown to be an appropriate animal model for testing this syndrome in a toxicological effect protocol. The search of the target biomolecules triggering the mechanism was approached using radiolabeled [^{32}P]DFP (Johnson,1969a). Brain tissue treated with [^{32}P]DFP indicated binding of DFP to all sensitive phosphorylable sites in proteins. The fraction of sites that can be protected by a previous incubation with a non-neuropathic OP (TEPP) were considered irrelevant sites. From the remaining sites, the small number that can be protected by binding with a neuropathic compound (mipafox) were considered candidates to contain the target of the toxic mechanism. From the total phosphorylable sites (around 600 pmol/g fresh tissue), about 200 pmol/g was blocked by the non-neuropathic TEPP. The fraction of phosphorylable sites is a potential target for binding with mipafox and was quantified to be about 33−39 pmol/g (Johnson, 1969a).

TABLE 53.11 Inhibition by DFP on esterases component in soluble fraction of peripheral nerve.

	*E*1 (%)	*k*1 ($nM^{-1}.min^{-1}$)	I_{50} (30 min) (nM)	*E*2 (%)	*k*2 ($nM^{-1}.min^{-1}$)	I_{50} (30 min) (nM)	*R* (%)
A	38.9	0.0187	1.2	43.3	$4.1 \cdot 10^{-3}$	5.7	17.9
B	40.7	0.0274	0.8	41.7	$5.2 \cdot 10^{-3}$	4.4	17.6

The kinetic constants (ki) and the proportions of obtained esterase components from the different inhibition experiments with DFP. The I_{50} values were calculated from the kinetic constants for each component. (A) Experiment of time-progressive inhibition with different concentrations in a 3D fitting; (B) Experiment of fixed time inhibition with different concentrations. The R^2 coefficients were: 0.980 (A); 0.986 (B).

53.7.3.2 The target site identified as an esterase: neuropathy target esterase

Johnson (1969b) assumed that phosphorylable sites would be serine-containing proteins. Several carboxylesters were tested looking for a selective substrate able to interact in the same site (able to reduce the speed of [^{32}P]DFP labeling on the mipafox binding fraction). Phenyl-phenyl acetate (PPA) was selected as that substrate. In other studies, phenyl valerate (PV) was observed to be more selective and has been used for decades for testing the target site, the neurotoxic esterase, and was later named the NTE. NTE has been monitored as the PVase activity resistant to 40 μM paraoxon (20 min) ("B" activity) and sensitive to 40 μM paraoxon plus 60–150 μM mipafox ("C" activity) with NTE being the difference between the activity in B and C.

53.7.3.3 Protection and induction of neuropathy: the role of the aging reaction

It has been noted that some carbamates or esterase inhibitors, if dosed before DFP, were able to protect the onset of neuropathy (Johnson and Lauwerys, 1969). A series of studies were conducted for understanding the age-related sensitivity, structure–activity relationship with many OPs (Johnson, 1975a), motor nerve dysfunction (Lowndes et al., 1974), and protection by carbamates, phosphinates, and sulfonyl fluorides (Johnson, 1975b).

While some OPs include neuropathy, phosphinates, carbamates, and sulfonyl fluorides do not, but they rather protect from a further dose of a neuropathic compound. It was hypothesized to be related to the ability of the OP of the dealkylating reaction called an aging reaction. This was more clearly demonstrated by using radiolabeled DFP (Clothier and Johnson, 1979a,b).

The aging process involves dealkylation of one isopropyl group (Fig. 53.6). This was demonstrated by both molecular and enzymatic approaches. The loss of time of the capacity of the inhibited NTE to be reactivated by a nucleophilic reagent (fluoride ion) was demonstrated confirming the aging reaction. In contrast with AChE, the dealkylated isopropyl group in the DFP-inhibited NTE remains bound to the other site ("Z") of the protein (Fig. 53.7). This group may be released to the medium as isopropyl alcohol by alkaline treatment. This was demonstrated molecularly using DFP labeled with ^{3}H and ^{32}P. The molar ratio (^{3}H-isopropyl)/(^{32}P) is 2:1 in the inhibited enzyme and it is converted to 1:1 in the aged protein, confirming that one of the isopropyl groups has been released.

The structure–activity relationship, the relationship of the capacity to induce neuropathy, and the capacity of causing the aging reaction have been demonstrated in a wide range of OPs (Johnson, 1982). Therefore, the proposed hypothesis was that blocking the site itself is not a sufficient requirement and that an additional modification of the function of NTE is needed. The protein alteration after the aging reaction is able to trigger the pathophysiological process to induce neuropathy.

This pathological process is involved in a number of molecular events, including alteration of neurofilament phosphorylation by Ca^{2+}/calmodulin-dependent protein kinase. Alteration of the microtubule has been reported from the laboratories of Abou-Donia and Gupta (Gupta and Abou-Donia, 1993, 1999; Gupta et al., 2000). Also, using DFP as a model, c-fos mRNA expression has been reported (Gupta et al., 2002b; Damodaran and Abou-Donia, 2000; Damodaran et al., 2000, 2001), as well as glyceraldehyde-3-phosphate dehydrogenase (GAPDH) mRNA in the CNS of hens treated with DFP (Damodaran et al., 2002). Early alterations are induced by DFP on the PKA/p-CREB pathway and differential persistence of beta-tubulin subtypes in the CNS of hens are proposed to contribute to OPIDN (Damodaran et al., 2009).

53.7.3.4 Testing delayed neuropathy

The capacity of inducing neuropathy means that the compound should be able to induce a high degree of inhibition of NTE in a condition in which the animals survive the

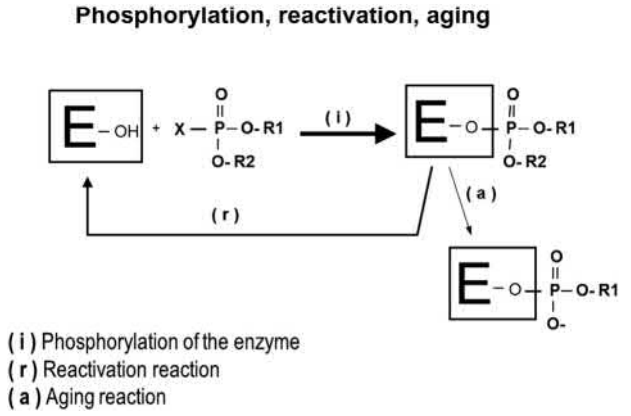

FIGURE 53.6 Reaction of phosphorylation and aging of OPs on esterases. R is an alkyl or aryl group. X is the so called "leaving group."

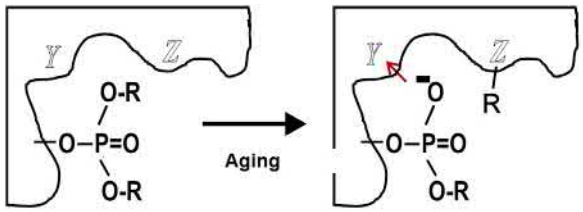

FIGURE 53.7 Aging of the DFP phosphorylated NTE protein. The aging process is a dealkylation reaction. In the case of AChE, the alkyl group is released to the medium as the corresponding alcohol. This figure represents the case of NTE with DFP in which the isopropyl group remains attached to the protein and is released to the medium only after an alkaline treatment. The nature of the "Z" site remains unknown.

acute cholinergic effect. A standard test has been adapted by the OECD as protocols 418 and 419 (OECD, 1995a,b) and by other regulatory agencies. The method involves dosing of animals with a single $5 \times LD_{50}$ dose or repetitive dose in animals protected with atropine and observed for 21 days, accompanied with measuring NTE activity in the nervous system in a group of animals sacrificed 24 h after dosing.

An in vitro approach has also been proposed based on the relative inhibition of AChE and NTE in the hen brain homogenate or in human neuroblastoma cells, followed by testing the aging reaction by the loss of capacity or being reactivated with a nucleophilic reagent (Sogorb et al., 2010). Examples of the ratio of I_{50} AChE/NTE for some nerve agents are shown in Table 53.12. The higher ratio suggests a higher possibility of inducing delayed neuropathy.

Delayed neuropathy has been tested in adult hens/chickens, which are considered the only suitable model. However, repeated exposure with DFP has demonstrated a structural disruption of myelinated axons and persistent impairments of axonal transport in the brains of rats (Naughton et al., 2018). This and other studies in rodents suggest that the rodent model might also be suitable for the neurodegenerative effects caused by OPs. To date, only hens have been considered a suitable model of delayed neuropathy caused by DFP and other OPs after an acute dosing.

Advanced molecular approaches are still needed to be applied to DFP studies. Proteome analysis of rat plasma after DFP intoxication have been evaluated as a simulant of nerve agents (Chaubey et al., 2019).

53.7.3.5 Molecular and genomic characterization of NTE and its role in embryonic development

The molecular identification of NTE protein and its genomic identification (encoding gene: PNPL6) was the result of research conducted by Glynn et al. (1993). For this process, proteolysis of [^{3}H]DFP-labeled polypeptide was also approached. After isolation, using a specific biotinylated inhibitor, molecular cloning was possible (Glynn et al., 1994). The protein catalytic domain was isolated and used for some studies and phospholipase activity was demonstrated and proposed to be involved in neuronal maintenance (Atkins et al., 2002; Glynn, 2005; Mühlig-Versen et al., 2005; Read et al., 2009).

A role of NTE in the embryonic development was envisaged in studies with NTE-deficient mice (Moser et al., 2004). The expression of NTE in mouse embryonic stem cells in differentiation (Pamies et al., 2010) and the alteration of pathways during differentiation by silencing mRNA NTE encoding gene (PNPL6) in mouse and human cells (Pamies et al., 2014a,b), but not inhibition by a neuropathic compound such as mipafox (Pamies et al., 2014a,b). This suggested that its role in embryonic development has a relationship neither with its enzymatic property nor with the same mechanism inducing delayed neuropathy in adults.

In short, the history of understanding delayed neuropathy, the identification of the target protein and the molecular events including the aging reaction in the mechanism inducing the neurodegenerative syndrome, has been very closely related to the use of DFP as a tool for research studies.

TABLE 53.12 I_{50} on AChE and NTE.

53.8 Concluding remarks and future directions

DFP is a dialkylfluorophosphate synthesized in the 1930s when looking for insecticides, warfare agents, and other applications. Although it has never been used as a chemical warfare agent, it has been extensively used in research as a model compound of AChE inhibition and in other toxicological, pharmacological, and biomedical studies, due to its lower toxicity compared to the G-series nerve agents. DFP is detoxified by hydrolysis by A-esterases as the enzyme DFPase (not present in human) and by binding to B-type esterases as the tyrosine residue of albumin and the serine residue on cholinesterases. The acute toxicity is caused by inhibition of AChE and delayed neuropathy is related to the initial inhibition of the so-called NTE. DFP is known to bind and inhibit serine-proteases and other unidentified esterases. DFP is still used as a tool for many toxicological and pharmacological applications in which the consequence of protease inhibition or cholinergic effects is needed for studying a pharmacological or cell biology process.

Chapter 54

Physiologically based pharmacokinetic modeling of chemical warfare agents

54.1 Introduction

Pharmacokinetics (PK) is the quantitative determination of drug or chemical movement (time-course concentration) throughout the body. One of the basic principles of pharmacology and toxicology is that the effect of a drug or chemical is directly related to its concentration at some target site or receptor in the different tissues of the body. This premise is the critical reason and continued justification for the development of improved PK descriptions of chemical warfare agents (CWAs). Mathematical models are applied to this type of data to simplify or reduce the description of the basic chemical–biological processes of absorption, distribution, metabolism, and excretion (ADME). These model types are driven by the basic premise that significant pharmacological or toxicological understandings are gained by knowing the internal drug/chemical concentration at the target site. Most often termed "classical" PK models, they reduce the entire body mass to either one or two mathematical compartments that represent the volume of blood, plasma and/or readily accessible extracellular spaces, and a deep compartment storage representing other tissues. The advantage of this analytical approach is the determination of a simple global description of a chemical's behavior in the body, and potentially the concentration at major target receptor sites. The major disadvantage is that these empirical models are poor at interspecies extrapolation, since the parameters do not have a physiological interpretation, and it is difficult to predict how they change when the underlying physiology changes.

Physiologically based pharmacokinetic (PBPK) models are a special type of PK model that attempts to provide more definition to the model analysis by incorporating physiological factors into the model design, like tissue volumes, blood flow rates, and species-specific enzyme characteristics that can more accurately differentiate the dose–response relationship for a chemical or drug in one species from that of another species. The power of this approach is to be able to perform laboratory studies, both in vitro and in vivo, in common experimental species to develop a complete PBPK model, and then extrapolate these results to predictions in humans based on in silico experimentation.

PBPK models have become useful analytical tools to interpret PK data and to interpret data from complex chemical exposure scenarios. These models are mathematical constructs that allow the coordination of species-specific physiology, chemical-specific information, and the experimental protocol for the chemical(s) of concern. The power of PBPK models lie in aiding the ability of scientists and decision makers to simulate the time-course concentration of chemicals in experimental animals and humans and to better determine estimates of actual chemical doses delivered to the target tissue, thereby providing a better prediction of response. Due to the physiologically based nature of these models, simulations of experimental data can be performed by one exposure route to validate the PBPK model, and then this model can be used to simulate and predict the kinetics and pharmacodynamics (PD) in the human by one or multiple exposure routes. This provides decision makers with a fairly rapid method of comparing

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00054-4

results from in vitro and in vivo laboratory studies, to potentially real-world exposure scenarios. Perhaps the most useful application of these models lies in a strongly animal data-based PBPK-PD model being used to make predictions about human responses to CWAs, across a broad range of doses and CWA types, in light of not being able to actually conduct human exposure studies.

CWAs are represented by any one of a number of chemicals exhibiting very high toxicity by various mechanisms. This chapter covers CWAs with structures as simple as carbon monoxide (CO) and as complex as botulinum toxin or ricin proteins. While this chapter could address the development of PBPK models of CWAs in general, the focus will primarily be on the organophosphate based nerve agents typically represented by sarin (GB; isopropyl methylfluorophosphonate).

54.2 Development of PBPK models

Most attempts at describing PK and PD descriptions of CWAs have used classical kinetic models that are often fit to one set of animal experimental data, at lethal doses, with extrapolation to low-dose or repeated-exposure scenarios with limited confidence. This is due to the inherent nonlinearity in high dose to low-dose extrapolations. Also, the classical approach is less adept at addressing multidose and multiroute exposure scenarios, as occurs with agents like *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX), where there is pulmonary absorption of agent as well as dermal absorption. PBPK models of chemical warfare nerve agents (CWNAs) provide an analytical approach to address many of these limitations.

There are only a few PBPK models that have been developed to describe the PK and PD of CWNAs. Maxwell et al. (1988) developed a PD model for soman in the rat describing the inhibition of acetylcholinesterase (AChE) in different tissues, with mass balance equations including parameters for blood flow, tissue volumes, soman metabolism and tissue/plasma partition coefficients. This effort resulted in an accurate prediction of AChE activity in eight different tissues after intramuscular soman dosing and was able to reproduce dose–response inhibition from 10% up to 100% of the brain AChE activity. Gearhart et al. (1990) used diisopropylfluorophosphate (DFP) as a model compound for CWNAs, to develop a PBPK-PD model describing the PK of DFP and the inhibition of AChE and BuChE in all the pertinent tissues of the body (Fig. 54.1). This model construct was able to predict the PK of DFP and inhibition of AChE and BuChE after acute and repeated doses by three different routes. Recently, the PBPK-PD model for DFP was reparameterized to predict GB kinetics, inhibition of AChE, and regenerated GB from bound AChE sites on red blood cells (RBCs; Gearhart et al., 2005).

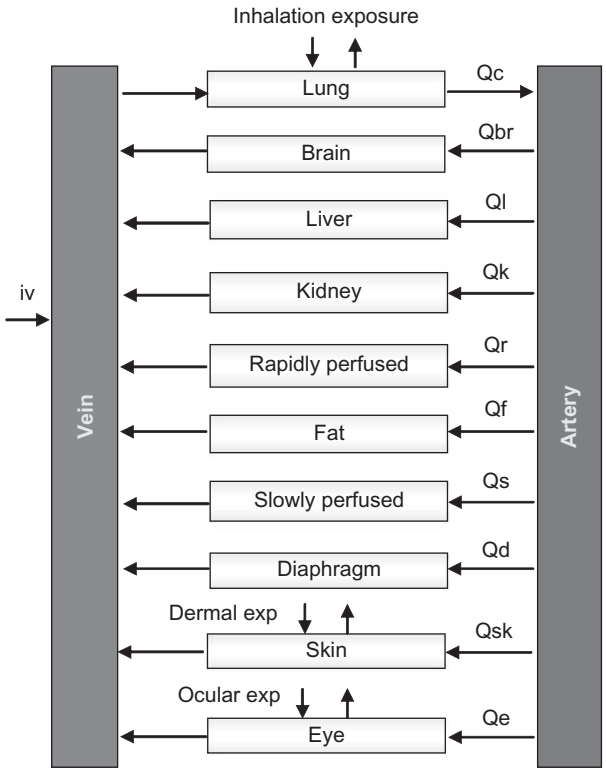

FIGURE 54.1 PBPK-PD model schematic of sarin in the Hartley guinea pig. This model structure allows for the simulation of experimental studies with dosing by IV or SC dosing and IH exposure. This model design was based on Gearhart et al. (1990) and adapted to simulate the PK and PD of sarin in the guinea pig.

The most recently developed PBPK-PD models for CWNAs have continued to focus exclusively on the most potent G agent, soman (GD), due to its rapid aging rate for permanent binding to serine sites on cholinesterase and resultant resistance to therapeutic countermeasures. The main expanded application in these modeling efforts is to multiple species, providing greater confidence in the application of the PBPK-PD method for eventual extrapolation to predictions in the species of concern (namely, humans). Sweeney et al. (2006) augmented the intravenous (IV) exposure model of Langenberg et al. (1997) for GD in guinea pigs, to predict subcutaneous dosing and inhalation exposure, as well as adding the rat and marmoset species. Both of these changes are significant additions, as subcutaneous dosing is the most common experimental method for controlled CWNA challenge to determine efficacy of therapeutic treatments. Inhalation is the primary route of threat exposure for G agents, which tend to readily form vapors, and any of the other CWNAs which, while having very low vapor pressures, still can present an inhalation hazard via aerosol droplets.

Chen and Seng (2012) extended the PBPK model simulation for GD from these previous efforts to include the

pig species, as well as the PD component predicting the inhibition of AChE and carboxylesterase (CarbE) in blood and tissues. One significant area of needed validation from Chen and Seng's model is the assumption that tissue/blood partition coefficients for GD were identical across all species for all tissues, as well as other model parameter assumptions, which could have a critical impact on the broader application to more diverse simulation scenarios (Ruark et al., 2013). For the most significant step of extrapolation to the human species and making predictions about CWNA lethality, few of these parameter values are likely to be available, an area in which Quantitative Structure Activity Relationship (QSAR) analysis can provide a viable impact (Knaak et al., 2004; Ruark et al., 2013).

There are three basic critical components to PBPK models: (1) species-specific physiological parameters, (2) chemical-specific parameters, and (3) specific experimental details for the studies to be simulated. Species-specific physiological parameters are the organ weights and blood flow rates for the defined compartments in the PBPK model. These values are most often available in the published literature and when lacking, are derived from the closest like species. Chemical-specific parameters that are unique for each chemical are the tissue solubility (partition coefficient), metabolism of the parent compound, and plasma and tissue-binding characteristics. Tissue solubility is most often measured experimentally for the volatile CWNAs by the vial equilibration method (Gargas et al., 1989). Existing models for the physiological distribution of CWNAs are based on a limited number of data sets for each agent and typically rely on single exposures at relatively high doses, often in the supra-lethal range (van der Schans et al., 2003). Mathematical models of these data have been developed, but extrapolation to low-level exposures has proven problematic (Sweeney and Maxwell, 1999). Further, there are very little experimental data and essentially no modeling efforts for repeated low-level exposures (Benschop et al., 1991). Thus, new experimental data at the appropriate dose ranges appear to be required for further refinement and extension of existing PBPK models.

Much of the animal data on the biological effects of low-level exposure to GB and other nerve agents has been collected via the subcutaneous or intramuscular route, particularly in guinea pigs, because of their lack of CarbE. A good deal of data has also been collected by this dosing route or intramuscular dosing in rats, miniature pigs, and nonhuman primates. The primary exposure route of interest for human exposure is almost exclusively inhalation or dermal contact, so the quantitative implications of these laboratory exposure data for human health risk assessment is not straightforward. The most reliable tool for extrapolating across both species and exposure routes is PBPK modeling, in which species differences in physiology are taken directly into account, and equivalent systemic and tissue doses for different routes of exposure can be calculated. Such extrapolation procedures, exemplifying the integration of diverse data sets in both animals and humans, are illustrated in Fig. 54.2. Here, the lower pentagon represents the dermal (or subcutaneous) exposure route for different species, while the upper pentagon represents inhalation exposure. The arrow represents the extrapolation of subcutaneous exposure data in the guinea pig to apply them to human inhalation exposure situations. In this example, the relevant biological effects observed in the guinea pig at specific subcutaneous exposures are noted. The guinea pig PBPK model then allows blood and tissue concentration time-courses corresponding to these doses to be calculated. Assuming that similar biological effects occur at similar target-site concentrations across species, the necessary inhalation exposure corresponding to the same blood and tissue concentrations in the humans can then be back-calculated using the human PBPK model for the agent. By using PBPK models in this way, human inhalation exposures are thereby quantitatively linked to the rich animal response and health effects databases.

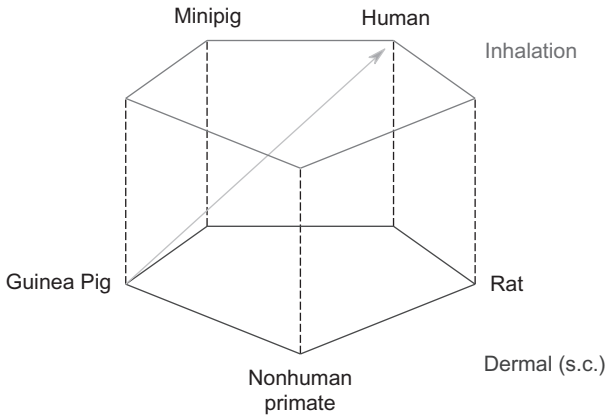

FIGURE 54.2 Schematic illustration of combined interspecies and route-to-route extrapolation. The arrow represents the extrapolation of guinea pig subcutaneous exposure data to human inhalation exposure situations.

54.3 Need for improved measures of CWNA exposure—the use of PBPK analysis of data

Historically, cholinesterase activity has been used to evaluate exposure of humans and animals to nerve agents. Unfortunately, circulating cholinesterase activity is a relatively insensitive and imprecise marker of nerve agent exposure. By contrast, regeneration of nerve agents from inhibited enzymes using a high fluoride concentration

(fluoride regeneration) is well suited to monitoring absorbed doses resulting from low-level exposures to GB, GD, and other CWNAs (Polhuijs et al., 1997; Jakubowski et al., 2001, 2003; Adams et al., 2004). This technique has not yet been applied systematically for kinetic modeling of CWNA exposures in guinea pigs. Recently, a method for regenerating GB from blood and tissue has been developed and validated in rat, guinea pig, and pig models and provides a sensitive and quantitative means for estimating the kinetics of GB in blood (Jakubowski et al., 2004). This method is based on fluoride ion regeneration of the protein-bound agent. Fluoride ion-regenerated sarin (R-GB) was found in blood and tissues of miniature pigs exposed to sarin vapor levels ranging from miosis to lethality. The R-GB in these samples was analyzed by gas chromatography−mass spectrometry (GC−MS) after a C18 solid-phase extraction sample preparation that included fluoride ion addition and pH adjustment. Serial blood samples taken before and during miosis-level GB inhalation exposures resulted in RBC R-GB levels that steadily rose during the exposure. This demonstrated the ability of the R-GB assay as a biometric of exposure. The slopes of the lines created by plotting R-GB versus time closely correlated to the experimental exposure level. Therefore, the rates of GB absorption in these animals were proportional to the GB exposure concentration. In contrast to R-GB, monitoring AChE activity was an ineffective indicator of exposure at miosis levels in these experiments.

54.4 Relationship between regenerated sarin and AChE activity and its use as a dose surrogate

Regenerated sarin S_R from RBCs is experimentally related to AChE activity A, as shown in Fig. 54.3. It is apparent that the relationship can be adequately described in terms of a Michaelis−Menten equation, as follows:

$$A = A_{max}\left[1 - \frac{S_R}{S_R + K_m^{eff}}\right], \qquad (54.1)$$

where $A_{\max} = A_{\max} = 0.623$, and $K_m^{eff} = 0.006$. Note that K_m^{eff} is not the true K_m for GB binding to AChE, which is the concentration of sarin needed to fill half the AChE receptors, since we do not know that the regenerated sarin is the same as the original exposure concentration. (If there were additional sarin binding sites than AChE, for example, the regenerated sarin would underestimate the exposure concentration, and the true K_m would be larger than K_m^{eff} by a certain factor.) The fact that these data fit so well to an M−M type equation strongly suggests that there is a simple proportionality between K_m^{eff} and the "true" K_m, and that sarin regenerated from RBCs is a suitable surrogate for the original exposure to sarin in blood (Fig. 54.3).

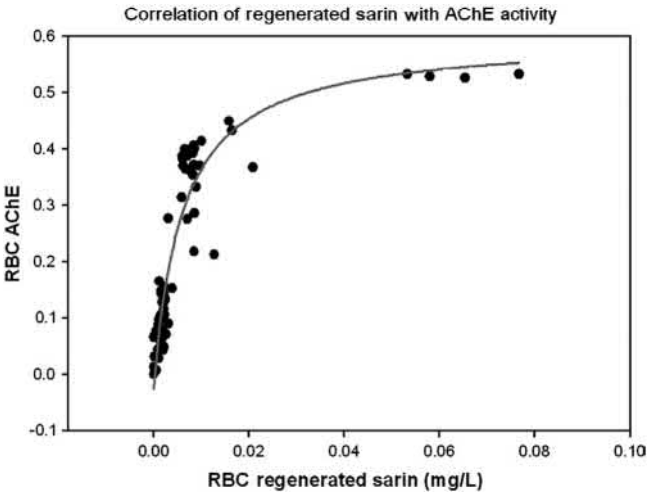

FIGURE 54.3 Plot of RBC AChE activity as a function of regenerated RBC sarin.

Regenerated sarin from RBCs at high doses may exceed the total available binding capacity of the AChE receptors associated with the RBCs. There are, therefore, additional sarin binding sites proposed to be associated with RBCs that continue to bind sarin well after the AChE receptors are filled, and therefore may comprise the bulk of the regenerated sarin at high concentrations. We thus have proposed two competing binding processes: one high-affinity, low-capacity site that dominates the binding of sarin at low concentrations, and which normally releases sarin very slowly, if at all (the AChE receptors); and one relatively low-affinity, high-capacity site, that releases sarin rapidly compared with the circulation time of the blood (Fig. 54.4). This latter site would dominate at higher concentrations, and in the absence of any evidence for its saturation even at these high concentrations, we approximate it as a first-order process described with simple association and dissociation rate constants k_{on} and k_{off}.

54.5 General PBPK model structure

The basic structure of the PBPK model used to describe GB PK and PD followed that of the PBPK-PD model for DFP (Gearhart et al., 1990). Tissue compartments (Fig. 54.2) were added to the previous model structure describing the eye and the skin, where before, these compartments had been lumped together in rapidly perfused or slowly perfused tissues. The eye was added to provide the means of predicting miosis during CW agent exposure, from the systemic absorption of chemicals, but more importantly, from the amount of chemical absorbed directly to the eye structures via the ocular surface via

absorption and diffusion. Adding this compartment also provided a mechanism of addressing the PD effects of sarin on the eye, by correlating inhibition of AChE enzyme levels in the iris with levels of miosis. The skin was added primarily to provide an exposure route for those agents that have a significant dermal absorption potential. Decreases in absorption due to upper respiratory tract (URT) deposition were accommodated by refining the model as shown in Fig. 54.5.

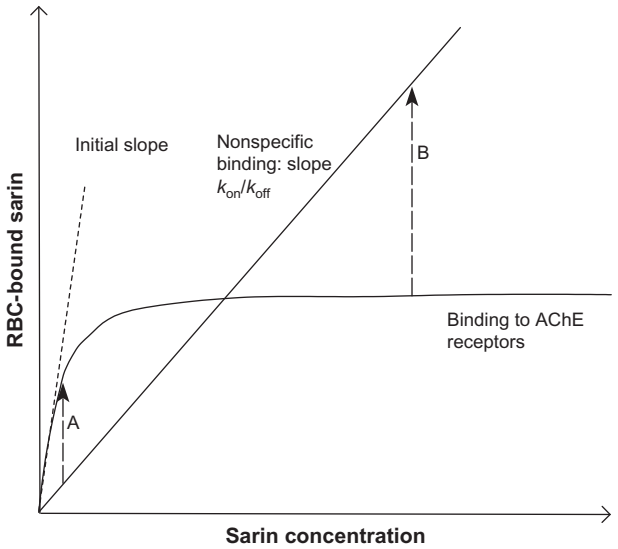

FIGURE 54.4 Hypothetical bound GB versus free sarin concentrations for saturable AChE binding, and linear nonspecific binding. The AChE binding has a higher initial slope, so it will dominate in a competitive situation at low doses (A), but it is saturable, so it will eventually be swamped by the nonspecific binding at higher doses (B).

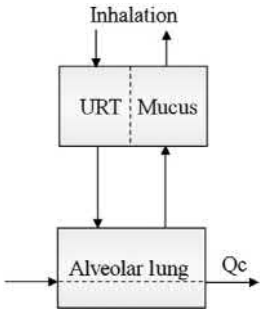

FIGURE 54.5 Detailed schematic for URT interactions for inhalation exposures.

PBPK parameters for individual organ weights were obtained from Breazile et al. (1976); Altman and Katz (1979), and Peeters et al. (1980). Blood flows for most organs were obtained from Peeters et al. (1980) or were scaled from other rodent species. The partition coefficients were based on the values used for DFP (Gearhart et al., 1990) and soman (Langenberg et al., 1997), as well as the cholinesterase and sarinase values for tissue and blood.

The description of the interaction of GB with the mammalian system of the guinea pig followed that as described by Gearhart et al. (1990) for the CWA simulant DFP in rodents and Gearhart et al. (2005) in the Göttingen miniature pig. The description of sarin binding to AChE is shown in Fig. 54.6. Sarin interaction with AChE is described by a bimolecular rate constant, causing loss of AChE activity. The inhibited AChE sites represent the amount of sarin, which can be regenerated from the RBCs.

54.6 PBPK simulation of cholinesterase inhibition and regenerated GB

The main focus of this effort was to develop and validate methods to relate and integrate CWNA toxicity data across routes of exposure in a common species. The specific goal is to compare uptake and clearance kinetics of similar sublethal doses of GB in the blood of guinea pigs exposed to the agent by acute intravenous (IV), inhalation (IH), or subcutaneous (SC) injection. GB regenerated from blood was used as the dose metric to compare the uptake and clearance kinetics of similar doses of GB administered to guinea pigs by an IV, SC, or IH route of exposure. The resulting database will be used to derive a quantitative ratio (SC/IH) of systemically absorbed agent that will allow predictions of the atmospheric GB concentration relevant to a second species based upon subcutaneous injection exposures.

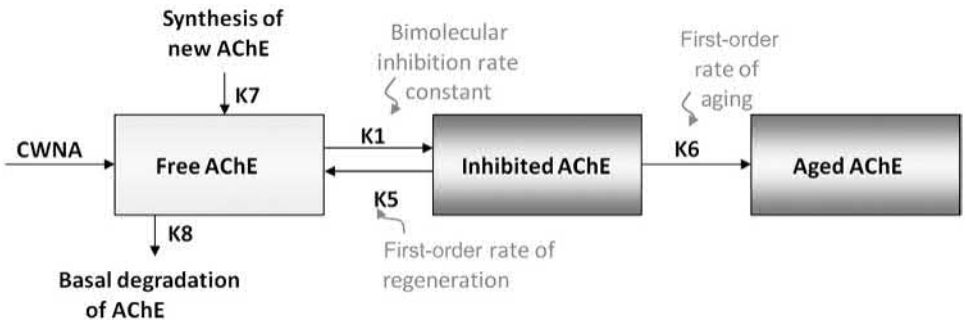

FIGURE 54.6 Schematic for AChE inhibition by sarin.

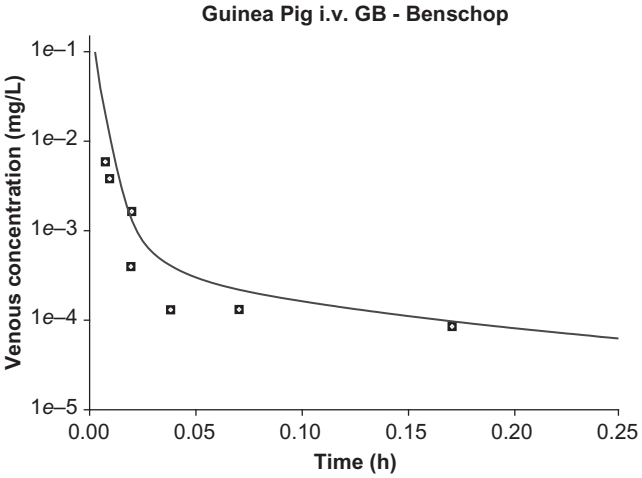

FIGURE 54.7 PBPK-PD simulation of AChE inhibition in the guinea pig after an IV GB dose of $0.8 \times LD_{50}$ (0.0042 mg/kg body weight) (data from Benschop and De Jong, 2001—19.2 μg/kg).

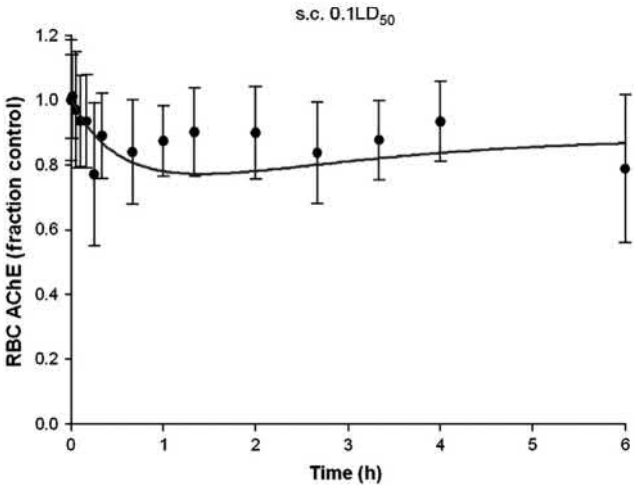

FIGURE 54.8 PBPK-PD simulation of AChE inhibition in the guinea pig after a SC dose of $0.1 \times LD_{50}$ (0.0042 mg/kg body weight).

Guinea pigs were exposed to sublethal levels of GB by IV, IH, and SC routes. Serial blood samples were collected in order to determine simple uptake and clearance kinetics using regenerated agent as a dose metric in a single dose (delivered via IV, SC, and IH). The resulting database was used to derive the PBPK model. This model will be used to determine a quantitative ratio (SC/IH) of a systemically absorbed agent that will allow predictions of the atmospheric GB concentration relevant to the increased guinea pig data sets based upon subcutaneous injection exposures.

Simulation of inhibited cholinesterase and regenerated GB versus the plotted data are exhibited in Figs. 54.7–54.13. The methods of GB exposures or dosing shown in the figures are for either the IV, SC, or IH route. In most cases, the experimental data was well represented by the PBPK-PD model simulations. Those instances where the greatest deviation occurred between the model and the data occurred most likely because of data variability, such that the trend of the data would not follow a reproducible model behavior (Fig. 54.11), or cases where there is still some question about the strength of the model parameters being used. Figs. 54.7–54.10 show the model simulation of some of the key data used to determine model behavior. In each of these cases, the simulations provide a good representation of the overall magnitude and tread of the data. In some cases, as in Figs. 54.7 and 54.9, there are points during the simulation when there is either an overestimation or underestimation of the data. This type of variation between PBPK-PD simulations and data is a common occurrence whenever there is an attempt to exactly simulate time-course kinetic data for such toxicologically active a compound as GB. If it appears that significant decreases or increases in the

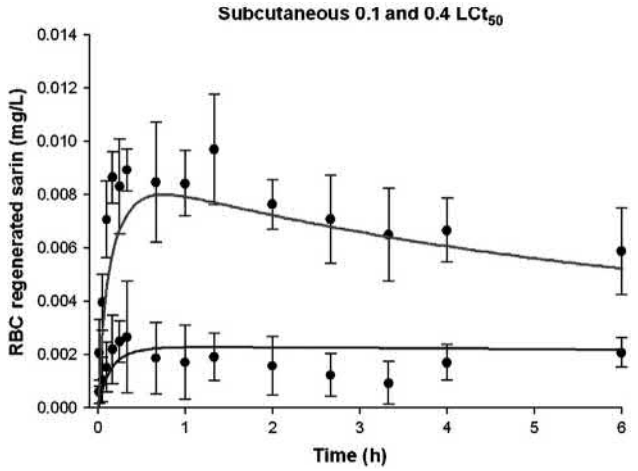

FIGURE 54.9 PBPK-PD simulation of regenerated sarin in the guinea pig after a SC dose of $0.1 \times LD_{50}$ (0.0042 mg/kg body weight) and $0.4 \times LD_{50}$ (0.0168 mg/kg body weight).

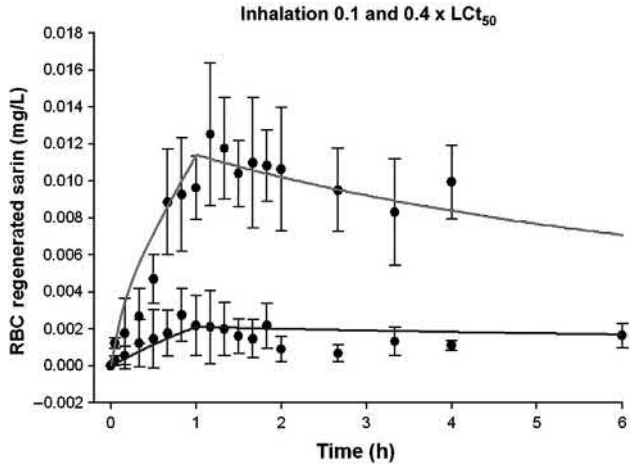

FIGURE 54.10 PBPK-PD simulation of regenerated sarin in the guinea pig after a 1-h IH exposure to sarin vapor at $0.1 \times LC_{50}$ (0.4 mg/m^3) or $0.4 \times LC_{50}$ (1.6 mg/m^3).

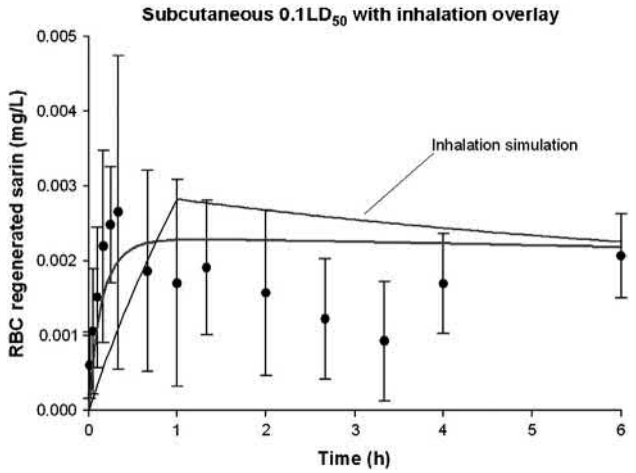

FIGURE 54.11 Overlay of the simulation of regenerated RBC sarin after a $0.1 \times LD_{50}$ SC dose of sarin versus IH dosing simulation at the inhalation concentration required to reproduce the SC data.

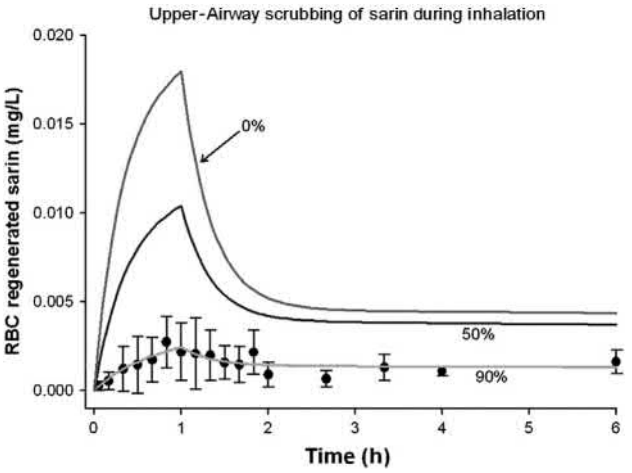

FIGURE 54.13 Upper-airway scrubbing simulations. As was previously seen with the simulation of minipig inhalation exposures, a significant percentage of the inhaled dose was scrubbed by the URT, with the best fit to the data requiring the loss of 90% of the inhaled dose.

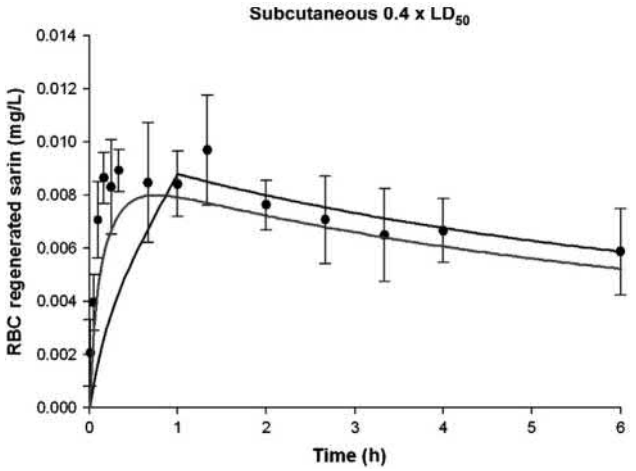

FIGURE 54.12 PBPK-PD simulation of an exposure of guinea pigs to the SC concentration equaling 0.4 of the lethal concentration affecting 50% of the exposure population (LD_{50}).

actual experimental values are indications of real mechanisms and not just animal-to-animal variability, then that may be simulated using more sophisticated methods, as with stochastic processes where actual fluctuations in blood flows or shunting of blood could cause changes in represented concentrations outside the normal trend of the data. Certainly one major issue not addressed in this chapter is the effects of GB on its own PK, which in turn has a significant impact on key PBPK parameters such as blood flow and respiratory ventilation parameters. A well-known response to severe CWNA exposure is a suppression of the cardiac output and respiratory ventilation, both of which could alter measured PK and PD endpoints, and if not modulated in the PBPK-PD model, lead to overestimation or underestimation of data.

54.7 Concluding remarks and future directions

The overall performance of the PBPK-PD model in predicting both the concentration of regenerated GB and the inhibition of RBC AChE was very successful for both the SC and IH routes of exposure at these doses. Previously published studies showing the significant deposition of GB in the URT were confirmed in this analysis of the inhalation of GB in the guinea pig at 0.1 and 0.4 times the LC_{50} for this species. The PBPK-PD model was utilized to equate the delivered dose of GB by SC exposure to what would be obtained after IH exposure. In this analysis, it was determined that at lower GB inhalation concentrations, there is a significant amount of deposition of the agent on the URT (Fig. 54.13), material that is both hydrolyzed and resultantly inactivated, or else it is bound by a mechanism such that it presently is hypothesized to have limited activity. This is one aspect of this analysis that requires further study. To determine the actual IH concentration that would correlate with a particular SC dose, the PBPK-PD model was exercised repeatedly, and the simulation output was overlaid on the SC simulations. This process is shown in Figs. 54.11 and 54.12 for the 0.1 and 0.4 SC LD_{50} levels, respectively. This calculation showed that to reproduce the SC $0.1 \times LD_{50}$ of 0.0042 mg/kg (Fig. 54.11), required an inhalation concentration of 0.08 ppm for a 1-hour inhalation exposure. This value is very close to the experimentally determined value for the inhalation $0.1 \times LC_{50}$ of 0.05 ppm. The SC $0.4 \times LD_{50}$ of 0.0168 mg/kg required an inhalation concentration of 0.28 ppm for a 1-hour inhalation exposure (Fig. 54.12). Further simulations will need to be carried out to confirm these apparent relationships.

A previously developed PBPK-PD model for the CWNA surrogate DFP was parameterized to simulate the concentration and effects of low-level CWAs in the guinea pig after exposure by IH and SC injection. The model code was written to account for absorption of CWAs from multiple sites (respiratory tract—lower and upper, dermal, and ocular) after vapor or SC exposure. References to guinea pig physiology in the literature were used to determine the majority of organ volumes and blood flows, while some parameter values were scaled from other species. Unique features of this PBPK/PD model structure were physiological compartments for the eyes, as a source of external CWA absorption and as a site of cholinesterase binding, and the skin, as a dermal absorption pathway. One initial PD endpoint developed in this model was CWA inhibition of cholinesterases (such as AChE and BuChE). Covalent binding of sarin to cholinesterases and other proteins was also estimated by a novel parameter based on fluoride ion regeneration of the agent. The PBPK/PD model was used to simulate AChE inhibition after inhalation and subcutaneous injection of CWA and to predict potential PD effects at different tissue target sites. This preliminary model will provide a quantitative tool to predict the physiological consequences of low-level, nonlethal exposure to CWNA exposure.

55.1 Introduction

The first organophosphorus (OP) warfare nerve agents (WNA), tabun (GA) and sarin (GB), were developed in the 1930s by Gerhard Schrader. These, and the even more toxic soman (GD), developed in 1944, are members of the so-called G-agents. Together with VX, developed in 1952 in the United Kingdom, these compounds have emerged as the major WNA known to have been produced and weaponized. The WNA are alkylphosphonic acid esters. Tabun contains a cyanide group. Sarin, cyclosarin, and soman contain a fluorine acyl radical and are methylphosphonofluoridate esters. These WNA contain a C−P bond not found in organophosphate pesticides. The C−P bond is very resistant to hydrolysis. VX contains a sulfur and is an alkylphosphonothiolate.

The mechanism of extremely high toxicity of these agents is excessive cholinergic stimulation caused by inhibition of acetylcholinesterase (AChE) at nervous system synapses. WNA are direct AChE inhibitors reacting rapidly with a serine hydroxyl group in the active site of AChE with the formation of a phosphate or phosphonate ester. The phosphorylated enzyme regenerates very slowly, rendering the enzyme inaccessible for its physiological substrate acetylcholine (ACh). The chirality around the phosphorus atom largely influences the toxicity of these agents as documented in the case of soman whose P(−) isomers are much more toxic than the P(+) isomers (van der Schans et al., 2007; Benschop and De Jong, 1991; Jokanović, 2009a).

Signs and symptoms of the cholinergic syndrome occurring in acute poisoning with WNA and other OP compounds are predictable from their biochemical mechanism of action and are directly related to the levels of AChE activity. After exposure to WNA the symptoms of poisoning occur quickly depending on the dose taken mainly by inhalation (G-agents). These symptoms include miosis (unreactive to light); sweating, rhinorrhea, lacrimation, and salivation; abdominal cramps and other gastrointestinal symptoms; respiratory difficulties and cough; dyspnea, constriction sensation in the chest, wheezing; twitching of facial muscles and tongue, tremors, and fasciculations; bradycardia and ECG changes, pallor, and cyanosis; anorexia, nausea, vomiting, diarrhea, and involuntary urination and defecation. These signs and symptoms are accompanied by central effects such as dizziness, tremulousness, and confusion; ataxia; headache, fatigability, and paresthesia. Finally, seizures, convulsions, twitching, coma, and respiratory failure may occur. Death usually occurs due to respiratory failure resulting from a combination of central and peripheral effects, paralysis of the respiratory muscles, and depression of the brain respiratory center (Karchmar, 2007; World Health Organization, 1986; Marrs and Vale, 2006; Jokanović, 2009a, 2015a, 2018; Jokanović et al., 2011).

In the case of G-agents the intact agent is present in the organism for only a few hours. The dominant metabolic pathway of G-agents is hydrolysis, a process mainly mediated by so-called A-esterases, and the metabolic products formed are corresponding *O*-alkyl methylphosphonic acids in the case of sarin, cyclosarin, and soman (Fig. 55.1). VX is a less suitable substrate for A-esterases. There are also reports discussing a possible role of prolidase (EC 3.4.13.9), a naturally occurring enzyme, in hydrolysis of G-agents. In addition to hydrolysis, binding reactions of WNA to proteins such as AChE, serum cholinesterase (ChE), carboxylesterase (CarbE), albumin, and other macromolecules also occur. Touvrey and coauthors (2019) recently reported the interaction of human bile salt-activated lipase, also denoted as pancreatic lipase, with sarin, tabun, VX, their surrogates, and paraoxon. The interaction of OP with the lipase could represent an additional detoxification mechanism (Jokanović, 2019).

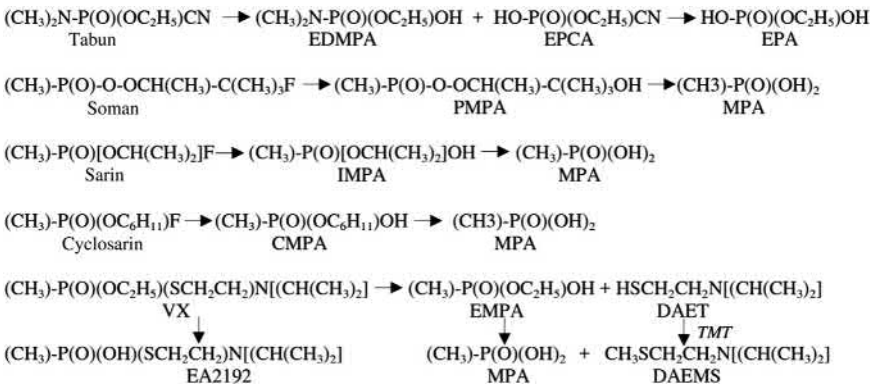

FIGURE 55.1 Metabolic detoxification of tabun, soman, sarin, cyclosarin, and VX. EDMPA, ethyl dimethylaminophosphoric acid; EPA, ethyl phosphoric acid; EPCA, *O*-ethyl-cyanophosphoric acid; IMPA, isopropyl methylphosphonic acid; PMPA, pinacolyl methylphosphonic acid; CHMPA, cyclohexyl methylphosphonic acid; EMPA, ethyl methylphosphonic acid; MPA, methylphosphonic acid; DAET, 2-(diisopropylamino) ethanethiol; DAEMS, 2-(diisopropylaminoethyl) methylsulfide; *TMT*, thiol S-methyltransferase (EC 2.1.1.9) (Nakajima et al., 1998; Katagi et al., 1999; Jokanović, 2001, 2009b, 2015b; Evans et al., 2008; Black, 2010; Tenberken et al., 2010; Reiter et al., 2011; Black and Read, 2013; Kranawetvogl et al., 2013; Son et al., 2019).

The toxicological importance of binding reactions of WNA to these proteins is in the decrease in free unbound concentration of WNA in blood, which causes less AChE inhibition in the nervous system. Both WNA and OP pesticides lose their acyl radicals when they react with AChE, ChE, and CarbE and other proteins. After binding to AChE and ChE the phosphoryl residues of soman, sarin, cyclosarin, tabun, and VX undergo an intramolecular rearrangement with subsequent loss of one phosphoryl group known as the aging reaction.

In addition, due to the reversibility of the binding reaction of sarin and soman to CarbE, it appears that CarbE is involved in the metabolic detoxification of these agents to their corresponding nontoxic metabolites, isopropyl methylphosphonic acid (IMPA) and pinacolyl methylphosphonic acid (PMPA) (Jokanović et al., 1996; Jokanović, 2009b, 2015b).

One of the important proofs which support the significance of detoxification reactions of WNA in the body was presented by Fonnum and Sterri (1981), who reported that only 5% of LD_{50} of soman in rats or about 5 μg/kg reacts with AChE causing acute toxic effects, while the remaining 95% passes through various metabolic reactions.

In this chapter the mechanisms involved in biotransformation of WNA are discussed. Mechanisms of biotransformation of OP pesticides are beyond the scope of this chapter and interested readers are referred to other publications (Jokanović, 2001, 2009a; Chambers et al., 2001; Tang et al., 2006).

55.2 Chemical aspects of biotransformation of nerve agents

The G agents are anticholinesterase substances that at sufficient concentrations can be toxic or fatal by any route of exposure. Differences in volatility and water solubility result in varied degrees of persistence and variations in the likelihood of exposure by certain routes. Of the G agents, tabun gives rise to the greatest number of degradation products. The metabolites of tabun, EDMPA and EPCA (Fig. 55.1), are apparently unstable, while the EPA is an excretion metabolite of tabun as well as of certain pesticides and plasticizers (Tenberken et al., 2010; Black and Read, 2013; Jokanović, 2015b). The final metabolite of tabun is a phosphate (Black, 2010). Toxicity data are available only for a limited subset of the tabun degradation products. One of the tabun hydrolysis products, dimethylamine, is moderately toxic in terms of acute lethality but causes irritation of the human respiratory tract (Munro et al., 1999).

Sarin is metabolized to IMPA, which slowly undergoes further hydrolysis to the very stable MPA. IMPA also forms in the course of spontaneous reactivation of sarin-inhibited CarbE and ChEs. IMPA has shown low toxicity in rats and mice in all toxicity tests conducted except mild skin irritation in rabbits. Limited data suggest that MPA is nontoxic in terms of acute oral toxicity in the rat and mouse, but it showed irritant effects in the human eye and skin (Munro et al., 1999; Jokanović, 2009a, 2015b; Son et al., 2019; Young and Capacio, 2019).

In the study of Little et al. (1986) a single sublethal dose (80 μg/kg) of radiolabeled sarin was administered intravenously to mice and the tissue distribution was followed for 24 h. Within 1 min, sarin was distributed to the kidneys, lungs, brain, lungs, heart, and diaphragm. Thereafter, the concentrations in all tissues rapidly declined and within 15 min only trace quantities of [^{3}H] sarin were found in the brain. Within the first minute, about half of the labeled sarin was in the form of IMPA. The highest concentrations of sarin and its metabolites

were found in the kidneys. Lower concentrations of IMPA and MPA were detected in the liver, suggesting a minor role for the liver in the detoxification of sarin.

Shih et al. (1994) injected rats subcutaneously with a single dose of 75 μg/kg of sarin, cyclosarin, and soman and measured excretion of the hydrolyzed metabolites, the alkylmethylphosphonic acids, including IMPA and corresponding MPAs. MPA was a major and common metabolite of the three compounds. Urinary excretion over the first 24 h accounted for approximately 90% of the administered doses of sarin and cyclosarin. Almost total recoveries of the given doses for sarin and cyclosarin in metabolite form were obtained from the urine. Urinary elimination was found to be rapid and the terminal elimination half-life of sarin metabolites in urine was 3.7 h. Most of the administered dose of sarin was retrieved from the urine in metabolite form after 2 days. The terminal elimination half-life of cyclosarin in urine was 9.9 h. Soman metabolite showed a biphasic elimination curve with terminal half-lives of 18.5 and 3.6 h. Soman was excreted at a slower rate with a recovery of only 62%. The first phase of elimination of soman results from enzymatic hydrolysis of the inactive P(+) isomers, and the slower phase is from the active P(−) isomers (Benschop and De Jong, 1991). The elimination study in rats determined IMPA in blood up to 14 h post-exposure, CHMPA up to 2 days, and PMPA up to at least 3 days.

The distribution, metabolism, and elimination of sarin in humans appear to resemble the findings in animals. Minami et al. (1997, 1998) detected the sarin metabolite IMPA in urine of humans after the terrorist attack in Tokyo in 1995. They found peak levels of IMPA or MPA in urine 10−18 h after exposure. The levels of IMPA in urine correlated with the clinical symptoms. They also found evidence of distribution of sarin to the human brain in four of the 12 people who died after exposure. IMPA and MPA were detected in the urine of a patient poisoned with sarin in Matsumoto (Nakajima et al., 1998).

Biotransformation products of soman include pinacolyl methylphosphonic acid (PMPA) and MPA. No biologic data were found for PMPA (Munro et al., 1999; Jokanović, 2009b). It has been shown that the toxic C(±)P(−)-isomers of soman react rapidly with covalent binding sites. The less toxic C(±)P(+)-isomers are hydrolyzed several orders of magnitude faster than the C(±)P(−)-isomers. The low toxicity of the C(±)P(+)-isomers is primarily due to a low intrinsic reactivity toward AChE and rapid metabolic hydrolysis (van der Schans et al., 2007). The levels of C(±)P(−)-isomers remain toxicologically relevant for periods of 50−100 min in rats, guinea pigs, and marmosets at doses of 2−3 LD_{50} (Benschop and De Jong, 1991).

VX is a potent anticholinesterase agent that can act by dermal, oral, and inhalation routes of exposure. There are certain characteristics of VX which make the agent different from G-agents: (1) VX is present in blood as protonated amine; (2) it is hydolyzed at a much slower rate than G-agents; (3) it reacts more slowly with CarbE (due to its positively charged quaternary ammonium group) and A-esterases, and (4) VX can be metabolized by other routes such as oxidation reactions at nitrogen and/or sulfur (Black, 2010; Jokanović, 2009b, 2015b). A few of the metabolic products may retain some anticholinesterase activity (such as EA2192) (Munro et al., 1999), but hydrolysis of one or more alkyl ester bonds of organophosphonic acids results in generally nontoxic alkyl methylphosphonic acids EMPA and MPA. MPA is resistant to further hydrolysis. Munro et al. (1999) discussed the metabolic degradation products of VX in mammals and found that there are about 25 such products and each had shown different levels of toxicity.

There are three phosphorus-containing metabolites of VX: EA2192 (which has shown some anticholinesterase activity), EMPA, and MPA (not AChE inhibitors) (Fig. 55.1). EMPA appears to be the major metabolite of VX in urine (Black and Read, 2013). The presence of EA2192 metabolite in humans is important since it retains the 2-diisopropylaminoethylthio substituent that confirms exposure to VX (Black and Read, 2013). After intravenous and dermal administration of sublethal doses of VX to swine both VX and EA2192 could be quantified during 540 min after exposure (Reiter et al., 2011). In addition, there are two nonphosphorus metabolites of VX—DAET and its methylation product DAEMS identified in human serum from the victim of the Osaka VX accident (Tsuchihashi et al., 1998). The conversion from DAET to DAEMS is catalyzed by thiol S-methyltransferase (EC 2.1.1.9) (Reiter et al., 2011).

Benschop et al. (2000) and van der Schans et al. (2003) studied the toxicokinetics of VX stereoisomers in hairless guinea pigs and marmosets. Following an intravenous dose of 28 μg/kg (marmosets) or 56 μg/kg (guinea pigs), VX was found in the blood at toxicologically relevant levels even after 6 h. Detoxification proceeded at a slower rate in marmosets than in guinea pigs. The VX metabolite EMPA (Fig. 55.1) was found in the blood of the exposed animals; however, the metabolite contributed only 5% to the recovery of the phosphonyl moieties related to the VX dose. Metabolites of VX were also evaluated in in vitro studies by treating liver homogenates and plasma from hairless guinea pigs, marmosets, and humans with the radio-labeled compounds, ^{35}S-VX. The potential toxic metabolite VX-*N*-oxide was not found. Desethyl-VX was found after incubation of VX in plasma of all three species; however, because of its slow rate of formation, Benschop et al. (2000) concluded that it would be unlikely that VX would be present at toxicologically relevant levels after administration of VX in vivo. In vitro

studies with ^{35}S-VX revealed that a significant part of the thiol-containing leaving group (*S*-2-[*N*,*N*-diisopropylamino]ethane thiol) was bound to albumin.

Tsuchihashi et al. (1998) developed a method for identification of VX metabolites in serum collected from a victim of the Osaka VX incident. In the serum sample, both EMPA and 2-(diisopropylamino-ethyl)methylsulfide (DAEMS) were detected. The techniques using GC-MS and GC-MS-MS were applicable to biological samples such as serum. These results provided the first documented identification of the specific metabolites of VX in victim's serum and clarified a part of the metabolic pathway of VX in the human body. In addition, methods have been developed for measuring the VX-inhibited AChE hydrolytic product EMPA (Noort et al., 1998, 2002).

55.3 Esterases involved in the metabolism of warfare nerve agents

Numerous esterases can react with OPs but in a different way. The first classification was given by the late Professor Aldridge (1953). In the first group there were esterases that hydrolyze OPs as substrates, and among them particularly their uncharged esters, that are not inhibited by these compounds. This group of enzymes was called *A-esterases*, although in the literature there are many other names for the same group of enzymes given according to the substrate hydrolyzed (paraoxonase, somanase, sarinase, etc.) or their chemical structure (phosphotriesterases, phosphorylphosphatases, anhydrases of OP compounds). In the second group of enzymes interacting with OPs were *B-esterases*, which are inhibited with OPs in the progressive reaction that is time- and temperature-dependent. This group of enzymes comprises AChE, ChE, CarbE, trypsin, chymotrypsin, and other enzymes. In the third group were *C-esterases* that do not interact with OP. It is paradoxical, but basically true, that OPs can be substrates for both A- and B-esterases because their concentration in blood and tissues is decreased in the presence of these enzymes (Jokanović, 2009b).

The mechanisms of interaction of A- and B-esterases with WNA and other OPs are similar. B-esterases initially form Michaelis complex with an OP inhibitor producing phosphorylated or inhibited enzyme that either reactivates very slowly or does not reactivate at all. However, after formation of Michaelis complex with OP A-esterases catalyze hydrolysis of OP and their catalytic activity and turnover rate are very high.

55.3.1 A-esterases

In a classification from 1992 (International Union of Biochemistry, 1992) hydrolases of OP were described as a special entity of "phosphoric triester hydrolases," which comprises three groups of enzymes: (1) phosphoric monoester hydrolases (EC 3.1.3), (2) phosphoric diester hydrolases (EC 3.1.4), and (3) phosphoric triester hydrolases (phosphotriesterases) (EC 3.1.8). Phosphoric triester hydrolases are further divided into two similar subgroups: aryldialkylphosphatases (EC 3.1.8.1) and diisopropylfluorophosphatases (EC 3.1.8.2).

Aryldialkylphosphatases take part in hydrolysis of aryldialkylphosphates producing dialkylphosphate and aryl alcohol. These enzymes react with substrates such as paraoxon (Fig. 55.2), but also with phosphonates and phosphinates. Other names for this group of enzymes are hydrolases of OPC, A-esterases, paraoxonases, PON1, aryltriphosphatase, and aryltriphosphate dialkylphosphohydrolase. They are inhibited with compounds that form chelates like EDTA since they require the presence of divalent ions, mainly Ca^{2+} (Walker, 1993). Some fractions of the enzyme purified from human serum were able to hydrolyze both paraoxon and phenylacetate and it was thought for a long time that the same enzyme was responsible for both. However, enzymes hydrolyzing aryl esters are classified as arylesterases (EC 3.1.1.2).

Diisopropylfluorophosphatases take part in hydrolysis of diisopropylfluorophosphate (DFP) and similar compounds producing diisopropylfluorophosphoric acid and fluoride ion (Fig. 55.2). These enzymes react with phosphorus anhydride bonds such as those between phosphorus and acyl radical (F^-, Cl^-, CN^-) in highly toxic OPC such as soman, sarin, tabun, and DFP, and they were accordingly named somanase, sarinase, tabunase, DFPase, diisopropylfluorophosphate fluorohydrolase, OPA anhydrase, OPAA, and OP acid anhydrolase. They are also inhibited by chelating agents, and their activity requires the presence of divalent ions such as Mg^{2+}, Mn^{2+}, Co^{2+}, and Cd^{2+}, but not Ca^{2+} (Walker, 1993; Kondo et al., 2004). They exist in several forms, even in different tissues of the same species, which react differently with substrates.

In the literature there are papers reporting an important role of senescence marker protein-30 (SM-30) in the

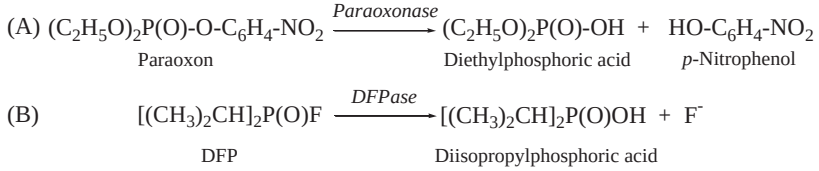

FIGURE 55.2 (A) Hydrolysis of paraoxon with aryldialkylphosphatase (paraoxonase, EC 3.1.8.1) and (B) hydrolysis of diisopropylfluorophosphate (DFP) with diisopropylfluorophosphatase (DFPase) (EC 3.1.8.2).

hydrolysis of diisopropylfluorophosphate (DFP) and similar substrates (Kondo et al., 2004; diTargiani et al., 2010). SM-30 protein was given the code EC 3.1.8.2, which was previously assigned to DFPase. After checking all available data it appears that both SM-30 and DFPase are the same enzymes and that their names are synonyms! DFPase is, therefore, a 34-kDa metalloprotein expressed predominantly in the liver and kidney of mammals. Although the identity of the metal ion is not clearly established, it was shown that the activity of purified DFPase from rat liver was stimulated by $MgCl_2$, $MnCl_2$, $CoCl_2$, and $CdCl_2$ (Kondo et al., 2004). It has been linked with the regulation of calcium homeostasis and the protection of cells from apoptosis. Consistent with these observations, it was found that the sequence of DFPase was identical to that of a Ca^{2+}-binding protein, regucalcin. Rat liver DFPase was shown to hydrolyze DFP, phenyl acetate, and gluconolactones. In vivo studies with SMP-30 knockout mice confirmed its role in the hydrolysis of DFP in the liver of these animals (diTargiani et al., 2010). A reduction in DFPase expression might account for the age-associated deterioration of cellular functions and enhanced susceptibility to harmful stimuli in aged tissue (Kondo et al., 2004).

In the literature published during the last 40 years the term PON1 apparently covers both phosphoric triester hydrolases. In further text, in order to avoid possible confusion, the term A-esterase will be generally used for enzymes hydrolyzing OPs along with other terms (such as PON1, paraoxonase, etc.) as they appear in original references.

The molecular weight of human A-esterases is between 43 and 45 kDa. Human A-esterase is a protein of 355 amino acids having two polymorph sites in which arginine or glutamine are located at position 192 and methionine or leucine at position 55 (La Du et al., 1993; Li et al., 1995). The former accounts for three genotypes (QQ, RR, and QR) relating to the catalytic properties of two forms of an enzyme (types R and Q allozymes), which hydrolyze certain organophosphates at different rates. Its three-dimensional structure is also known (Benning et al., 1994; Vilanova and Sogorb, 1999). At the active site of A-esterases there are two metal cations connected via a common ligand, and most of the other protein groups are bound to this binuclear site through imidazolium side chains from histidine groups (Benning et al., 1994). The activity of these enzymes largely depends on Ca^{2+} that represents a necessary factor for maintaining the function of the active site and it is also possible that Ca^{2+} directly participates in catalytic reactions or maintain the conformation of amino acids at the active site. In addition, in the case of paraoxon, Ca^{2+} facilitates the release of diethylphosphate from the active site, probably by polarizing bond P═O, which makes the phosphorus atom much more sensitive to the nucleophilic attack of hydroxyl ions (Vitarius and Sultatos, 1995; diTargiani et al., 2010). Human A-esterases can hydrolyze many OPs, among them paraoxon, soman, sarin, tabun, chlorpyriphos and chlorpyriphos oxon, DFP, dichlorvos, diazoxon, and pyrimiphos methyl oxon.

The R allozyme (Arg192) hydrolyzes the organophosphate paraoxon at a high rate; however, it has a low activity toward sarin, soman, and diazoxon. Lower activity means that more sarin would be bioavailable to exert its anticholinesterase effects. The Q allozyme, on the other hand, has high activity toward sarin, soman, and diazoxon (and low activity toward paraoxon). Thus, individuals with the Q allozyme (QQ or QR) are expected to have greater hydrolysis of sarin than individuals homozygous for the R allele (RR) (Costa et al., 1999, 2005). In Caucasian populations, the frequency of the R allele is about 0.3, but the frequency is 0.66 in the Japanese population (Yamasaki et al., 1997; Costa et al., 2006). This would make individuals in the Japanese population more sensitive to the toxicity of sarin, a fact that may have contributed to their morbidity and mortality after the terrorist attacks in 1995. The concentration of PON1 in human plasma (about 60 mg/L) varies between individuals by as much as 13-fold. The PON1 activity level is determined by a combination of complex genetic interactions and environmental/dietary factors, giving rise to a 40-fold variation in PON1 for a single individual (Rochu et al., 2007). The relationship between paraoxonase polymorphisms and toxicity of OP compounds was further discussed in an excellent article by Costa et al. (2006) and other papers from his team.

Paraoxonase (PON1) is a member of a family of proteins that also includes PON2 and PON3, the genes of which are placed on the long arm of human chromosome 7 (q21.22). PON2 and PON3 have about 65% homology to PON1, but they cannot hydrolyze WNA and other organophosphates (Draganov et al., 2005; Aviram and Rosenblat, 2008). PON1 is synthesized primarily in the liver and a portion is secreted into the plasma, where it is associated with high-density lipoprotein (HDL) particles (Costa et al., 2005). The crystal structure for a recombinant PON1 indicates that it is a six-bladed β-propeller, with two calcium ions in the central tunnel, one of which is essential for enzyme activity and the other for enzyme stability (diTargiani et al., 2010). The primary physiological role of PON1 appears to be protection of low-density lipoproteins (LDL) from oxidative modifications (Mackness et al., 1993; Aviram et al., 1998; Vilanova and Sogorb, 1999; Rochu et al., 2007). Human PON1 is apparently involved in drug metabolism and in preventing atherosclerosis (diTargiani et al., 2010). Endogenous PON1 is associated with HDL that represents its main carrier in blood and this association has been considered

as a crucial element in the increased stability and half-life of PON1 in the circulation (Gaidukov et al., 2009; Veliyaveettil et al., 2012). In addition to its role in lipid metabolism and cardiovascular disease and atherosclerosis, PON1 has been shown to play a role in the metabolism of drugs and xenobiotics containing aromatic carboxyl esters (Costa et al., 2003). It is also suggested that PON1 hydrolyzes various lactones, including naturally occurring lactone metabolites.

The differences in the activity of A-esterases due to polymorphisms may have an important effect on the toxicity of OP in humans who are occupationally or accidentally exposed. In this respect, it was proposed that humans expressing lower activity of A-esterases could be more susceptible to the toxic effects of OP and there were suggestions that such individuals should not be exposed (Mackness, 1989). Hernandez et al. (2004) have confirmed this hypothesis, suggesting the association of paraoxonase phenotypes with susceptibility of humans to OP pesticide toxicity. However, additional studies are needed to fully understand the effects of A-esterase polymorphism on the capacity of detoxification and toxicity of OP.

55.3.1.1 Toxicological relevance of A-esterases

A-esterases purified from *Pseudomonas diminuta* given to mice decreased inhibition of AChE in brain and ChE in serum in poisoning with paraoxon and DFP, and this effect was less significant in poisoning with soman and sarin (Tuovinen et al., 1994). Purified A-esterases have shown a protective effect when given to mice before poisoning with tabun (Ashani et al., 1991a).

It was reported that PON1 preferentially hydrolyzes the less toxic soman enantiomers (Yeung et al., 2008). Injection of human PON-1 was found to protect guinea pigs against 1.2 LD_{50} of racemic sarin and soman (Veliyaveettil et al., 2012).

Haley et al. (1999) investigated PON1 genotype and serum enzyme activity in a group of 25 ill Gulf War veterans and 20 controls. Ill veterans were more likely than controls to possess the R allele (QR heterozygotes or R homozygotes) and to exhibit lower enzyme activity. This study raised the possibility that the R genotype (low sarin-hydrolyzing activity) may represent a risk factor for illness in Gulf War veterans. However, because of the very small number of participants included in the study, such findings require confirmation in a larger population (Furlong, 2000a). La Du et al. (2001) have also found reduced sarinase and somanase levels in plasma obtained from Gulf War veterans. In a similar study, in a group of 152 UK Gulf War veterans, the PON1 activity was lower in veterans than in a control group, but the differences were independent of PON1 genotype (Mackness et al., 2000). However, in both studies there were no indications about the extent of exposure to nerve agents and the possible effects of such exposures.

55.3.2 B-esterases

B-esterases are the group of enzymes that can be inhibited by OP compounds in the progressive reaction that is time- and temperature-dependent. This group of enzymes comprises AChE (EC 3.1.1.7), ChE (EC 3.1.1.8), CarbE (EC 3.1.1.1), chymotrypsin, trypsin, and some other enzymes. A common feature of these enzymes is that they have a serine hydroxyl group at the active site that enables them to react with OP in a similar fashion. AChE, ChE, and CarbE are members of the α/β hydrolase family and have a high degree of overall homology in their amino acid sequences, but they differ in several critical regions that produce differences in their biochemical properties. The most significant biochemical differences in these esterases are related to the extent of aging of the OP-inhibited esterase, the size of the active site, and the ability of the OP-inhibited enzyme to undergo spontaneous or oxime-induced reactivation (Doctor et al., 2001).

55.3.2.1 Serum cholinesterase

While the biological role of ChE is still unclear, it is known that soman, sarin, tabun, and VX bind to ChE, without any apparent toxic effects, decreasing the amount of free WNA available for inhibition of AChE in the central nervous system and erythrocytes (Jokanović, 2009a). Pretreatment with human plasma ChE (hBChE) has protected laboratory mice (Ashani et al., 1991b) and monkeys (Raveh et al., 1997) from lethal and other acute toxic effects of VX exposure. Human BChE is now in an advanced stage of development as a bioscavanger and is close to obtaining marketing approval as a pretreatment for OP poisoning (Saxena et al., 2011a; Trovaslet-Leroy et al., 2011). It is estimated that a dose of 200 mg is required to protect a human against 2 LD_{50} of soman (Saxena et al., 2011a). hBChE reacts with OP to form the 1:1 complex and an i.m. or i.v. injection protects animals against 3−5 LD_{50} soman, tabun, and VX (Lenz et al., 2007). A dose up to 250 mg/70 kg of hBChE is able to protect humans from 1 LD_{50} of OP (Ashani and Pistinner, 2004). Such a dose of hBChE is required because of the stoichiometric and irreversible reaction between hBChE and OP (Trovaslet-Leroy et al., 2011). Animal studies have shown that administration of large doses of hBChE provide protection against up to 5.5 LD_{50} of soman or 8 LD_{50} of VX (Saxena et al., 2011a). Pretreatment with 7.5 mg/kg completely prevents toxicity in minipigs exposed to sarin by inhalation (Saxena et al., 2011b). hBChE derived from plasma is present in the blood of guinea pigs up to 4 days without any signs of toxicity

(Saxena et al., 2011a) and without any adverse effect in rats (Nachon et al., 2013). The behavioral and physiological safety of plasma hBChE was established at 21 mg/kg in mice (Ilyushin et al., 2013) and 30 mg/kg in rhesus monkeys (Myers et al., 2012).

The structure, function, genetic variants, potential uses of human butyrylcholinesterase, and its role in toxicology of OPs have been reviewed by Lockridge (2015) and Masson and Nachon (2017).

ChE is a serine esterase glycoprotein, composed of four 85-kDa subunits, synthesized mainly in the liver, which does not have any known physiological function. From the liver, ChE is secreted to plasma and its activity correlates with the physiological and/or pathological condition of the liver. ChE can be found in more than 40 genetic variants differing in their susceptibility to chemicals (Jokanović and Prostran, 2009). ChE may have roles in cholinergic neurotransmission (Mesulam et al., 2002), other nervous system functions (cellular proliferation and neurite growth during the development of the nervous system), and in neurodegenerative disorders (Darvesh et al., 2003).

Variability in plasma ChE activity is a parameter of concern for characterization of population susceptibility to nerve agent exposure. Selective inhibition of AChE i ChE had no effect on acute soman toxicity to mice (Clement, 1984). Since VX reacts with ChE, and very slowly with CarbE (due to its positively charged quaternary ammonium group), it appears that ChE may have a significant role in detoxification of VX. Wide variations in ChE activity seen in individuals not exposed to OPs, caused by genetic, physiological, and pathological conditions, as well as interactions with many drugs, may strongly influence the susceptibility of those individuals to OP compounds (Jokanović and Maksimović, 1997). It is possible that individuals with lower ChE activity may be more susceptible to the effects of OPs, including nerve agents.

55.3.2.2 Carboxylesterases (EC 3.1.1.1)

The mammalian CarbEs comprise a multigene family whose gene products are located in the endoplasmic reticulum (Hosokawa and Satoh, 2006). CarbEs are the enzymes that hydrolyze esters and thioesters or amide groups of carboxylic acids. They are also mentioned in the literature as aliesterases and esterase D. CarbE have a very important role in metabolism of lipids, endogenous fatty acids, esters, steroids, and a large number of ester-containing drugs and prodrugs such as salicylates, clofibrate, procaine, lorazepam, cilazapril, and other angiotensin-converting enzyme inhibitors, narcotics (cocaine, heroin), and capsaicin. CarbEs also participate in detoxification of pesticides (carbofuran, pyrethroids, OPs), acrylates, mycotoxins (T2 toxin), and esters of nicotinic acid (Cashman et al., 1996). Certain isoenzymes of hepatic microsomal CarbE are involved in the metabolic activation of some carcinogens and are associated with hepatocarcinogenesis (Hosokawa and Satoh, 2006). Similar enzymes to CarbE are arylesterases (EC 3.1.1.2) that hydrolyze aromatic esters of carboxylic acids. However, this classification is not perfect since CarbEs hydrolyze some aromatic esters (i.e., phenyl valerate, phenyl butyrate) and arylesterases hydrolyze certain aliphatic esters. These two enzymes can be clearly differentiated according to their interaction with OP since CarbEs are inhibited with OPs while arylesterases can hydrolyze some OPs that contain an aromatic group, such as paraoxon and chlorpyriphos oxon, and because of this they were sometimes confused with A-esterases.

The CarbE profile in humans is not well known. While CarbEs were considered to be absent from the blood plasma of humans (Li et al., 2005), they are, indeed, present in human erythrocytes and monocytes as well as in human liver, kidney, lung, skin, and nasal tissue (Cashman et al., 1996). Additional literature documents the presence of CarbEs in many human tissues and fluids, including brain, milk, mammary gland, pancreas, small intestine, colon, stomach, placenta, and plasma and serum (Chanda et al., 2002; Kaliste-Korhonen et al., 1996). The lung CarbEs are associated with alveolar macrophages (Munger et al., 1991). Further, CarbEs are present in human tissues and organs where exposure to nerve agent vapors would likely first occur (nasal tissues and the lung), would be distributed (erythrocytes, monocytes, plasma), and would generate effects (brain, stomach, colon, etc.). Chanda et al. (2002) indicate that full characterization of the OP-protective capabilities of CarbEs requires assessment not only of the amount but also of the affinity exhibited by CarbEs for the inhibitor as well as the total CarbE activity unlikely to be inhibited. The detoxification potential of CarbEs is apparently complex and is an area requiring further studies.

CarbEs are proteins of molecular weight between 47 and 65 kDa that can be found in the microsomal fraction of many mammalian tissues (Satoh and Hosokawa, 1998). CarbEs are synthesized in the liver and secreted into plasma (via the Golgi apparatus) where they are present in soluble form. Their physicochemical and immunological properties and the sequence of amino acids are very similar, while their specificity toward various substrates is different (Hosokawa et al., 1995; Satoh and Hosokawa, 1998). CarbEs belong to the group of esterases having serine at their active site that hydrolyze esters of carboxylic acids in a biphasic reaction. In the first phase, carboxylic ester acylates the hydroxyl group of serine at the active site, and in the second phase serine is being deacylated in the presence of water (Augustinsson, 1958).

The active site of CarbE comprises a peptide isoleucine-phenylalanine-glycine-histidine-serine-methionine-glycine-glycine, with serine and histidine directly participating in biochemical reactions. The physiological substrate for CarbE is probably *O*-acetyl sialic acid (Satoh and Hosokawa, 1998). CarbE can be differentiated from other serine esterases AChE (EC 3.1.1.7) and ChE (EC 3.1.1.8) in that AChE and ChE react with positively charged esters such as acetylcholine and butyrylcholine and can be inhibited with carbamates, while CarbE does not react with positively charged esters and inhibition with carbamates occurs only at high concentrations. Inhibition of CarbE does not cause any known toxic effects. The classification and nomenclature of CarbEs were proposed by Satoh and Hosokawa (1998) and readers are also referred to an excellent book chapter (Hosokawa and Satoh, 2006) for more details.

55.3.2.3 The relationship between CarbE activity and toxicity of warfare nerve agents

Several studies have shown that triorthocresyl phosphate (TOCP) and its active metabolite CBDP (2-/*o*-cresyl/-4H-1:3:2-benzodioxaphosphorin oxide) (specific irreversible inhibitor of CarbE and weak anticholinesterase agent) potentiate toxicity of soman, sarin, and tabun (Bošković, 1978; Clement, 1984; Jokanović, 1989) but not of VX agent (Bošković, 1978), probably because VX in physiological conditions is positively charged and a weak inhibitor of CarbE (Maxwell, 1992). Bošković (1978) found that pretreatment of mice with CBDP increased the s.c. toxicity of soman 19.1-fold, and its i.p. toxicity 17.8-fold. For other nerve agents he observed an increase of s.c. toxicity of sarin, tabun, and VX of 11-, 5-, and 0.24-fold, respectively. Clement (1984) observed that the potentiation of soman toxicity in mice after previous administration of TOCP or CBDP was directly related to plasma CarbE and not to activity of CarbE in liver and other tissues. This effect of TOCP and CBDP was explained by phosphorylation of active sites at CarbE that occupies the binding sites for other OPs, increasing their concentration in the circulation and therefore their acute toxicity (Jokanović, 2001, 2009b, 2015b). Binding of soman to CarbE in rodents occurs specifically with the most toxic stereoisomer of the agent (Cashman et al., 1996).

The detoxification potential of endogenous CarbE to protect against the lethal effects of WNA exposure was tested by Maxwell (1992), who observed that a wide range in potentiation of toxicity of different OPs in vivo cannot be correlated with reactivity of these compounds toward CarbE, showing that soman toxicity in rats with inhibited CarbE was potentiated sixfold, respectively, in spite of their similar inhibitory power for CarbE. It was concluded that detoxification of OP via CarbE is very important for highly toxic OPs such as soman, sarin, tabun, and paraoxon with LD_{50} of < 2 μmol/kg, while it is less important for less toxic OPs such as DFP ($LD_{50} = 9.75$ μmol/kg) and dichlorvos ($LD_{50} = 98.4$ μmol/kg). Having in mind that relatively higher concentrations of OP insecticides have to be achieved in the circulation and tissues in order to exert toxicity, a dominant factor in detoxification of less toxic OPs is A-esterases as their catalytic activity is proportional to substrate concentration and their K_m value is in the millimolar range (Jokanović, 2009b, 2015b).

Contrary to these findings of decreased CarbE activity increasing toxicity of many OPs, there are also data showing that increased CarbE activity can decrease the toxicity of OPs. CarbE activity can be increased by about 80% after repeated administration of phenobarbital to rats and mice by a mechanism of enzyme induction which caused a decrease in soman and tabun toxicity by twofold, while toxicity of sarin was not affected, probably because plasma CarbE inhibited with sarin spontaneously reactivated very rapidly in vitro and in vivo with half-times of 18 and 120 min, respectively (Bošković et al., 1984; Clement, 1984; Jokanović, 1989, 2009b; Jokanović et al., 1996).

Various OPs inhibit both CarbE and AChE at similar concentrations ranging from 1 to 1000 nmol/L. CBDP, dichlorvos, DFP, and paraoxon show higher affinity toward CarbE in vitro and as a result their acute toxicity is lower in contrast to highly toxic OPs, soman and sarin, that have four to six times higher affinity for AChE. This relationship was confirmed in vivo after administration of 0.9 LD_{50} of these compounds (Maxwell, 1992). Rat plasma CarbE appears to be more sensitive for soman and sarin than CarbE in rat liver and brain, and can be completely inhibited at sublethal doses. Significant inhibition of CarbE in liver can be obtained only at multiple lethal doses (Bošković et al., 1984). Even when two-thirds of rat liver was removed by partial hepatectomy, 5 LD_{50} of soman was not sufficient to achieve significant inhibition of rat liver CarbE (Jokanović, 1990). Somani et al. (1992) found that interspecies variation in response to some nerve agents may be accounted for largely by CarbE binding.

In a study of the mechanism of interaction of CarbE with some OPs in vitro it was found that this reaction is not irreversible, but reversible due to rapid spontaneous reactivation of inhibited CarbE (Jokanović et al., 1996; Jokanović, 2001, 2009b). The highest rate of spontaneous reactivation was obtained for plasma CarbE inhibited with sarin and the half time of reactivation was 18 min. These results were also confirmed in experiments in vivo in which rats were treated with 0.5 LD_{50} of soman, sarin, and dichlorvos (Jokanović et al., 1996). Calculated half-times of reactivation for plasma CarbE of the rats treated with 0.5 LD_{50} dichlorvos, sarin, and soman were 1.2, 2.0,

and 2.7 h, respectively. Similar results were reported by Gupta et al. (1987a) who found 50% of spontaneous reactivation of plasma CarbE 24 h after poisoning of rats with 100 μg/kg soman. Gupta et al. (1987b) also reported 94% of reactivation of plasma CarbE in rats treated with 200 μg/kg tabun, but 7 days after poisoning. Human CarbE1 reactivated spontaneously after phosphorylation by the most toxic P_s stereoisomer of sarin but not soman or cyclosarin (Hemmert et al., 2010). Spontaneous reactivation of CarbE hydrolyzing phenyl valerate inhibited with paraoxon in vitro was observed by Barril et al. (1999).

55.3.2.4 The role of CarbE in detoxification of OP

CarbEs participate in detoxification in three different ways. The first is hydrolysis of ester bonds in OPs that contain them, such as malathion (World Health Organization, 1986; Fukuto, 1990). The second is binding of OPs to CarbE and other proteins, which decreases the concentration of free OP in the circulation that can react with AChE in vital tissues (Clement, 1984; Jokanović, 1989, 2009b). The third role is related to all OPs that can phosphorylate CarbE by binding to serine hydroxyl group at its active site (Jokanović et al., 1996; Jokanović, 2001, 2009b, 2015b). During spontaneous reactivation this phosphoryl residue is separated from the enzyme-accepting hydroxyl group from water as its new acyl radical. This newly formed OP (i.e., organophosphoric acid) is a much less potent, if at all, esterase inhibitor that represents nontoxic metabolite of the parent OP. In the case of nerve agents the corresponding metabolites formed EDMPA (for tabun), IMPA (for sarin), and PMPA (for soman) are shown in Fig. 55.1. CarbE activity recovered in this reaction can be inhibited again by other OP molecules. The active role of CarbE in this process is in its involvement in metabolic transformation of OP to its nontoxic and biologically inactive metabolites. Because of the rapid spontaneous reactivation of CarbE, one active site at the enzyme can metabolize numerous OP molecules and this reaction does not occur according to the stoichiometric ratio 1:1, depending only on the stability of the bond between phosphorus from OP and oxygen from the serine hydroxyl group. Tissues in which this "turnover" is rapid, such as plasma, have a higher capacity for detoxification of OPs than expected only on the basis of the catalytic activity of CarbE. This reaction can be very important under conditions of repeated (subchronic or chronic) exposure to low doses of nerve agents and other OP that could be inactivated through the reaction with CarbE without any apparent toxic effect (Jokanović, 2015b).

The role of CarbE as a bioscavanger involved in detoxification of nerve agents and other OPs was investigated. The ideal OP bioscavanger would have a fast rate of reactivity for a broad range of OP compounds, a slow rate of aging, and the ability to reactivate to increase its stoichiometry as a bioscavanger. Evaluation of CarbE on these criteria suggests that it is an important candidate as an OP bioscavanger (Doctor et al., 2001). One of the most important advantages of CarbE is that OP-inhibited CarbE does not undergo the rapid aging that prevents oxime-induced reactivation of OP-inhibited cholinesterases. This means that OP-inhibited CarbE can be reactivated yielding an active enzyme, involved in further metabolism of OP molecules, and an inactive OP metabolite (Jokanović, 2015b).

Another advantage of CarbE is the much greater size of its active site compared to AChE (10-fold difference) and ChE (sixfold difference) (Saxena et al., 1999). The large active site volume of CarbE minimizes steric hindrance effects at the active site and maximizes the potential for reactivation. In a study investigating the structural specificity of AChE, ChE, and CarbE, Maxwell et al. (1998) reported that AChE could accommodate OP inhibitors containing only one bulky group (e.g., isopropyl, pinacolyl, phenyl), ChE could accommodate OP inhibitors containing two of the smaller bulky groups (like isopropyl), while the active site of CarbE was sufficiently large to accommodate up to two of the largest bulky groups (e.g., phenyl groups). Therefore, CarbE had the ability to metabolize the broad spectrum of OP inhibitors. The only exception to this observation is, due to fewer aromatic residues in the active site of CarbE in comparison to ChE, reduced affinity of CarbE for positively charged OP inhibitors (such as VX) and this effect apparently has little importance for nerve agents (except VX) and OP pesticides since a few of them are positively charged (Doctor et al., 2001).

55.3.2.5 Prolidase (EC 3.4.13.9)

There are data in the literature showing that prolidase (EC 3.4.13.9), a naturally occurring enzyme of mammalian and bacterial origin, is involved in hydrolysis of G-type nerve agents. Recombinant HuPON1 and DFPase showed 10-fold lower activity toward sarin compared to recombinant human prolidase (Cheng et al., 1999; diTargiani et al., 2010; Nachon et al., 2013). Constante et al. (2012) reported that partially purified human liver prolidase hydrolyzed DFP and various nerve agents, while skin and kidney prolidase presented significantly lower activity against soman, tabun, and VX. The biochemical characteristics of prolidase purified from human erythrocytes, liver, kidney, and fibroblast cells are well known. However, OP hydrolyzing activity of prolidase is still not well understood (Wang et al., 2006; diTargiani et al., 2010; Chandrasekaran et al., 2013).

Human prolidase is a 54-kDa binuclear Mn^{2+}-dependent enzyme which breaks the amide bond in dipeptides containing proline or hydroxyproline as the C-terminal amino acid. It plays a crucial role in the recycling of proline. Prolidase is found in most tissues and in several animal species. Deficiency of this enzyme in humans results in a syndrome with a highly variable clinical phenotype, such as chronic recurrent infections, mental retardation, splenomegaly, skin lesions, and the excretion of massive amounts of iminopeptides in urine (Wang et al., 2006; Chandrasekaran et al., 2013).

55.4 Lipase

Touvrey et al. (2019) identified human bile salt-activated lipase, also denoted as pancreatic lipase, as a potential target for OP. They determined bimolecular inhibition rate constants for the reaction of the enzyme with sarin, tabun, VX, their surrogates, and paraoxon. Finally, they determined different OP-inhibited X-ray structures that would help the design of variants with potential OP-hydrolyzing properties. This finding appears to be the first time that the interaction of several OPs with a lipase has been discussed. Interaction of OP with the lipase could serve as another detoxification mechanism, in addition to OP reaction with serum ChE, CarbE, and PON, that can decrease the amount of free OP in the circulation available for AChE inhibition (Jokanović, 2019).

55.5 Protein binding

Proteins are amphotheric structures containing anionic and cationic reactive sites. Proteins can also participate in other interactions with xenobiotics through the formation of hydrogen bonds, polarity, electrostatic, and Van der Waals forces. Many xenobiotics can bind to proteins from blood such as albumin and B-esterases. Easy binding to proteins occurs with substances that are ionized at physiological pH and those soluble in lipids such as OP. After binding of OP to proteins such as CarbE, ChE, AChE, and other macromolecules, these agents are metabolized since their acyl radical is released and phosphoryl residue remains bound to proteins. This unspecific binding of OP to blood proteins decreases the OP concentration in the circulation and tissues, preserving AChE activity at target sites (Jokanović, 2009b). Binding of OP to proteins can be limited by steric hindrance, protein conformation factors that do not allow OP molecules to access all binding sites at the protein. The involvement of secondary noncholinergic targets (neuropathy target esterase, fatty acid amide hydrolase, arylformamidase, acylpeptide hydrolase, and other macromolecules) in OP toxicity was reviewed by Casida and Quistad (2004).

Albumin is the most abundant protein found in plasma, having a half-life of about 20 days. It is a 67-kDa multifunctional monomer synthesized and secreted by the liver. Albumin has esterase-like and aryl acylamidase activities but it does not have a catalytic active-site serine (Marsillach et al., 2013). The high concentration of albumin in plasma (30−60 g/L) may balance the poor reactivity of this protein with OPs (Jokanović, 2009b, 2015b).

Williams et al. (2007) found that sarin, soman, cyclosarin, and tabun phosphorylate a tyrosine residue on albumin in human blood. The tyrosine adducts with soman and tabun were detected in guinea pigs receiving therapy 7 days following subcutaneous administration of 5 LD_{50} of the respective nerve agent. Bao et al. (2012) reported formation of soman, sarin, and VX adducts with the tyrosine residue of albumin when rats were exposed to sublethal doses of the nerve agents. In blood samples taken from sarin-, soman-, cyclosarin-, or tabun-treated marmosets, tyrosine adducts were detected after 23 or 24 days (Read et al., 2010). Li et al. (2008) have shown that soman covalently binds to albumin at tyrosine 411 and that the adduct was stable ($t_{½} = 20$ days). However, although the concentration of albumin in plasma is very high, its reactivity with soman was apparently too slow to play a major role in detoxification of the agent. The authors concluded that soman−albumin adducts could be useful for the diagnosis of soman exposure. In addition, OP pesticides covalently bind to albumin and the adduct was stable for more than 7 days (Tarhoni et al., 2008).

Tyrosine adducts were found in guinea pigs and marmosets poisoned with sarin, soman, cyclosarin, and tabun. VX, being less reactive than other WNA, formed an adduct in human plasma in vitro only at high concentrations (Williams et al., 2007; Black, 2010; Black and Read, 2013). Tyrosine adducts were less sensitive than ChE as biomarkers with respect to exposure levels, but were more stable and did not undergo an aging reaction like OP bound to serine esterases (Read et al., 2010). However, albumin might have a larger capacity for OP binding compared to ChE and other esterases.

55.6 Concluding remarks and future directions

After more than five decades of research into the biotransformation of nerve agents soman, sarin, tabun, and VX it can be concluded that several enzymes have a significant role in this process. Enzymes capable of hydrolyzing these agents (A-esterase, PON1) were very efficient in breaking down the bond between phosphorus and acyl radical and their activity was proportional to substrate concentration. Esterases such as cholinesterases and CarbEs act by binding of OP molecules to the hydroxyl

group placed in their active site, decreasing free concentration of the agents in blood, thus preventing inhibition of acetylcholinesterase at target sites and subsequently their toxic effects. In addition, binding of OP to CarbEs is reversible, indicating an active role of the enzyme in metabolic detoxification of nerve agents and other OPs. The importance of prolidase and lipase is still unclear and requires further studies. It is necessary to further investigate the role of these enzymes and other macromolecules in detoxification of OP compounds and their possible application in prophylaxis and treatment of OP poisoning in humans.

Chapter 56

Laboratory analysis of chemical warfare agents, adducts, and metabolites in biomedical samples

M.J. van der Schans
TNO, Rijswijk, The Netherlands

56.1 Introduction

Chemical warfare agents (CWAs) are the most toxic compounds ever produced. The need for the analysis of biomedical samples can have several purposes. First, the agents themselves may be detected in their intact form in the case of toxicokinetic studies, which is essential for a better understanding of the toxicological processes. Toxicokinetic studies provide a quantitative basis for the development of new strategies for prophylaxis and therapy against intoxication with CWAs. Second, verification of exposure to CWAs is another goal that requires analytical methodology for biomedical samples. Verification of exposure is needed for several reasons:

1. In the case of a CWA exposure, military personnel need a rapid diagnosis to ascertain the level of exposure and the identity of the agent, in order to give victims adequate medical treatment.
2. Low-level exposures to nerve agents might be associated with unexplainable phenomena such as the Gulf War syndrome (Central Intelligence Agency, 1997).
3. In the case of a terrorist event, or other cases of alleged use, unambiguous verification is needed to verify the exposure. Analyses of biomedical samples can also be used as evidence in a court of justice or international community (United Nations, 1986). In the summer of 2013, the OPCW, commissioned by the United Nations, collected environmental and biomedical samples in Syria (UN Report, 2013). The analysis of the biomedical samples provided evidence that sarin was used in the city of Saraqueb, Syria, in April 2013 (John et al., 2018). The events in Syria revealed that biomedical samples are very important. In a case that victims show clear symptoms of poisoning, it provides a clear direction for sampling. In the case of environmental sampling, these indications are often less clear and, moreover, often it is not possible to enter the affected (or occupied) area. On the other hand, victims can often reach the forensic team on their own or they are brought to the team. Ultimately, in the case of a small-scale attack, the biomedical samples of a single intoxicated person might be the only indication. Methodologies for the verification of exposure to chemical warfare agents have been published in special issues of the *Journal of Analytical Toxicology* (Barr, 2004, 2008; Black, 2008). The methodology of the clinical methods has also been reviewed by Noort et al. (2002), Noort and Black (2005), Black and Noort (2005, 2007), and Capacio et al. (2008a,b, 2019). This chapter is not meant as a duplicate for these references. It will discuss the updated analytical methods that are needed for the analysis of biomedical samples. Most of the analytical methods rely on chromatographic techniques like gas and liquid chromatography. The progress in instrument development on the detection site has been tremendous in the last few decades. Analyses based on mass spectrometry are now more or less routine. Triple quadrupole and high-resolution mass spectrometers have become affordable and automated standard configurations with mass spectrometers now fulfilling the analytical needs for most types of analyses. Analyses of chemical warfare agents themselves might need some additional requirements. For example, it might be necessary to measure an intact agent at extremely low concentrations, because only these levels are relevant in view of the high toxicity of the agents.

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00056-8

In that case, it might be considered to utilize large-volume sample introduction. This puts higher demands on the analytical configurations because the introduction of larger sample volumes also increases the matrix effect, which puts extra demands on the selectivity of the analysis. In the special case of nerve agents, it might be desirable to distinguish the stereoisomers of these compounds from each other, which requires a rather complicated analytical configuration. In this chapter the methods for the bioanalysis of CWAs or their biomarkers are briefly described and in the case that the instrumentation for a particular analysis is more sophisticated than a standard configuration, it is discussed in more detail.

56.2 Nerve agents

56.2.1 Analysis of intact nerve agents

Nerve agents are organophosphorus (OP) compounds that rapidly inhibit acetylcholinesterase (AChE), which results in an accumulation of acetylcholine (ACh), leading to muscle fasciculations and paralysis, and finally resulting in death (Dacre, 1984). For toxicokinetic studies it is required to analyze the intact agent. The toxicokinetic studies create insight into the distribution and elimination of the agents and indicate until which time toxicologically relevant concentrations are still present in the circulation (Benschop and De Jong, 2001; Van der Schans et al., 2008b). In view of the high toxicity of nerve agents, these toxicologically relevant concentrations are in the pg/mL range. Using gas chromatography, these levels can only be measured when large-volume samples can be introduced into the column. With higher sample volumes, the matrix effect also is increased, and it puts higher requirements to the selectivity of the analysis. Another challenging factor is that nerve agents are chiral compounds with an asymmetrical phosphorus atom (Benschop, 1975; Benschop and De Jong, 1988). The difference in toxicity of the two isomers is several orders of magnitude, the P (−)-isomers being the most toxic (Benschop et al., 1981, 1984; Benschop and De Jong, 1988). In the case of toxicokinetic studies, it is important to differentiate between the two isomers because it is essential to know which isomer is still present in the circulation. Chiral gas chromatography can fulfill this requirement for G-agents like sarin and soman. Soman has two asymmetric atoms, phosphorus and carbon, in the pinacolyl group. Therefore, the compound consists of four different stereoisomers. An optical active stationary phase like beta-cyclodextrin can be used to separate the isomers of sarin (Spruit et al., 2001). Chirasil-Val columns can be used to separate the four isomers of soman (Benschop and De Jong, 1991; Benschop et al., 1981, 1985). The Chirasil-Val stationary phases were synthesized at the TNO Prins Maurits Laboratory. Smith and Schlager (1996) and Yeung et al. (2007) reported the use of commercially available gamma-cyclodextrin-based columns that are also capable of separating the four isomers of soman.

In the case of toxicokinetic studies the chiral columns were installed in a two-dimensional GC configuration according to the heart cutting method. First, the introduction of large-volume samples requires additional selectivity from the chromatographic system to alleviate the matrix effect. Second, the fragile optical active phase needs to be protected from the "dirty" extracts of the biosamples and the condensating solvent in the column. Samples are introduced by thermodesorption tubes filled with Tenax absorption material. The components are cryo-focused in a cold trap and after a certain desorption time, flash injected into the first column. According to the heart cutting technique, one small section of the effluent of the first column is collected in a cold trap and then re-injected on the second analytical column with the chiral selective phase (Due et al., 1993). The isomers of soman can be detected in the blood of guinea pigs at levels down to10 pg/mL blood (Benschop and de Jong, 1991).

The chiral separation of VX isomers was achieved using normal-phase liquid chromatography with a Chiracel OD-H column. The separation of the enantiomers of VX was first described by Kientz et al. (1994). They used a thermo-ionic detector for the selective detection of phosphorus compounds. Unfortunately, this technique was not robust enough. The same separation was also described by Van der Schans et al. (2003) using electrochemical detection. The system could be used to study the stereo-selective degradation of VX in in vitro samples such as liver homogenates and plasma. Although the electrochemical detection was rather sensitive (absolute detection limit 25 pg), the method was not selective enough to measure low levels of VX in extracts of biological matrices at a relevant level (<10 ng/mL). VX can be relatively easily extracted from blood or plasma using organic extraction with hexane (Bonierbale et al., 1996). Relevant levels of VX in blood could be detected down to 1 ng/mL using a two-dimensional offline LC−GC separation (Van der Schans et al., 2003). Smith (2004) published the same separation using a single quadrupole mass spectrometer using atmospheric pressure chemical ionization (APCI). In that paper, he focused on the separation and detection of VX to study the stereo-selective degradation of VX in plasma. Reiter et al. (2008) published the chiral separation of VX isomers with gas chromatography using a HYDRODEX-β -TBDAc column. In the same article, the authors reported also the chiral separation of VX isomers using LC-MS with a Chiral AGP column. Using this analytical method, they were able to study the percutaneous toxicokinetics of VX in pigs Reiter et al. (2008).

56.2.2 Verification of exposure to nerve agents

There are several strategies available to verify an exposure to nerve agents. It is not feasible to measure the intact reagent, since the half-life of these agents is only a few hours, which means that they disappear within a day after exposure (Benschop and de Jong, 2001; Van der Schans et al., 2008b, 2019). Metabolites, often alkylmethylphosphonic acids, are better biomarkers because they circulate for a longer period of time and are gradually excreted in urine (Shih et al., 1994; Fredriksson et al., 1995; Nagao et al., 1997a; Nakajima et al., 1998; Noort et al., 1998; Barr et al., 2004). Several methodologies have been published to analyze these metabolites, which were found in plasma and urine. The alkylmethylphosphonic acids can be isolated from plasma or urine using liquid−liquid extraction (Noort et al., 1998; Katagi et al., 1997; Barr et al., 2004) or solid-phase extraction (Hamelin et al., 2014). Most methods for determination of these compounds are based on liquid chromatography or gas chromatography, which requires derivatization (Black and Muir, 2003). Selective tandem MS techniques facilitated by triple quad instruments or high-resolution MS instruments enabled the detection of hydrolysis products in plasma and urine down to the pg/mL range (Driskell et al., 2002; Barr et al., 2004; Riches et al., 2005; Evans et al., 2008; Swaim et al., 2008; Hamelin et al., 2013, 2014). This concentration is so low that hydrolysis products can be detected in urine up to 1 week after exposure (Riches et al., 2005). The hydrolysis product of sarin was also detected in samples from victims of the attack with sarin in Tokyo (Nagao et al., 1997b; Matsuda et al., 1998) and from victims of the attack with sarin in Syria (John et al., 2018).

Nerve agents bind to proteins such as acetylcholinesterase (AChE) and butyrylcholinesterase (BuChE). These proteins are not excreted or metabolized rapidly (typical half-life is 12 days for BuChE; Hall et al., 1984), which means that adducts to proteins can serve as retrospective biomarkers for exposure to nerve agents (Polhuijs et al., 1997; Black et al., 1999; Fidder et al., 2002; Van der Schans et al., 2004a). The enzymatic measurement of AChE activity, known as the Ellman assay, is the easiest method to determine a nerve agent exposure (Ellman et al., 1961; Halbrook et al., 1992). The method is based on the enzymatic cleavage of the substrate acetylthiocholine where after thiocholine reacts with 5,5′-dithiobis-(2-nitrobenzoic acid), which forms 2-nitro-5-thiobenzoate, a yellowish product that can easily be measured with a low-cost colorimeter. The method has been optimized for high-throughput analysis (Doctor et al., 1987; Halbrook et al., 1992; Worek et al., 1999; Eyer et al., 2003) and is also available in fieldable kits (Taylor et al., 2003). Major drawbacks of the method are, first, that the identity of the nerve agents cannot be elucidated from this measurement. Second, the intra- and interpersonal variation of the ChE activity implies that a decrease in ChE activity must be relatively large to be significant (Brock, 1991; Lotti, 1995; Wilson et al., 1997; Nigg and Knaak, 2000). Third, the de novo synthesis of the enzyme restores the enzyme activity within several days to within the range of the control values. Low-level exposures to nerve agents or exposures that took place several weeks before the biosample could be taken cannot be detected using this method. Therefore, instead of looking for a decrease in AChE activity, it is more efficient to detect the ChE fraction that is inhibited by the nerve agent. In that case, it is also better to look at BuChE, which has several advantages over AChE. First, BuChE is a protein present in plasma, which is an easier sample matrix to process than whole blood. Second, the concentration of BuChE is approximately 80 nM, which is approximately 10 times higher than the concentration of AChE in blood (Myers, 1952; De Jong and Wolring, 1984). This automatically means that the concentration of that biomarker is higher and therefore easier to detect. The most straightforward method to detect the adduct of nerve agent is the fluoride reactivation method (Heilbronn, 1964, 1965; De Jong and Van Dijk, 1984; Polhuijs et al., 1997). During incubation of a plasma sample with fluoride ions, the nerve agent adduct is released from the protein and can be extracted in a GC-compatible solvent and subsequently analyzed with GC. The lowest detectable degree of inhibition that can be determined with this method depends on the type of GC detector. Typical reasonably priced detectors like the nitrogen phosphorus detector (NPD), flame photometric detector (FPD), and mass selective detector show absolute detection limits of about 1 pg, which means that a concentration of 1 ng/mL can be detected using an injection volume of 1 μL. A concentration of 1 ng/mL of nerve agent is equivalent to 5−7 nM, which corresponds with approximately 10% BuChE inhibition. In order to be able to determine lower degrees of inhibition, higher sample volumes have to be injected, which puts higher demands on the selectivity of the separation and detection method. Another option is to improve the selectivity of the detector. Chemical ionization with ammonia as a reaction gas is a relatively soft ionization mode, which ensures a more selective detection of only compounds with sufficient proton affinity (Degenhardt et al., 2004; Jakubowski et al., 2004). Another more expensive but recently affordable option, is to use a high -resolution MS or tandem MS instrument, which can provide sensitivity and selectivity for the sensitive detection of low-degree inhibition (Degenhardt et al., 2004; Lee and Lee, 2014). When the large-volume technique or the sample has been preconcentrated by evaporating the solvent, low degrees of inhibition down to 0.1% can be confirmed (Holland et al., 2008).

The method has been used to analyze samples from victims of the sarin attack in the Tokyo subway (Polhuijs et al,1997) and samples that were taken from victims that were exposed to sarin in Syria in 2013 (John et al., 2018). The method has also been used to verify exposure to VX in accidental exposures (Solano et al., 2008). The method is also used in toxicological studies to determine the distribution of nerve agents in tissues (Adams et al., 2004). The persistence of the biomarkers was also studied in rhesus monkeys that were injected with a sign-free dose of nerve agent. Regenerated sarin could be detected up to 54 days after exposure (Van der Schans et al., 2004a).

A major drawback of the fluoride reactivation method is that not all nerve agent adducts are amenable to fluoride reactivation, with the aged adduct of soman the best known example. This problem can be solved by looking at the BuChE enzyme itself. Fidder et al. (2002) published a method based on the LC−MS/MS analysis of a nerve agent phosphorylated nonapeptide (FGES*AGAAS) derived after pepsin digestion of inhibited butyrylcholinesterase (BuChE). The phosphorylated nonapeptide is best analyzed with an LC tandem MS instrument using the single reaction monitoring (SRM) mode. The mass of the parent ion depends on the mass of the nerve agent that is conjugated to the peptide. During the fragmentation process, the phosphyl moiety of the nerve agent is removed first and the characteristic daughter ions are *m/z* 778, 673, and 602, which are all fragments of the native peptide. Fig. 56.1 shows the mass spectrum of the nonapeptide with methylphosphonic acid adduct, resulting after exposure to a rapidly aging nerve agent such as soman. This mass spectrum has been acquired on a QTOF instrument with accurate mass determination. The spectrum shows that the mass difference between the protonated parent ion and the highest fragment corresponds with the theoretical mass of methylphosphonic acid. With this result, high-resolution mass spectrometers show their added value in unambiguous identification of CWA adducts. Product ions of the phosphorylated nonapeptide could successfully be identified within 5 ppm deviation from their chemical formulas. The analysis of the phosphorylated nonapeptide was successfully applied on plasma samples that were taken from victims who had been exposed to sarin in the Tokyo subway in 1995 (Polhuijs et al., 1997; Fidder et al., 2002) and from victims of the attack with sarin in Syria in 2013 (John et al., 2018). Fidder et al. (2002) used a procedure to extract BuChE from plasma using home-fabricated procainamide gels. In the last couple of years the sample preparation procedure for the isolation of BuChE from plasma has been further improved. Sporty et al. (2010) described the use of antibody-loaded magnetic beads to isolate BuChE from plasma, which resulted in a better sample clean-up and better possibilities for automation of the method. Carter et al. (2013) optimized the method further for quantitation of the nerve agent adduct and Knaack et al. (2012) developed a method enabling high throughput of samples. Schopfer et al. (2019) reported the use of Hupresin affinity chromatography to purify BuChE as an alternative for the isolation of BuChE using antibodies. The analysis of FGESAGAAS nonapeptide adducts is nowadays also used for biomonitoring for exposure to other cholinesterase inhibitors. For example, Schopfer et al. (2010) and Johnson et al. (2015) used the same peptide for diagnosis of 2-(ortho-cresyl)-4H-1,3,2-benzodioxaphosphoran-2-one (CBDP) exposure.

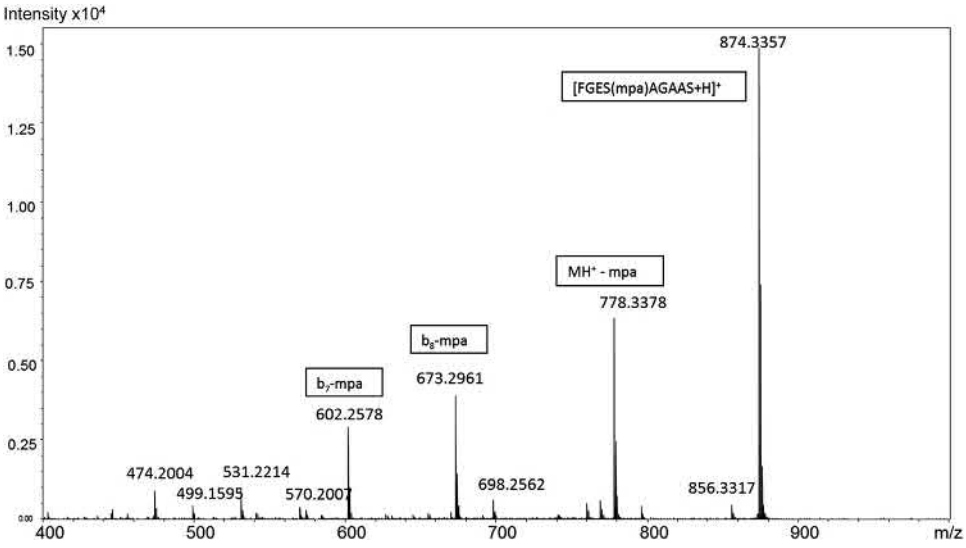

FIGURE 56.1 MS-MS chromatogram of protonated ion $[MH]^+$, *m/z* = 874.3357 representing the nonapeptide FGESAGAAS with methylphosphonic acid adduct. The mass difference between $[MH]^+$ and "$[MH]^+$-mpa" (*m/z* 95.9979) is identical to the theoretical mass of methylphosphonic acid (*m/z* 95.9976).

Due to the low concentration of the biomarkers, the analyses are target directed because a full scan would be at the cost of sensitivity, which means that low-level exposures cannot be detected. However, this is a serious problem in the case where the identity of the nerve agent is not known beforehand. Some progress has been achieved to solve this problem. The number of different OPs exceeds several thousand, but the number of different masses is only 170. Since the OPCW Schedule 1 nerve agents consist only of saturated alkyl groups with mass increments of 14 units the number of mass possibilities can be further reduced to 36 masses, which means that only 36 MRM transitions have to be recorded (Van der Schans et al., 2008a). It is anticipated that the newest mass spectrometers will be able to acquire all MRM transitions, relevant to all nerve agents. Another approach was published by Noort et al. (2006). The phosphorylated serine residue of nerve agent-inhibited BuChE can be converted under alkaline conditions into a dehydroalanine residue that can subsequently react with a generic tag, yielding a mutual product, whatever the identity of the nerve agent. The resulting product can be detected in the most sensitive single reaction monitoring mode of the mass spectrometer.

In addition to BuChE, albumin is also a target protein for nerve agents, especially at Tyr^{411}, be it with a lower affinity than BuChE. After digestion with pronase, the phosphorylated tyrosine can be detected with LC-MS. Therefore, nerve agent adducts to albumin are also a valuable biomarker for nerve agent and pesticide exposure (Black et al., 1999; Williams et al., 2007; Read et al., 2010; Van der Schans et al., 2013; Crow et al., 2014).

In the case of an intoxication with VX, the leaving group upon binding to proteins is diisopropylethane-thiol. The compound is that specific for VX that it can serve as a representative biomarker of exposure of VX. The compound circulates in plasma and can be analyzed with GC after extraction with an organic solvent (Bonierbale et al., 1996). The free thiol group is amenable to react with proteins such as albumin where it will bind with various Cys residues to form a disulfide bond. Kranawetvogl et al. (2017, 2018) reported the analysis of a Cys*-Pro dipeptide and a Met-Pro-Cys* tripeptide derived after digestion with pronase, being the most prominent additional biomarker of exposure to VX.

56.3 Sulfur mustard and lewisite

There is a variety of biomarkers that can verify an exposure to sulfur mustard. Analogous to the nerve agents, biomarkers can be distinguished in metabolites that are excreted in urine and adducts to proteins. Thiodiglycol (TDG) and its oxidation product thiodiglycol sulfoxide (TDG-sulfoxide), are the oldest biomarkers of exposure to sulfur mustard (Black and Read, 1988, 1991). The compounds can be isolated from urine or plasma using solid-phase extraction and detected with GC-MS. Wils et al. (1985, 1988) treated TDG with hydrochloric acid to convert TDG back into sulfur mustard. Black and Read (1991) reported a method that detects TDG, TDG-sulfoxide, and their acid-labile esters, as the single analyte thiodiglycol. In both cases the recovered analytes were converted to the bis(pentafluorobenzoyl) derivative of thiodiglycol and detected by GC-MS using negative ion chemical ionization. The limits of detection were 1 ng per 0.5-mL sample of urine. Later the sensitivity of the method was further improved using GC-tandem MS (Riches et al., 2007). The biomarker has been detected in the urine of victims that were exposed to sulfur mustard in the Iran−Iraq War in the 1980s (Wils et al., 1985, 1988) and later in urine of persons that were accidently exposed to sulfur mustard (Jakubowski et al., 2000).

The drawback of these TDG and TDG-sulfoxide as biomarkers is that they suffer from high background levels. In that respect, a series of more specific metabolites were discovered by Black et al. (1991). Sulfur mustard reacts with glutathione, which is then further metabolized by the β-lyase enzyme. Two β-lyase metabolites have been identified in the urine from exposed individuals: 1-methylsulfinyl-2-[2-(methylthio)ethylsulfonyl] ethane (MSMTESE) and 1,1′-sulfonylbis[2-(methylsulfinyl)ethane] (SBMSE). MSMTESE and SBMSE can be reduced using $TiCl_3$ and analyzed by GC/MS/MS as a single analyte: 1,1.-sulfonylbis[2-(methylthio)ethane] (SBMTE) (Black et al., 1991; Black and Read, 1995a,b; Young et al., 2004; Daly et al., 2007). MSMTESE and SBMSE can also be analyzed individually without reducing the two analytes to a common analyte using electrospray LC-MS/MS (Read and Black, 2004a,b; Halme et al., 2011; Li et al., 2013; Liu et al., 2017). To date, no background levels of SBMTE have been found in the urine of unexposed individuals, including studies where urine samples from over 100 individuals were analyzed using two different assay methods (Boyer et al., 2004; Young et al., 2004). These metabolites have been measured in persons that were accidently exposed but were also analyzed in scientific animal experiments in order to study the toxicology of the agent and the persistence of the biomarker in the circulation (Black et al., 1992a,b; Barr et al., 2005, 2008; Lin et al., 2014).

Analogous to nerve agents, sulfur mustard binds to proteins and the protein adducts are a potential biomarker for exposure to sulfur mustard (Black et al., 1997a,b). The sulfur mustard adduct to N-terminal valine of globin in blood can be analyzed after a sample preparation procedure known as the modified Edman degradation (Fidder et al., 1996a,b; Noort et al., 1996, 1997, 2000, 2004a,b). The lower limit of detection for the assay was determined

using in vitro exposures of sulfur mustard in human whole blood and was determined to be equivalent to a 100 nM exposure level (Fidder et al., 1996a,b; Noort et al., 2004a). The method has been applied to samples from victims that were exposed to sulfur mustard in the Iran−Iraq War in the 1980s (Benschop et al., 1997). The persistence of the biomarker was also studied in marmosets that received a dose of 4.1 mg/kg i.v. The valine adduct could be detected up to 94 days after exposure (Noort et al., 2002).

Sulfur mustard binds also to cysteine in albumin and this adduct can be analyzed as a tripeptide Cys*-Pro-Phe, where sulfur mustard binds to the cysteine residue. The modified tripeptide can be detected after isolating albumin using affinity chromatography, enzyme digestion with pronase, and analysis of the alkylated peptide fragment using LC-tandem mass spectrometry. Exposure levels down to 10 nM could be detected using this method (Noort et al., 1999, 2000, 2004b; Liu et al., 2015). In a retrospective study, rats were injected with a dose of 0.3 mg/kg. The modified tripeptide could be detected up to 7 days after the injection (Noort et al., 2008). The adduct to the *N*-terminal valine in hemoglobin could still be detected after 28 days.

Several other authors published various methods on the same biomarker. Pantazides et al. (2015) treated the precipitated plasma proteins with proteinase K, followed by further sample cleanup using solid-phase extraction and analysis with LC-tandem MS. Andacht et al. (2014) ruggedized the method further to enable enhanced throughput for quantification of sulfur mustard adducts. The same method can also be used for the detection of nitrogen mustard adducts (Pantazides et al., 2019). The alkylated tripeptide is one of the most important biomarkers and has been measured in plasma samples from accidently exposed persons (Smith et al., 2008). Further modifications to the method detecting the same adduct site but detecting as a shorter peptide, HETE-Cys-Phe, have also been published (Gandor et al., 2015; John et al., 2016). The methods have also been used for the forensic analysis of samples obtained from victims that were exposed to sulfur mustard in a crisis region in the Middle East in 2015 (John et al., 2019).

The histidine residue in the globin protein is another target for binding of sulfur mustard (Black et al., 1997b). Following digestion with pronase, the sulfur mustard histidine analyte (HETE-His) could be detected with LC tandem MS after exposure of human blood at an exposure level of 10 μM sulfur mustard in vitro (Noort et al., 1997).

Analogous to the fluoride reactivation method for nerve agents, the sulfur mustard adduct can also be released from the protein by alkaline hydrolysis and is measured as thiodiglycol. A precipitation step during the sample preparation removes endogenous thiodiglycol before it is released from the protein (Capacio et al., 2004, 2008a,b; Lawrence et al., 2008). Unlike the nerve agents, the analyses can be target directed and the mass spectrometer can be operated in the most sensitive SIM or SRM mode.

Sulfur mustard, being a strong alkylating agent, can also react with DNA. In particular, the guanine base is susceptible for alkylation resulting in the formation of *N*7-[2-[(2-hydroxyethyl)thio]-ethyl]guanine adduct. Wei et al. (2011) reported an analytical method based on the digestion of DNA from exposed whole blood followed by analysis with LC-tandem MS. The sulfur mustard guanine adduct is also excreted in urine and Fidder et al. (1996a,b) published a method using GC-MS or LC-MS/MS. Recently, sulfur mustard adducts to the other bases of DNA have also been discovered (Yue et al., 2014), but the relevance of this biomarker in real cases is still under investigation (Zubel et al., 2017, 2019). In addition to the methods based on instrumental analysis, sulfur mustard adducts to DNA can also be detected using immunoassays. Antibodies that can recognize the sulfur mustard adducts have been raised. In an immunoslotblot assay, exposures to sulfur mustard could be verified in DNA obtained from blood or skin (Benschop et al., 1997; Van der Schans et al., 1994, 2002, 2004b).

In the case of toxicokinetic studies of sulfur mustard, typical concentrations at 10−100 pg/mL in blood were found and could not be measured with a normal GC−MS configuration. The utilization of large-volume sample introduction by thermodesorption and two-dimensional chromatography (analog to the configuration for chiral nerve agent analysis) enabled the detection of sulfur mustard levels down to 10 pg/mL (Oostdijk et al., 2007). The two-dimensional chromatography was necessary at that time to ensure sufficient selectivity. Nowadays these studies could be performed using GC-MS/MS systems operating in SRM mode that also ensures sufficient selectivity (Nawała et al., 2016). Langenberg et al. (2016) described toxicokinetic studies of sulfur mustard that were performed using two-dimensional chromatography coupled with MS.

The number of methods to verify an exposure to lewisite is limited. Chlorovinylarsonous acid (CVAA) can be found as the main metabolite in urine. Wooten et al. (2002) developed a simple assay based on solid-phase microextraction (SPME) and gas chromatography-mass spectrometry (GC-MS) after derivatization of CVAA with 1,3-propanedithiol (PDT). Fidder et al. (2000) developed a method based on extraction of bound and unbound 2-chlorovinylarsonous acid (CVAA), a major metabolite of L1, from whole blood after treatment with 2,3-dimercapto-1-propanol (BAL). Subsequent to derivatization with heptafluorobutyryl imidazole, the CVAA-BAL

derivative could be analyzed at a 40-fmol level by means of gas chromatography-mass spectroscopy (GC-MS). Using this procedure, in vitro exposure of human blood to 1 nM lewisite could be determined. The same procedure was applied to the analysis of human urine samples spiked with CVAA.

56.4 Concluding remarks and future directions

The development of sophisticated analytical instruments, mainly based on mass spectrometry, enabled several analyses for bioanalysis of chemical warfare agents. Toxicokinetic studies at relevant levels (down to 10 pg/mL blood) could be performed. Exposures to CWAs can be verified up to several weeks after exposure, because of the persistence of the biomarkers and also because of the sensitive and selective instrumentation. It is anticipated that future equipment will be even more sensitive, enabling exposures that occurred weeks after the exposure to be tracked down. Better sensitivity is also desirable, in order to meet the criteria that are in place for the identification of a compound meeting the forensic standards. Meanwhile the OPCW fully recognized the relevance of biomedical samples and implemented a system of biomedical proficiency tests (bioPT). Within the framework of this bioPT, criteria for unambiguous verification of exposure have been defined (Mamidanna, 2016). The criteria dictate that the identification of each test chemical must be based on at least two different analytical methods, or one analytical method for two different biomarkers confirming the exposure of a particular chemical. Sections 56.2 and 56.3 showed that multiple methods are available to verify an exposure. For nerve agents, hydrolysis products can be analyzed with LC-MS or GC-MS. Protein adducts of nerve agents can be divided into BuChE and albumin adducts. For sulfur mustard, urine metabolites such as the β-lyase metabolites can be analyzed. For proteins there is a wide variety of sulfur mustard adducts that can be detected. Tables 56.1 and 56.2 show an overview of the biomarkers that were discussed. Secondly, a total of at least five identification points must be obtained to achieve sufficient analytical data for the identification using a maximum of three techniques. Information-rich techniques such as HR-MS provide more

TABLE 56.1 Major biomarkers for nerve agent exposure.

Matrix	Biomarker	Analyte	Analytical technique
Urine, plasma	Alkylmethylphoshonic acid	Alkylmethylphoshonic acid	LC-MS/MS GC-MS/MS (after derivatization)
Plasma	Adduct to BuChE	Phosphorylated nonapeptide	LC-MS/MS
Plasma	Adduct to various proteins	Regenerated OP- fluoridate	GC-MS/MS
Plasma	Adduct to albumin	Phosphorylated tyrosine	LC-MS/MS

TABLE 56.2 Major biomarkers for sulfur mustard exposure.

Matrix	Biomarker	Analyte	Analytical technique
Urine, plasma	Thiodiglycol	Thiodiglycol	LC-MS/MS, GC-MS/MS (after derivatization)
Urine, plasma	Thiodiglycol-sulfoxide	Thiodiglycol-sulfoxide	LC-MS/MS, GC-MS/MS (after derivatization)
Urine	ß-lyase metabolites, MSMTESE, SBMSE	MSMTESE SBMSE SBMTE (after reduction of MSMTESE and SBMSE with $TiCl_3$)	LC-MS/MS
Plasma	Alkylated globine	HETE-Val	GC-MS/MS (after derivatization)
Plasma	Alkylated globine	N1-HETE-His N3-HETE-His	LC-MS/MS
Plasma	Alkylated albumin	[S-HETE]-Cys-Pro-Phe	LC-MS/MS
Blood	Alkylated DNA	N7-[2-[(2-hydroxyethyl)thio]-ethyl]guanine	LC-MS/MS, immunoslotblot

points (up to four), while low-information techniques provide less points, for example, two points for one transition in an MRM analysis. Mathews et al. (2017) showed that higher confidence in identification is obtained when HR-MS is utilized.

Another interesting development is comprehensive GCxGC. Comprehensive GC offers great selectivity and resolution, ideal for complex samples such as biomedical samples. The combination with time of flight mass spectrometry offers the possibility to analyze in a full-scan mode, not target directed, with the availability of a full mass spectrum that will meet the forensic standards. The utility has been demonstrated for the detection of CWAs in complicated matrices such as fuel (Reichenbach et al., 2003). The method has also been used for the analysis of regenerated sarin in inhibited plasma (Van der Meer et al., 2010). Finally, it may be expected that the sample preparation will be further automated. A promising approach was published by Carol-Visser et al. (2008) and more recently by Bonichon et al. (2018), based on the online digestion and analysis of sulfur mustard adducts on albumin and the sarin adduct to BuChE, respectively.

Chapter 57

On-site detection of chemical warfare agents

Yasuo Seto
RIKEN SPring-8 Center, Hyogo, Japan

57.1 Introduction

Chemical warfare agents (CWAs) were employed in World War I and World War II, and during the Cold War, and they continue to be produced and stockpiled even today (Somani, 1992; Gupta, 2015). In the 1980s, Iraq used sarin (GB) and sulfur mustard (HD) in the Iran−Iraq conflict (Black et al., 1994). In 1992, the Chemical Weapons Convention, a treaty prohibiting the development, production, stockpiling, and use of chemical weapons and mandating their destruction, was ratified, and came into force in 1997 (Organization for the Prohibition of Chemical Weapons, 2019). However, in the interim, the Japanese doomsday cult group Aum Shinrikyo deployed GB in the Japanese city of Matsumoto in 1994, and then, more infamously, in the Tokyo subway system in 1995. In both these attacks, many defenseless people were poisoned, some fatally (Seto et al., 2000). The Tokyo subway sarin gas attack and the more recent US postal anthrax letter attacks in 2001 (Inglesby et al., 2002) presented a renewed threat of chemical and biological terrorism globally. In the Syrian war, many citizens were killed by GB and HD (John et al., 2018; United Nations, 2013). In 2017, Kim Jong Nam was assassinated using VX at Kuala Lumpur International Airport in Malaysia (Radio Free Asia, 2017). In 2018, a remerging nerve agent, Novichok, was used in Great Britain for assassination (Franca et al., 2019). To realize a safe and secure society, it is highly recommended that authorities at national levels establish a more strengthened crisis management system for civil defense (Seto, 2006a).

In addition to the known attacks, various CWA stockpiles have been discovered in former Japanese military force facilities during land excavations (Ohashi, 2004). Injuries due to direct contact with CWAs that leaked from containers in Samukawa, Japan, have been reported (Hanaoka, 2004), and some complaints were received in Kamisu, Japan, concerning damage to human health (neurological disorders) caused by drinking water likely contaminated with degradation products from arsenic vomiting agents (Ishii et al., 2004).

In the crisis management of chemical warfare terrorism cases (Society for Countermeasures Against Chemical, Biological, Radiological, Nuclear and Explosive Terrorism, 2008) and chemical weapon disposal, CWAs were monitored in public places, security checks at territorial borders, airports, large event venues, executive facilities, and demilitarization spots housing chemical weapons for protection against terrorism and workers' health. With regard to consequence management, on-site detection is initially performed by first responders for personal protection; on-site samples are then transported to laboratories for analysis for investigation and for identification of emergency lifesaving measures. In incident management, laboratory analysis is performed to provide evidence for courts in order to prosecute offenders and prevent future crimes (Fig. 57.1). Among these detection schemes, rapid on-site detection is the most important for the minimization of disasters in order to eliminate the prolonged times required for transporting on-site sample specimens to a laboratory for analysis (Smith, 2002; Harris, 2002; Fittch et al., 2003). Various types of measuring technologies have been used for on-site detection and laboratory identification of CWAs and are discussed here.

57.2 Properties of chemical warfare agents

CWAs are low-molecular-weight synthetic compounds that are fast-acting and sometimes lethal, even at low

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00057-X

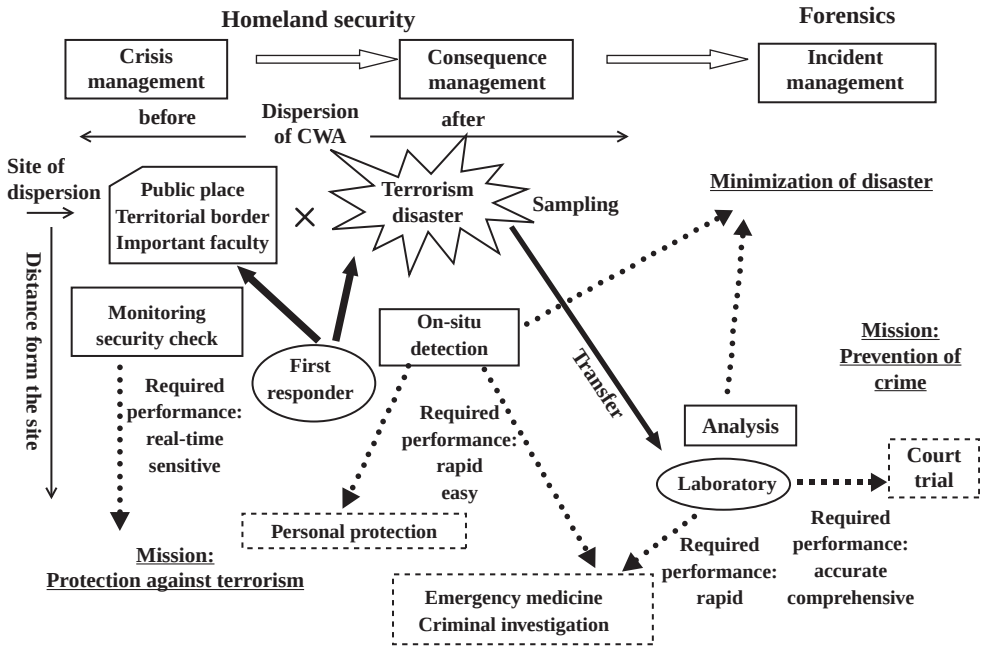

FIGURE 57.1 Detection and identification in chemical terrorism countermeasures and chemical weapon disposal.

levels (Somani, 1992; Stewart et al., 1992; Marrs et al., 1996; Ellison, 2000); in terms of physical properties, CWAs can be classified into gaseous blood agents, gaseous choking agents, volatile nerve agents, volatile blister agents, nonvolatile vomit agents, and nonvolatile lachrymators (tear gases) (Fig. 57.2). The physical and toxicological properties of CWAs vary in many ways; namely in molecular weight, melting point, boiling point (vapor pressure), vapor density, durability in air, lethal concentration, incapacitating concentration, smell, water solubility, stability in water, effect on skin, and antidote prospects. In particular, except for slow-acting agents that manifest toxicity after several hours, such as phosgene (CG) and HD, CWAs are fast-acting. Deadly poisonous organophosphate nerve agents and toxic blister agents are registered as scheduled compounds in the CWC. Although CWAs show toxicity by skin contact and intake, inhalation toxicity against CWA vapor is mainly considered with respect to chemical warfare/terrorism cases and chemical weapon disposal, and the development of analytical technologies is conducted with the aim of CWA detection in the vapor phase. The parameter used in the description of CWA toxicity is the lethal dose value (LCt_{50}, $mg \cdot min/m^3$); this value indicates the vapor concentration leading to a 50% incidence of death in human beings with 1 min of inhalation.

57.3 Concept of on-site detection

In chemical warfare terrorism countermeasures, we must consider the dispersion of various types of CWAs, including toxic industrial chemicals (TICs), except for overt cases such as previous notices of criminal acts. If clear symptoms of CWA-exposed casualties are manifest, it is possible to narrow down the types of CWAs detected. On the other hand, for chemical weapon disposal, the possible types of dispersed CWAs are obvious. In the case of exposure to CWA vapor and subsequent intoxication, monitoring technology is very important for exposure minimization and effective medical treatment. However, the requirements for the optimal performances of on-site detection technologies are not clear, with most protocols depending only on previous experience. Namely, the on-site monitoring of CWAs is quite different and an unknown field compared to other monitoring situations; therefore, not only researchers, but also first responders, have little idea of how to detect CWAs on site. Some of the required criteria for successful on-site detection are as follows: knowledge of the possible types of CWAs and their limits of alarm (LOAs), response time, time required to start the detector, recovery time after the previous alarm, accuracy (affected by interference and false positives), state of alarm, operational performance (i.e., the required technology and training), maintenance, and cost of introduction and maintenance. In addition, operational conditions, durability, and portability of necessary machinery should be considered.

For considering toxicity manifestation time and vapor dispersion situations in cases of terrorism, it is necessary to initiate the alarm for a vapor concentration of less than the vapor concentration of 1/100 of LCt_{50} within 1 min. In the case of GB, the required detection sensitivity is

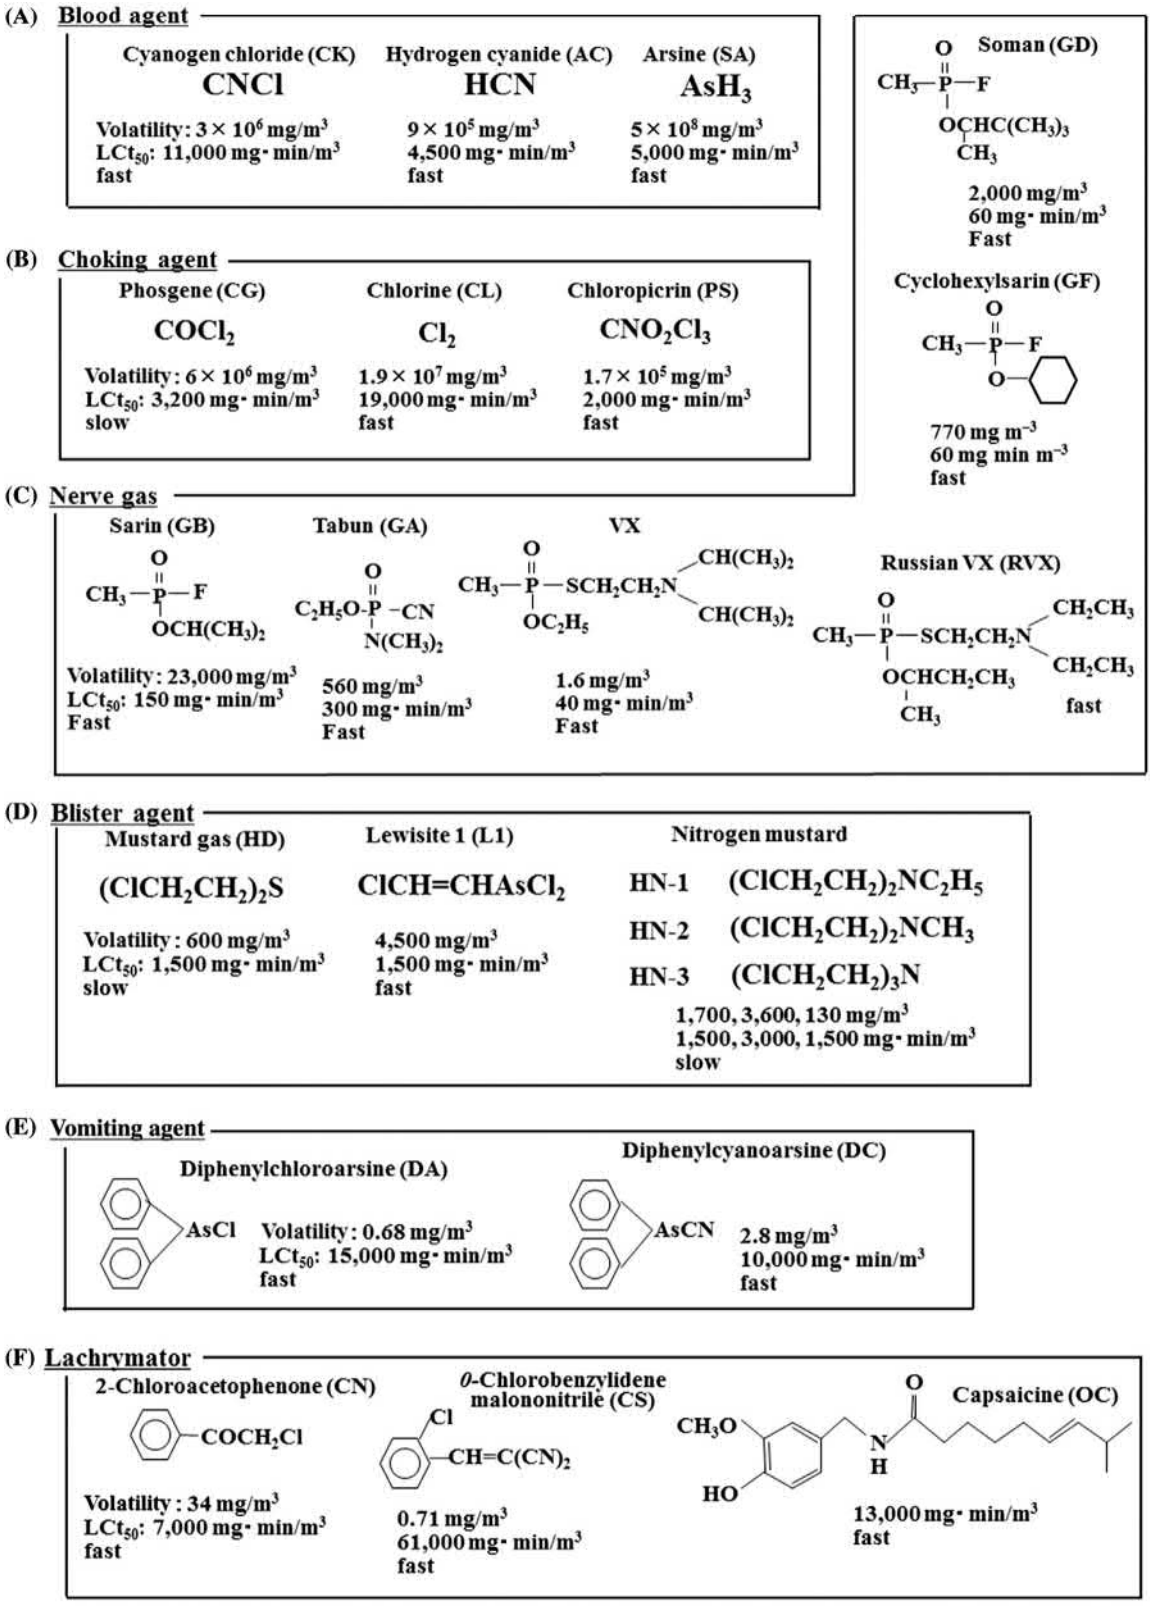

FIGURE 57.2 Chemical structures, volatility (at 25°C), and inhalation toxicity data of chemical warfare agents.

0.15 mg/m^3; at this level, humans show no signs of intoxication, nor is there a detectable odor. In chemical weapon disposal situations, because workers are present at the sites for a prolonged time, the time-weighted average (TWA) values, which are approximately 1/100,000 of LCt_{50}, are adopted as the monitoring target for allowed operational conditions. An alarm time of less than several minutes is desired. There is a tradeoff relationship between LOA, alarm time, detection accuracy, and operation; furthermore, for detection equipment employing one detection mechanism, raising the LOA prolongs the alarm time and increases the frequency of false positives.

In previous instances for which on-site detection technology had not yet been well developed, field damage and injuries to victims were traditionally observed and understood by using our senses; CWAs were identified through laboratory analysis and diagnostics after transferring the on-site samples and victims' samples to specific laboratories and emergency medical hospitals. To minimize the damage caused by terrorist activity, it is vital to obtain as much information as possible about the types and concentrations of the dispersed CWAs, which is now possible because of the technological development and large numbers of laboratory analytical technologies. Fig. 57.3 shows the concepts in the determination of CWAs. Remote detection (stand-off detection) is the method to detect CWAs away from the dispersed site using spectroscopic technologies, and can be divided into the following two types: (1) passive detection, which refers to the detection of light emitted from the target and is mostly limited to infrared light; and (2) active detection, which detects the secondary light (fluorescent or absorbed light—i.e., ultraviolet, visible, or infrared) emitted from the target after the sample is irradiated with primary light using equipment brought to the site, with lasers usually employed as the irradiating light source.

Because the vapor concentrations of CWAs used for terrorism are low due to their high toxicities, and terrorism is predicted to occur at civilian locations where various types of interfering compounds exist, it is often difficult to fulfill on-site detection requirements. "Suction detection" is the method to detect CWAs by directly measuring CWAs through suction of vapors in the field, and is further divided into the following two types: (1) continuous monitoring, which involves continuous drawing of on-site air samples and detection using fixed or movable equipment; and (2) point detection, which is used to detect CWA vapor by first responders by moving portable devices into the field. In terms of CWA detection, *real-time detection* refers to the alarm signal given under the continuous drawing of air samples, while in collection detection mode, the alarm is given by detection with cycling measurements after air samples have been collected. *Collection off-site analysis* refers to CWA detection in the laboratory using collected samples transferred from the field. For solid or liquid samples and dispersed surfaces, CWAs are detected by direct contact with the detector; alternatively, they are detected by measuring the sampled or stripped specimens by inserting them into the detectors. Finally, large trailers containing mobile chemical laboratories equipped with analytical machines are used for detection via on-site analysis.

The assessment of dangerous terrorism and chemical weapon disposal situations by detecting fast-acting CWAs quickly at low-concentration levels must be rapid (Sidell et al., 2003). For people escaping from or arriving at the dangerous sites, injuries and casualties must be taken care of with proper emergency treatment (such as securing aeration and administering antidotes). The roles of the first responders are to install protective masks and gear and to perform zoning of the dangerous sites. Field-deployability, rapid alarm capability, and ease of automated operation are most important for on-site detection, with the low frequency of false positives being a secondary requirement; however, if the frequency of false-positive alarms is high during a response, it will disturb the proper and timely activities of responders at the terrorism-affected or chemical weapon disposal sites. Various types of on-site CWA detection devices have been used by military organizations worldwide (Fittch et al., 2003), and some have been introduced for civil defense organizations such as mobile police teams, fire-defense teams, and coastguards for the purposes of counterterrorism.

CWAs can be measured by detecting the chemical constituent; the technologies for chemical detection can

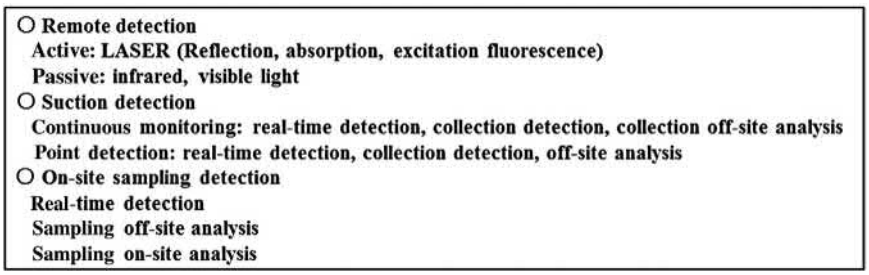

FIGURE 57.3 Concept of on-site detection for chemical warfare agents.

adopt different mechanisms depending on the target substances (Paddle, 1996). The discrimination level varies between the screening and identification methods. At present, most field equipment utilizes detection paper, gas detection tubes, ion mobility spectrometry (IMS), flame photometric detection (FPD), photoionization detection (PID), surface acoustic wave (SAW) detection, vibrational spectroscopy including Fourier transform/infrared spectrometry (FT/IR) and Raman spectroscopy, or combined GC-MS technologies. Furthermore, chemical sensors, biosensors, and micro total analysis systems (μTAS) have been extensively developed. Except for highly discriminating technologies such as chromatographic or spectrometric measurements, many detectors signal an alarm only for restricted chemical species. The representative species are nerve agents, blister agents, blood agents, including gaseous choking agents, and TICs. Vomit agents and lachrymators are not considered because of the mechanical impossibility for detecting such nonvolatile agents and their low toxicity. Nerve agents are the most preferred target, followed by blister and blood agents. So far, CWA detection technology has been developed and utilized for deployment during military missions; thus, it is not guaranteed that such on-site equipment would work properly for real CWAs in civil defense. Considering the present situation of developed terrorism countermeasures and on-site needs, greater emphasis should be placed on the scientific development of on-site detection technology. Several research groups are engaged in the evaluation of commercially available detection equipment and are presently developing new detection technologies. Our laboratory has evaluated some commercially available detection equipment using authentic CWAs. In the following section, the evaluation results obtained in the author's laboratory are discussed (Seto, 2006a, 2006b, 2014, 2015; Seto et al., 2005, 2007).

57.4 The present situation of detection technology

With regard to remote detection technology, the active method of measuring the reflected light from laser irradiation provides higher sensitivity than the passive method; however, the machinery for this technique is too large (on the ton scale). As for passive methods, spectroscopic measurements of CWA emission (specifically infrared light and the corresponding devices) were utilized in military applications. These machines can instantaneously and continuously detect the CWA vapor; however, because of background interference, practical utilization by civilian means remain a far-off prospect. Recently, remote-sensing technology using passive infrared light has been advanced (System Assessment and Validation for Emergency Responders Program, 2016), and now hyperspectral imaging machines are available (Bruker Corporation, 2019a,b). Furthermore, in addition to ultraviolet, visible, and infrared light, a wide range of other light wavelengths such as milliwave and terahertz light can be detected, in addition to laser excitation and resonance Raman scattering.

57.4.1 Classical manual method

The classical manual detection tools still in use are suction detection, detection paper, and gas detection tubes, which can detect the presence of CWAs by visualizing the color changes manifested by the reaction between the reagents and CWAs. Detection paper shows an instant color change in the presence of liquid forms of CWAs with a sensitivity of several $\mu g/cm^2$ (Toyobo, Japan; M8 and M9 paper, US military). Two types of pigments and pH indicators are impregnated in the cellulose paper; the paper turns brown or orange on the addition of a droplet of GB, soman (GD), or tabun (GA) [G agents in the North Atlantic Treaty Organization (NATO) code]; turns red when exposed to a droplet of HD or lewisite 1 (L1) (H agents); and turns to black or deep green with VX (a V agent). This coloring reaction is based on the solubility of the agents in organic solvent; thus, almost all organic solvents except water would show a false positive. Dimethyl methylphosphonate, acetone, toluene, and ethyl acetate show a false positive for G agents; 2-mercaptoethanol, carbon tetrachloride, and aniline show a false positive for H agents; and diethylamine shows a false positive for V agents. Because of the high probability of false positives, detection paper seems impractical for civilian defense (Seto et al., 2005).

Gas detection tubes show a color change with vapor CWAs with a sensitivity close to mg/m^3 concentration levels. The specific reagents are impregnated into a silica-gel support in a glass tube. When needed, both sides of the tube are opened by a cutter, the appropriate air sample volume is drawn, and the extent or length of coloring is checked by the naked eye. Commercial industrial-use gas detection tubes (Komyo Kika; Gastec, Japan) are available for the detection of blood and choking agents. However, for special agents such as nerve agents, the Dräger Safety gas detection tube (in Germany) is adequate (Takayama et al., 2007).

For nerve agents, the phosphoric acid ester tube shows a red color, which is based on a sequence of complicated procedures involving butyrylcholinesterase (BuChE) inhibition, substrate butyrylcholine hydrolysis, and pH indication. Positive results are shown for cholinesterase inhibitors. For HD, the thioether tube exhibits a yellow color, which is based on the reaction with silver chloride

and chloramines. HD stimulants show false positives. For L1, the arsine and organic arsenicals tube shows a black color; a sequential procedure involving two types of chemical reactions allows the separate detection of both inorganic and organic arsenicals and, based on the reduction by zinc and hydrochloride and subsequent complex formation with gold and mercury, yields a gold-colored colloid. For nitrogen mustard 1 (HN 1), nitrogen mustard 2 (HN 2), and nitrogen mustard 3 (HN 3), the organic alkaline nitrogen compounds tube shows an orange-red color, which is based on the Dragendorf reaction. For hydrogen cyanide (AC), the hydrogen cyanide tube shows a pink color, which is based on oxidation by mercury chloride and subsequent pH indication. For cyanogen chloride (CK), the cyanogen chloride tube also shows a pink color, which is based on the reaction with pyridine and barbituric acid. For CG, the phosgene tube shows a blue-green color, which is based on the chemical reaction with *p*-dimethylbenzaldehyde/*N,N*-dimethylaniline. For chlorine (CL), the chlorine tube shows an orange color, which is based on a chemical reaction with *o*-tolidine. The LOA (i.e., the minimum concentration giving three positive results within three trials), response time, and interference of the stimulants and solvents are shown in Table 57.1. The operation involves a complicated procedure of breaking the inner liquid tube and subsequent incubation in a number of detection tubes. However, the procedure is quite tedious when employing protective gear and gloves, requiring several minutes from the start of the operation until tube coloration is observed. The gas detection tube is recommended as a supplemental means for ascertainment of CWA species after IMS screening.

TABLE 57.1 Detection performance of Dräger gas detection tubes.

Gas detection tube	Agent	Limit of alarm (mg/m^3)	Response time (min)	Remark
Phosphoric acid ester	Sarin	0.002	5–6	
	Soman	0.02	5–6	
	Tabun	0.5	5–6	
	VX	2	5–6	
	Dichlorvos			False positive at 1 mg/m^3
	Methomyl			False positive at 50 mg/m^3
	Dimethylmethyl-phosphonate			Negative at 2300 mg/m^3
Thioether	Mustard gas	2	2	
	2-Chloroethylethyl sulfide			False positive at 2.4 mg/m^3
	1,4-Thioxane			False positive at 2.4 mg/m^3
	Diethylether			Negative at 20000 mg/m^3
Organic arsenic compound and arsine	Lewisite 1	4	2	
	Diphenylchloro-arsine			Negative at 100 mg/m^3
Organic alkaline nitrogen compounds	Nitrogen mustard 1	10	1	
	Nitrogen mustard 2	10	1	
	Nitrogen mustard 3	10	1	
Hydrogen cyanide	Hydrogen cyanide	0.3	1	
	Cyanogen chloride			Negative at 100 mg/m^3
Cyanogen chloride	Cyanogen chloride			
	Hydrogen cyanide			Negative at 100 mg/m^3
Phosgene	Phosgene	1	1	
Chlorine	Chlorine	0.8	1	

57.4.2 Photometric method

The photometric type of detection is based on the photometric or electronic response manifested by the physical-chemical reaction of CWAs. The FPD instrument detects CWAs by measuring the specific phosphorus or sulfur emission line produced via combustion with hydrogen gas. AP2C (PROENGIN, 2019) is a handy portable automated FPD manufactured by Proengin (based in Saint Cyr l'Ecole, France). This detector responds rapidly to both vapor and liquid forms of phosphorus containing CWAs in the GV mode and of sulfur-containing CWAs in the H mode. Approximate concentration levels of 0.1 and 1 mg/m^3 for nerve agents and HD are detected in the GV and H modes, respectively (Seto et al., 2005, 2007). The stimulants containing phosphorus or sulfur show false positivity, and CWAs containing neither phosphorus nor sulfur are not detected. A flame ionization detection (FID) instrument such as MicroFID II (INFICON, 2019a) detects nonspecific combustible CWAs by measuring ion production manifested by combustion with hydrogen; the LOA of this method is at sub-mg/m^3 levels of vapor concentrations. The PID instrument detects numerous types of CWAs in a nonspecific fashion, which is based on the measurement of the produced ion current of charged gas ions by irradiation with ultraviolet light. RAE Systems (based in San Jose, California) manufactures the ppbRAE 3000 +, which has an LOA on the level of several tens of mg/m^3 (Honeywell International Inc., 2019; Seto et al., 2007).

Chemical sensor technology adopting acoustic waves (Harris, 2002) is also available for CWA on-site detection. The CWAs are adsorbed reversibly onto the arrayed cells of the specific liquid phase polymer, and the acoustic wave numbers change according to the mass increase due to CWA adsorption. CWAs can be detected and discriminated by analyzing the respective wave number changes (Harris, 2003; Grate, 2000); discriminating power is increased by increasing the number of polymer cells. Portable detectors adopting arrayed SAW devices are commercially available. ChemSentry, manufactured by BAE Systems (USA), adopts 10 different polymer cells and identifies CWAs as "NERV" for nerve agents, "BL" for blister agents, and "BLOOD" for blood and choking agents. The LOA is rather high, the response and recovery time is long, and the number of false positives is high (Matsushita et al., 2005). This chemo-adsorptive sensor technology provides the possibility of increased discrimination by adopting arrayed cells, but because of the strong adsorption of CWAs, disturbs quick and reversible binding on the polymer arrays.

57.4.3 Ion mobility spectrometry method

The IMS instrument is most frequently used for military and civil defense missions to detect not only CWAs (Makinen et al., 2010), but also explosives and illicit drugs (Eiceman and Stone, 2004; Eiceman and Karpas, 2013). The drawn air sample is ionized commonly by a $\beta-$ emitter or through corona discharge under atmospheric pressure, and the ionized water-cluster molecules (reactant ion peak, RIP) react with CWA molecules in the reaction region. The generated cluster ions (positive or negative) periodically traverse through the drift region and are detected on the collector. The ion mobility depends on their charge and molecular mass over cycles of several milliseconds (Fig. 57.4). CWAs are recognized according to ion mobility of the resulting peak or peaks, and semiquantified according to the ion peak height (St Louis et al., 1990). In the positive ion mode, a protonated water cluster combines with the targets; in the negative ion mode, a water and carbon dioxide cluster attached to oxygen combines with the targets, and ammonia or organic solvents are introduced as dopants (Puton et al., 2008) into the drift region, which raises the sensitivity and discriminating power. Easily ionizable nerve agents show high sensitivity, while weakly ionizable blister agents do not. Low-molecular-weight blood and choking agents do not produce characteristic cluster ions; therefore, detection sensitivity is low. Because of atmospheric pressure ionization, the devices are manufactured to be rather compact, and their response times are fast. However, the resolution of the produced target ions is low compared to MS, leading to frequent false positives by many types of organic solvents. To raise the sensitivity and accuracy, the ionization mechanism has been improved using electrospray, laser desorption, matrix-assisted laser desorption, and the development of new hardware (Kolakowski and Mester, 2007). MS machines are combined with an IMS instrument for molecular assignment of the produced ions (Kanu et al., 2008). Field-portable instruments based on field asymmetric IMS (FAIMS) and differential mobility spectrometry (Guevremont, 2004) are now commercially available (Chemring Group, 2019). A typical FAIMS result for HD measured by an Owlstone FAIMS machine (Owlstone Inc., 2019) is shown in Fig. 57.5.

An aspiration-type device is based on discrimination by the pattern recognition of several IMS cells of different ion mobilities and polarities (Utriainen et al., 2003; Zimmermann et al., 2007). Environics Oy (based in Mikkeli, Finland) manufactures M90 (type D1-C), an aspiration-type 160 μCi ^{241}Am-bearing IMS, adopting six IMS cells and one semiconductor cell, which provides vapor detection of GB, GD, GA, and GF (LOA: sub-mg/m^3) as a NERVE mode alarm with a false-positive alarm against vapors of phosphorus stimulants such as dimethyl methylphosphonate. HD, L1, and HN 3 vapors (LOA: several mg/m^3) cause a BLISTER mode alarm; however, HD stimulants such as 2-chloroethyl ethyl sulfide vapor also cause a false-positive alarm. AC or CK gas shows a

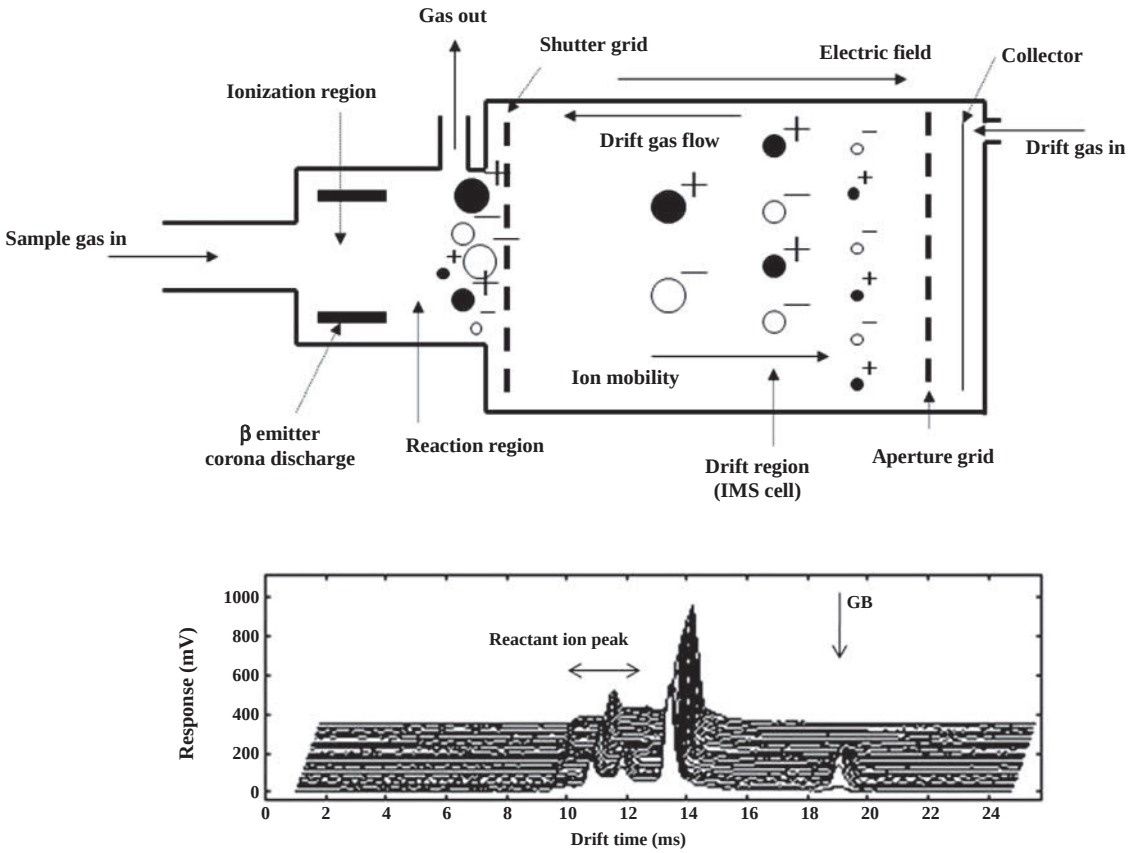

FIGURE 57.4 Ion mobility spectrometry. Detection mechanism and an exemplified spectrum. SABRE4000 (Smiths Detections Ltd., ionization ^{63}N) detected GB.

false BLISTER alarm. CG and CL cause a BLOOD mode alarm. The LOA is rather low for volatile CWAs and high for gaseous CWAs, the response and recovery time is short, and the frequency of false positives is moderate (Kishi et al., 2010). An aspiration-type IMS, ChemPro100i, from the same Finnish company, adopts 16 IMS cells and one semiconductor cell (Zimmermann et al., 2008), providing similar recognition (Environics Oy, 2019).

LCD-3.2E, a corona discharge-type short drift tube IMS instrument, developed by Smiths Detection (based in London), is a useful detector showing two types of alarm: "G" for nerve agents, and "H" for other CWAs (Sekioka et al., 2007). The advanced version (LCD 3.3) provides an agent-name alarm (Smiths Detection, 2019a). This machine adopts an ammonia dopant, raising the sensitivity and discriminating power. Maintenance requires that the sieve pack be frequently exchanged for proper operation. Tables 57.2 and 57.3 show the LOA, response and recovery times, and interference toward CWAs (Satoh et al., 2015). SABRE 4000, also manufactured by Smiths Detection, is a long-drift tube (high-resolution) IMS providing an agent-name alarm. As shown in Tables 57.4 and 57.5, the LOA is rather low, the response and recovery time is short, and the frequency of false positives is low (Yamaguchi et al., 2010). AIRSENSE (based in Schwerin, Germany) manufactures GDA2, a multisensor system consisting of an IMS, a semiconductor, a metal oxide, and a PID, enabling identification and quantification of not only CWAs, but also TICs (AIRSENSE Analytics, 2019).

Discriminative detection of nerve agents and blister agents is possible because the positive marker ions formed from such agents are well separated. However, detection of gaseous CWAs, blood agents, and choking agents, is comparably difficult. The negative maker ions formed from such agents cannot be separated from the RIP under the ionization of β-emitter or corona discharge, because the RIP in the negative ion mode is composed of various ions with a relatively wide peak shape. Atmospheric electron emission is another ionization where only superoxide anion is produced as the negative RIP, and specific marker ions are formed from gaseous CWAs and well separated from the RIP (O_3^-), enabling discriminative detection (Seto et al., 2019). Schematics of the atmospheric electron emission device and the typical spectra are shown in Fig. 57.6.

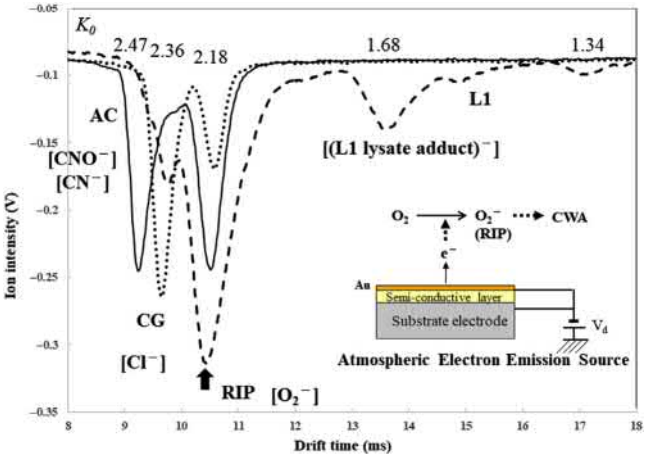

FIGURE 57.6 Negative ion mode ion mobility spectra of hydrogen cyanide (9 mg/m^3, solid line), phosgene (442 mg/m^3, dotted line) and lewisite 1 (50 mg/m^3, broken line) with atmospheric electron emission ionization. The charging voltage for electron emission, the drift length, and voltage of the IMS instrument were 20 V, 7 cm, and 1981 V, respectively. The K_0 values and the chemical structures for the separated ion peaks are shown.

57.4.4 Vibrational spectroscopy

The FT/IR instrument detects and identifies CWAs by noninvasively and instantly measuring the infrared spectrum of the air sample (Mukhopadhyay, 2004). Because the absorption coefficients of the IR band peaks are relatively low, the light path lengths should be long to raise the detection sensitivity. Considering the interference of water and carbon dioxide, their characteristic absorbance peaks in the low-wave number region (fingerprint region) are used as specific markers. Open path FT-IR has been developed to detect CWAs spread in the field by measuring IR spectra in the open space between the detector and the retroreflector at the distal end, achieving the path length over 100 m (Griffiths et al., 2009). Alternatively, the multiple reflection method has been used to lengthen the light path in the sample cell to achieve a path length of about 10 m, and the portable automated machines are now commercially available (Gasmet, 2019). MKS Instruments (based in Andover, Massachusetts) provides an automated FT-IR machine, AIRGARD (MKS Instruments, 2019), which adopts about 10 m multiple reflection path length gas cell (0.4 L), high flow rate (6–10 L/min) and rolling background algorism, enabling highly sensitive identification (LOD: around 0.1 mg/m^3) without background interference (Phillips and Tan, 2010). Fig. 57.7 shows the FT-IR operational flow and the detection result of GB. A sensitive method is also reported using an attenuated total reflectance device by adsorbing the target analytes from the vapor onto the solid-phase microextraction adsorbent (Bryant et al., 2007). Smiths Detection provides a portable FT-IR instrument, HazMatID (Smiths Detection, 2019b), which uses a diamond sensor and an extended onboard spectral library containing spectra for many organic compounds, including CWAs and suspected white powder materials.

A handful of Raman spectroscopy instruments are commercially available to match the identification of unknown liquid and solid samples in the forensic and homeland security regions (Izake, 2010), including First Defender (Thermo Scientific, 2019). Rigaku Corporation (based in Tokyo, Japan) provides a Raman spectrometer, ProgenyResQ CQL, which allows the quick identification of unknown solid and liquid chemicals using a vast sample library, including explosives, TICs, CWAs, white powders, and narcotics. This machine adopts a laser excitation of 1054 nm, preventing interference from fluorescent compounds (Rigaku Corporation, 2019). As shown in Fig. 57.8, 1054 nm excitation is superior to 785 nm excitation in identifying CWAs. In 785 nm excitation, Raman spectra are ill-shaped for HN3 and a mixture of L1 and gasoline (Kondo et al., 2018)

57.4.5 Gas chromatography

The GC instrument detects CWAs by measuring the peak response appearing on the GC column (Makas and Troshkov, 2004). CWAs are distinguished on the basis of retention time and their detectability by specific detection devices (Henry, 1997). Combined with an automated air collection–thermal desorption system, GC provides very sensitive detection (lower than μg/m^3) of nerve agents and blister agents over a 10-min. cycle. O. I. Corporation (based in Pelham, Alabama) manufactures the movable GC-based MINICAMS (O.I. Corporation/Xylem Inc., 2019). GC can be hyphenated with other detection systems, such as SAW (Williams and Pappas, 1999) and IMS (Buryakov, 2004; GAS, 2019), enabling it to be used to detect CWAs while having a compact body and field portability.

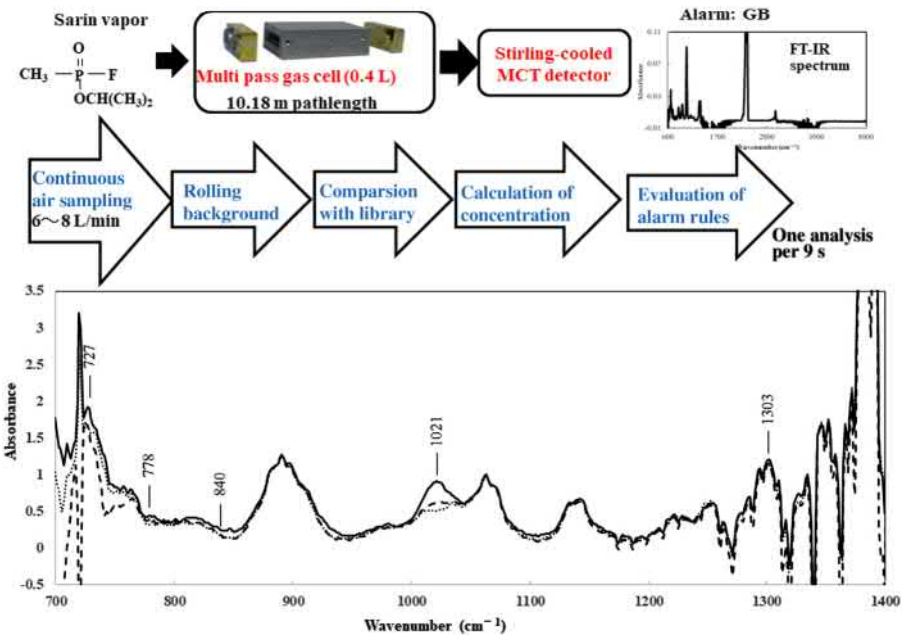

FIGURE 57.7 (A) Portable Fourier-transformed infrared spectroscopy instrument, AIRGARD; (B) operational flow; (C) fingerprint regions of infrared spectra of sarin in *n*-hexane 1320 mg/m^3 in air. Dotted line: sarin 0 mg/m^3; broken line: sarin 0.66 mg/m^3; solid line: sarin 2.2 mg/m^3.

57.4.6 Mass spectrometry

By miniaturizing the laboratory-type MS instrument and making it portable and resistant to mechanical shock, the machine can be used to detect CWAs in the field (Wise and Guerin, 1997; Smith et al., 2011a). MS provides high-resolution power, but to maintain a vacuum, the device must be large, complicating its operation. Electron ionization is usually used because of the benefit of abundant mass spectra data libraries availability (Virkki et al., 1995). On-site MS adopts a hydrophobic membrane inlet system to eliminate oxygen and nitrogen from the ionization region. The adsorbed CWAs are next introduced to the ionization region. The small molecules and strong adsorptive compounds cannot be detected by this ionization-type MS. Vapor forms of CWAs can be directly measured by atmospheric pressure chemical ionization (APCI) MS technologies such as direct analysis in real time (DART) (Nilles et al., 2009), selective ion flow MS (Francis et al., 2009), chemical ionization reaction time-of-flight MS (Cordell et al., 2007), and plasma desorption ionization MS (Iwai et al, 2015). The Riken group (based in Wako, Japan) and the author have developed an elemental analytical system using an electron cyclotron resonance ion source MS to detect CWAs (Urabe et al., 2014).

GC-MS technology can also be downsized for field use (Henry, 1997). Resistive column heating (low thermal mass) technology (Sloan et al., 2001) provides rapid on-site confirmation of a wide range of CWAs. Inficon (based in Bad Ragaz, Switzerland) manufactures Hapsite, a field-portable GC-MS instrument (INFICON Co., Ltd, 2019b). Vapor is withdrawn for 30 s into the Tenax preconcentration system and thermally desorbed into a nonpolar capillary column with an elevated temperature control; the separated components are finally analyzed using an electron ionization quadrupole mass spectrometer. GB, GD, GA, and HD are detected and identified within 12 min, with postulated LOD values of 0.2, 0.5, 8, and 0.3 μg/m^3 (Sekiguchi et al., 2006). The new type of the same instrument, Hapsite ER, adopting Tri-Bed TA microconcentration, provides excellent determination against CWAs (Fig. 57.9). Even gaseous CWAs can be detected by direct gas analysis by bypassing the microconcentration and GC separation (Nagashima et al., 2015). For nonvolatile nerve agents, VX and RVX, the VX-G conversion tube is used to convert VX and RVX to volatile ethylsarin and isobutylsarin by fluoridation reaction (Ohrui et al., 2017). PerkinElmer Inc. (based in Waltham, Massachusetts) produces a field-portable GC-toroidal ion-trap MS machine, Torion T-9 with a solid-phase microextraction sampling inlet for CWA and related compound determination in water samples (PerkinElmer Inc., 2019; Contreras et al., 2008; Smith et al., 2011b).

57.4.7 Other sensor technologies

As for sensor technologies, chemical sensors can be used for detecting CWAs. Electrochemical sensors composed of multiwalled carbon nanotubes on indium tin oxide surfaces in connection with ferrocene–amino acid conjugates have been developed for detecting nerve agent

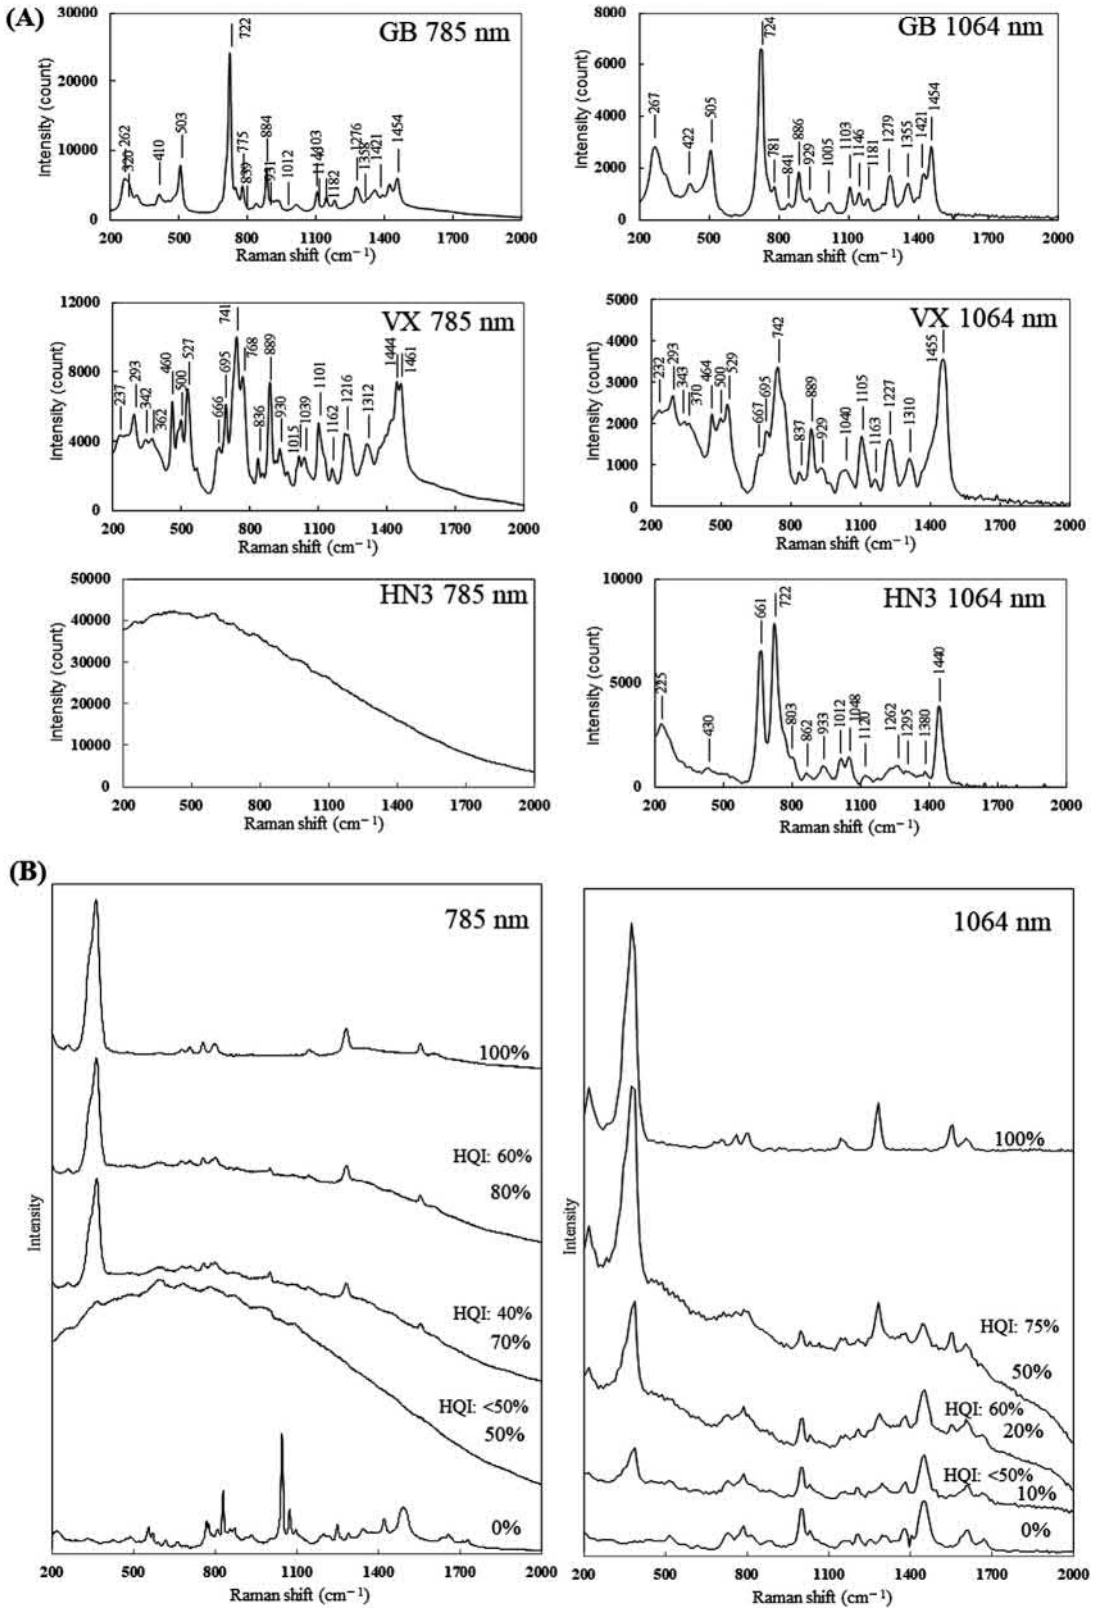

FIGURE 57.8 Raman spectra of chemical warfare agents. (Upper chart) Raman spectra of neat sarin, VX and nitrogen mustard 3 measured with the excitation of 785 and 1064 nm. CWAs were measured using a HAPSITE ER. GB: 34 mg/m^3; GD: 10 mg/m^3; GA: 22 mg/m^3; GF: 14 mg/m^3; HD: 2.4 mg/m^3; HN1: 6.5 mg/m^3; HN2: 12 mg/m^3; HN3: 7.4 mg/m^3; CN: 2 mg/m^3; PS 3.7 mg/m^3; IS: internal standard (BPFB). Analytical conditions: microtrap desorption, Tri-Bed TA 15 mg, 5 s at 60°C, to 180°C; column, low thermal mass DB-1 0.25 mm × 15 m, 1 μm thickness), flow: nitrogen 2 mL/min; oven: 60°C (1 min), 6°C/min to 80°C, 12°C/min to 120°C, 26°C/min to 180°C (2 min); temperatures, membrane 80°C, valve oven 70°C, probe 60°C, NEG 400°C; MS, electron ionization, $m/z = 45-300$, 70 eV, 300 μA, 0.79 s/scan.

degradation products and related compounds in water (Khan et al., 2008). Electrochemical sensors developed by Riken Keiki Ltd. (based in Tokyo, Japan) provide sensitive and specific detection of gaseous CWAs (Riken Keiki Co., Ltd, 2019), and newly developed gold nanoparticle dispersed carbon fiber electrodes to selectively detect blistering agents in cooperation with Kumamoto University (in Kumamoto, Japan) and our group (Matsuura et al., 2010). The field-portable instrument (SC-90, 1.9 kg) was able to detect HD vapor with an LOA of 1.5 mg/m^3.

Biosensors utilizing CWA target enzymes have been developed over the past decades (Guerrieri et al., 2005; Zayats et al., 2003; Walker and Asher, 2005). Acetylcholinesterase (AChE) is fixed on the sensor chip for nerve agent detection; by reaction with nerve agents, substrate hydrolysis velocity is lowered because of enzyme inhibition (Anzai, 2015), and the resulting electric response from a reaction, such as the formation of hydrogen peroxide by choline oxidase, can be monitored (Palleschi et al., 1992). A biosensor device utilizing organophosphorus hydrolase (Russell et al., 1999; Karnati et al., 2007) and a chemical sensor utilizing nerve agent-reactive fluorescent reagent (Zhang and Swager, 2003) have also been developed. Sanders et al. developed a unique, remote, tissue-based biosensor for the field detection of GB, GD, and HD vapors by photosynthetic fluorescence induction measurements with target cyanobacteria (Sanders et al., 2001). However, these types of sensors are still not available for practical use. To detect AC, tyrosinase is fixed onto glassy

carbon; after increasing the concentration of AC on the colloidal mineral, its inhibition is monitored by electrochemically measuring polyphenol hydrolysis (Shan et al., 2004). Nerve agents and blister agents easily hydrolyze to form characteristic compounds, and the hydrolyzed CWAs can be analyzed in wet systems utilizing μTAS capillary electrophoresis (Wang, 2004). A field-portable multiple biosensing instrument has been developed for detecting complex hazardous material of nerve agents, biological toxin ricin, and *Bacillus anthracis* bacteria (Saito et al., 2018), where GB and VX in the aerosol are collected with mist by a cyclone unit, microfluidically delivered to the reaction cell mixed with the recombinant human AChE and acetylthiocholine (substrate), and the remaining substrate is measured electrochemically on screen-printed carbon electrode. Nine ng/m^3 GB could be detected.

57.5 Comparison of existing on-site detection technologies

In terms of required detection performance criteria for use by first responders, the detection sensitivity, detection accuracy, response time, recovery time, and operation are selected; among the detection equipment examined, these items are compared in Table 57.6. The numerical data are derived from our experiments. The evaluations are grouped into three categories (OK, Δ, X). A perfect device cannot be assigned that meets all the CWA detection requirements. Low sensitivity, false alarms, and strong adsorption of CWAs on devices are particularly serious problems. The gas detection tube system, which permits the detection of a wide range of CWA vapors, suffers from tedious operation and a slow response. The IMS-based detectors, which permit rapid and sensitive detection of nerve and blistering agents, show low sensitivity to gaseous agents and false positives in response to some compounds. The FPD-based detector, which permits rapid and sensitive detection of nerve agents and HD, gives false negatives when exposed to nonphosphorus and sulfur CWAs. The PID-based detector shows nonspecific and low detection sensitivity. The SAW-based detector does not permit sensitive detection of CWAs. The FT-IR instrument, which permits noninvasive and constant detection, shows moderate sensitivity. The GC-based detector with a concentration system, which permits sensitive detection of nerve agents and blister agents, suffers from tedious operation and a slow response. The GC-MS-based detector, which permits sensitive identification of almost all kinds of CWAS, suffers from complicated operation and slow response. Nonvolatile vomit agents and lachrymators cannot be detected using any of these equipments.

57.6 Development of new on-site detection technologies

Fig. 57.10 shows a performance map of on-site CWA detection equipment distributed by physical properties of the agents. CWAs are represented in terms of volatility and molecular weight, and the target agent territories and drawbacks of the detection equipment can be noted. This figure appears to show that the detection of gaseous agents and nonvolatile CWAs should be improved. For achieving a more sensitive and continuous monitoring of both volatile and nonvolatile CWAs, the National Research Institute of Police Science, in coordination with Hitachi Ltd., (based in Tokyo, Japan) has developed on-site detection methods utilizing counter-flow introduction (CFI) APCI MS (see Fig. 57.10). CFI-APCI-MS technology provides soft ionization of the suctioned CWAs by corona discharge (APCI) and introduction of only the produced primary target ions into the mass analyzer; the secondary interfering ions are excluded from the ionization region (CFI). The CFI-APCI technology is superior in terms of noise ion reduction, realizing ultrasensitive detection. Adopting an ion-trap mass analyzer (MS^n function), almost all types of CWAs, including vomit agents and lachrymators, are detected within several seconds with the LOD in the sub-μg/m^3 area (Seto et al., 2014; Okumura et al., 2015) (DS-1000; Fig. 57.11).

The monitoring tape method (Nakano and Nagashima, 2001) detects hazardous gases by spectrophotometrically measuring the color change on the tape or tab impregnated with specific reagents after reacting with the suctioned air sample (Fig. 57.12). The machines using this technology, developed by Riken Keiki Ltd., are commercially available. A diffusion-type apparatus is used as the portable machine, and by selecting the appropriate tab, the machine can monitor the desired gases. A transmission-type apparatus is used as the fixed monitor machine, and provides more sensitive detection. Riken Keiki and the author have developed a three tab-arrayed detector (FP-100), whereby three types of gaseous CWAs can be detected simultaneously and specifically with LODs lower than 1 mg/m^3 within 1 min. Blood agents (such as AC, CK, and arsine) and choking agents (such as CL and GC) and L1 can be detected.

57.7 Concluding remarks and future directions

A recommended on-site detection system for considering on-site CWA detection requirements and the status of present detection technologies is shown in Fig. 57.13. For portable detectors utilized by first responders, a combination of IMS instrument, a machine employing the arrayed monitoring tape method, and an electrochemical sensor is desirable. This combination encompasses the detection of

MS EI	X	Δ	Δ	X	Δ	OK	OK	OK
						minutes	minutes	portable

The values depicted are limits of alarm and respective times experimentally measured by the author's group.
[a]*OK: acceptable; Δ: improvement is required; X: not acceptable.*
[b]*Ionization: atmospheric electron emission.*
[c]*Direct gas analysis bypassed of GC separation.*
[d]*VX and RVX detection using VX-G conversion tube.*

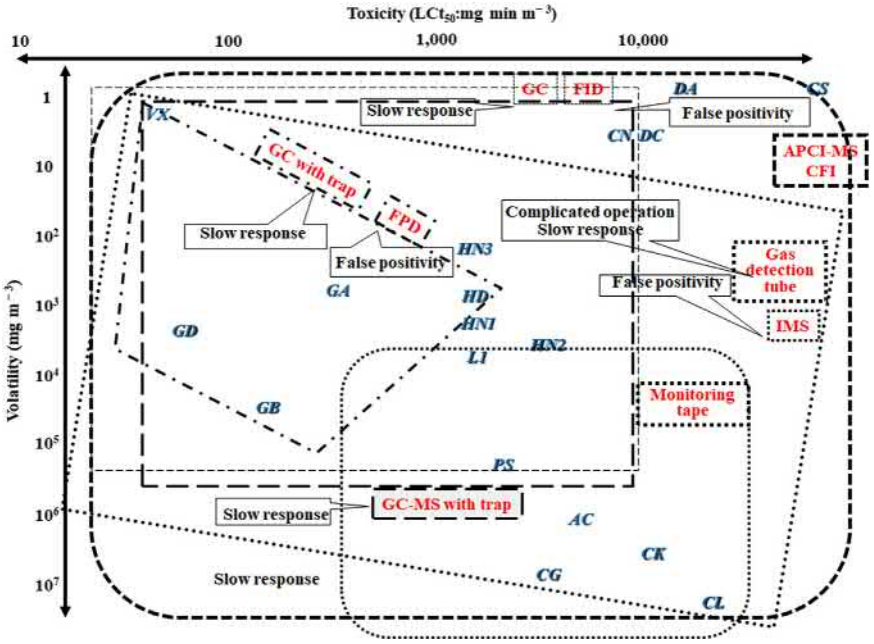

FIGURE 57.10 Performance of on-site CWA detection equipment in terms of target toxicities and volatilities. CWAs are shown in italics. The acceptable detection boundaries achieved for appropriate technologies are shown. Particular drawbacks for certain technologies are also described. *Reproduced with permission from Seto, Y., Sekiguchi, H., Maruko, H., et al., 2014. Sensitive and comprehensive detection of chemical warfare agents in air by atmospheric pressure chemical ionization ion trap tandem mass spectrometry with counter-flow introduction. Anal. Chem. 86, 4316–4326.*

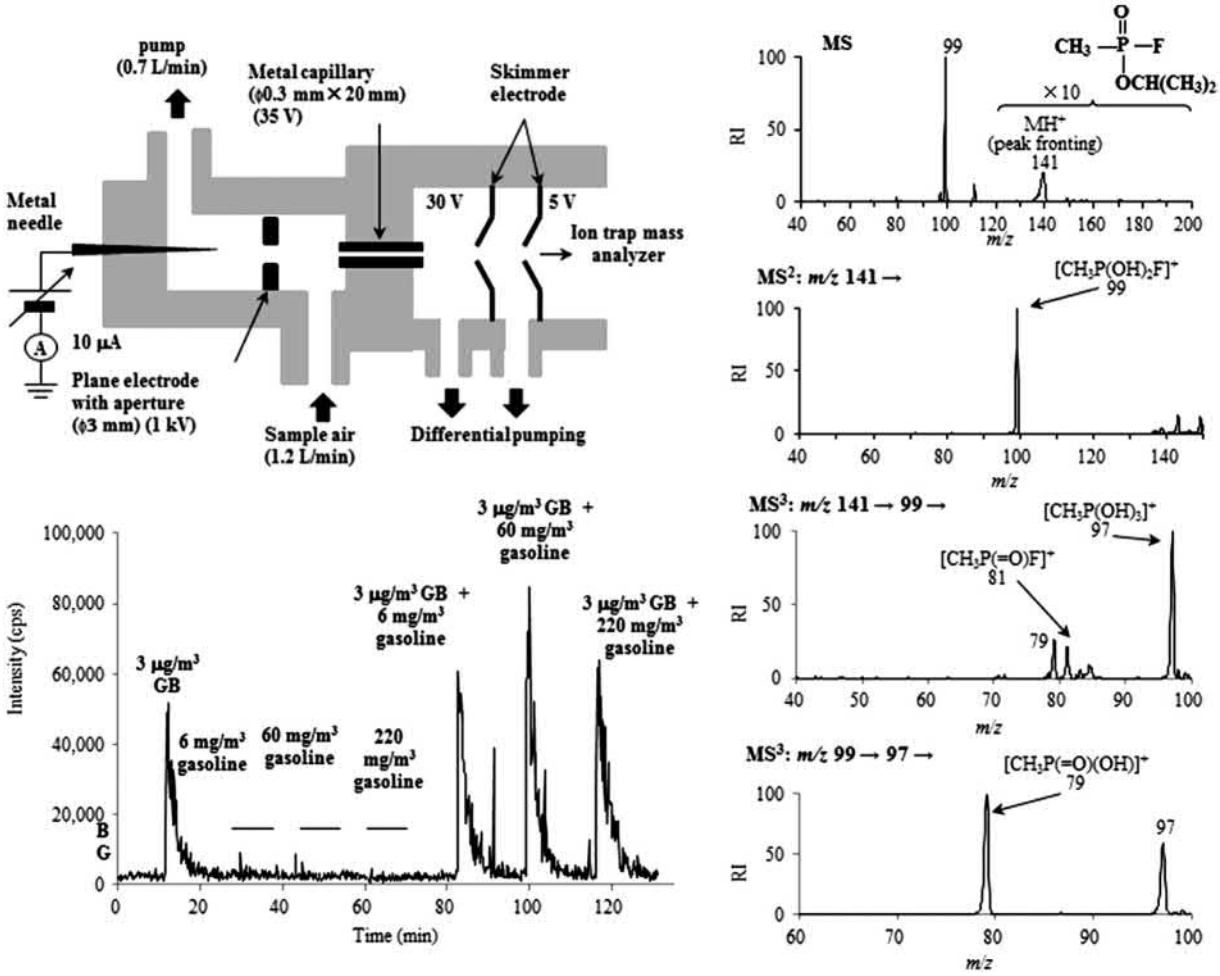

FIGURE 57.11 Counter-flow introduction/atmospheric pressure chemical ionization mass spectrometer. (Left upper) Structure of ionization chamber; (left lower) signal time response for sarin by MS^3 ($MH^+ \rightarrow m/z$ 99 $\rightarrow m/z$ 97) for sample air introduction with and without sarin and gasoline vapors; (right) MS^n mass spectra for sarin.

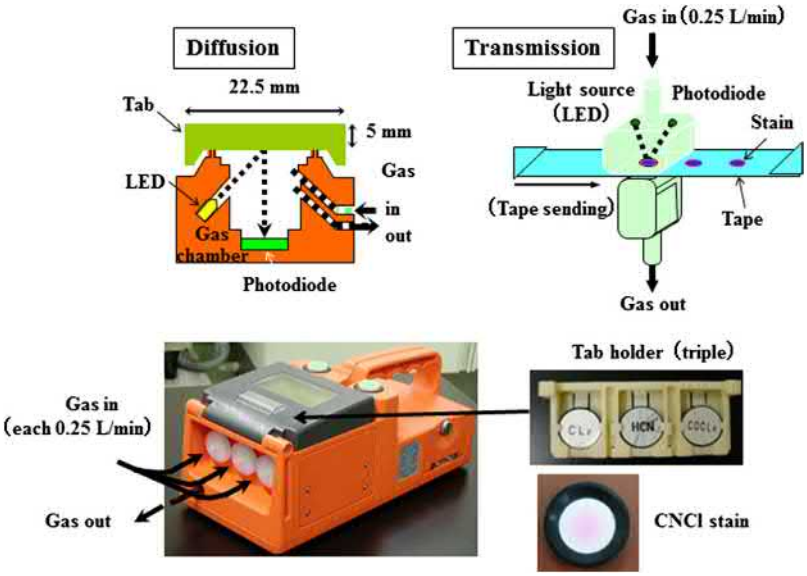

FIGURE 57.12 Monitoring tape method. Schematic detection mechanism of diffusion (upper left) and transmission (upper right) types of apparatus and arrayed diffusion-type detector (lower).

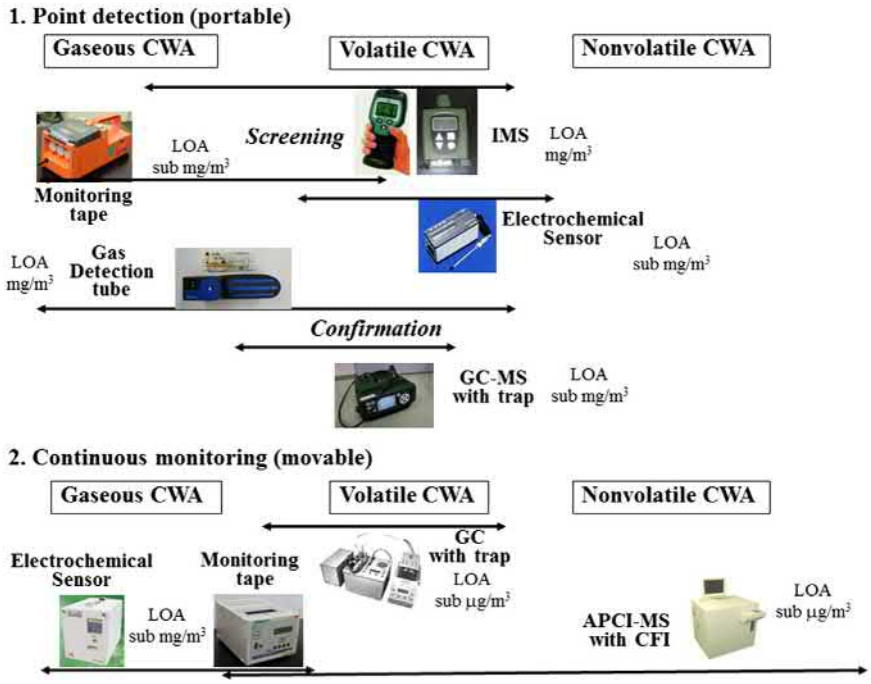

FIGURE 57.13 Recommended combinations of on-site detection equipment for point detection and continuous monitoring equipment for gaseous CWAs (blood agents, choking agents), volatile CWAs (nerve agents, blistering agents), and nonvolatile CWAs (vomiting agents, lachrymators). The acceptable detection boundaries for the technologies are shown, along with the LOA values.

CWA forms from the gaseous to the volatile state. GC-MS and gas detection tubes further assist in identifying the detected CWAs. Nonvolatile CWAs are still out of the detection range of portable machines. For movable detectors, highly sensitive detection equipment is necessary; the combination of CFI-APCI-MS and a lined set of machines using the transmission-type monitoring tape method or electrochemical sensor is almost ideal, handling all the CWAs with the required sensitivity. It is anticipated that new sensing technologies will be developed in the future that will overcome the problems of large size, false positives, low sensitivity, and narrow range of detection.

Chapter 58

Neuropathy target esterase as a biomarker and biosensor of delayed neuropathic agents

Rudy J. Richardson[1], John K. Fink[2], R. Mark Worden[3], Sanjeeva J. Wijeyesakere[4,*] and Galina F. Makhaeva[5]

[1]*Department of Environmental Health Sciences, Department of Neurology, Center of Computational Medicine and Bioinformatics, University of Michigan, Ann Arbor, MI, United States,* [2]*Department of Neurology, University of Michigan, Ann Arbor, MI, United States,* [3]*Department of Biomedical Engineering, Department of Chemical Engineering and Materials Science, Michigan State University, East Lansing, MI, United States,* [4]*Department of Environmental Health Sciences, Department of Microbiology and Immunology, University of Michigan, Ann Arbor, MI, United States,* [5]*Institute of Physiologically Active Compounds, Russian Academy of Sciences, Chernogolovka, Russia*

58.1 Introduction

Delayed neuropathic (DN) agents represent a new functional class of potential organophosphorus (OP) threats that have heretofore not been used in warfare or terrorist acts. Nevertheless, efforts should continue for the further development of faster methods for specific detection of DN agents in the environment and in biological samples (Kurochkin et al., 2009; Makhaeva et al., 2009). Moreover, it is vital to develop effective medical countermeasures against DN agents for at least four reasons: (1) These chemicals can readily be produced by rather straightforward modifications of the structures of conventional nerve agents or OP insecticides. (2) Warning signs and symptoms of toxicity may be lacking until 1−4 weeks after exposure, when the permanent sensory deficits and paralysis associated with OP compound−induced delayed neurotoxicity (OPIDN) ensue. (3) There are no established means of preventing or treating OPIDN. (4) A successful attack on a population with DN agents would produce an epidemic of debilitating neurological illness. In addition to the damaging effects of the disease itself, such an event would precipitate widespread fear and alarm akin to that of the polio epidemics of the 1950s and as recently seen on a much smaller scale with outbreaks of the polio-like illness, acute flaccid myelitis (Cartwright and Wessol, 2019).

This chapter begins with a review of current understanding about the chemistry and mechanism of action of DN agents. It then describes how existing knowledge can be applied to generate biomarkers and biosensors for discriminating between conventional and DN agents. The chapter ends by indicating future work needed to address the potential threat of DN agents and the promise of NTE and OPIDN research for understanding, preventing, and treating other neurodegenerative diseases, such as amyotrophic lateral sclerosis (ALS).

58.2 Organophosphorus compounds

58.2.1 Conventional nerve agents versus delayed neuropathic agents

Conventional nerve agents, such as sarin and soman, are OP compounds of pentavalent phosphorus that are well known as threats in the context of warfare and terrorism (Sidell and Borak, 1992). These substances produce acute cholinergic toxicity and death via inhibition of acetylcholinesterase (AChE) in the central and peripheral nervous systems (Marrs et al., 1996).

Unlike conventional nerve agents, DN agents produce permanent neurological dysfunction in the form of OPIDN rather than cholinergic toxicity and death (Richardson and Makhaeva, 2014; Richardson et al., 2013). Like conventional nerve agents, DN agents are OP compounds of pentavalent phosphorus that are readily synthesized, but they are designed to inactivate neuropathy target esterase

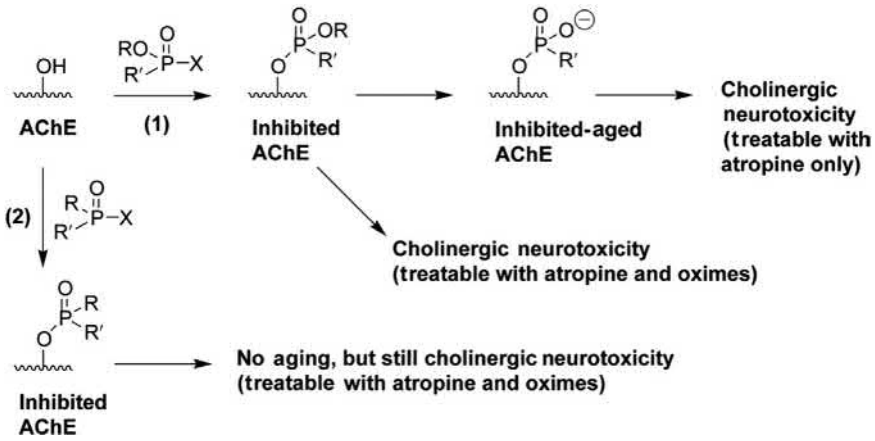

FIGURE 58.1 Reaction of acetylcholinesterase (AChE) with an organophosphonate in pathway (1) yields a phosphonylated (inhibited) enzyme, which can undergo net loss of an R-group to yield an inhibited-aged enzyme. Inhibition alone produces cholinergic toxicity that is treatable with both atropine to counteract excess acetylcholine at muscarinic acetylcholine receptors and oximes to reactivate AChE. Aging does not change the type of toxicity, but it renders the enzyme intractable to reactivation, so that treatment with oximes becomes ineffective. Reaction of AChE with an organophosphinate in pathway (2) yields a phosphinylated (inhibited) enzyme and produces cholinergic toxicity, but because of the stability of the C−P bonds linking the R- and R′-groups to phosphorus, the phosphinyl moiety on AChE does not undergo aging, so that both atropine and oximes can be used in therapy. R, R′, substituted or unsubstituted alkyl or aryl groups, which can be different or equivalent. X, primary leaving group, for example, fluoride. *Reproduced with permission from Richardson, R.J., Makhaeva, G.F., 2014. Organophosphorus compounds. In: P. Wexler (Ed.), Encyclopedia of Toxicology, third ed., vol. 3. Elsevier, Ltd., Oxford, pp. 714−719.*

(neurotoxic esterase, NTE) in preference to AChE (Makhaeva et al., 2012, 2013; Wu and Casida, 1995). Because of this selectivity, DN agents may elicit little or no warning signs of acute cholinergic toxicity, so that victims of DN agents might not know they have been exposed until OPIDN develops 1−4 weeks later.

Cholinergic toxicity from OP compounds can be elicited solely by inhibition of AChE (Richardson, 2018). However, the AChE−OP conjugate can undergo an additional reaction ("aging") entailing loss of an OP ligand (side chain or R-group) to yield a negatively charged phosphoryl adduct on the active site serine. Although the aging reaction of organophosphylated AChE has practical implications for therapy, it does not change the qualitative nature of the toxicity (Fig. 58.1).

In contrast to the situation with AChE inhibitors and cholinergic toxicity, decades of toxicological research have shown that inhibition of NTE on its own is apparently insufficient to produce OPIDN. Inhibition is the obligatory first step, but it appears that this must be followed by aging of the NTE−OP conjugate in order to trigger axonal degeneration (Fig. 58.2) (Moser et al., 2019; Richardson and Makhaeva, 2014; Richardson et al., 2013).

Consequently, interactions of NTE with DN agents certainly result first in a loss of physiological function of enzymatic activity. However, the seeming dependence of OPIDN on the aging reaction implies a gain of toxic function resulting from a particular chemical modification of the protein rather than, or in addition to, loss of NTE activity. However, neurodegenerative diseases can involve both processes, as exemplified by loss of normal function through protein misfolding and gain of toxic function via the deleterious action of the misfolded proteins (Winklhofer et al., 2008).

Thus, DN agents are distinct from conventional nerve agents in several respects. Furthermore, especially in view of their ease of synthesis, absence of initial signs or symptoms of exposure, and lack of prophylactic or therapeutic measures, it is conceivable that rogue nations or terrorist groups might consider DN agents attractive as weapons of permanent incapacitation against military and/or civilian populations. Therefore, part of an effective chemical defense strategy is to develop methods for detecting DN agents and distinguishing them from conventional nerve agents. This can be done by exploiting the sensitivity and selectivity afforded by appropriate biomarkers and biosensors (Kohli et al., 2007a, 2010, 2014; Makhaeva et al., 2003; Malygin et al., 2003; Srivastava et al., 2010; Sigolaeva et al., 2010, 2013).

58.2.2 Organophosphorus compounds of pentavalent versus trivalent phosphorus

In this chapter, DN agents are defined as OP compounds of pentavalent phosphorus that produce OPIDN. Examples shown in Fig. 58.3 are ethyl *n*-octylphosphonofluoridate (EOPF) and 2-(2-methylphenoxy)-4H-l,3,2-benzodioxaphosphorin-2-oxide, abbreviated as [2-(2-methylphenoxy)-BDPO] or CBDP, the active metabolite of the archetypal DN agent, tri-*o*-cresyl phosphate (TOCP) (Wu and Casida, 1995). TOCP was the causative agent of major outbreaks of OPIDN affecting over

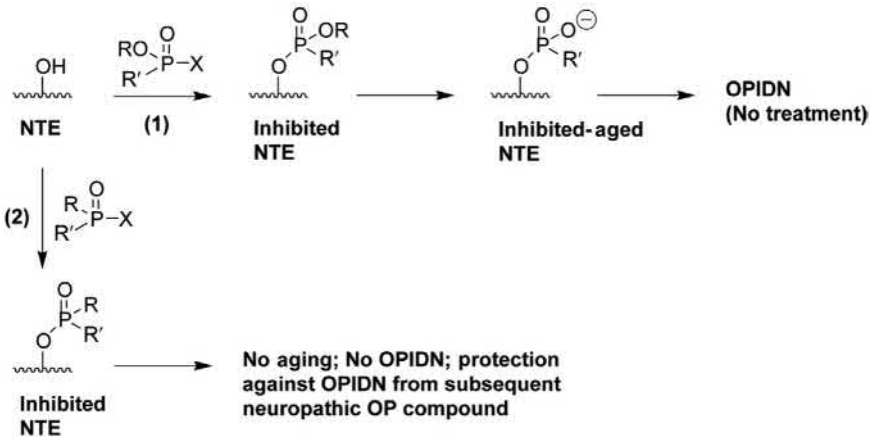

FIGURE 58.2 Reaction of neuropathy target esterase (NTE) with an organophosphonate in pathway (1) yields a phosphonylated (inhibited) enzyme, which can undergo net loss of an R-group to yield an inhibited-aged enzyme. Inhibition alone does not produce organophosphorus (OP) compound-induced delayed neurotoxicity (OPIDN); both inhibition and aging are required, and there is no treatment for the neuropathy. Reaction of NTE with an organophosphinate in pathway (2) yields a phosphinylated (inhibited) enzyme, but because of the stability of the C−P bonds linking the R- and R′-groups to phosphorus, the phosphinyl moiety on NTE does not undergo aging, so that OPIDN does not occur. Inhibition of NTE with a nonaging inhibitor is not biologically inert—it protects against subsequent exposures to neuropathic (ageable) NTE inhibitors. R, R′, substituted or unsubstituted alkyl or aryl groups, which can be different or equivalent. X, primary leaving group, for example, fluoride. *Reproduced with permission from Richardson, R.J., Makhaeva, G.F., 2014. Organophosphorus compounds. In: P. Wexler (Ed.), Encyclopedia of Toxicology, third ed., vol. 3. Elsevier, Ltd., Oxford, pp. 714−719.*

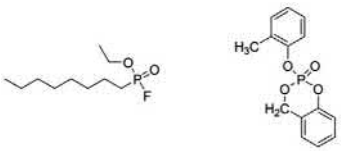

FIGURE 58.3 Examples of delayed neuropathic (DN) agents containing pentavalent phosphorus: ethyl *n*-octylphosphonofluoridate (EOPF) and 2-(2-methylphenoxy)-4H-l,3,2-benzodioxaphosphorin-2-oxide [2-(2-methylphenoxy)-BDPO or CBDP], the active metabolite of the archetypal DN agent, tri-*o*-cresyl phosphate (TOCP) (Wu and Casida, 1995).

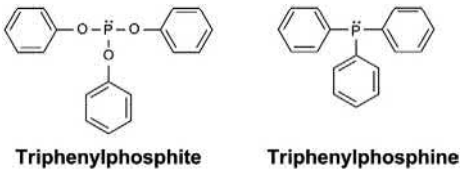

FIGURE 58.4 Examples of neuropathic organophosphorus compounds containing trivalent phosphorus: triphenylphosphite and triphenylphosphine (Eto, 1974).

70,000 people during the past ∼90 years (Johnson and Glynn, 2001); it has also been implicated recently in the etiology of aerotoxic syndrome (Heutelbeck et al., 2016; Schopfer et al., 2014) as well as ALS and other neurodegenerative diseases (Merwin et al., 2017).

However, there are also OP compounds of trivalent phosphorus that produce neurological injury. Examples shown in Fig. 58.4 are triphenylphosphite and triphenylphosphine. Comparatively little is known about the neuropathic trivalent OP compounds, but the clinical course and spatial−temporal pattern of lesions that they produce vary from OPIDN (Lehning et al., 1996), and the mechanisms of action of these compounds appear to differ from that of the DN agents. For example, triphenylphosphite produces a syndrome of delayed axonopathy and other neurodegenerative changes that could represent a variant of OPIDN, possibly via inhibition/aging of NTE (Abou-Donia, 1992; Fioroni et al., 1995; Padilla et al., 1987; Tanaka et al., 1990; Carlson and Ehrich, 2004). However, although triphenylphosphite inhibits NTE in vitro and in vivo, the nature of the adduct formed with NTE has not been elucidated, and the aging reaction of triphenylphosphite-inhibited NTE has apparently not been studied. Triphenylphosphine is another trivalent OP compound that produces delayed axonopathy, but its pathogenesis and mechanism appear to differ from those of triphenylphosphite or neuropathic OP compounds of pentavalent phosphorus. Among other differences, triphenylphosphine does not inhibit NTE in vitro or in vivo (Davis et al., 1999; Padilla et al., 1987).

With the foregoing in mind, the remainder of this chapter will deal exclusively with OP compounds of pentavalent phosphorus.

58.3 Organophosphorus compound−induced delayed neurotoxicity

OPIDN, also known as OP compound−induced delayed polyneuropathy (OPIDP), can be produced within 1−4

weeks of a single exposure to a DN agent. With compounds that are highly selective for NTE, the first week of this period can be clinically quiescent (Davis and Richardson, 1980; Lotti, 1992; Lotti and Moretto, 2005; Richardson and Makhaeva, 2014; Richardson et al., 2013). Pathogenesis involves progressive distal degeneration of sensory and motor axons in peripheral nerves and spinal cord tracts. Accordingly, symptoms begin with paresthesias in the distal extremities followed by sensory loss, ataxia, and flaccid paralysis. Once the disease is initiated, it advances inexorably. In keeping with its unknown mechanism of neurodegeneration, there is no cure or treatment other than general supportive therapy. Over a period of months to years, some regeneration of peripheral nerve axons may occur to reinnervate muscle. Nevertheless, the concomitant persistence of injury to descending inhibitory pathways in the spinal cord prevents complete functional recovery and permits only a shift from flaccid to spastic paralysis (Richardson and Makhaeva, 2014; Richardson et al., 2013).

Because of the insidious onset and permanent debilitating effects of OPIDN, it is essential to be able to predict the potential of a given OP compound to produce this disease as opposed to causing acute cholinergic toxicity. Furthermore, it is important to develop specific and stable biomarkers and biosensors of exposure to DN agents and devise countermeasures against them (Kohli et al., 2007a; Makhaeva et al., 2003; Malygin et al., 2003; Sigolaeva et al., 2010, 2013). To accomplish these goals, it will be necessary to acquire a level of mechanistic understanding of interactions between DN compounds and target macromolecules akin to what has been achieved for conventional (anti-AChE) nerve agents. Although there is much left to be learned about the pathogenesis and mechanism of OPIDN, sufficient knowledge exists about the apparent initiating events, that is, inhibition and aging of NTE, to provide a foundation for the development of biomarkers and biosensors of DN agents.

58.4 Neuropathy target esterase

58.4.1 Definition of neuropathy target esterase and its potential normal or pathogenic roles

NTE (UniProtKB/Swiss-Prot Q81Y17; PLPL6_HUMAN) has been categorized as a lysophospholipase (EC 3.1.1.5), owing to its ability to hydrolyze phosphatidylcholine to glycerophosphocholine (UniProt, 2019). It is also known as patatin-like phospholipase domain-containing protein 6, whose gene name is PNPLA6, because the catalytic domain of NTE encompasses a region with sequence homology to patatin, a phospholipase found in potatoes and other plants. Thus, it appears that NTE can function biochemically as a phospholipase, but its precise physiological role remains to be firmly established (Glynn, 2013; Richardson et al., 2013; Wijeyesakere and Richardson, 2010).

The human PNPLA6 gene encoding NTE has 37 exons and 25 transcripts (Ensembl, 2019). Thus, it is not surprising that the UniProt entry for human NTE lists four protein isoforms attributed to alternative splicing along with 10 computationally mapped potential isoforms (UniProt, 2019). Although UniProt has adopted isoform-4 with 1375 amino acid residues as the canonical sequence, this chapter defines human NTE as isoform-2, which is the sequence initially reported by Lush et al. (1998), consisting of 1327 amino acids and having a molecular weight without post-translational modifications of 146 kDa. The protein has a transmembrane domain near the *N*-terminus (residues 9−31) and three tandem putative cyclic nucleotide binding domains (residues 163−262, 480−573, and 597−689), in addition to the patatin domain (residues 933−1099), which contains the catalytic active site (Wijeyesakere et al., 2007; Wijeyesakere and Richardson, 2010).

The three-dimensional structure of NTE has not been experimentally determined, but a homology model of the patatin domain indicates that the active site serine (Ser^{966}) is located on a "nucleophilic elbow" characteristic of serine hydrolases (Wijeyesakere et al., 2007). Moreover, the model indicates that the catalytic site of NTE consists of a novel Ser-Asp catalytic dyad, as in patatin and mammalian cytosolic phospholipase A2 ($cPLA_2$), rather than the classical catalytic triad (Ser-Asp/Glu-His), as found in many serine hydrolases including AChE (Dodson and Wlodawer, 1998).

Mutations have been identified in NTE that are associated with a form of motor neuron disease (NTE-MND) (Rainier et al., 2008, 2011). Constructs containing NTE-MND mutations within the catalytic domain result in expressing NTE protein that has altered inhibition and aging kinetics (Hein et al., 2010a). In addition, cultured fibroblasts from human subjects with NTE-MND exhibit decreased NTE catalytic activity (Hein et al., 2010b). However, although fibroblasts from human subjects heterozygous for an insertion mutation that was expected to truncate the NTE protein had markedly reduced NTE activity (40%−43% of control), these subjects were asymptomatic, indicating that decreased NTE activity alone was insufficient to produce disease.

More recently, additional human NTE mutations have been cataloged that exhibit a variety of disease phenotypes, including spastic paraplegia, spinocerebellar degeneration, and photoreceptor degeneration resulting in blindness (Hufnagel et al., 2015; Kmoch et al., 2015; Topaloglu et al., 2014).

NTE was first identified as the presumptive target of neuropathic OP compounds in the initiation of OPIDN (Johnson, 1970). Its activity in cells and tissues is operationally defined as the enzymatic hydrolysis of the

nonphysiological substrate, phenyl valerate, which is resistant to inhibition by diethyl 4-nitrophenyl phosphate (paraoxon) and sensitive to inhibition by *N,N′*-diisopropylphosphorodiamidic fluoride (mipafox) under specified conditions of preincubation with inhibitors and subsequent incubation with substrate (Johnson, 1977; Kayyali et al., 1991; Makhaeva et al., 2007).

Because the full-length protein is difficult to isolate or produce, human recombinant *N*TE *est*erase domain (NEST) has been used as an NTE surrogate for studies in vitro that require pure protein rather than a crude preparation containing NTE (Kropp et al., 2004). NEST comprises residues 727−1216 of NTE; it has been shown to be the shortest segment of NTE that retains esterase activity. Moreover, the catalytic properties of NEST, including its response to OP inhibitors, closely resemble those of full-length NTE (Atkins and Glynn, 2000; Atkins et al., 2002; Kropp et al., 2004; Van Tienhoven et al., 2002). The catalytic activity of NEST has been shown to alter the fluidity of bilayer lipid membranes (Greiner et al., 2010), and NEST has been incorporated into a biosensor for the detection of DN agents (Kohli et al., 2007a, 2014).

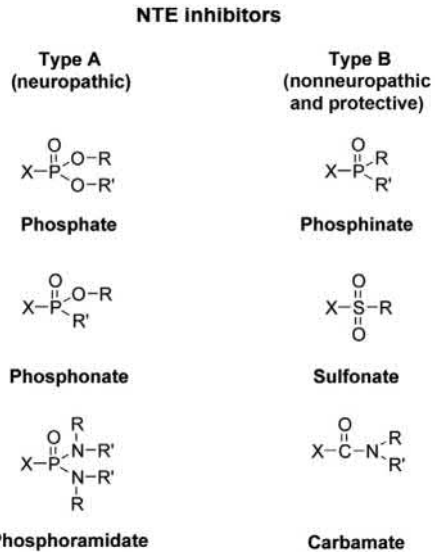

FIGURE 58.5 Subclasses of neuropathy target esterase (NTE) inhibitors. Type A NTE inhibitors include phosphates, phosphonates, and phosphoramidates; these are neuropathic and capable of aging. Type B NTE inhibitors include phosphinates, sulfonates, and carbamates; these are non-neuropathic and not capable of aging. However, inhibition of NTE with a type B inhibitor will protect against organophosphorus compound-induced delayed neurotoxicity (OPIDN) from subsequently administered type A inhibitors. *Reproduced with permission from Richardson, R.J., Makhaeva, G.F., 2014. Organophosphorus compounds. In: P. Wexler (Ed.), Encyclopedia of Toxicology, third ed., vol. 3. Elsevier, Ltd., Oxford, pp. 714−719.*

58.4.2 Role of neuropathy target esterase in organophosphorus compound−induced delayed neurotoxicity

Early studies indicated that the initial molecular events in OPIDN are the concerted inhibition and aging of a threshold level (>70%) of NTE in the central and peripheral nervous systems (Glynn, 1999; Johnson, 1974, 1982; Lotti, 1992). As with other serine esterases, inhibition of NTE is thought to occur by nucleophilic attack of the active site serine (Ser966) at the phosphorus of the OP compound, with displacement of a primary leaving group. Aging of the phosphylated enzyme presumably involves loss of a second ligand, leaving a negatively charged phosphyl moiety covalently attached to the active site. Note that "phosphyl" is used as a generic term for the various types of OP compounds that might be used as inhibitors of serine esterases, for example, phosphates, phosphonates, phosphinates, and phosphoramidates.

The apparent necessity for aging of NTE as a trigger for OPIDN came about from analyses of structure−activity relationships. These studies revealed that NTE inhibitors fall into two functional categories, types A and B (Davis and Richardson, 1980; Davis et al., 1985; Johnson, 1975) (Fig. 58.5).

Type A NTE inhibitors produce OPIDN and include certain phosphates, phosphonates, and phosphoramidates. When type A compounds inactivate NTE, it rapidly becomes intractable to reactivation by powerful nucleophiles, for example, oximes or fluoride. This inability to be reactivated has been interpreted as evidence of aging. Because loss of reactivatability takes place within minutes of inhibition by type A inhibitors and OPIDN takes 1−4 weeks to develop, aging of NTE is not the rate-limiting step in the disease process (Johnson, 1982).

Type B NTE inhibitors do not produce OPIDN and include certain phosphinates, carbamates, and sulfonates. NTE conjugates with type B compounds are considered not to undergo aging; those formed from carbamates and phosphinates can be reactivated; moreover, carbamylated, phosphinylated, or sulfonylated NTE cannot undergo further reactions to produce a stable charged species. Despite the fact that inhibition of NTE by type B compounds does not result in OPIDN, this reaction is far from being biologically inert. Pretreatment of animals with type B inhibitors protects them against OPIDN from subsequently administered type A inhibitors, presumably by blocking the formation of aged NTE (Davis et al., 1985; Johnson, 1990; Richardson, 1984) (Fig. 58.2). Protection against type A inhibitors by type B inhibitors is effective as long as inhibition of NTE by type B compounds is >30%, thus preventing inhibition and aging of the >70% of NTE required for induction of OPIDN.

It would appear that the ostensible requirement for aging of NTE in the development of OPIDN is not merely

to ensure irreversible inhibition of the enzyme. Prolonged suprathreshold inhibition (>70%) of neural NTE in vivo by repeated dosing of nonaging inhibitors does not cause neuropathy (Johnson, 1970, 1974, 1982). Moreover, repeated low-level dosing with aging inhibitors to produce a prolonged steady-state inhibition that is below threshold (<70%) does not result in OPIDN until a higher single dose is superimposed that raises the inhibition level above threshold. In the latter scenario, there is still a delay of 10–14 days from the high point of inhibition (and presumed concomitant aging) until signs of neuropathy appear (Johnson and Lotti, 1980; Lotti and Johnson, 1980). These results suggest that simple loss of catalytic activity of NTE is not the damaging event in OPIDN. Thus, the notion has arisen that the "biochemical lesion" that triggers OPIDN is the formation of a chemically modified (aged) protein that has gained a toxic function in the neuron (Glynn, 2000; Richardson, 1984; Richardson et al., 2013).

The pathogenic role of aged NTE is not known, but it is tempting to speculate that it may be involved in an axonal self-destruct program that has been proposed to be an important mechanism in neurodegenerative disorders, for example, motor neuron disease (Raff et al., 2002). Such a program might be triggered by chemically modified NTE acting through a gain of toxic function mechanism. On the other hand, experiments with conventional NTE knockouts (Moser et al., 2004; Mühlig-Versen et al., 2005; Winrow et al., 2003) and conditional NTE knockouts (Akassoglou et al., 2004; Read et al., 2010), along with demonstrations of a likely role of NTE in membrane lipid metabolism (Glynn, 2013; Quistad et al., 2003; Van Tienhoven et al., 2002; Zaccheo et al., 2004; Zhu et al., 2016) and endoplasmic reticulum stress (Sunderhaus et al., 2019), indicate that lethality or neuropathology can result from a loss of function of NTE (Glynn, 2006). However, the two possibilities—gain of toxic function and loss of physiological function—are not necessarily mutually exclusive and can in fact coexist in various neurodegenerative diseases (Winklhofer et al., 2008). In any event, while the physiological and pathogenic roles of NTE are being deciphered, the fact that an excellent correlation exists between inhibition/aging of NTE and induction of OPIDN is sufficient to enable the pragmatic use of this information for the development of biomarkers and biosensors for DN agents (Makhaeva et al., 2003, 2007).

58.5 Kinetics of organophosphorus inhibitor–serine hydrolase interactions

58.5.1 Introduction

The inhibitory and postinhibitory steps in the interaction of an OP compound with a serine hydrolase (E-OH), such as NTE or AChE, are illustrated in Fig. 58.6. The mathematical relationships describing the kinetics of irreversible inhibition of serine esterases by OP compounds and postinhibitory reactions of the enzyme–inhibitor adduct (conjugate) summarized here were elegantly set forth in the classic work by Aldridge and Reiner (1972), and synopses are available in other sources (Clothier et al., 1981; Main, 1980; Richardson, 1992). The equations featured below provide a basic foundation for determining the inhibitory potency of OP compounds against serine hydrolases as well as the rates of reactivation or aging of the inhibited hydrolases. Such approaches can be employed to assess the neuropathic potential of compounds and to distinguish conventional nerve agents from DN agents using biomarkers and biosensors. For more complex scenarios beyond the scope of this chapter, other equations have been developed (Estevez and Vilanova, 2009).

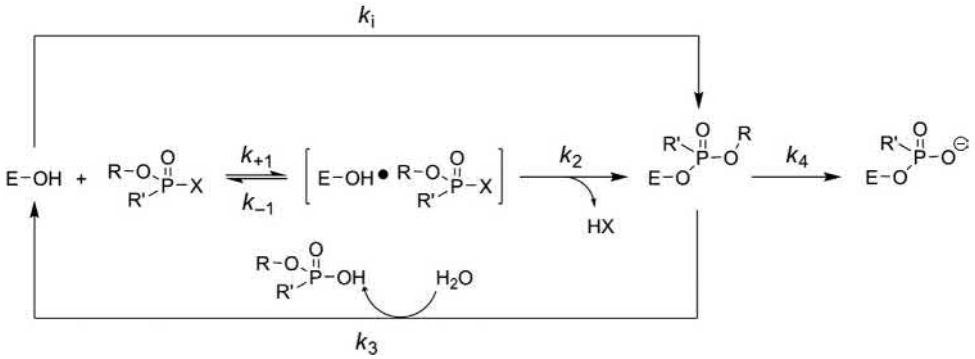

FIGURE 58.6 Reactions between a serine hydrolase and an organophosphonate inhibitor showing associated rate constants. The initial reversible reaction with forward (k_{+1}) and back (k_{-1}) rate constants forms a Michaelis-type complex. The complex can undergo phosphonylation (rate constant k_2) with expulsion of the primary leaving group, X. The overall progress of the reaction from enzyme to phosphonylated (inhibited) product is characterized by the bimolecular rate constant of inhibition, k_i. The phosphonylated enzyme can undergo spontaneous reactivation (hydrolysis in the presence of excess water) described by the pseudo-first-order rate constant, k_3, or undergo net loss of the R-group (aging) characterized by the first-order rate constant, k_4 (Richardson, 1992).

58.5.2 Inhibition

The first step leading to E-OH inhibition is a reversible association of the OP compound (depicted in Fig. 58.6 as a phosphonate) and enzyme to form a Michaelis-type complex (shown in square brackets); the associated rate constants for the forward (k_{+1}) and reverse (k_{-1}) reactions are shown on the double arrow. The active site serine hydroxyl of the hydrolase then engages in a nucleophilic attack on the phosphorus atom of the OP inhibitor, displacing the primary leaving group ($X-$), resulting in a phosphonylated enzyme with net loss of HX. The primary leaving group, $X-$, is typically a conjugate base of a strong acid, HX, such as HF. The phosphonylation rate constant is shown as k_2 (Richardson, 1992).

Considering only the first two steps in the reaction sequence, which is appropriate for most acylating inhibitors, the affinity of the inhibitor for the enzyme is given by the Michaelis-type equilibrium constant, K_d, as shown in Eq. (58.1). Note that Aldridge and Reiner (1972) denote this constant by K_a, while here, we use K_d, according to the terminology of Main (1980):

$$K_d = \frac{k_{-1} + k_2}{k_{+1}} \tag{58.1}$$

The overall progress of the reaction from E-OH and inhibitor to phosphonylated enzyme is characterized by the bimolecular rate constant of inhibition, k_i. This important measure of inhibitory potency is determined by measuring the activity remaining as a function of time of preincubation with various concentrations of inhibitor. The substrate is added after the preincubation interval (Richardson, 1992). When the inhibitor concentration $[OP] << K_d$, k_i is given by Eq. (58.2).

$$k_i = \frac{k_2}{K_d} \tag{58.2}$$

So-called ideal first-order kinetics of inhibition are obtained under the commonly observed conditions when the concentration of the Michaelis-type complex is small, k_2 is high, k_3 is much smaller than k_2, and $[OP] > 10[E\text{-}OH]$, where [E-OH] = concentration of native enzyme. In such cases we have Eq. (58.3).

$$\ln\left(\frac{v}{v_0}\right) = \frac{k_2[OP]t}{[OP] + K_d} \tag{58.3}$$

In Eq. (58.3), v is the rate of enzymatic hydrolysis of its substrate at time $= t$, and v_0 is the rate at time zero. Substituting (% activity/100) for (v/v_0) and letting $k' = k_2[OP]/([OP] + K_d)$ yields Eq. (58.4).

$$\ln\left(\frac{\%\ \text{activity}}{100}\right) = -k't \tag{58.4}$$

Thus, primary plots of ln(% activity/100) versus t will be straight lines with slopes $= -k'$ as shown in Fig. 58.7A. In addition, the experimentally determined dependence of % (activity remaining) on the preincubation time (t) and inhibitor concentration [OP] is given by Eq. (58.5).

$$\ln\frac{\%\ \text{activity}}{100} = -k_i[OP]t \tag{58.5}$$

Setting Eqs. (58.4) and (58.5) equal to each other gives Eq. (58.6).

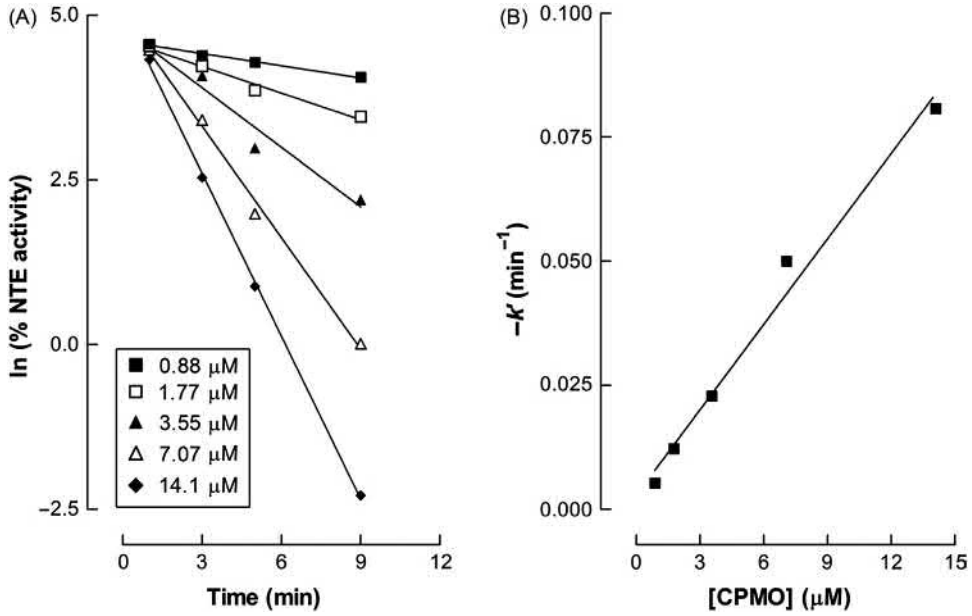

FIGURE 58.7 (A) Primary kinetic plots of ln(% NTE activity) versus time for various indicated concentrations of chlorpyrifos methyl oxon (CPMO). (B) Slopes ($-k'$) of primary kinetic plots versus inhibitor concentration. Data are for hen brain microsomal NTE at pH 8.0 and 37°C. *Reproduced with permission from Kropp, T.J., Richardson, R.J., 2003. Relative inhibitory potencies of chlorpyrifos oxon, chlorpyrifos methyl oxon, and mipafox for acetylcholinesterase versus neuropathy target esterase. J. Toxicol. Environ. Health Part A 66, 1145–1157.*

$$k' = k_i[\mathrm{OP}] \tag{58.6}$$

Therefore, a secondary plot of $-k'$ versus [OP] will yield a straight line with slope $= k_i$ as shown in Fig. 58.7B. The k_i value thus obtained is an indication of the inhibitory potency of a given compound against a particular serine hydrolase. As stated above, k_i is a measure of the overall progress of the reaction between the inhibitor and enzyme to yield the organophosphylated product. However, it is important to realize as shown in Eq. (58.2) that k_i is a composite of K_d, which is an indication of the affinity of the inhibitor for the enzyme, and k_2, which is an indication of the rate of phosphylation of the enzyme by the inhibitor. Inspection of Eqs. (58.2) and(58.5) shows that the units of k_i are $[\mathrm{OP}]^{-1}t^{-1}$; for example, the k_i obtained for chlorpyrifos methyl oxon (CPMO) against hen brain microsomal NTE at pH 8.0 and 37°C (Fig. 58.7) is $5.82 \times 10^4\ \mathrm{M}^{-1}\ \mathrm{min}^{-1}$ (Kropp and Richardson, 2003; Richardson, 1992).

Under certain conditions, it is possible to determine the K_d and k_2 components of k_i separately. For example, if the secondary plot is not linear, this is an indication of an appreciable concentration of a Michaelis-type complex. In this case, the K_d term must be included; by combining Eqs. (58.3) and(58.4) and rearranging, we have Eq. (58.7).

$$\frac{[\mathrm{OP}]}{k'} = \frac{K_d}{k_2} + \frac{[\mathrm{OP}]}{k_2} \tag{58.7}$$

Thus, a Wilkinson plot of $[\mathrm{OP}]/k'$ versus [OP] will yield a straight line with slope $1/k_2$, a y-intercept of K_d/k_2, and an x-intercept of K_d. Moreover, from Eq. (53.2), $k_i = k_2/K_d$; therefore, the reciprocal of the y-intercept gives k_i (Richardson, 1992).

An especially useful relationship is given by substituting a % activity of interest into Eq. (58.5) to yield the inhibitor concentration at a given time of preincubation with enzyme that would yield the particular percent activity. For example, when $[\mathrm{OP}]_{50} = I_{50} =$ the inhibitor concentration required to produce 50% inhibition of the enzyme at a given time, t, of incubation of enzyme and inhibitor at defined conditions of pH, temperature, and ionic strength before adding substrate, we have Eq. (58.8).

$$[\mathrm{OP}]_{50} = I_{50} = \ln 2/k_i t \approx 0.693/k_i t \tag{58.8}$$

Note that in Eq. (58.8) k_i and I_{50} are reciprocally related and that I_{50} is time dependent. It is valid to calculate an I_{50} from a k_i value when ideal kinetics are observed. However, it is not valid to calculate a k_i from an experimentally determined fixed-time I_{50}, because the I_{50} alone contains no information about the kinetic behavior of the inhibition reaction. In addition, if inhibitory potency is assessed by measuring fixed-time I_{50} values, it is essential to report the time of preincubation along with the concentration, because the I_{50} decreases as the preincubation time increases (Aldridge and Reiner, 1972; Clothier et al., 1981; Richardson, 1992). For example, using Eq. (58.8), the 20-min I_{50} for chlorpyrifos methyl oxon against hen brain microsomal NTE at pH 8.0 and 37°C may be calculated from the k_i given above to be $0.693/(5.82 \times 10^4\ \mathrm{M}^{-1}\ \mathrm{min}^{-1})(20\ \mathrm{min}) = 5.95 \times 10^{-7}\ \mathrm{M} \approx 0.60\ \mu\mathrm{M}$ (Kropp and Richardson, 2003).

58.5.3 Reactivation

In Fig. 58.6, the phosphonylated enzyme can undergo spontaneous reactivation via hydrolysis to yield free enzyme and a phosphonic acid, with an associated pseudo-first-order rate constant, k_3 (the reactivator, water, is present in great excess). The spontaneous rate constant of reactivation, k_3, can be obtained from Eq. (58.9).

$$\ln\left(\frac{100}{\%\ \text{inhibition}}\right) = k_3 t \tag{58.9}$$

The % reactivation in a reactivation experiment is determined by Eq. (58.10).

$$\%\ \text{inhibition} = \left[\frac{A - A_t}{A - A_0}\right] \times 100 \tag{58.10}$$

In Eq. (58.10), A is the activity of the control, A_t is the activity of the inhibited enzyme at time t, and A_0 is the activity of the inhibited enzyme at $t = 0$. In practice, reactivation is studied by preincubating the enzyme with a concentration of inhibitor that rapidly produces essentially complete inhibition. The inhibitor and enzyme are then rapidly separated or the preparation is diluted sufficiently to prevent further appreciable inhibition of free enzyme, and the return of enzyme activity is measured at timed intervals. The slope (k_3) of the least-squares best-fit line from a plot of ln(100/% inhibition) versus t is determined using linear regression from the initial linear portion of the curve. From Eq. (58.9), it can be seen that the units of k_3 are t^{-1}, for example, min^{-1}, and that the half-life, $t_{1/2}$, the time required for 50% reactivation, can be determined from Eq. (58.11).

$$t_{1/2} = \ln 2/k_3 \approx 0.693/k_3 \tag{58.11}$$

The apparent half-life of reactivation can range from minutes to weeks, depending upon the enzyme, inhibitor, pH, and temperature. Reactivation can appear to be slow or nonexistent if aging has occurred, because the aged form of the phosphylated enzyme is stable to hydrolysis and will not reactivate (Jianmongkol et al., 1999; Richardson, 1992).

58.5.4 Aging

As shown in Fig. 58.6, the inhibited esterase can also undergo aging, for example, via net loss of a labile R-group to yield the negatively charged phosphonyl adduct on the active site serine of the enzyme. Aging is characterized by a first-order rate constant, k_4, and the operational definition of this reaction is the time-dependent loss of the ability to reactivate the inhibited enzyme by powerful nucleophiles, such as fluoride ion or oximes. The method of determining aging is similar to that for reactivation. Enzyme is preincubated with a concentration of inhibitor sufficient to produce essentially complete inhibition in a relatively short time. Aliquots are then treated with a reactivator such as fluoride or an oxime and the amount of activity relative to a nonreactivated sample is measured. The first-order rate constant of aging, k_4, can be determined from Eq. (58.12).

$$\ln\left[\frac{100}{\%\ \text{reactivation}}\right] = k_4 t \tag{58.12}$$

In an aging experiment, the % reactivation is determined by Eq. (58.13).

$$\%\ \text{reactivation} = \left[\frac{AR_1 - AI_1}{AR_0 - AI_0}\right] \times 100 \tag{58.13}$$

In Eq. (58.13), AR_1 = activity of reactivated enzyme at t_{aging}, AR_0 = activity of reactivated enzyme at $t = 0$, AI_1 = activity of inhibited enzyme without reactivator at t_{aging}, and AI_0 = activity of inhibited enzyme without reactivator at $t = 0$. The slope (k_4) of the least-squares best-fit line from a plot of ln(100/% inhibition) versus t is determined using linear regression from the initial linear portion of the curve. From Eq. (58.12), it can be seen that the units of k_4 are t^{-1}, for example, min^{-1}, and that the aging half-life, $t_{1/2}$, the time required for 50% aging, can be determined from Eq. (58.14).

$$t_{1/2} = \ln 2/k_4 \approx 0.693/k_4 \tag{58.14}$$

The apparent half-life of aging depends upon the enzyme, inhibitor, pH, and temperature. However, NTE inhibited with most neuropathic agents exhibits aging half-lives on the order of several minutes, so that the 1–4-week delay between exposure and appearance of signs of OPIDN is not due to the time required for aging of phosphylated NTE (Jianmongkol et al., 1999; Johnson, 1982; Kropp and Richardson, 2007; Richardson, 1992).

58.5.5 Relative inhibitory potency

The neuropathic potential of an OP compound depends upon its ability to inhibit NTE (and presumably for the NTE–OP conjugate to undergo aging). However, an OP compound will not be able to inhibit NTE to a sufficient degree to produce OPIDN if its cholinergic toxicity is too high to permit survival of a neuropathic dose. Therefore, the neuropathic potential of an OP compound is a relative concept that depends upon the ability of the compound to inhibit NTE compared to its anti-AChE activity. Compounds can be screened in vitro for relative inhibitory potency (RIP) by measuring k_i or I_{50} values and calculating a ratio, as shown in Eq. (58.15).

$$\text{RIP} = \frac{k_i(\text{AChE})}{k_i(\text{NTE})} \tag{58.15}$$

Because of the reciprocal relationship between the k_i and I_{50} described by Eq. (58.8) above, the RIP for fixed-time I_{50} values (determined at the same fixed-time, t) is given by Eq. (58.16).

$$\text{RIP} = \frac{I_{50}(\text{NTE})}{I_{50}(\text{AChE})} \tag{58.16}$$

Thus, when the RIP > 1, the compound is a more potent inhibitor of AChE than NTE, and cholinergic toxicity would be expected to predominate over OPIDN. In fact, when the RIP > 1, the dose required to produce OPIDN tends to be greater than the median lethal dose (LD_{50}) for the compound (Kropp and Richardson, 2003; Richardson, 1992). Note that the RIP is simply a ratio of inhibitor potencies, and it could have been defined the other way around, with the k_i for NTE in the numerator. However, the convention used in this chapter defines the RIP as shown in Eqs. (58.15) and(58.16).

For example, although chlorpyrifos methyl oxon (CPMO), the active metabolite of the insecticide chlorpyrifos methyl, would seem to be a potent inhibitor of NTE, with $k_i = 5.82 \times 10^4\ \text{M}^{-1}\ \text{min}^{-1}$ and 20 min $I_{50} = 0.595\ \mu\text{M}$, it is a much more potent inhibitor of AChE, with a $k_i = 1.09 \times 10^7\ \text{M}^{-1}\ \text{min} - 1$ and 20 min $I_{50} = 3.18 \times 10^{-9}$ M (3.18 nM), so that the RIP for this compound is 187. This value is >> 1, indicating that OPIDN could not be produced unless the dose were >> LD_{50} and aggressive therapy for cholinergic toxicity were instituted (Kropp and Richardson, 2003). In contrast, the compound di-*n*-pentyl 2,2-dichlorovinyl phosphate (*n*-pentyl DCV) has an RIP of 0.03 and produces OPIDN at a dose of 2 mg/kg, which is much lower than the LD_{50} dose of 26 mg/kg (Richardson, 1992). OP inhibitors with extremely high selectivity for NTE have been synthesized, for example, ethyl *n*-octylphosphonofluoridate (EOPF) (Fig. 58.3) (Wu and Casida, 1995), which has 20-min I_{50} values for mouse brain NTE and AChE of 0.02 and 54 nM, respectively, yielding an RIP value of 3.7×10^{-4} (i.e., about 2700 times more potent for NTE than AChE) (Wu and Casida, 1996). Note that EOPF is a

chiral compound, and the reported I_{50} and RIP values are for the racemic mixture. Given that inhibitory potency can vary considerably between *R* and *S* forms of OP compounds (Wu and Casida, 1994), it would be of interest to carry out such measurements on resolved isomers.

Because RIP values can encompass several orders of magnitude above and below 1, it is convenient to visualize such data using log (RIP) values as shown in Fig. 58.8. It can readily be seen that higher positive numbers correspond to greater cholinergic propensity, as typified by the insecticide active metabolite, CPMO. Likewise, larger negative numbers correspond to greater neuropathic potential, as exemplified by the DN agent, EOPF. It is also interesting to see the steady progression from cholinergic to neuropathic tendency exhibited by the homologous series of dialkyl 2,2-dichlorovinyl phosphates (dichlorvos, DCV) compounds. In this and other series of alkyl OP inhibitors, increasing length of alkyl chains tends to produce decreasing potency against AChE and increasing potency against NTE until maximum selectivity is reached, after which potencies and selectivity decline (Richardson, 1992; Malygin et al., 2003). The highest potency for NTE appears to have been achieved with certain phosphonofluoridates, where the sum of alkyl and alkoxyl chain length is 12−16 atoms, including O and P; in this series, EOPF has the highest potency and selectivity for NTE (Wu and Casida, 1995, 1996).

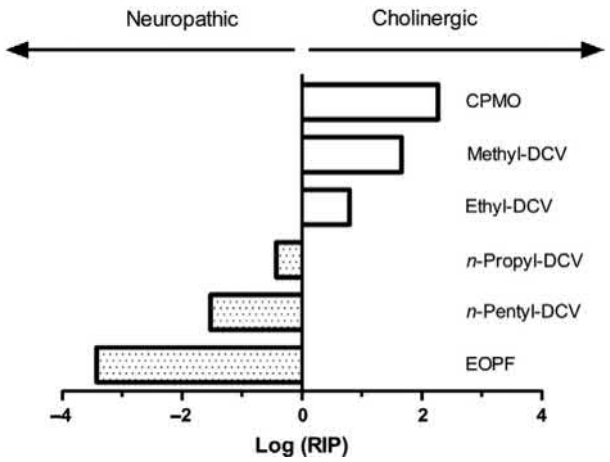

FIGURE 58.8 Spectrum of log values of relative inhibitory potency (RIP) = k_i(AChE)/k_i(NTE), where k_i = bimolecular rate constant of inhibition. As log(RIP) becomes more positive, cholinergic potential increases; as log(RIP) becomes more negative, delayed neuropathic potential increases. CPMO, chlorpyrifos methyl oxon. DCV derivatives refer to symmetrical dialkyl 2,2-dichlorovinyl phosphate (dichlorvos) compounds. EOPF, ethyl *n*-octylphosphonofluoridate. *Data from Kropp, T.J., Richardson, R.J., 2003. Relative inhibitory potencies of chlorpyrifos oxon, chlorpyrifos methyl oxon, and mipafox for acetylcholinesterase versus neuropathy target esterase. J. Toxicol. Environ. Health Part A 66, 1145−1157; Richardson, R.J., 1992. Interactions of organophosphorus compounds with neurotoxic esterase. In: J.E. Chambers, P.E. Levi (Eds.), Organophosphates: Chemistry, Fate, and Effects. Academic Press, San Diego, pp. 299−323; and Wu, S.Y., Casida, J.E., 1996. Subacute neurotoxicity induced in mice by potent organophosphorus neuropathy target esterase inhibitors. Toxicol. Appl. Pharmacol. 139, 195−202.*

Determinations of RIP carried out in vitro using preparations of AChE and NTE can only assess the neuropathic potential of OP compounds that are direct-acting inhibitors, that is, compounds that do not require metabolic activation. Such preparations would also not detect effects of detoxification that might occur in vivo. To account for the possibility of metabolic activation/deactivation, the system can be augmented by preincubating the compound of interest with xenobiotic metabolic enzymes (or chemical activators, e.g., bromine) before mixing with AChE or NTE preparations (Barber et al., 1999). The concept of the RIP can also be extended to assaying AChE and NTE ex vivo and calculating activity ratios after dosing laboratory animals with the compound of interest. Because the adult hen is the species of choice for assessing the neuropathic potential of OP compounds, this species could also be used for ex vivo RIP determinations (Richardson, 1992; Richardson et al., 1993). However, despite the fact that rats and mice are not as suitable as hens for studying the clinical and histopathological effects of DN agents, rodent species have AChE and NTE in their nervous systems and can therefore serve as sources of these enzymes for in vitro or ex vivo determinations of neuropathic potential (Novak and Padilla, 1986; Quistad et al., 2003; Wu and Casida, 1996; Makhaeva et al., 2014).

58.6 Biomarkers

58.6.1 Introduction

A widely quoted definition of "biomarker" is that it is "a characteristic that is objectively measured and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention" (Atkinson et al., 2001). Although this definition was developed from the standpoint of pharmacology and therapeutics, it can easily be modified to apply to toxicology. In a toxicological setting, a biomarker would consist of an appropriate measure of a chemically induced pathological process, for example, a response to a toxicant that could be considered injurious or diagnostic of potential injury. Ideally, a toxicological biomarker would represent a biological response that would be pathognomonic of a specific agent or at least a selective indicator of the effects of a class of agents. Thus, a biomarker of a DN agent would involve more than measuring the mere presence of the compound; instead, it would assess a distinctive and preferably early feature of the pathogenesis of OPIDN. Because the earliest known molecular events

associated with OPIDN are the inhibition and aging of NTE, the appropriate biomarkers of DN agents would be measurements of these reactions, which could be done via determination of inhibition and aging using enzymology, or through identification of the resulting OP−NTE conjugates using mass spectrometry.

58.6.2 Enzymological measurements of neuropathy target esterase inhibition and aging

NTE activity in lymphocytes and platelets was discovered by Dudek and Richardson (1978, 1982), characterized in human populations (Bertoncin et al., 1985; Maroni and Bleecker, 1986), and used in animal (Makhaeva et al., 2003; Richardson and Dudek, 1983; Richardson et al., 1993; Schwab and Richardson, 1986) and human (Lotti et al., 1983, 1986; McConnell et al., 1999) studies to monitor exposures to potentially neuropathic OP compounds. NTE activity is not found in erythrocytes or in plasma or serum. These studies indicate that NTE in lymphocytes, platelets, or whole blood can be assayed and used as a biomarker of exposure to DN agents, particularly if the blood samples are taken within 24 h of acute exposures. Attempts to measure the aging of NTE in lymphocytes or platelets of exposed subjects have apparently not been done. However, given that aging of NTE inhibited by DN agents typically occurs within a half-life of a few minutes (Clothier and Johnson, 1979; Johnson, 1982), aging would be complete by the time that lymphocyte samples could be taken and assayed for activity. Nevertheless, as stated above, given the apparent requirement for aging as well as inhibition of NTE in OPIDN, to help rule out false positives arising from inhibition by type B (nonaging) NTE inhibitors (Fig. 58.5), aging studies ought to be undertaken in future work. As noted below, mass spectrometry can be used to identify the phosphyl adduct on the inhibited enzyme, thus differentiating between inhibited and aged forms.

In keeping with the concept of the RIP discussed in Section 58.5.5, inhibition of lymphocyte and/or platelet NTE and possibly erythrocyte LysoPC hydrolase should be used in conjunction with inhibition of erythrocyte AChE and plasma butyrylcholinesterase (BChE) to assess the likelihood that an exposure to OP compounds would produce cholinergic and/or DN effects. Erythrocyte AChE inhibition has long been used as a biomarker of exposure to conventional nerve agents or OP insecticides (Lotti, 1995; Wilson and Henderson, 1992). BChE can be sensitive to both conventional and DN agents, and its inhibition could thus serve as a general biomarker for OP agents (Jiang and Lockridge, 2013; Kropp and Richardson, 2007; Van der Schans et al., 2008).

58.6.3 Identification of neuropathy target esterase−organophosphorus conjugates using mass spectrometry

Mass spectrometry has proved to be an excellent tool for identifying the OP conjugates (adducts) of serine hydrolases such as AChE and BChE (Doorn et al., 2000, 2001b, 2003; Elhanany et al., 2001; Jennings et al., 2003; Jiang et al., 2013a,b; Kropp and Richardson, 2007; Li et al., 2007; Schopfer et al., 2014; Van der Schans et al., 2008). One approach is to reactivate inhibited esterases with fluoride and to detect the liberated OP fluoridate using gas chromatography−mass spectrometry; however, this technique cannot be used if the esterase conjugate has aged (Degenhardt et al., 2004; Solano et al., 2008). Because NTE inhibited with DN agents undergoes rapid aging (Johnson, 1982), it is important to be able to detect the aged adducts. Therefore, peptide mass mapping would be the current method of choice, whereby the active site peptide containing the phosphyl moiety on the active site serine is identified using mass spectrometry following digestion of the inactivated esterase with trypsin or other proteases (Doorn et al., 2003; Jiang et al., 2013a,b). Although some DN agents have extremely high potency and selectivity for NTE, in general there will be some degree of inhibitory overlap with other serine hydrolases (e.g., see Fig. 58.8). Accordingly, in addition to examining NTE, it would be useful to acquire mass spectrometry data on OP conjugates of other potential esterase targets, such as AChE and BChE, with particular attention being paid to the aged species.

The classical view of the aging reaction of OP-inhibited serine esterases, based on studies of soman-inhibited AChE, is that aging involves an SN1 reaction at a ligand carbon and transient formation of a carbocation that dissociates from the enzyme (Michel et al., 1967; Shafferman et al., 1996). The traditional model has been confirmed using mass spectrometry for BChE inhibited by a variety of phosphates and phosphonates and allowed to age in the presence of [18O]-H_2O (Li et al., 2007). Thus, it appears that cholinesterases inhibited by phosphates or phosphonates undergo aging via SN1 cleavage of an O−C bond rather than SN2 cleavage of a P−C bond.

However, it is important to realize that mechanisms of inhibition and aging can differ depending upon the esterase, inhibitor, and stereochemistry of the inhibitor. For example, the aging of AChE inhibited by ethyl *N*,*N*-dimethylphosphoramidocyanidate (tabun) was shown to proceed via hydrolytic P−N bond scission with loss of dimethylamine (Elhanany et al., 2001). However, BChE inhibited by tabun analogs was shown to age differently, depending on chirality (Jiang et al., 2013b). Thus, the *Sp* tabun analog aged via deamination, whereas the *Rp*

isomer aged by dealklation. In addition, the mechanism of inhibition of AChE, BChE, and cholesterol esterase by the resolved stereoisomers of isomalathion has been shown to differ between the (1*R*) and (1*S*) forms, and the mechanism of aging in each case appears to proceed via SN2 displacement of a secondary leaving group by water, involving cleavage of a P−S bond (Doorn et al., 2000, 2001a, 2001b, 2003). A subsequent study of BChE inhibited with racemic isomalathion confirmed that the major pathway for aging involved scission of the P−S bond, but relatively small peaks in the mass spectrum indicated that O−C and S−C cleavage could also occur as minor pathways (Li et al., 2007). Such studies are useful, in that they demonstrate the "signatures" of OP conjugates arising from different agents on particular esterases.

For NTE inhibited by phosphates or phosphonates, the aging mechanism has been thought to be consistent with an SN2 reaction at phosphorus (Johnson, 1982), although this hypothesis has not been rigorously tested. With respect to stereochemical influences on aging, limited studies indicate that both enantiomers of certain phosphonates inhibit NTE, but only one enantiomer undergoes aging (Johnson et al., 1985, 1986). As expected, the isomer that inhibits NTE and ages produces OPIDN. In contrast, the isomer that inhibits NTE without aging does not produce OPIDN. Furthermore, the nonaging isomer protects against neuropathy from subsequent administration of a neuropathic OP compound (Johnson and Read, 1987; Johnson et al., 1988). Some racemic phosphonates have been found to produce OPIDN at lower than expected threshold levels of inhibited/aged NTE (i.e., <70%), possibly because of potentiation or promotion of subclinical axonopathy by the nonaging enantiomer, presumably by the action of the nonaging enantiomer on one or more targets other than NTE that could be involved in repair or regeneration of neural lesions (Lotti, 1992).

Perhaps the most thoroughly investigated compound with respect to inhibition and aging of serine hydrolases is diisopropylphosphorofluoridate (DFP). Using a variety of techniques, this compound has been shown to inhibit AChE (Clothier and Johnson, 1979; Kropp and Richardson, 2006; Millard et al., 1999a, 1999b; Ordentlich et al., 1996, 1998), BChE (Kropp and Richardson, 2007; Li et al., 2007; Masson et al., 1997), NTE (Clothier and Johnson, 1979; Williams, 1983; Williams and Johnson, 1981), and NEST (Kropp et al., 2004) by organophosphorylation of the active site serine followed by aging to yield a monoisopropylphosphoryl adduct, as shown in Fig. 58.9. Esterase adducts have been directly demonstrated using mass spectrometry for AChE (Kropp and Richardson, 2006), BChE (Kropp and Richardson, 2007; Li et al., 2007), and NEST (Kropp et al., 2004), and in the case of BChE, the mechanism of aging has been unequivocally demonstrated to involve

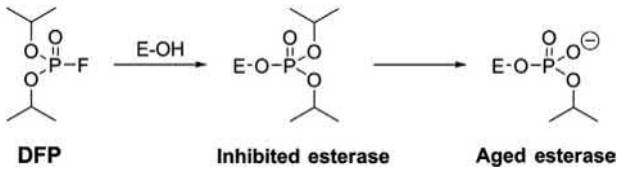

FIGURE 58.9 Inhibition and aging of serine esterases by diisopropylphosphorofluoridate (DFP). The active site serine is organophosphorylated in the inhibition step. Aging results in net loss of an isopropyl group to yield the monoisopropylphosphoryl esterase. This mode of inhibition and aging has been established for acetylcholinesterase (AChE), butyrylcholinesterase (BChE), and neuropathy target esterase catalytic domain (NEST) (Kropp and Richardson, 2007).

scission of an O−C bond in an isopropyl group (Li et al., 2007). These results, taken together with those for soman-inhibited AChE (Michel et al., 1967) and BChE inactivated with a variety of phosphonates and phosphates (Li et al., 2007), indicate that it is reasonable to expect that aging of phosphonylated or phosphorylated serine esterases, including NTE and NEST, will proceed via O−C bond scission. This insight enables accurate prediction of the biomarker species to be sought in the mass spectra of serine esterases inhibited with phosphonates or phosphates.

Among the type A inhibitors of NTE (Fig. 58.5), the phosphoramidates are perhaps the most enigmatic to be studied to date. For example, mipafox, the phosphoramidate analog of DFP, is capable of producing suprathreshold inhibition (>70%) of neural NTE in vivo and causing OPIDN (Davis and Richardson, 1980). Therefore, mipafox-inhibited NTE was expected to undergo aging (Davis et al., 1985). Indeed, early studies showed that NTE inhibited by mipafox was intractable to reactivation, indicating the possibility of aging as a mechanism for yielding a nonreactivatable enzyme (Johnson, 1982). In the case of mipafox-inhibited NTE, however, nonreactivation was thought to be too rapid to measure by standard kinetic approaches (Johnson, 1982). Consequently, aging of mipafox-inhibited NTE had only been inferred and not directly demonstrated. Subsequently, Milatovic and Johnson (1993) showed that NTE inhibited by mipafox could be reactivated by prolonged treatment with KF at acidic pH. This surprising finding led to the conclusion that aging had not occurred after all. Instead, it was surmised that an unusual property of the bond between the phosphoramidate and the active site serine was responsible for the stability of the complex as well as the perturbation of NTE that leads to OPIDN.

It had been known for some time that esterases inhibited by mipafox are resistant to reactivation, but conventional aging could not be proved or disproved by classical techniques. It is also known that the phosphoramido hydrogen on *N*-alkylphosphoramidates is acidic and that its removal yields a resonance-stabilized anion

(Eto, 1974). Such a mechanism would explain the relative stability of phosphoramidated esterases in a manner that does not require loss of an alkylamino group to yield a negative charge on the adduct (Richardson, 1995). Moreover, reprotonation of the phosphoramide anion would generate a neutral species subject to attack by a nucleophile and account for the reactivation of mipafox-inhibited NTE at low pH. Under the acidic conditions usually employed for peptide mass spectrometry, the putative anion would be reprotonated. Thus, it can be hypothesized that the species attached to NTE after its inhibition by mipafox and allowing time for aging is the intact *N*,*N*′-diisopropylphosphorodiamido moiety. Such a result would indicate that the inhibited enzyme has not lost an isopropyl or isopropylamino group due to an aging process analogous to the net loss of an isopropyl group in the aging of DFP-inhibited NTE or NEST.

In contrast to the results for mipafox-inhibited NTE, early limited studies indicated that mipafox-inhibited BChE or AChE undergo irreversible aging, because the enzymes could be reactivated soon after inhibition, but not after 18 h (Milatovic and Johnson, 1993). The chemistry of phosphoramidates suggests that aging could involve hydrolytic loss of an alkylamino group. For example, acid-catalyzed P−N bond fission has been observed for certain *N*-alkyl phosphoramidates (Eto, 1974) and the aging of tabun-inhibited AChE has been shown to proceed via P−N bond scission with loss of dimethylamine (Elhanany et al., 2001).

Considerations of probable mechanisms of aging for mipafox-inhibited serine esterases suggest that mass spectrometry studies would support a deprotonation mechanism for NTE or NEST and hydrolytic P−N bond scission for AChE and BChE. These expectations were borne out for human recombinant NEST, which was used as a surrogate for NTE (Kropp et al., 2004), and BChE, respectively (Kropp and Richardson, 2007). However, mipafox-inhibited AChE gave the surprising result, confirmed by immunoprecipitation and mass spectrometry, of apparent loss of both isopropylamine groups to yield a simple phosphate adduct on the active site peptide (Kropp and Richardson, 2006). However, further mass spectrometric investigations of mipafox-inhibited human AChE that could not be reactivated found only the intact mipafox adduct on the active site peptide (Mangas et al., 2016). Moreover, mass spectrometric studies of the aging of tabun−BChE conjugates demonstrated that the *Rp* isomer of the tabun analog aged by dealkylation to yield a phosphyl adduct with a dimethylamine R-group attached (Jiang et al., 2013b). Furthermore, these investigators showed that P−N bonds are acid-labile, so that treatment of the *Rp*-tabun−BChE conjugate with acid liberated dimethylamine to yield a simple phosphate adduct on the BChE active site peptide. Thus, taking together the results of Jiang et al. (2013b) and Mangas et al. (2016), we now conclude that our report of "aging" of mipafox-inhibited AChE to yield a simple phosphate adduct was in fact an artifact of the acidic conditions used to prepare samples for mass spectrometry. Nevertheless, as pointed out by Jiang et al. (2013b), the acid-lability of P−N bonds can be used diagnostically in a stepwise mass spectrometric procedure to demonstrate the existence of acid-cleaveable phosphyl adducts on esterases.

Mass spectrometry has also been successfully employed to detect BChE products arising from reaction with 2-(2-methylphenoxy)-BDPO (CBDP), which has been implicated in aerotoxic syndrome (Carletti et al., 2011). Interestingly, the final aging product was a simple phosphoserine adduct. A subsequent study showed that sequential aging steps first yield an *o*-cresyl phosphoserine conjugate followed by formation of a simple phosphoserine adduct (Schopfer et al., 2014).

58.7 Biosensors

58.7.1 Nanostructured electrochemical biosensors to measure enzyme activity

Recently developed nanofabrication methods using layer-by-layer (LBL) self-assembly provide exciting new opportunities to design multilayered, functional, biosensor interfaces to measure enzyme activity. Since the LBL technique was first introduced (Decher and Hong, 1991), significant work has been done to fabricate polymer and organic thin films through alternating deposition of positively and negatively charged polyelectrolyte species on solid surfaces (Decher, 1997; Decher et al., 1992; Lvov et al., 1994; Ruths et al., 2000; Schmidt et al., 1999).

Polyelectrolyte layers typically have a thickness on the order of a nanometer, allowing ultrathin interfaces to be fabricated that have minimal mass-transfer resistance. LBL self-assembly using polyelectrolytes is thus well suited for biosensor development studies, because, by minimizing mass-transfer resistances, the intrinsic enzyme kinetics can be measured. LBL assemblies of polyelectrolytes have been used to develop nanostructured biosensor interfaces that encapsulate enzymes (Hassler et al., 2007; Kohli et al., 2006, 2007a; Sokolovskaya et al., 2005) and functional nanoparticles (Kohli et al., 2005, 2007b).

Electrochemical biosensors that measure the activity of a protein have been widely used to determine analyte concentrations, in both research and commercial applications (Prodromidis and Karayannis, 2002). Biosensors can detect protein activity either directly (Hassler and Worden, 2006) or indirectly through reaction coupling (Peteu et al., 1996, 1998). The indirect approach greatly

expands the range of enzyme activities that can be characterized using electrochemical biosensors. For example, reaction coupling has been used to measure NTE activity outside of the electrode, for example, in blood samples (Makhaeva et al., 2003, 2007, 2016a; Sigolaeva et al., 2010, 2013) or AChE, BChE, and NEST activity incorporated into the electrode (Kohli et al., 2007a, 2014). Differential inhibition of multiple esterases has been used to define the "esterase profile" of a compound—an index that can be used to predict the net biological effect of an esterase inhibitor (Makhaeva et al., 2016b).

58.7.2 Electrochemical biosensor arrays for high-throughput analysis

Microsystem technologies, particularly thin-film deposition of microelectrodes and formation of microfluidic channels, have been widely applied to biological analysis systems (Bergveld, 1996; Urban, 2000), such as DNA-processing chips (Raisi et al., 2004) and other lab-on-chip implementations (Kovacs, 2003; McFadden, 2002; Ziegler, 2000). Most of these devices rely on optical transduction mechanisms (Rabbany et al., 1994; Vo-Dinh et al., 2003) that often cannot quantitatively measure several important protein activities, such as redox reactions.

In contrast, enzymatic redox reactions are readily measured using versatile electrochemical techniques. Traditionally, electrochemical measurements are performed at the "beaker scale," but newer technologies allow such systems to be miniaturized for improved performance and high-throughput analysis. Complete three-electrode electrochemical cells, including thin-film Ag/AgCl reference electrodes, have been integrated on silicon surfaces (Yun et al., 2004). Thin-film reference electrode stability has been improved using Nafion or polyurethane coatings (Nolan et al., 1997) and complex micromachined structures (Suzuki, 2000; Suzuki et al., 1999). A remaining challenge is to adapt these new technologies to the construction of miniaturized electrochemical arrays for high-throughput protein activity characterization. Such biosensor array platforms must be compatible with the self-assembled biosensor interfaces, thus establishing requirements for electrode materials, geometries, surface smoothness, and overall array architecture (Huang et al., 2013).

58.7.3 Assembly of electrochemical biosensor interfaces for serine hydrolases

The natural reaction substrates and products of serine esterases are not electrochemically active. In order to transduce these esterase activities into an electrical signal, a two-enzyme reaction pathway can be assembled on a gold electrode. In the first reaction, the esterase of interest converts a phenyl ester (e.g., phenyl valerate) into phenol (Fig. 58.10). In the second reaction, tyrosinase converts phenol first to catechol, and then to *o*-quinone (Fig. 58.11), which can be electrochemically reduced back to catechol at an electrode, yielding a measurable current (Eq. 58.17) (Kohli et al., 2007a, 2010).

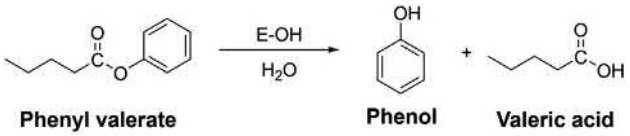

FIGURE 58.10 Reaction of a serine esterase with phenyl valerate to yield phenol and valeric acid (Kayyali et al., 1991).

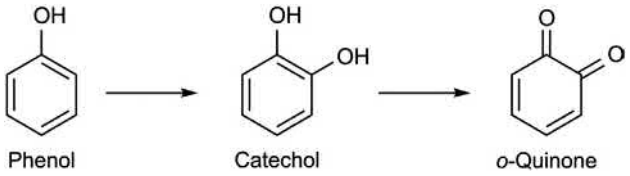

FIGURE 58.11 Reactions catalyzed by the two activities of tyrosinase. Phenol is first oxidized to catechol and then to *o*-quinone. *Reproduced with permission from Kohli, N., Srivastava, D., Sun, J., Richardson, R.J., et al., 2007a. Nanostructured biosensor for measuring neuropathy target esterase activity. Anal. Chem. 79, 5196–5203.*

$$o-\text{Quinone} + 2H^+ + 2e^- \rightarrow \text{Catechol} \qquad (58.17)$$

Tyrosinase is a copper-containing oxidase (Coche-Guerente et al., 2001; Forzani et al., 2000), which possesses the two different activities illustrated in Fig. 58.11. In the first step, referred to as the hydroxylase or cresolase activity, molecular oxygen is used to hydroxylate phenol to form catechol. In the second step, known as the catecholase activity, the enzyme oxidizes catechol to *o*-quinone, which is simultaneously oxidized by oxygen to its original form, with the production of water. The *o*-quinone is electrochemically active and can be reduced back to catechol, as illustrated in Eq. (58.17). Such electrodes have been used to determine esterase activities in blood samples (Sigolaeva et al., 2013).

By co-immobilizing tyrosinase with a serine esterase on a gold electrode, it is possible to establish a multistep reaction pathway that allows the activity of the esterase to be determined indirectly via measurement of *o*-quinone reduction at the electrode. The molecular architecture of a bi-enzyme sensor interface is shown schematically in Fig. 58.12 (Kohli et al., 2010).

In practice, the fabrication of these bi-enzyme biosensors is relatively straightforward. Gold electrodes are scrupulously cleaned in "Piranha solution" [(concentrated) H_2SO_4: 30% (w/w) H_2O_2, 7:3 (v/v)] and then dipped in a

5 mM solution of thioctic acid in ethanol for 30 min. The electrodes are washed with ethanol, dried under nitrogen, and dipped in positively charged poly-L-lysine (PLL) solution for 45 min. The PLL solution is prepared by adding 12 mg of PLL in 50 mL of 20 mM phosphate buffer (pH 8.5). The electrodes are then rinsed with water and dipped in an aqueous solution of negatively charged tyrosinase (0.2 mg/mL) for 1 h. The last two steps are repeated 3.5 times to create 3.5 PLL-Tyr bilayers, with PLL being the topmost layer. The electrodes are washed with water and dipped in a 0.1 mg/mL solution of a serine esterase (e.g., AChE, BChE, or NEST) in 100 mM phosphate buffer, pH 7.0, for 1 h. The electrodes are then washed with water, dried under nitrogen, and dipped in phosphate buffer (0.1 M, pH 7.0) for testing. All steps are done at room temperature (approximately 22°C) (Kohli et al., 2007a).

58.7.4 Electrochemical measurements of serine esterase activity

The electrochemical properties of serine esterase-containing biosensor interfaces are readily characterized. Each biosensor is immersed in a stirred buffer solution and maintained at a potential of −100 mV (vs an Ag/AgCl reference electrode). For example, NEST activity was measured indirectly via the output current of the electrode for a variety of phenyl valerate concentrations. As shown in Fig. 58.13, the first step involves the diffusion of the ester (e.g., phenyl valerate) through a stagnant film from bulk solution to the enzyme layer. The NEST enzyme then hydrolyzes phenyl valerate to phenol, which is then oxidized to *o*-quinone by tyrosinase. Reduction of *o*-quinone at the surface of the electrode generates a current and regenerates catechol, which can then be

reoxidized by tyrosinase. This internal recycling between catechol and *o*-quinone provides a mechanism for signal amplification, thereby enhancing biosensor sensitivity (Kohli et al., 2007a).

The response of the biosensor to aliquots of ester can be measured at a variety of pH values and applied potentials. For a typical NEST biosensor, the highest signal-to-background ratio is obtained at pH 7.0 and a working electrode potential of −0.1 V relative to an Ag/AgCl reference electrode. At this potential, addition of phenyl valerate to a stirred aqueous solution triggers a rapid increase in the NEST biosensor signal, with a time constant of about 5 s. BChE can be substituted for NEST, with a similar current versus time response using phenyl valerate as substrate. For AChE, phenyl acetate is a better substrate than phenyl valerate. Current increases linearly with phenyl acetate concentration ($R_2 = 0.989$) in the range of 0.5−16 μM, reaching saturation at approximately 40 μM. Current versus time response and concentration calibration curves similar to those obtained for NEST and AChE can be obtained for BChE in the bi-enzyme electrode. Sensitivities of the electrodes obtained from the slopes of the initial linear portions of the concentration calibration curves were found to be 180, 25, and 87 $nA\mu M^{-1}\,cm^{-2}$ for AChE, BChE, and NEST, respectively, where AChE used phenyl acetate, and BChE and NEST used phenyl valerate as substrate. Control experiments were also done in which each of the substrates was delivered to a gold electrode containing only PLL-Tyr bilayers. The current sensitivities obtained in these control experiments were negligibly small—always less than 0.5 $nA\mu M^{-1}\,cm^{-2}$, indicating that the signal is mediated by the esterase activity (Kohli et al., 2007a).

The ability of the biosensors to detect chemical agents was confirmed by adding a known serine esterase inhibitor, phenylmethylsulfonyl fluoride (PMSF), to the solution. The electrode response decreased in a concentration-dependent manner (Kohli et al., 2007a). Using a combination of biosensors containing different target enzymes, for example, AChE and NEST, it would be possible to obtain real-time differential data that could be used to distinguish exposures to conventional versus DN agents.

58.8 Concluding remarks and future directions

Fortunately, DN agents have not yet been used in warfare or terrorism. However, their possible use must be considered seriously, because it is straightforward to design and synthesize these compounds based on established methods in OP chemistry. Thus, a conventional insecticide or nerve agent can be reengineered to produce a DN agent. The use of DN agents would be catastrophic, because there are no accepted means of prophylaxis or treatment, and the effects are devastating and permanent. NTE is the presumptive target for initiation of OPIDN. Accordingly, lymphocyte NTE has been used as a biomarker of exposure, and the NTE catalytic domain (NEST) has been incorporated into a biosensor for detection of DN agents. However, the three-dimensional structure of NTE as well as its precise physiological function and role(s) in the pathogenesis of OPIDN and other neurodegenerative diseases remain to be elucidated. Therefore, further structural and mechanistic understanding is needed in order to improve upon existing biomarkers and biosensors and to develop preventive and therapeutic measures for DN agent exposures. Finally, because the early pathogenesis of Alzheimer's disease (AD), Parkinson's disease (PD), and motor neuron diseases (MNDs), including ALS, involve distal axonopathy (Salvadores et al., 2017), lessons learned from studies of NTE and OPIDN could be applied to developing interventions for these neurodegenerative diseases.

Chapter 59

The cross-linking action of organophosphorus poisons; Implications for chronic neurotoxicity

Oksana Lockridge and Lawrence M. Schopfer

University of Nebraska Medical Center, Eppley Institute, Omaha, NE, United States

59.1 Introduction

Exposure to organophosphorus (OP) pesticides or nerve agents produces an acute toxic response, via a well understood mechanism (Masson and Nachon, 2017). Inhibition of acetylcholinesterase activity results in accumulation of acetylcholine and overstimulation of acetylcholine receptors. The consequence can be respiratory failure and death.

Another way in which OP can cause health issues has been identified in licensed pesticide applicators. These workers developed neurologic symptoms, though they had no history of acute toxicity from exposure to pesticides. It has been proposed that neurologic symptoms were caused by chronic low-dose exposure to OP pesticides (Kamel et al., 2007). Chronic low-dose OP exposure is associated with depression, anxiety, and suicide (Voorhees et al., 2017). Epidemiologic evidence also links low-dose OP exposure to increased risk of Parkinson's disease (Wang et al., 2014) and Alzheimer's disease (Yan et al., 2016). Studies in rodents confirm the relationship between chronic low-dose OP exposure and neurotoxicity (Moser et al., 2005; Hernandez et al., 2015; Voorhees et al., 2019).

A mechanism to explain neurotoxicity and dementia from long-term, low-dose OP exposure is needed. We propose a mechanism that involves a newly discovered function of OP, namely OP catalyzed cross-linking of proteins.

59.2 Chemical reactions of organophosphorus poisons

OP esters are highly reactive chemicals. The most studied reactivity of OP esters is covalent bond formation with the active site serine of the serine esterases including acetylcholinesterase, butyrylcholinesterase, and carboxylesterase. Initial OP modification of the active site serine of acetylcholinesterase and butyrylcholinesterase is followed by a reaction termed "aging" in which an alkyl group on the OP is displaced (Michel et al., 1967; Millard et al., 1999). This reaction results in essentially irreversible inhibition of the cholinesterases. In contrast, OP-inhibited human carboxylesterase-1 spontaneously regains activity with a half-life of 45 h after inhibition by sarin (Hemmert et al., 2010).

The acute toxicity of nerve agents and OP pesticides is due to inhibition of acetylcholinesterase activity at neuromuscular junctions. OP esters also make covalent bonds with the active site serine of serine proteases, including trypsin, chymotrypsin, and thrombin, though this has been documented only in vitro with purified proteins. The serine proteases are less sensitive to OP inhibition than acetylcholinesterase and butyrylcholinesterase, requiring higher concentrations of OP to achieve inhibition. The mechanism of OP adduct formation on serine has been known since 1954 (Schaffer et al., 1954).

A second action of OP was discovered in 2005 by analyzing OP-treated proteins using mass spectrometry (Peeples et al., 2005). It subsequently was found that OP make stable adducts on tyrosine and lysine in proteins that have no active site serine (Grigoryan et al., 2009; Lockridge and Schopfer, 2010). These studies with pure proteins were the foundation for the discovery of a new biomarker of OP exposure in human blood. It was found that humans who poisoned themselves by ingesting chlorpyrifos or dichlorvos have OP adducts on tyrosine 411 of serum albumin (Li et al., 2010, 2013; van der Schans et al., 2013). Studies

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00059-3

in guinea pigs, rats, rabbits, and monkeys have shown that the nerve agents sarin, soman, cyclosarin, VX, and tabun also make stable adducts on tyrosine and lysine in albumin (Williams et al., 2007; Bao et al., 2012; Sun et al., 2017; Lee et al., 2018; Fu et al., 2019). Based on studies with pure proteins and cultured cells, it is expected that almost any protein can be modified on tyrosine and lysine by OP, though to date studies in humans and animals have identified only albumin OP adducts.

A third action of OP was discovered in 2014 when it was reported that the nerve agents VX, Russian VX, and Chinese VX catalyze the formation of internal cross-links in ubiquitin (Schmidt et al., 2014). Our laboratory confirmed the cross-linking action of OP, using chlorpyrifos oxon as the model OP. We found that treatment of pure proteins with 1.5 mM chlorpyrifos oxon resulted in internal cross-links as well as cross-links between proteins (Schopfer and Lockridge, 2018, 2019). The cross-links were between the epsilon amino group of lysine and the gamma carboxyl group of glutamic or the beta carboxyl of aspartic acid. Only specific residues were cross-linked. The degree of cross-linking for a particular pair ranged from about 1% to 10%.

59.3 Cross-linking mechanism

The mechanism by which OP esters cross-link proteins is illustrated in Fig. 59.1 with chlorpyrifos oxon as the OP. In the first step, chlorpyrifos oxon makes a covalent bond on the side chain of lysine in a protein. The products of the first step are a diethoxyphospho-lysine adduct in the protein and 3,5,6-trichloro-2-pyridinol. In the second step, the OP-modified lysine can react with the side-chain carboxyl group of a nearby glutamic acid. This yields an ε-aminolysine γ-glutamate isopeptide bond between two proteins and releases the diethoxyphosphate group from lysine. A similar reaction can occur with the side-chain carboxyl group of aspartic acid. These isopeptide bonds can link proteins to make high-molecular-weight fused protein aggregates, which can be seen on an SDS gel. Internal isopeptide cross-links within one protein are also found.

59.4 Mass spectrometry identifies cross-linked peptides

The isopeptide bond is resistant to proteolytic cleavage by trypsin and to fragmentation during electrospray mass spectrometry. This resistance makes it possible to identify cross-linked peptides by mass spectrometry. Dipeptides linked through an isopeptide bond are identified by their mass and fragmentation pattern. An example of mass spectrometry data for a cross-linked peptide is shown in Fig. 59.2.

A 1 mg/mL solution of purified porcine tubulin in pH 8.5 buffer was treated with 1.5 mM chlorpyrifos oxon for 7 days at 37°C (Schopfer and Lockridge, 2019). Control tubulin was treated under the same conditions but without added chlorpyrifos oxon. Excess chlorpyrifos oxon was removed by dialysis before the sample was reduced, carbamidomethylated, and digested with trypsin. The trypsin-digested sample was subjected to liquid chromatography-tandem mass spectrometry on the 6600 triple-TOF mass spectrometer (AB Sciex). Data were searched for cross-linked peptides using the free Batch-Tag program in Protein Prospector (University of California San Francisco Mass Spectrometry Facility http://prospector.ucsf.edu/prospector/mshome.htm). Protein Prospector reported MSMS spectra of potential cross-linked peptides.

It was essential to manually evaluate each MSMS spectrum to be sure the Protein Prospector assignment was a real cross-link. Our criteria for a cross-linked peptide are as follows. (1) The smallest peptide in the cross-

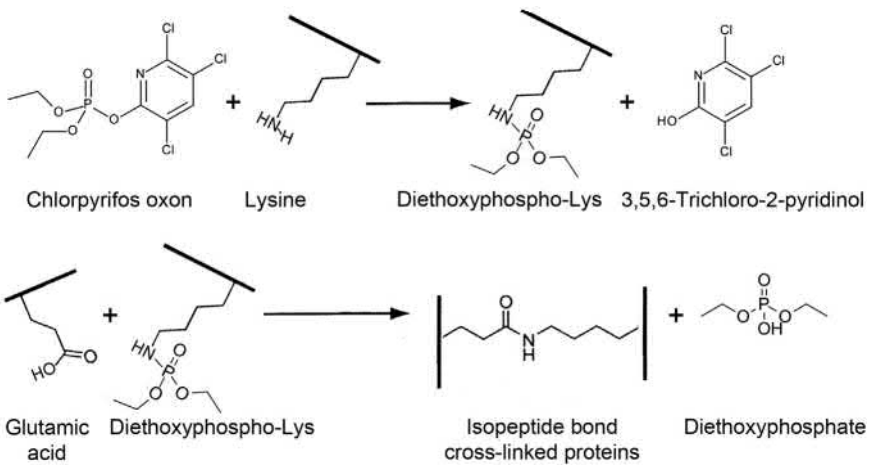

FIGURE 59.1 Chlorpyrifos oxon makes a covalent bond with the ε-amino group of lysine, thus activating the lysine for reaction with a nearby carboxyl group to yield cross-links between proteins and cross-links within a protein.

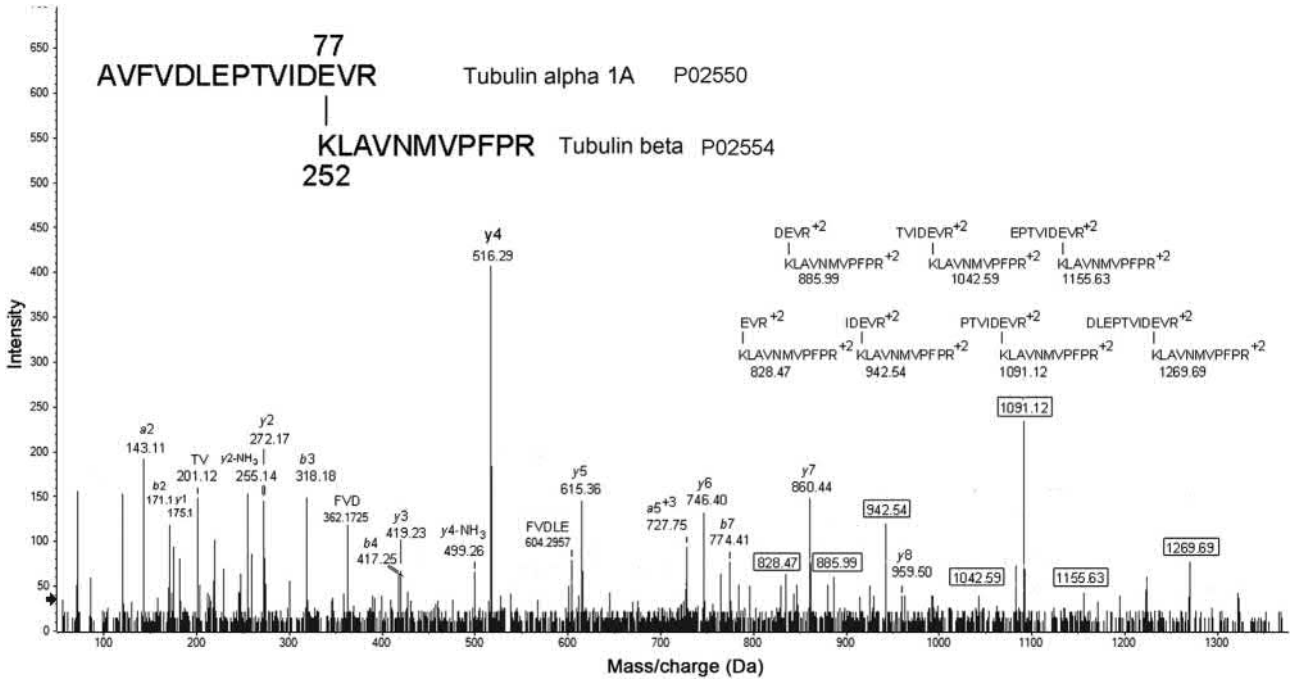

FIGURE 59.2 MSMS fragmentation spectrum of isopeptide cross-linked peptides produced by treatment of purified tubulin (*Sus scrofa*) with 1.5 mM chlorpyrifos oxon. The seven boxed masses are for fragment ions that support the cross-link between E77 of tubulin alpha 1A and K252 of tubulin beta. The structures of the doubly charged cross-linked ions are shown. A *b*-ion series for tubulin alpha 1A includes *b*2, *b*3, *b*4, and *b*7. A *y*-ion series for tubulin beta includes *y*1, *y*2, *y*3, *y*4, *y*5, *y*6, *y*7, and *y*8. The parent ion was positively charged with a monoisotopic mass/charge of 743.4085 for $[M + 4H]^{+4}$. The Uniprot accession number for tubulin alpha 1A is P02550 and for tubulin beta is P02554.

linked pair contains a minimum of four residues. (2) The mass of the parent ion is consistent with the mass of the two peptides minus 18 Da due to loss of a water molecule during the cross-linking reaction. (3) For cross-links between monomers of the same protein, the potential cross-linked peptide is not a contiguous linear sequence. (4) The primary amino acid sequences of both peptides are represented in the MSMS spectrum by a series of either b-ions or y-ions. (5) The MSMS spectrum of the cross-linked peptide candidate includes cross-linked fragments containing components from both peptide chains. (6) Control protein not treated with OP does not have the cross-linked peptide pair. The cross-linked peptide pair in Fig. 59.2 satisfies these criteria.

Cross-linked peptide pairs were also found when 0.1 mM chlorpyrifos oxon was used. Similar cross-links were found when 0.1 mM dichlorvos, chlorpyrifos (precursor of chlorpyrifos oxon), diazinon, diazoxon, and monocrotophos were used.

When 1.5 mM chlorpyrifos oxon was used, a portion of the lysine-containing peptide from the cross-linked pair was found to be modified on the lysine by diethoxyphosphate. But when 0.1 mM chlorpyrifos oxon was used, diethoxyphosphate labeling was not detected on the lysine peptide from the cross-linked pair even though cross-linking was seen. This suggests that the cross-linking reaction with activated diethoxyphosphate-labeled lysine is faster than the formation of diethoxyphosphate-lysine adducts when the chlorpyrifos oxon concentration is low.

59.5 The consequences of treating tubulin with chlorpyrifos oxon

Treatment of porcine tubulin, human albumin, mouse albumin, bovine casein, and human butyrylcholinesterase with 1.5 mM chlorpyrifos oxon yielded cross-links between lysine and glutamic acid, or lysine and aspartic acid. However bovine gelatin, bovine aprotinin, and chicken lysozyme formed no detectable chlorpyrifos oxon-induced cross-links. Tubulin was more susceptible to chlorpyrifos oxon-induced cross-linking than the other proteins, yielding 10 cross-linked peptide pairs in tubulin compared to two cross-linked peptide pairs in human albumin (Schopfer and Lockridge, 2019). Treatment with 1.5 mM chlorpyrifos oxon caused porcine tubulin to aggregate into nonreducible high-molecular-weight species as shown in Fig. 59.3.

Chlorpyrifos oxon perturbs GTP-induced polymerization of tubulin into microtubules, as shown in Fig. 59.4. Images were acquired by atomic force microscopy (Grigoryan and Lockridge, 2009). Bovine tubulin in pH 7.0 buffer was pretreated for 30 min with

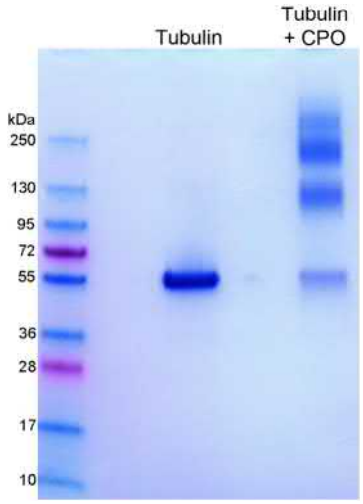

FIGURE 59.3 SDS polyacrylamide gel stained with Coomassie blue. Incubation of porcine tubulin with 1.5 mM chlorpyrifos oxon (CPO) for 7 days at pH 8.5 and 37°C, caused the 55 kDa tubulin to polymerize into nonreducible protein multimers.

0.005−0.10 mM chlorpyrifos oxon before GTP was added to initiate tubulin polymerization. In the absence of chlorpyrifos oxon, addition of 1 mM GTP polymerized tubulin into straight, well-structured, and individually separated microtubules (Fig. 59.4B). This can be contrasted with tubulin in the absence of GTP (Fig. 59.4A). Pretreatment with 0.005 mM chlorpyrifos oxon (Fig. 59.4C) caused a drastic reduction in the number and length of microtubules. Pretreatment with 0.010 mM chlorpyrifos oxon (Fig. 59.4D) increased the number of short microtubules. Pretreatment with 0.025 mM chlorpyrifos oxon (Fig. 59.4E) stimulated microtubule polymerization, increasing their density and clustering. Pretreatment with 0.050 mM chlorpyrifos oxon (Fig. 59.4F) caused the microtubules to clump. Pretreatment with 0.10 mM chlorpyrifos oxon (Fig. 59.4G) yielded short tubulin clusters. For comparison, the effect of a known microtubule polymerization inhibitor, colchicine, is shown in Fig. 59.4H. It was concluded that concentrations as low as 5 μM chlorpyrifos oxon interfered with microtubule formation.

Chlorpyrifos oxon disrupts the microtubule structure in vivo. We isolated microtubules from the brains of mice treated with nonlethal doses of chlorpyrifos oxon and examined the microtubules by atomic force microscopy (Jiang et al., 2010). We found that microtubules isolated from the brains of control mice were decorated with many proteins, but microtubules from chlorpyrifos oxon-treated mice had fewer associated proteins, suggesting disruption of microtubule function in vivo, as a consequence of exposure to chlorpyrifos oxon. Microtubules are polymers of tubulin dimers whose function is to maintain cell structure and provide tracks for transporting cell components between the cell nucleus and the axon. Disruption of the microtubule structure is consistent with our hypothesis (see below) that OP exposure causes cytoskeleton proteins (including tubulin) to cross-link, thus initiating the steps that lead to permanent loss of neuronal function.

59.6 Implications for neurotoxicity

A unifying hypothesis to explain neurodegenerative diseases including Alzheimer's, Parkinson's, Huntington's, and prion disease has been developed by Brady and coworkers (Brady and Morfini, 2017; Zamponi et al., 2017). The Brady hypothesis includes the following steps. (1) Aggregated proteins stimulate kinase activity in neurons. (2) The activated kinases phosphorylate motor proteins in excess. (3) The excessively phosphorylated motor proteins drop their cargo. (4) Loss of cargo deprives neurons of constituents that maintain neuron function. (5) Neurons slowly lose their connections to other neurons. (6) Clinical symptoms develop as a consequence of disruption of the neural network. Our finding that OP pesticides are cross-linking agents suggests a way to incorporate OP-induced neurotoxicity into the Brady hypothesis. Namely, OP toxicants promote formation of protein aggregates that initiate the process leading to clinical symptoms.

The published literature on the effects of OP treatment fits the Brady hypothesis in that OP exposure leads to aggregation of proteins in the neuron, to hyperphosphorylation of proteins involved in axonal transport, to impaired axonal transport, and to a decrease in neuronal connectivity. Specifically, studies in neuroblastoma cells, cell-free systems, and animals have shown that: (1) diazoxon and chlorpyrifos oxon induce protein aggregation in mouse neuroblastoma cells (Flaskos et al., 2011; Sachana et al., 2014). (2) OP induce hyperphosphorylation of neurofilaments (Gupta and Abou-Donia, 1995; Sindi et al., 2016), Tau protein (Gupta and Abou-Donia, 1999), calcium/cAMP-response element-binding protein (Schuh et al., 2002), tubulin and microtubule-associated protein 2 (Choudhary et al., 2001). (3) OP cause impaired axonal transport (Gupta et al., 1997; Gearhart et al., 2007; Hernandez et al., 2015; Naughton and Terry, 2018). (4) Mice treated with a subclinical dose of chlorpyrifos for 5 consecutive days had a 50% decrease in synaptic spine density 3 months after the last chlorpyrifos treatment (Speed et al., 2012), thereby reducing connectivity to other neurons.

59.7 Zero-length cross-links between lysine and glutamic acid or lysine and aspartic acid

We have found that treatment of pure proteins with chlorpyrifos oxon, dichlorvos, chlorpyrifos (precursor of

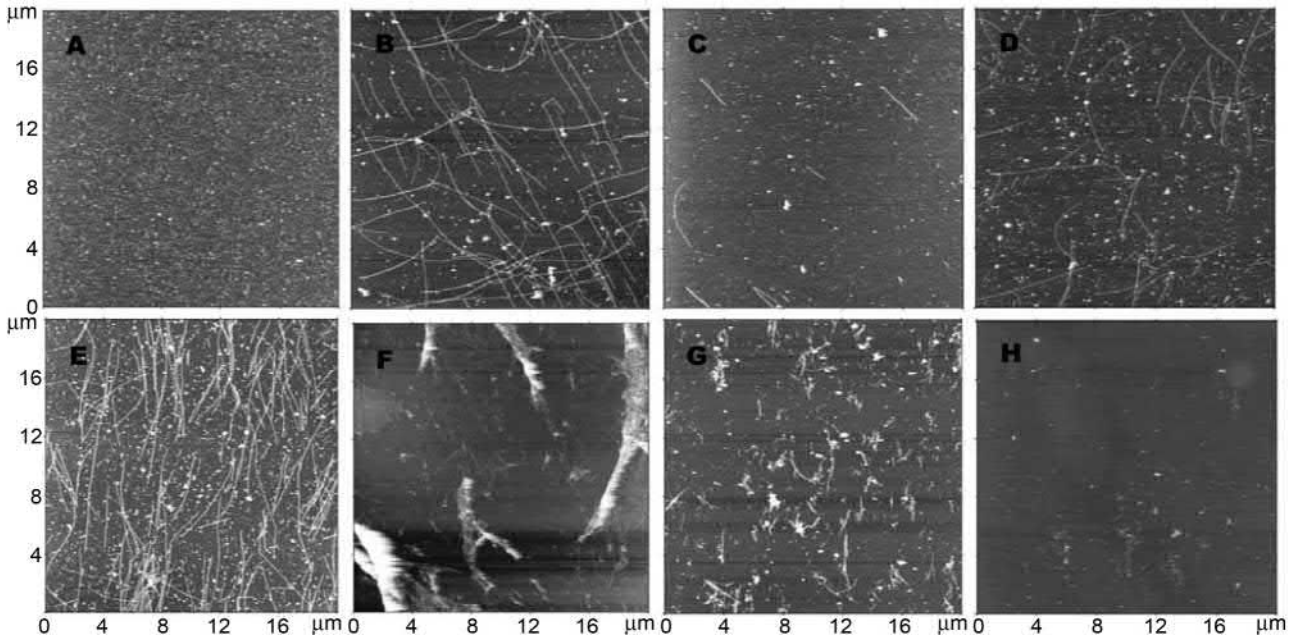

FIGURE 59.4 The effect of chlorpyrifos oxon on GTP-induced polymerization of tubulin, monitored by atomic force microscopy. (A) 0.1 mM bovine tubulin control, no GTP, no chlorpyrifos oxon; (B) 0.1 mM tubulin polymerized with 1 mM GTP, no chlorpyrifos oxon; (C) inhibition of GTP-promoted polymerization of tubulin by pretreatment with 0.005 mM chlorpyrifos oxon for 30 min before addition of GTP; (D) pretreated with 0.010 mM chlorpyrifos oxon before addition of GTP; (E) pretreated with 0.025 mM chlorpyrifos oxon before addition of GTP; (F) pretreated with 0.050 mM chlorpyrifos oxon before addition of GTP; (G) pretreated with 0.10 mM chlorpyrifos oxon before addition of GTP; (H) polymerization inhibited by 0.025 mM colchicine. Pharmacol. 240, 143–148 with permission from Elsevier and Copyright Clearance Center.*

chlorpyrifos oxon), monocrotophos, diazinon, and diazoxon induces proteins to form cross-links between and within proteins. The residues in the cross-link are lysine and either glutamic or aspartic acid. The cross-link is zero length because atoms from the OP are absent in the cross-link. The mass of a cross-linked dipeptide is the sum of the masses for each peptide minus 18 Da for loss of a water molecule. The OP-activated lysine releases the OP during reaction with the carboxyl group to make the isopeptide bond (see Fig. 59.1).

The ability of OP to induce protein cross-linking is a novel finding. Schmidt et al. (2014) reported that VX made internal, zero-length, isopeptide cross-links within ubiquitin that resulted in cyclic structures. Schopfer et al. reported the cross-linking action of chlorpyrifos oxon on a variety of proteins yielding both internal, cyclic structures and protein–protein linkages (Schopfer and Lockridge, 2018; Schopfer and Lockridge, 2019). The only other chemical that is known to make zero-length cross-links is carbodiimide.

To date, no enzyme is known that catalyzes formation of an isopeptide bond between lysine and glutamic acid, or lysine and aspartic acid. Transglutaminase catalyzes cross-linking of the side chain of lysine to the side chain of glutamine to form a stable isopeptide bond (Murthy et al., 2009). Mammalian as well as bacterial transglutaminases have this capability (Bechtold et al., 2000). Mass spectrometry easily distinguishes between OP-induced (lysine to Glu or Asp) and transglutaminase-induced (lysine to Gln) cross-linked peptides. Future studies of human and animal tissues will be able to identify proteins cross-linked in vivo by exposure to OP.

59.8 Concluding remarks

In conclusion, we hypothesize that chronic neurotoxicity from low-dose OP exposure could be initiated by protein aggregates that develop as a consequence of OP-induced cross-linking activity.

60.1 Introduction

Determination of the activity of blood cholinesterases [red blood cell (RBC) AChE and plasma BChE] is currently the most important tool for confirmation of poisoning from a highly toxic organophosphate nerve agent (OPNA) for monitoring the recovery progress of an intoxicated person, and for forensic study purposes (Karalliedde et al., 2003; Pope et al., 2005; Bajgar, 2004, 2005; Eddleston et al., 2005; Pakravan et al., 2016). It is necessary to examine the whole picture of intoxication, that is, not only biochemical assays but also clinical signs, allowing more precise assessment of the prognosis for the intoxication. The evidence supporting AChE as the primary target of OPNA action has been confirmed and summarized by many authors (Bajgar, 1985, 1991; Taylor, 1985; Marrs, 1993; Marrs et al., 1996; Lotti, 2000). It includes the following observations: (1) symptoms of organophosphorus compound (OP) poisoning are similar to those of the AChE inhibitor physostigmine; (2) the in vivo LD_{50} value for a variety of OPs correlates well with the inhibition efficacy to AChE determined in vitro; and (3) cholinesterase reactivators (e.g., oxime reactivators), anticholinergics (e.g., atropine, benactyzine), and spontaneously reactivating AChE inhibitors (e.g., carbamates) can reduce OP toxicity. However, there is a variety of documented data showing that AChE inhibition is not the only important biochemical change in the body during intoxication. These data have described many other changes that accompany the development of intoxication and may contribute to OP toxicity. They have included changes to other enzymes (e.g., BChE, neurotransmitters, immune changes, anaphylactic reaction, behavior, etc.). The evidence includes the data indicating that prophylactic/therapeutic drugs might also have multiple sites of action (e.g., cholinergic or noncholinergic) similar to those observed during intoxication (Bardin and van Eeden, 1990; Bajgar, 1991, 1992; Cowan et al., 1996; Kassa, 1998; Soukup et al., 2010, 2013).

The first reaction of OPs is interaction with cholinesterases in the bloodstream (Bajgar, 1985, 1991; Benschop and de Jong, 2001) and then in the target tissues, the peripheral and central nervous systems (Bajgar, 1985, 1991; Bardin and van Eeden, 1990; Green, 1958, 1983; Marrs, 1993; Marrs et al., 1996). The delayed neurotoxic effect is due to something other than cholinesterase inhibition. The neuropathy target esterase (NTE) has been described as the main target site for this symptom, however, only some OPs are neurotoxic in that sense (Abou-Donia and Lapadula, 1990; Lotti, 1992; Johnson, 1990, 1992; Johnson and Glynn, 1995; Slotkin et al., 2008; Estevez et al., 2018).

The mechanism of AChE inhibition for all OPNAs is practically the same—it is enzyme inhibition via phosphorylation or phosphonylation of the esteratic (active) site of AChE. Monitoring the changes in cholinesterase activity and their development during intoxication is at present the best way for determining the severity of OP poisoning, as well as the reaction to antidotal therapy.

Both the toxicodynamics and toxicokinetics of OPNA can be explained by their biochemical characteristics of interacting with cholinesterases and other hydrolases in the

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00060-X

organism. Inhibition of AChE and BChE in the blood is practically the first target for OPs according to the principle "first come, first served" (Benschop and de Jong, 2001).

AChE and BChE differ in their enzymatic properties and physiological functions (Massoulié et al., 1993; Darvesh et al., 2003; Thapa et al., 2017). Additionally, there are other cholinesterases, such as benzoylcholinesterase, propionylcholinesterase, etc. (Falugi et al., 2002; Hubbard et al., 2008). AChE splits neurotransmitter acetylcholine at the cholinergic synapses (synaptic clefts). It was also observed in the RBCs but its function is not fully known. It probably participates in cell-to-cell interactions (Assis et al., 2018). Similarly, the function of BuChE aktivity in plasma was only partially revealed, though there is evidence that BChE plays an important role in cholinergic neurotransmission and could be involved in other nervous system functions, including neurological diseases (e.g., Alzheimer's disease). BChE is also involved in nonspecific detoxification processes of ester-type local anesthetics and other compounds (Darvesh et al., 2003; Lockridge, 2015).

60.2 Determination of cholinesterases

Determination of cholinesterase activity is based on many principles. In general, an enzyme is added to the buffered or unbuffered mixture and a reaction begins once an appropriate substrate is added. Different parts of the reaction mixture are continually determined, that is, unhydrolyzed substrate or reaction products, either directly or indirectly (Augustinsson, 1971; Holmstedt, 1971; Witter, 1963). Conditions must be chosen very carefully (Dingova and Hrabovska, 2015; Reiner and Simeon-Rudolf, 2000).

According to the procedure and laboratory instrumentation, the most common methods of cholinesterase determination are as follows: electrometrical (e.g., Michel, 1949), titration (e.g., Nenner, 1970), manometric (e.g., Witter, 1963), colorimetric detection of the unhydrolyzed substrate (e.g., Hestrin, 1949), direct measurement of the pH change using an indicator (Dingova and Hrabovska, 2015; Winter, 1960), spectrophotometric (e.g., Siders et al., 1968; Voss and Sachsse, 1970; Worek et al., 1999a, b), fluorimetric (e.g., Sasaki, 1964; Kusu et al., 1990),

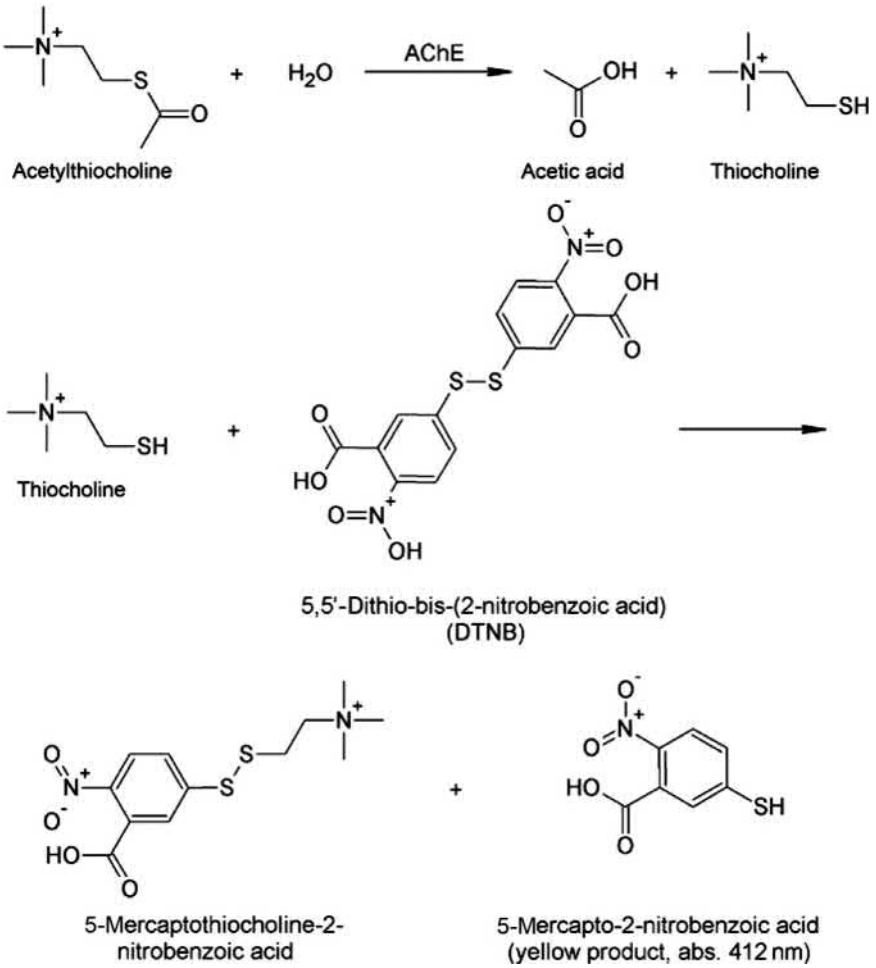

FIGURE 60.1 Acetylthiocholine is hydrolyzed by AChE/BChE to acetic acid and thiocholine, which forms yellow 5-mercapto-2-nitrobenzoic acid after reaction with Ellman's reagent.

radiometric (e.g., Israel and Lesbats, 1987), calorimetric (Konickova and Wadso, 1971), polarographic (Fiserova-Bergerova, 1969), enzymatic (Abernethy et al., 1986; Israel and Lesbats, 1987), and others, for example, near-infrared spectroscopy (Domjan et al., 1998). These methods are also suitable for the detection of cholinesterase inhibitors using biosensors (Brimijoin and Rakonczay, 1986; Ciriello et al., 2018; Cremisini et al., 1995; De Jong and Benschop, 1988; Miao et al., 2010; Walker et al., 2007) or immunochemical assay for detection of chemical warfare agents (Lenz et al., 1997a,b).

A very sensitive and commonly used method for cholinesterase determination was described by Ellman et al. (1961). This assay is based on hydrolysis of the thiocholine substrates acetyl- and butyrylthiocholine or others. When the substrate is cleaved, the relevant acid and thiocholine are released and thiocholine is detected by its SH-group using 5,5′-dithiobis-2 nitrobenzoic acid forming 5-mercapto-2-nitrobenzoic acid and determined spectrophotometrically at 412 nm (maximum absorbance). Slightly different wavelengths (e.g., 405 nm, 436 nm) may be used according to the specific instrument, to avoid interferences (Fig. 60.1).

Occasionally, the Ellman method is used with specific inhibitors in order to selectively inhibit the activity of either AChE or BChE and there are many modifications described in the literature. This method is in good correlation with other described methods. It is sufficiently specific and sensitive and it is used for different purposes in many laboratories around the world. Expression of AChE activity varies greatly, usually as μmoles of substrate hydrolyzed per min (time) per mL of material examined (e.g., plasma, serum) or per mg of tissue (wet, dry, mg of nitrogen, etc.). From these values, the expression of enzyme activity in international units (symbol: U) can be derived (quantity of enzyme catalyzing μmol of substrate per min at standard conditions). In the clinical laboratory, enzyme activity can also be expressed as katal (symbol: kat) per liter, that is, 1 mol of substrate hydrolyzed/s/liter or kg (kat/L or kat/kg), which is the hydrolysis of 1 mol of substrate hydrolyzed/s/liter or kg (mol/s/L or mol/s/kg). For conversion, 1 kat corresponds to 60,000,000 U or conversely 1 U corresponds to 0.000,000,016,666,666,7 kat. There are many publications addressing the review and modifications of cholinesterase determination. One of the last works written for improving Ellman's method (Ellman et al., 1961), including a description of the methods, is a paper published by Worek et al. (1999a).

60.3 Factors influencing the activity of cholinesterases

The influencing of BChE activity by gamma-irradiation, stress, gravidity, some neurological and psychiatric disorders, hormones, and medical drugs has been demonstrated (Brown et al., 1981; Bajgar, 1985, 1998; Darvesh, 2016). The elevation of BChE activity is not as common as an increase in children with nephritic syndrome has been observed. An elevated ratio of BChE/LDL cholesterol indicates an increase in the risk of cardiovascular diseases (Kutty, 1980; Navratil and Bajgar, 1987). The involvement of BChE in fat (cholesterol) metabolism has been studied and correlated (Han et al., 2019; van Lith et al., 1991; Van Lith and Beynen, 1993). The relationship between BChE activity and experimentally induced diabetes mellitus in rats is also mentioned (Annapurna et al., 1991). BChE activity in serum can be regarded as a biomarker for Parkinson's disease and related dementia (Dong et al., 2017).

In clinical biochemistry, BChE determination in plasma or serum is more frequently used than that of AChE in RBCs. Except for intoxication with OPs or carbamates, a BChE decrease indicates either a decrease in enzyme synthesis or a decrease in the number of production cells in the liver (Masopust, 1983). A special case of diminished BChE activity is the hereditary presence of atypical variants of BChE (Brown et al., 1981; Whittaker, 1980). There are many other factors influencing BChE activity and the diagnostic importance of diminished BChE activity is important for the following states: congenital deficiency, liver damage, acute infection, inflammation, chronic malnutrition, metastasis (especially liver), myocardial infarction, dermatomyositis, intoxication with carbon disulfide or mercury, and obstructive jaundice (Kutty, 1980; Molphy and Ratthus, 1964; Bardin and van Eeden, 1990; Bajgar, 1991).

Determination of AChE activity is not generally performed in clinical laboratories. A decrease in RBC AChE activity in pernicious anemia has been demonstrated; diminished erythrocyte AChE activity is typical for paroxysmal nocturnal hemoglobinemia and ABO incompatibility (Rakonczay, 1988). AChE activity in the erythrocyte membrane can be considered an indicator of membrane integrity. Increased AChE activity in rectal biopsy is of great diagnostic significance in Hirschsprung's disease, especially in the presence of its atypical molecular form (Bajgar and Hak, 1979; Rakonczay, 1988; Saldanha, 2017). There are other papers demonstrating increased AChE activity in the amniotic fluid during pathologic development of the neural tube (Bonham and Attack, 1983). AChE activity in the erythrocytes and cerebrospinal fluid is also diminished in some endogenous depressions and other psychiatric disorders and is probably also connected with behaviors related to stress situations. However, the results presented are not quite clear at present (for a review see, e.g., Bajgar, 1985; Rakonczay, 1988; Bohnen et al., 2007; Martucciello, 2008; Saldanha, 2017).

60.4 Diagnosis of organophosphorus compound poisoning

The determination of cholinesterases in the blood is the basic method for diagnosis and therapy monitoring for OP poisoning, though some doubts exists, preferring the clinical signs of poisoning as a leading tool for diagnosis and monitoring (Bardin and van Eeden, 1990). The determination of AChE and BChE activity in whole blood is possible. The decrease in these activities is a good marker but diagnostic validity is limited in that some factors causing a decrease in blood cholinesterases are present. This information is important, along with the anamnestic data (exposure to OP). The determination of red blood cell AChE or plasma BChE is more informative. There are some discussions regarding whether AChE or BChE activity is more important for diagnosis. In general, AChE activity in the red blood cell can be considered more important for diagnosis of nerve agent poisoning than plasma BChE activity. However, there are some discussions dealing with the validity of BChE determination. This enzyme has been described as a poor marker of OP poisoning and it has been proposed to exclude its analysis from recommended biochemical procedures (Molphy and Ratthus, 1964; Wyckoff et al., 1968; Bardin et al., 1987a,b). The temporal profile of BChE was studied in a cohort of 25 OP-poisoned patients to examine their relationship to the development of intermediate syndrome. The study suggests that BChE reflects the clinical course of poisoning and that intermediate syndrome may be associated with persistent BChE inhibition (Khan et al., 2001). Israeli authors also described a direct correlation between the degree of BChE inhibition levels and the severity of intoxication with OP (Weissmann-Brenner et al., 2002). According to Aygun et al. (2002), in the acute phase of OP poisoning, a low level of AChE supports the diagnosis of OP poisoning but it does not show a significant relationship to the severity of poisoning. Cander et al. (2011) confirmed the validity of AChE activity for the quick diagnosis of poisoning, however its efficiency at predicting outcome in patients with OP intoxication has not been established. The preference of AChE determination has been demonstrated by Worek et al. (1999b)—BChE activity determination for diagnosis and therapeutic monitoring provides no reliable information on AChE status. This is in agreement with the author's experimental results (Bajgar, 1998). In some cases, plasma BChE activity is a good marker for diagnosis of OP pesticide poisoning. It is necessary to exclude diminishing BChE activity caused by other reasons. In all cases, simple cholinesterase determination gives information about the decrease in enzyme activity without specification of the factor causing this phenomenon. A more detailed specification is possible using special methods not available in all clinical laboratories.

For occupational medicine purposes, the determination of cholinesterases in the blood of workers with OP is obligatory. A decrease of activity below 70% of normal values is an indicator that the worker should not come into contact with OPs. However, the normal values varied within the laboratories depending on the method/specific conditions of determination.

For practical purposes (individual and interindividual variation), determination of individual norm activity is recommended (this approach is better than calculating the decrease from an average value), as well as a separate determination of both cholinesterases. Enzyme activity in whole human blood corresponds to about 10% of BChE and 90% of AChE. This is different from rats where this activity ratio is 29% of BChE and 71% of AChE (Bajgar, 1972). Erythrocyte AChE activity seems to be more useful for these purposes than BChE activity in the plasma.

There are other biological materials available for special purposes—amniotic fluid, cerebrospinal fluid, and bioptic materials. From these samples, tissue obtained via rectal biopsy is used most frequently (diagnosis of Hirschsprung's disease). Elevated AChE activity in the rectal tissue/homogenate (detected histochemically/biochemically) is a good diagnostic marker indicating a need for surgical treatment of Hirschsprung disease and a criterion for the diagnosis and management of obstipation (Kobayashi et al., 2002). The presence of an unusual AChE band after electrophoretic separation supports the diagnosis (Bajgar and Hak, 1979; Rakonczay, 1988). The same (either AChE elevation or the presence of a new electrophoretic AChE form) in the amniotic fluid can be applied for the diagnosis of malformation of the neural tube development during pregnancy (Bonham and Attack, 1983). AChE activity in the cerebrospinal fluid is also changed in some pathological states; however, this information has little diagnostic validity and can be considered a complementary analysis (Koponen and Riekkinen, 1991).

In OP poisoning, it is necessary to check vital functions (cardiac, ventilation) and other clinical signs and, per symptoms, to apply different biochemical analyses and treatment. Diagnostic criteria are mostly based on patient history and respiratory symptoms (Bardin et al., 1987a,b; Bardin and van Eeden, 1990). Serum electrolytes (especially potassium), blood urea nitrogen (BUN), and creatinine are necessary to assess the degree of volume depletion by the secretory losses. Arterial blood gas, blood pH, glucose, lactate, and pyruvate allow assessment of the degree of hypoxia/hypercapnia/acidosis in the presence of respiratory distress. The neurological examination includes recording of the muscle action potential of M. abductor digiti minimi after stimulation of N. ulnaris. A quantitative correlation could be shown between red blood cell AChE activity and paraoxon concentration in

the plasma. In these cases, muscle function was severely disturbed when red blood cell AChE activity was inhibited more than 90% (Thiermann et al., 2002).

Direct determination of the toxic agent (OPNA) in the circulating system is also possible. However, the parent compound will circulate intact for a short period of time and detection will not be possible after a few hours of exposure. Metabolites circulate for a longer time period and are mostly excreted in the urine. A metabolite of sarin (*O*-isopropyl methylphosphonic acid) could be traced in urine and plasma from victims after the Tokyo subway sarin terrorist attack (Noort et al., 1998, 2002). For some OP pesticides (parathion, paraoxon), detection of *p*-nitrophenol in the urine is an indicator of exposure (Bajgar, 1985). However, the retrospectivity of these methods is limited. Detection using an immunoassay of nerve agents is now in progress. The antibodies against soman may have the appropriate specificity and affinity for immunodiagnosis of soman exposure (Lenz et al., 1997a,b; Miller and Lenz, 2001). Antibodies directed against certain NA were also considered for treatment of NA intoxication (Grognet et al., 1993).

The methods for determination of blood cholinesterase inhibition (AChE and BChE) do not allow identification of the OP and do not provide reliable evidence for exposure at inhibition levels less than 10%−20%. Moreover, they are less suitable for retrospective detection of exposure due to de novo synthesis of enzymes. Recently, a method was developed which is based on reactivation of phosphylated cholinesterase and carboxylesterase (CaE) by fluoride ions. Treatment of the inhibited enzyme with fluoride ions can inverse the inhibition reaction, yielding a restored enzyme and a phosphofluoridate, which is subsequently isolated and quantified by gas chromatography and phosphorus-specific or mass spectrometric detection (De Jong and van Dijk, 1984; Polhuis et al., 1997; Polhuijs et al., 1997). Human (and monkey) plasma does not contain CaE but its BChE concentration is relatively high [70−80 nM (Myers, 1952; De Bisschop et al., 1987)], much higher than the concentration of AChE in blood [c.3 nM (Heath, 1961)]. The plasma of laboratory animals, such as rats and guinea pigs, contains considerable concentrations of CaE, in addition to cholinesterases. This method allows partial identification of the OP, whereas the lifetime of the phosphylated esterase (and consequently the retrospectivity of the method) is only limited by spontaneous reactivation, in vivo sequestration, and aging. The rate of the latter process (aging) depends on the structure of the phosphyl moiety bound to the enzyme and on the type of esterase. Phosphylated CaEs generally do not age. Based on this method for retrospective detection of exposure to OP, the exposure of victims in the Tokyo incident to an OP, probably sarin, could be established from analysis of their blood samples (Fidder et al., 2002; Polhuis et al., 1997; Polhuijs et al., 1997). Fluoride-induced reactivation of OP-inhibited AChE is a reliable and retrospective method to establish OP exposure. It is limited to compounds that could be regenerated with fluoride ions. A novel and general procedure for diagnosis of exposure to OP, which surpasses the limitations of the fluoride reactivation method, has been described (Van der Schans et al., 2002). This method is based on the rapid isolation of BChE from the plasma by affinity chromatography and digestion with pepsin, followed by liquid chromatography and the mass spectrometric analysis of phosphylated nonapeptides, which result after the pepsin digestion of inhibited BChE. The method can be applied for the detection of exposures to various OP pesticides and NA (including soman). This approach is very valuable and represents a new field for the improvement of diagnosis with NA and OP. A comprehensive review of the methods for retrospective detection of exposure to toxic scheduled chemicals has been published by Noort et al. (2001, 2002). The same principle, digestion of enzyme and subsequent analysis using liquid chromatography and tandem mass spectrometry, was successfully used for determination of NA exposure using RBCs. Before the determination, human RBC AChE was immunopurified in order to obtain a sufficient amount of inhibited enzyme for analysis (Dafferner et al., 2017).

As was mentioned previously, a decrease in cholinesterase activity is indicative (after the exclusion of other factors) of an exposure to OPNA or other cholinesterase inhibitors. This simple determination does not allow for decisions regarding antidotal therapy (especially the repeated administration of reactivators) and it has low prognostic validity. Therefore, a new test of the reactivation has been described (Bajgar, 1991). The principle of the reactivation test is double determination of the enzyme, the first without and the second with the presence of a reactivator in the sample. The choice of reactivator is dependent on the availability of the oxime, however, in principle it is necessary to have in these parallel samples the same concentrations of reagents. The concentration of the reactivator (usually trimedoxime, but other oximes such as obidoxime, pralidoxime, or HI-6 are also possible) must not be higher than the oxime concentration which causes the oximolysis (hydrolysis) of the substrate (acetyl- or butyrylthiocholine), that is, the oxime concentration is lower than 10^{-3} M because higher concentrations of oximes cause artificial hydrolysis of the substrate (Patocka et al., 1973; Worek et al., 2012).

OP poisoning is very complex and there are many biochemical changes to be determined. The assessment of sensitivity and specificity was rather subjective, however, it is clear that the following parameters are the most sensitive: (1) cholinesterase determination, (2) possible determination of OP metabolites in the blood, and (3) possible determination of the phosphonyl moiety on the target enzyme. In intoxications where convulsions occurred, tension of the blood gases is also a good marker; however,

these changes are not very specific. The same approach can be applied to lactate. This is not surprising because of the existence of convulsions, including convulsions of the diaphragm (and thus disturbed ventilation, low oxygen saturation, and an increase in acid metabolites). It should also be mentioned that the validity of these parameters changes during intoxication. The changes in transaminases, LDH and γ-GT, indicating liver damage can be caused by solvents used in commercially available OP insecticides. A low validity in the number of RBCs or leukocytes is also indicated. As for CS and TAT—stress markers—it is clear that OP intoxication represents a stress situation. In this scenario, an increase in ALT can also be considered a stress marker and not indicative of liver damage.

Determination of AChE or BChE molecular forms can be interesting and useful for improvement of the diagnosis of OP poisoning. It was demonstrated that these forms are inhibited in different manners—some forms are resistant (low molecular weight), and others are very sensitive (high molecular weight). When total AChE activity is determined, the value obtained is a "mean of the activities of these forms." The changes in the cyclic nucleotides are interesting but not very valid for blood. They were determined during animal experiments with toxic OC and are of more interest in connection with the nervous system. Esterases and AP, generally hydrolases, are sensitive but the inhibition potency of different OPs is variable. For nerve agents, these hydrolases are not especially valid, but for some OP insecticides (malathion) they are sometimes more sensitive than cholinesterases. In conclusion, diagnosis of OP poisoning represents a serious problem. The development of new specific methods (fluoride reactivation, tandem MS analysis of enzymatic digestion of AChE or BChE) is of high importance for more precise diagnosis of OPNA poisoning. An extensive review by Noort et al. (2002) addressing biomonitoring of exposure to chemical warfare agents (not only nerve agents) is strongly recommended. From a practical point of view in the clinical laboratory, it is necessary to monitor basic physiological functions, cholinesterases, and other biochemical parameters not only for diagnostic purposes but also preferably for the regulation of treatment.

60.5 Monitoring of blood cholinesterase activity in workers exposed to nerve agents

60.5.1 Introduction

For occupational medicine purposes, the determination of cholinesterases in the blood of workers exposed to OPs is obligatory. However, the normal values vary within the laboratories depending on the method of analysis.

Systematic monitoring of workers exposed to nerve agents was performed at the University of Defense, Department of Toxicology, during 1962−63. However, results presented expand over 40 years (1964−2004). Due to the large amount of data, the results are limited to RBC AChE only, though plasma BChE activity was also determined.

60.5.2 Methods for determination

Modified Hestrin's method (Hestrin, 1949) was used initially. This method is based on colorimetric detection of unhydrolyzed substrate, acetylcholine. Acetylcholine reacts with hydroxylamine quantitatively in alkaline solution after a reaction with $FeCl_3$. The activity was determined in RBC hemolysate distilled water (1:20). The method was modified and activity was expressed as μmoles of hydrolyzed acetylcholine/min/mL.

In 1964, a method described by Winter (1960) using an Auto Analyzer (Technicon, United States) system was evaluated. This method is based on determination of acetic acid released from the hydrolyzed substrate (acetylcholine) and detected with phenol red. AChE activity in RBC hemolysate (1:10, distilled water) was determined (pH 7.6, phosphate buffer, 37°C). The activity was expressed as μmol of acetic acid/10 min.

From 1972 to 1975, Ellman's method (Ellman et al., 1961) modified for Auto Analyzer was used. Enzyme activity was expressed as ncat/L. The same method was used for enzyme determination using a kinetic method and Vitatron (Eefde, Holland, 976-90) and Uvicon 952 (Kontron Instruments, Switzerland instrumentation, 1991−2004).

60.5.3 Correlation among methods

To achieve comparable results (unification of the activity, i.e., one scale), all activities were recalculated to nkat/liter (nkat/L). Recalculation of enzyme activity was performed as follows:

U/L = 16.6667 nkat/L. However, when using different substrates (esters of choline and thiocholine), correction was made according to correlation analysis ($y = 2.0188x + 2.2458$ and $r_{xy} = 0.9998$). Moreover, this correlation was demonstrated previously including not only Ellman's and Winter's methods (Ellman et al., 1961; Winter, 1960), but also a potentiometric method.

60.5.4 Subjects

International inspectors: 28 males (two determinations, 2000 and 2002), 7 selected (more determinations), age unknown.

Students: 21 medical students, 10 female, 11 male, age 19–20 years.
Workers in the Department of Toxicology: 18 males, from these, 9 were selected for long-term study; and 23 females, from these 13 were selected for long-term study. Last determination was performed at age 60 (female) and 65 (male).
Age at the beginning of study: 24–40 years (male), 19–48 years (female). All determinations were performed from 1964 to 2004.

60.5.5 Statistical analysis

Due to the large number of data, only RBC AChE results are shown. A simple survey began with division of AChE activities (female and male). The next step was analysis of individual results and trends. Some attempts were made to detect a decrease of AChE activity in case of potential exposure to nerve agents. The results are not fully evaluated and may be considered preliminary.

60.5.6 Results and discussion

The results with Hestrin's method (Hestrin, 1949) are documented as an average activity of RBC AChE. Normal AChE activity was determined to be 104.9 ± 8.5 nkat/L and coefficient of variation was 27.1%. This method was relatively difficult and data are shown for information only. The results of AChE activities for all persons are shown in Fig. 60.2.

Selected results of RBC AChE activity determination for all results are shown in Table 60.1.

The correlation of activities in hemolysate and whole blood is shown in Fig. 60.3.

In general, there were some tendencies to decrease cholinesterase activity, especially RBC AChE activity. Some rare examples of suspect intoxications were observed in the cholinesterase monitoring as well as an RBC AChE decrease in workers during their work with high concentrations of nerve agents (e.g., inhalation exposure experiments) (Fig. 60.4).

In a practical way, the best picture of cholinesterase was achieved using individual norms for RBC AChE. This appears to also be a sensitive parameter for monitoring cholinesterase changes in exposed workers, followed by sensitivity for whole blood hemolysate. Plasma BChE activity is not as specific or sensitive a parameter. A 30% decrease of individual normals seems to be critical for further consideration. In conclusion, cholinesterase

determination in blood (especially RBC AChE) is a good parameter for assessing and monitoring workers who are exposed to highly toxic nerve agents.

Variation of RBC AChE is relatively high. Therefore, individual levels were considered more accurate, and the 30% decrease from individual norms was selected to be the limit of exclusion of workers from active work with nerve agents. Further decrease can be considered a significant diagnostic marker for suspected intoxication. According to the decrease, classification of steps of intoxication can be assumed: a decrease by 30%–50% indicates mild poisoning, further inhibition (50%–70%) medium, and severe (70%–90%) intoxication. This decrease is in good agreement with results on human and animals (Bajgar, 1992). An observed higher AChE activity for males was not significant. This coincides with other results (Augun et al., 2002). Similar results were obtained from other authors showing no significant differences in RBC AChE activity between males and females (Rumenjak, 1998) with a tendency toward increased activity with age (not significant). In general, the values of RBC AChE activity are quite comparable with results from other authors (Augun et al., 2002; Rumenjak, 1998; Zhou et al., 2003).

60.6 Concluding remarks

1. Sensitivity of blood cholinesterases as a diagnostic parameter for monitoring of workers exposed to nerve agents was demonstrated.
2. Sensitivity to detect some changes in incidents of nerve agent exposure decreases as follows: RBC AChE > whole blood cholinesterases > plasma BChE.
3. Normal enzyme activity detected with different methods correlates well.
4. RBC AChE or whole blood cholinesterase can be considered a good marker for monitoring nerve agent exposure.

Acknowledgments

This study was funded by a grant from the Ministry of Defense of the Czech Republic—"Long-term organization development plan Medical Aspects of Weapons of Mass Destruction of the Faculty of Military Health Sciences, University of Defence in Brno."

Thanks are due to former researchers of the Department of Toxicology, Drs A. Jakl, V. Hrdina, and J. Tulach (in memoriam) for beginning this work and to Mrs. M. Zechovska and M. Gregorova (in memoriam) for technical assistance.

Chapter 61

Potential agents that can cause contamination of animal feedingstuff and terror

Robert W. Coppock[1] and Margitta M. Dziwenka[2,3]

[1]Toxicologist and Associates, Ltd, Vegreville, AB, Canada, [2]Health Sciences Laboratory Animal Services (HSLAS), Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada, [3]ToxAlta Consulting, Vegreville, AB, Canada

61.1 Introduction

Foodstuffs (intended for human consumption) and feedingstuff (any single or multiple materials, including supplements, whether processed, semiprocessed, or raw, which is intended to be fed to food-producing animals) are vulnerable to terrorist attacks and forensic actions (Kosal and Anderson, 2004). A terrorist attack is intended to cause political instability and/or loss of a sense of security by inflicting injury, death, and economic loss to civilian populations (WHO, 2002). The organizations and individuals that commit acts of terrorism generally have multiple objectives (Spitzmuller and Park, 2018). In general, their motives focus on inflicting challenges to economic, social, and political stability, and intimidation of the target population. The interactions between food and terrorism are complex (Adelaja et al., 2018). This chapter is on a specific aspect of agroterrorism and has the theme of one medicine (one health) concept, wherein human health is interconnected to animal feedingstuffs because harmful chemicals in animal feedingstuff can become harmful residues in animal-sourced foodstuffs (Fig. 61.1) (Buttke, 2011). Most authors, in their discussions on agroterrorism, focus on the weaponization of infectious agents (WHO, 2002; Buttke, 2011; Keremidis et al., 2013). However, chemical and physical agents, used as weapons and forensic activities, are equally important in targeting feedingstuff (Neher, 1999; Kosal and Anderson, 2004). Finished feeds and supplements can contain cereal grains, food processing byproducts, rendered fats, etc. sourced from differing nations, and contamination of animal feedingstuff can result in multinational contamination of animal source foodstuffs (Fig. 61.1). Using chemical or physical agents, the terrorists can kill food-producing animals and/or create a food safety issue (Neher, 1999; Kosal and Anderson, 2004). Potentially harmful residues to human health can occur with and without the exposed food-producing animals showing signs of ill health. These residues can result in regulatory actions that remove these products from the market and can result in costly and highly debated disposal procedures (Shah, 1978).

Illegal residues of chemicals and/or radioisotopes in animal-source foods has both one-health and economic consequences. Terrorists contaminating feedingstuff can result in illegal residues in foodstuffs and have a large financial impact (van Larebeke et al., 2001; Lascano Alcoser et al., 2011; Hoogenboom et al., 2015; Hens et al., 2016). A specific case study showed that one incident of contamination of feed-grade animal fat with liquid transformer dielectric resulted in feedingstuff being contaminated with polychlorinated biphenyls (PCBs), chlorinated dibenzofurans, and polychlorinated dibenzodioxins/furans (PCDFs/PCDDs). This incident cost the Belgian government about €465 million, exclusive of any impact on human health (Buzby and Chandran, 2003). Essential defenses against agroterrorism and agrocrime can be expensive and come with opportunity costs because countermeasures require diversion of resources that could otherwise be used for enhancing agricultural enterprises. Emergency preparedness must include infrastructure and professional personnel for all events and hazards inclusive of terrorism and acts of agrocrime against livestock, poultry, and companion animals and the animal-to-human food web (Saliki, 2000). This infrastructure also serves in

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00061-1

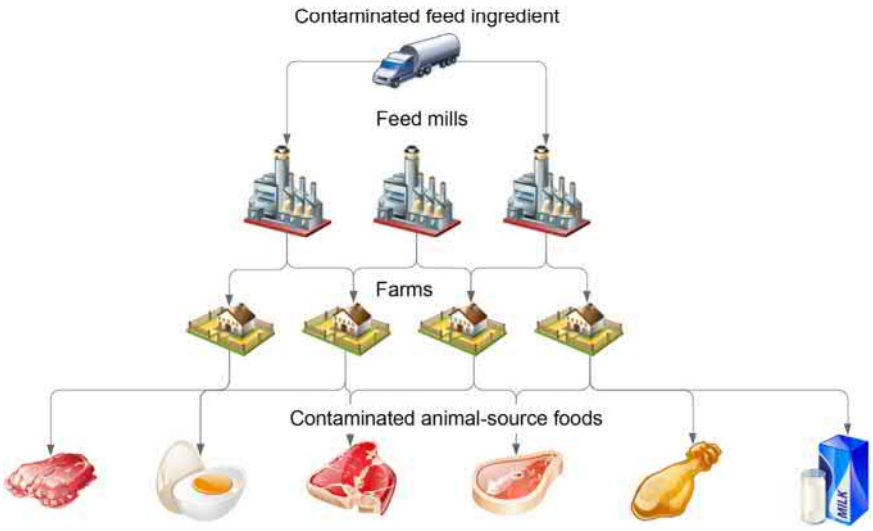

FIGURE 61.1 This diagram shows the potential for distribution amplification of chemically contaminated feedingstuff and the potential for large-scale human exposure to harmful and illegal chemicals. *Credit: B.E. Coppock.*

the diagnosis and prevention of diseases in domestic and wild animals. Timely decision making is essential in determining if the etiology of diseases in livestock is chemical−physical agents or infectious agents (Neher, 1999; Kosal and Anderson, 2004; Malisch, 2017; EU, 2018). The toxicologic focus of an investigation often lags until laboratory evidence shows the likelihood of infectious etiology is unlikely. Laboratory information that provides timely holistic scope and etiology of the incident is essential for timely decision making and food safety. The required infrastructure for comprehensive emergency preparedness includes full-service government-subsidized diagnostic laboratories for animals. Acts committed by terrorists and criminal perpetrators can overwhelm laboratory, regulatory, public health, and other resources (WHO, 2002; Kosal and Anderson, 2004). Well-rehearsed multiple-hazard protocols to deal holistically with an attack on food-animal production and the food supply chain are essential for emergency preparedness and a coordinated prompt response inclusive of food safety.

The FAO recognizes the safety of feedingstuff as being required to ensure animal health and food safety (FAO, 2015). The challenges in the feedingstuff industry are meeting the demand while ensuring feed safety. There is an increase in the diversity of byproducts from food and biofuel manufacturing that are used as ingredients in animal feedingstuff and the feed manufacturing industry has worldwide sourcing of these materials (FAO, 2008). Chemical and physical hazards in feedingstuff can have a negative impact on human health and impose a large expense on public and private sectors. Hazards can be introduced into feedingstuff with the source materials or through carryover as well as introduced during handling, storage, and transportation (FAO-IFF, 2010). The presence of the offending substance(s) can result from accidental or deliberate contamination by forensic or terrorism activities. Handling and manufacturing facilities provide opportunities for point source act-of-terror-linked adulteration of feedingstuff that results in wide distribution of chemical and physical agents (Fig. 61.1) (Kosal and Anderson, 2004). Depending on the feedingstuff, specific industries and livestock sectors can be targeted with significant economic losses. The product produced at the farm could be a target with large economic consequences (Wein and Liu, 2005). Terrorist attacks can also indirectly contaminate feedingstuff with chemical and physical agents resulting in collateral damage to the human food chain. For example, radioactive substances from a dirty bomb can contaminate forages, cereals, and other feedingstuff, and emissions from a fire can be deposited over a large area of agricultural land. Remobilization of radioisotopes from the Chernobyl exclusion zone by wildfire is considered a risk (Evangeliou et al., 2014). Smoke from a fire in a building containing PVC plastic contaminated growing corn with PCDDs/DFs. The corn was harvested as silage and was subsequently found to contain PCDDAs/DFs. A study on the contaminated silage showed the PCDDs/DFs were transferred from silage to milk (Hoogenboom et al., 2015). Persistent organic pollutants (POPs) have potential for weaponization for use by terrorists to adulterate animal feeds with the sole purpose of creating widespread harmful and illegal residues in animal-source foodstuffs with the potential for significant economic consequences including to human health. The practice of feeding animal fat back to animals can concentrate POPs in the human food web. Many of the POPs are bioconcentrated in food-producing animals and a large feedingstuff contamination incident has been shown to have multigenerational effects in humans (Blanck et al., 2000; Small et al., 2011; Terrell et al., 2015;

Walker et al., 2019). Companion animals can be exposed through chemically contaminated animal products being incorporated into pet foods (Brown et al., 2007). Attacks on companion animal feedingstuff resulting in illness and deaths in pets could have considerable emotional impacts on animal owners. The melamine−cyanuric acid adulteration of protein imported into the United States for formulating pet foods caused ill-health and deaths (Puschner et al., 2007). This incident was a criminal activity to increase profits by falsely increasing assay results for protein by the addition of melamine−cyanuric acid and was not related to terrorism.

61.1.1 Agricultural food ecosystem and terror

A brief review of the agri-food ecosystem is important in the discussion of terrorist-linked toxicology of animal feedingstuff. Generally, the activities and technologies in agriculture are maximized for human control and economic gain. All aspects in feedingstuff production, including supplements, drugs, and chemicals, can be targets for terrorists. Harmful agents and organisms can be directly or indirectly added to feedingstuff. Additions of regulatory agency-approved feed additives and drugs that are off-label for a particular livestock species or off-label in terms of excessive amounts added to the feedingstuff can cause animal deaths and/or illegal residues in edible animal products (Doonan et al., 1989; Kosal and Anderson, 2004; Baynes et al., 2016). Some drugs and feed additives have approved label usage in one country and are illegal to use in another (Centner et al., 2014). Thus, adulterants could be added forensically or added by terrorists to disrupt commerce by causing a food safety incident. The vulnerability of animal feeds can be illustrated by the reported large-scale toxicological incidents inclusive of chemical residues in edible animal products. Feed contamination incidents have important economic and human health consequences (Carter, 1976; Lok and Powell, 2000; Kosal and Anderson, 2004; Malisch, 2017; Walker et al., 2019). There is likely an underreporting of occurrences of feedingstuff-linked animal intoxications, with fragmentary governmental infrastructure to collect, process, and use veterinary toxicoepidemiological data (Guitart et al., 2010).

In agriculture, the margin between safe and unsafe practices is exceptionally close. Time- and weather-sensitive farming activities include seeding, watering, fertilizing, weed, and other pest control, harvesting inclusive of methods, preservation-storage, and shipping. All aspects of the system require that chemical contamination of feedingstuff does not occur, or the chemicals used in production remain within government-specified maximum allowable limits by following withdrawal times, etc. The chemicals used in the agroecosystem are essentially unprotected and are vulnerable to contamination attacks by terrorists. Terrorist attacks may not be directly focused on the agroecosystem but can indirectly narrow the margins between safe and unsafe agricultural practices and have huge impacts on feedingstuff and foodstuffs. For example, terrorists can disrupt the distribution of electrical and fossil fuel energy, availability of water, and also target critical industries, logistics, and infrastructure serving the agricultural sectors. Disruption of harvesting and preservation of feedingstuff increases the risk for proliferation of toxigenic fungi and mycotoxin production. Disruption of water availability can stress growing plants and increase the susceptibility of a crop to plant pathogens, including field fungi that produce mycotoxins. The agroecosystem food web also includes manufacturing of feedingstuff and foodstuffs. Food-producing animals in the agroecosystem are vulnerable to mycotoxins and persistent chemicals that are bioconcentrated and these can be relayed to humans via edible animal products (Malisch, 2017). Animal byproducts containing chemical residues can be "recycled" and used as ingredients in feedingstuff.

61.2 Mycotoxins and toxigenic fungi

61.2.1 Background

There are alleged uses of mycotoxins as chemical weapons (Tucker, 2001; Haig, 1982). Mycotoxins and mycotoxigenic fungi could be used for terrorist attacks on both feedingstuff and foodstuffs (Klassen-Fischer, 2006; Rai and Varma, 2010). In addition to generally low consideration of mycotoxins as the etiology of disease, the clinical presentations caused by mycotoxins are not unique and can be misdiagnosed (Paterson, 2006). Thus, a delay in the identification of mycotoxins as the causal agent(s) could occur over a considerable period of time. Delay in recognition can increase the number of animals and humans intoxicated. A large-scale human and animal exposure to mycotoxins occurred during World War II because the agroecosystem was disrupted by the war (Joffe, 1978). There are endemic exposures to mycotoxins in Africa and other parts of the world because of drought, economic hardships, wars, and agricultural practices. Mycotoxin contamination of foodstuffs and feedingstuff can be "collateral damage" from terrorism and war because of disruptions to agricultural practices, manpower, logistics, disruption of water availability, and restricted supply of energy resources. Toxigenic fungi are considered to have ubiquitous distribution. The triggers for mycotoxin production preharvest are growth-stressed plants with reduced resistance to fungal infections, and temperature and moisture levels in stored foods and feedingstuff (Coppock and Jacobsen, 2009). Mycotoxin

production can occur in the field, in wet conditions, and during transport and storage. Foodstuffs, considered unfit for human consumption, can be diverted to animal feedingstuff and cause mycotoxicosis in domestic animals, including pets. In addition to adverse effects on human and animal health, mycotoxin contamination can cause substantial economic hardship because of trade restrictions and bias.

61.2.2 Applications of biotechnology

It should be assumed that the effective use of mycotoxins as terrorist weapons can be increased with the use of biotechnology. Development of fungi for bioterrorism has been reported to share technologies with the military development of fungi for use as weapons (Paterson, 2006). It is possible for aggressive strains of toxigenic fungi to be isolated or developed that produce mycotoxins at lower temperatures and moisture levels than would be considered the usual limits for a particular fungal species (Miller, 2016; Moretti and Susca, 2017). Also, fungal varieties can be genetically modified (GM) in a manner that would enhance toxin production by removing the environmentally activated "restrictors" of toxin production. The adaptation of mycotoxigenic fungi and mycotoxins for terrorist activities likely follows the science used in fungal genetic research and biotechnology.

61.2.3 Fungal biocontrol agents

Fungal biocontrol agents (FBCAs) could be used in terrorist activities. Some FBCAs have been developed using bioselection and others using GM technologies (Paterson, 2006). A number of FBCAs produce mycotoxins (toxigenic fungi) and have been used to control unwanted vegetation. FBCAs are candidates, for example, *Fusarium oxysporum*, can be used to reduce the biomass produced of certain plants that are the source of illicit drugs (Charudattan et al., 2011). The same technologies can be used to target crops used as feedingstuff in livestock and poultry production and in the production of plant fibers.

61.2.4 Economic losses from the use of fungi and mycotoxins as weapons

The use of toxigenic fungi and mycotoxins for bioterrorism can have significant economic consequences inclusive of the impact on human and animal health. Increasing the environmental prevalence of aggressive strains of toxigenic fungi could increase the estimated world impact of mycotoxins from $2.5 billion to a substantially higher number. The estimated losses may be underestimated because projected annual loss in the United States from aflatoxin contamination is estimated at a maximum of $1.7 billion/year without including the economic impact on human and animal health (Mitchell et al., 2016). International commodity trading of dry cereal grains could be used as a method of disseminating the spores of GM aggressive toxigenic strains of a particular fungus. Once released into the environment, the GM fungi would likely be impossible to control. Many plant fungal pathogens are also producers of mycotoxins (Logrieco et al., 2002). The use of plant fungal pathogens as weapons would most likely increase the probability of crops being contaminated with mycotoxins. In national and international trade, feedingstuff and foodstuffs contaminated with mycotoxins can influence consumer/buyer preferences and trade, and have devastating economic consequences, especially in developing countries (Unnevehr, 2002).

61.2.5 Terrorism using mycotoxin-contaminated feedingstuff

Incidences of mycotoxicoses in livestock caused by imported feedingstuff that are not linked to terrorist activities have been reported from the use of mycotoxin-contaminated byproducts in formulating ruminant, horse, poultry, and swine feedingstuff (Loosmore and Markson, 1961; Wilson et al., 1990). As a terrorist tactic, mycotoxin-contaminated feedingstuff could be purchased at a bargain price and resold. For example, mycotoxin-contaminated feedingstuff ingredients could be exported and used to formulate animal feeds in multiple countries importing the ingredient. The backlash of such an event could have major economic consequences on the exporting country. Strains of toxigenic fungi that produce mycotoxins that are not commonly included in mycotoxin screens during import testing could be used with huge economic consequences (Gruber-Dorninger et al., 2017). There are incidents not linked to terrorism, where pet foods have been contaminated with aflatoxins and subsequently caused illness and deaths of companion animals (Arnot et al., 2012; Wouters et al., 2013).

61.2.6 Residues in edible tissues

Food-producing animals ingesting mycotoxin-contaminated feedingstuff can have residues in edible animal products (Coppock and Dziwenka, 2019; Coppock et al., 2018). Incidents of mycotoxin-contaminated feedingstuff being fed to food-producing animals and subsequent transfer of mycotoxins and their toxic metabolites into foodstuffs are a public health concern (Volkel et al., 2011). Residues of some mycotoxins in feedingstuff and animal-source foods are regulated in most countries. The concern for residues of mycotoxins in edible animal products has primarily been focused on regulated residues of aflatoxins in dairy

products. Terrorist-linked contamination of feedingstuff with mycotoxins would have an economic impact on trade in all dairy and other animal-source foods.

61.3 Microbial toxins

61.3.1 Botulism toxin

61.3.1.1 Background

The highly toxic botulism neurotoxins (BoNTs) produced by *Clostridium botulinum* are potential terrorist weapons via addition to foodstuffs and feedingstuff and are given priority as a choice by belligerents for weaponization (Woudstra et al., 2013). The saprophytic anaerobe, *C. botulinum*, is a ubiquitous Gram-positive spore-forming organism and BoNTs can easily be produced at a low cost. Botulism generally occurs after preformed BoNTs are consumed in foodstuff and feedingstuff. Botulism can also occur by *C. botulinum* growing in vivo in the gut or in anaerobic wounds causing toxicoinfection (examples are infant botulism, visceral botulism in domestic animals, and wound botulism) (Anniballi et al., 2013; Mariano et al., 2019). Potential routes of exposure to BoNTs and *C. botulinum* spores are oral, inhalation, and dermal (wound botulism). BoNTs can be added directly to foodstuffs and feedingstuff. The *C. botulinum* spores or substances with high spore counts can be intentionally added to foodstuffs and feedingstuff and, if favorable conditions exist, BoNTs can be formed before consumption occurs. The *C. botulinum* spores in foodstuffs and feedingstuff can, under favorable conditions, trigger in vivo formation of BoNTs by toxicoinfection. Clinical reports have shown that botulism occurs in livestock and some outbreaks in ruminants have been associated with feedstuff containing carrion, chicken litter, bakery waste, ensiled chicken litter, and in horses and ruminants consuming alfalfa cubes and wet (high water activity, a_w) anaerobic feedingstuff packed in plastic, respectively (Kinde et al., 1991; Braun et al., 2005; Lindstrom et al., 2010). Spores of *C. botulinum* can be excreted in milk or milk may be contaminated during milking, and there is evidence that BoNTs are excreted in milk (Bohnel and Gessler, 2013).

61.3.1.2 Mechanism of action

BoNTs, after internalization by the cholinergic nerve terminals, cleave snare proteins and thereby block docking of the vesicles, thus preventing the release of acetylcholine from the presynaptic membrane (Pirazzini and Rossetto, 2017). Clinical signs of botulism are weakness, tremors, recumbency, laryngeal paresis, and other signs of nervous system dysfunction (Braun et al., 2005). For further details on toxicity of botulism, readers are referred to Gupta (2018).

61.3.1.3 Potential production and use

Spores of *C. botulinum* and BoNTs can be produced and/or incorporated into ingredients used in feedingstuff. Carrion, providing favorable incubation conditions exist, can serve as a substrate in feedingstuff for *C. botulinum* to grow and produce toxins. There is some evidence that insect larvae take-up and concentrate BoNTs and are unaffected by BoNTs (Hubalek and Halouzka, 1991). Insect larvae containing BoNTs can be used to contaminate animal feedingstuff and there is a trend to use insect larvae as a source of protein. The economics of a simulated terrorist attack by placing BoNTs in milk at a farm bulk tank or in a milk transport tank demonstrates in a "table top" model the "bow tie" far-reaching distribution effect with an estimate cost, including of human health care, of $8 billion (USD) (Wein and Liu, 2005).

61.4 Plant toxins

61.4.1 Toxins in seeds

Poisonous plants and their seeds could be used to adulterate feedingstuff (Keremidis et al., 2013). Seeds of poisonous plants have become incorporated into animal rations and have resulted in animal intoxication (Burrows and Tyrl, 2001). Grain screenings that contain high levels of toxic plant seeds and/or mycotoxins, could be distributed by a terrorist as a potential feed ingredient. Toxic seeds can be directly introduced into animal rations. The safety of screenings generally comes under government regulations. Screenings that do not meet regulations could be incorporated into animal feedingstuff as a terrorist tactic.

61.4.2 Castor beans (ricin)

61.4.2.1 Background

Castor beans (*Ricinus communis* L.) are grown commercially for castor oil, which is used in cosmetics, coatings, and also has industrial and automotive applications including biodiesel (Patel et al., 2016). There is approximately 1 tonne of residual cake containing ricin produced for every 0.5−0.6 ton of oil produced. Castor bean cake is sold as fertilizer, composted product (may be toxic if ingested), soil enhancers, and other uses, and in some countries it is used in limited quantities as a feed supplement. The castor bean and residual cake contain a cocktail of lectins that are not easily detoxified (Gomes et al., 2018). Ricin, a potent lectin in castor beans and residual cake, is soluble in water over a wide range of pH values. The ricin content of castor beans varies with the growing conditions and genetics of the plant. A general guide is a gram of castor beans contains 1−2 mg of ricin and ricin levels can be as high as 20 mg/g castor beans. Five

percent of the total protein in castor beans can be ricin, and biologically active ricin is present in the waste mash (castor cake) after the oil has been extracted. The ricin content of the extracted mash generally is 1%–10% (w/w). Ricin should be considered relatively heat-stable at temperatures used for food processing (Audi et al., 2005; Janik et al., 2019). The seed husks of *R. communis* are also poisonous and the recognized tolerable level is 10 mg of seed husks per kilogram of feed. A fatal dose in cattle is estimated to be 0.5 mg/kg body mass (Alexander et al., 2008). The ricinine piperidine alkaloid, a toxin of lesser potency, is found in all parts of the castor plant and is heat-stable. Ricinine stimulates the central nervous system (Ferraz et al., 1999).

61.4.2.2 Weaponization of ricin

Ricin has been used to commit murder and kill animals. It captures the interest of both terrorist organizations and agencies involved in protecting populations from terrorists. It is available in larger quantities using inexpensive technologies to extract it in its crude form from castor seed meal, a byproduct that has a low sale value. Ricin generally is not considered a weapon of mass destruction but is considered a weapon for locational use. Its distribution in a common feedingstuff ingredient could have substantial consequences. Some authors consider ricin a weapon more likely to be chosen by a "lone wolf" type of terrorist with an understanding of extraction and distribution technology.

61.4.2.3 Toxicity and mechanism of action

The seed coat of the castor bean needs to be fractured for the ricin to be released (Burrows and Tyrl, 2001). Ricin in extracted mash or cake is biologically available. Most animal species, including birds, are sensitive to castor bean poisoning. The severity of intoxication depends on the dose of ricin, and with ingestion of seeds, the number of seeds ingested and the liberation of ricin by degradation of the seed coat by some form of mastication. Ricin is absorbed from the gastrointestinal tract. The estimated lethal dose of castor bean seeds by species is given in Table 61.1. It is likely that the lethal dose for some species is lower than the doses found in the literature. Due to degradation in the rumen, mature ruminants are considered to be more resistant to ricin than are young ruminants and monogastrics.

Ricin is a lectin-type globular glycoprotein. It is a type-2 ribosome-inactivating protein (RIP) with A and B chains (Audi et al., 2005; Bolognesi et al., 2016; Janik et al., 2019). Ricin is absorbed from the gastrointestinal tract. Cells have a slow uptake of ricin and this can explain the lag time between exposure and onset of clinical signs. The ricin B chain attaches to the surface of the plasma membrane at the galactose-containing

TABLE 61.1 Sensitivity of different species to castor bean intoxication by oral exposure.

Species	Lethal[a] castor bean mass/ kg of body mass	Comment
Horse	7–240 mg	Considered the most sensitive species
Human	225 mg	Dose altered by the degree of mastication
Duck	0.7–1.2 g	1/8 duck died at 16 days after treatment. Grinding of the seeds by the proventriculus can be a variable in determining toxicity
Chicken	10–14 g	Grinding of the seeds by the proventriculus can be a variable in determining toxicity and values could be considerably lower for macerated seeds
Goose	400 mg	Grinding of the seeds by the proventriculus can be variable in determining toxicity
Rabbit	1.2 g	Mastication considered to be required
Pig	1.2 g	Mastication is required; 0.5 g husks/kg body mass is also fatal
Goat	5 g	Age of ruminant can be a factor as the rumen microbes inactivate ricin. Inactivation by the rumen and degree of mastication of seeds are factors in toxicity.
Sheep	1–2 g	Age of ruminant can be a factor as the rumen microbes inactivate ricin; 1.4–2.8 mg ricin-containing cake fed for 8 months and caused intestinal pathology
Cattle	1–2 g	Age of ruminant can be a factor as the rumen microbes likely inactivate ricin. Considered to be more resistant to intoxication than sheep

[a]*It is likely that the lethal dose for some species is lower than the doses found in the literature.*

glycoproteins, pits are formed, and ricin is internalized by endocytosis and forms an intracellular vesicle. The vesicles containing ricin coalesce and form endosomes. The internalized ricin can dissociate from the endosomes and be transported to lysosomes for degradation or the vesicles can be removed from the cell by exocytosis. Ricin can bleb off the endosome and return to the cell surface by vesicular and tubular structures, or it may be transported to the Golgi apparatus. In the Golgi apparatus, the A chain undergoes retrograde transport to the endoplasmic reticulum. Cleavage of the A and B chains occurs here. From the endoplasmic reticulum, the ricin A chain is translocated to the cytosol. Here, the ricin A chain catalytically inactivates ribosomes. The A chain is an enzymic polypeptide that catalyzes the N-glycosidic cleavage of adenine from 28S rRNA loupe in the 60S ribosomal subunit. The removal of adenine from 28S rRNA in the ribosome destroys its functionality and thereby blocks protein synthesis. One ricin A chain can enzymatically inactivate 1500 ribosomes/min. Using other mechanisms, ricin causes the release of inflammatory mediators. Ricinine is a central nervous system stimulant and is theorized to, in the nervous system, inhibit the postsynaptic γ-aminobutyric acid receptor subtype A and to alter the release of glutamate. It is excreted in the urine and if identified in serum and urine is a biomarker of castor bean intoxication. The only treatment for ricin intoxication is supportive care.

61.4.2.4 Analytical methods

Analytical methods used to identify ricin include immune methods (ELISA) and liquid chromatography/mass spectrometry (LC/MS) (Duracova et al., 2018). Gastric contents can be assayed, and ricin can be detected in blood and body fluids by radioimmunoassay and LC/MS (Mouser et al., 2007). Ricinine levels can be assayed in serum and urine using LC/MS (Roen et al., 2013). Polymerase chain reaction methods are available to detect the DNA in castor beans.

61.4.2.5 Clinical and pathological findings

Clinical signs of ricin intoxication from ingestion are high morbidity, abdominal pain, emesis, diarrhea, and lethargy leading to death. Hematemesis and melena may be observed. Clinicopathology includes elevated hepatic enzymes in serum, hyperphosphatemia, and sometimes hypoglycemia. Electrolyte imbalance can occur because of diarrhea and emesis. Pathological findings in a dog were hepatocellular necrosis with fibrosis of central veins and sinusoids, and lymphocytic infiltrate (Mouser et al., 2007). Jejunal mucosa can be eroded and infiltrated with leukocytes, and the tunica muscularis can also be affected. Hemorrhage can be observed in the mucosal and muscular layers. Necrosis can be seen in the spleen. Renal pathology has also been reported.

61.4.3 Other plant source type 2 RIPs

Abrin is a plant source type 2 RIP and is a candidate for weaponization (Chaturvedi et al., 2015). It is found in *Abrus precatorius* (also known as rosary pea, Indian licorice, jequirity bean). The toxicology of abrin is considered to be very similar to ricin. The seeds of *A. precatorius* are not used as oilseed but are used in ethnic medicine. A similar *Abrus* toxin is pulchellin, produced by *Abrus pulchellus*. The rosary pea has been reported to be more toxic than castor beans. Like castor beans, the rosary pea must be masticated to release the toxins (Burrows and Tyrl, 2001). Species sensitivity is variable, and horses are considered to be the most sensitive. The mature goat is considered to be a more resistant species, and seed in the form of 2 g/kg body weight is reported as a lethal dose. The reported lethal dose of seeds for the horse is approximately 100 mg/kg body mass and for cattle it is reported to be 600 mg/kg body weight. This observation provides some evidence that abrin is denatured in the rumen.

61.5 Rapidly acting and easily available substances

61.5.1 Cyanide

Cyanide (CN^-) is considered a terrorist weapon by the oral and inhalation routes of exposure and can be added to feedingstuff and water. It has a history of use as a fumigant and in controlling problem wildlife, and unwanted feral "domesticated" animals. It also has alleged use as an agricultural terror agent in livestock drinking water. A common feed ingredient laced with cyanide could have wide distribution from a single source. Cyanide is also considered a low-technology terrorist weapon for a "lone wolf" or a terrorist group.

61.5.1.1 Mechanism of action

The toxicology of CN^- is complex. The lethal effect of cyanide is blockage of cytochrome C oxidase and loss of electron transfer, and the end result is that molecular oxygen is not utilized. In addition to cytochrome C, other cytochromes are adversely affected by forming complexes with cytochrome iron. The oxidized cytochrome−CN complexes are stable. However, the complex is relatively unstable in a chemically reductive environment and creating an endogenous reductive environment is a mechanism of action for antidotal agents.

61.5.2 Insecticides and drugs

To adulterate animal feedingstuff and poison animals, terrorists could use licensed insecticides and drugs. Large numbers of cattle and other domestic livestock, including poultry, have been contaminated and poisoned with insecticides that were inadvertently and forensically incorporated into feedingstuff (Neher, 1999; Guitart et al., 2010). Coordinated efforts are required to diagnose, contain, and eliminate insecticide- poisoned and contaminated animals from the food web, including feedingstuff obtained from rendered animals. There have been instances in which transport devices have been used to transport and temporally store insecticides, and treated seeds, and then subsequently used for silage and other feedingstuff. These activities resulted in livestock poisonings and contamination. The use of insecticides that are persistent organic compounds (POCs) for terror actions may also present a residue problem in the surviving animals and may require a huge input of governmental and other resources to prevent and remove contaminated edible products from the foodstuff and feedingstuff pipelines. The toxicology and treatment of insecticide poisoning have been discussed in detail in Gupta (2018). Drugs licensed for specific indications and species, can be used to adulterate feedingstuff and cleaning-sanitizing agents. Stafford et al. (2018) reported the addition of fipronil, a broad-spectrum insecticide used as a treatment for ectoparasites in companion animals, which was intentionally added to the cleaning product DEGA-16. This incident was not linked to terrorism. The altered DEGA-16 containing fipronil, used to control red mites (*Dermanyssus gallinae*) that affect chickens, was sold to chicken producers and egg producers in 16 countries including Switzerland and China (EU, 2017). The EU Rapid Alert System was activated because of illegal residues in poultry-sourced foodstuffs (EU, 2018). The damage was estimated at over $39 M with 258 companies unable to sell products during the foodstuff recall period. The estimated loss did not include the impact on markets and reputation. Also, because of this incident, foreign egg producers penetrated markets located in the European Union. This incident shows that residues of illegal substances in edible animal products can have large consequences and trigger regulatory action to protect public health. This incident shows that terrorists can easily adulterate a product resulting in huge financial consequences.

61.6 Persistent organic compounds

61.6.1 Background

POCs, also known as POPs (persistent organic pollutants), could be candidates for a terrorist attack on livestock. Most POCs are biomagnified in the food web. The health, economic, and political impact from their use in a terrorist attack would likely be huge financial loss, including health care, based on the impacts from reported inadvertent contaminations of feedingstuff (Carter, 1976; Kay, 1977; Reich, 1983; Terrell et al., 2015; Malisch, 2017; Walker et al., 2019). The majority of POCs are bioconcentrated in body lipids. Most of these compounds require high doses to cause acute illness in humans, livestock, poultry, and fish. At low doses the resultant illness in food-producing animals is generally less evident and these animals and their products are used as foodstuffs. The human health issues from long-term exposure to POPs has increasing recognition. There are residues in edible animal products and rendered animal products used in animal feedingstuff. The occurrences of POCs contaminating feedingstuff and feed ingredients are underappreciated (Kim et al., 2007). The lack of specific clinical signs and lesions increases the risk of nonrecognition and contaminated animals passing slaughter inspections, and subsequently their products being consumed by humans and their byproducts being used in feedingstuff. For the POCs, the safety of foodstuffs and feedingstuff are reliant on chemical analyses (Kim et al., 2007). Occurrences of POCs being relayed from contaminated animal-source foods to humans and their byproducts to feedingstuff are known (Kay, 1977; Reich, 1983; Fries, 1985; Huwe and Smith, 2005; Kim et al., 2007; Covaci et al., 2008).

Historical incidents are discussed to show the economic and health impacts that can be caused by feedingstuff becoming contaminated with POPs. Reich (1983) reported that from 1969 to 1974, excluding the Michigan polybrominated biphenyls (PBBs) incident, the dollar loss to livestock and poultry producers by identified chemical contamination was $21.5 million. The PBB incident in Michigan, likely the largest in US history, is given as an example. The cause of this incident was a PBB flame-retardant (approximately 200−400 kg), intended for use in plastic, which was shipped to a feed mill instead of magnesium oxide. The PBBs were subsequently mixed into livestock feedingstuff (Carter, 1976; Reich, 1983). More than 40 years later, the health effects of this incident are being elucidated, demonstrating the long-term multigenerational impact on human health, and the long-term healthcare-linked costs which have never been estimated (Small et al., 2011; Terrell et al., 2015; Jacobson et al., 2017; Walker et al., 2019). Environmental sources of POCs can be introduced into feedingstuff and require regulatory responses. Clay mineral, contaminated with polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs), was introduced into mineral mixes. Other incidents of contaminated clay clearly show that feedingstuff contamination can occur over a substantial period of time before the contamination is recognized and

foodstuffs and feedingstuff are protected by regulatory action (Hayward et al., 1999; Hoogenboom et al., 2010). Orange peel, bakery waste, recycled fat, choline chloride, and zinc oxide can all be used as feed ingredients and these products have been contaminated with POPs, resulting in contamination of animal-source foodstuffs (Malisch and Kotz, 2014). Proactive analytical surveillance for POPs requires substantial resources consisting of highly trained personnel, sophisticated laboratory procedures, and infrastructure to meet laboratory safety requirements. The analytical and personnel support for investigations into POCs contaminating livestock feedingstuff can challenge budgets, quarantines can impose harsh economic consequences on livestock and poultry producers, and there can be political pressure on regulatory agencies to restrict or delay investigations (Reich, 1983; Deshingkar, 2002). Some of the highest levels of POPs in consumed foodstuffs have occurred because of feedingstuff being contaminated. The health impacts of POPs in the human diet are likely underappreciated and there is evidence to show the effects can be multigenerational (Blanck et al., 2000; Kim et al., 2007; Walker et al., 2019).

61.6.2 Potential economics of terror attacks using persistent organic pollutants

The history of incidents clearly shows that feedingstuff contaminated with POCs has caused large economic losses and impacts on animal and human health. Most POCs are biomagnified in the food web. If feedingstuffs have a wide distribution, then the measurable economic impacts and regulatory costs can be immense. In the Michigan (US) PBB disaster, 500 farms were under quarantine (Carter, 1976). More than 865 tons of feedingstuff, 29,800 head of cattle, 5920 hogs, 1470 sheep, 1.5 million chickens, 34,500 kg of dairy products, and 5 million eggs were destroyed (Carter, 1976). The total cost was estimated at more than $215 million at 1983 currency value and this loss did not include human health (Reich, 1983). In the ball clay incident, it was estimated that 1.7 million eggs per day (at that time approximately 1% of the US egg production) and 35% of the farm-reared catfish were contaminated with PCDDs/DFs (Hayward et al., 1999). These animal-source foodstuffs, contaminated with PCDDs/DFs, were consumed by humans (Fiedler et al., 1997; Rappe et al., 1998). In the United States, more than 400 upright silos were coated with a PCB-containing resin that migrated into silage. The livestock and their edible products were contaminated with PCBs (Sweeney et al., 2001). In Belgium, a tank of animal fat (animal feed ingredient) feed was contaminated in January 1999 with a PCB (congener closely matched Aroclor 1260/1254) containing PCDDs/DFs and caused an unprecedented feedingstuff and foodstuff crisis (Lok and Powell, 2000). It is estimated that 150 kg of PCBs with PCDDS/DFs contaminated the recycled animal fat. Nine feed manufacturers used the contaminated oil to formulate poultry and other livestock feedingstuff. There was a considerable lag time for the government to engage regulator action. Several countries banned imports of animal source foodstuffs and products containing animal-sourced ingredients. Estimates losses from this disaster are US $1.5 billion (Lok and Powell, 2000). No estimates have been made regarding the human healthcare cost of these incidents.

61.7 Heavy metals and metalloids

Heavy metals and metalloids have been used forensically to maliciously poison livestock and nonforensic incidents of lead poisoning occur. Arsenic has a history of weaponization (Li et al., 2016). Lead is readily available to terrorists, for example, from discarded lead batteries. Humans can be exposed to heavy metals in meat-stuffs and milk from domestic animals.

61.7.1 Lead

Lead is readily available in the form of spent lead acid batteries and lead gunshot. Pulverized lead is not rapidly identified in animal feedingstuff, allowing a successful terrorist attack. Lead poisoning incidents with lead-acid batteries, lead gunshot, and environmental sources account for the majority of cattle poisonings in North America. Lead is excreted in milk, deposited in bones, liver, and kidney, and is considered a food safety issue (Coppock et al., 1991). Cattle that are asymptomatic for plumbism can excrete lead in milk (Bischoff et al., 2014). Lead poisoning is likely underdiagnosed and can be confused with thiamin-responsive polioencephalomalacia in cattle (Coppock et al., 1991). The favorable clinical response to thiamine therapy could result in failure to diagnose plumbism. Lead is solubilized by silage fluids and migrates in the liquid phase of silage (Coppock et al., 1988; Bischoff et al., 2014). A small amount of lead can poison a large number of livestock. Lead isotope profiling can be used in forensic investigations to identify the source of lead (Buchweitz et al., 2015).

61.7.2 Arsenic

Arsenic is used to maliciously poison livestock. Arsenic can be mixed with feedingstuff and water, or just made available to cattle. Cattle voluntarily consume arsenic (Schild et al., 2019). Arsenic is used in agrocrime and has been used for crimes of revenge. In acute arsenic poisoning, survival is generally low. Arsenic could have been used in acts

of terrorism targeting cattle (Kosal and Anderson, 2004). Arsenic could be used by a "lone-wolf" terrorist.

61.8 Concluding remarks and future directions

Feedingstuff is essentially unprotected from chemical adulteration by agrocrime and terrorist attack. The psychological and sociological profiling of terrorist and terrorism-orientated groups involved suggest that feedingstuff is more likely to be attacked by small groups and "lone-wolf"-type terrorists. Historical review of feedingstuff being contaminated with chemicals, especially persistent organic pollutants, has shown that the costs can be billions of dollars, exclusive of human health impacts, and these incidents have not been linked to terrorism. A simulation using a terrorist attack on milk using BoNTs showed that a primary estimated cost of $8 billion would primarily be in human health care (Wein and Liu, 2005). Forty years after a PPB incident in Michigan (United States), multigenerational human health impacts are being identified. Recognition of chemical contamination of feedingstuff and rapid responses are required to protect foodstuffs. The European Union has the RASFF (Food and Feedingstuff Safety Alerts) for consumer protection. Feedingstuff could be contaminated as collateral damage from other acts of terrorism, for example wildfires, building fires and fire runoff water, and dirty bombs. More emphasis and study need to be placed on feedingstuff as a target for terrorists. Feedingstuff can be targeted without the affected animals showing overt signs of illness and with chemical resides in edible animal products and rendered animal products. Identification of chemical adulterants in feedingstuff requires substantial infrastructure in trained personnel, equipment, and laboratory facilities. The future direction is to fully recognize the one-health−one-medicine concept that has to be used in the management of chemical and radioisotope contamination of feedingstuff. Laboratory capacity to analyze feedingstuff and foodstuff must be developed and maintained. Terrorist attacks outside the agri-food sector can result in collateral chemical and radioisotope contamination of animal feedingstuff and this must be included in the emergency plan to prevent consumption of chemically contaminated foodstuffs.

Chapter 62

Chemical warfare agents and risks to animal health

Tina Wismer
ASPCA Animal Poison Control Center, Urbana, IL, United States

62.1 Introduction

Animals are susceptible to all four basic types of military agents: choking (such as chlorine gas and phosgene), blister (such as mustard, lewisite, and phosgene oxime), blood [such as cyanide and hydrogen cyanide (HCN)], and nerve agents [such as tabun, sarin, soman, and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX)]. They can also be affected by incapacitating agents such as 3-quinuclidinyl benzylate (BZ), riot control agents (RCAs), ricin, and abrin. Since chemical warfare agents (CWAs) can be deployed by a variety of inexact methods (including bombs, spray tanks, rockets, missiles, land mines, and artillery projectiles), domestic and wild animals living in proximity to human populations can be affected (USACHPPM, 2001a). Americans are estimated to have 89.7 million dogs, 94.2 million cats, and 7.6 million horses (Bedford, 2019). In addition to pets, livestock are very important potential targets of attack as they have secondary ramifications for human health and disruption of the food chain.

The Centers for Disease Control and Prevention (CDC) Strategic Planning Working Group, as part of their preparedness plan for possible terrorist attacks using biological or chemical weapons, has called for "prompt diagnosis of unusual or suspicious health problems in animals" (Anonymous, 2000a). The CDC recommended establishing "criteria for investigation and evaluation of suspicious clusters of human and animal disease or injury and triggers for notifying law enforcement of suspected acts of chemical terrorism." With many of the military agents, there are few initial indicators of a chemical attack. It has been proposed that animals could serve as sentinels for chemical terrorism. These animals would be similar to the canaries used by coal miners in the United Kingdom and the United States to provide early warning of deadly mine gases.

Throughout history, it has been noted that during chemical warfare attacks, animals may also be affected. A newspaper article from World War I gives details of the effects on animals during an unspecified type of gas attack (Anonymous, 1918):

> *horses suffer much from the noxious fumes, and are subsequently thrown into a state of nervous terror on again scenting them. Mules are more inclined to stand their ground, and appear as if trying not to breathe . . . Cats quickly scent the gas, and run about howling. Guinea pigs are first to succumb . . . Rats and mice emerge from their holds, and are found dead in quantities, which as the soldiers say, is the only advantage of a gas attack by the enemy.*

The soldiers believed that different species of animals may be more sensitive to certain types of gas attacks than humans:

> *Poultry of all kinds are useful for giving warning, ducks and fowl becoming agitated 10 min or so before the oncoming gas clouds. . . . Only the sparrow seems to disregard the poisonous vapor, and sparrows chirp on where horses are asphyxiated, and bees, butterflies, caterpillars, ants and beetles die off in great numbers. The gas at once kills snakes, and earthworms are found dead in their holes many inches below the ground.*

Not much has changed in using animals as sentinels over the years. Crates of rabbits were placed on the cargo deck of ships transporting nerve gases during World War II, and the crew were instructed to watch for sudden animal deaths that could signal a gas release (Brankowitz, 1987). Even today, with the development of sophisticated biosensor technology, the use of animals as sentinels continues to

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00062-3

be explored (Paddle, 1996). The US Environmental Protection Agency (EPA) is now considering evidence regarding the use of animals as sentinels for chemical threats (EPA, 2006).

Some of the CWAs that may pose the greatest risks to animal health are described next. For information on their mechanism of action, readers are referred to Section II of this book.

62.2 Chemical warfare agents

62.2.1 Chlorine gas

62.2.1.1 Clinical signs

Chlorine gas is very irritating, and in concentrated amounts, it can even be corrosive. The eyes, skin, nose, throat, and mucous membranes can all be affected. Inhalation can lead to rhinorrhea, dyspnea, hypoxemia, ataxia, syncope, muscle weakness, tachypnea, laryngospasm, bronchospasm, pneumonitis, pulmonary edema, and death (Noe, 1963; Evans, 2005).

Ocular exposure can result in severe pain and blindness. Dermal exposures cause erythema and pain, and high concentrations of chlorine gas can cause dermal burns (Raffle et al., 1994).

62.2.1.2 Kinetics

Respiratory, dermal, and ocular irritation starts immediately. The speed of onset and severity of signs is directly related to the concentration (Bingham et al., 2001). Acute lung injury peaks in 12−24 h. With mild exposure, signs disappear within 6 h, but can continue for more than 24 h with severe exposures. Death usually occurs within 48 h (Decker, 1988). Exposure to moderate or severe concentrations can result in chronic respiratory dysfunction (Decker, 1988). This can be career- or life-ending if the affected animal is an equine athlete or a working dog.

62.2.1.3 Decontamination and treatment

Move animals into fresh air and onto higher ground. Monitor respiratory rates and oxygenation status ($Sp\mathrm{O}_2$). If coughing or dyspnea develops, provide supplemental oxygen and ventilation. Bronchodilators should be used to counteract bronchospasm (Wang et al., 2004). Sedation and pain control may be needed so that the animal can be handled safely.

Corticosteroid use is controversial. Animal models have shown positive results; however, administration to humans has not been shown to provide any significant change (Traub et al., 2002; Chen et al., 2013). Multiple other therapies have been used in laboratory situations to decrease lung injury: antioxidants (McGovern et al., 2010; Zarogiannis et al., 2011; Wigenstam et al., 2015), cAMP-elevating agents (Hoyle et al., 2016), heparin (Zarogiannis et al., 2014), and nitric oxide modulating agents (Honavar et al., 2017).

For ocular exposure, the eyes should be flushed with generous amounts of tepid 0.9% saline or tap water for at least 15 min. After flushing, fluorescein should be used to stain the eyes and check for corneal ulcers (Grant and Schuman, 1993). Bathing with dish soap and water will remove chlorine from the skin and fur or feathers.

Chlorine does not leave an environmental residue, so animals may be returned to affected pastures within hours to days, and more quickly in warm environments (Munro et al., 1999). When entering the area contaminated with chlorine gas, rescuers should wear self-contained breathing apparatus (SCBA) and protective clothing (i.e., gloves, gowns, and masks) until the gas dissipates. The risk for secondary contamination of rescuers is low. Chlorine gas does not bind to leather or fabrics.

62.2.1.4 Species susceptibility

Chlorine gas is heavier than air and will settle in low areas. Pets and smaller livestock may be more at risk than humans due to their proximity to the ground. There are no controlled studies showing that animals are more sensitive to chlorine gas or that they will develop signs sooner than humans.

62.2.2 Phosgene

62.2.2.1 Clinical signs

Most animal exposures to phosgene are from inhalation, but there can also be dermal exposures to the liquefied material. The severity of pulmonary injury correlates with the concentration and length of exposure, and initial symptoms are not always a good indicator of prognosis (Diller, 1985; Bingham et al., 2001). Dyspnea, cough, cyanosis, and hemoptysis can progress to hypoxemia and hypoventilation (Borak and Diller, 2001). Death is from anoxia secondary to pulmonary edema (Borak and Diller, 2001; Proctor and Hughes, 2004).

Animals may develop secondary organ damage from anoxia. Dogs experience bradycardia, followed by tachycardia and progressive hypotension with severe phosgene poisoning (Patt et al., 1946). With concentrations greater than 200 ppm, phosgene can enter the blood and cause hemolysis and coagulopathies (Sciuto et al., 2001). Direct contact with liquid phosgene can cause dermal burns (Proctor and Hughes, 2004). Ocular exposure to both liquid phosgene and highly concentrated phosgene gas can cause severe eye irritation and corneal opacification (Grant and Schuman, 1993; Proctor and Hughes, 2004).

Prognosis is directly related to the severity of pulmonary injury. Animals that survive the first 24–48 h still have a guarded prognosis. These animals are more susceptible to infectious agents, as they have suppressed natural killer cell activity. Infections may become evident 3–5 days after exposure. Animals may develop chronic exercise intolerance and abnormal pulmonary function (Borak and Diller, 2001). Working dogs and horses may no longer be able to fulfill their functions.

62.2.2.2 Kinetics

Respiratory signs develop 2–6 h postexposure in most patients, but can be delayed up to 15 h with exposures to lower concentrations (<3 ppm) (Borak and Diller, 2001). Concentrations of 3–5 ppm cause immediate conjunctivitis, rhinitis, pharyngitis, bronchitis, lacrimation, blepharospasm, and upper respiratory tract irritation. Extended (170-min) exposure was fatal (Diller 1985; Proctor and Hughes, 2004). Exposure to 50 ppm for 5 min or longer will cause pulmonary edema and rapid death (Chemstar, 1996a,b; Borak and Diller, 2001; RTECS, 2008). If the animal survives, pulmonary edema begins to resolve in 2–3 days.

62.2.2.3 Decontamination and treatment

Move animals to fresh air and higher ground. Bathe animals with soap and water and flush eyes for 15 min with tepid water or 0.9% saline. Animals should be monitored for 24 h for the development of pulmonary edema (Borak and Diller, 2001). If animals are coughing or dyspneic, administer 100% oxygen. Intubate and ventilate as needed. Patients with pulmonary edema should be managed the same as an acute respiratory distress syndrome (ARDS) patient (i.e., mechanical ventilation with oxygen and positive end-expiratory pressure). The mechanism of phosgene-induced lung injury is complex and not fully understood. Many treatments have been tried including bronchodilators (Kennedy et al., 1989), antiinflammatories (Guo et al., 1990; Chemstar, 1996a,b), xanthine derivatives (Zhang et al., 2010), antioxidants, ACE inhibitors, and TRP inhibitors (Sciuto et al., 1995; Holmes et al., 2016) to reduce injury. Intravenous fluids should be used for cardiovascular support, but monitored for overhydration. Colloids are preferred over crystalloids, as they will remain in the vascular space for a longer period of time. Oxygen supplementation will resolve most of the arrhythmia.

Phosgene is nonpersistent in the environment. Moisture reduces air concentrations (Borak and Diller, 2001). The potential for secondary contamination of rescue personnel is low, but rescuers should wear proper protective clothing. Phosgene gas does not persist in fabric or leather.

62.2.2.4 Species susceptibility

Phosgene is heavier than air and will settle close to the ground. This can affect species that are low to the ground or that are pastured in low-lying areas. There is no indication that animals are affected before or at lower levels than their human counterparts.

62.2.3 Mustard gas

62.2.3.1 Clinical signs

Mustard gas is a vesicant that is toxic by all routes of exposure (oral, inhalation, dermal, and ocular) (Sidell et al., 1997; Pohanish, 2002). Mustard causes both localized and systemic cellular damage, and tissues with high cell turnover are the most affected (NATO, 1973). Mustard gas can produce erythema, severe pruritus, blistering, ulceration, and necrosis of exposed skin (Borak and Sidell, 1992; Dacre and Goldman, 1996; Budavari, 2000; Pohanish, 2002).

Ocular exposure can cause pain, lacrimation, corneal ulceration, swelling, blepharospasm, and blindness (NATO, 1973; Borak and Sidell, 1992; Dacre and Goldman, 1996; Garigan, 1996). Pathognomonic signs of mustard gas poisoning include porcelain-white areas in the episcleral tissues and the formation of large, varicose veins (Grant and Schuman, 1993). Conjunctivitis and keratopathy can be seen chronically after exposure (Grant and Schuman, 1993).

Inhalation of small amounts of mustard gas produces nasal discharge, sneezing, epistaxis, and coughing within 12–24 h of exposure. Higher concentrations or longer exposures can cause pulmonary damage, hypoxia, and respiratory acidosis. Seizures may be seen with acute high doses (Sidell et al., 1997).

Mustard gas is also a radiomimetic (Sidell et al., 1997). It destroys precursor cells in the bone marrow, leading to leukopenia, thrombocytopenia, pancytopenia, and anemia (Borak and Sidell, 1992; Dacre and Goldman, 1996). Infection can be seen secondary to bone marrow damage (Sidell et al., 1997). Bone marrow aplasia and death can be seen in severe cases.

62.2.3.2 Kinetics

Both liquid and vaporized mustard have rapid skin penetration. The higher the dose, temperature, and humidity, the quicker the absorption (NATO, 1973). Mustard is dermally absorbed through hair follicles and sweat glands within minutes. Cellular reactions begin within 1–2 min of mustard making contact with skin or mucous membranes, but clinical effects are delayed between 2 and 24 h (Grant and Schuman, 1993; Sidell et al., 1997).

The skin initially pales and then becomes erythematous within a few hours of exposure (Requena et al., 1988).

Erythema, blisters, bulla, and small vesicles form over 2−24 h. The blisters can progress for several more days. Erythema resolves over 3−7 days, while ulcers take 6−8 weeks to heal (Garigan, 1996; Sidell et al., 1997). Discoloration (brown or black hyperpigmentation) commonly occurs after resolution of the burns, especially in areas with thinner skin (Requena et al., 1988).

Ocular absorption happens within minutes. Clinical signs begin within 1−12 h depending on the concentration (Requena et al., 1988). Inhalation produces respiratory signs (rhinorrhea, sneezing, epistaxis, and coughing) within 12−24 h of exposure. A severe exposure produces a productive cough, tachypnea, pulmonary edema (rare), and pulmonary hemorrhage within 2−4 h. Ingestion of small amounts can cause hypersalivation and vomiting within 24 h, while larger amounts can cause gastrointestinal bleeding (rare) and bloody diarrhea within 3−5 days.

Mustard preferentially accumulates in fatty tissue (Somani and Babu, 1989). Mustard is excreted in the urine over 72−96 h after i.v. administration in rats and mice (Dacre and Goldman, 1996). Complete blood count (CBC) changes are not evident for 3−5 days postexposure. Leukopenia usually occurs between days 7 and 10 (Garigan, 1996).

62.2.3.3 Decontamination and treatment

Animals should be moved into fresh air. Emesis is not recommended, and activated charcoal administration after oral ingestion is controversial. Sodium thiosulfate (2% solution) given orally may help in cases of oral exposure (Borak and Sidell, 1992; Dacre and Goldman, 1996). Perforation and stricture formation can follow esophageal burns.

For ocular exposures, flush eyes with tepid water for at least 15 min. Follow with 2.5% sodium thiosulfate ophthalmic to help neutralize the mustard. The eyes need to be decontaminated quickly, as late flushing of the eye provides no benefit (Sidell et al., 1997). Topical ophthalmic antibiotics and pain control should be used if corneal lesions are present (Sidell et al., 1997).

Animals need to be bathed with copious amounts of soap and water. If dermal decontamination is not implemented quickly, mustard will react with the skin and cannot be easily removed (Sidell et al., 1997). Sodium thiosulfate (2.5% solution) can be used dermally to neutralize mustard exposures (Garigan, 1996). Animals may also be bathed with dilute (0.5%) hypochlorite solutions (Borak and Sidell, 1992). Monitor for dermal burns. Secondary infection is common. Topical silver sulfadiazine can be applied to all burns, and an Elizabethan collar used to decrease ingestion of the ointment and self-trauma. All equine and ovine patients should be inoculated with tetanus toxoid. Vaccination of other species should be determined on a case-by-case basis.

Monitor for respiratory irritation. If seen, monitor arterial blood gases and pulse oximetry. Thoracic radiographs may be taken, but there can be a lag time of up to 2 days before infiltrates are seen (Smith, 1999). Nebulization with 2.5% sodium thiosulfate or *N*-acetylcysteine may help neutralize the mustard gas (Garigan, 1996). Provide oxygen, ventilation, and inhaled beta agonists if needed. Dexamethasone, promethazine, vitamin E, melatonin, nitric oxide synthase inhibitors, protease inhibitors (such as doxycycline), and surfactant replacement have all shown beneficial effects against mustard gas poisoning in laboratory animals (Requena et al., 1988; Weinberger et al., 2011). Anticoagulants and fibrinolytics may help reduce bronchial exudates and fibrin casts (White et al., 2016).

Serial CBCs with platelets should be monitored for 2 weeks after exposure. Antibiotics should be given if leukopenia develops (Sidell et al., 1997). Mustard can be detected in urine and body tissues for up to 1 week post-exposure using gas chromatography-mass spectrometry (GC-MS; Vycudilik, 1985). This can confirm the diagnosis but is not likely to be of value in the management of the patient.

Mustard is persistent in the environment; it may remain for up to 1 week in temperate areas. It disappears in about 1 day in hot climates and in desert conditions. Since mustard binds to vegetation for days to weeks, grazing animals need to be kept away from these areas (USACHPPM, 2001b).

Rescue personnel must wear protective clothing, eye protection, and a respirator, as the potential for secondary contamination is high (HSDB, 2008). Mustard gas will penetrate wood, leather, rubber, and paints.

62.2.3.4 Species susceptibility

Dermal absorption of mustard varies greatly by species, and fur can be protective (Smith et al., 1997). However, rats absorb about 75% of a dermal dose through their skin, while only 20% is absorbed through human skin (Smith, 1999). The rat dermal LD_{50} is only 5 mg/kg, while the mouse and human dermal LD_{50}s are 92 and 100 mg/kg, respectively (RTECS, 2008). With oral dosing, humans appear to be much more susceptible (oral LD_{50} 0.7 mg/kg for humans, and 17 mg/kg for rats). Due to these variable results, more studies are needed to determine if animals would make good sentinel animals.

62.2.4 Lewisite

62.2.4.1 Clinical signs

Lewisite is an arsenical compound that acts locally as a vesicant but also causes systemic effects including decreased adenosine triphosphate (ATP) production and

increased capillary permeability (Sidell et al., 1997; HSDB, 2008). Pulmonary edema or ARDS can develop (Sidell et al., 1997).

Signs can be seen when lewisite is contacted dermally, orally, ocularly, inhaled, or ingested. Dermal and respiratory exposures are seen most frequently. Lewisite causes dermal, ocular, and respiratory lesions similar to those caused by mustard gas. Exposure to lewisite is very painful. Both vapor and liquid lewisite can penetrate skin. Reddening of the skin is followed by tissue destruction (EPA, 1985a; Goldman and Dacre, 1989; Sidell et al., 1997; Pohanish, 2002). Severe edema develops secondary to increased capillary permeability. Dermal burns are deeper than those seen with mustard gas and are quicker to appear (Goldman and Dacre, 1989; Sidell et al., 1997).

Ocular exposure causes immediate pain, lacrimation, and blepharospasm. Without rapid decontamination, within 1 min, permanent blindness may occur (EPA, 1985a; Pohanish, 2002). In livestock, this is a death sentence, as they cannot survive on the range when blind.

Inhalation of vapor causes irritation to the nasal passages, rhinorrhea, and violent sneezing (HSDB, 2008). Coughing and hemoptysis commonly occur (Sidell et al., 1997; HSDB, 2008). Arrhythmias and renal dysfunction are due to hypovolemia from fluid loss. After inhalation, dogs developed necrotizing pseudomembranous laryngotracheobronchitis (Goldman and Dacre, 1989). Death can occur within 10 min after inhalation of high concentrations (EPA, 1985a).

62.2.4.2 Kinetics

Immediate pain occurs upon inhalation, dermal, or ocular contact with lewisite. Skin penetration occurs within 3−5 min, especially following liquid exposures (Sidell et al., 1997). The skin becomes red, then gray, within 15−30 min after exposure (EPA, 1985a; Goldman and Dacre, 1989; Sidell et al., 1997; Pohanish, 2002). Severe blisters develop within 12 h. The blisters rupture about 48 h after occurrence, with large amounts of fluid seeping from the site. Healing is generally complete within 4 weeks.

Lewisite has extensive tissue distribution (HSDB, 2008). The highest concentrations were found in the liver, lungs, and kidneys in rabbits (> seven times blood concentration). The elimination half-life of arsenic in rabbits is 55−75 h (HSDB, 2008). For further details on toxicity of arsenic and lewisite, see Chapter 21.

62.2.4.3 Decontamination and treatment

Remove animals from affected areas. If any coughing or respiratory distress, monitor blood gases and SpO_2. Provide oxygen and assisted ventilation as needed. Nebulized beta agonists (and possibly corticosteroids) can be used to treat bronchospasm. Monitor electrolytes and packed cell volume (PCV), as there can be fluid shifts out of the vasculature (Goldfrank et al., 2002). Watch for liver and kidney failure.

As lewisite is a vesicant, emesis is not recommended in those species that can vomit (such as dogs, cats, swine, and ferrets). Dilution with milk or water is recommended. Activated charcoal is not helpful. Endoscopy can be performed very carefully to determine the extent of injury. Esophageal perforation, stricture formation, or both may occur.

The eyes should be flushed with copious amounts of tepid water for at least 15 min. If 5% dimercaprol [also known as *British antilewisite (BAL)*] ophthalmic ointment can be applied within 2 min, this may prevent a significant reaction. Application of up to 30 min after exposure will lessen the ocular reaction but will not prevent all damage (Goldfrank et al., 2002).

Animals should be washed with water and dilute household bleach (5% sodium hypochlorite) as soon as possible. Application of a 5% BAL ointment within 15 min can be effective in diminishing the blistering effects of lewisite (Smith, 1999). Remove BAL ointment with soap and water after 5 min. Leaving the ointment on too long can cause stinging, itching, or urticaria. Burns should be managed with pain control, antibiotics, and debriding as needed.

A chelator should be given if there is dyspnea, pulmonary edema, or skin burns larger than palm size (Goldfrank et al., 2002). BAL is the traditional arsenic chelator, but it has numerous side effects. The deep intramuscular injections are very painful and BAL can cause hypertension, tachycardia, and vomiting. 2,3-Dimercaptosuccinic acid (DMSA, Succimer) can also be used to chelate arsenic (Graziano et al., 1978). 2,3-Dimercapto-1-propanesulfonic acid (DMPS) is used in Europe and has been effective in protecting rabbits from the lethal effects of lewisite (Aposhian et al., 1982).

Lewisite remains in the environment for about 24 h, and it can react with water to form a solid arsenoxide that also has vesicant properties. Affected areas can be treated with strong alkalis to form less harmful substances. Rescue personnel need to wear protective clothing and masks, as the risk for secondary contamination is high. Carcasses should be disposed of properly, either buried deeply (away from water supplies), rendered, or incinerated to ensure safety of the food supply.

62.2.4.4 Species susceptibility

Lewisite has the potential to cause skin lesions in any species, but the risk is greatest in hairless animals, such as pigs, and decreases in fur-covered species (Smith et al., 1997). Mice and rats appear to be almost twice as

susceptible to dermal lewisite exposures as humans (LD_{50} equals 12, 15, and 30 mg/kg, respectively) (Sidell et al., 1997; DeRosa et al., 2002; RTECS, 2008). More studies are needed to determine if rodents would be good sentinel animals.

62.2.5 Phosgene oxime

62.2.5.1 Clinical signs

In both its liquid and vapor forms, phosgene oxime causes severe pain and local tissue destruction upon contact with skin, eyes, and mucous membranes (Sidell et al., 1997). Signs depend on its route of entry, as phosgene oxime exerts its greatest effects in the first capillary bed it encounters.

Dermal, ocular, and respiratory lesions are similar to those caused by mustard gas. Inhalation and oral absorption may cause respiratory tract irritation, dyspnea, and pulmonary edema. Dermal lesions are erythematous and extremely painful. With ocular exposure to phosgene oxime, very low concentrations can cause lacrimation, inflammation, and temporary blindness, while high concentrations can cause permanent corneal lesions and blindness (Sidell et al., 1997; USACHPPM, 2001c). Death is generally due to respiratory arrest.

62.2.5.2 Kinetics

Complete absorption occurs in both dermal and inhalational exposures within seconds (Sidell et al., 1997). Dermal lesions form quickly; grayish tissue damage may be seen within several minutes, and within 1 h, the area becomes edematous. Phosgene will spread in sweat and move to other nonexposed areas of the body (DeRosa et al., 2002). The skin turns brown, and blistering occurs the next day. It takes about 3 weeks for desquamation, necrosis, crust formation, and purulent exudate to occur (Sidell et al., 1997). Pain can last for several days, and healing of dermal lesions can take from 1 month to over a year. Pulmonary edema can be seen on thoracic radiographs within 2 h of high-dose exposure, 4–6 h of moderate exposure, and approximately 8–24 h after low-dose exposure (Sidell et al., 1997).

62.2.5.3 Decontamination and treatment

Animals should be moved into fresh air. Emesis and activated charcoal are not recommended due to the irritant and corrosive effects of phosgene oxime. Dilution with milk or water is recommended for oral ingestions. Sedation and pain control (opioids) may be needed to allow safe decontamination.

Irrigate eyes with tepid water until pH returns to neutral and remains so for 30 min after irrigation is discontinued (Brodovsky et al., 2000). Speed to decontamination after ocular exposure is important since phosgene oxime is absorbed within seconds. Corneal ulcers should be treated with atropine ophthalmics to prevent synechiae formation, and other ophthalmics to aid in reepithelialization (Grant and Schuman, 1993; Brodovsky et al., 2000).

The animal should be bathed with copious amounts of water and a mild soap. Phosgene oxime reacts quickly with tissue, and decontamination is not expected to be entirely effective after pain has been produced. Sodium hypochlorite (0.5%) or isotonic sodium bicarbonate can help neutralize phosgene oxime that has not yet reacted with tissue. Burns should be managed with topical silver sulfadiazine and systemic antibiotics as needed (Roberts, 1988). Horses and sheep should receive tetanus prophylaxis. Other species should be vaccinated on a case-by-case basis.

Monitor oxygenation and thoracic radiographs following significant exposures. Administer oxygen, intubate, and provide assisted ventilation if needed. Nebulized beta-adrenergic agonists can help if bronchospasm develops. Administer i.v. fluids, but monitor for overhydration (Goldfrank et al., 2002).

Phosgene oxime is nonpersistent in the environment, and it hydrolyzes rapidly in aqueous alkaline solutions. Veterinary personnel and rescuers should wear aprons, rubber gloves, and masks when treating patients to avoid secondary contamination.

62.2.5.4 Species susceptibility

There are no controlled studies showing that any species of animal would make a good sentinel for phosgene oxime exposure.

62.2.6 Cyanide and hydrogen cyanide

62.2.6.1 Clinical signs

Cyanide and HCN are classified as blood agents. They inhibit cellular respiration, oxygen utilization, and ATP production, causing deprivation of oxygen to the body at the cellular level (Way et al., 1988). Both arterial and venous blood appears cherry red and unhaired skin may also appear pink due to the accumulation of oxyhemoglobin (Bingham et al., 2001; HSDB, 2008).

Cyanide exposure can cause transient central nervous system (CNS) stimulation, followed by syncope, ataxia, dyspnea, seizures, paralysis, apnea, coma, and death (Hall and Rumack, 1986). The odor of bitter almonds may be noted in gastric or ruminal contents and expired breath. Initial tachypnea is followed by respiratory depression. Chickens develop tachypnea, have rapid eye blinking, hypersalivation, and lethargy (Wiemeyer et al., 1986). Blindness may occur from cyanide-induced damage to the optic nerve and retina (Grant and Schuman, 1993).

Metabolic and lactic acidosis is commonly seen. Death can occur within minutes.

62.2.6.2 Kinetics

Cyanide and HCN can be absorbed by all routes (inhalation, oral, ocular, and dermal). There is rapid diffusion into tissues, and cyanide irreversibly binds to its target sites. Cyanide is metabolized by rhodanese in the liver to thiocyanate and excreted in the urine (Hall and Rumack, 1986). Without administration of an antidote, the half-life for the metabolism of cyanide to thiocyanate is 20 min to 1 h (Feldstein and Klendshoj, 1954).

62.2.6.3 Decontamination and treatment

Remove animals from the affected area. Irrigate eyes for at least 15–20 min with tepid water. Bathe animals thoroughly with soap and water.

Blood gases and serum electrolytes should be monitored (Hall and Rumack, 1986). Blood cyanide levels can confirm exposure, but are not clinically useful. Provide supplemental oxygen with assisted ventilation as indicated. Acidosis (pH $<$ 7.1) should be corrected with i.v. sodium bicarbonate, but may not resolve until after the administration of antidotes (Hall and Rumack, 1986). Benzodiazepines or barbiturates can be used to control seizures.

Cyanide toxicosis progresses so rapidly that treatment is rarely administered to animals in time. If the animal is still alive, but in respiratory distress or a coma, antidotal agents may still be life-saving. The classic treatment for cyanide intoxication includes several steps. Sodium nitrite is given via i.v. over 15–20 min (fast administration causes hypotension). Sodium nitrite reacts with hemoglobin in the RBCs to form methemoglobin. Methemoglobin combines with free cyanide to form cyanomethemoglobin. Sodium thiosulfate is given next and supplies sulfur for the rhodanese reaction (Hall and Rumack, 1987). The sulfur reacts with cyanomethemoglobin to form hydrogen thiocyanate, which is excreted in the urine.

Hydroxocobalamin (Cyanokit) is the newer option and works by combining with cyanide to form cyanocobalamin (vitamin B_{12}) (Hall and Rumack, 1987). Hydroxocobalamin has been shown to reduce mortality in rats, mice, and beagles and has the advantage of producing neither methemoglobinemia nor hypotension, as sodium nitrite does (Hall and Rumack, 1987; Borron et al., 2006).

HCN is lighter than air and has a long half-life in air. However, in open spaces, HCN is rapidly dispersed and is diluted to nontoxic concentrations. Cyanide does not bind to soil or plant material but can mix with water. Contaminated water can be treated with ozone, hydrogen peroxide, or calcium/sodium hypochlorite bleach. Rescue personnel should wear boots, gloves, goggles, full protective clothes, and a self-contained positive-pressure breathing apparatus as the potential for secondary contamination is high (NIOSH, 2005).

62.2.6.4 Species susceptibility

There are significant interspecies differences in the toxicity of HCN (Sousa et al., 2003). Dogs appear to be more susceptible than humans to cyanide poisoning. This is thought to be due to lower levels of endogenous rhodanese (hepatic enzyme that catalyzes the sulfuration of cyanide to thiocyanate) (Aminlari and Gilanpour, 1991). Barcroft (1931) exposed both a man and a dog simultaneously to HCN gas. The 70-kg man and 12-kg dog were exposed to HCN concentrations between 500 and 625 ppm in an airtight chamber. The dog became ataxic at 50 s, unconscious at 74 s, and began to have seizure at 90 s. At 91 s, the man walked out of the exposure chamber with no symptoms, although over the next 10 min, he developed transient nausea and difficulty concentrating (Barcroft, 1931). As HCN is lighter than air, it is probably not that the small dog experienced a higher exposure than the human.

The LDLo (oral) for HCN in humans, dogs, and rabbits is comparable (5.7, 4, and 4 mg/kg, respectively) (Sax and Lewis, 1989). Dogs may be good sentinel animals as they appear to have increased susceptibility relative to humans based on physiological differences. More controlled studies are required, however.

62.2.7 Military nerve agents

62.2.7.1 Clinical signs

Military nerve agents are probably the most toxic of the known CWAs. Military nerve agents are divided into G (for "Germany") agents (such as sarin, soman, and tabun) and V (for "venomous") agents (such as VX). These agents are organophosphates (OPs). Acute exposure to OPs can cause muscarinic, nicotinic, and CNS signs. Muscarinic effects include salivation, lacrimation, urination, dyspnea, diarrhea, and emesis (SLUDDE), along with miosis, bradycardia, hypotension, and bronchoconstriction. Nicotinic effects include muscle fasciculation and weakness (including the diaphragm), tachycardia, hypertension, and mydriasis. CNS effects include restlessness, anxiety, seizures, and coma (Garigan, 1996). VX has CNS effects that are unrelated to AChE activity and prolonged effects may be seen following convulsive doses (Young et al., 1999). Death is due to paralysis of the diaphragm, increased bronchial secretions, or depression of the respiratory center (Garigan, 1996).

While the volatile G agents present a vapor hazard, VX has a high dermal toxicity, even through intact skin, as the liquid does not evaporate quickly (Berkenstadt et al., 1991;

Sidell et al., 1997). A very small drop on the skin may cause sweating and fasciculations at the site. A larger dermal drop may cause loss of consciousness, seizures, apnea, and flaccid paralysis. The toxicity of these substances, listed in descending order on a per-weight basis, is VX, soman, sarin, and tabun (HSDB, 2008). Soman produced severe delayed neuropathy in the atropinized hen assay at 1.5 mg/kg (Willems et al., 1984).

62.2.7.2 Kinetics

Nerve agents can be absorbed by any route (ocular, oral, inhalation, dermal) (HSDB, 2008; RTECS, 2008). The onset of signs and duration of effects depend on the form of nerve gas (vapor, liquid) and the route of exposure. With inhalation, local signs of nasal discharge and respiratory noise begin within 1 min to several minutes and signs can last for a few hours (mild exposure) up to 1–2 days (severe exposure) (Pfaff, 1998). Inhalation of a large amount of the vapor will result in sudden loss of consciousness, apnea, flaccid paralysis, and seizures within seconds to 2–3 min (Sidell et al., 1997). Peak effects are seen within 20–30 min, and death is usually due to respiratory failure (Berkenstadt et al., 1991). Liquid nerve agents applied dermally cause signs starting 3 min to 2 h after exposure. Signs last for 3–5 days.

Ocular exposure to vapor causes miosis, conjunctival hyperemia, and eye pain within 1 min to several minutes. Signs can last 2–3 days. Liquid tabun penetrates the eye quickly and can result in death nearly as rapidly as an inhalational lethal dose (1–10 min) (EPA, 1985b). Ingestion of the liquid causes muscarinic, nicotinic, and CNS signs about 30 min after exposure, the signs can last several hours up to 2–5 days.

Volume of distribution varies little for each of the nerve agents. Sarin is distributed to the brain, liver, kidney, and plasma (Little et al., 1986). Soman and tabun have the highest levels in the hypothalamus (Hoskins et al., 1986; Wolthuis et al., 1986). Soman is unique in that it has apparent storage in body "depots" and is released over time, which can result in eventual death in animals that survive the initial dose (Wolthuis et al., 1986).

Most military nerve agents undergo aging of the OP–enzyme complex, which makes it resistant to therapies (Young et al., 1999). The aging $t_{1/2}$ is only a few minutes for soman, about 5 h for sarin, and greater than 40 h for VX and tabun (Garigan, 1996).

62.2.7.3 Decontamination and treatment

Administer oxygen and remove the animals from the toxic environment. For ocular exposures, flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Wash all animals three times with either soap and water, dilute bleach solution (1:10 with water), ethanol, or a tincture of green soap (Cancio, 1993). Towelettes impregnated with alkaline chloramine and phenol are used by the military (M291 Skin Decontaminating Kit, Rohm and Haas).

Due to the rapid development of signs, emesis is not recommended after oral ingestion. Seizures can be controlled with diazepam or barbiturates as needed. Assisted ventilation may be necessary if signs progress.

Atropine is an antidotal treatment to reverse the muscarinic signs. It blocks the effects of accumulated acetylcholine (ACh) at the synapse and should be continued until the nerve agent is metabolized. Over-atropinization can cause hyperthermia, tachycardia, agitation, mydriasis, and ileus, which can be life-threatening in the horse.

Oximes are used to treat the nicotinic effects (muscular weakness, diaphragmatic weakness, etc.). Pralidoxime (2-PAM) is the oxime of choice in the United States, and is most effective when administered in the first 1–3 h. Due to the quick aging of soman, 2-PAM is rarely given soon enough to be effective (Sidell et al., 1997). 2-PAM can be given up to 48 h after exposure to VX and tabun, due to slow aging (Sidell and Groff, 1974).

AChE activity can be tested in plasma, serum, or whole blood. In most animal species, 80% or more of the total blood AChE activity is in the RBCs, as compared to 50% in humans; therefore, whole blood is the preferred sample for most veterinary diagnostic labs. Inhibition of RBC AChE is interpreted as follows: (1) 10%–20%, no reliable evidence of exposure; (2) 30%–50%, mild poisoning; (3) 50%–70%, medium or moderate; and (4) 70%–90%, severe intoxication. Cholinesterase levels can take weeks to months to return to normal (Grob, 1956; Rengstorff, 1985).

Environmental persistence is estimated to be 0.5–1 day for tabun, 1–2 days for soman, and 5 days for sarin (Garigan, 1996). VX is an oily liquid that remains in the environment for weeks or longer after being dispersed (Garigan, 1996; Sidell et al., 1997; Munro et al., 1999; Budavari, 2000). Contaminated soil should be treated with alkaline substances (such as sodium carbonate, sodium bicarbonate, calcium hydroxide, or calcium carbonate) or chlorine compounds (sodium hypochlorite or calcium hypochlorite) (EPA, 1975).

Protective equipment (rubber gowns, aprons, and gloves), along with respiratory protection, must be worn by rescuers and veterinary personnel. Leather and fabrics absorb OPs and are extremely difficult to decontaminate. Collars, muzzles, and other items should be incinerated. For further details on decontamination of nerve agents, see Chapter 73.

62.2.7.4 Species susceptibility

Nerve agent susceptibility varies widely between species. Animals may be more at risk for greater exposures than

nearby human populations. Both the G and V nerve agents are heavier than air, and animals closer to the ground will be more affected (Rabinowitz et al., 2008). Some species differences can make animals more sensitive than humans, while others will make them more resistant. Rats may be less susceptible than humans, since they possess aliesterases that can reduce the toxicity of certain nerve agents such as soman and tabun (Fonnum and Sterri, 1981; Gupta and Dettbarn, 1987). These enzymes are not present in humans. Nasal breathers, such as rodents, are capable of partially detoxifying nerve agents in the nasal pathways, presumably by hydroxylation and other mechanisms (Garamone, 2003). Carboxylesterase (CarbE) activity in guinea pigs and rabbits may provide protection from soman, when compared to humans (Maxwell et al., 1987).

RBC AChE activity also varies among species. Pigs, sheep, dogs, rabbits, and cats have less RBC cholinesterase activity than humans, which has been associated with increased susceptibility to nerve agents (Leng and Lewalter, 1999; Anonymous, 2000b).

The LCt_{50} (50% lethal concentration via inhalation) for military personnel for different nerve agents has been estimated from animal studies. Humans appear to be more sensitive to tabun than other animals. The LCt_{50} for tabun is 70 mg min/m^3 for humans, 320 mg min/m^3 for dogs, 450 mg min/m^3 for rats, and 960 mg min/m^3 for rabbits (Anonymous, 2000a; NRC, 2003). Goats are more sensitive than humans to VX. The LCt_{50} for goats is 9.2 mg min/m^3, while the human LCt_{50} is 15 mg min/m^3 (Anonymous, 2000a; NRC, 2003).

It is unknown if animals may have decreased dermal absorption compared to humans due to their protective fur or feathers. Comparing dermal exposures in humans and other species also shows differences for the various nerve agents. Mice appear to be more sensitive to dermal sarin than humans; the LD_{50} values for each are 1.08 and 28 mg/kg, respectively (Sidell et al., 1997; RTECS, 2008). The dermal LD_{50} for tabun in mice is 1 mg/kg; for rats, it is 18 mg/kg, and for humans, it is 14 mg/kg. Mice may be slightly more resistant to dermal soman, with LD_{50}s of 7.8 mg/kg for mice and 5 mg/kg for humans.

There are a few cases where shared exposures to nerve agents have been reported for both animals and humans. In 1968, there was an accidental release of two different nerve agents (one is thought to have been VX) in Utah. A flock of sheep that was grazing near the base was noted to be acting "crazy in the head," and thousands died less than 24 h later (Boffey, 1968). Nearby humans, cattle, dogs, and horses did not develop symptoms. The sheep had severely depressed cholinesterase levels, as did the cattle and horses. Cholinesterase testing of dogs and humans was normal. The sheep may have been more affected due to higher exposures through ingestion of contaminated pasture, or by spending more time in the vicinity of the chemical release.

A way that animals could provide an early warning is via their sense of smell. Most animals have much more sensitive olfactory systems than humans. Animals may be able to be trained to sense low nerve gas concentrations (Dalton, 2003).

62.2.8 3-Quinuclidinyl benzilate

62.2.8.1 Clinical signs

3-Quinuclidinyl benzilate (BZ) is a centrally acting synthetic anticholinergic agent. BZ is used as a hallucinogenic and incapacitating CWA. It is about 25 times more potent than atropine and has a very long duration of action. BZ is disseminated as an aerosol, with the primary route of absorption through the respiratory system.

BZ affects both the peripheral nervous system (PNS) and CNS. It inhibits glandular secretions ("dry as a bone"), leading to a dry mouth and foul breath (Holstege, 2006). Cutaneous vasodilation and skin flushing may be noted ("red as a beet") due to decreased capillary tone. Hyperthermia ("hotter than Hades") is due to inhibition of sweating and inability to dissipate heat. Vision loss ("blind as a bat") occurs from a loss of accommodation reflexes, decreased depth of field secondary to ciliary muscle paralysis and mydriasis (Holstege, 2006). Paralytic ileus, which can be fatal to horses, is commonly seen as a result of anticholinergic toxicity (Ketchum and Sidell, 1997; Holstege, 2006).

CNS signs of disorientation, agitation, tremor, ataxia, stupor, coma, and seizures may occur from inhibition of central muscarinic receptors (Ketchum and Sidell, 1997; Holstege, 2006). It is unknown if animals hallucinate like people, but they do appear distressed. Rhabdomyolysis and myoglobinuric renal failure can be seen secondary to seizures and agitation (Holstege, 2006). Sinus tachycardia, hypertension and tachypnea may occur (Ketchum and Sidell, 1997; Holstege, 2006).

62.2.8.2 Kinetics

BZ is lipophilic and easily crosses the blood–brain barrier (BBB), leading to CNS effects. Signs are dependent on the dose and time after exposure. Prolonged effects may occur depending on the dose of BZ absorbed. Tachycardia and dry mouth develop within 15 min to 4 h after exposure, and peak effects occur at 8–10 h (Ketchum and Sidell, 1997). Binding to high-affinity muscarinic acetylcholine receptors (mAChRs) is essentially irreversible for the first 6 h. BZ is excreted via the kidneys (Holstege, 2006). Without treatment following an incapacitating dose, recovery is gradual, requiring 72–96 h (Ketchum and Sidell, 1997).

62.2.8.3 Decontamination and treatment

Move into fresh air and monitor for respiratory distress. Supplemental oxygen and assisted ventilation may be required. Nebulized beta-adrenergic agonists should be used if bronchospasm develops. Due to the method of distribution (aerosol), most exposures are expected to be via inhalation. However, with animals' tendency to groom, dermal exposures can also become oral exposures.

Flush eyes with copious amounts of tepid water for at least 15 min. Animals should be bathed with soap and water. Bathing will not only remove the BZ, but will also provide external cooling to combat hyperthermia. BZ may be detected in urine, serum, or blood, but clinical use is minimal.

Benzodiazepines can be used to control agitation and seizures and prevent rhabdomyolysis.

Treat arrhythmias symptomatically (lidocaine, propranolol, etc.). Physostigmine can be used to treat severe arrhythmias, but it is ineffective if given during the first 4–6 h following the onset of BZ effects.

Monitor electrolytes and renal function tests in symptomatic patients. Administer i.v. fluids to maintain urine output and to protect the kidneys from myoglobinuria. The prognosis is good if animals do not develop rhabdomyolysis or secondary infection. No chronic problems are expected from BZ itself (Holstege, 2006).

BZ is stable and environmentally persistent. "Off-gassing" may occur from contaminated patients. Goggles and masks should be worn by all personnel until the animals are decontaminated (Holstege, 2006). Remove contaminated collars, leashes, harnesses, halters, and other devices, and discard them, as leather and fabrics absorb BZ.

62.2.8.4 Species susceptibility

There are no studies demonstrating that animals are more sensitive than humans.

62.2.9 RCAs (lacrimators)

62.2.9.1 Clinical signs

Chloroacetophenone (i.e., CN, mace, tear gas), chlorobenzylidene malonitrile (i.e., CS, super tear gas), and oleoresin capsicum (OC; pepper spray) are lacrimators used in riot control. They are solid chemicals administered as a fine dust or aerosol spray rather than being true gases. Exposure to lacrimators causes immediate pain, blepharospasm, lacrimation, rhinorrhea, coughing, and sneezing, but usually no permanent tissue damage (Grant and Schuman, 1993; Blain, 2003). With higher ocular concentrations, chemical burns with keratitis and loss of the corneal epithelium may occur (Hoffman, 1967). Oral ingestion can cause eye irritation, lacrimation, vomiting, and diarrhea (Blain, 2003). Laryngospasm may occur due to the irritant effects; it can progress to pulmonary edema, bronchospasm, and bronchopneumonia.

Dermal contact with lacrimators is very painful (Pinkus, 1978). Erythema and blisters are common. The extent of dermal effects depends on the thickness of the stratum corneum, and the extent of exposure (Blain, 2003). High concentrations can cause first- and second-degree burns of the skin (Stein and Kirwan, 1964; Hu et al., 1989). For further details on toxicity of RCA, see Chapter 12, Blister agents.

62.2.9.2 Kinetics

The effects of lacrimators occur very quickly. Pain, salivation, coughing, rhinorrhea, sneezing, and erythema begin within seconds of exposure and can last approximately for an hour (Blain, 2003). Laryngospasm, bronchospasm, and pulmonary edema may occur up to 48 h (usually 12–24 h) postexposure (Folb and Talmud, 1989). Gastrointestinal signs resolve over 24 h (Solomon et al., 2003). Erythema disappears over 48 h and coughing may persist for weeks after exposure (Blain, 2003). One of the CS metabolites is cyanide, but cyanide toxicosis does not appear to occur (Cucinell et al., 1971).

62.2.9.3 Decontamination and treatment

Animals may need to be sedated to be able to treat them safely. Move animals into fresh air and monitor for respiratory distress. Supplemental oxygen may be needed. Laryngospasm may require intubation to permit adequate ventilation. Inhaled beta-2 agonists (i.e., albuterol and salbutamol), corticosteroids, and aminophylline may help reduce bronchospasm (Folb and Talmud, 1989). Thoracic radiographs should be monitored if pulmonary edema is expected (Stein and Kirwan, 1964).

Flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Diphoterine solution can be used for decontamination of both eyes and skin after exposure to lacrimators (Viala et al., 2005). Ocular signs resolve approximately 3–7 min after diphoterine application. Animals should be bathed with soap and copious amounts of cold water. Using small amounts of water can actually increase irritation (Lee et al., 1984). Topically applied magnesium hydroxide–aluminum hydroxide–simethicone suspension (Maalox Max) caused resolution of signs within 2 min of application following exposure to OC. If chemical burns develop, clean wounds with a mild, disinfectant soap and water. Pain control and antibiotics may be needed. Tetanus toxoid should be given if burns are present. With oral ingestions, antacids may help decrease gastrointestinal signs.

Secondary contamination is common and personnel should wear aprons, rubber gloves, and masks as needed. Contaminated items can be washed in cold water (hot

water will cause residual gas to vaporize) with soap or allow nonwashable items to air out for a few days. Most lacrimators dissipate quickly, but CS may be micronized and mixed with an antiagglomerant agent (CS1), which remains active for up to 5 days. A similar formulation mixed with silicone (CS2) remains in the environment for up to 45 days (Hu et al., 1989).

62.2.9.4 Species susceptibility

There are no controlled studies showing that animals are more sensitive to lacrimators than humans.

62.2.10 Ricin and abrin (toxalbumins)

62.2.10.1 Clinical signs

Ricin and abrin are toxalbumins, which are plant lectins with a specific affinity for animal cell receptors. Ricin is from *Ricinus communis* (castor bean plant, castor oil plant, mole bean). The castor bean plant is grown throughout the United States as an ornamental. Most animals are exposed to ricin by eating the seeds, but ricin has been used as a CWA. Abrin is found in the *Abrus precatorius* plant (Buddhist rosary bead, crab's eyes, Indian bead, jequirity bean, rosary pea).

Variable toxicity is seen in cases of oral ingestion. Seeds swallowed whole may not cause any problems at all (Kinamore et al., 1980). The amount of toxalbumins in the seeds will vary by size, weight, moisture content, region, season, and the period of plant growth at the time of harvesting. The ricin content of castor beans can vary from 1% to 10% (Balint, 1974). The abrin content in *A. precatorius* seeds is estimated at 0.15% (Lin et al., 1971). Toxicity and death have occurred with ingestions of one to two chewed beans of either plant. Ricin levels can be measured in plasma and urine but are not clinically useful (Kopferschmitt et al., 1983).

Vomiting, abdominal pain, and bloody diarrhea are the most common signs seen after ingestion (Kopferschmitt et al., 1983). Toxalbumins cause severe gastrointestinal lesions of the oropharynx, esophagus, and stomach. The lesions are clinically similar to alkaline burns. Fluid losses can lead to dehydration, electrolyte disturbances, hypotension, and tachycardia (Ingle et al., 1966).

Liver damage occurs in toxalbumin toxicosis, resulting in elevated liver values. Glycogen stores decrease, gastrointestinal absorption of glucose decreases, and hypoglycemia occurs (Lampe, 1976). Mild to moderate CNS depression is commonly observed. Seizures are reported more frequently in animals than in people (Hart, 1963).

Ricin is among the most toxic compounds known when given parenterally. Parenteral toxicity is much greater than oral toxicity. The oral lethal dose of ricin is estimated to be 1 mg/kg (Kopferschmitt et al., 1983). When given by injection, the lethal dose of ricin drops to about 1 μg/kg (Budavari, 2000). With an inhalation exposure, signs seen are cough, dyspnea, arthralgias, fever, and death (Griffiths et al., 2007). Other organ system dysfunctions may not occur. For more details on toxicity of ricin and abrin, see Chapter 28. For other toxic chemicals as potential chemical warfare agents, see Chapter 27, and for toxicokinetics and toxicodynamics of DFP, see Chapter 53.

62.2.10.2 Kinetics

Gastrointestinal effects usually develop in under 6 h (Kopferschmitt et al., 1983). The cytotoxic effects on the liver, CNS, kidney, and adrenal glands may not occur for 2–5 days postexposure. With an inhalation exposure, symptoms begin within 8 h. Death occurs about 48 h after a parenteral or oral exposure (Budavari, 2000).

Glycoproteins are poorly absorbed from the gastrointestinal tract. Many cell surfaces contain receptors specific for ricin and the toxin is taken up by active transport. The primary site of distribution of ricin is the liver, spleen, and adrenal cortex in the mouse. A high concentration was also found in the bone marrow (Godal et al., 1984). In rats, abrin is distributed primarily to the liver (12%) and kidney (3%) (Lin et al., 1971).

The metabolism and elimination of toxalbumins is poorly understood. Ricin is eliminated by first-order kinetics when injected i.v. into mice and human cancer patients (Godal et al., 1984). The plasma half-life in humans is about 2 days (Kopferschmitt et al., 1983).

62.2.10.3 Decontamination and treatment

There are no specific treatments for toxalbumin exposure. Aggressive decontamination is recommended. With ingestions, emesis should be induced in asymptomatic species that can vomit (e.g., dogs, cats, ferrets, and swine). Activated charcoal can bind orally ingested toxalbumins. Monitor asymptomatic animals for 8 h for dehydration, electrolyte disturbances, elevated liver enzymes, and hypoglycemia. Intravenous fluids are very important to maintain normovolemia and urine output. Caprine, ovine, and murine antiricin antibodies have been tested but are not clinically available (Lemley and Wright, 1991; Wannemacher et al., 1991; Whitfield et al., 2017).

If the toxalbumin was distributed by air, move the animal into fresh air and monitor for respiratory distress. If cough or dyspnea develops, administer supplemental oxygen. Wash animals thoroughly with soap and water. Eyes should be flushed with copious amounts of tepid 0.9% saline or water for at least 15 min. Other treatments are the same as for an oral exposure.

62.2.10.4 Species susceptibility

There are no controlled studies demonstrating that animals are more susceptible to developing acute effects than humans.

62.3 Concluding remarks and future directions

The lack of controlled studies comparing animals and humans needs to be addressed if animals are to be used as sentinels. The existing studies and anecdotal reports do not provide enough convincing evidence (Rabinowitz et al., 2008). Sentinels would need to demonstrate easily recognizable signs before the emergence of human illness. A good sentinel could have either greater susceptibility to a particular toxin relative to humans or a shorter latency time from exposure to onset of signs (Cottrell and Morgan, 2003).

With any suspicious outbreaks, the local health department, poison center, law enforcement agencies, and the US Federal Bureau of Investigation (FBI) should be contacted immediately. Due to the absence of a nationwide surveillance system for animal diseases, the responsibility for detecting possible outbreaks of unusual symptoms in animals will fall to several different groups of people. Farmers, agriculture officials, veterinarians, animal control officers, wildlife rehabilitators, (animal) poison control centers, and the lay public (such as animal owners) may all be involved in detecting outbreaks.

During a chemical warfare incident, the human casualties should be addressed first, followed by the animal casualties. Situations in which herds of livestock or flocks of poultry are affected are going to be much more complex to manage than exposures to house pets. The simple logistics in getting the personnel and equipment to the site of exposure can be daunting, if not impossible. Handling livestock can be dangerous, especially for untrained personnel. The use of antidotes and other pharmaceuticals must be documented in food-producing animals and withdrawal times for meat and milk must be followed. In many herd situations, humane euthanasia may be the best solution.

Chapter 63

Threats to wildlife by chemical and warfare agents

Robert W. Coppock[1] and Margitta M. Dziwenka[2,3]

[1]Toxicologist and Associates, Ltd,Vegreville, AB, Canada, [2]Health Sciences Laboratory Animal Services (HSLAS), Faculty of Medicine and Dentistry, University of Alberta, Edmonton, AB, Canada, [3]ToxAlta Consulting, Vegreville, AB, Canada

63.1 Introduction

Wildlife, in its natural habitat, has an economic value inclusive of the experience of viewing, amateur and commercial photography, research, and the preservation of genetic diversity and natural ecosystems (Sangpikul, 2017). In many countries, wildlife-based ecotourism and other related commercial enterprises are important contributors to the gross domestic product. Ecotourism is a growing industry, especially if a country has unique or rare wildlife species and ecosystems. Wildlife has traditional value in aboriginal cultures as a source of food, as materials for garments, footwear, and shelter, religious ceremonies, and is essential for aboriginal people to live in synchrony with nature. Some countries are investing in the intensive management of wildlife and wildlife habitats to sustain wildlife as a renewable resource (Child et al., 2019). Sport and trophy hunting of wildlife is a source of income for governments in licensing fees and taxes from employment of local people as guides and from taxation of accommodation and travel infrastructure. Worldwide, governments are under pressure to protect and ensure wildlife survival, inclusive of the ecosystems necessary for wildlife to feed, breed, and thrive. Protection of wildlife resources relies on governments enacting and enforcing a variety of laws and regulations (Sellar, 2009; Linacre, 2009; Maisels et al., 2013). A form of wildlife-ecological terrorism has been used to deprive self-sustaining aboriginal people of the necessities of life provided by the ecosystem for their independent existence. Wildlife poaching is a criminal activity generally focused on protected predators, damage-causing herbivores and predators, and poaching animals for economic gain from the sale of animal-source protein and illegally obtaining body parts for monetary gain (Sellar, 2009; Cooper and Cooper, 2013; Maisels et al., 2013). Wildlife have a similar sensitivity to the toxic effects of physical and chemical agents as domestic animals. Toxic chemicals have been and can be used as terrorist weapons to target wildlife.

Terrorism is a systematic use of violence to create fear and economic deprivation to achieve political and other objectives (Stankov, 2018). Terrorist activities are generally performed to destabilize society and undermine governmental control, create economic hardship, and deprive targeted human populations (Gleick, 2006). Grudge is emerging as a motivator for committing terrorism and is a reason humans react to unwanted actions of animals (Stankov, 2018; Ntemiri et al., 2018). Terrorists are opportunistic, and target that have long-term impacts are attractive (UN-CTED, 2017). Counterterrorism is difficult in rugged terrains and in prime wildlife habitat areas. By using the ecosystem that supports wildlife as their operational platform, terrorists can avoid detection by antiterrorism technology and trained personnel that are used in populated areas. Wildlife terrorist and commercial poachers use “guerilla-type” hit-and-run tactics (Desphande, 2009). Wildlife can be a direct or indirect target for terrorist attacks, and terrorist activities against wildlife can be undertaken to disrupt or destroy regional income (Felbab-Brown, 2018). Terrorist attacks against governmental and commercial operations can occur in more remote areas, and such attacks could have an immense impact on wildlife, including fish and other aquatic organisms. In some countries, military belligerents undertake hit, run, and hide warfare, and bushmeat (meat from wildlife) is an important part of their rations. Wildlife can be

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00063-5

used in counterterrorism efforts as sentinels of chemical agents released by terrorists. The anomalous behavior of sentinel species equipped with tracking devices can be used to monitor the movement of belligerents (Rabinowitz et al., 2008; Sahin and Ercan, 2008).

There have been reports of wildlife suffering direct and indirect damage during armed conflicts, causing food shortages and disruption to the local economies (Brown, 1999; de Merode et al., 2007; Hanson et al., 2009; Nellemann et al., 2014; Felbab-Brown, 2015; Hanson, 2018). Some authors describe the environmental impact of armament races and wars as the treadmill of environmental destruction (Clark and Jorgenson, 2012). Hostile activities and terrorism are interconnected. Wildlife and their habitats can suffer as collateral damage from air and other attacks by belligerents and also military actions undertaken to reduce hiding places for belligerents and actions taken to reduce the bushmeat that these belligerents rely on for food (Olson and Morton, 2019). In addition, illegal trade in wildlife parts can be an important source of revenue to support belligerent activities (Beyers et al., 2011; Felbab-Brown, 2015, 2018). Corrupt government officials can also profiteer from the sale of wildlife parts. People displaced by terrorism and other forms of conflict may be forced to depend on bushmeat for survival.

Wildlife, especially scavengers, can destroy forensic evidence. The evidence required in the prosecution of poachers and wildlife terrorism can be destroyed by scavenging wildlife. Wildlife itself can be an impediment to forensic investigations, for example homicide, by destroying or otherwise altering evidence (Linacre, 2009; Sincerbox and DiGangi, 2018). For example, birds and rodents scavenging can impact the recovery of biological evidence during forensic investigations (Chipman et al., 2004). Counterterrorism devices can fortuitously impact procedures to reestablish endangered wildlife. For example, X-ray devices used in counterterrorism and used to detect smuggling in wildlife parts can damage semen and embryos from endangered species being shipped to other locations to ensure heterogenicity (Gloor et al., 2006).

63.2 Infrastructure and potential widespread chemical contamination

The resiliency of an ecosystem to human depredation is important when considering activities undertaken in human conflict (Orians and Pfeiffer, 1970; Banout et al., 2014). The effects of chemicals used to control an ecosystem during conflicts can have long-term multigenerational consequences (Frey, 2013). Dams holding water impoundments are considered a terrorist target (UN-CTED, 2018). Uncontrolled release of water from impoundments has large-scale impacts on humans and all terrestrial and aquatic animals living in the drainage basin. The reasons for impounding freshwater are generally multifaceted, including water for domestic, agricultural, and industrial uses, and energy storage for hydroelectrical generation. Mine and other industrial wastewaters are stored by impounding in tailing ponds (waste slurry storage facilities) (Rico et al., 2008; UNEP, 2017). These liquefied wastes contain toxic leftovers after the valuable elements and other components are removed from ores, slurries, and/or process water. These impoundments can contain antimony, arsenic, cadmium, copper, lead uranium, zinc, process chemicals including cyanide, fine mineral particulates, etc. (Hudson-Edwards, 2016). These impoundments can contain an immense amount of heavier-than-water waste materials and dams holding these impoundments of mining waste have failed, resulting in the sudden release of kinetic energy and toxic materials resulting in large-scale disasters (Bowker and Chambers, 2016). Dams holding back liquefied waste, due to their lack of best-practice construction, can be inherently unstable (Bowker and Chambers, 2016; Schoenberger, 2016; UNEP, 2017). Terrorist and military destruction of dams weaponizes the kinetic energy and toxic materials contained by these dams. Water impoundments can be weaponized by clandestine methods that cause failure of dams (Nett and Ruttinger, 2016). At this time, no reports of large-scale releases of toxic water linked to terrorism or warfare have been found. Examples are given to illustrate the scale of these disasters because of their enormous potential for environmental impact, and the destruction of human life and health. The failure of the Fundao tailings dam on November 5, 2015, is historically the worst release of toxic water (60 million m^3) in Brazil (Marta-Almeida et al., 2016). There were 18 confirmed deaths and one person missing. For 17 days, the released tailings traveled through the Rico Doce River basin before reaching the Rio Doce estuary in the Eastern Brazilian Marine Ecoregion of the Atlantic. In some regions the riparian deposits of tailing mud were 40 cm thick. Studies have estimated the tailings dispersed for hundreds of kilometers in the Atlantic estuary and impacted marine biota (Marta-Almeida et al., 2016; Gomes et al., 2017). In Italy, breach of the Val di Stava dam released an estimated 180,000 m^3 of liquid tailings into Stava and caused 268 deaths. The contents were discharged into the Aviso River and caused extensive environmental damage. The failure of the Mount Polly dam in Cariboo Region of British Columbia (Canada) released approximately 25 million m^3 of liquified tailings into Polley Lake and subsequently along Hazeltine Creek channel into the west basin of Quesnel Lake (Petticrew et al., 2015; Byrne et al., 2018; Hatam et al., 2019). It is estimated that the tailing pond materials will have a long-term effect on the biota in Quesnel Lake and present a potential hazard to aquatic food webs and

the growth and survival of important fish species and the biogeochemical cycle. Aquatic species are used by aboriginal peoples living in this area. The release of 50–100 tonnes of cyanide from a tailings pond into the Sasar River, and eventually reaching the Danube River, had a devastating impact on aquatic wildlife in Eastern Europe (Cunningham, 2005). Recently, the tailing pond dam at the Vale Mine in Brazil collapsed causing loss of human life and large long-lasting environmental impacts. One can only imagine the public and political reaction that would have occurred if this incident was claimed to be an act of terrorism.

63.3 Pyroterrorism and wildlife

Pyroterrorism can cause collateral damage to wildlife, or wildlife and habitat can be a direct terrorist target. Pyroterrorism is the use of an incendiary attack (weaponizing fire) to achieve the objectives of the terrorist, and pyroweapons are used in military conflicts (Baird, 2006; Marsden et al., 2014). A well thought through pyroterrorism plan can be easily and inexpensively accomplished, be a huge media event, and compared to other targets, offers low risk of being apprehended (Marsden et al., 2014; Desphande, 2009). Pyroterrorism, in terms of igniting wildfires (bushfires), generally has built-in media coverage of the inferno. Terrorist-linked and/or anarchist-linked wildfires are considered to have occurred in Spain, Estonia, Greece, Turkey, and Israel, but links of wildfires to terrorists are likely underinvestigated (Marsden et al., 2014; Desphande, 2009). Wildfires can have huge economic loses, including the destruction of personal and environmental assets, habitat, the cost of firefighting, the loss of human life, and negative impacts on surface and ground water (Baird, 2006; Desphande, 2009; Rodrigues et al., 2019). Wildfires have also been shown to have impacts on wildlife habitats and wildlife dynamics (Nimmo et al., 2018). Fish and other aquatic organisms, and animals in the food chain, can be impacted by runoff water, including the runoff of water after its use in firefighting (de Vries et al., 2017; Robinne et al., 2018). Rain water, which is atmospheric wash water, can contain pollution emitted during wildfires and be deposited long distances from the fire site. Wildfires remove vegetation, generally increase water runoff after rainfall events and thereby increase toxic substances and sediment entering aquatic systems (Brito et al., 2017; Nunes et al., 2017; Jensen et al., 2017; Hallema et al., 2018). Lands quarantined because of contamination with radioactive compounds are considered targets for pyroterrorism. The radionuclides at the contaminated site become incorporated in the biota and are released in the products of combustion (Evangeliou et al., 2014). Building fires also have environmental impacts (Noiton, 2001). The most visible chemical release during a fire is smoke, less visible are the thousands of cubic meters of water used to extinguish a building fire (Scholz, 2014). Extinguishing water that is not vaporized (fire-water) can run off the fire site and contaminate surface water (Holemann, 1994). Fire-water can also contaminate ground water, the fire-water runoff contains products of combustion, chemicals stored in the building when the fire occurred, and chemicals used in firefighting. The polluted fire-water can cause major environmental impacts in the receiving waters that last for years and also result in the need for expensive remediation (Flowles, 2001; Giger, 2009). Runoff water from even small structural fires can present a threat to aquatic ecosystems (Noiton, 2001). In summary, chemicals released by wildfires and individual building fires can have significant short- and long-term effects on the health of wildlife and the ecosystem.

63.4 Candidate chemical agents

63.4.1 Background

Chemical agents inclusive of pesticides have a history of being used for various reasons to kill wildlife (Ogada, 2014). Chemical agents have also been used to poison water sources to prevent use by insurgents (Purkitt and Burgess, 2002). Wildlife and humans can share the same surface water; in this case, it is unknown if wildlife will be affected. Pesticides are used to control damage-causing wildlife and are used in poaching. There are worldwide concerns regarding illicit pesticides being used for clandestine activities including terrorism and their impact on non-target wildlife (Whitlow et al., 2005; UNICRI., 2016; Patocka et al., 2018). Under regulations, certain pesticides, because of their toxicity, have restricted use and some governments have banned them. Pesticides that are obsolete and no longer manufactured or prohibited in one country may legitimately be manufactured and sold in another country, making them available for smuggling activities (Shakarjian et al., 2016). Compounds that are highly toxic when ingested orally are considered candidate chemicals for weaponization and are especially dangerous to wildlife because residual levels in carcasses can cause relay toxicity in scavenging and opportunistic feeders.

63.4.1.1 Tetramethylenedisulfotetramine

63.4.1.1.1 Background

Tetramethylenedisulfotetramine (2,6-dithia-1,3,5,7-tetraazatricyclo[3.3.1.13,7]-decane,2,2,6,6-tetraox- ide, tetramine, TETS, TMDT, CAS No. 80-12-6) has historical use as a one-dose pesticide, but is reemerging as an illicit synthetic neurotoxic chemical and is a potential chemical warfare agent (Barrueto et al., 2003; Whitlow et al., 2005;

Shakarjian et al., 2016; Patocka et al., 2018). TETS accounts for many human deaths due to accidental and forensic exposures (Wang et al., 2016). It is an odorless, tasteless, white, crystalline powder with a solubility in water of 250 mg/L [ToxNet. https://chem.nlm.nih.gov/chemidplus/rn/80-12-6 (accessed March 2019)], and it can be used in water and food baits. It is estimated that 50% of the rodenticides in China contain TETS, where the Chinese name is "Du Shu Qiang" (Patocka et al., 2018; Owens et al., 2009). TETS is considered to be 100 times more toxic than cyanide and a lethal dose for humans is 7–10 mg and it is considered to be one of the most dangerous toxic substances that can be used in food and water baits (Whitlow et al., 2005). TETS can be used as a lethal seed coating and is translocated to plants in sufficient quantities for the plant to be fatal to rodents and lagomorphs (Spencer et al., 1954; Shakarjian et al., 2016). TETS persists in soil and lethal levels can be translocated to plants for up to 4 years. TETS is also used in fabrics as a stiffening and antifungal agent (Patocka et al., 2018). TETS has been identified in accidental and homicidal poisonings (Shakarjian et al., 2016).

63.4.1.1.2 Mechanism of action

TETS has a short latency between oral ingestion and onset of clinical signs. It selectively and irreversibly binds with the neuronal γ-aminobutyric acid A receptor ($GABA_A$) and disrupts physiological regulation of the chloride channel (Zhao et al., 2014; Shakarjian et al., 2016). The net toxicological effect is dysregulation of membrane regulation of chloride and subsequent depression of neuronal inhibition in the central nervous system (CNS). TETS is a noncompetitive inhibitor of the $GABA_A$ receptor and, compared to insects, has a 300–5000-fold selective affinity for the mammalian $GABA_A$ receptor. Inhibitory activity in the CNS is decreased and clinical manifestations include seizures, with onset occurring 20–30 minutes after TETS ingestion. The toxicity of TETS is generally considered to be more potent than sodium monofluoroacetate. The oral LD_{50} of TETS for most species is 0.1–0.3 mg/kg of body weight. Rabbits dosed with TETS at 0.4 mg/kg body weight and killed 1 hour later had detectable levels (0.07–0.238 μg/g) in the liver, kidney, heart, and lung (Xiang et al., 2001). TETS can be identified in liver after being fixed in formalin for 4 months (Xiang et al., 2001). TETS is excreted in urine, which can be used for forensic investigations (Zeng et al., 2006). Scavenging animals and birds can be poisoned with TETS because of the stability of TETS in tissues and body fluids. There appear to be sex and age differences in sensitivity to TETS with females and younger animals likely being more sensitive than mature males (Laukova et al., 2018).

63.4.1.1.3 Pathology and detection

The pathology of TETS in humans has been reported (Zhang et al., 2011). Pathological observations in poisoned humans were edema of the brain, hemorrhages in the brain stem, and myocardial degeneration in the papillary muscles. Cardiac myopathies of varying distribution are a common finding in the majority of species. A reasonable assumption is that similar pathology and levels in tissues and urine would occur in other species. Human tissues and urine can be assayed for TETS (Xiang et al., 2001; Zeng et al., 2006). Analytical methods for TETS include liquid chromatography-mass spectrometry and gas chromatography-mass spectrometry and immunoassay (Owens et al., 2009; Vasylieva et al., 2017).

63.4.1.2 Sodium monofluoroacetate and sodium fluoroacetamide

63.4.1.2.1 Background

Sodium monofluoroacetate (SMFA; compound 1080) and sodium fluoroacetamide (SFA, compound 1081) are candidate chemicals for terrorists and criminal activities targeting humans, domestic animals, and wildlife (Holstege et al., 2007). Mechanistically, the toxicology of SFA is the same as SMFA (Wang et al., 2016). SMFA is a white powder that has the appearance of flour or sugar and is stable in storage over a long period of time and is heat-stable to 200°C. It is soluble in water but insoluble in ethanol and lipids. In water solution, SMFA is degradable by microorganisms. Both SMFA and SFA were/are used as single-exposure pesticides and, because of their toxicity, have been banned or placed on licensed restricted use by many governments. One use is control or elimination of nonindigenous problem wildlife. As an interesting comment, SMFA and closely related compounds are the poisonous principal in several species of plants growing in South America, Africa, and Australia (Lee et al., 2014). The use of SMFA as a poison to eliminate unwanted animals and birds is restricted in many countries, primarily because of large kills in nontarget species (Ataria et al., 2000). Countries with nonindigenous mammal populations use SMFA to control non-native animal species that disrupt and endanger indigenous wildlife (Potter et al., 2006; Allen et al., 2014). The water solubility of SMFA means that it can easily be added to water, baits, and feedstuffs and is generally accepted for consumption by target and nontarget species. The use of SMFA can be limited to use in devices that target problem predators. For example, SMFA in some jurisdictions has been limited to neck collars containing multiple SMFA-filled chambers that are ruptured when the predator attempts a fatal attack on the neck (Burns and Connolly, 1995). SMFA is also considered to have the potential for weaponization.

In 2014, an incident occurred in New Zealand wherein the terrorist or blackmailers alleged to have contaminated milk products as a protest against the government approval of SMFA to control non-native fauna (Cooney et al., 2016). No milk was found to actually contain SMFA. There are recent reports of SMFA-linked livestock and pet poisonings and the forensic issues were not clearly identified (Giannitti et al., 2013; Brower et al., 2017; Adaska et al., 2018). These reports also point out the resources and manpower required to establish a diagnosis when the etiology is a restricted toxic substance.

63.4.1.2.2 Toxicology of sodium monofluoroacetate

SMFA is absorbed from the gastrointestinal tract, respiratory tract, mucous membranes, and wounds (Holstege et al., 2007). Different routes of exposure do not have a remarkable effect on toxicity. The mechanism of action for SMFA is blockage of the mitochondrial tricarboxylic acid cycle. The toxication reaction is fluoroacetate being converted to fluoroacetyl-CoA and subsequent conversion to fluorocitrate by citrate synthase. The enzyme aconitase catalyzes the conversion of citrate to isocitrate and is inhibited by fluorocitrate. Inactivation of aconitase blocks the tricarboxylic acid cycle. The heart and CNS are simultaneous targets for SMFA. Animals poisoned by SMFA are a hazard to scavengers, opportunists, and carnivores. The sensitivity of species to SMFA is given in Table 63.1.

TABLE 63.1 Estimated lethal dose of SMFA in selected animals.

Mammal or bird	Lethal dose (mg/kg body wt)
Dog	0.1–0.2
Coyote and fox	0.1–0.3
Cattle	0.2–0.7
Pig	0.3–0.4
Cat	0.3–0.5
Horse	0.5–1.8
Human	0.5–5.0
Goat	0.5–0.7
Magpie	0.6–2
Rabbit	0.8
Chicken	6–18
Duck	7–9

Hematological and biochemical profiles and histopathological evaluation of experimental intoxication by sodium fluoroacetate in cats. Hum. Exp. Toxicol. 29, 903–913 (Collicchio-Zuanaze et al., 2010).

63.4.1.2.3 Clinical signs of intoxication

Clinical signs of SMFA toxicity are due to the effects on the CNS and heart. Herbivores can show more cardiac signs as compared to carnivores. The sequence of cardiac events is arrhythmias, tachycardia, inefficient pumping (weak pulse), and death when the heart starts to fibrillate. Clinical signs observed include ataxia, collapse, and a short interval of agonal struggling and seizures (Robinson, 1979). Carnivores can have neurological signs of hyperesthesia, aimless wandering, frenzied running, vocalization, incoordination, emesis, opisthotonus, coma, and death. Thermoregulation may also be disrupted. Death occurs anywhere from 1 to 24 hours after ingestion of SMFA. Poisoned birds can "fall" from the sky and die soon after hitting the ground or show nervous system signs and an inability to fly. Relay (secondary) intoxication by SMFA and its metabolites can occur. An animal that has ingested SMFA and vomits can be lethally intoxicated, and the animal ingesting the vomit can also be lethally intoxicated (Brower et al., 2017). Animals poisoned by SMFA can repetitively be lethal to animals and birds that consume them by relay poisoning.

63.4.1.2.4 Pathology and forensic chemistry

Pathological findings in SMFA poisoning are those of acute heart failure and hypoxia. Focal to diffuse degenerative to necrotic lesions occur in the myocardium. Inflammatory exudates may be observed. Skeletal muscular lesions were observed in mallard ducks experimentally poisoned with SMFA (Ataria et al., 2000). Tissues and body fluids can be assayed for SMFA and its metabolites by gas or liquid chromatography methods (Giannitti et al., 2013; Cooney et al., 2016; Adaska et al., 2018).

63.4.1.3 Cyanide

63.4.1.3.1 Background

Cyanide (CN^-) is poisonous to essentially all animal species and is a listed chemical for potential weaponization by terrorists. Cyanide, in different chemical formulas, can be admixed in a variety of baits, including water. Cyanide is also used in the extraction of gold and silver ores and presents environmental risks (Donato et al., 2007; Griffiths et al., 2014). Catastrophic release of a large volume of tailing pond slurry containing high concentrations of cyanide and heavy metals into river systems has

occurred but this event was not linked to terrorism (UNEP, 2000; Macklin et al., 2003; Cunningham, 2005). The rupture in January 2000 of a Romanian dam holding 100,000 m^3 of cyanide-contaminated slurry water caused an environmental disaster (Macklin et al., 2003; Cunningham, 2005). An estimated 50–100 tonnes of cyanide and heavy metals were released into the Sasar River and then flowed through the Lapus River to the Somes River, then to the Tisza River, and finally emptied into the Danube River. The breach in the dam was attributed to a number of factors, including a sequence of rainfall occurrences. Scientific evaluations showed this event caused severe mortalities in the aquatic system. It is feasible that terrorist or criminal activities could target dams holding tailings ponds and cause a huge sudden release of contaminated water, creating a down-river environmental disaster that targets drinking water safety, wildlife, tourism, and international relations. Cyanide also has a history of being used to control unwanted wildlife and is toxic in the marine environment (Wiemeyer et al., 1986). Vehicles transporting cyanide for mining and other uses could be a target of terrorists and used to release cyanide into flowing water (Kravitz and Blair, 2019).

63.4.1.3.2 Toxicology

The pathophysiology of acute cyanide poisoning is due to its rapid diffusion into tissues and impairment of oxidative phosphorylation and other biochemical pathways (Beasley and Glass, 1998). The primary enzyme target is cytochrome oxidase by the high affinity of CN^- for ferric iron in the oxidized enzyme. Oxygen utilization is inhibited, and lactate accumulation rapidly causes metabolic acidosis. Clinical signs of cyanide intoxication in birds have been described (Wiemeyer et al., 1986). The progression of clinical signs of cyanide poisoning in vultures is ataxia, eye blinking, head bowing, wing droop, increased ataxia, seizures with tail fanning, opisthotonus, gasping, and death. The progression of clinical signs in kestrels, owls, and quail is reported to be more violent. Exemplary lethal dose 50 (LD_{50}) of cyanide is given in Table 63.2. Time from ingestion to death is dose-dependent. Terrorist and criminal actions that release cyanide into the environment, especially into aquatic ecosystems, can kill large numbers of wild animal species. Release of cyanide-polluted water can have long-term consequences on a freshwater ecosystem (Lakatos et al., 2003). Cyanide poisoning of wildlife can also be collateral damage from arson-type terrorist activities due to its presence in runoff water from firefighting and in runoff from burnt-over lands (Barber et al., 2003). Freshwater fish are highly sensitive to free cyanide and fish mortality can occur at concentrations of less than 20 μg CN^-/L of water (Barber et al., 2003; Eisler and Wiemeyer, 2004). The lethal level of cyanide in rainbow trout is changed by water temperature and exercise (McGeachy and Leduc, 1988). Young fish are generally more sensitive to the adverse effects of cyanide on thyroid hormone homeostasis (Brown et al., 2004). Exposure to cyanide can reduce the number of viable eggs produced by sexually maturing rainbow trout (Lesniak and Ruby, 1982). Cyanide can be used in poaching to stun, kill, and harvest fish and its use can have long-term consequences on the aquatic ecosystem (Authman et al., 2013).

TABLE 63.2 Estimated LD_{50} of cyanide in wildlife.

Bird or animal	LD_{50} (mg/kg body wt)
Black vulture	4.8
American kestrel	4
Eastern screech owl	8.6
European starling	17
Chicken	21
Japanese quail	10
Coyote	4.1

63.5 Selected pesticides

63.5.1 Background

Pesticides and neurotoxic chemical warfare agents could be used in acts of terrorism against a targeted wildlife population, or wildlife can be killed as collateral damage. There is a societal movement to restrict the use of and/or ban highly toxic pesticides (European Parliament, 2014). The reasoning for these restrictions and/or banning these pesticides is multifactorial, including small volume required for single-dose killing, relay poisoning, demonstrated forensic uses, and the potential for weaponization. Restricted and/or banned pesticides can be smuggled from a country of use, and illegally sold or made available for use (UNICRI., 2016). Pesticides, including restricted and banned substances, are used forensically to kill wildlife (Ogada, 2014; Botha et al., 2015; Ntemiri et al., 2018). Birds and other wildlife, particularly scavengers, are poisoned by consuming the carcasses of intentionally poisoned animals including birds. Granular pesticides, likely mistaken for food, can be voluntarily ingested by some bird species. Vertebrate deaths have been reported from forensic and off-label use of insecticides (Botha et al., 2015). Mathematical models can be used to

estimate the probability of bird deaths resulting from field application of pesticides (Mineau, 2002). Birds, mammals, fish, and other aquatic organisms can be nontarget species from pesticides that enter water systems from surface water. Highly lethal pesticides are used in poaching and could be used by terrorists to target wildlife. The toxicology of pesticides in birds has recently been reviewed (Sobhakumari et al., 2018).

63.5.2 Incidents of intoxication

Waterways and flood areas can be contaminated with pesticides, especially insecticides, and result in bird deaths (Hunt et al., 1995; Elliott et al., 2008). Granules of carbofuran in flooded fields have been incriminated as the cause of duck deaths and the cause of death in raptors scavenging dead or debilitated ducks. Seeds treated with insecticides to control insect damage can be toxic to birds (Millot et al., 2017). A "lone wolf" could use treated seeds to poison seed-eating birds. Bats in a county administration building were poisoned with dichlorodiphenyltrichloroethane (DDT) (Buchweitz et al., 2018). The source of the banned DDT and the perpetrator were not identified, and the most likely route of exposure was dermal. Some people kill bats because of a psychological reaction to scenes depicted in horror movies (chiroptophobia) and fear of zoonotic diseases caused by bat-borne Lyssavirus.

63.6 Castor bean (*Ricinus communis*)

63.6.1 Background

The castor bean and its poisonous principal ricin have been identified as having potential for weaponization. Ricin is a Category B terrorism agent and Schedule 1 chemical warfare agent. Annually, 400,000−610,00 tons of castor beans are grown and crushed to produce castor oil, with ricin remaining in the meal (cake) byproduct (Patel et al., 2016). Various preparations of *Ricinus communis* also are used in traditional medicine (Marwat et al., 2017). There are inconclusive reports of Canada geese being killed due to castor bean ingestion. In Texas, castor bean intoxication could have been the cause of deaths of 10,000 ducks in 1967, and 2000 ducks in 1969−70 (Jensen and Allen, 1981). The death of 1673 ducks occurred again in Texas in 1971. A castor bean was found in the gastrointestinal tract of one duck during pathological examination and castor beans had been grown in the area. Although inconclusive, this report does incriminate voluntary ingestion of castor beans as the cause of death in ducks. Sheep and dogs poisoned by voluntary ingestion of castor beans have been reported (Roels et al., 2010). A potential terrorist activity could be making castor beans available to wildlife.

63.6.2 Toxicology and pathology

Ricin, a toxalbumin that inactivates ribosomes, is the toxic principal in *R. communis*. It is in the seeds and the meal byproduct. Ricin, after a series of steps of being taken into the cell and activated, damages the 28S rRNA and thereby inhibits protein synthesis (Grela et al., 2019). One molecule of ricin in the cytosol can be fatal to a cell. Ducks taken from the area where 2000 ducks had died in 1969 through 1970 were examined by diagnostic procedures (Jensen and Allen, 1981). The toxins of *Clostridium botulinum* and other pathogenic bacteria were not identified. Catarrhal enteritis was identified with hemorrhage into the intestine. Seed parts suggestive of *R. communis* were found in scrapings of the wall of the proventriculus. Fatty degeneration of hepatocytes was also observed. In a study in which ducks were force-fed whole castor beans (Jensen and Allen, 1981), progressive signs of acute intoxication were passage of blood-streaked mucus, leg paresis, loss of mobility of the wings, sitting, prone recumbency, and death. Necropsy findings were whole and fragments of castor beans and congestion of the liver. Histopathology changes included severe fatty degeneration of hepatocytes, granulocytic infiltration into portal areas, pulmonary congestion, and peribranchial hemorrhage, and necrosis and hemorrhage were observed in the spleen. These findings support the field observation that some waterfowl may consume castor beans that can result in fatal intoxication. For comparison, the reported histopathology in dogs after consumption of castor beans resulting in fatalities are, for the kidney, renal tubular degeneration and necrosis in a multifocal arrangement (Roels et al., 2010). Glomerular lesions are eosinophilic fluid-appearing material and unidentified debris surrounding the glomerular capillaries. Fibrin was not observed, and the focal thickening of the Bowman's capsular membrane was characteristic of a membranous glomerulonephritis. Lesions in the jejunum were congestion and hemorrhage in the mucosa, focal enterocyte necrosis occurring in the villus crypts, erosion and disruption of villi, infiltration by degenerative leukocytes, and abundant nuclear debris. Focal areas of hepatic degeneration were observed and the heart lesion was myocardial degeneration. Splenic and lymph node follicles had pyknotic and karyorrhectic nuclei. In sheep ingesting castor beans, there was hyperemia and hemorrhage in the abomasum and intestinal tract (Aslani et al., 2007). Histopathology showed hemorrhage, coagulation necrosis, and mononuclear infiltrate in the abomasum, and ulcerative fibrinous enteritis. The liver showed hepatocellular degeneration and centrilobular necrosis. Histopathology in the heart was both subepicardial and subendocardial hemorrhage with multifocal coagulative necrosis of the myocardium. The kidneys showed acute tubular necrosis and medullary

hemorrhage. The observation that wild ducks voluntarily ingest castor beans provides evidence that there is risk that terrorists could successfully use ricin against wild ducks and other wild waterfowl species.

63.6.3 Water baits

Water baits can be used by terrorists to deliver toxic substances to target wildlife. Water-soluble toxic substances are used in water baits to control animal pests. Generally, these substances are nonirritating, odorless, tasteless, and highly toxic. The substances used in water baits are substances that kill by single lethal dose. Toxic substances that can be weaponized for use to poison water supplies are of concern to military planners. For wildlife, a small nonflowing water source is used, and substances to enhance attraction can be added to the water. Sodium nitrite in a micronized coating is being tested to control wild pigs (wild boars) populations (Snow et al., 2018). Sodium nitrate is also water-soluble, is a contaminate of ground water, and could be used in water baits. The nitrite reacts with iron (ferrous) in hemoglobin to form methemoglobin (oxidized ferric form). Methemoglobin has very low oxygen-carrying capacity and causes hypoxia, loss of consciousness and death. The solubility of sodium nitrite is 820 g/L of water at 20°C. Sodium azide has been used as a terrorist weapon and can be added to water.

63.7 Concluding remarks and future directions

Wildlife as a direct or indirect target generally has not been considered in the emergency management of terrorist events using chemical agents. Wildlife, because of economic value and emotional attachment, can be a direct target, and because they can be important sources of food and income for some regions and countries. Disruption of revenues from ecotourism could be an objective for terrorists. Wildlife can also be collateral damage from terrorist attacks and acts of war. Government restrictions and bans on pesticides and other toxic substances do not reduce their use against wildlife targets (Chiari et al., 2017). Regardless of the cause, wildlife can be intoxicated when chemicals and physical agents are released into the environment. Emergency planning needs to include terrorist attacks on wildlife, especially in areas where wildlife is concentrated during breeding and migration, and where wildlife congregates during the nonbreeding season. Hopefully, the shooting of mountain gorillas, an act of ecoterrorism to disrupt the Virunga National Park, is not an indication that these events will become more common (Jenkins, 2008; Actman, 2018). There is a need to develop better models for investigating and understanding the total impact of all causes of incidents involving wildlife because these incidents have much in common with the damage caused by terrorism and warfare (Etterson, 2013). The methods and procedures for forensic investigations of wildlife deaths need continual development along with diagnostic infrastructure (Linacre, 2009).

Chapter 64

Pharmacological prophylaxis against nerve agent poisoning: experimental studies and practical implications

Jiri Bajgar[1], Josef Fusek[2], Jiri Kassa[2], Kamil Kuca[1] and Daniel Jun[2]

[1]*Department of Chemistry, Faculty of Science, University of Hradec Kralove, Hradec Kralove, Czech Republic,* [2]*Department of Toxicology and Military Pharmacy, Faculty of Military Health Sciences, University of Defense, Hradec Kralove, Czech Republic*

64.1 Introduction

Inhibitors of cholinesterases are very important chemicals in the group of organophosphates (OPs). These compounds are used in industry, in veterinary and human medicine, and unfortunately in military [chemical warfare agents (CWAs)/nerve agents] and terrorist activities (Japanese incidents in 1994−95). The bulk of these compounds is used as pesticides (insecticides, acaricides, etc.). According to the World Health Organization (WHO), more than 1 million serious accidental and 2 million suicidal poisonings with insecticides occur worldwide every year, and of these approximately 200,000 deaths occur, mostly in developing countries (Eyer, 2003; Bajgar et al., 2004, 2007a). The mechanism of action, prophylaxis, and treatment of intoxications with OPs are currently a very timely topic.

The term *prophylaxis* is sometimes unclear. Generally, it is limited to medical countermeasures applied just before penetration of a toxic agent into the organism without further antidotal therapy. It is also described as a pretreatment, but usually antidotal treatment is performed. Thus, when treatment is unnecessary, it can be described as prophylaxis. Although successful prophylaxis can be observed for some OPs, full protection of the organism without postexposure treatment, especially for soman poisoning, remains open. When treatment is given after the exposure, the term *posttreatment* is used. It is obvious that when the drug is administered prior to nerve agent exposure with the aim of protecting the organism, exposure to these agents is expected, and therefore postexposure therapy can be used; that is, *pretreatment* could be considered the right term. The term *prophylaxis* used in this chapter is limited to medical countermeasures applied shortly before penetration of a toxic agent into the organism with the aim of protecting the organism against the toxic agent.

Prophylaxis against nerve agents has been described and summarized in various publications (Bajgar, 2009, 2012; Bajgar et al., 2004, 2007a, 2013; Bajgar and Klement, 2011; Layish et al., 2005; Patocka et al., 2006; Tuorinsky, 2008; Elsonghorst et al., 2013; Kuca et al., 2013). The basic mechanism of action of OPs is based on their ability to inhibit the enzyme acetylcholinesterase (AChE; EC 3.1.1.7) at cholinergic peripheral and central synapses (Marrs et al., 1996; Bajgar et al., 2004; Masson, 2011; Colovic et al., 2013). In general, prophylaxis can be focused on protection of AChE against inhibition using reversible cholinesterase inhibitors. The level of OP can be diminished by using enzymes that hydrolyze these agents or enzymes that bind the agents (to specific proteins or to antibodies) and thereby reduce the OP level and inhibition of cholinesterases—AChE and butyrylcholinesterase (BuChE) (EC 3.1.1.8; the scavenger effect) in the organism; this can be described as detoxification. Another approach to prophylaxis is based on using present antidotes and other drugs (Bajgar et al., 2004, 2007a, 2009, 2012, 2013; Bajgar and Klement, 2011; Kuca et al., 2013). Different drugs or their combinations can also be used. A simple schema describing the fate of the agent in the organism and possible target sites for prophylaxis is shown in Fig. 64.1.

In the schema, basic reactions for the effect of nerve agents are indicated—they are penetration of the agent

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00064-7

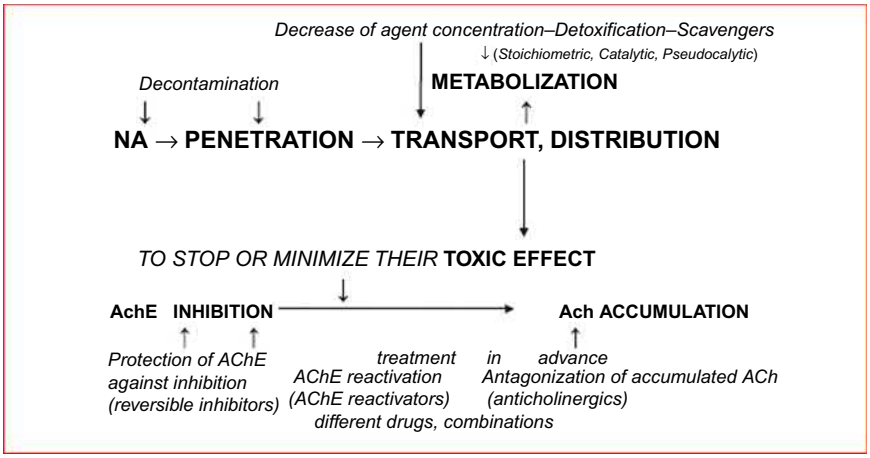

FIGURE 64.1 Four basic reactions of OP in the organism (in capitals) and possible approaches for prophylaxis (in italics). *Modified from Bajgar, J., 2004. Organophosphates nerve agent poisoning: mechanism of action, diagnosis, prophylaxis and treatment. Adv. Clin. Chem. 38, 151–216; Bajgar, J., 2009. Development of antidotes against nerve agents in the Czech Republic. ASA Newslett. 09-06 (135), 7–9; and Gupta, R.C., 2009. Handbook of toxicology of chemical warfare agents. In: Gupta, R.C. (Ed.), Handbook of Toxicology of Chemical Warfare Agents. Academic Press/Elsevier, Amsterdam, p. 1147.*

into the organism through different ways of administration; after penetration into the blood (transport system), the agent is distributed to the places of metabolic and toxic effects. To stop or minimize the toxic effect, different possibilities can be explored. Because inhibition of AChE is the main trigger and basic pharmacodynamic factor, protection against AChE inhibition is one possible process using reversible AChE inhibitors. Treatment in advance (administration of anticholinergics and reactivators) is another possibility, and the use of different drugs minimizing the toxic action is the third possible approach for prophylaxis. Certainly, all these principles can be combined.

64.2 Protection of acetylcholinesterase against inhibition

Intact AChE is a basic requirement for normal function of the organism, and thus for effective prophylaxis. The enzyme is changed in a way that will make it resistant to OP. This can be achieved by using reversible inhibitors, preferably carbonates (CMs), which are able to inhibit AChE reversibly, and after spontaneous recovery of the activity (decarbamylation) normal AChE serves as a source of an active enzyme.

The ability of some CMs to protect an organism poisoned with an OP has been known for many years (Koelle, 1946; Koster, 1946). Physostigmine and neostigmine have been used to protect animals against DFP. The number of OPs studied for protection has been expanded, as well as the number of CMs studied. The results are very dependent on experimental conditions; nevertheless, the protective effects of physostigmine, aminostigmine, pyridostigmine, and others against AChE inhibition caused by different OPs (mostly soman) have been demonstrated (Patocka, 1989; Marrs et al., 1996; Tonkopii, 2003). It has been described that weak inhibitors are able to protect cholinesterases from strong inhibitors (paraoxon; Petroianu et al., 2005a, 2007). Non-OP inhibitors were also tested (Kassa et al., 2012; Lorke et al., 2012, 2013; Petroianu et al., 2013). It appeared from many studies that the cholinesterase inhibitor pyridostigmine was the most promising prophylactic drug, particularly against soman poisoning (Gordon et al., 1978, 2005; Patocka et al., 1991; Anderson et al., 1992; Koplovitz et al., 1992; Maxwell et al., 1993; Bajgar et al., 1994; Kassa and Bajgar, 1996; Kassa and Fusek, 1998, 2000; Tuovinen, 1998; Koupilova and Kassa, 1999; Kassa et al., 2001a,b). On the basis of these results, pyridostigmine was introduced into some military units as a prophylactic drug against nerve agents. Its prophylactic effect (like the effects of other CMs) is increased with its dose; however, with a higher dose, the side effects are also increased. This problem can be solved by adding pyridostigmine-antagonizing drugs, anticholinergics.

Many anticholinergics have been tested for their ability to protect the organism against intoxication with soman (and other nerve agents). On the basis of this research, the prophylactic combination PANPAL, composed of pyridostigmine with trihexyphenidyl and benactyzine (Bajgar et al., 1994, 1996; Kassa and Bajgar, 1996; Kassa and Fusek, 1998, 2000; Fusek et al., 2000, 2006; Kassa et al., 2001a), was introduced into the Czech army, and later into the Slovak army. The presence of anticholinergics allowed for an increase in the pyridostigmine dose and, simultaneously, an increase its prophylactic efficacy (Kassa et al., 1997; Bajgar et al., 2004, 2007a; Fusek et al., 2006). Moreover, prophylaxis with PANPAL improves following postexposure antidotal therapy with anticholinergics and oximes (Bajgar et al., 2004; Kassa, 2006). The prophylactic antidotal combination called PANPAL has no side effects, as demonstrated on volunteers: no statistically significant different changes in the actual psychic state, as well as no negative changes in the dysfunction time, were observed. An improvement of the tapping test following PANPAL administration was

demonstrated. A decrease in the heart frequency 60 min following PANPAL administration lasting 480 min and returning to normal values within 24 h was demonstrated (Fusek et al., 2006).

Other CMs also have a good prophylactic efficacy, especially physostigmine and aminostigmine (due to their central effect which is contrary to pyridostigmine; Tuovinen and Hanninen, 1999; Kim et al., 2002; Tonkopii, 2003). Experimental studies with transdermal administration of physostigmine suggest a serious interest in the prophylactic use of this drug (Levy et al., 1992; Jenner et al., 1995; Walter et al., 1995; Kim et al., 2005; Cho, 2012; Cho et al., 2012). A similar approach was described with scopolamine (Che et al., 2011).

Structurally different inhibitors from the CM and OP groups were also studied. From these compounds (preferably binding to the AChE anionic site), tacrine, its 7-methoxyderivative (7-MEOTA) and huperzine A, were considered and experimentally studied with respect to prophylaxis in vitro and in vivo (Bajgar, 2004). The most interesting results were obtained with huperzine A (Lallement et al., 2002; Gordon et al., 2005; Bajgar et al., 2007b; Karasova et al., 2009; Wang et al., 2013).

64.3 Scavengers

Keeping AChE intact can be achieved by eliminating the agent before its penetration into the target sites containing the enzyme. In this case, the detoxification principle can be used in two different ways: administration of enzymes splitting the OP or specific enzymes (cholinesterases) that bind the OP. The enzymes that hydrolyze nerve agents are called *catalytic* scavengers, and the enzymes that bind nerve agents are described as *stoichiometric* scavengers. OPs are bound to the exogenously administered enzyme or decomposed by the enzyme and thus the nerve agent level in the organism is decreased (the action of a "scavenger"). Enzymes, which hydrolyze OPs, were thoroughly studied by Raveh et al. (1992) and Li et al. (1995). Catalytic scavengers are enzymes displaying a turnover with OP nerve agents as substrates, allowing rapid and efficient protection (Masson et al., 1998; Ditargiani et al., 2010; Gupta et al., 2011; Kuca et al., 2013; Otto et al., 2013). Paraoxonase and similar enzymes are prospective hydrolyzing scavengers (Aharoni et al., 2004; Rochu et al., 2008; Valiyaveettil et al., 2010, 2011a,b; Trovasler-Leroy et al., 2011). On the other hand, many studies have been completed using cholinesterases as scavengers. AChE was used as a prophylaxis against OP poisoning, and a correlation has been found between protection and the blood−enzyme level in mice (Wolfe et al., 1987; Raveh et al., 1989). BuChE and AChE were observed to be very effective in protection against OP intoxication (Ashani et al., 1991; Doctor et al., 1991, 1997, 2002; Maxwell et al., 1993, 1998; Moore, 1996; Saxena et al., 1997; Bird et al., 2010). The idea to use the plasma as a source of cholinesterase to eliminate nerve agent action after peritoneal dialysis with human plasma in rats was also described (Bajgar et al., 1982), but without further development.

The administration of enzymes as scavengers seems to be very promising: the enzyme is acting at the very beginning of the toxic action, without interaction with the target tissues and without side effects (Doctor et al., 1997, 2002; Saxena et al., 2004, 2011; Huang et al., 2007). All of these features are of great interest, and they are yielding practical results—namely, isolation of the enzyme, examination for lack of an autoimmune response, and establishment of pharmacokinetic and pharmacodynamic properties (Saxena et al., 2002). Recombinant human BuChE can be produced from the milk of transgenic goats (Cerasoli et al., 2005) commercially produced as Protexia. Moreover, BuChE pretreatment also showed protective effects on AChE inhibition in the brain regions following low-level sarin inhalation exposure: the enzyme (BuChE) administered into the bloodstream does not influence erythrocyte AChE, plasma BuChE activity is increased, and the brain AChE is not affected. Following intoxication with a nerve agent, the agent is bound to plasma BuChE (now existing in excess), and proportionally bound to erythrocyte AChE; both enzymes are inhibited, however, to a lesser extent in comparison with the unpretreated situation. The part of the nerve agent bound to both enzymes represented a loss of the agent, and the diminished level of nerve agent is able to penetrate the brain. Therefore, AChE activity in the brain is protected (Sevelova et al., 2004; Bajgar et al., 2007c).

The efficacy of cholinesterases as a bioscavenger of OP can be enhanced by combining enzyme pretreatment with oxime reactivation, since the scavenging capacity extends beyond a stoichiometric ratio of cholinesterases to OP. Human BuChE has previously been shown to protect mice, rats, and monkeys against multiple lethal toxic doses of OP anticholinesterases (anti-AChEs; Maxwell, 1992; Allon et al., 1998). An interesting approach can be simultaneous administration of BuChE and reactivators; BuChE acts as a scavenger binding the nerve agents. A reactivator acting as a *pseudocatalytic* bioscavenger reactivates BuChE simultaneously, and reactivated enzyme serves as a new scavenger (Jun et al., 2007; Kovarik et al., 2010).

This approach was tested using human BuChE (Jun et al., 2011). The best reactivators were trimedoxime and obidoxime, but only in the case of OP insecticides (paraoxon, methamidophos, and leptophos; Jun et al., 2007, 2011; Musilova et al., 2009). Thus, currently available reactivators cannot be of interest and practical use as pseudocatalytic scavengers for nerve agents.

Given our increasing knowledge of bioengineering and biotechnology, recombinant human BuChE with a good protective effect against nerve agents was obtained from transgenic animals. A connection between these two enzymes (binding and hydrolyzing) is possible, with the aim of obtaining a modified enzyme splitting OPs and simultaneously reacting with AChE as a scavenger (Broomfield et al., 1997). Antibodies against OPs are at the research stage and are more focused on the detection of OPs (Lenz et al., 1997; Miller and Lenz, 2001).

Current progress in prophylaxis against nerve agents is summarized in the review of Bajgar et al. (2019).

64.4 Prophylaxis with current antidotes

The aim of this approach was to achieve a sufficient level of antidotes in the blood circulation before intoxication, so the antidotes can be tested as prophylactics. This can be characterized as "treatment in advance." The problem with their use, however, is the timing, duration, and achievement of sufficient levels of these antidotes after administration. The antidotes currently used for the treatment of OP poisoning in this context include anticholinergics, reactivators, and anticonvulsants (Bajgar et al., 2004, 2007a). The prophylactic efficacy of antidotes (as demonstrated in treatment studies) is good; administration of the antidotes typically takes place very shortly (i.e., within minutes) after intoxication. Another study showed good prophylactic efficacy of pyridostigmine or ranitidine with pralidoxime against paraoxon poisoning (Petroianu et al., 2005b, 2006). Extension of the duration of the effects of the antidote by achieving sufficient levels in the blood by oral administration is not possible (especially reactivators, as they are decomposed in the gastrointestinal tract) and therefore is excluded. Consequently, other routes of administration were sought. Transdermal administration of one of the most effective reactivators (HI-6) was shown to be the most realistic approach (Dolezal et al., 1988; Bajgar, 1991). The final result was a new prophylactic transdermal antidote TRANSANT, containing the patch impregnated with HI-6. This preparation was clinically tested (including dermal sensitivity) without any harmful effects; field testing was also successful, and TRANSANT was introduced into the Czech army and later into the Slovak army (Bajgar et al., 2004; Fusek et al., 2007). If its administration is combined with PANPAL, the two anticholinergics contained in PANPAL are able to prevent and treat symptoms of nerve agent poisoning. Therefore, a combination of TRANSANT and PANPAL administered as a pretreatment provides the best prophylactic efficacy compared to pyridostigmine or PANPAL administered alone (Bajgar et al., 2004). The anticonvulsant benzodiazepine drugs (e.g., diazepam, midazolam, alprazolam, triazolam, and clonazepam) were studied, but isolated prophylactic administration did not work to very good effect (Herink et al., 1990, 1991; Kubova et al., 1990).

64.5 Prophylactic use of other drugs

Prophylactic administration of different drugs (alone or in combination) against intoxication with OPs was studied. Calcium antagonists (e.g., nimodipine), neuromuscular blockers (e.g., tubocurarine), adamantanes (e.g., memantine), and the opiate antagonist meptazinol (Galli and Mazri, 1988; Gupta and Dettbarn, 1992; McLean et al., 1992; Marrs et al., 1996; Karlsson et al., 1998; Stojiljkovic et al., 1998) were also tested, offering different results with limited practical utility. On the other hand, a positive prophylactic effect has been demonstrated with procyclidine (e.g., antimuscarinic, antinicotinic, and the anti-NMDA receptor drug; Myhrer et al., 2002, 2003), metoclopramide (Hasan et al., 2004), clonidine (Loke et al., 2001), or procyclidine and donepezil (Haug et al., 2007). The prophylactic effect of a group of drugs with anticholinergic and/or antiglutamatergic properties (e.g., benactyzine, biperiden, caramiphen, procyclidine, and trihexyphenidyl), with respect to their anticonvulsant properties, was studied to prevent damage of the central nervous system induced by seizures. Only procyclidine and caramiphen antagonized soman-induced seizures (Myhrer et al., 2008a; Schultz et al., 2014). Among the different drugs tested, procyclidine appears to be an effective anticonvulsant, with few cognitive side effects (Myhrer et al., 2008b). Procyclidine with physostigmine (administered transdermally) showed very good prophylactic efficacy against soman in dogs; moreover, this efficacy was increased by using antidotal therapy with HI-6 and atropine (Kim et al., 2005). Special importance can be placed on suramine (a protease inhibitor). Administration of this compound prior to soman intoxication (and followed by administration of atropine) showed good prophylactic effects (Cowan et al., 1996). However, all these studies are experimental, and they have not reached the practical output stage. The combinations of various drugs as prophylactics can be of very different character. They can be used simultaneously (a combination of different drugs) or as a pretreatment and a posttreatment with different antidotes. Administration of pyridostigmine (or other AChE inhibitors) prior to intoxication and treatment with different drugs is a typical example (Anderson et al., 1992, 1997; Kassa, 1995; Bajgar et al., 1996; Kassa and Bajgar, 1996; Tuovinen and Hanninen, 1999; Kim et al., 2002). Aerosolized scopolamine was described to protect guinea pigs against inhalation toxicity to sarin (Che et al., 2011). There are other combinations as well, such as the administration of triesterase (Tuovinen and Hanninen, 1999; Tuovinen et al., 1999), procyclidine

TABLE 64.1 **Drugs used in the prophylaxis against OP nerve agent poisoning (relatively promising drugs are in bold).**

Principle	Drug group	Drug	Duration	Equipment of the army	Efficacy	Comment
Protection of cholinesterase against inhibition	Carbamates	**Pyridostigmine, Aminostigmine, Physostigmine**	8 h	PYRIDOSTIGMINE BROMIDE	+++	Dose limited, side effects. Alone is not very effective, following antidotal treatment enhances its effect
		Syntostigmine, Eptastigmine, Mobam				
		Decarbofuran, Heptylphysostigmine				
	Others	**Huperzine A**				
		Tacrine, Methoxytacrine				
	Organophosphates					
		TEPP, Paraoxon				
		Ethyl-4-nitrophenylphosphonate				
	Aminophenols	Eseroline				
Simulation of treatment	Anticholinergics	**Biperidene**, **Scopolamine**, **Benactyzine** Atropine, Aprophen, Hyoscine				Transdermal administrations of scopolamine, physostigmine and HI-6 were studied
		Adiphenine, Caramiphen				
		Pentamethonium, Mecamylamine				
		Trihexyphenidyl				
	Reactivators	HI-6				
		PAM, Obidoxime, Trimedoxime, Methoxime	8 h	TRANSANT (HI-6, transdermal administration)	+	Alone is not effective
	Others	**Suramine** Benzodiazepines, Tubocurarine Memantine, Procyclidine Nimodipin, Clonidine				
Detoxification	Cholinesterases enzymes hydrolyzing OP monoclonal antibodies against OP	**Butyrylcholinesterase, Mutants**				Very perspective PROTEXIA
		Acetylcholinesterase				
		Triesterase Paraoxonase				
Combinations			8 h	PANPAL (pyridostigmine, trihexyphenidyle, benactyzine)	++++	Efficacy is increased with following antidotal treatment
				PANPAL + TRANSANT	+++++	In combination, the best prophylactic efficacy

(Kim et al., 2002; Myhrer et al., 2002, 2003), clonidine (Loke et al., 2001), or sustained release of physostigmine and scopolamine (Meshulam et al., 2001). The results depend on experimental conditions, but this approach (administration of different drugs) has yielded some good results. However, up to now, they have been only on an experimental level.

Clearly, there is a wide range of prophylactics. The drugs used in prophylactics against nerve agents are summarized in Table 64.1. Some of them (bold in the table) can be studied further. Only three prophylactics have been introduced by armies—pyridostigmine alone; PANPAL, composed of pyridostigmine, benactyzine, and trihexyphenidyl; and TRANSANT (dermal administration of HI-6). Another prophylactic drug, Protexia, can be considered as well. The efficacy of different prophylactics against nerve agents expressed as prophylactic indexes is shown in Fig. 64.2.

Current prophylactics have a few problems. Reversible cholinesterase inhibitors have side effects caused by their parasympathomimetic activity. This issue can be addressed by adding anticholinergic drugs. Isolated administration of anticholinergics also can be helpful prophylactically; however, this effect can be supported by adding reversible inhibitors. The main problem with bioscavengers is immunoreaction, which can be solved by modifying the scavenger. Using the approach of the treatment in advance, reactivators are used, but the main issue is their route of administration. Further, conducting additional research into improving prophylaxis is difficult.

A comparison of the features of different prophylactics is summarized in Table 64.2. Various criteria are used, including cost, side effects, and difficulty of use. The best combination of effects, cost, and accessibility is observed when PANPAL and TRANSANT are used together. These prophylactics are shown in Fig. 64.3.

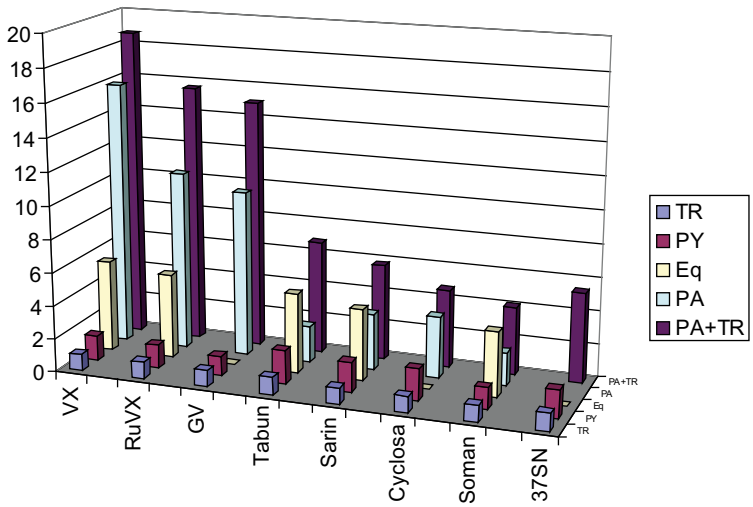

FIGURE 64.2 Efficacy (expressed as a prophylactic index) of different prophylactics (TR: TRANSANT; PY: pyridostigmine; Eq: equine butyrylcholinesterase; PA: PANPAL; PA + TR: combination of PANPAL and TRANSANT) against selected nerve agents in rats. The results are means only. Prophylactic effect of equine butyrylcholinesterase was not tested for 2-(dimethylamino)ethyl *N,N*-dimethylphosphoramidofluoridate (GV), cyclosarin, and 37SN. *Elaborated using data from Bajgar, J., 2009. Development of antidotes against nerve agents in the Czech Republic. ASA Newslett. 09-06 (135), 7–9; Bajgar, J., Klement, C., 2011. Chemical warfare agents misuseable in the civilian sector, history and misusing of CWA (in Czech). In: Klement, C. (Ed.), Extraordinary Events in the Public Health Service (in Slovak). TABLE 64.2 Comparison of various prophylactics using different criteria of their evaluation.

Criterion	Pyridostigmine	PANPAL	Protexia	TRANSANT
Introduced in other armies	Yes	No	No	No
Introduced in the Czech army	No	Yes	No	Yes
Accessibility	++++	++	++	++
Cost	+	++	++++	+++
Difficulty to use	+	+	++(i.v., i.m.)	++(self-help)
Prophylactic effect	+	+++	+++	Ineffective alone
Side effects in recommended dose	No	No	Antigenic properties	No
Duration of prophylaxis	6–8 h	6–8 h	5–8 h	8 h
Increase of effect of followed antidotal treatment	+	++	No	++

FIGURE 64.3 Two prophylactics: PANPAL (top) and TRANSANT (bottom).

It appears from these results that simple prophylaxis (without postexposure treatment) against OPs is insufficient. Therefore, pyridostigmine is important as a prophylactic drug, especially when it is combined with postexposure antidotal treatment. For further development, it is necessary to search for novel prophylactic drugs and new routes of administration. In this context, preparations of cholinesterases are of special importance for the development of more effective prophylactics.

64.6 Concluding remarks and future directions

There are many drugs being tested for their prophylactic efficacy against nerve agent intoxication. However, only three of these (pyridostigmine alone, PANPAL, and TRANSANT) have been introduced into military practice. The prospective approach for the future seems to be to search for more effective drugs or their combinations using modern techniques (e.g., molecular modeling), including new routes of administration, and the use of purified enzymes, especially cholinesterases and paraoxonases produced by biotechnology.

65.1 Introduction

Ever since the so-called G-agents (NATO code, denoting their German origin)—tabun (GA), sarin (GB), and soman (GD) were synthesized by Gerhard Schrader and his co-workers at IG Farben Industrie in Nazi Germany in the late 1930s and early 1940s—antidotes against these extremely toxic organophosphorus compounds (OPCs) started to be developed. The V-agents ("V" taken from the word "venomous"), like *O*-ethyl-*S*-(diisopropylamino)-ethyl methyl phosphonothioate (VX), were discovered by a British scientist Dr. Ranajit Ghosh in 1952 and later added to the US armamentarium (Stojiljković, 2019).

Despite some specificities and differences, all these compounds, called nerve agents, have the same very distinct mechanism of action: they irreversibly inhibit the acetylcholinesterase (AChE) in all human tissues and, depending on the gravity of intoxication, pose a serious threat to human survival. The resulting accumulation of acetylcholine (ACh) in the cholinergic synapses causes overstimulation of central and peripheral muscarinic and nicotinic receptors. On the clinical level, these biochemical effects manifest themselves as acute cholinergic syndrome, that occurs in the case of intoxication with OPC or carbamates, with the only difference being in the fact that the carbamate-induced AChE inhibition is reversible and therefore self-limited (Suzuki et al., 2017). It includes muscarinic (miosis, hypersalivation, lacrimation, bronchorrhea, bronchoconstriction, nausea, vomiting, increased motility of the bowels, bradycardia, and hypotension), nicotinic (mydriasis, tachycardia, hypertension, fasciculations, and necrosis of skeletal muscles), and central (motor incoordination, tremors, convulsions, respiratory depression, and coma) signs of toxicity (Vale and Lotti, 2015).

The route of intoxication by nerve agents varies, but by far the most likely ones are inhalational and percutaneous. In the case of inhalational poisonings, the onset of the acute cholinergic syndrome is very fast and there is a need for equally fast administration of antidotes (Sidell and Borak, 1992; Yokoyama et al., 1996; Okumura et al., 1996). This situation occurred with tabun during the Iraq−Iran War in the 1980s (Razavi et al., 2014) and with sarin in the infamous Aum Shinrikyo sect attacks in Matsumoto, with 7 fatalities (Yoshida, 1994; Suzuki et al., 1997; Okudera et al., 1997) and in the Tokyo subway, with 12 fatalities (Suzuki et al., 1995; Nozaki et al., 1995a; Nozaki and Aikawa, 1995; Masuda et al., 1995) in 1994 and 1995, respectively. Three individual cases of assassination attempts with VX on former Aum Shinrikyo's members and anti-AUM activists happened in December 1994 and January 1995, with one fatality (Nozaki et al., 1995b; Zurer, 1998; Morimoto et al., 1999). The latest and highly profiled proven case of use of nerve agents was the assassination of Kim Jong-nam, the estranged half-brother of North Korean president Kim Jong-un in Kuala Lumpur, Malaysia, when VX was smeared across his face, causing percutaneous poisoning (BBC News, 2017).

All these incidents suggest a very real danger from the use of nerve agents both in armed conflicts and as a mean of chemical terrorism, which warrants further improvement of both prophylactic and therapeutic countermeasures (Stojiljković, 2019).

65.2 Prophylaxis against intoxication with nerve agents

Use of standard antidotes—atropine, oximes, and diazepam—in the treatment of experimental intoxications with sarin and VX assures high protective ratios (PRs). For example, guinea pigs poisoned with sarin or VX therapy with atropine and oxime pyridinium methane sulfonate (P2S) resulted in PRs of 38 and 25, respectively (Leadbeater, 1988). A much more serious problem is represented by intoxications with tabun or soman, where, under the same conditions, very modest PRs were obtained—2.5 and 1.3, respectively (Leadbeater, 1988). It must be pointed out, however, that P2S is not an oxime that can reactivate AChE inhibited by tabun or soman (Bošković et al., 1984; Ćetković et al., 1984). Trimedoxime (TMB-4), obidoxime (LüH-6), or, more recently, oxime K203 are much better oximes against tabun poisonings (O'Leary et al., 1961; Inns and Leadbeater, 1983; Kuca et al., 2018), while oxime HI-6 achieves the best results in rodents intoxicated with soman (Bošković, 1981; Clement and Lockwood, 1982; Shih, 1993; Antonijević and Stojiljković, 2007). If we compare the PRs in rats treated with atropine and appropriate oxime intoxicated with various nerve agents, it appears that PRs obtained in animals poisoned with sarin or VX are still 5−15 times higher than those after poisoning with tabun or soman (Jokanović and Stojiljković, 2006; Stojiljković and Jokanović, 2006).

It is estimated that even well-trained military personnel can be exposed to 5 median lethal doses (LD_{50}) of soman and this is why it is expected for antidotes to be able to reach this level of protection, that is, PR 5 or higher (Dunn and Sidell, 1989). Having in mind the mentioned results for tabun and soman, the use of atropine and oxime treatment cannot meet this requirement and this is why this treatment after exposure to soman will not afford protection against more than 1.5 or 2 LD_{50} (Rickett et al., 1987). This is the main reason for the concept of adding a prophylactic antidote.

Koster (1946) was first to report on the favorable interaction between a carbamate—physostigmine—and an organophosphate (OP) AChE inhibitor—diisopropylfluorophosphate (DFP). He successfully used physostigmine as pretreatment in cats exposed to DFP and protected cats from dying after i.v. administration of 30 LD_{50} of DFP. The pretreatment regimen included a large dose of physostigmine (1 mg/kg) and a small dose of atropine (0.3 mg/kg) that was added to antagonize the muscarinic effects of physostigmine. The pretreatment interval was 3.5 h. Thereafter, Koelle (1946) demonstrated that physostigmine protected AChE from irreversible inhibition by DFP in rat brain homogenates in vitro and formulated that this finding is the reason for Koster's phenomenon.

Fleisher and Harris (1965) discovered that it was dealkylation of the soman−AChE complex that made it resistant to reactivation by oximes—the phenomenon known as aging of the AChE−soman complex. In this study, the $t_{1/2}$ of aging of the soman−AChE complex in vitro was only 2.2 min. The authors clearly showed that physostigmine 1 mg/kg i.v. injected 5 min after atropine 10 mg/kg i.v. and 15 min before soman s.c. assured a PR of 3.8 (relative to atropine alone). They also showed that after the challenge with soman 1.5 LD_{50} s.c., all the rats pretreated with physostigmine survived and were without any symptoms of poisoning, in comparison with only 50% of those animals pretreated with atropine alone. The difference in brain AChE activity 24 h after soman challenge between these two groups was also significant—58.5% versus 15.4%, respectively. What is even more important, it was shown that the aging reached a maximum 30 min after soman intoxication, when in nonpretreated rats 84.6% of all AChE activity was inhibited, of which 50% belonged to the aged portion of the enzyme, while in rats pretreated with physostigmine these percentages were much lower—41.5% and 6%, respectively. The authors concluded that the preventing by physostigmine of the interaction between soman and AChE is a very successful way to avoid not only its inhibition by soman, but also to decrease the aging of the soman−AChE complex (Fleisher and Harris, 1965).

Further investigation in the field of potential prophylactic antidotes ensued and best protection was obtained with pyridostigmine in guinea pigs (Berry and Davies, 1970; Gordon et al., 1978). Definite affirmation of pyridostigmine prophylaxis was confirmed when in experiments in guinea pigs poisoned with tabun, sarin, soman, or VX and treated with atropine, various oximes and diazepam PRs of 76, 380, 20, and 410 were obtained, respectively (Inns and Leadbeater, 1983).

The essence of this concept is reversible inhibition of a portion of AChE by a carbamate, which protects these molecules of AChE from being irreversibly inhibited by DFP or any other nerve agent (Koelle, 1946). In this case, inhibition of the remaining AChE activity by an OPC creates a nonlife-threatening situation, since over the time carbamate dissociates—decarbamylates the active center of AChE, in quantities sufficient to maintain normal transmission in cholinergic synapses (Dirnhuber and Green, 1978). The opposite sequence of administration—OPC first and carbamate second—only potentiates the cholinergic toxic effects (Koster, 1946; Takahashi et al., 1987), since carbamate inhibits the portion of AChE that remained uninhibited by the OPC (Green, 1983).

So far, more than 50 compounds have been investigated as potential prophylactic agents against poisoning with nerve agents. Some of them have been abandoned, others are still under the investigation, while some were

introduced in the corresponding equipment of modern armies. A survey of such medicines is contained in Table 65.1.

65.2.1 Use of acetylcholinesterase inhibitors in prophylaxis of poisoning with nerve agents

The most successful prophylactic schemes include carbamate AChE inhibitors physostigmine (Koster, 1946; Berry et al., 1971; Harris and Stitcher, 1984; von Bredow et al., 1991b), neostigmine (Berry et al., 1971; Heyl et al., 1980), pyridostigmine (Berry et al., 1971; Dirnhuber et al., 1979; Hauser et al., 1981; Inns and Leadbeater, 1983; Harris and Stitcher, 1984; Maxwell et al., 1988; von Bredow et al., 1991a), and some newer synthetic carbamates, like ferrocene carbamate (Gordon et al., 1978; Karlsson et al., 1984).

65.2.1.1 Physostigmine

Physostigmine, also called eserine, is a *N*-monomethyl carbamate isolated from the Calabar bean (*Physostigma venenosum* Balfour) by Jobst and Hesse (1864) and de novo synthesized by Julian and Pikl (1935). Physostigmine reversibly inhibits AChE in mammalian peripheral tissues and in the brain (Deyi et al., 1981; Harris and Stitcher, 1984). As a consequence, when administered as a triple prophylactic regimen with atropine and mecamylamine, it provides protection against 2.6 LD_{50} of soman in rats (Harris et al., 1980). Under the same conditions, this alkaloid assures a PR of 6.9 against DFP poisoning in rats (Harris and Stitcher, 1984). With the addition of atropine alone or with atropine and P2S, physostigmine pretreatment exerts similar efficacy in other species intoxicated with soman, and especially in guinea pigs, where the attained PR of the triple prophylactic regimen reaches 10.7 (Berry et al., 1971). It was confirmed that this antidotal effect is based on protection of AChE from soman-induced irreversible inhibition in vital organs (Deyi et al., 1981).

Physostigmine owes its prophylactic efficacy to the fact that it readily passes the blood–brain barrier, enters the CNS, and binds reversibly to the brain AChE, which is the main target of soman and other nerve agents (Somani and Khalique, 1986; Somani, 1989; Somani and Dube, 1989). This readiness to access the brain centers is, however, also a potential drawback of physostigmine, since it can induce some incapacitating central effects (Stojiljković et al., 1989) and for this reason it is frequently combined with small doses of lipophilic anticholinergics, such as scopolamine or procyclidine (Myhrer et al., 2013).

65.2.1.2 Neostigmine

Neostigmine is a quaternary *N,N*-dimethyl carbamate synthesized by Aeschlimann and Reinert (1931) as a physostigmine analog. Neostigmine rapidly, due to lack of central effects, replaced physostigmine in the treatment of myasthenia gravis (Remen, 1932; Walker, 1934; 1934–1935). Although its hydrophilicity and exclusively peripheral action dictated its use with central and peripheral antimuscarinic atropine and predominantly central antinicotinic mecamylamine, neostigmine had good results in prophylaxis of soman intoxications (Harris et al., 1980). From a practical point of view, neostigmine is inferior to peripherally acting carbamate pyridostigmine because of stronger stimulation of the digestive tract, which is unfavorable for a prophylactic agent.

65.2.1.3 Pyridostigmine

Pyridostigmine is an analog of neostigmine, also with *N, N*-dimethyl carbamate structure, synthesized by Urban and Schnider in 1945 (Randall et al., 1955). The frequency and severity of cholinergic adverse effects (i.e., nausea, vomiting, increased salivation, diarrhea, and abdominal cramps) of pyridostigmine are lower than in neostigmine (Duphar, 1987). Although pyridostigmine also does not penetrate the brain (Birtley et al., 1966), it is among the potential prophylactic agents and by far the most tested one, owing to its much longer prophylactic interval (4 h) than physostigmine (Gordon et al., 1978). If administered 30 min before the nerve agent and if supplemented by postexposure therapy consisting of atropine and oxime P2S, pyridostigmine produces PRs of 22, 21.5, 8, and 26.3 in guinea pigs poisoned with tabun, sarin, soman, or VX, respectively (Gordon et al., 1978). Pyridostigmine pretreatment 0.2 mg/kg and postexposure treatment with atropine protect monkeys against 28 LD_{50} of soman (Dirnhuber et al., 1979). In guinea pigs poisoned with nerve agents, the best protection was provided by pretreatment with pyridostigmine and treatment with atropine, oxime, and diazepam. Extremely high PRs were thus obtained—for tabun 76, for sarin 370, for soman 20, and for VX 410 (Inns and Leadbeater, 1983).

The Czech Army developed a special prophylactic antidote PANPAL designed to overcome the shortcomings of pyridostigmine (Kassa, 2006). It contains two tablets—PANPAL A with benactyzine hydrochloride 8 mg and trihexyphenidyle 6 mg, and PANPAL B containing pyridostigmine bromide 35 mg (Bajgar et al., 2019). The content of the first tablet, consisting of very liposoluble anticholinergics that gain rapid access to the brain (Stojiljković et al., 1989) assures early occupation of cholinoceptors in the CNS to counteract the effects of the accumulating acetylcholine, while at the same time, pyridostigmine from the second tablet protects from inhibition

of AChE in the peripheral tissues (Kassa, 2006). Experiments in rats and mice poisoned with tabun and treated with standard antidotes atropine, obidoxime, and diazepam, became more resistant to the tabun-induced lethality when they were pretreated with pyridostigmine, benactyzine, and trihexyphenidyle than when the pretreatment contained pyridostigmine only (Kassa and Vachek, 2002).

65.2.2 Prophylactic use of oximes

Prophylactic use of oximes has not attracted a lot of interest, although some experiments with osmotic minipumps that maintained constant plasma concentrations of pralidoxime or asoxime strongly potentiated the PRs (up to 72) of postexposure treatment with atropine and diazepam against an OP insecticide quinalphos in dogs (Bokonjić et al., 1987). An attempt to develop asoxime tablets with regular and retarded absorption was unsuccessful, because of very low oral bioavailability of asoxime—5.42% and 8.07% for classic and retard tablets, respectively (Maksimović et al., 1987). Further applied research in this area enabled the Czech Army to produce TRANSANT, a transdermal patch with asoxime (Bajgar et al., 2009; 2019).

65.2.3 Use of *N*-methyl-D-aspartate-receptor-blocking drugs in prophylaxis against organophosphorus compounds

Memantine hydrochloride (1-amino-3,5-dimethylaminoadamantane) is an adamantine derivative used in various conditions affecting the central nervous system (CNS) (Wesemann et al., 1983). It acts as a noncompetitive antagonist of *N*-methyl-D-aspartate (NMDA) receptors for excitotoxic transmitter glutamate (Bormann, 1989; Kornhuber et al., 1989, 1991), which explains its neuroprotective effect (Seif el Nasr et al., 1990; Erdö and Shäfer, 1991). Gupta and coworkers in the late 1980s started a series of experiments, where memantine 18 mg/kg s.c. was successfully

used along with atropine 16 mg/kg s.c. as pretreatment against convulsions, muscle necrosis, and death induced by intoxications with tabun, sarin, soman, or VX (Gupta and Dettbarn, 1992; McLean et al., 1992). It was shown that memantine pretreatment decreased four times the ED_{50} of HI-6 for an antilethal effect in mice poisoned with soman, by counteracting the soman-induced convulsive activity (Antonijević et al., 2011).

Memantine pretreatment shows dose- and time-dependency. In a separate set of experiments, it was confirmed that only doses of 18 mg/kg and above (36 and 72 mg/kg) significantly potentiate the atropine/HI-6 PR against soman in rats. When an appropriate dose is selected, the pretreatment interval of memantine can be even nonexistent (0 min, meaning that it can be successfully used as a posttreatment) or as long as 8 h before soman exposure. The highest PR of 10.11 was assured with memantine 36 mg/kg injected s.c. 60 min before soman (Stojiljković et al., 2019).

Procyclidine has a wider portfolio of activities; it blocks muscarinic, nicotinic, and NMDA receptors. Its use as a prophylactic antidote along with physostigmine prevented the occurrence of convulsions induced by up to 2 LD_{50} of soman (Myhrer et al., 2004). It is combined with physostigmine and these two prophylactic drugs, administered prophylactically for 3 days via osmotic minipumps protected rats from the lethal, convulsant, and CNS-damaging effects of soman (Choi et al., 2004). The same combination was used in dogs poisoned with soman, but delivered from transdermal patches allowing for continuous liberation of active substances into the bloodstream. In this experiment, postexposure therapy with atropine and asoxime assured a PR of 2.7, prophylactic patch 4.7, and their combination 9, showing a clear case of potentiation among these prophylactic and postexposure antidotes (Kim et al., 2005). These results imply that a physostigmine/procyclidine patch might be a good alternative for pyridostigmine prophylaxis and subsequent use of diazepam (Cho et al., 2012).

Procyclidine prophylaxis is obviously dose-dependent (Fig. 65.1). An increase in its dose allows for not only survival after increasing doses of soman, but also prevents the occurrence of soman-induced convulsions. In this particular experiment, procyclidine, administered 30 min before soman along with a fixed dose of physostigmine of 0.1 mg/kg i.p. was given in doses of 1, 3 and 6 mg/kg i.p., while the doses of soman tested were 1.3, 1.6, and 2 LD_{50} (Myhrer et al., 2004).

As shown in Fig. 65.1, if a sufficiently high dose of procyclidine was injected prophylactically (6 mg/kg),

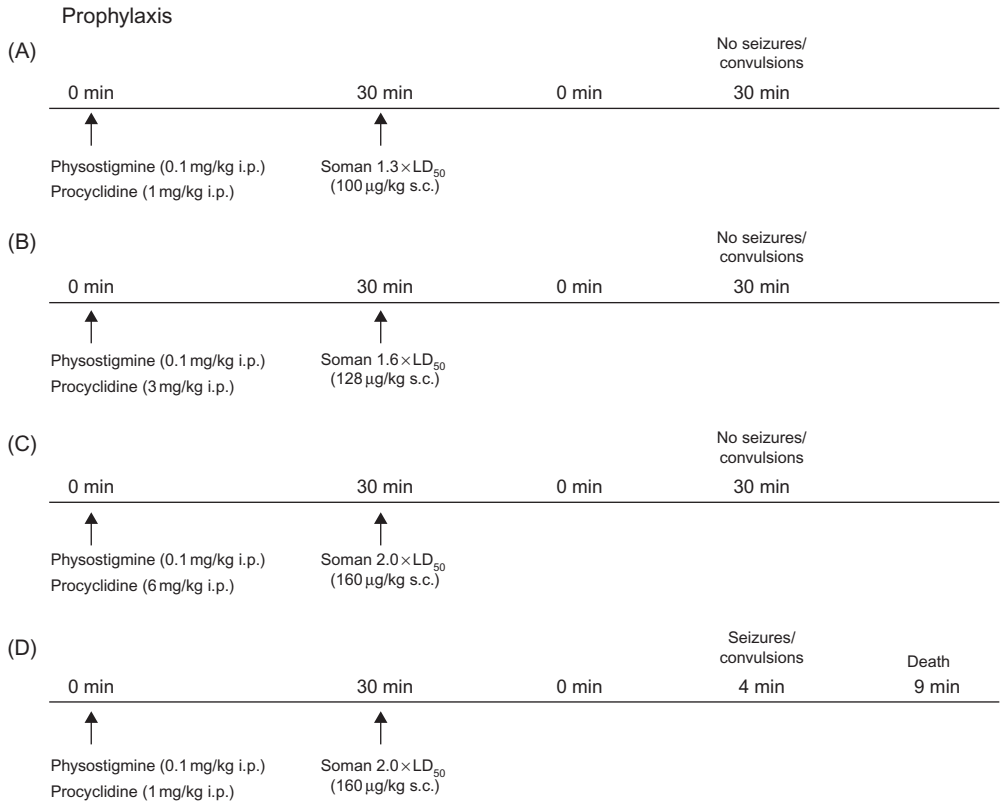

FIGURE 65.1 Experimental design for demonstration of anticonvulsant effects of a fixed dose of physostigmine combined with increasing doses of procyclidine relative to increasing doses of soman (A–C). Insufficient dose of procyclidine compared with soman results in early death (D).

even the highest dose of soman (2 LD_{50}) did not cause convulsions and death, while if the dose of procyclidine was low (1 mg/kg), the same dose of soman would in 4 min result in convulsions and, after 9 min, death. The dose-dependency of the prophylactic dose of procyclidine follows the concentration-dependent binding of procyclidine at the phencyclidine site at the *N*-methyl-D-aspartic acid (NMDA) receptor that leads to their blockade (Myhrer et al., 2004).

65.2.4 Adverse effects of prophylatic regimens

The mentioned requirement that a successful candidate for a prophylactic drug against OPC and especially nerve agents—to be able to protect against at least 5 LD_{50} of the OPC in question— is not the only one. Another aspect is safety, which means that an ideal prophylactic drug should not impair the physical and psychological functions of the human body. The main controversy is in the fact that the agents that act not only peripherally (i.e., outside the CNS), but also gain access to the brain, are the most efficient prophylactic drugs against OPCs, since the CNS is the main point of their attack. At the same time, however, such prophylactic antidotes tend to adversely affect the normal brain functions, at least at a dose that affords effective prophylaxis. For example, even the lowest dose of memantine tested—1 mg/kg s.c.—significantly increases spontaneous motoric activity in rats (Stojiljković et al., 2019).

When it comes to centrally acting carbamates, such as physostigmine, they themselves have AChE-inhibiting properties, which can be partly compensated by combining them with low doses of very lipid-soluble anticholinergics (e.g., procyclidine, scopolamine, benactyzine, trihexyphenidyl, aprophen, etc.). Even these small doses of anticholinergics per se have some adverse effects of their own, which complicates the overall tolerability of such a prophylactic regimen. For example, Sket (1993) showed that in female rats pretreated with physostigmine the same supralethal dose of soman induces the first signs of poisoning earlier than in nonpretreated rats. As a general rule, practically all pretreatment drugs tested so far, that is, physostigmine, galantamine, benactyzine, trihexyphenidyl, procyclidine, and even only peripherally acting carbamate pyridostigmine, induce per se some level of incapacitation of the laboratory animals at doses effective against nerve agents, which represents a serious problem in the development of prophylactic antidotes (Myhrer and Aas, 2016). A possible strategy would be to give prophylactically only moderate doses of drugs and compensate them later, during the treatment of poisoned individuals (Myhrer et al., 2004).

65.2.5 Bioscavengers against nerve agents

Nerve agent bioscavengers can be defined as biological molecules—proteins and enzymes—that may prevent intoxication by binding and inactivating nerve agents before they can reach their target organs. They can be divided into two classes: stoichiometric and catalytic bioscavengers. Stoichiometric bioscavengers "sacrifice themselves" by binding irreversibly to molecules of nerve agents, while catalytic bioscavengers destroy the molecules, remaining intact during the process (Goldsmith and Ashani, 2018). Currently, only Protexia is available for human use (Bajgar et al., 2019). It is a pegylated form of a recombinant human butyrylcholinesterase (Mumford and Troyer, 2011) that becomes 50% inhibited in vitro when added to a nerve agent in a stoichiometric ratio of 1:1 (Cerasoli et al., 2005). It was successfully tried in vivo in guinea pigs percutaneously poisoned with VX 2.5 LD_{50}, when Protexia, injected i.m. 2 h after exposure to VX, prevented death and alleviated signs of cholinergic poisoning in all exposed animals (Mumford and Troyer, 2011). Human butyrylcholinesterase seems to be behaviorally safe in monkeys per se, and after challenging them with an otherwise lethal dose of soman (Myers, 2019).

Even better results are expected from catalytic scavengers. Human paraoxonase-1 (PON-1) is certainly one of them, albeit its affinity for OPCs is only moderate and the turnover rate is slow. Therefore, prophylactic use of native human PON-1 cannot result in dramatic protective effects against nerve agents (Lenz et al., 2007). For this reason, further efforts were invested in the development of mutants of human PON-1 (Yeung et al., 2004; Aggarwal et al., 2016). Although the first efficacy results are favorable (Worek et al., 2014), their immunogenicity and plasma half-lives in humans have yet to be determined (Lenz et al., 2007).

65.3 Treatment of intoxication with nerve agents

Current principles of postexposure treatment of poisonings with nerve agents include a triple regimen, that is, use of causal antidotes—AChE reactivators and of two classes of symptomatic antidotes—anticholinergics and anticonvulsants.

65.3.1 Anticholinergics

Although this class of medicines acts as symptomatic antidotes by blocking cholinergic receptors in the periphery and in the CNS, they represent the basis of any effective treatment of nerve agent poisonings, in experimental animals and in humans alike. Among them, a subclass of antimuscarinics is significantly more important than the

other, antinicotinics. The reason for that is because primarily overstimulation of muscarinic receptors is responsible for the suppression of the activity of vital centers in the brain (Škrbić et al., 2017).

Among them, atropine is by far the best known and most widely used antimuscarinic. Although it passes through the blood–brain barrier into the brain, its relative lipophilicity is low in comparison with the other antimuscarinics, such as scopolamine, benactyzine, and aprophen (Stojiljković et al., 1989). Atropine assures high and dose-dependent PR against carbamate AChE inhibitors and especially those that act on this enzyme in the brain, like physostigmine (Stojiljković et al., 2018). At the same time, antinicotinics hexamethonium and d-tubocurarine are much more efficient against strictly peripherally acting carbamates, like pyridostigmine (Stojiljković et al., 2018). Nevertheless, there is only modest protection against OPCs and nerve agents (if any) by atropine monotherapy (Inns and Leadbeater, 1983; Leadbeater et al., 1985). Addition of antinicotinics increases PRs primarily against carbamates, but also to a limited extent also against OPCs (Parkes and Sacra, 1954). Recent results confirm that a bispyridinium antinicotinic compound MB327 protects guinea pigs from soman poisoning when administered along with atropine and avizafone (Price et al., 2018). Experiments with the same compound in mice intoxicated with tabun, sarin, or soman showed that addition of MB327 increases the LD_{50} of all three nerve agents treated with atropine or atropine and asoxime. This increase, however, reached statistical significance only in the case of sarin (Kassa et al., 2016).

65.3.2 Acetylcholinesterase reactivators

This class of drugs act as causal antidotes, since they reactivate AChE irreversibly inhibited by OPCs and in this way remove the cause of the poisoning. They all contain the oxime functional group in their molecules and this is why they are also called oximes. The older monopyridinium oximes, such as pyridine-2-aldoxime dichloride (2-PAM) and its methanesulfonate salt (P2S), are effective reactivators of sarin- and VX-inhibited AChE and hence their combinations with atropine assure reasonably high PRs against these two nerve agents. At the same time, they are totally ineffective against tabun and soman. The next generation were trimedoxime (TMB-4) and obidoxime (LüH-6) that are effective reactivators of tabun- but not soman-inhibited AChE, with good antidotal efficacy against tabun, sarin, and VX.

Asoxime (HI-6) was one of the products of Ilse Hagedorn's laboratory, known as H-oximes, and it was the first oxime known to reactivate AChE previously inhibited by soman, the nerve agent that represented the most difficult target for treatment. Although also a bispyridinium oxime with low lipophilicity, it gains some access into the CNS in concentrations high enough to reactivate AChE and in this way act as a true causal antidote (Ligtenstein and Kossen, 1983; Ligtenstein et al., 1988). Use of the atropine/asoxime combination, with or without diazepam, therefore became the gold standard of antidotal treatment against soman (Pantelić and Maksimović, 1982; Jokanović and Stojiljković, 2006; Stojiljković and Jokanović, 2006). In order to cover all four major nerve agents, a combination of asoxime and obidoxime was tried, with good results against inhibition of AChE induced by tabun, sarin, soman, VX, and cyclosarin (Worek et al., 2007).

All H-oximes obviously have non-AChE-mediated effects known as "direct pharmacological effects" (Van Helden et al., 1996; Jokanović and Prostran, 2009; Jokanović, 2012). The existence of these not well elucidated antidotal mechanisms is obvious, because without them it would be impossible to explain findings like that of the Canadian authors who registered PR as high as 5 in tabun-poisoned guinea pigs treated with atropine and asoxime 125 mg/kg i.p., that is, with an oxime that cannot reactivate tabun-inhibited AChE (Hamilton and Lundy, 1989). Asoxime therefore became a component of dual and triple autoinjectors, the other two components being atropine and avizafone, a hydrosoluble version of diazepam. Due to asoxime's instability in water, it has to be stored as a powder and dissolved in atropine solution practically upon the autoinjector activation (Bajgar, 2010).

The H-oxime with broadest reactivation specter is HLö-7 (Löffler, 1986), an oxime that can reactivate AChE inhibited by all four major nerve agents, tabun, sarin, soman, and VX, but also the one inhibited by cyclosarin (DeJong et al., 1989; Worek et al., 1994a,b, 1995; Lundy et al., 1992). On the protection level, it proved to be more effective than asoxime against tabun and VX, while asoxime was more effective than HLö-7 in animals poisoned with sarin, soman, and cyclosarin (Lundy et al., 1992; Eyer et al., 1992). Despite its broad spectrum, it never became a candidate for autoinjectors due to several factors that include greater per se toxicity than asoxime, difficult synthesis, and instability in water solutions (Dawson, 1994).

K-oximes, named after two Czech researchers Kamil Kuča and Kamil Musilek, represent a potentially important step forward (Musilek et al., 2005). These oximes, and especially K-203, can reactivate even tabun-inhibited AChE. Their commercial exploitation however seems currently to be a remote possibility (Musilek et al., 2007).

It is important to underline that the oximes used currently by military personnel—2-PAM, P2S, obidoxime, and asoxime—although they also come in monocomponent autoinjectors, are generally used only as an addition to atropine, since their PRs when used alone are modest.

65.3.3 Anticonvulsants

The toxic accumulation of acetylcholine that follows AChE inhibition in brain triggers convulsions that induce the occurrence of neuronal death and structural lesions of the CNS on one hand and compromisation of the function of the respiratory center leading to central respiratory paralysis. Numerous studies have shown that early administration of atropine, but also of some other antimuscarinics or/and antinicotinics, can prevent the occurrence of seizures. However, once the seizures become fully developed, they lose sensitivity to anticholinergics and can be stopped only after administration of anticonvulsants (Myhrer et al., 2004).

Two classes of anticonvulsants were used against nerve agents—benzodiazepines and glutamate receptor antagonists.

65.3.3.1 Benzodiazepines

Although the addition of oximes to atropine potentiates its PR, the inclusion of benzodiazepines into a triple regimen usually results in further potentiation of PR in animals poisoned with nerve agents. Their mechanism of action includes stimulation of the frequency of opening of $GABA_A$ receptors that results in the influx of chloride anions and in hyperpolarization of cell membranes in the CNS. As a result, neurons become less susceptible to the generation of seizures (Sellström, 1992; Jokanović, 2015).

Among the benzodiazepines, diazepam is most frequently used. Its drawback is its insolubility in water and hence inability to be packed in an autoinjector, but also a relatively slow onset of action. Experiments in rodents have shown that any delay in administration of diazepam after exposure to soman significantly diminishes its anticonvulsive efficacy (McDonough et al., 2010). Consequently, even a diazepam dose of 20 mg/kg could not treat convulsions induced by 1.6 LD_{50} of soman when injected more than 40 min after soman (Shih et al., 1999).

Avizafone (lysyl peptido-amino-benzophenone diazepam or pro-diazepam) is a hydrosoluble complex that liberates diazepam and can be used in autoinjectors (Clair et al., 2000). It was shown in a clinical trial that avizafone, after injection, assures significantly higher concentrations of diazepam in plasma than diazepam itself and that this maximum is reached earlier (Abbara et al., 2009). On the efficacy level, avizafone performed better than an equimolar dose of diazepam, when administered with atropine to guinea pigs poisoned with sarin (Taysse et al., 2003) or soman (Taysse et al., 2006). Armies of the United States, Canada, and Norway have autoinjectors with diazepam, while the United Kingdom and the Netherlands use autoinjectors with avizafone (Aas, 2003).

There is some experience with midazolam, a very potent hydrosoluble benzodiazepine, that has faster onset of action and potentiates better the PRs of atropine/asoxime combinations in rodents intoxicated with nerve agents (Bokonjić and Rosić, 1991; McDonough et al., 1999, 2009). Other benzodiazepines, like clonazepam, were rarely tried against nerve agents (Lipp and Dola, 1980; Shih et al., 1991b).

65.3.3.2 Glutamate receptor antagonists

Most of the drugs belonging to this class act as NMDA receptor antagonists, although NBQX actually blocks another two classes of ionotropic glutamate receptors—AMPA (quisqualate) and kainite receptors (Löscher and Hönack, 1994; Filliat et al., 1998). Ketamine, dizocilpine (MK-801), phencyclidine (PCP), gacyclidine (GK-11), tenocyclidine, and memantine belong to this therapeutic group (Shih et al., 1991b; Dorandeu et al., 2005). Their mechanism of action is simple—they block noncompetitively an open channel of NMDA receptors and thus prevent them from overstimulation by the excitotoxic amino acid glutamate. The resulting effect is anticonvulsant and neuroprotective. Representatives of this class were used successfully to prevent or stop soman-induced convulsions.

Tenocyclidine, a phencyclidine derivative, and its adamantane derivatives, augmented the protection afforded by atropine and asoxime against soman in mice, assuring PRs within the range of 5.40−7.12 (Skare et al., 2002). In a separate experiment, tenocyclidine was administered to guinea pigs pretreated with pyridostigmine, poisoned with 2 LD_{50} of soman and treated with atropine. In this experiment, tenocyclidine was able to block the already existing status epilepticus, even if administered 60 min after the onset of convulsions (Carpentier et al., 1994).

Gacyclidine was injected in pyridostigmine-pretreated monkeys 45 min after they were poisoned with 8 LD_{50} of soman and treated with atropine/2-PAM/diazepam. Gacyclidine increased survival, and normalized the EEG activity. In addition, 3 weeks after poisonings, serious neuropathological sequelae were found in animals that did not receive gacyclidine, but not in those ones that did. This was strong proof of the antidotal, anticonvulsant, and neuroprotective effect of gacyclidine against soman intoxication (Lallement et al., 1997, 1998).

Of possible importance for further research is the finding that caramiphen, a compound with combined anticholinergic and anti-NMDA properties, stops the soman-induced seizures, decreases neuronal loss, and neuronal degeneration even when administered 30 or 60 min after soman (Figueiredo et al., 2011). Both caramiphen and procyclidine can be combined with the well-known antiepileptic drug levetiracetam to stop soman-induced seizures in rats, when applied either before or after soman (Myhrer et al., 2011).

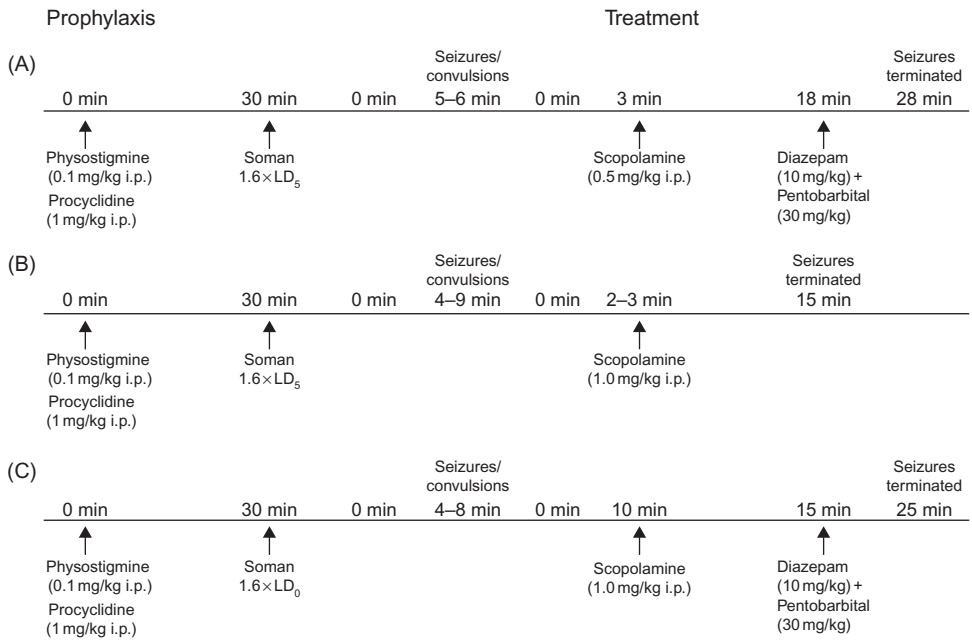

FIGURE 65.2 Experimental design for demonstration of how insufficient prophylactic treatment can be compensated for by adjunct postexposure treatment. A low dose of scopolamine requires additional treatment (A). A high dose of scopolamine is sufficient to terminate seizures (B). A high dose of scopolamine given outside the cholinergic window requires additional treatment (C).

It was later shown in nonpretreated primates that even when the postsoman exposure therapy atropine/2-PAM/diazepam is delayed for 30 or 45 min, gacyclidine was able to stop the soman-induced seizures and prevent neuropathological changes from developing (Lallement et al., 1999a,b). Toxicity of gacyclidine is lower than in other NMDA receptor antagonists and is believed that it results from its binding to some non-NMDA receptor sites (Hirbec et al., 2001).

The latest experimental results indicate that soman-induced convulsions induce a "maladaptive trafficking" between $GABA_A$- and glutamate receptors in the brain, leading to a decrease of the number of $GABA_A$-receptors and an increase of the population of NMDA- and AMPA-receptors. The addition of NMDA-receptor-blocking agent ketamine to midazolam increased its anticonvulsant potential against soman. However, if postponed for 40 min after soman injection, only ketamine seems effective. According to this receptor trafficking hypothesis, diminishing efficacy of benzodiazepines that follows the duration of the untreated seizures is the result of the shift in sizes between the $GABA_A$- and NMDA-/AMPA-receptor populations (Niquet et al., 2019).

65.3.3.3 Time- and dose-dependency of administration of drugs for prevention and treatment of nerve agent-induced convulsions

The occurrence of convulsions following acute intoxication with soman or other nerve agents depends on the presence and dosage of prophylactic antidotes (e.g., memantine, physostigmine, and procyclidine) and of the nature and timing of the administration of postexposure antidotes. As mentioned earlier, the use of qualitatively and quantitatively adequate prophylactic antidotes in rats exposed to soman up to 2 LD_{50} eliminates the need for postexposure therapy (Fig. 65.1; Myhrer et al., 2004). In the case of administration of inadequately low doses of prophylactic procyclidine (1 mg/kg), convulsions leading to quick death would ensue and postexposure treatment becomes absolutely necessary (Fig. 65.2).

In the experiment presented here, 1.6 LD_{50} of soman was used and scopolamine, a very liposoluble antimuscarinic drug, had to be used, but its effect depended on its dose and time of administration. When its dose was 1 mg/kg i.p. and when it was injected 4−9 min after the occurrence of convulsions, they ceased after another 15 min. When the dose of scopolamine was lower (0.5 mg/kg) and the timing remained the same as in the previous experiment, the convulsion would be stopped only after administration of diazepam (10 mg/kg) and pentobarbital (30 mg/kg). The same combination had to be used to stop the soman-induced convulsions even after 1 mg/kg of scopolamine, but administered 10, instead of 3 min after the onset of convulsion (Fig. 65.2; Myhrer et al., 2004).

As mentioned earlier, even the use of benzodiazepines has a narrow window of effectiveness following intoxication with nerve agents, since with the passage of time these convulsions became more dependent on the glutamatergic receptor activity and relatively independent on the activity of cholinergic receptors and even the $GABA_A$/benzodiazepine-receptor complex. As a result of

this process, glutamatergic receptor antagonists remain the only solution for the delayed treatment of such convulsions (Lallement et al., 1999a,b; Niquet et al., 2019).

65.3.3.4 Autoinjectors

As mentioned earlier, modern armies try to protect their personnel against combat use of nerve agents. For this purpose, they supply their soldiers with autoinjectors, devices usually with one or two chambers that can, once activated, stick a needle into the muscle and deliver a solution containing antidotes. In this manner, precious time is saved in administering quickly needed medication. Some of these autoinjectors are monocomponent, containing only one antidote, usually atropine, an oxime, or an anticonvulsant (diazepam or avizafone). The choice of an oxime varies, depending on the specific country and its doctrinal approach to the treatment of nerve agent intoxications. For example, pralidoxime is used in the United States (2-PAM) and the United Kingdom (P2S), obidoxime in Germany, the Netherlands, Norway, and Finland, and asoxime in Canada and Sweden (Aas, 2003).

In some cases, an autoinjector contains atropine and an oxime as a combination. In the case of atopine/asoxime autoinjectors, these two components need to be stored separately due to rapid degradation of asoxime in water solutions. This problem is solved by storing the atropine solution in one chamber and the lyophilized powder of asoxime in the other (dual-chamber autoinjectors). The fact that solubility of asoxime in the form of dichloride (HI-6 Cl) is not optimal is overcome by replacing this salt with dimethanesulfonate (HI-6 DMS) that has an even better pharmacokinetic profile and certainly better water-solubility. A three-chambered autoinjector contains atropine, oxime, and diazepam (in the form of avizafone), and would be ideal for the treatment of nerve agent intoxications (Bajgar, 2010).

65.4 Concluding remarks and further directions

Further research aimed at continuous improvement of the efficacy and tolerability of prophylactic and postexposure antidotes against poisonings with nerve agents is an absolute necessity. Currently, pyridostigmine tablets represent the official prophylactic antidote in the majority of NATO countries, although the result of their use assures only partial protection, since this carbamate does not pass the blood–brain barrier and does not protect the AChE of the CNS from inhibition by nerve agents. Prophylactic regimens containing a combination of the centrally acting carbamate physostigmine and an anticholinergic could be a better solution, especially in the form of transdermal patches. As an alternative, prophylactic regimens that include the use of stoichiometric or catalytic scavengers deserve further attention.

The antimuscarinic drug atropine, monopyridinium oxime pralidoxime salts (2-PAM, P2S), bispyridinium H-oximes (trimedoxime, obidoxime, asoxime, HLö-7), K-oximes (K-207), and anticonvulsants (benzodiazepines, glutamate receptor antagonists) remain the main pillars of postexposure treatments of intoxications with nerve agents. To protect military personnel, autoinjectors are being developed, with an ideal of having atropine, universally active oxime (or a combination of obidoxime and asoxime) and diazepam, avizafone or midazolam as anticonvulsants, all in one autoinjector. Further improvement of existing autoinjectors is expected in the future.

Chapter 66

Physiologically based pharmacokinetic/pharmacodynamic modeling of countermeasures to nerve agents

66.1 Introduction

Physiologically based pharmacokinetic/pharmacodynamic (PBPK/PD) modeling has proven useful in many areas of toxicology and therapeutics. This quantitative, mechanism-based approach has allowed limited experimental in vivo and in vitro data to be quantitatively integrated with physiological data to facilitate predictions of the behavior of organisms under different exposure conditions. Specifically, it has been used for:

- Extrapolation across species (particularly experimental animals to humans)
- Extrapolation across dosing scenarios (such as high to low doses)
- Extrapolation across routes of exposure

Models have been developed for a number of chemical warfare (CW) agents (Langenberg et al., 1997; Worek et al., 2005; Aurbek et al., 2006; Sweeney et al., 2006; Van der Merwe et al., 2006; see also Chapter 58: Neuropathy target esterase as a biomarker and biosensor of delayed neuropathic agents) and surrogates, including diisopropyl fluorophosphate (DFP) (Gearhart et al., 1990, 1994), diazinon (Poet et al., 2004), and chlorpyrifos (Timchalk et al., 2002a,b). In the case of agent countermeasures, PBPK/PD modeling also allows the prediction of therapeutic efficacy under varying exposure scenarios. Specifically, it may allow therapeutic regimens to be optimized to particular exposure scenarios (routes, exposure times, concentrations). To do so, PBPK/PD models of individual agents and countermeasures must be combined to take into account their interactions, whether they are pharmacokinetic or pharmacodynamic. Such modeling of agent or (multiple) counteragent combinations is an example of mixtures modeling (Krishnan et al., 1994).

There is little in literature approaching a complete model of the kinetic and dynamic interaction of nerve agent (NA) and its current (multiagent) or potential countermeasures. There have been, however, a number of important steps in that direction, both on the level of model development and in the experimental generation of data useful for the development and validation of such models.

We restrict our discussion here to countermeasures of NAs and do not discuss other chemical agents such as mustards and cyanide and their antidotes. However, the modeling ideas outlined here can also apply to other agents.

66.2 Background

Organophosphate compounds (OPs), such as the NAs, sarin (GB), soman (GD), tabun (GA), and VX, exert their toxicity via inhibiting acetylcholinesterase (AChE). As a result, Acetylcholine (ACh) accumulates in the synapses and neuromuscular junctions, resulting in hyperstimulation of muscarinic and nicotinic cholinergic receptors. Clinical symptoms include salivation, lacrimation, urination, defecation, and possibly convulsions (Myhrer et al., 2007).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00066-0

At moderate to high doses, seizures rapidly progress to *status epilepticus* (SE), which can lead to irreversible brain damage or death (Filliat et al., 1999; Carpentier et al., 2001). Survivors suffer long-lasting cognitive deficits and behavioral changes (McDonough et al., 1995) largely attributable to neuronal degeneration of hippocampal structures. Under acute high-level exposures, the focus of countermeasure treatment is the prevention of seizures, respiratory failure, and bradycardia due to convulsive spasms. For low-level exposures, and for the survivors of high exposures, the concern shifts to minimizing the cognitive impact of the agent that may or may not be related to the degree of seizure activity.

McDonough and Shih (1997) hypothesized that NA-induced seizures follow three main phases. Initially, approximately 5 minutes after exposure, hypercholinergic activity triggers the seizure. A transitional phase of cholinergic and glutamatergic hyperactivity follows as a self-sustaining glutamate−NMDA receptor (NMDAR)-mediated positive feedback loop begins to develop. After approximately 40 minutes, a predominantly glutamatergic phase sustains seizures, leading to neuronal damage predominantly in the hippocampus, amygdala, piriform cortex, thalamus, and entorhinal cortex across species (Olney et al., 1983; Wade et al., 1987; Carpentier et al., 1990; Fosbraey et al., 1990; Lallement et al., 1992; Solberg and Belkin, 1997).

High levels of glutamate are directly neurotoxic because overstimulation of glutamate ionotropic receptors allows excessive influxes of Na^{2+} and Ca^{2+}, causing prolonged depolarization of postsynaptic membranes (Bittigau and Ikonomidou, 1997). A cascade of events results from the delayed Ca^{2+} overload, leading to excitotoxic cell necrosis (McDonough and Shih, 1997; Solberg and Belkin, 1997). In addition, as the time lapse before anticonvulsant treatments increases, the Ca^{2+} influx induces transcription factors that mediate significant increases in damaging pro-inflammatory peptides, such as IL-1β, IL-6, and mRNA of TNF-α (Chapman et al., 2006).

The content of this chapter is not inclusive in the sense of taking one through the complete development and validation of a complex PBPK/PD model, which would describe the kinetics of each component, together with the pharmacodynamic interactions between selected NAs and countermeasures. Rather, this chapter briefly describes some examples of progress made in quantitative modeling and exploring how specific countermeasures interfere in this NA-induced cascade of events, and how such quantitative approaches could be used to develop improved treatment regimens.

66.3 Current countermeasures

Conventionally, NA poisoning is treated by a combination of prophylactic and post-exposure therapy, which target the three post-exposure phases of neurotransmitter systems described. Prophylactic treatments are designed to circumvent aging of the NA−AChE complex and consist of carbamate anticholinesterases (e.g., pyridostigmine) to bind AChE reversibly. Current carbamate pretreatment regimes bind 30%−40% of available red blood cell (RBC) AChE, thereby protecting some of the enzyme from irreversible OP binding (McDonough and Shih, 1997). Carbamates, however, are not without side effects. Partial AChE blockage by pyridostigmine results in a transient overstimulation of the AChR, mimicking mild NA poisoning with nausea, diarrhea, shortness of breath, and dizziness (Abraham et al., 2002). Moreover, repeated prophylactic administration of carbamates is associated with detrimental and debilitating changes in nerve and muscles function (Hudson et al., 1986).

Standard post-exposure treatments include concurrent administration of anticholinergics, such as the muscarinic cholinergic blocker atropine sulfate, and AChE reactivators, such as obidoxime and pyridine-2-aldoxime methylchloride (also known as 2-PAM). Oximes cannot reactivate OP-inhibited AChE that has already "aged." Therefore, traditional oxime treatment is considered to be less effective for those agents such as soman, for which aging is rapid (Worek et al., 2005).

If seizures develop, then treatments that attempt to attenuate the hyperglutamatergic phase are required. Anticonvulsants, such as the benzodiazepine, diazepam, may be used. Diazepam is a lipophilic agonist of the γ-aminobutyric acid A ($GABA_A$) receptor, the most predominant inhibitory receptor of the CNS. The $GABA_A$ receptor is ubiquitously distributed. Therefore, its activation or inactivation affects virtually all brain regions, making dosage critical. Treatments with traditional benzodiazepines depend on administration within a very narrow time span to be effective because profound neuropathological changes are usually detected within 20 minutes of the onset of seizures (Lallement et al., 1994; Leadbeater et al., 1985; McDonough et al., 1995; Shih et al., 1999). By themselves, benzodiazepine anticonvulsants provide limited protection, and seizures recur with desensitization of $GABA_A$ receptors (Goodkin et al., 2005). In addition, diazepam has consistently failed to eliminate the neuropathological changes resulting from NA-induced seizures (McDonough and Shih, 1997). Furthermore, in many battlefield and civilian exposure scenarios for NAs, pretreatments are unrealistic and post-exposure anticonvulsants are likely to be delayed. Epidemiological studies have shown that time to seizure treatment in the United States varies broadly, with only approximately 41% of all patients receiving their first antiepileptic drug within 30 minutes (Pellock et al., 2004).

66.4 Novel countermeasures

Because of the undesirable side effects of the standard treatment regimes, and because of limitations of

traditional benzodiazepines to adequately control seizures, the need for alternative therapeutics still exists. The focus of OP intoxication treatment is also expanding from immediate survival to include the prevention of long-term cognitive deficits. Other antidotes have been proposed that demonstrate promise in reducing excessive glutamatergic activity and/or prevent destabilization of Ca^{2+} homeostasis, because excitotoxic mechanisms of seizure activity ultimately result in Ca^{2+} overload and activate various enzymes that lead to necrosis of the cell. Attempts have been made by blocking the *N*-methyl-d-aspartate (NMDA) or alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, two subtypes of CNS glutamate receptors (Braitman, 1989; Lallement et al., 1994; McDonough and Shih, 1997; Raveh et al., 2003). NMDA-type glutamate receptors are glutamate-gated cation channels whose permeability to Ca^{2+} underlies aspects of normal synaptic plasticity. Excess Ca^{2+} influx through NMDARs mediates cell death in certain neurodegenerative pathologies. Therefore, neurons must precisely control NMDAR synaptic density, which is negatively regulated by global neuronal activity.

A number of glutamate receptor antagonists have demonstrated neuroprotective and anticonvulsive effects in animals (Urbanska et al., 1998). The high-affinity NMDAR antagonist, ketamine, has shown promise when administered intramuscularly with atropine sulfate up to 30 minutes after poisoning (Dorandeu et al., 2005). Other noncompetitive NMDA antagonists, like dizocilpine (MK-801) and *N*-(1-[2-thienyl]cyclohexyl)3,4-piperidine (TCP), display the ability to terminate seizures when treatment is delayed by 40 minutes but seriously decrease respiration (Carpentier et al., 1990; Shih, 1990; Shih et al., 1991; McDonough and Shih, 1997; Shih and McDonough, 1997).

An unusual NMDAR antagonist that recently demonstrated potent neuroprotection against GD-induced seizure-related brain damage in rats is dexanabinol. Dexanabinol is a nonpsychoactive synthetic cannabinoid that acts as a highly selective, low-affinity NMDAR antagonist (Feigenbaum et al., 1989; Eshhar et al., 1993). In GD-exposed rats ($1.6 \times LD_{50}$ subcutaneous), dexanabinol administered intraperitonealy at either 5 or 40 minutes after the onset of seizures reduced median brain lesion volume 86% and 81%, respectively (as assessed by microtubule-associated protein 2 [MAP2]-negative staining) (Filbert et al., 1999). When administered 5 minutes after seizure onset and repeated every 6 hours up to 24 hours, 98% reduction was seen. However, it is not known if the same degree of protection would be afforded if measurements were taken later than 24 hours after seizure onset. Dexanabinol did not diminish seizure activity in any of the GD-treated rats, suggesting that its neuroprotective effects may be due to its properties as a potent antioxidant and free radical scavenger, as well as its ability to inhibit the production of tumor necrosis factor-alpha (TNF-α) (Shohami et al., 1997), thus also blocking the signal transduction pathway that activates nuclear factor B (NFB).

Data to date also indicate that enzyme-based bioscavengers show much promise for the next generation of pretreatments or antidotes, with potentially no observable side effects. Candidate bioscavenger proteins either bind and sequester toxic OPs (such as serum cholinesterases and carboxylesterases) or catalytically break down the OP into nontoxic products (such as human serum organophosphorus acid anhydride hydrolases [OPAH] or paraoxonase [HuPON]). These scavengers, as well as carboxylesterase (CarbE), are each capable of providing protection against $2-16 \times LD_{50}$s of GD, GB, or VX, depending on the scavenger and the test species (rat, mouse, rabbit, guinea pig, or rhesus monkey), with little to no deficits in behavioral testing (Li et al., 2005). Human clinical trials of several bioscavengers are now underway that could lead to FDA licensure.

Human serum paraoxonase (HuPON1) is a Ca^{2+}-dependent enzyme that effectively hydrolyzes many toxic AChE-inhibiting organophosphates (Blum et al., 2008). HuPON1 is present in high-density lipoproteins of human plasma and plays an important role in protecting lipoproteins and cell membranes from oxidative damage. Because it is a human enzyme (Li et al., 2005), it could potentially be used as either a prophylaxis or medical post-treatment for NA exposure, without causing adverse immune reactions (Draganov and LaDu, 2004). Human PON1 has catalytic activity against the pesticide paraoxon and the NAs sarin (GB), soman (GD), and cyclosarin (GF), but shows only minimal activity against the nerve agent VX (Blum et al., 2008). The advantage of catalytic scavengers is the very small amount of the exogenous enzyme needed to hydrolyze and detoxify large amounts of NA.

66.5 PBPK/PD modeling

For obvious ethical reasons, only animal experiments can be used to evaluate new NA antidotes. However, the extrapolation of data from animals to humans is hampered by marked species differences. Currently, quantitative analyses addressing the co-treatment of countermeasures and medicinal treatments simultaneous with or immediately preceding or after NA exposures have been very limited. The current paradigm thus relies on experimentation in various animal models to determine efficacy and then, following the classical model for pharmaceutics, scales the animal results to the human exposure scenario. In the case of NA countermeasures, short of controlled human experimental studies, this leaves a large

uncertainty factor regarding the protection of military personnel from NA threats and may severely limit or compromise operational risk management (ORM). One solution to this dilemma is to develop validated mathematical models to predict the biological impact of simultaneous and sequential low-level exposures to specific NAs, together with specific countermeasures, countermeasure combinations, and dosing regimens.

PBPK/PD models can be used to explore the interactions between agents, countermeasures, and the organism to integrate multiple animal (in vivo and in vitro) and human (typically in vitro) data sets and to develop tools for countermeasure design and dosing regimen selection to maximize countermeasure administration efficacy. The models make quantitative use of differences in physiological parameters between test animals and humans, such as organ blood flow. The result of this approach is the development of an interaction model quantifying competition for AChE binding sites between specific agents and countermeasures, as well as other relevant pharmacodynamic and pharmacokinetic modes of interaction and the development of methods to optimize countermeasure therapies for specific NA exposure scenarios in humans.

The process of applying mathematical constructs to describe experimental results often reveals patterns in the agent's pharmacokinetics or dynamics that might not otherwise be discernable. Failure of a model's simulations to predict experimental measurements sometimes prompts questioning of the data, such as the reliability of the quantitative methods, sample collection, or exposure techniques. More often, it may indicate that greater complexity in the structure of the model is required to capture the behavior of the data. This is another primary reason for developing models, that is, to create hypotheses (model structures) that are falsifiable, leading to improved models and improved predictions in an iterative process.

There are currently a number of critical toxicological data gaps related to NA exposure at both acute high levels and repeated low levels. Many of these gaps are due to the impossibility of conducting controlled human experiments involving NA exposure. Filling these data gaps for exposure to NAs is essential for predicting performance degradation of personnel, enhancing risk assessment modeling tools, and defining detection thresholds that are physiologically relevant. The purposes of filling such data gaps are to develop a valid method for predicting dose–response effects for exposures to low NA agent concentrations/doses over long durations, and to identify threshold exposure conditions at which toxicologically significant effects occur. PBPK/PD modeling provides a means to fill these gaps. Because of the physiologically based nature of these models, simulations of experimental data can be performed by one exposure route in a particular species to develop and validate the PBPK model, and then that model can be used to simulate and predict the kinetics and pharmacodynamics in another species, such as the human exposed via another exposure route. The power of PBPK/PD models thus lies in aiding the ability of scientists and decision-makers to make reliable quantitative predictions concerning the potential health effects of real-life human exposures. In addition, this modeling approach can be useful for the development of meaningful therapeutic animal models. After all, therapeutics that have been successfully tested in animals can ultimately be tested in human clinical trials. However, their therapeutic efficacy against NAs can only be tested in animals.

66.6 Development of PBPK/PD models

Critical components to PBPK models include species-specific physiological parameters and chemical-specific parameters. Species-specific physiological parameters include the organ weights and blood flow rates for the defined compartments in the PBPK model. These values are most often available in the published literature (Brown et al., 1997; Peeters et al., 1980) and, when lacking, can be derived by appropriate scaling factors from similar species. Chemical-specific parameters may include tissue to blood partition coefficients and metabolic rate constants, which may be measured experimentally or predicted, as described in the next section on quantitative structure–activity relationship (QSAR) methods. The basic structure of a PBPK model used to describe pharmacokinetics and pharmacodynamics of a compound is similar to the model presented in Fig. 66.1, which predicts the absorption, distribution, metabolism, and excretion (ADME) of the oxime, TMB-4 (Sterner et al., 2013).

Although PBPK models can be used to predict ADME, they can be expanded to quantitatively describe the compounds pharmacological mechanism(s). Fig. 66.2 shows a schematic representation of the pharmacodynamic processes involved in the interactions between NAs such as sarin with the organism (via AChE inhibition), together with interactions with pretreatments (pyridostigmine bromide [PB]) and countermeasures (oxime, atropine, and diazepam). When this PD submodel is linked to the PBPK model via the simulated concentration of a particular NA or therapeutic in a selected target tissue (i.e., plasma, RBCs, diaphragm, and brain), it provides a framework for describing these biochemical processes quantitatively. Linking it with the PBPK model also puts the biochemical processes into a physiological context. This allows extrapolation of results to multiple species, to description of relevant exposure scenarios to address potential health effects, and to optimization of pretreatment and countermeasure delivery.

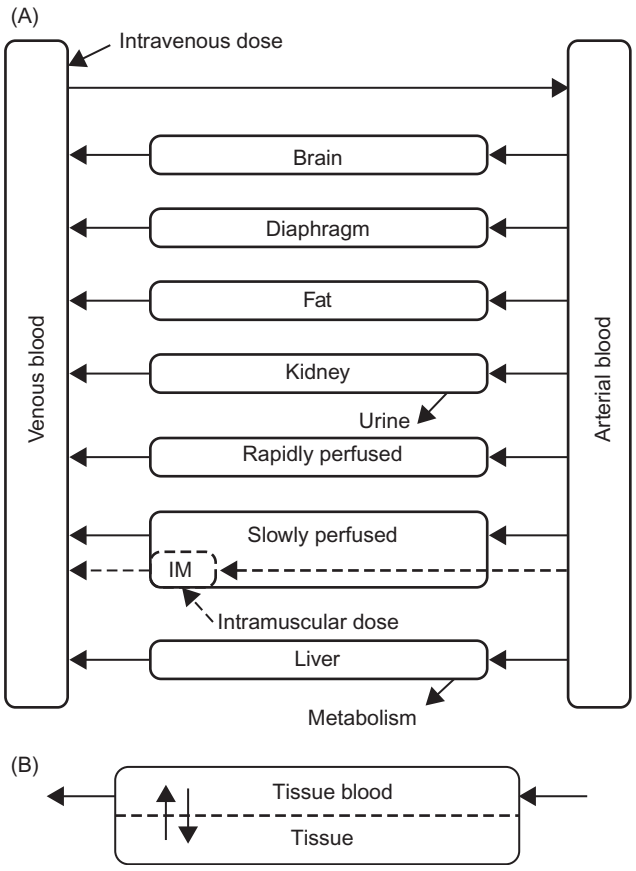

FIGURE 66.1 PBPK model schematic of the distribution of the oxime TMB-4 in rats and humans. Each tissue compartment depicted in schematic A includes diffusion limitation as shown in schematic B (Sterner et al., 2013).

66.7 Experimental and QSAR methodologies to predict blood and tissue partition coefficients

As shown in Fig. 66.1, PBPK modeling utilizes mathematical compartments that conceptually represent the physiology of an organism to depict the pharmacokinetics of chemicals exposed to the body. Traditional PBPK models depend on knowing the partitioning of the agent in key tissues of the organism. The distribution of a chemical within a tissue/compartment is most commonly represented by the following Eq. (66.1) (Krishnan et al., 2001):

$$\frac{dA_t}{dt} = PA\left(CV_t - \frac{C_t}{P_t}\right) \tag{66.1}$$

where A = amount of chemical in the tissue, PA = permeation area cross product for the tissue, CVt = concentration in venous blood emerging from the tissue, Ct = concentration in tissue, and Pt = tissue−blood partition coefficient. Note that $A = Ct \times Vt$, where Vt is the volume of the tissue.

PBPK modeling relies heavily on a proper definition of the partition coefficient because this parameter drives chemical uptake into the tissue. It is generally identified for PBPK modeling as the concentration ratio of the fraction in the tissue to the fraction in the blood at equilibrium (Schmitt, 2008), as shown in Eq. (66.2).

$$P_t = \frac{C_{\text{Tissue}}}{C_{\text{Venous}}} \tag{66.2}$$

The vial equilibration method is the most common in vitro method for determining partition coefficients for volatile or semivolatile materials and has been used most successfully for volatile organic solvents (Gargas et al., 1988). Tissues are harvested from the species of interest and incubated with the test compound until equilibrium is reached between the tissue and the headspace in the vial. The blood/air or tissue/air partition coefficients are given by the ratio of the concentrations of the chemical in the blood or tissue relative to its concentration in the headspace. Tissue−blood partition coefficients are calculated from the respective tissue/air and blood/air values. A number of operational equations have been derived to calculate these ratios under specific experimental conditions. Time to steady state is critical and should be optimized for the test compound. Metabolism of the compound in exposed tissue samples must be controlled. Analysis is performed by gas chromatography in a verified linear range. Human tissues can be obtained from tissue bank organizations to provide species specificity to models developed with human data. To estimate partitions for compounds of low volatility or nonvolatility, the in vitro filtration method of Jepson et al. (1994) can be used. Limitations of all such in vitro methods include issues of how representative the tissue sample is of the often quite heterogeneous tissue in the animal, and how closely the in vitro tissue preparation approximates the in vivo state. In addition, for highly lipophilic compounds, issues related to adsorption of the material onto glass and other surfaces need to be addressed.

Identifying the partition coefficient of a chemical for PBPK modeling is difficult because of the fact that most experimental methods fail to address this proper definition. In vivo methods most commonly track the kinetics of the chemical (radio-labeled or not). However, if enzymes are not properly inhibited, then metabolites can also be tracked instead of the parent compound, leading to contamination of the measured partition coefficient by the more water-soluble metabolite. Experiments are most commonly performed via a single dose at different routes of exposure, rarely leading to the steady state. To reach steady state, a critical point at which measurements should be made, a constant intravenous infusion of a chemical over an extended period of time until the concentration in the blood and tissue becomes constant must

be made. Finally, protein binding is most commonly not accounted for, leading to a total concentration measured instead of the available free fraction. Compounds bound to proteins such as albumin, globulin, and lipoproteins reduce a chemical's tendency to partition into or out of tissues. This can be an extremely important issue depending on the chemical because some are upwards of 90−95% bound in the blood (Poulin and Krishnan, 1996a). These in vivo experimental issues are rarely addressed, which leads to utilization of in vitro measurements where there is greater control of the system.

Because experimental determinations of partition coefficients are slow and expensive, and are fraught with difficulties, particularly for NAs, an alternative is to predict tissue partitioning from more readily available chemical properties (particularly chemical structure), together with key biological properties of the tissue itself, such as its lipid composition, by means of QSAR (Ruark et al., 2008; Sterner et al., 2008). The pharmaceutical industry has utilized QSAR to obtain information of new drug candidates rapidly to help alleviate bottlenecks in the discovery process. A drawback to these models is that they have limited predictive power for scaling across species and to other compounds. However, by utilizing novel mechanistically based methods specifically suited to PBPK modeling, estimations of chemical warfare nerve agent partition coefficient properties can be developed.

Tissue distribution is predicted utilizing a variety of descriptors that range from both chemical-specific to tissue-specific, allowing for universal application of the methods across all species, tissues, and chemicals. A compound's structure and their physiochemical properties, such as the log of the octanol:water distribution (LogP) and the octanol:water distribution mixture of different ionic forms (LogD), are commonly utilized in partition coefficient QSAR, or quantitative structure−property relationships (QSPR) models because they describe the relative affinity for a chemical between hydrophilic and hydrophobic phases. Octanol, being amphiphilic, represents the phospholipid bilayer, which provides a barrier for the cell, separating the extracellular from its intracellular components. However, many studies have shown that octanol is not a perfect surrogate for all lipids within organisms and many are beginning to pursue other surrogates such as vegetable oil and specific phospholipid membranes (Poulin et al., 1999; Schmitt, 2008). Other relevant properties include a wide range of descriptors predicted from ab initio calculations such as H-bonding acidity and basicity parameters, polarity, polarizability, molar refraction, McGowan volume, energies of the lowest unoccupied molecular orbital (E_{lumo}) and the highest occupied molecular orbit (E_{homo}), the maximum positive and negative atomic charge ($\sum Q$), the solvation of free energy (ΔG), as well as many others (Zhang and Zhang, 2006).

As far as tissue characterization is concerned, the fractions of lipid and water tend to be the dominating factors that influence partitioning into or out of the tissue. Some QSPR studies have included proteins that account for an electrostatic interaction with the amino or carboxyl terminal ends of an ionized chemical at physiological pH, as well as some nonspecific binding for neutral compounds. However, a recent QSPR model developed by Schmitt (2008) identified that nonspecific binding to proteins is approximately 40-fold weaker than to lipids. Therefore, proteins may only become of importance for tissues such as muscle and lung that contain a greater fraction of proteins than that of lipids. There have also been attempts at differentiating between phospholipids and neutral lipids (Poulin and Krishnan, 1995a,b, 1996a,b,c; Poulin and Theil, 2000, 2002; Poulin et al., 2001). Rodgers and Rowland (2006, 2007) later differentiated between acidic and neutral phospholipids to account for another electrostatic interaction with ionized chemicals within the tissue. There is also a need to distinguish between tissue and interstitial space, because the interstitial space is highly representative of blood plasma. Other tissue components that may be of interest include DNA, RNA, and intracellular organelles. Binding to DNA appears to be highly correlated with β-blockers; however, the fraction of DNA in tissue is too low to make a substantial difference in the current predictions (Rodgers et al., 2005a,b). Some authors have also suggested differences in intracellular organelle pH as another means of accounting for differences in tissue partitioning for ionized chemicals (MacIntyre and Cutler, 1988; Ishizaki et al.,1996; Daniel and Wojcikowski, 1999; Siebert et al., 2004); however, the overall volume of these organelles in relation to the cytoplasm is very low, most likely not resulting in substantial differences.

Optimization of predictions can be made utilizing linear as well as nonlinear relationships by means of statistical methods to correlate chemical and physiological descriptors to experimental data sets. These statistical methods include multilinear partial least-square analysis, principal component analysis, and neural networking. Many of these tools are included in QSPR/QSAR packages through companies such as Advanced Chemistry Development, SemiChem, EduSoft, BioByte, TOPKAT, MDL, ChemSilico, Pallas, Pharma Algorithms, and others.

A review of the literature will reveal that several QSPR equations have been developed to predict PCs of drugs for use in PBPK models and many are suitable for a wide variety of chemicals. It appears that the greatest deviations in predicted versus experimental measurements of PCs are largely due to an experimental uncertainty or misinterpretations of the data rather than incorrectness of the models. Strategies still need to be developed for other

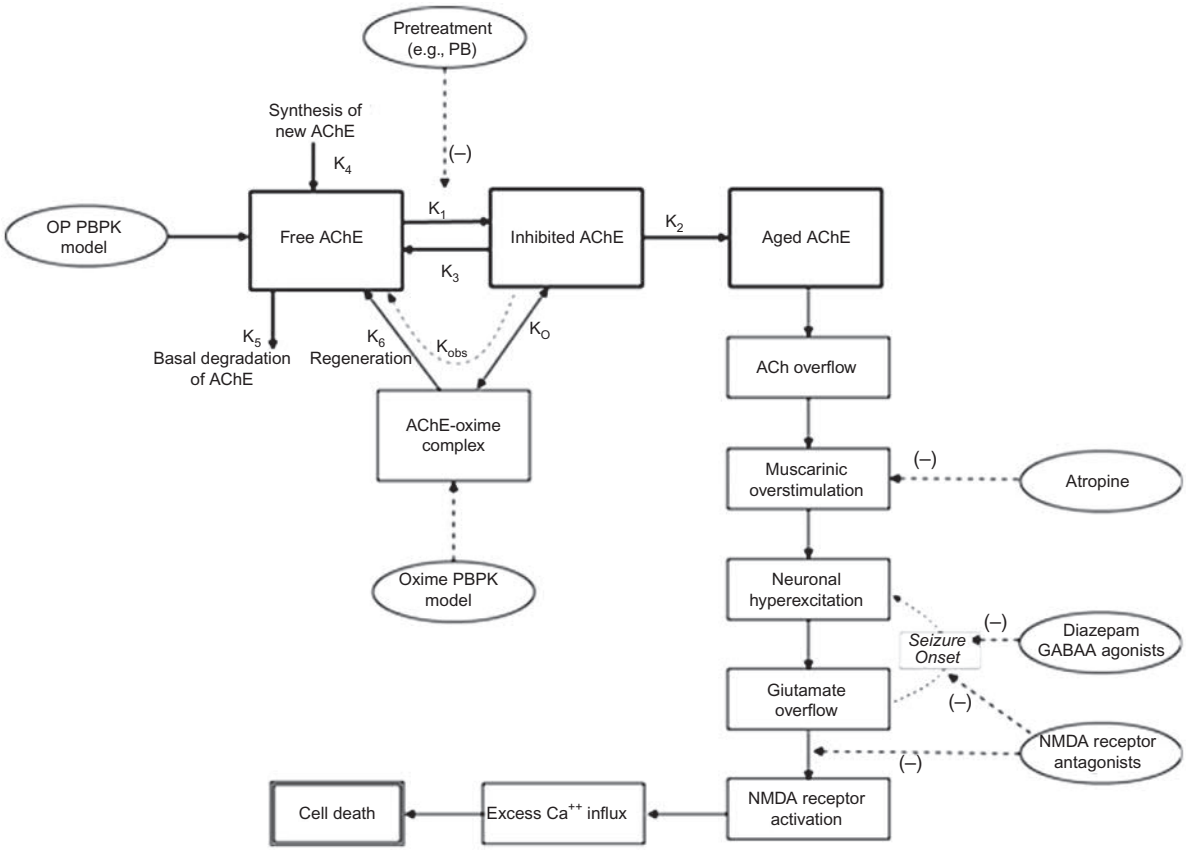

FIGURE 66.2 Schematic for a PD model of AChE inhibition and aging by OPs such as sarin, together with the interaction of pretreatment (pyridostigmine bromide [PB]), and countermeasure treatment (oxime). Pyridostigmine acts as a reversible cholinesterase inhibitor, oxime acts as an AChE regenerator. k_{obs} is an "effective" first-order rate that can be derived as: $k_{obs} = (k_r * [Ox])/(K_D + [Ox])$, when $[Ox] \gg [\text{Inhibited AChE}]$. Potential links for the countermeasures atropine, a muscarinic receptor antagonist, and diazepam, a positive allosteric modulator of the GAB_{AA} receptor and NMDA antagonists, are shown without detailed kinetic interactions.

macromolecular binding (ά-acid glycoprotein) and processes such as blood−brain barrier (BBB) permeation and active transport, but it appears that the methods thus developed are suitable for preliminary PBPK modeling.

66.8 Interaction PBPK/PD model for NAs and countermeasures

As stated, a number of PBPK/PD models have been developed for individual nerve agents (sarin, VX, soman, and cyclosarin) in multiple species. Chapter 58 in the current volume discusses the development of such models. Standalone PBPK or compartmental models have also been developed that describe the pharmacokinetics of certain countermeasures, such as diazepam (Igari et al., 1983; Gueorguieva et al., 2004) and oximes (Stemler et al., 1990; Sterner et al., 2013). However, to date, few models for specific countermeasures have been harmonized and linked to NA PBPK/PD models to be able to quantitatively describe their pharmacokinetic and pharmacodynamic interactions. This is partly due to the fact that most PBPK/PD models developed for NAs and other OPs focus on the inhibition of ChEs as the critical endpoint. The lack of a mathematical description of the disruption of other complex biochemical pathways presents a problem for linking these NA models to those of many countermeasures. For example, the conventional NA countermeasures, atropine and diazepam, as well as many novel countermeasures, do not directly impact ChE kinetics because they act at sites distinct from the active site of the esterases, such as muscarinic, $GABA_A$, or NMDARs (Fig. 66.2).

Interactive models that have been developed and validated exist for countermeasures that compete with NA inhibition of ChE or the regeneration of the free enzyme from its inhibited state, such as pyridostigmine and oximes, respectively. Numerous data in the literature describe the kinetics of interaction between nerve agents (and other OPs) and specific countermeasures at active enzyme sites of concern. For example, Davies and Green (1956) have measured the rate of reactivation of inhibited erythrocyte ChE by various oximes (Table 66.1).

TABLE 66.1 Rate of activation of inhibited erythrocyte ChE by various oximes and hydroxmic acids.

Compound	Inhibitors		
	TEPP	DFP	Sarin
Diisonitrosoacetone	8.4	0.8	24.3
Monoisonitrosoacetone	6.8	0.7	22.1
*iso*Nitrosoacetophenone	10.7	5.1	4.1
*iso*Nitrosoacetylacetone	0.7	NA	1.1
Picolinohydroxamic acid	2.9	0.6	0.2
Micotinohydroxamic acid metabolide	0.3	0.05	0.3

Rates of reactivation are given in L/mol/min.: temp. = 25°C, pH = 7.4.

	2-PAM	0.003	3837	1–5
	HI 6	0.028	1037	0.5–4
	HLö 7	0.011	599	0.3–3

Source: Modified from Worek, F., Thiermann, H., Szinicz, L., 2004. Reactivation and aging kinetics of human acetylcholinesterase inhibited by organophosphonylcholines. Arch. Toxicol. 78, 212–217.

More recently, Worek et al. (2004) determined kinetic rate constants of inhibition, reactivation, and aging for different NAs, pesticides, and oximes with human erythrocyte AChE (see Fig. 66.2 and Table 66.2), as described by the reactions listed here:

$$[E] + [OP] \rightarrow^{k1} [EP]$$
$$[EP] + H_2O \rightarrow^{k2} [EA]$$
$$[EP] + H_2O \rightarrow^{k3} [E] + [OP]$$
$$[EP] + [OX] \leftrightarrow^{kD} [EPOX] k_D \rightarrow^{kr} [E] k_r + [POX]$$

where [E] is the active enzyme (i.e., AChE), [OP] is the organophosphorus compound, [EP] is the reversibly phosphylated AChE, [EPOX] is the Michaelis–Menten-type phosphyl-AChE-oxime complex [EPOX], [OX] is the oxime, [POX] is the phosphylated oxime, and [EA] is the dealkylated, "aged" AChE. The reaction rates used describe the bimolecular inhibition (*k1*), aging (*k2*), spontaneous (*k3*), and oxime-induced reactivation. The dissociation rate, K_D, is equal to the ratio [EP] × [OX]/[EPOX] and (*kr*) represents a first-order rate constant for the displacement of the phosphyl residue from [EPOX], resulting in regenerated enzyme and a phosphorylated oxime.

Hence, both a high affinity of the oxime to the "inhibited" or phosphylated AChE and a high regeneration rate (*kr*) are critical for oxime efficacy. Using in vitro enzyme kinetic constants and in vivo inhibitor and oxime concentrations, Worek et al. (2005) were able to extrapolate the percent of AChE inhibition in humans after sarin or cyclosarin (intravenous) and a simultaneous intramuscular injection of various oximes. Similarly, kinetic models have been developed to predict a dose range of human butyrylcholinesterase (HuBChE) required to maintain an adequate residual RBC AChE level after exposure to sarin, soman, or VX (Ashani and Pistinner, 2004). These and other data sets can be readily integrated into the full PBPK/PD modeling framework, as shown in Figs. 66.1 and 66.2. For example, Fig. 66.3 shows a simulation of RBC AChE inhibition and regeneration in the Rhesus monkey after exposure to sarin, followed by 2-PAM administered at 9 minutes after sarin and produced using the PBPK/PD model for sarin presented in Chapter 58. The lower simulation represents AChE inhibition after sarin exposure alone, whereas the upper simulation was generated by fitting an effective first-order rate constant $\left(k_3^{\text{eff}}\right)$, which can be derived as shown in Eqs. (66.3) and (66.4). Improved simulation of the early time points of AChE regeneration may be achieved through linking the sarin model with a PBPK for 2-PAM, which would capture the distribution phase of the countermeasure as well taking into account its affinity.

$$k_{\text{obs}} = \frac{k_r^*[Ox]}{K_D + [Ox]} \tag{66.3}$$

$$k_3^{\text{eff}} = k_3 + k_{\text{obs}} \tag{66.4}$$

Specific model features relevant to the agent's route of exposure and its biological effect can be incorporated when appropriate, for example, quantitative models for ciliary removal of NAs in the upper respiratory tract

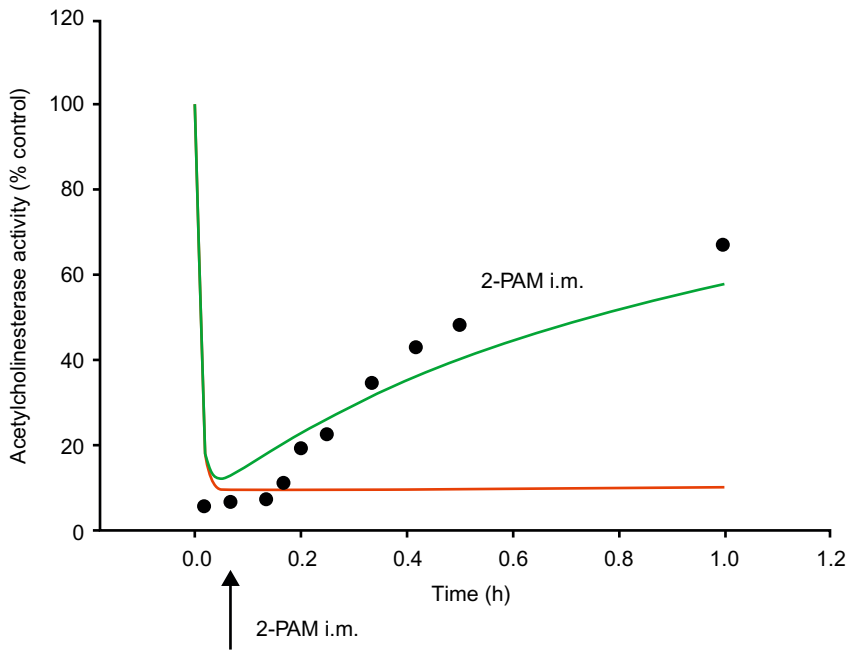

FIGURE 66.3 RBC AChE inhibition in Rhesus monkey after administration of sarin 0.75 LD_{50} (15 μg/kg) intravenous, and with 2-PAM (25.8 mg/kg) administered intramuscularly at 9 minutes after sarin intravenous administration. Atropine was administered (0.4 mg/kg) intramuscularly 15 minutes before sarin administration. The filled circles indicate experimental data (Woodard et al., 1994); the curves show our PBPK model simulations of AChE activity after sarin, both with (upper curve) and without (lower curve) 2-PAM administration.

during inhalation exposure. In addition, it is important to take into account (and incorporate into the model) the limitations of the analytical methods used to quantify circulating and tissue levels of NA, such as the regeneration of NA from its binding sites. For example, it is desirable to model competition for AChE binding sites at erythrocytes and at target sites in the brain; the former because this regenerated NA from RBCs can be interpreted to calculate a measure NA systemic exposure and the latter, of course, because of the health impact. In general, the PBPK models can be linked via interaction processes at target sites.

Pharmacokinetic/PD models have been developed and used to predict the pharmacological effect of seizure activity for several anticonvulsants for which drug receptor kinetics were available from either in vitro or ex vivo binding studies. Diazepam, an agonist of the $GABA_A$ receptor, is among the NA antidotes, for which pharmacodynamic impact on electroencephalogram (EEG) activity has been modeled. Dunhof et al. (2007) have developed compartmental kinetic models for various anticonvulsants and modeled their ligand receptor pharmacodynamics. EEG parameters have been used as pharmacodynamic endpoints (Tuk et al., 1999; Van der Graaf et al., 1999; Bueters et al., 2003; Dunhof et al., 2007). These receptor binding models predict changes in receptor binding and pharmacodynamics as a function of changes in the pharmacokinetics of the ligand as described in Eq. (66.5):

$$E(C) = E_{\mathrm{maxA}} \cdot \left(\frac{C_{\mathrm{A}}^{\mathrm{N}}}{K_{\mathrm{A}} + C_{\mathrm{A}}} \right) \tag{66.5}$$

When $E(C)$ is the observed effect at concentration C, E_{max} is the maximal effect (based on EEG components), K is the concentration at half-maximal effect, and N is the Hill factor, a constant expressing the sigmoidicity of the concentration−effect relationship. Subscripts A refer to the specific ligand of a ligand-gated ionotropic receptor.

Unfortunately, the impact of anticonvulsants on NA-induced seizures has not been modeled in this way. Given that many countermeasures have different ligand receptor interactions, such an approach would need to be expanded to the other excitatory and inhibitory neurotransmitters and their respective receptors, which are involved in seizure induction and sustainment. However, validation of such an approach, using components of gross EEG recordings, may not be plausible because of the large number of ionotropic channels represented. An endpoint such as sustained elevated glutamate may be more appropriate.

In addition, many target receptors undergo rapid changes in their level of expression during status epilepticus. $GABA_A$ receptors are undergoing rapid internalization, whereas AMPA and NMDARs are increasing at excitatory synapses, aggravating the loss of inhibitory tone (Naylor et al., 2005; Naylor, 2010). Fig. 66.4 illustrates a basic model of $GABA_A$ receptor trafficking that can be developed into a full PBPK/PD model to include time-critical changes in target receptor activity (Merrill, 2012), leading to benzodiazepine pharmacoresistance. Such a model could be expanded to include other therapeutic targets, such as the NMDAR; when linked with

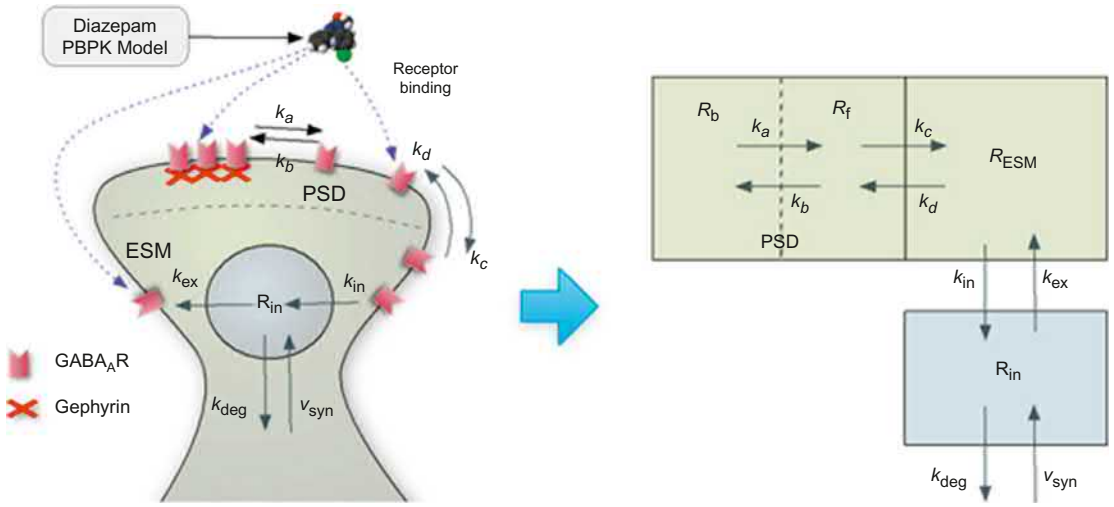

FIGURE 66.4 Simplified model of GABA$_A$R trafficking. *Rb* and *Rf* represent surface GABA$_A$*Rs* within the PSD that are either bound to scaffolding proteins or free, respectively. R_{ESM} represents extrasynaptic GABA$_A$Rs and R_{in} represent internalized receptors. First-order rates are used to describe binding (*kb*) and unbinding (*ka*) of receptors to scaffolding proteins within the PSD, lateral movement between the synaptic and extrasynaptic membrane (*kc* and *kd*), internalization (k_{in}), recycling and membrane insertion (k_{ex}), and degradation (k_{deg}). Synthesis of nascent receptors is described with a zero-order rate, V_{syn}. *Adapted from Merrill, E., 2012. A Mechanism-Based Model to Describe GABAA Receptor Trafficking and Benzodiazepine Pharmacoresistance during Status Epilepticus. (Electronic Dissertation). Retrieved from: <https://etd.ohiolink.edu/>.*

PBPK models for the corresponding therapeutics, they can be used to optimize dosing based on the time from onset of status epilepticus.

Although the receptor targets of various NA countermeasures vary distinctly, be they ion channel-linked, G-protein-linked or enzyme-linked, their pharmacodynamic effects often converge on the final steps leading to the disruption of intracellular Ca^{2+}, beyond which cell death is inevitable. Hence, ultimately, a systems biology approach may provide the best predictions of countermeasure efficacy, especially for modeling long-term low-level effects. The Systems Biology Markup Language (SBML) project is an effort to create a machine-readable format for representing computational models in biology. SBML provides an input and output format, so that different software tools can operate on the same representation of a model, removing chances for errors in translation. SBML also provides convenient model databases, such as Biomodels (www.biomodels.net) for sharing these models. Neural Open Markup Language (NeuroML) similarly facilitates building, simulating, testing, and publishing of models describing channels, neurons, and networks of neurons. Future integration, via a common computational language, of these molecular and cellular level models with PBPK models will permit the development of multiscale models that will link external exposure and tissue dosimetry with NA-induced neurotoxicity. This multiscale approach is necessary for quantitative assessments of the health risks associated with NA exposure.

66.9 Health effects assessment and countermeasure optimization

Once validated, PBPK/PD models can be used to predict efficacy of specific countermeasures, countermeasure combinations, and dosing regimens for specific NAs and combinations thereof. To do so, appropriate measures of efficacy need to be defined. Perhaps the simplest way to estimate the effectiveness of a particular countermeasure is to determine the degree of a receptor activation *at the target site of concern* (e.g., brain or brain region) at a certain time or period of time after the administration of the countermeasure(s), compared with the situation in which no countermeasure is administered. Expressed as a simple ratio, countermeasure effectiveness (CE) may be written in terms of the time-weighted average concentration (from time $t = T_1$ to $t = T_2$) of receptor occupancy (obtained from the PBPK/PD model):

$$\mathrm{CE} = \frac{\int_{T_1}^{T_2} [E]_c \mathrm{d}t}{\int_{T_1}^{T_2} [E] \mathrm{d}t}$$

Here, the numerator is calculated by running the model in the presence of the countermeasure, whereas the numerator is obtained in the absence of countermeasures. The ratio CE can be calculated under a variety of countermeasure dosing regimens to determine an optimum for each specific NA exposure scenario. Clearly, if such an exploration of countermeasure effectiveness were to be conducted experimentally, without the benefit of

modeling, then it would be prohibitively expensive and time-consuming, thus demonstrating the usefulness of the modeling. The information obtained in this way would provide a rational basis for designing countermeasure delivery systems for optimized effectiveness. Ultimately, such an approach would also aid in the design of novel countermeasures, either to be used alone or to be integrated into an optimized countermeasure delivery "package."

A separate, although related, application of the proposed modeling approach is the development of meaningful therapeutic animal models based on rational animal to human scale-up. In such an application, dosing regimens for existing countermeasures and countermeasure combinations, and particularly novel countermeasures, can be tested in experimental animals with the knowledge that the results obtained can be extrapolated to humans by taking into account the appropriate species differences incorporated into the models.

66.10 Concluding remarks and future directions

It can be expected that, in the near future, PBPK/PD models will be developed that can predict the interaction between mixtures of NAs and countermeasures and their opposing pharmacodynamic effects. Validation of such complex modeling efforts is data-intensive and will rely on compilation of existing in vitro, in vivo, and ex vivo data. Unfortunately, the majority of toxicological studies of NAs measure lethality, with little or no additional collection of time-course data of pharmacodynamic endpoints. Similarly, interaction studies between NAs and antidotes often measure only efficacy in terms of a reduction in cell death. This is understandable because of the difficulty and cost in measuring these NAs in biological matrixes and the large number of animals involved in collecting time-course data. Measurements of neurotransmitter changes after OP and countermeasure exposures are very difficult, and often there is uncertainty in deciding which biomarker is most predictive of an effect that is not easily quantifiable, such as cognitive deficits. PK/PD analyses may not always be possible if the relationships between the input (the concentrations of the NA and countermeasure) and the output become too indirect. However, it should always be remembered that even without formal concentration–effect analyses, there is always much to be gained if a pharmacological countermeasure test is performed with intensive sampling of PK and PD parameters. Differences in PK/PD parameters give quantitative information about different neurotransmitter systems in the central and peripheral nervous systems, which cannot be distinguished by pure statistical group comparisons. PK/PD analyses largely eliminate pharmacokinetic variability and provide detailed and functional characteristics of pharmacological systems in the brain or other target organs.

With specific regard to finding novel therapeutics for preventing or ameliorating NA-induced brain damage, PBPK/PD modeling provides a means to extrapolate experimental findings in animals to humans. Differences seen in the efficacy of different therapeutics may sometimes be explained by pharmacokinetics. Perhaps the therapeutic dose reaching a critical tissue, such as the diaphragm, heart, or brainstem is too little, too late, or not long enough. In addition, many of the animal toxicity studies performed to assess the efficacy of a therapeutic against NA measure a biomarker, such as cell death within 24 hours from NA exposure. Biomarkers measured at 24 hours may not always be indicative of outcome. Whether any protection seen at that point would still remain if the biomarker (e.g., cell death) were measured days, weeks, or months later then remains unknown. For example, damage seen in thalamus at 24 hours might later extend to areas with which it has strong reciprocal connections, such as the cerebral cortex. Finally, in the quest for antidotes that may rescue one from cognitive deficits later, when realistically administered beyond the time when the glutamatergic phase takes control of seizure activity (i.e., >40 minutes after NA exposure), predicting biomarkers that indicate the promotion of physiological balance in the brain, rather than the attenuation of seizure activity, may become the most important endpoints for predicting the efficacy of novel countermeasures.

Given the unsustainable cost and time involved in bringing novel therapeutics to market, the use of quantitative techniques to improve countermeasure development are being used increasingly more. Several opportunities exist in drug development, which could lead us on a more direct path toward finding suitable countermeasures, for example, more complete integration of the available knowledge of therapeutic candidates early in their development using PBPK/PD model(s) for NAs and countermeasures together. This should be started early, in the preclinical phases of drug development. Extrapolation of animal PBPK/PD models to humans for simulating initial clinical trials should be preformed to evaluate the design of proposed clinical trials of a drug development plan, and to provide proof of concept. This ability to mathematically explore various exposure–response relationships of NA(s) and countermeasure(s) is useful for designing optimal countermeasure regimens and identifying the limits of the therapeutic window after NA exposure. Uncertainty analysis of the parameters of the model may identify biomarkers that may be critical in describing the data. Ways of defining and decreasing the uncertainty in efficacy and safety (risk assessment) in the drug and disease model are needed.

Finally, the mechanisms (e.g., diffusion-limited transport, receptor binding, protein upregulation or desensitization) described in a particular NA countermeasure model should be updated as new information is generated, thereby using the models as knowledge management tools. Thus, modeling the PK/PD of neuroprotectants in the presence of NA may provide direction and guidance early during clinical development, when there is opportunity to change direction and plans.

The information in this chapter is provided for educational purposes only and does not necessarily represent endorsement by, or an official position of, the National Institutes of Health or any other Federal agency.

67.1 Introduction

Chemical warfare agents (CWAs) are highly toxic chemicals that have been used in military conflicts, beginning in World War I and continuing in more recent conflicts in Syria (Sellström et al., 2013) and during the Iran−Iraq War in the 1980s (Haines and Fox, 2014). Since the 2001 terrorist attacks in the United States, there has been an increased effort to better prepare for the potential deployment of biological, radiation/nuclear, and chemical weapons against civilian targets. Underscoring these concerns are events surrounding the use of the CWAs sarin and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methyl phosphonothioate (VX) by the terrorist organization Aum Shinrikyo against Japanese civilians in the 1990s (Vale, 2005; Yanagisawa et al., 2006). These concerns were reinforced when sarin was deployed against civilians in the suburbs of Damascus, Syria, in 2013, during the Syrian civil war (Dolgin, 2013). The US Department of Health and Human Services (HHS) and other federal agencies have developed and sustained a highly focused effort to assess, and if necessary, improve current emergency response capabilities in the event of a terrorist event. These efforts include both preventative capabilities such as personal protective equipment (PPE) for first responders who must enter a contaminated site, and medical response capabilities, such as safe and effective treatments and diagnostic tools to reduce mortality and morbidity after a chemical attack.

Medical countermeasures (MCMs) for mass casualty chemical events are also important for large-scale industrial accidents and general poisonings (Table 67.1). The 1984 Union Carbide industrial accident in Bhopal, India, released 40 metric tons of methyl isocyanate and resulted in over 3000 deaths. Transportation of toxic chemical can often lead to accidents such as the train derailments and leakage of chlorine (Fig. 67.1). Additionally, there is an exceedingly large number of general chemical poisonings from nonoccupational exposures. The Poison Control Centers in the United States receive millions of calls each year due to unintentional human exposures and poisonings. Taken together, chemical exposures from warfare, terrorism, industrial accidents, and general poisoning account for a large burden of illness and the availability of safe and effective medical treatments for these toxic exposures is a global unmet need.

CWAs can generally be divided into four broad categories: traditional nerve agents, such as sarin and VX; vesicating agents, such as sulfur mustard; pulmonary agents, such as chlorine and phosgene; and metabolic poisons, such as cyanide. Detailed descriptions of medical interventions for each of these CWAs can be found elsewhere in this book. The civilian chemical threat spectrum includes CWAs, toxic industrial chemicals (TICs), such as hydrogen sulfide, pesticides, such as parathion and brodifacoum, and pharmaceutical-based agents such as opioids. There are many other agents that pose a threat to civilians because of their toxicity and availability. Antidotes that are specific to a chemical will need to be developed, however, many of these chemicals can be grouped based on acute effects and pathologies they have in common, so that the therapeutics being developed will have a broader spectrum of activity, that is, efficacious

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00067-2

TABLE 67.1 Mass casualty chemical events.

	Examples
Chemical warfare	• World War I and II: thousands of fatalities • Iran–Iraq War (1980–88): thousands of fatalities • Current conflicts in the Middle East: unknown
Terrorism/nonmilitary malicious use	• Tokyo Subway Attacks (1995): thousands affected; 13 fatalities • Jonestown mass suicide (1978): 900 fatalities (TimeInc., 1979) • Tylenol and Excedrin poisonings (1980s): few fatalities
Industrial accidents	• Common occurrence; thousands of injuries and fatalities annually • Bhopal Union Carbide disaster (1984): 5000 fatalities
General poisonings	• Over 2 million calls to Poison Control Centers for human poison exposures each year (Poison Statistics National Data, 2016)

FIGURE 67.1 Train wreck and chlorine spill in Graniteville, SC, in 2005. *Accessed from www.cen.online.org, June 23, 2008.*

against more than one chemical threat. Chemical toxidromes have been developed (Ciottone, 2018) which include acetylcholinesterase (AChE) inhibitors, asphyxiants, anesthetics, caustic agents, blood agents, pulmonary agents, and opioids. Several antidotes under study (see below) show promise as being effective for more than one chemical threat.

67.2 Medical countermeasures used in civilian chemical incidents

Medical interventions must be appropriate for a diverse civilian population, and treatment strategies must be based on the toxicokinetics and pharmacokinetics of the chemical threat and the therapeutic agents, respectively. Most, but not all, chemical threat agents are fast-acting lethal poisons that lead to rapid cardiopulmonary arrest. However, exposure to these agents during a mass casualty event would likely lead to an exposure level gradient ranging from lethal doses close to the point(s) of release, to low-level exposures that are not toxic at all. The resultant opportunity for effective medical intervention is among those individuals that survive the immediate lethal effects until first responders arrive, and those who receive sublethal exposures but still need medical attention. These opportunities will depend on the route of chemical threat exposure and the method of drug delivery. How a toxic chemical enters the body often determines the time window for possible medical intervention, which is often very short. Thus, treatments must be administered easily and rapidly in a situation involving mass casualties. Both immediate and long-term effects of exposure to chemicals must be understood to ascertain whether treatments are needed and whether they can be developed. Drugs should be chemically and physically stable so that they are amenable to prepositioning and stockpiling, and pretreatments for first responders to a contaminated site should be considered, especially when decontamination is impossible.

If the action at the target site of the chemical agent does not cause immediate death, there are several strategies that can be employed to reduce the impending morbidity and lethal effects of chemical threat agents. While many of the effects will be treated symptomatically to restore cardiopulmonary function or other effects such as chemical burns and ocular damage, there are some specific treatments for nerve agents and cyanide available. Most nerve agents of concern are organophosphorus (OP) CWAs such as sarin, VX, tabun, and soman, or OP pesticides like parathion and chlorpyrifos. These agents inhibit AChE and cause an excess of the neurotransmitter acetylcholine (ACh) that causes overstimulation of cholinergic receptors. For OP nerve agents and OP pesticides, acute poisonings are treated with atropine sulfate to inhibit peripheral and central muscarinic effects, and pralidoxime chloride (2-PAM) to reactivate inhibited AChE. Atropine

blocks muscarinic cholinergic receptors in the parasympathetic nervous system to reduce excessive secretions and smooth muscle contraction (Jett and Spriggs, 2018). It does not have a significant therapeutic effect for central nervous system (CNS) toxicity, nor does it appear to work well at cholinergic synapses on skeletal muscle. Prolonged seizure activity (status epilepticus) after exposure to OPs is controlled by the benzodiazepine anticonvulsant diazepam, or the recently FDA-approved similar drug, midazolam (Seizalam).

There are two FDA-approved cyanide antidotes currently available: Cyanokit (hydroxo-cobalamin) and Nithiodote (sodium nitrite and sodium thiosulfate). Additionally, there is a third treatment, amyl nitrite, which has traditionally been packaged with sodium nitrite and sodium thiosulfate as the Cyanide Antidote Kit. Cyanokit and Nithiodote require intravenous administration by trained personnel. While these antidotes are effective for single cyanide poisonings, better antidotes for mass casualty events are a current unmet need. The first medical product in the United States for use on certain injuries caused by sulfur mustard was cleared recently. The product, Silverlon, can be appropriate for use on first- and second-degree skin burns caused by exposure to sulfur mustard. While there are no FDA-approved drugs for chlorine and other pulmonary agents, research is ongoing with several promising therapeutics. There are no other treatments specifically for other chemical threats, including the many toxic industrial and agricultural chemicals, as well as pharmaceutical-based agents that could be used in mass casualty civilian events.

Military research on the effects of the OP nerve agents and mustard gases has been ongoing for several decades since their discovery and use in past wars. This work, along with efforts in the nonmilitary research community, has led to the development of useful therapeutics and diagnostic tools primarily for use to protect soldiers on the battlefield. Of particular note are the development of more effective PPE, prophylactic drugs such as pyridostigmine bromide (PB) that reversibly binds to AChE (Haigh et al., 2005), and portable antidote kits like the MARK-1, Antidote Treatment Nerve Agent Autoinjector (ATNAA), and Duodote autoinjectors (Henretig et al., 2002). While there is mostly overlap in military and civilian research, there are some key differences. First, the typical soldier is fit and healthy and between the ages of 18−45, whereas the civilian demographic is much broader, including pediatric and elderly people, pregnant women, and individuals with preexisting medical conditions such as asthma, heart disease, and diabetes. These factors are extremely important when deciding the specific type and dosage of treatments that can be administered during a civilian chemical emergency. Fortunately, some military countermeasures can be adapted to special populations such as children (Baker, 2007; Rotenberg and Newmark, 2003). Second, there is a greater need for pretreatments for soldiers who enter into conflicts where chemical weapons are a possible threat. For the purpose of this chapter, we define pretreatments as those medical countermeasures to be administered before exposure. For both civilian and military events, personnel who would be pretreated with medical countermeasures include first responders, such as emergency medical technicians and persons responsible for site decontamination.

Emergency department medical personnel, who are likely to treat individuals shortly after a chemical incident, may also require pretreatment to prevent incapacitation from exposure to residue and off-gassing of CWAs from patients. These secondary exposures could be deadly and lead to more loss of life, both during and after an event. In theory, prophylactic drugs would be administered in conjunction with proper PPE to first responders before they enter a "hot zone." However, depending on the possible adverse effects and pharmacokinetics of the proposed drugs, there may be some operational difficulties in the implementation of a prophylaxis program. For example, compliance by otherwise healthy individuals may present an issue if there are potential side effects. These potential side effects that may occur when a countermeasure is administered to otherwise normal and unexposed individuals illustrate the importance of favorable safety profiles, especially if the intended indication is for prophylaxis use. Side effects in first responders and care providers could compromise their ability to respond effectively to chemical events involving civilians or to execute the military mission. The only pretreatment currently approved by the FDA for nerve agents is PB, which was first approved for treating myasthenia gravis and is now approved for treating intoxication by soman only. It is to be used by military troops at high risk of exposure to soman on the battlefield. PB is a reversible inhibitor of AChE and protects it from permanent inhibition by soman.

67.3 Research needs for civilian medical countermeasures

The current standard of care for nerve agents is effective, but there are some areas for improvement. For nerve agents, administration of 2-PAM will succeed only if irreversible covalent modification of the nerve agent + AChE complex has not occurred (a process called aging). Unaged AChE enzyme is thus restored to the active state and can continue the hydrolysis of ACh. If the enzyme complex is aged, then 2-PAM is totally ineffective and the nerve agent soman is a good example where rapid aging prevents 2-PAM from being useful. There is a need

to find better AChE reactivators, and those that have better penetrance of the blood–brain barrier to reverse the seizures associated with these compounds. Atropine is effective for blocking the overstimulation of cholinergic receptors in the periphery but less so in the CNS. Centrally acting cholinergic receptor antagonists are needed that have a favorable distribution in the CNS. Anticonvulsants such as midazolam and diazepam are used to prevent or treat seizures, but seizures can become refractory to these treatments and spontaneous recurring seizures often occur (Guignet et al., 2019). Whether there is sufficient time after an exposure to the CWA for a therapy to be beneficial depends on the initial effective dose. This determination is based on several factors, including the initial level of the agent released, proximity to the point of release, route of exposure, and duration of exposure. If the effective cumulative dose is low, the risk of an acute, life-threatening intoxication will likely not be an issue, but there is significant evidence that acute sublethal exposures to chemical nerve agents may be associated with long-term neurological sequelae. For example, the US National Toxicology Program concludes that acute sarin exposure is "known to be a neurological hazard to humans" based on a comprehensive unbiased systematic review of the long-term effects of sarin (NTP, 2019). These gaps in the overall treatment of OP nerve agents and pesticides are topics of current research.

Victims exposed to a sublethal concentration of the fast-acting poison cyanide are treated with ventilation and supportive care to delay mortality and morbidity until they can be taken to medical facilities. New and improved antidotes should have the following essential characteristics: (1) they can be administered by minimally trained individuals, possibly with intramuscular autoinjectors, oral, intranasal, or inhalational administration, (2) have a rapid onset and long duration of efficacy, (3) efficacy for all forms of cyanide and routes of cyanide exposure, (4) have a ready-to-use antidote not requiring preparation in the field, (5) stable for storage of many doses, and (6) be cost effective. Current research on better cyanide antidotes includes basic mechanistic research to discover targets, through preparing candidate therapeutics for advanced development and ultimate FDA approval and licensure. Cyanide research can be categorized as either cyanide-based or host-based. Cyanide-based research includes agents that bind cyanide and remove it from circulation, while host-based research focuses on the detoxification of cyanide by increasing its metabolism and elimination, or by direct interaction with targets of cyanide and other mechanisms that prevent or ameliorate acute and chronic toxicity. Special consideration is being given to alternate routes of administration and/or dosing regimens for new or already FDA-approved therapies that would be safer, more effective, or easier to administer during a mass casualty scenario. Specific subpopulations (e.g., pediatric and pregnant) that are more vulnerable are also a priority for civilian exposures. Finally, clinical efficacy studies are rare because of the obvious ethical challenges, however some studies may be possible in people who are exposed to cyanide accidentally, for example from smoke inhalation.

Another important area of research is to identify new approaches to mitigate the pulmonary edema that typically develops after lung injury caused by agents such as chlorine and phosgene. Some agents, such as chlorine and sulfur mustard, may also cause delayed toxicity after initial exposure or long-term pulmonary effects (such as fibrosis) years later (Wolfe et al., 2019). Therefore, medical interventions aimed at improving the long-term health outcomes of nonlethal exposures to pulmonary agents are also critical. Since the immune responses observed in the pulmonary system after sulfur mustard or TIC exposure share similar characteristics, it is likely that therapeutic drugs that prevent, slow, or halt the processes of inflammation and subsequent cellular damage are desired. While sulfur mustard is rarely fatal after acute exposure, treatments that reduce vesicant damage to the skin and initial injury to the lung are a priority.

The last area of research needed is basic mechanistic research with the many emerging chemical threats to civilians, including TICs and pharmaceutical-based agents. For many of the TICs, little is known about their toxicity mode of action and potential targets for therapeutic intervention. The need for good natural history models is important for determining how and when to administer potential treatments. The opioid crisis and the availability of these highly toxic drugs calls for research on MCMs that would be appropriate if they were used in deliberate attacks or accidental releases resulting in mass casualties. The research might include industrial accidents, natural disasters causing casualties, or deliberate attacks against civilians. Examples of research needs include safety and efficacy studies of naloxone and other FDA-approved drugs for use against fentanyl and its derivatives, especially as it relates to respiratory depression, and when these opioids are administered by a method consistent with a deliberate attack (e.g., aerosolized, in food or water, etc.). There may be other opioid overdose antidotes with greater safety and efficacy than naloxone and other FDA-approved drugs to match the higher potency of fentanyl analogs. Antidotes with longer half-lives so that multiple doses are not needed in rapid succession are also needed.

67.4 Research at the National Institutes of Health in the United States

The NIH Countermeasures Against Chemical Threats (CounterACT) program is part of the larger NIH Biodefense program and part of the HHS Public Health

Emergency Medical Countermeasures Enterprise (PHEMCE), which coordinates medical countermeasures-related efforts across the Department of Health & Human Services (HHS) and other US Government partners. The overarching goal of the CounterACT program is to integrate cutting-edge research with the latest technological advances in science and medicine to enhance the nation's medical response capabilities during chemical emergencies. This is a trans-NIH effort, involving partnerships with the National Institute of Neurological Disorders and Stroke (NINDS), the National Institute of Environmental Health Sciences (NIEHS), the National Eye Institute (NEI), the National Institute on Drug Abuse (NIDA), the National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS), the Eunice Kennedy Shriver National Institute of Child Health and Human Development (NICHD), the National Heart Lung Blood Institute (NHLBI), and the National Library of Medicine (NLM) to execute the overall NIH Strategic Plan and Research Agenda for Medical Countermeasures Against Chemical Threats. The CounterACT program employs a strategy of collaboration and partnership, it supports research aimed at the discovery and identification of better medical countermeasures, and guides their movement through the regulatory process in cooperation with other federal departments, agencies, and initiatives, such as the Biomedical Advanced Research and Development Authority (HHS BARDA), FDA Medical Countermeasures Initiative (MCMi), and the Defense Threat Reduction Agency (DoD DTRA).

NIH CounterACT has brought together the expertise of researchers in chemical warfare and a vast pool of NIH-funded experts in scientific areas that are relevant to the central questions being posed in the field. For example, if untreated, chemical nerve agents can cause seizures and neuropathological sequelae, conditions that share molecular mechanisms and phenotypes with many neurological illnesses such as epilepsy and stroke. These disorders are research areas that the NIH has supported for decades, and this has provided an unprecedented opportunity for CounterACT to engage researchers and neurologists in these fields. The partnership between HHS and DoD facilitated by CounterACT has led to effective collaborations among scientists who otherwise would rarely interact and produced promising, novel approaches in the development of medical chemical countermeasures. Research within CounterACT has resulted in the transition of several lead compounds to advanced development and FDA approval, as well as numerous publications in some of the most prestigious scientific journals (see www.ninds.nih.gov/counteract).

67.5 Contract core facilities

The overarching NIH Chemical Countermeasures Research Program (CCRP) is a trans-NIH initiative that includes both formal and informal collaborations with the NIH CounterACT program and its participating NIH institutes and centers. The NIH National Institute of Neurological Disorders and Stroke (NINDS) CounterACT program is the lead institute for the program. Oversight of the program is provided by the National Institute of Allergy and Infectious Diseases (NIAID), which manages the Biological Defense Program, the Radiological/Nuclear Program, as well as the Chemical Defense Research Program. The program supports an extensive extramural portfolio of academia, industry, and government research organizations. The portfolio includes research centers of excellence, individual research projects, contracts, support services, and Interagency Agreements (IAAs) with the DHHS and the Department of Defense, specifically the US Army Medical Research Institute of Chemical Defense (USAMRICD), US Army Combat Capabilities Development Command Chemical Biological Center (CCDC), and the Defense Technical Information Center (DTIC).

The NIH Chemical Countermeasures Research Program provides no-cost support services to investigators whose products show promising results as potential medical countermeasures in preliminary testing. These services include the CounterACT Neurotherapeutics Screening Program. This program identifies novel neurotherapeutics that may be administered with approved standard-of-care treatments to more effectively suppress status epilepticus activity and/or mitigate neuropathology after OP agent exposure. The services also include the CounterACT Efficacy Research Facility (CERF), which conducts pilot studies to characterize novel models of lethal and nonlethal effects. The facility obtains independent confirmation of product efficacy in validated small or large animal models of chemically induced toxicity. The CounterACT Preclinical Development Facility (CPDF) conducts non-Good Laboratory Practice (GLP) preclinical studies to characterize and optimize hits identified early in the discovery and development process. Lastly, the CounterACT Ocular Therapeutics Screening (COTS) Program conducts pilot studies to evaluate the efficacy of investigational MCMs against the acute and/or chronic effects of eye exposure to sulfur mustard. The chief purpose of these support services is to assist applicants and researchers in obtaining important proof-of-principle efficacy and/or preclinical data in support of subsequent research applications. An important mission of the NIH Chemical Countermeasures Research Program is to offer guidance to academic, commercial, and government investigators on the use of the NIH Core Facilities, and the grant application process. The NIAID CCRP/NINDS CounterACT program encourages investigators to contact the CCRP and/or CounterACT program staff for advice and guidance on how to advance potential models and therapies

from the initial idea, through the basic research and discovery stages, and forward into the early phases of product development.

67.6 Scope of research

The NIH CounterACT program focuses on basic and translational research on the development of novel therapeutics that will enhance medical response capabilities against chemical threats during an emergency to decrease morbidity and mortality of the civilian population. The emphasis of research is on identifying and optimizing lead compounds that are effective when administered after a chemical exposure has occurred (postexposure efficacy). Countermeasures that are only effective when administered prior to the chemical insult (prophylaxis efficacy) are of lower priority to the program. Therapeutics to prevent long-term or delayed chronic effects after an acute exposure, such as those to be administered after evacuation from the exposure site or during in-hospital care, are also within the purview of the program.

The scope of the research supported by the CounterACT program includes basic research to identify molecular mechanisms of acute toxicity, target and candidate identification and characterization, and lead candidate optimization through the development of appropriate human-relevant models (Fig. 67.2). The primary goal of this effort is to develop models of lethality and serious morbidity consistent with real-life civilian mass casualty scenarios. Using these models, the program supports the generation of in vivo, non-GLP toxicity, pharmacology, and efficacy studies consistent with the product's intended use in humans.

The NIH CounterACT program not only supports the discovery of novel compounds with requisite therapeutic activity and acceptable safety profiles, but also alternate routes of administration for FDA-approved therapeutics that would be safe and more effective to administer during a mass casualty scenario (e.g., intramuscular injection, etc.). Special consideration is given to research that is relevant to populations who are particularly vulnerable, including the young, the elderly, pregnant women, and individuals with preexisting medical conditions. Children and pregnant women, for example, have been shown to be much more sensitive to the toxicity of some CWAs and therefore, may require specialized medical management after exposure (Wright et al., 2016). Consequently, animal models and studies that address these vulnerabilities, as well as long-term effects after an acute exposure are of interest to the program.

67.7 Research on medical countermeasures for civilian chemical threats

Most of the research supported by CounterACT has been with OP CWAs or toxic pesticides. Centrally acting oximes that are more effective after aging of the AChE−OP complex have been the holy grail of OP medical countermeasures research for many years. Also, a big challenge with the use of 2-PAM is that it does not penetrate the blood−brain barrier very well, and its efficacy is controversial (Blumenberg et al., 2018). Novel centrally acting compounds based on substituted phenoxyalkyl oximes show promise in rat models using sarin and VX surrogates (Chambers and Meek, 2019). Reactivation of AChE is a complex problem and translational research in the

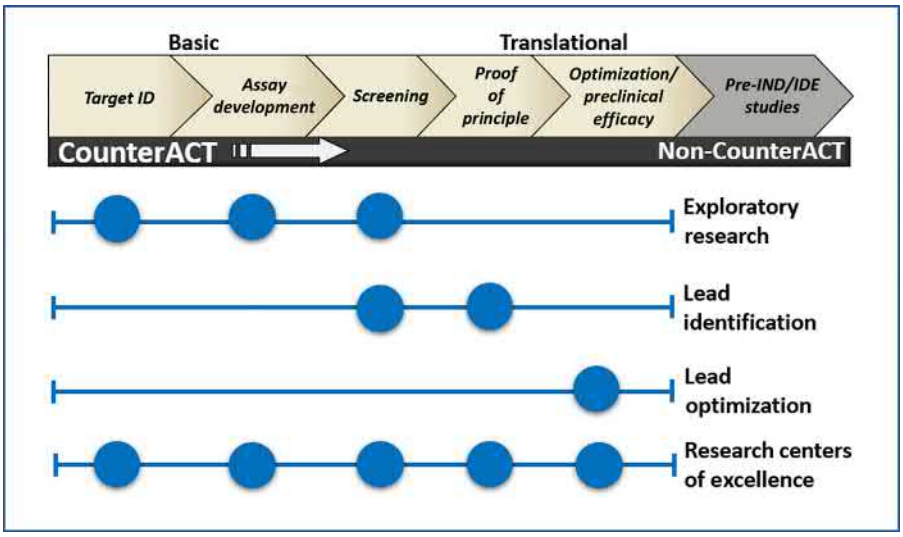

FIGURE 67.2 The NIH CounterACT program funds research across basic and translational science. Basic mechanistic research to identify targets for therapeutic development through lead compound identification and optimization is supported by the various programs. Optimized lead compounds are then poised for advanced development and FDA approval.

neurological research part of the NIH CounterACT program is supported by basic research to help study mechanisms of chemical agent toxicity and how antidotes work. For example, molecular events can now be studied by dynamic imaging in living systems with positron-emission tomography (Thompson and Gerdes, 2019). With regard to seizures, some research suggests that refractory SE caused by OPs may be controlled with a polytherapy approach targeting multiple neurotransmitter systems, rather than midazolam alone (Niquet et al., 2019). Likewise, the glutamate receptor antagonist LY293558 has shown significant promise as a new treatment for recurring seizures and behavioral effects caused by soman, and this is potentiated with the addition of caramiphen (Aroniadou-Anderjaska et al., 2019).

There is also substantial human and animal study evidence that lasting effects may occur in people who survive the acute lethal effects of OP agents (NTP, 2019). Diisopropylfluorophosphate (DFP) is a potent OP pesticide now routinely used as a research tool and it has been shown that the prostaglandin-E2 receptor is a potential target for attenuating DFP-induced hippocampal degeneration when a receptor antagonist is delivered well after status epilepticus has ended (Rojas et al., 2019). Inducible nitric oxide synthase inhibitors prevent some long-term effects after DFP exposure in a rat model and it is a promising follow-on therapy after the standard of care (Putra et al., 2019). Research has revealed that calcium homeostasis, and blockade of calcium release with antagonists ameliorate some of the long-term effects (Deshpande and DeLorenzo, 2019). Neuroinflammation and oxidative stress are also likely involved, and persistent histopathological damage in several brain regions after DFP exposure support this hypothesis (Guignet et al., 2019) and persistent neuroinflammation has been confirmed with in vivo imaging in the rat (Hobson et al., 2019). Oxidative stress brought on by OP-induced seizures may cause some of the long-term effects, but there is also the possibility of direct effects of the OP agents causing oxidative damage, and drug candidates like AEOL 10150 are being looked at as potential general antioxidants that could be used for OP and other chemical threats (Pearson-Smith and Patel, 2019).

Some chemical threats under study cause devastating neurological effects but are not OP compounds. Tetramine or TETS is a GABA-agent convulsant used as a rat poison and causes seizures similar, but not identical to the OP agents. Researchers are developing animal models (Pessah et al., 2016) and testing potential therapeutics that might work for both GABA and cholinergic chemical threats (Vito et al., 2014). The natural history of TETS toxicity is being studied; for example, it is much more potent to juvenile rats than adults (Laukova et al., 2019), and allopregnanolone and ganaxolone are effective in mice for the treatment of TETS-induced SE when administered by the intramuscular route (Zolkowska et al., 2018). Hydrogen sulfide is of major concern, and it has been shown that this compound produces lesions in the brain and the redox agent methylene blue may be an effective antidote (Haouzi et al., 2019).

Much progress on cyanide MCMs has also been made. Cobinamide, sodium tetrathionate, and sodium nitrite with sodium thiosulfate show promise for mass casualty cyanide poisoning. Cobinamide is a vitamin B12 analog that is more potent than hydroxycobalamin as a cyanide antidote, and can be administered by i.m. injection (Ng et al., 2019). It is also an effective antidote against hydrogen sulfide and several other toxic chemicals (Ng et al., 2019). Sodium tetrathionate is a sulfur donor that neutralizes cyanide by converting it to thiocyanate. Like cobinamide, intramuscular sodium rescues >80% of animals in mouse, rabbit, and pig models of cyanide poisoning (Hendry-Hofer et al., 2019). Sodium nitrite and sodium thiosulfate are currently approved for treatment of cyanide poisoning via intravenous injection. It has now been shown that the two drugs can be given by intramuscular injection to rescue animals in the mouse, rabbit, and pig models of cyanide poisoning (Bebarta et al., 2017). Dimethyl trisulfide (DMTS), a sulfur-based molecule present in garlic and onions, is safe and efficacious in rodent models of cyanide injection, ingestion, and inhalation. In lethal rabbit and swine models of cyanide poisoning, DMTS significantly enhances survival and is another promising candidate (Petrikovics et al., 2019). A phenotype-driven screening approach to discover new compound classes for cyanide MCMs has discovered the multivalent cyanide scavenger hexachloroplatinate (HCP) and the metabolic modulator glyoxylate, as potential novel cyanide antidotes (Morningstar et al., 2019). Importantly, both HCP and glyoxylate can be delivered by intramuscular injection. A cobalt complex of the Schiff-base macrocycle 2,12-dimethyl-3,7,11,17-tetraazabicyclo[11.3.1] heptadeca-1(17)2,11,13,15-pentaene (CoN4[11.3.1]) is also a viable option as a cyanide antidote (Praekunatham et al., 2019). Ongoing work is investigating the use of CoN4[11.3.1] in combination with a nitric oxide donor to reactivate cytochrome c oxidase, with further improved antidotal capability anticipated. Sulfanegen, a potential antidote for cyanide poisoning with a novel mechanism based on 3-mercaptopyruvate(3-MST) is being developed for the detoxification of cyanide (Patterson et al., 2016). Additionally, sulfanegen can be rapidly administered by intramuscular injection and has shown efficacy in several species of animal models.

Among the most worrisome of pulmonary chemical threat agents is chlorine. Chlorine inhalation can cause severe acute respiratory damage and failure of other organ systems. CounterACT researchers have shown that

oxygen administration can improve survival but may not reduce the probability of respiratory failure and does not improve cardiac and neuromuscular function (Okponyia et al., 2018). Various approaches including the use of nitrite (Honavar et al., 2017) and heparin (Zarogiannis et al., 2014), among others that have been studied as antidotes. Interestingly, chlorinated lipids are formed after exposure to chlorine and could serve as biomarkers and mediators for chlorine gas exposure and toxicity (Ford et al., 2016). Bromine is also being studied and the natural history and mechanism of toxicity is being elucidated so that better MCMs can be developed (Ahmad et al., 2019; Duerr et al., 2018). Another important pulmonary agent being studied is phosgene, which causes debilitating acute lung injury and other effects (Aggarwal et al., 2019). The mechanism of phosphine poisoning is being studied (Wong et al., 2017) and gold(I) complexes are showing some promise as antidotes to phosphine poisoning (Garrett et al., 2019).

Sulfur mustard and other vesicants are being studied at CounterACT Centers of Excellence and in several individual projects. In the lung, this compound causes bronchiolitis obliterans and pulmonary fibrosis (McGraw et al., 2018) and airway tissue plasminogen activator is a promising antidote under advanced development (Veress et al., 2015). A similar compound, nitrogen mustard, also causes pulmonary fibrosis and new insights from researchers indicate that lipid handling and metabolism drive macrophage foam cell formation in the lung (Venosa et al., 2019). In the skin, much is being learned about the mechanism of toxicity (Chang et al., 2018), and new candidate therapeutics are under study (Joseph et al., 2018; McElroy et al., 2016). The vitamin 25(OH)D is a very effective MCM for nitrogen mustard if the dose is timed correctly, or repeat dosing is employed (Das et al., 2018). These studies also led to the development of this treatment for sunburn.

Besides the well-known nerve and pulmonary agents, vesicants, and cyanide, the CounterACT program is working on lesser known agents that are a threat to civilians. Brodifacoum is a long-acting anticoagulant rodenticide that causes severe life-threatening anticoagulant effects. Although vitamin K1 (VK1) treatment effectively prevents mortality, additional methods are needed to reduce the long duration of VK1 treatment, which can last for months at high expense. This compound was used in the adulteration of K-2 synthetic marijuana that led to many illnesses and deaths in the US. CounterACT researchers tested the effects of cholestyramine and found it reduced mortality from 67% to 11% (Lindeblad et al., 2018). Metabolic and other agents like hydrogen sulfide (Ng et al., 2019), other pulmonary agents such as methyl isocyanate (Rancourt et al., 2019), and others are being studied along with a robust and growing portfolio of projects focused on developing MCMs for opioid threats such as fentanyl and its analogs. In this regard the program is focused on the use of opioids that result in mass casualties and require special MCMs suited for treating many victims in a short period of time.

The above discussion only covers a fraction of the literature base on chemical MCMs generated by the NIH CounterACT network of basic, translational, and clinical researchers. The program has also generated over 30 lead compounds poised for, or already transitioned to other agencies for, advanced development and approval by the FDA and inclusion in the Strategic National Stockpile.

67.8 Concluding remarks and future directions

Chemical threat agents have become more of a concern because of their recent use in terrorist incidents, warfare, and individual poisonings. The severe toxicity of these chemicals can be difficult to manage because of their often-rapid modes of action, causing severe injury or death within minutes. The US government continues to support research on improvement and optimization of chemical MCMs. The NIH CounterACT is part of a larger biodefense effort at NIH, it has a dual and complimentary mission: to support basic research focused on understanding chemical toxicities, and to use that knowledge to identify novel targets and develop promising candidate therapeutics for treating exposures that lead to mass casualties. At NIH, a broad research community that otherwise would not be involved in chemical weapons research is being engaged to take advantage of its critical expertise in areas of scientific endeavor relevant to the civilian and military research programs. The NIH program works in concert with the Chemical Medical Countermeasures program at BARDA. BARDA provides an integrated, systematic approach supporting the development and acquisition of the necessary vaccines, treatments, diagnostics, and other medical devices for public health emergencies, including many MCMs emerging from the basic research and preclinical development activities sponsored by NIH CounterACT. For example, NIH and BARDA supported the benzodiazepine drug Midazolam (Seizalam), which was recently approved for a status epilepticus indication and is slated to replace diazepam as a component of the three-drug regimen used to treat nerve agent intoxication. NIH CounterACT will continue basic and translational research on existing and emerging chemical threats, and work to improve preparedness in the United States for chemical emergencies.

Chapter 68

Pyridinium oximes in the treatment of poisoning with organophosphorus compounds

Milan Jokanović[1], Miloš P. Stojiljković[2], Bojan Kovač[3] and Dragana Ristić[3]

68.1 Introduction

Organophosphorus (OPs) compounds have long been used as pesticides and developed into warfare nerve agents such as tabun, soman, sarin, VX, and others. Exposure to even small amounts of an OP compound can be fatal. Death is usually caused by respiratory failure resulting from the paralysis of the diaphragm and intercostal muscles, depression of the brain respiratory center, bronchospasm, and excessive bronchial secretions. The mechanism of OPs poisoning involves phosphorylation of the serine hydroxyl group in the active site of acetylcholinesterase (AChE), which leads to inactivation of this essential enzyme. As a result of AChE inhibition, the accumulation of acetylcholine (ACh) at cholinergic receptor sites produces continuous stimulation of cholinergic fibers throughout the central nervous system (CNS) and peripheral nervous system (PNS), motor convulsions, and epileptic seizures. Accumulating evidence indicates that seizure events are linked to irreversible long-term compromise of cognitive functions and alteration of CNS electrical excitability. Presently, therapy of acute OP poisoning includes administration of atropine as a muscarinic acetylcholine receptor antagonist, together with an oxime, pralidoxime (2-PAM), HI-6, or congeneric *bis*-quaternary pyridinium compounds such as TMB-4 or LüH-6, and CNS depressants such as diazepam. When administered in vivo, quaternary oxime reactivators largely remain in blood and peripheral tissue capable of crossing the blood–brain barrier (BBB) in small amounts and reactivating OP-inhibited brain AChE. This chapter describes the mechanisms of OP action and the role of pyridinium oximes as AChE reactivators in the treatment of OP poisonings.

68.2 Interaction of cholinesterases with organophosphorus inhibitors

The different types of cholinesterases in the human body are characterized by their location in tissues, substrate affinity, and physiological function. The principal ones are acetylcholinesterase (EC 3.1.1.7, AChE), predominantly found in the nervous system and also present in the outer membrane of red blood cells. Plasma cholinesterases (EC 3.1.1.8, ChE), are another group of enzymes present in plasma, liver, cerebrospinal fluid, and glial cells. Under normal physiological conditions, AChE breaks down ACh, which is the chemical mediator responsible for conduction of nerve impulses at the sites of cholinergic transmission. Its physiological role in blood is not understood. On the other hand, ChE is also an esterase that can react in a similar way with most of the compounds that react with AChE. While the effects of inhibition of AChE can be fatal, depending on the dose taken, inhibition of ChE does not have any known consequences on normal body functions (Jokanović and Maksimović, 1997). ChE is a circulating plasma glycoprotein synthesized in the liver, which does not serve any known physiological function. Recent evidence indicates that ChE may have roles in cholinergic neurotransmission, other nervous system functions such as cellular proliferation and neurite growth during the development of the nervous system, and processes in neurodegenerative disorders (Darvesh et al., 2003).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00068-4

AChE terminates the action of ACh at the junctions of the various cholinergic nerve endings with their effector organs or postsynaptic sites. In the presence of OP inhibitors, AChE becomes progressively inhibited and is not further capable of hydrolyzing ACh to choline and acetic acid (Jokanović and Maksimović, 1997). Consequently, ACh accumulates at cholinergic receptor sites and produces effects equivalent to excessive stimulation of cholinergic receptors throughout the CNS and PNS.

Both substrate and inhibitors react covalently with the esterases in essentially the same manner due to the fact that acetylation of the serine residue at the AChE catalytic site is analogous to phosphorylation. In contrast to the acetylated enzyme which rapidly separates acetic acid and restores the catalytic site, the phosphorylated enzyme is stable (Fig. 68.1). Inhibited enzyme can be spontaneously reactivated at different rates depending on the OP having branched alkyl groups such as warfare nerve agents and it may occur at a very slow rate.

The variations in the acute toxicity of OPs are the result of their different chemical structures, rates of spontaneous reactivation, and aging. The aged form of phosphorylated AChE is resistant to both spontaneous and oxime-induced reactivation. For example, when inhibited with VX, AChE in red blood cells spontaneously reactivates at a rate of about 1% per hour for about the first 48 h, while the VX-AChE complex ages very little during this period. The soman−AChE complex does not spontaneously reactivate since the half-time for aging is about 2−4 min. The half-time for aging of the sarin−AChE complex is between 5 and 12 h, depending on experimental conditions, and only about 5% of the enzyme undergoes spontaneous reactivation. The half-time for aging of the tabun−AChE complex is about 46 h (Karczmar, 1984; Sidell, 1997; Stojiljković et al., 2001; Milatović and Jokanović, 2009). For OP pesticides containing dimethyl phosphate groups the half-time of spontaneous reactivation of phosphorylated AChE in vitro is about 1 h and the half-time of aging is 3.7 h, while these for diethyl phosphates are slower, being about 31−57 and 31 h, respectively (Worek et al., 1999; Mason et al., 2000; Eyer, 2003).

Although appearing with many phosphorylated AChE complexes, the aging reaction has the major clinical importance and is an imperative problem, particularly in the treatment of soman poisoning. Aging with soman occurs so fast that no clinically relevant spontaneous reactivation of AChE can occur before aging has taken place. Hence, recovery of function depends on the resynthesis of AChE, which is a relatively slow process. After soman exposure, it is important to immediately administer atropine and oximes so that some extent of AChE reactivation occurs before the entire AChE has aged. Even though aging occurs slowly in the case of other warfare nerve agents and OPs, early oxime administration is of high clinical importance for treatment efficiency.

68.3 Clinical aspects of acute organophosphorus poisoning

Signs and symptoms of acute poisoning with OPs are predictable from their biochemical mechanism of action and are directly related to the levels of AChE activity (Table 68.1). The types of effects manifested in these poisonings are muscarinic, nicotinic, and central signs and symptoms. The duration of effects is determined mainly by the properties of the compound: its liposolubility, the stability of the OP−AChE complex, and whether it is reactivatable after the use of cholinesterase reactivators, such as oximes. It is important to note that only OPs containing a P = O bond, known as direct inhibitors, are potent AChE inhibitors; while those having a P = S group, indirect inhibitors, must be metabolically activated to the P = O group (Jokanović, 2001, 2009, 2015). The signs and symptoms of poisoning with direct inhibitors appear quickly during or after exposure, while those with indirect inhibitors appear slower and last longer, even up to several days after cessation of exposure.

Clinical diagnosis is relatively simple and is based on medical history, circumstances of exposure, and the presence of clinical symptoms of poisoning. Confirmation of diagnosis can be made by measurement of red blood cell AChE or plasma ChE. Activities of these enzymes are accepted as biomarkers of exposure and/or toxicity of OPs. Red blood cell AChE is identical to the enzyme present in the target synapses and its levels are assumed to reflect the effects in target organs. Thus, red blood cell AChE is regarded as a biomarker of toxicity of these compounds. AChE in the brain is restored by de novo synthesis more

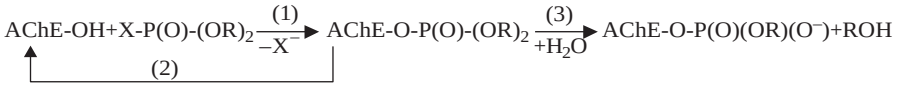

FIGURE 68.1 Interaction of acetylcholinesterase (AChE-OH) with organophosphorus compounds. Reaction 1 shows interaction of the organophosphate molecule with the serine hydroxyl group at the active site of AChE. Inhibited AChE cannot further serve its physiological function, which causes the accumulation of acetylcholine at the nerve endings. Reaction 2 is spontaneous reactivation of inhibited AChE, which occurs very slowly for most OP compounds. Reaction 3, called "aging," represents nonenzymatic time-dependent loss of one alkyl group (R) bound to the phosphorus. The aging reaction depends on the chemical structure of the inhibitor and leads to a stable nonreactivatable form of phosphorylated AChE. X is an acyl radical (i.e., Cl^-, F^-, CN^-, *p*-nitrophenol, etc.) (Jokanović, 2015).

TABLE 68.1 Signs and symptoms of poisoning with organophosphorus compounds (Jokanović, 2015).

Signs and symptoms			Severity of poisoning	Red blood cell AChE (% of control)
Muscarinic	Nicotinic	Central		
Nausea, vomiting, diarrhea, salivation, lacrimation, bradycardia and arrhythmia, bronchoconstriction, bronchosecretion		Headache, dizziness, drowsiness, anxiety	Mild	> 40
As above plus miotic pupils (unreactive to light), involuntary defecation and urination	Twitching of fine muscles, hyperreflexia, fasciculations	As above plus ataxia, psychosis, tremor, dysarthria, slurred speech	Moderate	20–40
	As above plus muscle weakness, reduced tendinous reflexes, paralysis affecting diaphragm and respiratory muscles	As above plus coma, convulsions, respiratory depression	Severe	< 20

rapidly than in erythrocytes where AChE activity is recovered via erythropoiesis. The level of activity of ChE should be carefully interpreted since the normal range in healthy subjects is relatively wide, rendering interpretation in individual patients difficult unless the results of previous estimations in the patient are available. Inhibition of ChE does not provide accurate information related to the clinical severity of the poisoning. Many OP insecticides, for example chlorpyrifos, demethon, and malathion, are apparently more potent inhibitors of ChE than they are of erythrocyte AChE and, consequently, ChE inhibition might occur to a greater extent than AChE inhibition (Jokanović, 2009).

The first 4–6 h are the most critical in acute poisoning with OP pesticides. If there is improvement in symptoms after initial treatment then the patient is very likely to survive if adequate treatment is continued (IPCS, 1998; Jokanović, 2009). The duration of effects is determined mainly by the properties of the compound: its liposolubility, the stability of the OP–AChE complex, and whether it is reactivatable after the use of cholinesterase reactivators such as pyridinium oximes.

The rate of spontaneous reactivation (Fig. 68.1, Reaction 2) can be accelerated by pyridinium oximes that have a chemical structure which "fits" the structure of the inhibited AChE. The oximes can only be of benefit as long as inhibited AChE is not completely converted to the aged form.

68.4 Antidotes in the treatment of organophosphorus poisoning

68.4.1 Atropine

Atropine acts by blocking the effects of excess concentrations of ACh at muscarinic cholinergic synapses following OP inhibition of AChE. Atropine is the initial drug of choice in acute OP poisoning that can relieve the following symptoms of OP poisoning: sweating, salivation, rhinorrhea, lacrimation, nausea, vomiting, and diarrhea. It can also help control bradycardia and circulatory depressions, dilating the bronchi, and abolish bronchorrhea. Atropine does not bind to nicotinic receptors and cannot relieve nicotinic effects of OPCs. In addition, there is evidence regarding the anticonvulsant properties of atropine in poisoning with soman and VX (McDonough et al., 1987; Zilker, 2005; Jokanović, 2009, 2015; Vučinić et al., 2018; Timperley et al., 2018).

The standard dosing of atropine depends on the severity of OP poisoning. The initial dose is usually 2 mg in an adult (0.02 mg/kg in a child) given every 5–10 min until hyperatropinization (flushing, dryness of the mouth, nose, lungs, and the skin, heart rate 80–100/min, normal blood pressure, mydriasis). The dose may be increased as required. Patients poisoned with OPs appear to be resistant to the toxic effects of atropine and may require relatively large doses of atropine administered over a prolonged period of time. According to IPCS (2002) in severe OP poisoning the total dose of atropine given during 5 weeks of treatment can be as high as 30,000 mg.

In an open-label randomized clinical trial, Abedin et al. (2012) compared the efficacy and safety of conventional bolus doses of atropine with individual incremental doses for atropinization followed by atropine infusion for management of OP poisoning. It was concluded that rapid incremental dose atropinization followed by atropine infusion reduced mortality and morbidity from OP poisoning and shortened the length of the total hospital stay and recovery. They recommended that incremental

atropine and infusion should become the treatment of choice for OP poisoning.

68.4.2 Diazepam

Benzodiazepines are CNS depressants, anxiolytics, and muscle relaxants. Their main site of action is at the gamma-aminobutyric acid (GABA) receptor. The $GABA_A$ receptor is a ligand-gated chloride ion channel and is part of a superfamily of receptors which also includes the nicotinic acetylcholine receptor and the glycine receptor. GABA is the major inhibitory neurotransmitter in the mammalian CNS. Benzodiazepines, including diazepam, alter GABA binding at the $GABA_A$ receptor site in an allosteric fashion but these drugs do not directly activate the receptors (Sellström, 1992; Marrs, 2004; Jokanović, 2015).

Currently, the most important anticonvulsant is diazepam. The combination of atropine and diazepam is more effective in reducing mortality than atropine or oxime alone. It was also shown that diazepam enhanced the efficacy of low doses of atropine. In the cholinergic nervous system, diazepam appears to decrease the synaptic release of ACh. The main consequence of the action of benzodiazepines in CNS is the hyperpolarization of neurons. This makes neurons significantly less susceptible to cholinergically induced depolarization. The ultimate result is cessation of the propagation of convulsions (Sellström, 1992; Marrs, 2004; Jokanović and Stepanović Petrović, 2016).

In patients poisoned with OPs, benzodiazepines may have a beneficial effect in reducing anxiety and restlessness, reducing muscle fasciculation, arresting seizures and convulsions, controlling apprehension and agitation, and possibly reducing morbidity and mortality when used in conjunction with atropine and an oxime. Diazepam should be given to patients poisoned with OPs whenever convulsions or pronounced muscle fasciculation are present. In severe poisoning, diazepam administration should be considered even before these complications develop. The recommended dose of diazepam in cases of OPS poisoning is 5−10 mg i.v. in the absence of convulsions and 10−20 mg i.v. in cases with convulsions, which may be repeated as required (Johnson and Vale, 1992; Jokanović, 2009, 2015).

It appears that other anticonvulsant benzodiazepines, such as midazolam, avizafone, and lorazepam, are just as effective in stopping nerve agent-induced seizures as diazepam in a hospital setting. In animal studies, midazolam was even more effective than diazepam (Bokonjić and Rosić, 1991; Timperley et al., 2018). The FDA and French army considered approval of midazolam as a treatment for nerve agent-induced seizures (Sidell et al., 2009; Masson, 2011; Jokanović, 2012, 2015). In addition to diazepam, Delacour and Dorandeu (2014) recommended administration of clonazepam in the management of severe OP poisoning.

Detailed therapeutic protocols used in the treatment of poisoning with OPs are presented in several excellent reviews (World Health Organization, 1986; Lotti, 1991; Bismuth et al., 1992; Johnson and Vale, 1992; Johnson et al., 2000; Marrs and Vale, 2006; Jokanović, 2009, 2012; Jokanović and Prostran, 2009; Jokanović et al., 2010; Balali-Mood and Saber, 2012; Vučinić et al., 2018; Timperley et al., 2018).

68.4.3 Oximes

Extensive studies over the past decades have investigated the mechanism of oxime action. There is convincing evidence that the antidotal potency of oximes is primarily attributed to their abilities to reactivate the phosphorylated cholinesterases. Oximes reactivate phosphorylated cholinesterases by displacing the phosphoryl moiety from the enzyme due to their high affinity for the enzyme and powerful nucleophilicity. The rate of reactivation depends on the structure of the phosphoryl moiety bound to the enzyme, the source of the enzyme, the structure and concentration of oxime that is present at the active site, the rate of postinhibitory dealkylation known as aging, and the steric hindrance effects between the oxime molecule and phosphoryl moiety attached to the active site of AChE (Jokanović and Stojiljković, 2006; Maxwell et al., 2008; Jokanović, 2015). Phosphorylated oximes are formed during the reactivation reaction and some of them appear to be potent inhibitors of AChE (Luo et al., 1999; Ashani et al., 2003; Worek et al., 2007). It was shown that phosphorylated oximes of 2-substituted pyridinium compounds (e.g., 2-PAM, HI-6) are unstable, while those of 4-pyridinium aldoximes are markedly stable (Ashani et al., 2003; Kiderlen et al., 2005; Worek et al., 2000) (Fig. 68.2).

Oximes bind to AChE as reversible inhibitors and form complexes with AChE either at the acylation (catalytic) site, at the allosteric site, or at both sites of the enzyme, and protect AChE from phosphorylation. When the reversible inhibitor binds to the catalytic site, the protection is due to direct competition between the OP and reversible inhibitor. Binding of a reversible inhibitor to the allosteric site induces indirect protection of the active site. Differences in the mechanisms of enzyme reactivation and protection demonstrate how stereochemical arrangements of oximes can play a role in the potency of their therapeutic efficacy. Direct pharmacological effects, such as direct reaction with OPs (Van Helden et al., 1996; Jokanović and Prostran, 2009; Jokanović, 2012), anticholinergic and sympathomimetic effects may also be relevant for the interpretation of antidotal potency of oximes.

Mono- and bispyridinium oximes are effective against OP-inhibited AChE in the PNS, but have limited

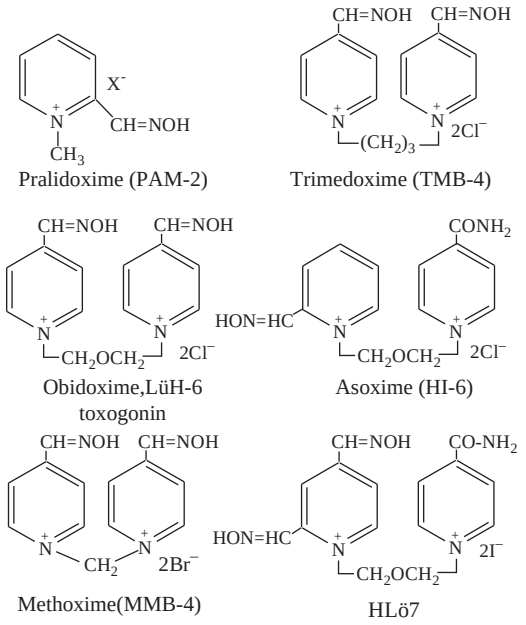

FIGURE 68.2 Chemical structure of pyridinium oximes used in treatment of OPC poisoning. X is an anion (in PAM-2 it can be Cl^-, I^-, or methanesulfonate).

penetration across the BBB. Limited penetration of HI-6 is due to its pharmacokinetic profile and the two quaternary nitrogen atoms in its structure. However, it appears that oxime penetration through the BBB is underestimated since soman can cause seizure-related opening of the BBB (Carpentier et al., 1990; Grange-Messent et al., 1999) and thus enable passage of higher oxime concentrations into the brain. Abdel-Rahman et al. (2002) have shown that 0.5−1.0 LD_{50} of sarin caused a dose-dependent increase in permeability of BBB in midbrain, brainstem, cerebrum, and cerebellum in rats 24 h after poisoning. Sakurada and coworkers (2003) have determined the amount of PAM-2 passing across the BBB at approximately 10% of the given dose, which may be effective in reactivation of OP-inhibited AChE in brain. Obidoxime concentrations in brain were estimated to be 3%−5% of plasma levels in rodents (Falb and Erdmann, 1969) and those of HI-6 to 10% of the serum highest concentration (Cassel et al., 1997). Several studies (Kassa; 2002; Shrot et al., 2009) suggested that such oxime concentrations in brain are apparently sufficient to produce biochemical and physiological effects in soman poisoning, particularly in specific brain regions, such as the medulla oblongata. These effects can contribute to survival following OP intoxication. Others claim that it is uncertain whether this amount is sufficient to reactivate nerve agent-inhibited AChE (Shih et al., 2011). When AChE reactivation was achieved in the pontomedullar region good therapeutic effects of oximes were observed and survival of poisoned animals correlated with the AChE activity in this region (Bajgar et al., 2007). In addition, it was suggested that in pralidoxime and obidoxime penetration through the BBB, a carrier-mediated transport mechanism might be involved (Lorke et al., 2008).

68.5 Pyridinium oximes in the management of poisoning with warfare nerve agents

68.5.1 Pralidoxime (PAM-2)

Pralidoxime was synthesized in the United States in 1955 (Wilson and Ginsburg, 1955). Its four salts, chloride (PAM-2 Cl), methiodide, methysulfate, and mesylate (P2S), were investigated and introduced into practice. PAM-2 is very effective in reactivating AChE inhibited with sarin or VX (Johnson and Stewart, 1970; Sidell and Groff, 1974; Harris and Stitcher, 1983; Mesić et al., 1991; Masuda et al., 1995; Nozaki and Aikawa, 1995), but was not successful in the reactivation of the tabun- or soman-inhibited enzymes (Inns and Leadbeater, 1983; Koplovitz and Stewart, 1994).

Because PAM-2, as a quaternary pyridinium salt, penetrates the BBB only to about 10% of its blood concentration, its prodrug pro-2-PAM (*N*-methyl-1,6-dihydropyridine-2-carbaldoxime hydrochloride), which is apparently rapidly oxidized in brain to PAM-2, was synthesized and tested in experimental animals. Pro-2-PAM provided some reactivation of sarin- and VX-inhibited AChE in the brain, blood, and peripheral tissues of guinea pig, which was reflected by a limited ability to block or terminate seizures elicited by these agents. Pro-2-PAM provided marginal reactivation of blood, heart, and spinal cord AChE inhibited by cyclosarin, but was not effective against cyclosarin-induced seizures (Shih et al., 2011). Pro-2-PAM was effective in the suppression and elimination of seizures/status epilepticus in DFP-treated guinea pigs. In addition, pro-2-PAM provided a significant reduction of neurological damage in DFP-poisoned guinea pigs. In both cases, PAM-2 was ineffective (DeMar et al., 2010). Clement (1979) reported that pro-2-PAM was effective in protecting mice poisoned with DFP and sarin, but very slightly effective against soman in guinea pigs. In summary, pro-2-PAM was not a significant improvement over PAM-2 with regard to prophylaxis against noted OPC. However, pro-2-PAM was less effective than PAM-2 in experimental poisoning with paraoxon in mice (Bošković et al., 1980; Jokanović and Stepanović Petrović, 2016).

When given together, atropine and PAM-2 act synergistically involving different mechanisms and the net effect is protection/treatment of animals poisoned with very high doses of certain OPs. Studies with nonhuman primates proved that the combination of atropine and

PAM-2 provided protection up to five times the LD_{50} of all known nerve agents except soman (Stojiljković et al., 2001) and against 128 LD_{50} of paraoxon (Murphy, 1986).

PAM-2 may be given by slow intravenous injection over 5−10 min, by intravenous infusion over 15−30 min, or by subcutaneous or intramuscular injection; it has also been given orally (Pralidoxime, 2009). The minimum therapeutic concentration of PAM-2 in plasma is 4 μg/mL and this level is reached in about 16 min after a single injection of 600 mg PAM-2 Cl (Pralidoxime, 2007).

In the treatment of OP poisoning, atropine and PAM-2 should be given as soon as possible and maintained as long as needed. When the effects of atropine become apparent, 1−2 g of PAM-2 chloride, iodide, or mesilate, should be given intramuscularly or intravenously and repeated after 1 h and then every 8−12 h if necessary. Alternatively, PAM-2 Cl may be given in an initial dose of 30 mg/kg by intravenous infusion over 20 min, or by intravenous injection over at least 5 min if pulmonary edema is present or infusion cannot be given; the initial dose is then followed by intravenous infusion at a rate of 8 mg/kg per hour (IPCS, 1998; Milatović and Jokanović, 2009; Pralidoxime, 2009). PAM-2 is relatively short acting (the apparent half-life of PAM-2 Cl is 74−77 min) and repeated doses may be needed, especially where there is any evidence of continuous absorption of the OPC (Pralidoxime, 2007). The treatment should be continued until no longer needed. This decision can be made on the basis of the clinical status of the patient, relatively high AChE activity in erythrocytes when compared to control values, and the absence of OPCs and/or OP metabolites in urine (Jokanović, 2009).

In some countries, autoinjectors are available for emergency use containing PAM-2, either alone or combined with atropine and/or avizafone, a water-soluble prodrug of diazepam (Pralidoxime, 2009). The French army is considering including water-soluble benzodiazepine midazolam in its autoinjector (Masson, 2011). Typical doses are 600 mg of PAM-2 Cl or 500 mg of PAM-2 mesilate given intramuscularly up to three times, depending on symptoms. In severe poisoning, PAM-2 may be given as a continuous infusion of 200−500 mg/h, titrated against response. A maximum dose of 12 g in 24 h has been suggested (Pralidoxime, 2009; Timperley et al., 2018).

PAM-2 has been very well tolerated in most cases (Pralidoxime, 2007). Adverse effects of PAM-2 in volunteers include dizziness, drowsiness, blurred vision, occasional diplopia, impaired accommodation, nausea, headache, tachycardia, hyperventilation, increased systolic and diastolic blood pressure, and muscular weakness. Tachycardia, laryngospasm, and muscle rigidity have been attributed to giving pralidoxime intravenously too quickly. Large doses of pralidoxime may cause transient neuromuscular blockade (Jager and Stagg, 1958; Sidell and Groff, 1971; Eyer, 2003; Pralidoxime, 2007, 2009). Forty to 60 min after intramuscular injection, mild to moderate pain may be experienced at the site of injection. Elevations in AST and/or ALT enzyme levels in blood were observed in one of six normal volunteers given 1200 mg of PAM-2 Cl intramuscularly, and in four of six normal volunteers given 1800 mg intramuscularly. Levels returned to normal in about 2 weeks (Pralidoxime, 2007). PAM-2 should be used cautiously in patients with renal impairment and a reduction in dosage may be necessary. Caution is also required in giving pralidoxime to patients with myasthenia gravis as it may precipitate a myasthenic crisis (Pralidoxime, 2009).

The clinical experience with the use of PAM-2 iodide, given with atropine and diazepam, in the treatment of the victims of Tokyo sarin attack in 1995 was very favorable (Sidell et al., 2009). However, PAM-2 should not be recommended as the drug of choice for the management of poisoning with all OPs due to its lack of efficacy against tabun and soman.

68.5.2 Trimedoxime (TMB-4)

TMB-4 Cl_2 was synthesized in the United States in 1957 (Poziomek et al., 1958). It is the only of the major bispyridinium oximes with a propylene bridge between the two pyridinium rings. It was shown that TMB-4 is a more potent reactivator of the DFP-inhibited AChE than PAM-2 (Hobbiger and Sadler, 1958) and better reactivator than LüH-6 in the case of the tabun-inhibited enzyme (Hobbiger and Vojvodić, 1966). TMB-4 was the first oxime that was efficient in the treatment of animals intoxicated with tabun (Schoene and Oldiges, 1973; Maksimović et al., 1980; Bokonjić et al., 1993). It could also protect animals poisoned with sarin or VX, but not those intoxicated with soman (Maksimović et al., 1980; Inns and Leadbeater, 1983; Binenfeld, 1986). While TMB-4 was the most toxic oxime among the "great four"—it was shown in mice that its LD_{50} is three, four, and eight times less than that for LüH-6, PAM-2 and HI-6, respectively (Clement, 1981).

68.5.3 Obidoxime (LüH-6, toxogonin)

After being introduced into medical practice in 1964, obidoxime showed significant potential as an antidote in poisonings with OPs (Erdmann and Engelhard, 1964). Given with atropine, obidoxime efficiently protected experimental animals against poisoning with tabun (Inns and Leadbeater, 1983; Maksimović et al., 1989), sarin (Inns and Leadbeater, 1983; Maksimović et al., 1989), and VX (Maksimović et al., 1989). Obidoxime was more effective than TMB-4 as an antidote against intoxication with tabun (Heilbronn and Tolagen, 1965). Similarly to PAM-2 and TMB-4, obidoxime was also inefficient in soman

poisoning in mice (Maksimović et al., 1980), guinea pigs (Inns and Leadbeater, 1983), and primates (Hamilton and Lundy, 1989). Obidoxime was more efficient than HI-6 against tabun intoxication. Similarly, obidoxime was more effective as a medical countermeasure following intoxication with most cholinesterase-inhibiting insecticides, while HI-6 was considered to be a better drug against soman-inhibited acetylcholinesterase (Aas, 2003). However, LüH6 was not a potent reactivator of tabun-inhibited human AChE (Worek et al., 2004; Lundy et al., 2011). In contrast to TMB-4, obidoxime, when administered with atropine in pyridostigmine-pretreated guinea pigs, could also provide some protection against soman (Inns and Leadbeater, 1983).

When administered to human volunteers by the intramuscular route, 5 mg/kg of LüH-6 produced a plasma concentration >4 mg/L, from 5 min after injection to 3 h (Sidell and Groff, 1970). Adverse effects of LüH-6 in male volunteers were described as pallor, nausea, burning sensation, headache, generalized weakness, sore throat, and paresthesia of the face (Simon and Pickering, 1976; Eyer, 2003; Marrs and Vale, 2006). Transient hepatotoxic effects of LüH-6 were reported in about 10% of severely poisoned patients (Marrs, 1991; Eyer, 2003).

Obidoxime can be given with atropine in the treatment of OP poisoning in a usual initial dose of 250 mg (4 mg/kg) by slow intravenous injection. This may be followed by intravenous infusion of 750 mg over 24 h, continued until the concentration of OP is below critical levels; alternatively, repeated doses of 4–8 mg/kg may be given at intervals of 2–4 h. It has also been given by intramuscular injection (Obidoxime chloride, 2009).

68.5.4 Asoxime (HI-6)

The first oxime that could reactivate soman-inhibited AChE and provide at least some protection to animals experimentally poisoned with this nerve agent was synthesized in 1966. It has been shown that HI-6 is more potent than LüH-6 and HS-6 [1-(4-hydroxyiminomethylpyridinium)-3-(4-carbamoylpyridinium)-2-oxa-propane dichloride] in the protection of various rodent species from intoxication with soman (Oldiges and Schoene, 1970; Inns and Leadbeater, 1983; Mesić et al., 1991; Lundy et al., 2011), as well as sarin and particularly VX (Maksimović et al., 1980; Inns and Leadbeater, 1983). HI-6 could not reactivate tabun-inhibited AChE (Clement, 1982; Ćetković, 1984; Kassa et al., 2008) and it was inefficient when used as the only oxime against poisoning with tabun (Maksimović et al., 1980; Inns and Leadbeater, 1983; Mesić et al., 1991; Bajgar, 2010). However, other studies found that HI-6 can provide a similar degree of protection against tabun and soman intoxication in primates (Hamilton and Lundy, 1989). It is also suggested that sufficiently high doses of HI-6 could even protect rats from multiple lethal doses of tabun (Lundy et al., 1989). HI-6 given with atropine protected guinea pigs from poisoning against 5 LD_{50} of soman or cyclosarin (Lundy et al., 2005). It was suggested that HI-6 is superior to the other oximes in treatment of cyclosarin-poisoned animals (Kassa, 2002).

The acute toxicity of HI-6 is the lowest among the six oximes (HI-6, PAM-2, TMB-4, LüH-6, HLö-7, MMB-4) (Maksimović et al., 1980; Clement, 1981; Rousseaux and Dua, 1989; Bartošova et al., 2006) with an LD_{50} value after i.m. administration to rats of 781 mg/kg.

HI-6 was introduced into clinical practice in Serbia in the early 1980s. It was administered to more than 200 patients poisoned with OP insecticides and volunteers. A clinical study with HI-6, administered intramuscularly at doses up to 500 mg to 22 healthy volunteers, revealed no adverse effects. However, with patients poisoned by several OP insecticides, HI-6 provided rapid reactivation of AChE in almost all cases except in dimethoate and phosphamidon poisoning (Kušić et al., 1985, 1991; Jovanović et al., 1990, 2010; Jokanović and Maksimović, 1995). Similar results regarding HI-6 tolerance were later found in a double-blind, placebo-controlled, single-dose study in 24 volunteers (Clement et al., 1995). Safety of HI-6 administration correlated with the recent report of Pohanka and his team (2011) who found that therapeutic doses of HI-6 are safe in dogs, but also indicating that 10-fold therapeutic doses can cause hyperglycemia.

Clinical studies have shown that HI-6 dosed at either 250 or 500 mg by the intramuscular route reached plasma concentrations >4 mg/L in 4–6 min. This concentration was maintained for 125 min following the lower dose of 250 mg and 200 min following the higher dose of 500 mg (Kušić et al., 1985; Jokanović and Maksimović, 1995).

HI-6 is considered to be a very promising bispyridinium oxime in medical treatment following exposure to most nerve agents. For these reasons HI-6 is involved in the equipment of the Czech, Slovak, Swedish, and Canadian armies as an antidote against nerve agent intoxication (Bajgar, 2010; Masson, 2011) and is under development in other countries (Lundy et al., 2011; Masson, 2011; Jokanović, 2012). A disadvantage of HI-6 compared to other available oximes is the lack of stability in aqueous solutions (Kušić et al., 1985; Aas, 2003).

In addition to the four pyridinium oximes that were introduced to clinical practice, the oximes HLö-7 and MMB-4 require attention after proving to be efficient against warfare nerve agents in animal studies.

68.5.5 HLö-7

Another important "Hagedorn oxime" (after LüH-6, HS-6, and HI-6), HLö-7 was also synthesized in Freiburg,

Germany, in 1986 (Löffler, 1986). Only HLö-7 could reactivate AChE inhibited by any of the four major nerve agents in vitro and in vivo (DeJong et al., 1989; Worek et al., 1994a,b, 1995), as well as AChE inhibited by cyclosarin (Lundy et al., 1992). In addition, HLö-7 more efficiently restored the neuromuscular transmission impaired by in vitro superfusion of the neuromuscular preparation with tabun, sarin, soman, or cyclosarin compared to PAM-2, LüH-6, and HI-6 (Alberts, 1990). It was found that HLö-7 induced a significant reactivation of AChE in mice diaphragm inhibited with tabun, sarin, soman, and cyclosarin (Clement et al., 1992). Both HI-6 and HLö-7 can antagonize sarin-induced hypothermia, proving that, when given with atropine, they can pass the BBB and gain access to the CNS (Clement, 1992; Clement et al., 1992), the toxicity of HLö-7 was 2.5 times higher than that of HI-6 (Clement et al., 1992). The cardiovascular tolerability of HLö-7 was similar, but still not as good as HI-6, at least in anesthetized guinea pigs (Worek and Szinicz, 1993). HLö-7 appears to be more effective than HI-6 against tabun and VX poisoning and less effective against sarin, soman, and cyclosarin intoxication (Lundy et al., 1992; Eyer et al., 1992). HLö-7-induced protection against tabun poisoning in guinea pigs was significantly better compared to HI-6, while HI-6 was only slightly more efficient than HLö-7 in soman poisoning (Melchers et al., 1994a,b). However, Kuča and coworkers (Kuča et al., 2005, 2011) reported that HLö-7 was not a good reactivator of tabun-inhibited AChE in vitro, possibly due to the presence of the lone electron pair on the tabun amide group.

The pharmacokinetic profile of HLö-7 was similar to that of HI-6. The mean absorption half-time of HLö-7 was about 14 min after intramuscular administration. Maximum HLö-7 concentration in plasma was reached after 30 min and the half-time of elimination was about 45 min (Eyer et al., 1992).

68.5.6 Methoxime (MMB-4)

MMB-4 is a structural analog of toxogonin, showing potent antimuscarinic activity (Amitai et al., 1980). It is a bispyridinium 4,4′-*bis*-aldoxime first described by Hobbiger and Sadler (Hobbiger and Sadler, 1959). MMB-4 is currently being proposed as a leading candidate for the replacement of PAM-2 as an oxime reactivator of nerve agent-inhibited AChE activity that can prevent lethality after warfare nerve agent exposure (Worek et al., 2010; Masson, 2011; Lundy et al., 2011). So far, the oxime MMB-4 has not undergone any clinical trials (Lundy et al., 2011).

MMB-4 was less toxic in mice (LD_{50} = 441 mg/kg, i.m.) than obidoxime (188 mg/kg, i.m.) but more toxic compared to HI-6 (671 mg/kg i.m.) (Bartošova et al., 2006). It was shown that MMB-4 was inferior to HI-6 in reactivation of peripheral AChE from soman-poisoned animals, although both oximes were better than PAM-2. In soman-poisoned rats MMB-4 was not successful in protection or reactivation of soman-inhibited AChE (Shih, 1993). Luo and coworkers (2008) found that MMB-4 was not a good reactivator of soman-inhibited AChE obtained from human and three monkey species where it was found to be less effective compared to HI-6. This is consistent with the findings reported in other studies (Lundy et al., 2011).

MMB-4 was also less effective in reactivation of cyclosarin-inhibited rat brain AChE and sarin-inhibited human or monkey AChE compared to HI-6 (Kuča and Patočka, 2004; Lundy et al., 2011). MMB-4 was found to be a weak reactivator of tabun-inhibited human AChE (Worek et al., 2004). However, experimental data indicate that MMB-4 was superior to PAM-2 in reactivating OP-inhibited AChE and in preventing lethality in OP-poisoned animals (Worek et al., 2010). It was also reported that MMB-4 was the most effective oxime in reactivation of ChE in blood and peripheral tissues in guinea pigs poisoned by sarin, cyclosarin, VX, and VR (Shih et al., 2010). In addition, MMB-4 was reported to be a better AChE reactivator than PAM-2 in paraoxon- and methylparaoxon-poisoned rats (Petroianu et al., 2006, 2007).

68.6 Pyridinium oximes in the management of poisoning with organophosphorus pesticides

The efficacy of pyridinium oximes has been demonstrated in experimental conditions and in many cases of patients poisoned with OP insecticides who have been treated in European clinics. In those cases the recommendations for PAM-2 dosing proposed by the WHO were followed (IPCS, 1998). Contrary to these findings, reports from Asia indicate that PAM-2 treatment was not sufficiently effective in their patients. However, in their studies PAM-2 was not used as recommended by the WHO (Cherian et al., 1997, 2005; De Silva et al., 1992; Johnson et al., 1996; Singh et al., 1995). In addition, these studies were apparently poorly designed due to suboptimal dose, short duration of treatment, long delay between patient exposure and PAM-2 administration, and the chemical structure of OP pesticides not being taken in account (Jokanović, 2009; Jokanović et al., 2010).

A particular problem in interpreting the beneficial role and efficacy of pyridinium oximes in clinical practice is a relative lack of published data, especially those evaluated in controlled clinical trials. Studies related to the efficacy of oximes in clinical settings showed the heterogeneity of

therapeutic approaches (i.e., dose regimen, oxime choice, and final outcome of the treatment) (Jokanović, 2009).

Jokanović et al. (2010) reviewed the experience gained in clinical management of 296 patients poisoned with OP insecticides at the Clinic of Toxicology of the National Poison Control Center in Military Medical Academy in Belgrade during the period of 1998–2007. Poisoning with dimethyl OP was confirmed in 246 patients (malathion, 153; dimethoate, 69; dichlorvos, 4; fenitrothion, 6; monocrotophos, 8), with diethyl OP in 38 patients (diazinon, 21; parathion, 9; phorate, 1; phoxim, 1; phosalone, 3; chlorpyriphos, 2; quinalphos, 1) and in 12 patients in whom OP was not fully identified. The majority of poisonings (92%) was due to deliberate ingestion of OP insecticides. Accidental inhalational poisonings were registered in 3.8% patients, accidental ingestion in 4.1% patients, and there were two cases of deliberate intramuscular and intravenous application of OP. Suicidal poisonings were usually oral, and the severity of poisonings depended on the toxicity, the amount of OP insecticides taken, and the time from exposure to admission to the Clinic of Toxicology and initiation of treatment. In this study 15.9% of OP-poisoned patients died, which was consistent with the findings of other authors (Eddleston et al., 2008), who reported case fatality generally greater than 15%. About 42% of the deceased patients died within 7 days, and lethal outcome occurred within hours in 18% patients due to the severity of poisoning.

In this study, 74 patients were treated with pralidoxime methylsulfate (Contrathion). The dosage regimen for severely poisoned patients included a loading dose of 400 mg by slow intravenous infusion, subsequently 200 mg/h continuous intravenous infusion administered in the first day, and continued as long as clinical signs of poisoning and OP insecticide and/or its metabolite were present in urine and blood. In moderate poisoning, 400 mg of Contrathion was followed by 400 mg/3–4 h. However, due to the economic crisis in Serbia, the Clinic of Toxicology did not have oxime available for several years and the patients were treated with atropine and diazepam only. In patients treated with atropine and oxime or atropine only, there were no differences in mortality. Atropine consumption was lower in the group of patients treated with an oxime, but the difference was significant only in the group of severely poisoned patients, where it was reduced by 30%. An update of the study was recently reported by Vučinić et al. (2018).

Eddleston et al. (2005) conducted a prospective study on 802 patients self-poisoned with chlorpyrifos, dimethoate, or fenthion. Compared with chlorpyrifos (8.0%), the proportion of fatalities was significantly higher with dimethoate (23.1%) or fenthion (16.2%) than was the proportion requiring endotracheal intubation (chlorpyrifos 15.0%, dimethoate 35.2%, fenthion 31.3%). Patients poisoned by the diethyl OP pesticide (chlorpyrifos) responded well to pralidoxime, whereas those to the two dimethyl OP pesticides (dimethoate, fenthion) responded poorly. The poor efficacy of PAM-2 in the treatment of human dimethoate and fenthion poisonings was in agreement with experimental studies reported by Jokanović and Maksimović (1995) who found that the antidotal efficacy of obidoxime, trimedoxime, PAM-2, and HI-6, when given with atropine and diazepam in rats dosed with 2 LD_{50} of the dimethoate was low. However, there was a discrepancy between fenthion-poisoned patients and animals in that PAM-2 was ineffective as an antidote in patients, whereas the four oximes showed considerable efficacy in rats.

In a randomized controlled trial, Pawar et al. (2006) studied the effects of very high doses of PAM-2 iodide (2 g loading dose, then 1 g either every hour or every 4 h for 48 h, then 1 g every 4 h until recovery) in 200 patients with moderate OP poisoning (excluding severely ill patients). The OP pesticides involved were chlorpyrifos (diethyl OP) and dimethoate (dimethyl OP). The dosing regimen was associated with reduced case fatality, fewer cases of pneumonia, and reduced time on mechanical ventilation. This study suggests that large doses of PAM-2 could have a positive effect on patients if they are treated early and have good supportive care.

An interesting clinical trial where PAM-2 chloride was investigated in 235 patients self-poisoned with OP insecticides was reported by Eddleston and coworkers (2009). The patients were randomized to receive PAM-2 ($n = 121$) or saline placebo ($n = 114$). PAM-2 produced substantial and moderate erythrocyte AChE reactivation in patients poisoned by diethyl and dimethyl compounds, respectively. Mortality was insignificantly higher in patients receiving PAM-2: 30/121 (24.8%) receiving PAM-2 died, compared with 18/114 (15.8%) receiving placebo. The authors concluded that, despite clear reactivation of erythrocyte AChE in diethyl OP insecticide-poisoned patients, they found no evidence that treatment with PAM-2 improves survival or reduces the need for intubation in patients with OP insecticide poisoning. However, this study suffers from a major methodological problem of randomization as the authors wrote that "more severely poisoned patients were allocated to pralidoxime" than to the placebo treatment. Based on this statement it is expected that more patients would die in the group treated with PAM-2 despite the oxime treatment. This was supported by another sentence present in this report that "patients died sooner in the pralidoxime group." In addition, there were other problems with this study such as the lack of atropine inclusion in both groups. The World Health Organization (1986) recommends treatment of OP-poisoned patients with atropine, PAM-2, and diazepam, and not only with PAM-2. There were also a relatively

small number of patients included in the study, relatively long and variable period between self-poisoning and administration of PAM-2 (mean 4.3 h, intervals 2.9−7.8 h) probably having an impact on aging of phosphorylated AChE, ethical issues such as why the patients in placebo group were allowed to die without the best possible treatment according to the WHO recommendations. Because of these and other problems, the results of this study shall be considered with caution.

Kušić et al. (1991) have tested the oxime HI-6 in OP pesticide poisoning in 60 patients. HI-6 was administered four times a day as a single 500 mg i.m. injection with atropine and diazepam treatment. Oxime therapy was started on admission and continued for 2−7 days. Most patients were treated with HI-6 and nine severely poisoned patients with quinalphos were treated with PAM-2 chloride (1000 mg four times per day). HI-6 rapidly reactivated human erythrocyte AChE inhibited by diethoxy OPs (phorate, pyridaphenthion, quinalphos) as well as that inhibited by dichlorvos, a dimethoxy OP. AChE inhibited with other dimethoxy OPs, dimethoate and phosphamidon, was reported to be resistant to HI-6 treatment, whereas reactivation with malathion was slow, with a reactivation half-time of 10 h. Both HI-6 and PAM-2 successfully reactivated AChE in quinalphos-poisoned patients, with HI-6 acting as a faster AChE reactivator than PAM-2.

Willems et al. (1993) reported that ethylparathion and methylparathion poisoning could be effectively treated with PAM-2 methylsulfate (plasma concentrations 4 mg/L) and atropine when pesticide concentrations in plasma were relatively low. In severe poisoning with pesticide levels in plasma above 30 μg/L, high PAM-2 concentrations in plasma (14.6 mg/L) did not provide any improvement. In addition, PAM-2 at concentrations of 6.3 mg/L was not effective in AChE reactivation in dimethoate poisoning where AChE was inhibited with its active metabolite omethoate.

It was reported that in parathion poisoning, an obidoxime dose of 250 mg i.v. administered as a bolus followed by infusion of 750 mg/day was effective, but AChE reactivation following severe poisoning did not occur until the concentration of paraoxon in plasma became low (Thiermann et al., 1997, 1999). Oxydemeton methyl poisoning responded to obidoxime therapy only when the oxime was instituted shortly after poisoning. In cases when obidoxime treatment was started too late, there was no reactivation of erythrocyte AChE and one of six patients died.

Nine patients intoxicated with OP pesticides were treated with PAM-2 methylsulfate (Contrathion) using a dose of 4.42 mg/kg as a bolus injection followed by continuous infusion of 1.14 mg/kg/h. In patients poisoned with ethylparathion or methylparathion, AChE reactivation could be obtained at low oxime concentrations (2.88 mg/L). In others, however, an oxime concentration as high as 14.6 mg/L was ineffective. The therapeutic effect of the oxime apparently depended on the plasma concentrations of the OP pesticides. Due to AChE reinhibition, reactivation was absent as long as these concentrations remained above 30 μg/L (Aragao et al., 1996).

In a clinical study involving 63 patients poisoned with organophosphorus insecticides, patients were divided into three groups: one was treated with atropine only, while the other two received atropine and either PAM-2 or obidoxime. Initial and maintenance intravenous doses for PAM-2 were 30 mg/kg and 8 mg/kg/h, respectively, and 8 mg/kg and 2 mg/kg/h, respectively, for obidoxime. The major clinical findings or AChE activities at the time of admission did not show statistically significant differences among the groups. Although the severity of intoxications, based on respiratory complications and duration of hospitalization, was higher in the atropine plus oxime groups, 12% and 50% of patients in the atropine and atropine plus obidoxime groups died, respectively. No mortality was found in the PAM-2 plus atropine group. The incidence of recurrent twitching and convulsions, repeated respiratory arrest, required mechanical respiration, required intensive care unit therapy, and duration of hospitalization were lower in the atropine plus obidoxime group than in the atropine plus PAM-2 group. Three of the patients who received the obidoxime combination therapy developed hepatitis and two of these died due to hepatic failure, which may indicate overdosage of obidoxime (Balali-Mood and Shariat, 1998).

In the study reported by Tsai and coworkers (2007) PAM-2 was administered to 56 patients within 48 h of OP pesticides poisoning. The average duration of PAM-2 treatment was 5.5 ± 4.9 days and the mean total dose was 16.4 ± 12.4 g. The mortality and length of stay did not improve with PAM-2 treatment. Days spent on ventilator support were decreased in patients treated with PAM-2 (6.7 ± 1.9 days) compared to those who were not (23.0 ± 4.8 days). However, there are many limitations in this study. For example, there was a relatively small number of treated patients, and a lack of data regarding the OP pesticides involved, dose taken, and AChE inhibition.

AChE inhibited by several OP pesticides, including dimethoate, demethon, triamiphos, ethoprophos, profenofos, fenamiphos, and pyridafenthion, was resistant to any attempt at reactivation with any oxime, probably due to the variations in phosphoryl moiety and distribution of electronic charge (Bismuth et al., 1992; Jokanović and Maksimović, 1995; Jokanović, 2009, 2012; Jokanović and Stepanović Petrović, 2016).

Jokanović and Maksimović (1995) studied the acute oral toxicity of 25 OP insecticides and one OP fungicide (pyrazophos) in the rat and the efficacy of antidotal

treatment involving TMB-4, LüH-6, PAM-2, and HI-6 (given with atropine and diazepam 1 min after poisoning) in animals dosed with 2 LD_{50} of the OP insecticides. The success of therapy was dependent on the chemical structure of the OPs. The oximes were potent antidotes in poisoning with the insecticides having phosphate structure, and provided some extent of antidotal protection in poisoning with phosphonates, phosphorothiolates, phosphorothionates, and phosphorodithioates. However, none were effective antidotes against dimethoate and pyridafenthion. This study has shown that TMB-4 was the most effective pyridinium oxime in the treatment of OP insecticide poisoning.

68.7 Concluding remarks and future directions

Despite the enormous efforts devoted to the synthesis and development of new pyridinium oximes as potential antidotes against poisoning with OPs in the past several decades, there have been no major advances in designing compounds that would be effective against nerve agents and other OPs. Only four compounds so far are applicable in human medicine. However, they differ in their activity in poisoning with warfare nerve agents and OP insecticides. There is still no universal broad-spectrum oxime capable of protecting against all known organophosphorus compounds.

HI-6 seems to be a promising choice for nerve agent poisoning because it was able to protect experimental animals from toxic effects and improve the survival of animals poisoned with sublethal doses, especially in the cases of soman and cyclosarin. HI-6 was also effective in poisoning with OP insecticides. MMB-4 is currently being proposed as a leading candidate for replacement of PAM-2 as an oxime reactivator of nerve agent-inhibited AChE activity that can prevent lethality after warfare nerve agent exposure. Available experimental evidence suggests that there are no clinically important differences between pralidoxime, obidoxime, and HI-6 in the treatment of nerve agent poisoning. On the other hand, obidoxime appears to be a good choice for the treatment of poisoning with OP insecticides. However, it is necessary to rigorously test these statements in properly designed randomized clinical trials.

Chapter 69

Novel cholinesterase reactivators

Kamil Musilek, David Malinak, Eugenie Nepovimova, Rudolf Andrys, Adam Skarka and Kamil Kuca
University of Hradec Kralove, Faculty of Science, Department of Chemistry, Rokitanskeho 62, 500 03 Hradec Kralove, Czech Republic

69.1 Introduction

The continuous threat of organophosphorus (OP) nerve agent misuse supports the development of antidotes with enhanced potency. In this chapter, we focus on antidotal therapy with cholinesterase reactivators. Although this group of compounds has been known for more than a half-century, there is no single compound that might counteract every nerve agent's lethal effects. This chapter describes in detail the design and synthesis of the cholinesterase reactivators that have been developed within the last decade. Within the design of novel molecules, special emphasis is placed on the structural requirements (structure−activity relationship) of these compounds. Finally, several new trends in the development of new reactivators are discussed.

69.2 OP AChE inhibitors

OP compounds are widely used in agriculture as pesticides (e.g., dichlorvos, diazinon, chlorpyrifos, and parathion), in industry and technology as softening agents and lubricant additives, and in the medical and veterinary fields as therapeutic agents (Gupta, 2006, 2015). Some OPs are declared as chemical warfare agents (CWAs), nerve agents, or both. Sarin, cyclosarin, soman, tabun, *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX), and Russian VX are well-known members of the OP nerve agent family (Table 69.1; Marrs, 1993; Bajgar, 2004, Gupta, 2015).

The history of nerve agents began prior to World War II in Germany. The first-known nerve agent, tabun (*O*-ethyl-*N*,*N*-dimethylphosphoramidocyanidate), was synthesized in the laboratories of IG Farben in Germany by Dr. Gerhard Schrader in 1936. Although the original aim of Schrader's studies was synthesizing pesticides, German authorities identified the deadly potential of OPs, and subsequently, many nerve agents, such as sarin, cyclosarin, and soman, were developed. A few decades later, the nerve agent VX was developed in the United Kingdom. Further developed nerve agents include intermediate volatile agents, an example of which is Agent GP, and A-agents or their precursors, so-called Novichoks (Fig. 69.1; Halamek et al., 2007; Nepovimova and Kuca, 2018).

During the Cold War, nerve agents were stored and prepared for potential military use, but were not used in military conflicts. However, they were misused by Saddam Hussein in Iraq in the Kurdish village of Birjinni (1988) and by the Japanese Aum Shinrikyo sect in Matsumoto (1994) and Tokyo (1995) (Tu, 2000). More recently, sarin was several times misused within the Syrian conflict (2013−18; John et al., 2018) and an agent from the Novichok family was proposed to be the cause of the intoxications of Sergei and Yulia Skripal in the UK (2018) (Nepovimova and Kuca, 2018).

Nerve agents phosphonylate serine Ser203 at the esteratic part of the active site of enzyme AChE (EC 3.1.1.7). AChE plays a key role in termination of the action of a neurotransmitter acetylcholine (ACh) in the peripheral nervous system and central nervous system, and persistent inhibition of AChE can lead to life-threatening consequences (Marrs, 1993).

Depending on the particular nerve agent, AChE is further irreversibly phosphylated via a time-dependent process called *aging*, defined as dealkylation of the phosphyl adduct to give a negatively charged adduct that is stabilized by interaction with catalytic His440 (Millard et al., 1999; Carletti et al., 2010). Aged enzymes cannot be restored by any nucleophilic reactivators. Because of the irreversible inhibition of AChE, the enzyme is not able to fulfill its physiological role in the organism—namely, splitting the neuromediator ACh at the synaptic clefts. Subsequently, ACh accumulates at the cholinergic synaptic junctions and persistently stimulates cholinergic receptors (Marrs, 1993).

The acute toxicity of nerve agents is usually attributed to excessive cholinergic stimulation caused by excess accumulation of ACh, followed by subsequent overstimulation

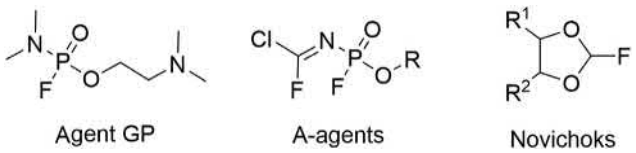

FIGURE 69.1 Proposed structure of new nerve agents (Halamek et al., 2007, Nepovimova and Kuca, 2018).

of cholinergic pathways and desensitization of cholinergic peripheral and central receptor sites (Bajgar, 2004). Symptoms of intoxication are as follows: when an individual is exposed to low amounts of a nerve agent, the initial symptoms include runny nose, contraction of the pupils, miosis, deterioration of visual accommodation, headache, slurred speech, nausea, hallucination, pronounced chest pain, and an increase in the production of saliva (muscarinic central and peripheral symptoms). At higher doses, the aforementioned symptoms are more pronounced, and coughing and breathing problems also occur. The individual may then begin to have convulsions (nicotinic symptoms) and may experience impaired ventilation, coma, and death. At even higher doses, an exposed individual would almost immediately go into convulsions and die from respiratory and cardiovascular failure. The initial stages of symptoms of an individual exposed to a nerve agent may vary depending on the particular nerve agent and the amount of agent the individual was exposed to (Bajgar, 2004).

69.3 Acetylcholinesterase (AChE; EC 3.1.1.7)

AChE is a serine hydrolase enzyme that belongs to the esterase family within higher eukaryotes. Enzymes of this family act on different types of carboxylic esters. The biological role of AChE is termination of transmission impulses at cholinergic synapses within the nervous system by rapid hydrolysis of neurotransmitter ACh. The monomer of AChE, with a molecular weight around 60,000, is an ellipsoidal molecule whose size is approximately $45 \times 60 \times 65$ angstrom (Å), consisting of a 12-strand, central, mixed β-sheet surrounded by 14 α-helices (Sussman et al., 1991). Each monomer contains one catalytic center composed of two compartments: the esteratic subsite containing the catalytic triad and the anionic subsite that accommodates the positive quaternary compartment of ACh. In human AChE, the esteratic subsite contains the catalytic machinery of the enzyme: a catalytic triad of Ser203, His447, and Glu334. The anionic subsite is defined by Trp86, Tyr337, and Phe338. Its role is to orient the charged part of ACh that enters the active center. This role is the main function of Trp and Tyr residues (Bourne et al., 2003). The recent rendition of the X-ray structure for AChE places the active catalytic site deep within a gorge-like fold of the protein. The aromatic gorge in the protein is approximately 20 Å deep and penetrates halfway into the enzyme. The active site lies at the

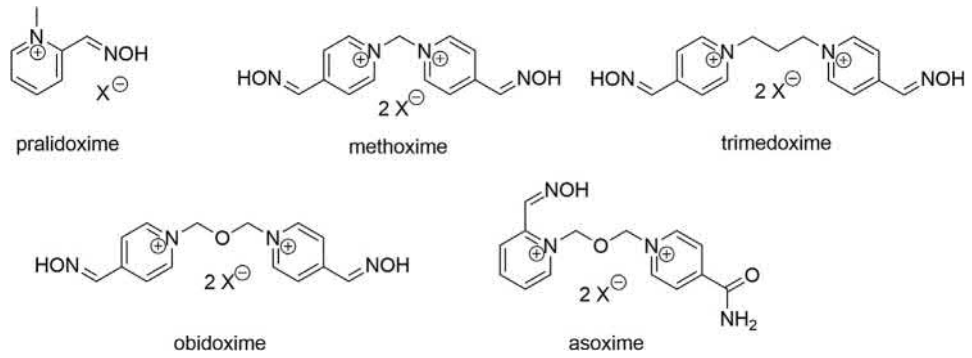

FIGURE 69.2 Standard AChE reactivators (Musilek et al., 2011).

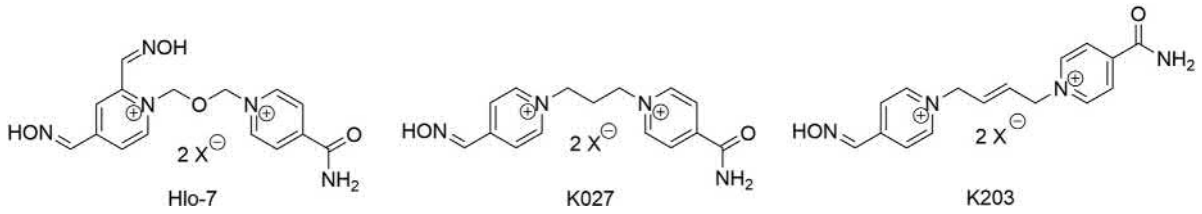

FIGURE 69.3 Selected AChE reactivators that are under development.

base of this gorge only 4 Å above the base, leading some to label this the "active gorge". The aromatic gorge is a more appropriate term because 40% of its content is composed of 14 aromatic residues, which is highly conserved from different species of AChE (Harel et al., 1993). The high aromatic content may explain studies that have proposed hydrophobic and anionic binding sites independently on the active site. Only a few acidic residues are present within the gorge. The aromatic residues play an important role in stabilization of the enzyme–substrate complex. Both electrostatic and hydrophobic effects are important here. The electrostatic potential map of AChE suggests that this enzyme, like the other enzymes with charged substrates, steers its substrate toward its gorge and into the active site.

The second anionic site of AChE, the so-called peripheral anionic site, is located at the active center gorge entry and encompasses overlapping binding sites for different activators and inhibitors. The peripheral anionic site consists of residues Tyr72, Trp286, and Tyr341. Binding of ligands to these residues may be key to the allosteric modulation of AChE catalytic activity (Bourne et al., 2003).

69.4 Antidotes for AChE inhibited by OP compounds

Antidotes developed for treatment of nerve agent intoxication can be divided into two types: prophylaxis, as preexposure administration of antidotes; and postexposure treatment, consisting of anticholinergic drugs, AChE reactivators, and anticonvulsants. The best-known prophylactic means are carbamates (e.g., pyridostigmine and physostigmine), oximes (e.g., asoxime and the Transant patch), and bioscavengers (e.g., butyrylcholinesterase (BChE), paraoxonase, and phosphotriesterase). The main drugs used for postexposure treatment are anticholinergic agents (functional antidotes) that antagonize the effects of accumulated ACh at cholinergic synapses, and AChE reactivators (called *oximes* concerning their functional oxime group) which restore AChE inhibited by the OP inhibitor (causal antidotes). Their effects are synergistic. Centrally active drugs such as benzodiazepines (e.g., diazepam or avizafone) are also used as anticonvulsants (Bajgar, 2004).

Pralidoxime chloride or mesylate (2-PAM), obidoxime chloride (LüH-6), methoxime chloride or mesylate (MMC-4 or MMB-4), trimedoxime chloride (TMB-4 or TMC-4), and asoxime chloride or mesylate (HI-6) are considered the most important commercially available AChE reactivators (Fig. 69.2). Other AChE reactivators are currently under development in different countries, including HLö-7, K027, and K203 (Fig. 69.3; Gorecki et al., 2019).

From a chemical point of view, standard AChE reactivators are monoquaternary or bisquaternary pyridinium salts bearing a functional oxime group in their molecules. The oxime in the form of oximate is able to split the bond between the OP and enzyme. Consequently, free-functioning AChE is released. Unfortunately, none of five commercial AChE reactivators is effective against all known nerve agents and OP pesticides (Table 69.2; Kuca et al., 2007). However, there are some novel experimental reactivators that might bring additional benefit to the postexposure antidotal treatment.

TABLE 69.2 Reactivation potencies of five commercially available oximes (Kuca et al., 2007).

	Pralidoxime	Trimedoxime	Obidoxime	Methoxime	Asoxime

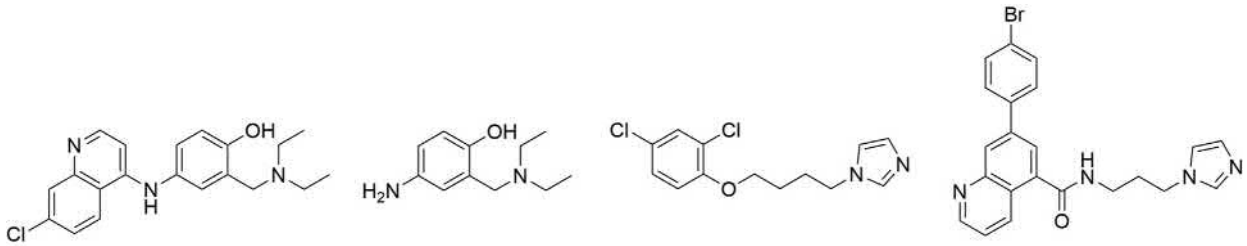

FIGURE 69.4 Uncharged nonoximes (Katz et al., 2015).

69.5 Design and synthesis of new AChE and BChE reactivators

To date, there are many scientific institutions around the world that are interested in the design, synthesis, and improvement of new antidotes against CWAs, especially nerve agents. This is because of the continuous threat of nerve agent misuse by terrorists. Finding a suitable oxime that is sufficiently effective against OP-inhibited AChE or >BChE (regardless of the type of OP compound) is a very important task. There are several reviews dealing with the synthesis of new cholinesterase reactivators (e.g., Musilek et al., 2007, 2011; Mercey et al., 2012; Korabecny et al., 2014; Sharma et al., 2015; Gorecki et al., 2016, 2017; Malinak et al., 2018a; Franjesevic et al., 2019). Several studies related to the design and synthesis of novel reactivators since 2013 are further discussed. The prepared compounds were sorted according to their chemical structure to uncharged non-oxime reactivators, uncharged oxime reactivators, and mono- or double-charged oximes reactivators.

69.6 Uncharged non-oxime reactivators

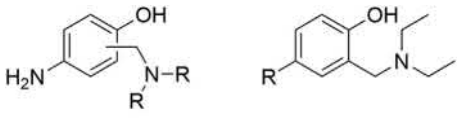
Katz et al. (2015) discovered Mannich phenol bases without oxime moiety (**1**−**4**; Fig. 69.4) that were studied on a reactivation mechanism and tested on NIMP-, SIMP-, paraoxon-, and DFP-inhibited human, mouse, and guinea pig AChE. Compound ADOC (**2**) was found to have a reactivation effect better than pralidoxime and further compound SP134 (**3**) was selected due to better reactivation of paraoxon and DFP, whereas compound SP138 (**4**)

was chosen due to better reactivation of NIMP and SIMP surrogates.

Cadieux et al. (2016) explored a series of compounds missing oxime moiety derived from ADOC (**5**–**6**; Fig. 69.5) and evaluate them on sarin-, cyclosarin-, VX-, and VR-inhibited hAChE. The phenolic fragment was found to be important for reactivation ability, however ADOC (**2**) resulted as the best compound and only worse or comparable to pralidoxime reactivation ability.

Katz et al. (2018) reported screening for compounds without oxime moiety (**7**–**8**; Fig. 69.6) that were tested on mouse AChE or human BChE inhibited by paraoxon. The non-oxime compounds were found to be weak reactivators of phosphylated AChE or BChE comparable with pralidoxime in some cases.

de Koning et al. (2018) developed compounds without oxime moiety derived from ADOC (**9**; Fig. 69.6) that were assayed on hAChE inhibited by VX, sarin, cyclosarin, tabun, and paraoxon. Some compounds showed similar reactivation ability to parent ADOC (**2**) molecule, but they were unfortunately not compared to a standard oxime reactivator. The inhibitory ability of novel compounds varied from low to high μM range. This study was further expanded by Horn et al. (2018) and four compounds including ADOC (**9**) were tested on hAChE inhibited by VX, sarin, cyclosarin, and paraoxon. One compound showed some ability to reactivate all OP species, but in most cases the effect was much lower than asoxime.



5 6

FIGURE 69.5 ADOC analogues (Cadieux et al., 2016).

69.7 Uncharged oxime reactivators

A series of seven novel uncharged compounds (Renou et al., 2013) combining 3-hydroxy-2-pyridinealdoxime with different peripheral site ligands was prepared and examined for VX- and tabun-inhibited human AChE (**10**; Fig. 69.7). Concerning in vitro reactivation of VX-hAChE, they were more efficient than pralidoxime, but less efficient than obidoxime and asoxime. Regarding tabun-inhibited AChE, only one compound reached a reactivation potency comparable to pralidoxime.

Kovarik et al. (2013) published a huge series of uncharged hydroxyiminoacetamides and hydroxyiminoimidazoles (**11**–**13**; Fig. 69.7) that were referred to as centrally acting oximes for OP-inhibited AChE. Among 135 novel oximes, compound RS194B (**4**) was highlighted to efficiently reactivate sarin, cyclosarin, and VX in a rate similar to pralidoxime under in vitro conditions.

Sit et al. (2014) developed uncharged or monocharged 2-hydroxyiminoimidazoles (**14**; Fig. 69.8) that were tested on BChE inhibited by analogs of sarin, cyclosarin, VX, and paraoxon in order to prepare an effective pseudocatalytic bioscavenger. The reactivation of hAChE was found to be slow, but several compounds were found to be better than TAB2OH (**38**) or commercial standard pralidoxime for reactivation of hBChE inhibited by cyclosarin and VX.

Renou et al. (2014) designed uncharged tryptoline-3-hydroxypyridinaldoximes (**15**; Fig. 69.8) to reactivate human acetylcholinesterase inhibited by VX, tabun, and paraoxon or human butyrylcholinesterase inhibited by VX. Two compounds were highlighted for reactivation of VX-, tabun-, and paraoxon-inhibited AChE in all cases better than pralidoxime and similar or slightly better than commercial standards trimedoxime, obidoxime, or asoxime for specific OPs. The reactivation of VX-inhibited BChE was found to be far better than pralidoxime, obidoxime and asoxime.

18 19 20

FIGURE 69.10 Tetrahydroacridine pyridine-aldoximes/amidoximes (Kliachyna et al., 2014).

McHardy et al. (2014) developed uncharged amide oximes and ketoximes (**16**–**17**; Fig. 69.9) that were designed to reactivate cyclosarin-inhibited AChE. The reactivation results were only compared to monoisonitrosoacetone (MINA) that does not belong among the standard oximes used for OP poisoning treatment. Some novel reactivators were found to be potent AChE inhibitors in the μM or nM range.

Kliachyna et al. (2014) presented uncharged tetrahydroacridine pyridine-aldoxime and -amidoxime hybrids (**18**–**20**; Fig. 69.10) and tested them for reactivation of AChE inhibited by VX, tabun, and paraoxon. One compound (**20**) resulted as a powerful reactivator of all tested OPs under in vitro conditions when compared to pralidoxime, trimedoxime, obidoxime, or asoxime. Some novel reactivators, including the most potent compound (**20**), were found to be potent AChE inhibitors in the μM or nM range.

Wei et al. (2014) prepared uncharged 2-hydroxyiminoimidazoles with peripheral binding ligand (**21**–**22**; Fig. 69.11) and evaluated them on sarin-, VX-, and tabun-inhibited hAChE. One compound (**22**) was found to be effective for sarin-inhibited hAChE better than asoxime, the same compound was comparable with asoxime for VX reactivation and results were comparable with trimedoxime for tabun reactivation in vitro. The novel reactivators were found to be moderate or weak AChE inhibitors in the mM or high μM range.

Wei et al. (2016) published uncharged *o*-hydroxybenzaldoximes (**23**; Fig. 69.11) for reactivation of soman-inhibited hAChE. The restoration of enzymatic activity was determined in various time intervals and was found better than pralidoxime, but far worse than asoxime reactivation ability.

Maraković et al. (2016) designed and prepared uncharged *N*-substituted-2-hydroxyiminoacetamides (**24**–**25**; Fig. 69.12) and screened them on sarin-, cyclosarin-, and VX-inhibited hAChE or hBChE. One compound was found to be beneficial for phosphylated hAChE with reactivation ability over 60% for all OPs and two compounds were found to be promising for phosphylated hBChE with a reactivation ability over 60% for all OPs, but data for a standard reactivator were not provided. The presented compounds resulted as moderate to weak inhibitors of hAChE and strong to moderate inhibitors of hBChE.

Katalinić et al. (2016) published an evaluation of uncharged imidazole or monocharged imidazolium compounds (**26**–**27**; Fig. 69.12) on hBChE inhibited by tabun, paraoxon, or VX. Two molecules were indicated to be able to exceed obidoxime reactivation of paraoxon and five molecules were able to exceed obidoxime and asoxime reactivation of VX. It has to be noted that the majority of the novel molecules were able to strongly inhibit hBChE in a low μM scale.

Wei et al. (2017) developed uncharged conjugates of salicylaldoximes with peripheral site ligands (**28**; Fig. 69.13) that were screened on hAChE inhibited by VX, sarin, tabun, and soman. Four compounds showed an

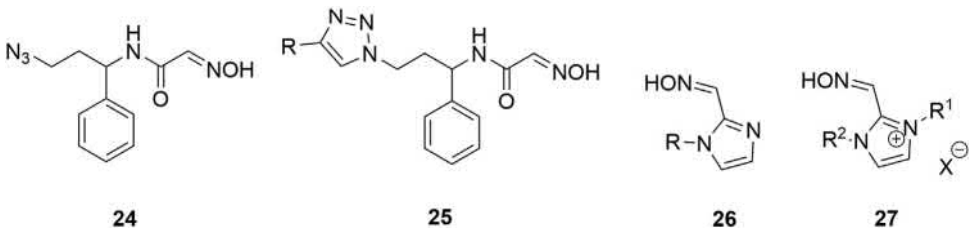

FIGURE 69.12 Uncharged *o*-hydroxybenzaldoximes and *N*-substituted-2-hydroxyiminoacetamides (Maraković et al., 2016; Katalinić et al., 2016).

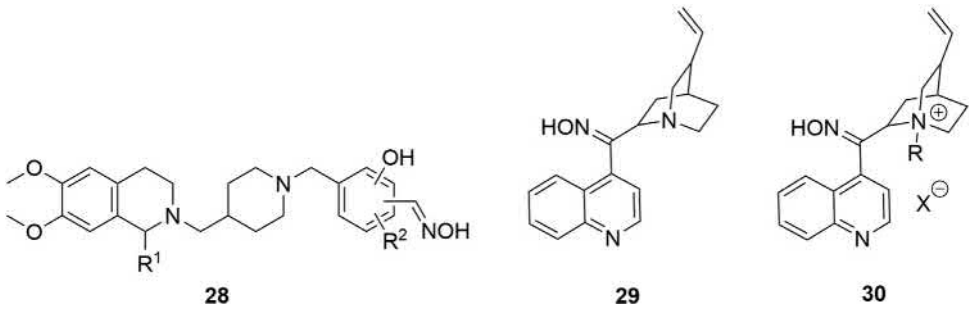

FIGURE 69.13 Salicylaldoximes and cinchona oximes (Wei et al., 2017; Katalinić et al., 2017).

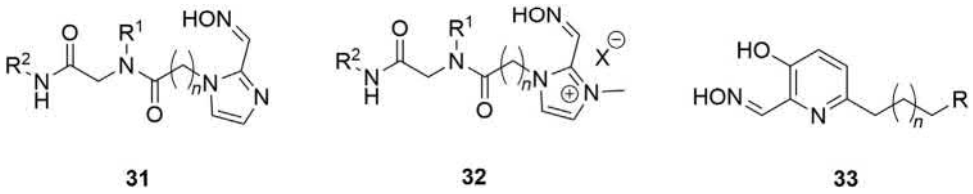

FIGURE 69.14 Uncharged imidazole oximes and 3-hydroxy-2-pyridine aldoximes (de Koning et al., 2017; Zorbaz et al., 2018a).

increased reactivation rate for VX and tabun comparable with obidoxime or asoxime, but none exceeded asoxime for sarin reactivation based on overall reactivation rate constant. The presented salicylaldoximes were moderate or weak inhibitors of hAChE.

Katalinić et al. (2017) published uncharged or monocharged cinchona oximes derived from 9-oxocinchonidine (**29**–**30**; Fig. 69.13) and screened them on sarin-, cyclosarin-, VX-, tabun-, and paraoxon-inhibited hAChE or hBChE. The oximes resulted in weak hAChE reactivators with the best reactivation of ~20% for VX. The better reactivation was observed for hBChE, but all novel compounds were found to be weaker reactivators for tested OPs than standards of asoxime, obidoxime, or K117. Notably, cinchona oximes showed higher inhibition of hBChE in the low μM or nM range.

de Koning et al. (2017) applied an Ugi multicomponent reaction for the synthesis of uncharged imidazole oximes or charged imidazolium oximes with peripheral site ligand (**31**–**32**; Fig. 69.14) that were tested on hAChE inhibited by sarin, cyclosarin, VX, and tabun. For sarin-, cyclosarin-, and VX-inhibited hAChE, the tested oximes were not able to exceed the reactivation ability of asoxime or obidoxime. For the tabun-inhibited enzyme, one compound showed reactivation ability comparable with obidoxime.

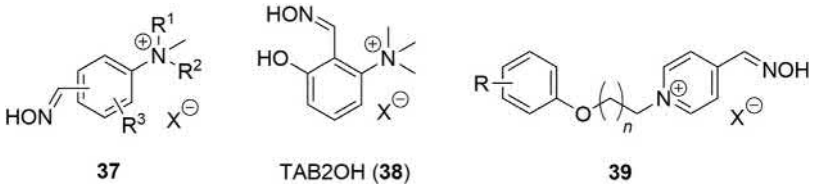

FIGURE 69.16 Trialkylammonium salts with aryloxime and monopyridinium salts with 4-positioned oxime (Radić et al., 2013; Chambers et al., 2013).

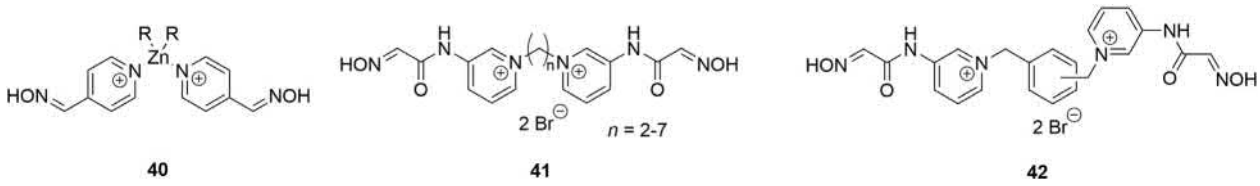

FIGURE 69.17 Zinc complexes of 4-hydroxyiminopyridine and pyridine-3-yl-acetamides (Konidaris et al., 2014; Karade et al., 2014).

Zorbaz et al. (2018a) published uncharged 3-hydroxy-2-pyridine aldoximes (**33**; Fig. 69.14) and evaluated them on hAChE or hBChE inhibited by VX, sarin, cyclosarin, tabun, and paraoxon. The reactivation rates of two oximes for VX-, tabun-, and paraoxon-inhibited hAChE were found to be greater than asoxime. The reactivation rates of several oximes for VX-, cyclosarin-, tabun-, and paraoxon-inhibited hBChE were found to be greater than asoxime. The presented aldoximes were strong to weak inhibitors of hAChE or hBChE.

Wei et al. (2018) designed uncharged conjugates of salicylaldoximes with peripheral site ligands (**34**–**35**; Fig. 69.15) that were evaluated on hAChE inhibited by VX, sarin, tabun, soman, and several OP pesticides. Based on a second-order reactivation rate constant, two compounds were found comparable with obidoxime for tabun reactivation, but they were no more efficient than asoxime for sarin and VX. Some oximes were found to be promising for OP pesticide reactivation when compared to reactivation ability of obidoxime. All compounds resulted as weak inhibitors of hAChE in the mM range.

de Paula et al. (2018) published a study on uncharged isatin-3-oxime (**36**; Fig. 69.15) that was evaluated on paraoxon-inhibited eel AChE. Isatin-3-oxime was found to be worse in reactivation of paraoxon when compared to pralidoxime or obidoxime.

69.8 Mono- or double-charged oxime reactivators

Radić et al. (2013) published trialkylammonium salts with aryloxime moiety (**37**–**38**; Fig. 69.16) for reactivation of paraoxon-, cyclosarin-, VX-, and sarin-inhibited AChE and BChE. The reactivation of AChE relative to pralidoxime was found to be low. The reactivation of BChE relative to pralidoxime identified compound TAB2OH (**38**) with 2-positioned aryloxime and 3-phenolic moiety that was most effective against VX-inhibited BChE.

Chambers et al. (2013) prepared monopyridinium salts with 4-positioned oxime and modified peripheral binding motif (**39**; Fig. 69.16). The compounds were tested on rat brain homogenates inhibited by sarin and VX surrogates (PIMP and NEMP) and their in vitro reactivation ability was found to be lower than pralidoxime or trimedoxime.

Konidaris et al. (2014) synthesized zinc complexes of 4-hydroxyiminopyridine (**40**; Fig. 69.17) and tested their reactivation on paraoxon-inhibited eel AChE. The reactivation ability was found to be far lower than for the reference compound obidoxime. Karade et al. (2014) synthesized a series of double-charged pyridine-3-yl-acetamides (**41**–**42**; Fig. 69.17) and tested them on sarin- and VX-inhibited hAChE. Some of prepared compounds were comparable with pralidoxime and one was

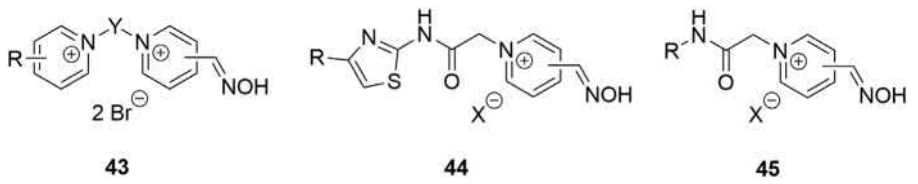

FIGURE 69.18 Double charged oximes tested on hBChE, *N*-thiazolylacetamido pyridinium oximes and pyridinium acetamides (Horn et al., 2015; Valiveti et al., 2015a,b).

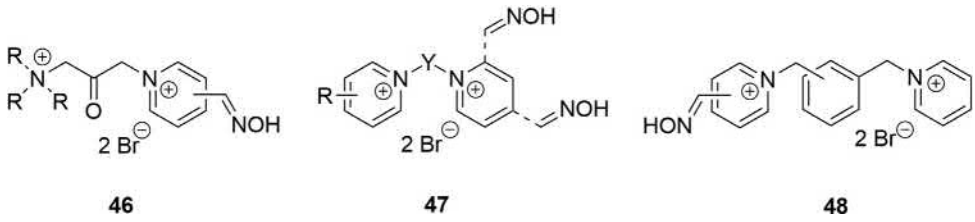

FIGURE 69.19 Monopyridinium oximes with ammonium fragment and double-charged bispyridinium oximes (Bobkova, 2015; Winter et al., 2016; Musilek et al., 2016).

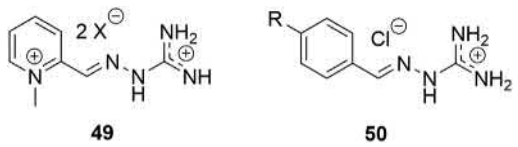

FIGURE 69.20 Monocharged guanylhydrazones (Petronilho et al., 2016).

comparable with obidoxime for sarin reactivation, whereas all novel compounds were found to be worse than obidoxime for VX reactivation concerning the overall reactivation rate constant.

Horn et al. (2015) analyzed the reactivation ability of formerly prepared double-charged oximes (**43**; Fig. 69.18) on BChE inhibited by paraoxon, tabun, and cyclosarin. The tested oximes have a low-to-negligible reactivating potency with paraoxon- and tabun-inhibited hBChE including the commercial oximes (pralidoxime, methoxime, trimedoxime, obidoxime, and asoxime), whereas several novel oximes showed a moderate-to-high potency with cyclosarin-inhibited hBChE. The majority of tested oximes resulted in poor inhibitors of hBChE in the high μM or mM range.

Valiveti et al. (2015a) presented a series of monocharged *N*-thiazolylacetamido pyridinium oximes (**44**; Fig. 69.18) and used them on the model of sarin-, *O*-ethylsarin-, and VX-inhibited hAChE. Concerning the overall reactivation rate constant, the novel oximes were found to be generally worse than pralidoxime and obidoxime for sarin inhibition. For *O*-ethylsarin inhibition, some oximes were comparable in reactivation ability with pralidoxime and one with obidoxime. Two oximes were better than pralidoxime, but none comparable with obidoxime for VX-inhibited AChE.

Valiveti et al. (2015b) published a series of monocharged pyridinium acetamides (**45**; Fig. 69.18) which were evaluated on sarin-, VX-, and tabun-inhibited hAChE. Three novel oximes were found comparable and two were better than obidoxime for reactivation of sarin. Additionally, two oximes were found to be comparable with obidoxime for VX reactivation and one oxime for tabun reactivation based on overall reactivation rate constant.

Bobkova (2015) presented a series of double-charged monopyridinium oximes with aliphatic ammonium fragment mimicking choline moiety (**46**; Fig. 69.19) that were tested on VX-inhibited hAChE. Three novel compounds were able to restore hAChE activity better than trimedoxime at varying concentrations.

Winter et al. (2016) tested a large series of double-charged bispyridinium oximes (**47**; Fig. 69.19) on tabun-, cyclosarin-, and paraoxon-inhibited hAChE. Several oximes were highlighted as reactivators for a single OP inhibitor, but no oxime could be rated as a broad-spectrum candidate from this in vitro evaluation.

Musilek et al. (2016) described double-charged bispyridium oximes bridged by xylene moiety (**48**; Fig. 69.19) that were subjected to testing on tabun-, ethylparaoxon-, methylparaoxon-, and DFP-inhibited hAChE. Some novel compounds were found to be better than pralidoxime, but they were not able to exceed the reactivation ability of obidoxime.

Petronilho et al. (2016) prepared monocharged guanylhydrazones (**49**−**50**; Fig. 69.20) as potential inhibitors or reactivators of eel AChE. Some compounds were found to be moderate eel AChE inhibitors, but all failed in reactivation ability when they were compared to pralidoxime.

57 58 59

FIGURE 69.23 Pyridine-3-yl-acetamides and Zinc database oximes (Karade et al., 2016; Berberich et al., 2016).

Amitai et al. (2016) developed a series of bifunctional mono- or double-charged pyridinium oximes with carbamate moiety (**51**–**53**; Fig. 69.21) and tested their reactivation of sarin-, cyclosarin-, and VX-inhibited hAChE. One compound was found to have a better reactivation rate for cyclosarin than pralidoxime, however all compounds were far worse than asoxime for all tested OPs. Novel compounds were proved to be inhibitors of hAChE on a low μM scale, which could be used for prophylactic purposes.

Sharma et al. (2016) prepared monocharged alkylated imidazolium oximes and double-charged imidazolium oximes with second oxime moiety (**54**–**55**; Fig. 69.22) for screening of sarin- and VX-inhibited hAChE. One double-charged compound was found to be better than pralidoxime for sarin reactivation, but all compounds failed to exceed reactivation of obidoxime and asoxime for both OPs. The novel compounds were found to be weak hAChE inhibitors in the mM range.

Chambers et al. (2016) prepared other series of monocharged phenoxyalkyl pyridinium oximes (**56**; Fig. 69.22) and evaluated them on surrogates of sarin- (PIMP) and VX-inhibited (NEMP) bovine brain AChE (bvAChE) in vitro. The compounds were poor reactivators of PIMP-inhibited bvAChE compared to pralidoxime and trimedoxime, which were unfortunately not tested as standards for NEMP-inhibited bvAChE, where the novel compounds provided a maximal reactivation of ~60%. Interestingly, in animal studies, some compounds were found to reactivate rat brain AChE more than pralidoxime in two time intervals.

Karade et al. (2016) designed another series of double-charged pyridine-3-yl-acetamides with pyridinium carboxamide moiety (**57**; Fig. 69.23) which were tested on sarin- and VX-inhibited hAChE. Two compounds were identified to exceed the reactivation ability for sarin-inhibited AChE and one for VX-inhibited AChE better than pralidoxime and obidoxime. The presented compounds resulted as weak inhibitors of hAChE.

Berberich et al. (2016) used virtual screening techniques to identify novel scaffolds from Zinc database and assayed six selected and double-charged compounds (**58**–**59**; Fig. 69.23) for reactivation ability on paraoxon-, DFP-, fenamiphos-, and methamidophos-inhibited hAChE. Five oximes were found to be promising in reactivation of all tested OPs when compared to pralidoxime. Some novel molecules showed a certain level of inhibition to hAChE higher than pralidoxime.

Bušić et al. (2016) prepared monocharged pyridoxal oxime analogs (**60**; Fig. 69.24) that were screened on tabun-, paraoxon-, or VX-inhibited hAChE and hBChE. The reactivation of hAChE or hBChE by novel compounds

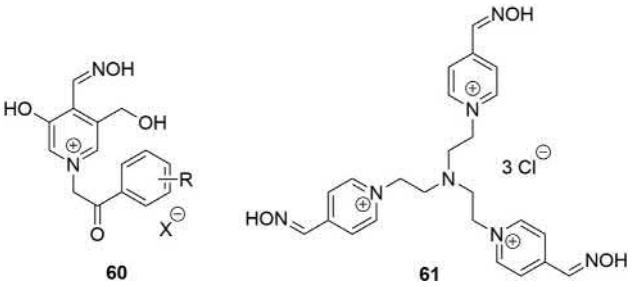

FIGURE 69.24 Pyridoxal oxime analogs and trisoxime (Bušić et al., 2016; Kuca et al., 2016).

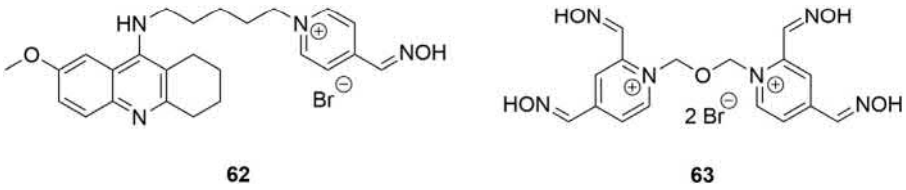

FIGURE 69.25 7-Methoxytacrine-4-pyridinealdoxime hybrid and tetroxime (Nepovimova et al., 2016; Kuca et al., 2017).

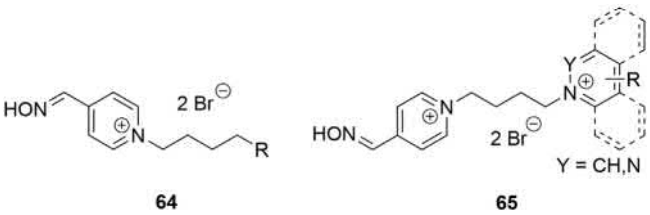

FIGURE 69.26 Double-charged reactivators and analogs of K048 (Kuca et al., 2018; Malinak et al., 2018b).

was found to be low compared to standards trimedoxime, obidoxime, and asoxime. The novel oximes resulted in moderate–high μM inhibitors of both enzymes.

Kuca et al. (2016) presented a triple-charged trisoxime compound (**61**; Fig. 69.24) that was tested on rat brain AChE inhibited by various OP species and compared to monocharged 4-pralidoxime (4-PA) and double-charged K074. The trisoxime reactivated sarin, VX, and DFP better than 4-PA and was comparable to double-charged K048, but remained almost inactive for other OPs.

Nepovimova et al. (2016) designed and prepared a monocharged 7-methoxytacrine–4-pyridinealdoxime hybrid (**62**; Fig. 69.25) for prophylactic purposes and screened it on tabun-, sarin-, VX-, and paraoxon-inhibited hAChE. The hybrid was found to be partially effective in reactivation of all OPs, but generally pralidoxime, 4-PA, or obidoxime. The hybrid was indicated as a potent hAChE inhibitor on a low μM scale.

Kuca et al. (2017) studied a double-charged tetroxime reactivator (**63**; Fig. 69.25) for reactivation of sarin, cyclosarin, VX, and tabun. Tetroxime was a poor reactivator in the majority of OPs when compared to pralidoxime with the exception of VX, where it showed enhanced reactivation ability.

Kuca et al. (2018) presented three double-charged compounds (**64**; Fig. 69.26) that were screened on paraoxon-inhibited hAChE and hBChE. The compounds generally resulted in weak reactivators for hAChE and hBChE compared to pralidoxime, obidoxime, or asoxime.

Malinak et al. (2018b) synthesized double-charged analogs of K048 (**65**; Fig. 69.26) that were tested on tabun-, ethylparaoxon-, methylparaoxon-, and DFP-inhibited hAChE. Several novel compounds were found to be effective reactivators for individual OPs with better ability than used standards, but none was considered to be a broad-spectrum molecule. The inhibitory effect of novel compounds varied from low to high μM levels.

Kim et al. (2018) conjugated tacrine with pyridinium moiety and produced monocharged hybrid oximes (**66**; Fig. 69.27) that were screened on paraoxon-inhibited eel AChE. Some compounds showed reactivation better then pralidoxime and asoxime. The majority of hybrid oximes were found to be strong inhibitors of eel AChE in the low μM range.

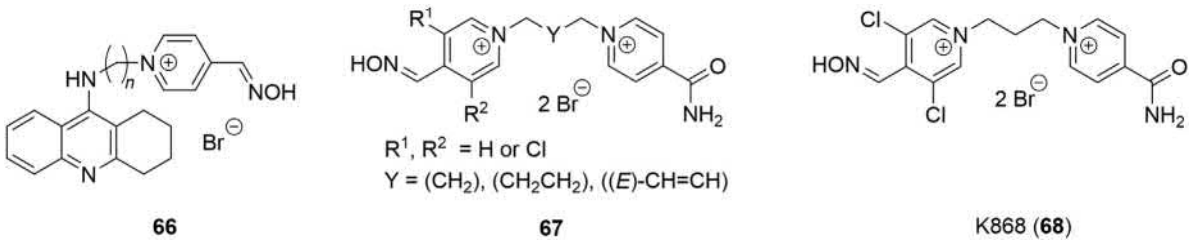

FIGURE 69.27 Tacrine-pyridinium-oximes and chlorinated oximes (Kim et al., 2018; Zorbaz et al., 2018b).

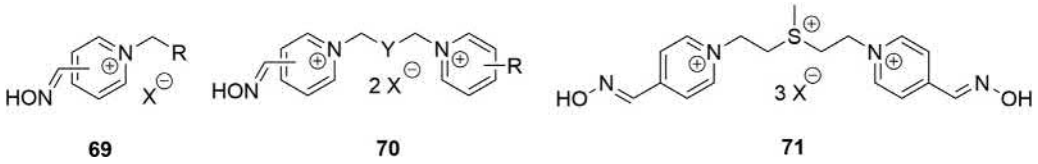

FIGURE 69.28 Monocharged or double-charged pyridinium oximes and triple-charged bisoxime (Bharate et al., 2019; Kuca et al., 2019).

Zorbaz et al. (2018b) designed and prepared double-charge chlorinated oximes derived from K027, K048, and K203 (**67**−**68**; Fig. 69.27) with the aim of enhancing the oximate formation and increasing the nucleophilicity toward the OP-AChE adduct. The chlorinated oximes were tested on hAChE inhibited by sarin, cyclosarin, VX, and tabun. The results showed that novel compounds had enhanced properties in reactivation of all used OPs compared to standards of pralidoxime or even asoxime. The reactivation of tabun was found to be worse than experimental standard K203. Oxime K868 (**68**) was identified to be the most broad-spectrum molecule for reactivation of sarin, cyclosarin, and VX, exceeding the potency of asoxime and also had some tabun reactivation ability (although minor), which is missing in the case of asoxime. The chlorinated oximes were found as medium to weak inhibitors of hAChE in the μM range. Zorbaz et al. (2019) further explored the investigation of chlorinated oximes for hBChE inhibited by sarin, cyclosarin, VX, and tabun for pseudo-catalytic scavenger purposes. Some chlorinated oximes displayed enhanced reactivation ability, namely for sarin- and tabun-inhibited hBChE that was better than pralidoxime or asoxime. Again, oxime K868 was the most broad-spectrum reactivator showing ability to counteract sarin, cyclosarin, VX, and tabun under in vitro conditions.

Bharate et al. (2019) synthesized monocharged or double-charged pyridinium oximes (**69**−**70**; Fig. 69.28) that were subjected to screening on paraoxon-, methylparaoxon-, and DFP-inhibited eel AChE. One novel monocharged oxime was a reactivator comparable in activity with pralidoxime. Two double-charged compounds were shown to reactivate OPs on a similar level as trimedoxime or obidoxime, however their structures were formerly known as K048 and K074.

Kuca et al. (2019) published a study on a triple-charged bispyridinium bisoxime (**71**; Fig. 69.28) that was tested on rat brain AChE inhibited by sarin, cyclosarin, VX, and tabun. The trisoxime was not able to reactivate cyclosarin and tabun, but showed some reactivation of sarin and VX that was rationalized by a molecular docking study.

69.9 In vitro evaluation of selected AChE reactivators

There are many available techniques to evaluate the reactivation activity of structurally different AChE reactivators (Holas et al., 2012). Probably the most frequently used is Ellmann's method (Ellman et al., 1961) which has its advantages and limitations (Sinko et al., 2007). Further, there is variability within the AChE species that can be used for in vitro evaluation. For instance, there is an extensive difference in inhibitory potency of paraoxon with human and guinea pig AChE (Worek et al., 2011), but only moderate differences of the reactivation between human and animal AChE were found. The availability of human AChE/BChE from recombinant sources or from human erythrocytes/plasma has much increased over the last decade. It seems to be important to prefer human sources of enzymes because the data obtained on, for example, eel or rat AChE might be highly different. The interspecies differences are also important for further in vivo evaluation (Herkert et al., 2011; Jaćević et al., 2019).

The tested OP species are related to the decision of the scientific group. Sarin, VX, tabun and OP pesticides are usually and most frequently tested. Sarin is an example of a volatile OP molecule, whereas VX is a representative of persistent OP compounds and tabun is one of the

most difficult reactivable OPs. The surrogates of nerve agents were formerly introduced (Meek et al., 2012; Cavalcante et al., 2019). Their use now allows a broader scientific community to prepare reactivation experiments with the same phosphylated enzymes as with the use of nerve agents. Prior to surrogates, such experiments were available only with low-toxicity OP pesticides (e.g., paraoxon).

Additionally, there are differences in protocols used for cholinesterase activity determination (Maček Hrvat et al., 2018). The results are almost incomparable among various laboratories, however data from one laboratory could be considered to be consistent, comparative, and informative. All results considered in the structure–activity relationship discussed below attempt to compare results obtained in different scientific groups with different methods on different cholinesterase species.

69.10 The structure–activity relationship and discussion

Three major classes of cholinesterase reactivators were developed in the last decade. The uncharged non-oxime reactivators were first described in 2015 and are the smallest group for AChE reactivation, consisting of compounds with various phenol bases. ADOC (**2**) was the most studied compound among them and it was predicted to form quinone methides which are reactive to AChE (de Koning et al., 2018). The aromatic phenol moiety with *o*-positioned tertiary amine hidden in the cycle was found to be the most promising to date. The reactivation ability of such non-oxime compounds was found to some extent to be comparable with pralidoxime, but in most cases it failed to reach reactivation ability of asoxime (Horn et al., 2018).

The uncharged oxime reactivators were being developed for the whole decade. The 3-hydroxy-2-pyridinealdoximes with different peripheral binding site ligands (e.g., tacrine, tryptoline, morpholine) were introduced with very interesting reactivation abilities toward multiple OP species under in vitro conditions (e.g., Zorbaz et al., 2018a). The 3-hydroxypyridine moiety is potentiating the oximate formation and thus reactivation. The peripheral binding site ligands help the molecule to accommodate in the OP-inhibited enzyme, but this structural fragment in some cases led to increased and unwanted cholinesterase inhibitory ability by the uncharged oxime. The in vivo data indicate that the dosing and achieving the appropriate plasma levels for reactivation of uncharged 3-hydroxy-2-pyridinealdoximes might be a problem (Calas et al., 2017).

The hydroxyiminoacetamides (e.g., Kovarik et al., 2013) were designed to be brain penetrable and attainable. There were shown to be very effective in vitro against multiple OP species with a lead structure of RS194B (**4**), but it should be noted that they were usually compared only to pralidoxime and not to more effective standards such as obidoxime or asoxime. However, animal studies revealed the rapid clearance of such small molecules from brain and body (Malfatti et al., 2017), which may limit their further development or use.

The 2-hydroxyiminoimidazoles are another structural group of cholinesterase reactivators which were prepared as uncharged or monocharged compounds (e.g., Wei et al., 2014; Katalinić et al., 2016). The oxime moiety was retained and the binding motif usually consisted of aromatic moiety with different spacer length. Several hit structures with modified aromatic fragments were found to be able to reactivate hAChE or hBChE in vitro. Some potent reactivators were found to have potent and unwanted cholinesterase inhibitors as well.

The *o*-hydroxybenzaldoximes and salicylaldoximes (Wei et al., 2016, 2017, 2018) were designed with phenolic moiety, helping the formation of oximate on the uncharged aromatic ring. The structure was expanded by a peripheral site binding fragment. Some compounds were able to reach reactivation levels of obidoxime or asoxime under in vitro conditions and were found relatively weak hAChE inhibitors. The in vivo data are not available to date. There were also other attempts to design potent uncharged oximes, such as cinchona oximes (Katalinić et al., 2017) or isatin-oxime (de Paula et al., 2018), but with poor reactivation efficiency.

The potential issue for all uncharged oximes is water/buffer solubility for in vivo applicability (Soukup et al., 2018). It has to be noted that reactivators are applied by i.m. injection dissolved in water and the starting dose ranges between 300 and 1000 mg for marketed reactivators. Thus, some level of solubility of uncharged compound in water should be retained for such a high dose, which is necessary to save lives. The in vivo data published to date indicate that this is a crucial issue for uncharged cholinesterase reactivators.

The monocharged and double-charged cholinesterases have been being developed for many decades. The pyridinium or imidazolium fragment with 2- or 4-positioned oxime moiety is usually used for reactivation and pyridinium-connected scaffold serves as an enzyme-binding motif. In some cases, quaternary nitrogen can be pulled out of the aromatic ring (Radić et al., 2013) while retaining a certain level of reactivation ability, or the quaternary ammonium fragment in a double-charged compound can serve as a peripheral binding part of the molecule (Bobkova, 2015). The monocharged compounds with proper peripheral binding motifs were found to have effective reactivation (Chambers et al., 2013), but the double-charged compounds usually have stronger binding

to phosphylated enzymes. However, the addition of quaternary nitrogen to form a triple-charged compound (Kuca et al., 2019) does not bring further reactivation benefit. Similarly, the introduction of strong cholinesterase inhibitors as peripheral binding motifs led in many cases to a decrease in the reactivation ability (Nepovimova et al., 2016; Kim et al., 2018). The addition of another oxime moiety to form bisoxime (e.g., methoxime, trimedoxime, obidoxime), trisoxime (Kuca et al., 2016), or tetroxime (Kuca et al., 2017) may increase the reactivation, although it is not necessary and might complicate the molecule binding in the OP-inhibited enzyme. The single oxime functional group with proper pK_a to form an oximate anion should be sufficient for OP reactivation. Most of the presented charged compounds have pK_a ~7.8−8.5, where oximate formation is limited (Musil et al., 2016). The introduction of chlorine atom(s) in close proximity to the oxime moiety decreased pK_a and helped oximate formation (Zorbaz et al., 2018b). This effect led to increased reactivation of sarin-, cyclosarin-, VX-, and tabun-inhibited hAChE or BChE and was even better than asoxime which serves as the gold standard in the field of cholinesterase antidotes (Zorbaz et al., 2018b, 2019). Thus, oxime K868 (**68**) seems to be a very promising molecule for further research and development.

69.11 Recent trends in the development of new AChE reactivators and future directions

Along with those AChE reactivators that are commercially available (namely, pralidoxime, trimedoxime, methoxime, obidoxime, and asoxime), there are several trends that are seen as promising.

The uncharged nonoxime or oxime molecules became of scientific importance and their reactivation ability under in vitro conditions in many cases reached used standards. However, their research and development have to continue due to unsolved in vivo issues that limit their current use and effectiveness in vivo (Calas et al., 2017; Malfatti et al., 2017; Soukup et al., 2018). Once they have a balanced pharmacokinetic profile, they could serve as brain protection against OP toxicity.

The charged oxime molecules are well known but possibly could be improved. A good example could be oxime K203 that is to date one of best reactivators of tabun-inhibited hAChE (reviewed in Gorecki et al., 2019). There are a few more, for example, K207 and K048, that are undergoing thorough evaluation against OP pesticide intoxications (Antonijevic et al., 2019; Lorke and Petroianu, 2019). More recently, the chlorinated oximes with pK_a-mediated properties emerged from the scientific community as broad-spectrum hAChE reactivators against multiple OP species (Zorbaz et al., 2018b).

Last but not least, the BChE reactivators are extensively being developed for pseudo-catalytic scavenger purposes (Kovarik et al., 2010). Such scavenger could neutralize the OP via BChE (as a stoichiometric scavenger) and further the inhibited BChE could be renewed by an oxime reactivator to be available repeatedly for nerve agent binding. For hBChE reactivation, the chlorinated oximes may be effectively used against multiple OP species (Zorbaz et al., 2019).

69.12 Concluding remarks and future directions

As discussed in this chapter, the threat of misuse of OP nerve agents by terrorist or military fractions continues. The requirements of agricultural production demand the use of OP pesticides, so deaths from these compounds in agricultural workers are increasing. There is no universal reactivator that could be applied in every case of OP nerve agent or pesticide intoxication. Thus, the development of new, effective, and safe cholinesterase reactivators is necessary.

Acknowledgments

Financial support from the Czech Science Foundation (no. 19-13628 S) and University of Hradec Kralove (Faculty of Science, no. VT2019-2021) is greatly appreciated.

70.1 Introduction

More than 60 years ago, it was discovered that certain organophosphorus (OP) insecticides could be enzymatically hydrolyzed by plasma, and it was determined that this hydrolysis was catalyzed by enzymes which were designated as A-esterases (Mazur, 1946; Aldridge, 1953). Aldridge's proposal that an A-esterase hydrolyzed both phenylacetate and paraoxon (the active metabolite of the OP insecticide parathion), was conclusively proven several decades later, when it was shown that recombinant paraoxonase/arylesterase catalyzed both activities (Gan et al., 1991). Studies in the late 1970s and early 1980s indicated that the plasma hydrolytic activity toward paraoxon was polymorphically distributed in human populations (Playfer et al., 1976; Eckerson et al., 1983; Mueller et al., 1983), suggesting a genetically based differential susceptibility to OP toxicity. The molecular basis of the paraoxonase (PON1) activity polymorphisms (Humbert et al., 1993; Adkins et al., 1993) and their role in the toxicity of OP compounds (Costa et al., 2003a, 2006, 2013; Davies et al., 1996; Li et al., 2000) have been elucidated. Furthermore, novel important roles of PON1 in the metabolism of oxidized lipids, in the bioactivation or detoxification of certain drugs, and in the hydrolysis of quorum-sensing factor, have also emerged, highlighting the multifaceted roles and importance of this enzyme. These latter aspects of PON1 are not discussed in this chapter, but the reader can refer to other publications for further details (Costa and Furlong, 2002; Mackness et al., 2002; Costa et al., 2003b; Draganov and La Du, 2004; Ozer et al., 2005; Ng et al., 2005; Camps et al., 2009; Furlong et al., 2010, 2016).

70.2 PON1 polymorphisms: defining PON1 status

PON1 is a member of a family of proteins that also includes PON2 and PON3, the genes for which are clustered in tandem on the long arms of human chromosome 7 (q21.22). PON1 is synthesized primarily in the liver and a portion is secreted into the plasma, where it is associated with high-density lipoproteins (HDLs) (Sorenson et al., 1999; Deakin et al., 2002). PON1 received its name from its ability to hydrolyze paraoxon, its first and most studied OP substrate. PON1 also hydrolyzes the active metabolites of other OP insecticides (e.g., chlorpyrifos oxon, diazoxon), as well as nerve agents such as sarin or soman. However, many other OPs are not hydrolyzed by PON1. Of the three PONs, only PON1 has OP-esterase activity, while all three are lactonases, displaying overlapping but distinct substrate specificities for lactone hydrolysis (Draganov et al., 2005). The crystal structure for a recombinant chimeric PON1 indicates that it is a six-bladed β-propeller, with two calcium ions in the central tunnel, one of which is essential for enzyme activity and the other for structural stability (Harel et al., 2004). However, recombinant PON1 differs from human PON1 in amino acid sequence and OP-esterase activity (Otto et al., 2009; Trovaslet-Leroy et al., 2011), thus the tertiary structure of native PON1 remains to be elucidated.

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00070-2

Plasma paraoxonase activity in human populations is polymorphically distributed, and individuals with high, intermediate, or low paraoxonase activity can be identified (Eckerson et al., 1983; Mueller et al., 1983; Geldmacher-von Mallinckrodt and Diepgen, 1988; Ginsberg et al., 2009), though, as shown later, the resolution of the three phenotypes is not revealed in an assay with a single substrate (Davies et al., 1996; Richter et al., 2009). Studies in the early 1990s led to the purification, cloning, and sequencing of human PON1 (Gan et al., 1991; Furlong et al., 1991; Hassett et al., 1991), and in the molecular characterization of its polymorphisms (Humbert et al., 1993; Adkins et al., 1993). Two common polymorphisms were observed in the *PON1* coding sequence: a Gln(Q)/Arg(R) substitution at position 192, and a Leu(L)/Met(M) substitution at position 55 (Humbert et al., 1993; Adkins et al., 1993). The gene frequencies of $PON1_{Q192}$ range from 0.75 for Caucasians of northern European origin, to 0.31 for some Asian populations (Brophy et al., 2002). In addition to these two polymorphisms in the coding region of *PON1*, several polymorphisms have been found in the noncoding, 5′ regulatory region of the *PON1* gene, the most significant being the C-108T polymorphism at an Sp1 binding site, with the −108C allele providing levels of PON1 about twice as high on average as the −108T allele (Leviev and James, 2000; Suehiro et al., 2000; Brophy et al., 2001a,b). Complete resequencing of *PON1* from 47 individuals (24 African Americans and 23 Europeans) has revealed more than 160 single nucleotide polymorphisms (SNPs; Furlong et al., 2008). Some of the few that have been characterized so far have allowed reconciliation of discrepancies between PCR analysis of codon 192 and determination of PON1 status (see below; Jarvik et al., 2003)

The L/M polymorphism at position 55 does not affect catalytic activity, but has been associated with plasma PON1 protein levels, with $PON1_{M55}$ being associated with low plasma PON1 (Blatter Garin et al., 1997; Mackness et al., 1998); this appears to primarily result from linkage disequilibrium with the low efficiency of the −108T promoter allele (Brophy et al., 2002), though some data indicate that $PON1_{M55}$ may be somewhat less stable than $PON1_{L55}$ (Leviev et al., 2001; Roest et al., 2007). In contrast, the Q/R polymorphism at position 192 significantly affects the catalytic efficiency of PON1. This polymorphism is substrate-dependent, as the $PON1_{R192}$ alloform hydrolyzes chlorpyrifos oxon and paraoxon more rapidly than $PON1_{Q192}$ in vitro (Li et al., 2000), while both PON1 alloforms hydrolyze diazoxon (Li et al., 2000) and phenylacetate (Furlong et al., 2006) with the same efficiency.

Though most studies investigating the association of PON1 polymorphisms with diseases have examined only the nucleotide polymorphisms (Q192R, L55M, C-108T) with PCR-based assays, it has been argued that measurements of PON1 function (plasma activity) are of greater relevance, as they measure the plasma activity of PON1, which is the most important factor that determines rates of detoxification of both endogenous and xenobiotic substrates. This functional genomic analysis is accomplished using a high-throughput enzyme assay involving two PON1 substrates (either diazoxon and paraoxon or a pair of nontoxic substrates) (Richter et al., 2004, 2008, 2009). This approach, which has been referred to as the determination of the "PON1 status" for an individual (Richter and Furlong, 1999), in addition to providing a functional assessment of the plasma PON_{192} alloforms, also provides the plasma level of PON1 for each individual, thus encompassing the two factors that affect rates at which PON1 detoxifies endogenous and exogenous substrates. Rates of detoxification of compounds that are not affected by the Q192R polymorphism are determined by plasma PON1 concentration. Rates of detoxification of other compounds for which rates are affected by the Q192R polymorphism are determined both by plasma PON1 levels and the PON1 alloform(s) in plasma. In all cases, it is important to determine PON1 plasma levels, and for some compounds the Q192R polymorphism as well. For this reason, many epidemiological studies that have analyzed SNPs alone have not provided useful findings.

For adequate risk assessment, it is important to know PON1 levels and activity. In a given population, plasma PON1 activity can vary up to 40-fold (Eckerson et al., 1983; Mueller et al., 1983; Davies et al., 1996; Richter and Furlong, 1999; Jarvik et al., 2000), and differences in PON1 protein levels up to 13-fold are also present within a single $PON1_{192}$ phenotype (QQ, QR, RR) in adults (Davies et al., 1996). Ample evidence is now available from studies investigating the role of PON1 in cardiovascular disease, that PON1 status (encompassing the Q/R genotype and levels of activity) is a much better predictor of disease than the *PON1* genotype alone (Jarvik et al., 2000; Mackness et al., 2001; Zhao et al., 2012; Bayrak et al., 2012).

70.3 PON1 and the toxicity of OP insecticides

Evidence that PON1 plays a role in modulating the toxicity of OPs has emerged over the past 30 years, though it had been already noted that species differences in PON1 activity correlated with susceptibility to OP toxicity (Brealey et al., 1980; Costa et al., 1987; Furlong et al., 2000). An earlier study by Main (1956) showed that intravenous (i.v.) administration of partially purified PON1 from rabbit serum protected rats from the toxicity of paraoxon. This initial observation was followed by other

studies, which utilized a similar approach; for example, i.v. administration of purified rabbit PON1 to rats protected the animals from the toxicity [indicated by the degree of acetylcholinesterase (AChE) inhibition] of chlorpyrifos oxon and paraoxon (Costa et al., 1990). Additional studies in mice provided evidence that i.v. administration of rabbit PON1 increased serum chlorpyrifos oxonase activity by 30- to 40-fold, and also protected animals against AChE inhibition caused by dermally applied chlorpyrifos oxon (Li et al., 1993). Since i.v. administration of PON1 only increases serum PON1 activity for a short duration, with a half-life of $\sim$6 h, additional experiments investigated whether other routes of administration for PON1 would extend its plasma half-life. When rabbit PON1 was given by the i.v. and i.p. (intraperitoneal) routes, plasma enzyme activity toward chlorpyrifos oxon increased 35-fold and the half-life was extended to 30 h. An even longer half-life, albeit with lower peak activity levels, was found when rabbit PON1 was given by the i.v. and i.m. (intramuscular) routes (Li et al., 1993). These studies also showed that rabbit PON1 could confer protection toward the parent compound, chlorpyrifos, and that protection was also present when the enzyme was given 30 min to 3 h following exposure (Li et al., 1995), suggesting a therapeutic potential for exogenous PON1 in cases of OP poisoning, possibly in combination with other conventional treatments.

In the following years, *Pon1* knockout ($Pon1^{-/-}$) and human *PON1* transgenic mice provided important new tools to investigate the role of PON1 in modulating OP toxicity. Plasma and liver from $Pon1^{-/-}$ mice have no detectable hydrolytic activity toward paraoxon and diazoxon, and very limited chlorpyrifos-oxonase activity (Shih et al., 1998; Li et al., 2000). $Pon1^{-/-}$ mice do not differ from wild-type animals in their sensitivity to demeton-S-methyl, an OP insecticide with a structure similar to malathion, and which is not a substrate for PON1 (Li et al., 2000), but have a dramatically increased sensitivity to chlorpyrifos oxon and diazoxon, and a slightly increased sensitivity to the toxicity of the parent compounds chlorpyrifos and diazinon (Shih et al., 1998; Li et al., 2000). A surprising finding of these studies is that the lack of PON1 did not affect the sensitivity of mice to paraoxon, the substrate for which the enzyme was named, despite the absence of any paraoxonase activity in plasma and liver (Li et al., 2000) (see also below).

When $Pon1^{-/-}$ mice were given exogenous PON1, resistance to OP toxicity was restored (Li et al., 2000). In these studies, purified human $PON1_{Q192}$ or $PON1_{R192}$ was injected, by the i.v. route, into $Pon1^{-/-}$ mice, and the effects of various OPs on brain and diaphragm AChE activity were determined (Li et al., 2000). $PON1_{R192}$ provided significantly better protection than $PON1_{Q192}$ toward chlorpyrifos oxon, a finding also confirmed by a study by Cowan et al. (2001), who administered recombinant adenoviruses containing human *PON1*-LQ or *PON1*-LR genes to BALB/c mice before challenge with chlorpyrifos oxon. Li et al. (2000) also showed that $PON1_{R192}$ and $PON1_{Q192}$ were equally effective in protecting against the toxicity of diazoxon, while neither alloform afforded protection against paraoxon toxicity.

Kinetic analyses of substrate hydrolysis by purified human $PON1_{R192}$ or $PON1_{Q192}$ provided an explanation for the above in vivo findings. The catalytic efficiency of both PON1 alloforms toward chlorpyrifos oxon was very high, with the $PON1_{R192}$ alloform having the highest catalytic efficiency. In the case of diazoxon, catalytic efficiency was still high, though lower than that toward chlorpyrifos oxon; however, there was little difference between the two $PON1_{192}$ alloforms. Though the $PON1_{R192}$ alloform was also much more efficient than the $PON1_{Q192}$ alloform in hydrolyzing paraoxon, its overall catalytic efficiency was very low, and not sufficient to protect against paraoxon toxicity in vivo (Li et al., 2000). This latter finding confirms the hypothesis that PON1 may not degrade paraoxon efficiently at low concentrations in vivo (Chambers et al., 1994; Pond et al., 1995).

Additional experiments were carried out in *PON1* transgenic mice, that is, mice expressing either human PON_{Q192} or human $PON1_{R192}$ on the knockout background (*Tg-hPON1*$_{R192}$ and *Tg-hPON1*$_{Q192}$), or mice expressing the human $PON1_{R192}$ on top of murine PON1. The latter mice, whose serum paraoxonase activity was 3.5-fold higher than wild-type mice, showed similar sensitivity to paraoxon as wild-type mice (Li et al., 2000), further confirming the inefficacy of PON1 for detoxifying paraoxon in vivo. *Tg-hPON1*$_{R192}$ mice were significantly less sensitive to the toxicity of chlorpyrifos oxon and chlorpyrifos than *Tg-hPON1*$_{Q192}$ mice, despite having the same level of PON1 protein in liver and plasma (Cole et al., 2005). Thus, these experiments in transgenic mice confirmed all previous observations. In addition, administration of a recombinant human PON1 variant ($hPON1_{K192}$) to $Pon1^{-/-}$ mice protected them against the toxicity of diazoxon, given either after or before the enzyme (Stevens et al., 2008).

Altogether, these animal experiments indicate that PON1 can modulate the acute toxicity of OPs in a compound-specific manner. In the case of chlorpyrifos oxon, both the level of expression and the Q192R genotype are important determinants of susceptibility, highlighting the importance of assessing PON1 status in potentially exposed individuals. With regard to diazoxon, protection or susceptibility is dictated primarily by the level of expression of PON1, independently of the Q192R genotype, stressing the importance of knowing PON1 levels. Perhaps ironically, PON1 status does not appear to play a role in modulating sensitivity to paraoxon toxicity due to the low catalytic efficiency of paraoxon hydrolysis.

There is limited evidence that PON1 status may also affect susceptibility to OP insecticides in humans. For example, some studies have investigated the role of PON1 in modulating chronic central and/or peripheral nervous system abnormalities, at times referred to as "dipper's flu," associated with exposure of sheep dippers to diazinon. Diazoxonase activity was found to be lower in cases than in controls (Cherry et al., 2002), and sheep dippers in the lowest quintile of serum diazoxonase activity had a greater risk of reporting ill health than those in the other quintiles (Mackness et al., 2003). These and additional findings (O'Leary et al., 2005; Mackenzie Ross et al., 2010; Cherry et al., 2011) suggest that ill health in sheep dippers was more pronounced in individuals who had a lower ability to detoxify diazoxon.

A few other studies are suggestive of a role of PON1 status in modulating susceptibility to various effects of OPs (Lee et al., 2003; da Silva et al., 2008; Lacasana et al., 2010; Singh et al., 2011). However, these studies lack detailed information on exposures, which hampers interpretation of the findings. Exposure to diazinon and to chlorpyrifos, but not to parathion, was found to be associated with an increased risk of Parkinson's disease in carriers of the $PON1_{M55}$ variant (low PON1 activity) (Manthripragada et al., 2010). Exposure to diazinon and chlorpyrifos was also associated with an increased risk of brain tumor in children with low PON1 activity (Searles Nielsen et al., 2005). Finally, a study in pesticide handlers in Washington State, exposed to various OPs (most notably chlorpyrifos), low PON1 catalytic efficiency (Q192), and low plasma activity were associated with increased degrees of plasma butyrylcholinesterase inhibition from baseline levels (Hoffman et al., 2009). A study by Sato et al. (2016) found that PON1 serum activity levels (but not PON1 SNPs) were correlated with urinary metabolites of fenithrothion oxon, chlorpyrifos oxon, and methylchlorpyrifos oxon, in a group of pest control workers.

Overall, human studies available so far provide limited initial evidence that low PON1 status may increase susceptibility to adverse effects of certain OP insecticides. However, further studies are certainly warranted, particularly to ascertain the contribution of PON1 to OP metabolism and toxicity at low levels of exposure.

70.4 PON1 and the toxicity of nerve agents

As said, some OP nerve agents, such as soman, sarin, tabun, and VX, are metabolized in vitro by PON1 (Davies et al., 1996; Rochu et al., 2007; Valiyaveettil et al., 2010). Information is scarce about VX (Peterson et al., 2011), while more information is available regarding the other compounds, particularly soman and sarin. Both sarin and soman are hydrolyzed to a higher degree by $PON1_{Q192}$ than by $PON1_{R192}$ (Davies et al., 1996), and plasma somanase activity and sarinase activity (both in U/L) were found to be 2143 and 335 for QQ homozygotes, and 992 and 38 for RR homozygotes, respectively (Davies et al., 1996). Thus, homozygotes for the $PON1_{Q192}$ allele hydrolyze sarin approximately 10 times better than individuals homozygous for the $PON1_{R192}$ allele, while the ratio is about two for soman (Davies et al., 1996). Results of a kinetic study confirmed these findings; catalytic efficiency for sarin was determined as 0.91 and 0.07 (ratio = 13) for $PON1_{Q192}$ and $PON1_{R192}$ homozygotes, respectively, while values for soman were 2.8 and 2.1 (ratio = 1.3) (Rochu et al., 2007). Soman exists as four stereoisomers (C + P +, C + P−, C−P +, C−P−), with both P− isomers displaying the highest in vivo toxicity; wild-type recombinant human PON1 was shown to stereoselectively hydrolyze soman, with a sixfold overall difference in catalytic efficiency (P + > P−) (Yeung et al., 2007). Further evidence that purified human PON1 and recombinant PON1 can hydrolyze soman and sarin has been provided by Valiyaveettil et al. (2010), who also reported hydrolysis of tabun.

In vivo studies in animals have shown that i.v. administration of naked DNA bearing the human $PON1_{Q192}$ cDNA to mice could elevate plasma somanase activity by about twofold (Fu et al., 2005). The pcDNA/PON1-treated mice survived in greater number and for a longer period after an acute dose of soman (0.2 mg/kg, s.c.) (Fu et al., 2005). More recently, Valiyaveettil et al. (2011a,b) reported that PON1 could protect guinea pigs from the acute toxicity of sarin and soman. In one study, small quantities of purified human or rabbit PON1 were given i.v. to guinea pigs 30 min before exposure to sarin or soman by microinstillation inhalation (846 and 841 mg/m^3, respectively, equivalent to $1.2 \times LC_{t50}$) (Valiyaveettil et al., 2011a). Although there was only a modest increase in plasma PON1 activity, PON1 from both species significantly increased survival time and antagonized several effects of the nerve agents, including AChE inhibition in brain. In a companion study, human recombinant PON1 expressed in *Trichoplusia ni* larvae, was given i.v. to guinea pigs 30 min before exposure to sarin or soman (Valiyaveettil et al., 2011b). Protective effects were essentially identical to those of the other study. In apparent contrast to these findings, a more detailed study by Hodgins et al. (2013) reported that administration of wild-type human PON1 purified from *Trichoplusia ni* larvae (Otto et al., 2010) or induced via adenoviral infection in mice, protected against the toxicity of the OP insecticides diazoxon and chlorpyrifos oxon, but not of several nerve agents (tabun, soman, sarin, cyclosarin). These findings re-emphasize the fact that human PON1 has a low catalytic activity toward nerve agents and suggest that there is

the need for developing novel human PON1 mutants with enhanced nerve agent-hydrolyzing activity. These studies also suggest that the *Pon1*$^{-/-}$ mouse may be a much better model than the guinea pig for two reasons: (1) there is no background OP hydrolase activity in the plasma of *Pon1*$^{-/-}$ mice, allowing for the pharmacokinetics to be clearly delineated; and (2) much less PON1 (purified or recombinant) is required to raise the plasma level of mice to quite high levels of activity (Li et al., 1993, 1995, 2000; Stevens et al., 2008).

There are different approaches for engineering recombinant PON1 variants with higher catalytic efficiency for treating OP exposures, which represents a major area of current research. One initiated by Tawfik and colleagues begins with the chimeric PON1 that they engineered for solubility and the determination of the crystal structure (Harel et al., 2004). The goal of this approach is to make the sequence of variants with high catalytic efficiency of agent hydrolysis (Aharoni et al., 2004) more "human-like," in order to minimize immunogenicity (Sarkar et al., 2012). A second approach is to begin with the native human rPON1 and introduce the minimal number of mutations required for the desired catalytic efficiency (Stevens et al., 2008). These two approaches are complementary and inform each other. Indeed, Ashani et al. (2011) found that several recombinant PON1 variants were capable of detoxifying cyclosarin in vitro, and similar findings were reported by Goldsmith et al. (2012), whose evolved PON1 had a 340-fold higher efficiency toward cyclosarin. These and other recombinant PON1s were also capable of protecting against OP nerve agent toxicity in vivo (Worek et al., 2014; Ashani et al., 2016; Mata et al., 2016).

The 1995 terrorist attack in the Tokyo subway system that left 12 people dead and over 5000 injured (Suzuki et al., 1995; Nagao et al., 1997) provided the opportunity to investigate the role of PON1 in modulating the toxicity of sarin in humans. The prevalence of the *PON1*$_{R192}$ genotype in the Japanese population is 0.66, compared with 0.25−0.30 in various Caucasian populations (Brophy et al., 2002; Yamasaki et al., 1997). Thus, Japanese individuals may have been more prone to sarin toxicity because of the low sarin-hydrolyzing ability of the PON1$_{R192}$ allozyme. However, among 10 of the victims of the Tokyo attack, seven expressed the *PON1*$_{192Q}$ genotype, with six Q/R heterozygotes and one Q/Q homozygote (Yamada et al., 2001). Thus, the genotype which confers high hydrolyzing activity toward sarin did not appear to provide protection from acute sarin poisoning. Several issues need, however, to be considered. First, only the Q192R genotype of those 10 individuals was analyzed, with no information on their PON1 status. In a Caucasian population, the range of sarinase activity among individuals with the QQ or QR genotype ranged from ∼0 to 758 U/L (Davies et al., 1996). Second, exposure to sarin in these seven QQ or QR individuals was indeed massive, as it caused death instantly or, with one exception, in less than 48 h (Yamada et al., 2001). Such high-dose exposure would be expected to overcome any potential protection afforded by the *PON1*$_{Q192}$ genotype. Third, and most importantly, the catalytic efficiency of sarin hydrolysis by PON1, even in QQ homozygotes, is low; the situation is thus similar (albeit reversed) to that of paraoxon, with one PON1$_{192}$ alloform hydrolyzing sarin with better efficiency, but still not sufficiently high enough catalytic efficiency to provide protection against nerve agent exposure.

A few studies have also investigated PON1 polymorphisms in US and UK troops that were deployed in the Persian Gulf area in 1990−91. Individuals who served in the Gulf War theater were potentially exposed to a wide range of biological and chemical agents, including sand, smoke from oil well fires, solvents, petroleum fuels, depleted uranium, anthrax and botulinum toxoid vaccinations, insecticides, pyridostigmine bromide, and nerve agents (IOM, 2000, 2003). Many of these veterans have complained of a range of unexplained illnesses including chronic fatigue, muscle and joint pain, loss of concentration, forgetfulness, and headache, symptoms that are often referred to as Gulf War syndrome (IOM, 2000, 2003). PON1 genotypes and plasma enzyme activity were investigated in a group of 25 ill Gulf War veterans and 20 controls (Haley et al., 1999). PON1$_{R192}$ homozygotes or PON1$_{Q/R192}$ heterozygotes were more likely to have neurologic symptoms than individuals homozygous for PON$_{Q192}$. Furthermore, low activity of the plasma PON1$_{Q192}$ isoform appeared to better correlate with illness than the PON1 genotype or the activity levels of the PON1$_{R192}$ genotype (Haley et al., 1999). This study would suggest that low PON1 status may represent a risk factor for illness in Gulf War veterans, though such findings necessitate further confirmation in a larger population (Furlong, 2000).

A similar study in a group of 152 UK Gulf War veterans, who self-reported the presence of symptoms associated with Gulf War syndrome, yielded somewhat different results (Mackness et al., 2000). Plasma paraoxonase activity and levels of PON1 protein were lower in veterans than in a control group, and these decreases were independent of the *PON1* genotype (Mackness et al., 2000). Thus, while in both studies a reduced plasma paraoxonase activity was found, in one case it was attributed to an overrepresentation of the low-activity PON1 isozyme (Haley et al., 1999), whereas in the other it was common to all *PON1* genotypes (Mackness et al., 2000). Though the latter study suggests that this group of veterans may have a decreased capacity to hydrolyze some OP insecticides, such as chlorpyrifos oxon, its significance is

hampered by the lack of information on the extent of exposure to such compounds among veterans (Costa et al., 2003a). An additional study compared *PON1* genotypes and plasma paraoxonase activity in groups of UK veterans from the Persian Gulf War who were symptomatic by self-reporting ($n = 115$), healthy Persian Gulf War veterans ($n = 95$), symptomatic Bosnia peacekeeping veterans ($n = 52$) and symptomatic nondeployed military controls ($n = 85$) (Hotopf et al., 2003). No differences in genotype distribution or PON1 activity were found between healthy and ill Gulf War veterans. However, individuals who were deployed to the Gulf had 25%–35% lower median PON1 values than the other two groups, and these differences were not explained by differences in $PON1_{192}$ genotypes between groups. Thus, $PON1_{192}$ genotype and activity were not associated with Gulf War syndrome but appeared to be the results of deployment in the Persian Gulf. Possible explanations suggested for such findings were the potential exposure of those who served in the Gulf to yet unknown agents which led to a long-term decrease in PON1 activity, and/or an overrepresentation in those two groups of individuals with the −108T allele, which is associated with lower PON1 levels (Hotopf et al., 2003). A study by Concato et al. (2007) found no differences in activities of paraoxonase and arylesterase between symptomatic and asymptomatic veterans of the first Gulf War. More recently, a lack of association between PON1 activity and genotypes and neurologic symptom complex or posttraumatic stress disorder in Gulf War era US veterans was also recently reported (Haines et al., 2017).

70.5 PON1 as a therapeutic agent

In recent years, there has been much interest in developing new means of antagonizing the toxicity of OPs, particularly of nerve agents (Masson and Rochu, 2009; Nachon et al., 2013). Current therapy for OP poisoning relies on the use of atropine, a cholinergic muscarinic antagonist, and on oximes, such as pralidoxime (2-PAM), to reactivate phosphorylated acetylcholinesterase before "aging occurs" (Lotti, 2000; Eyer et al., 2007). Anticonvulsant drugs such as diazepam may also be utilized to control OP-induced convulsions (Lotti, 2000). More efficacious pyridinium 4-aldoximes, such as obidoxime and trimedoxime, have also been developed; however, their ability to reactivate phosphorylated acetylcholinesterase is not fully exploited because of the formation of phosphoryloximes, which have themselves very high anticholinesterase activity. Interestingly, phosphoryloximes are rapidly hydrolyzed by PON1, with the $PON1_{Q192}$ allozyme being about 50-fold more active than $PON1_{R192}$ (Stenzel et al., 2007), suggesting that PON1 status would also influence the effectiveness and safety of these oximes (Eyer et al., 2007).

While current therapies are effective in preventing lethality, it has been suggested that they may not prevent behavioral deficits, incapacitation, loss of consciousness, or the potential for permanent brain damage caused by OP nerve agents (Lenz et al., 2007). Complementary approaches have thus focused on the use of human proteins that would act as biological scavengers for OP compounds. Such biological scavengers should have no effects on their own, particularly should not present an antigenic challenge to the immune system, should act rapidly and specifically, and should remain in circulation for a prolonged period (Lenz et al., 2007; Suzuki et al., 2010). Out of this general concept, two parallel approaches have emerged, one relying on stoichiometric, the other on catalytic, bioscavangers. Among stochiometric bioscavengers, B-esterases, such as acetylcholinesterase and butyrylcholinesterase, which react with OPs but do not catalyze their hydrolysis, have been utilized in several studies. Administration of these two proteins to rodents has been shown to afford protection toward two- to fivefold LD_{50} doses of sarin, soman, or VX (Wolfe et al., 1987; Doctor and Saxena, 2005; Lenz et al., 2007; Saxena et al., 2011). Of interest in this regard is human butyrylcholinesterase, either isolated from human plasma, or recombinant (Cerasoli et al., 2005).

While stoichiometric scavengers may offer some protection toward OP toxicity, high doses are needed to neutralize an equimolar amount of nerve agent (Ashani and Pistinner, 2004; Valiyaveettil et al., 2012). In contrast, a catalytic scavenger would afford similar or even higher protection at relatively low doses, as one molecule of a catalytic scavenger can hydrolyze a very large number of molecules of an OP (Sweeney and Maxwell, 2003; Stevens et al., 2008; Suzuki et al., 2010; Valiyaveettil et al., 2012; Worek et al., 2016; Masson and Lushchekina, 2016; Masson and Nachon, 2017; Goldsmith and Ashani, 2018). For example, it has been estimated that 3 μM sarin would be neutralized by 765 mg of human butyrylcholinesterase, but only 120–550 mg of $huPON1_{Q192}$ (depending on time) (Rochu et al., 2007), or a much lower dose of engineered recombinant human PON1 with significantly increased catalytic efficiency of agent hydrolysis. Several arguments would support the use of PON1 as a catalytic bioscavenger (Nachon et al., 2013). PON1 is a human protein, suggesting the possible absence of an immunological response. However, reports of PON1-induced cytotoxicity in macrophages need to be further investigated (Mackness and Mackness, 2010). Experiments in mice and guinea pigs have clearly shown that administration of purified human PON1 or of recombinant PON1 protects animals against the toxicity of specific OP compounds, provided that the

catalytic efficiency is sufficient (Li et al., 2000; Cowan et al., 2001; Stevens et al., 2008; Suzuki et al., 2010; Valiyaveettil et al., 2011a,b; Duysen et al., 2011; Hodgins et al., 2013). In this regard, novel ways to deliver PON1 are being investigated, in addition to administration of purified enzyme (e.g., Li et al., 2000) or of an adenoviral vector (e.g., Cowan et al., 2001; Duysen et al., 2011; Hodgins et al., 2013). For example, Gaidukov et al. (2009) showed that administration of BL-3050, a highly stable engineered human PON1−HDL complex, protected mice against the toxicity of chlorpyrifos oxon, and did not cause any apparent adverse effect on its own. In another study, human PON1 was re-engineered as an IgG−PON1 fusion protein, in which the 355 amino acid human PON1 was fused to the carboxyl terminus of the heavy chain of a chimeric monoclonal antibody against the human insulin receptor (Boado et al., 2011). This fusion protein, designated as HIR-Mab-PON1, was able to enter the brain when injected i.v. into nonhuman primates. This would be of much interest as PON1 is basically absent from brain cells (Giordano et al., 2011), while OPs easily penetrate the blood−brain barrier.

PON1 has been shown to hydrolyze soman, sarin, and tabun, though its catalytic efficiency toward OP nerve agents, in particular sarin, is low. It has been calculated that to provide a valuable medical countermeasure against intoxication by nerve agents, the catalytic efficiency of PON1 will need to be enhanced by one or two orders of magnitude (Rochu et al., 2007). Some direct evolution variants of a recombinant PON1 were found to exhibit a 10-fold faster detoxification of cyclosarin and soman (Amitai et al., 2006). Other huPON1 mutants with enhanced catalytic activity have also been described, though not in relationship to OP nerve agents (Yeung et al., 2004). Directed evolution of a chimeric PON1 made via mammalian gene shuffling, combined with high-throughput screening, led to an evolved variant of chimeric PON1 with a 100,000-fold higher catalytic efficiency toward the most toxic enantiomer of a coumarin analog of cyclosarin (Gupta et al., 2011). However, chimeric PON1 is expected to be immunogenic, hence its practical application is doubtful. Nevertheless, further efforts to develop human PON1 variants with increased catalytic efficiency toward nerve agents are warranted.

An additional approach would be that of stimulating the biosynthesis of natural PON1. Several compounds have been shown to stimulate the expression of PON1 (Costa et al., 2005, 2011). Among them are low doses of ethanol, some fibrates, statins, or dietary polyphenols such as quercetin (Gouedard et al., 2004a). The red wine ingredient resveratrol has been shown to increase PON1 activity nearly threefold in vivo (Gouedard et al., 2004b) and less than twofold in liver cells in vitro (Curtin et al., 2008). Interestingly, in the latter study, the increased PON1 afforded protection of cells against the toxicity of soman and sarin (Curtin et al., 2008). Modulation of PON1 activity by drugs or dietary agents is of interest, though more information of the regulation of the *PON1* gene is needed to devise approaches that would offer substantially larger increases in PON1. However, it has been also argued (Valiyaveettil et al., 2012) that a moderate increase of PON1 (less than twofold) may perhaps be sufficient to provide some protection against some of the symptoms of OP exposures, as shown by the protection seen against sarin and soman in guinea pigs (Valiyaveetil et al., 2011a,b). Nevertheless, as said, the low catalytic efficiency of nerve agent hydrolysis by native human PON1 may not be adequate to provide efficient protection against nerve agent exposure. The recent report by Hodgins et al. (2013) supports the point that the catalytic efficiency for hydrolysis of a specific OP must be sufficiently high to protect against exposure to that specific OP. Work by Chambers et al. (2015) appears to support these conclusions. These investigators identified a few small nucleophilic molecules which are capable of increasing PON1-mediated detoxification of a surrogate of sarin (nitrophenyl isopropyl methylphosphonate) and a surrogate of VX (nitrophenyl ethyl methylphosphonate) in vitro. When tested in vivo in rats, these molecules reduced the degree of inhibition of AChE by the sarin and the VX surrogates (Meek et al., 2015), further indicating that strategies aimed at increasing PON1-mediated detoxification in vivo may provide additional protective action in conjunction with existing therapeutic approaches.

70.6 Concluding remarks and future directions

Evidence from in vitro studies shows that PON1 can hydrolyze several OP compounds, including nerve agents. In vivo studies in rodents have also indicated that PON1 status can influence the acute toxicity of certain OPs, and that administration of exogenous PON1 can protect animals from OP toxicity. In the case of nerve agents, the catalytic efficiency of PON1 is relatively low, and PON1 status does not greatly influence an individual's susceptibility to their toxicity. However, recombinant variants can be engineered with enhanced catalytic activity toward nerve agents. The nonglycosylated, engineered recombinant PON1s with high catalytic efficiency for OP hydrolysis should be excellent candidates for use as catalytic biological scavengers, with both prophylactic and therapeutic applications. As previously suggested (Suzuki et al., 2010; Costa et al., 2011; Hodgins et al., 2013), efforts in this direction and those attempting to increase endogenous PON1 should proceed in parallel, as a combined strategy may prove successful. The increase in

endogenous PON1 levels should be efficacious for exposures to the OPs known to be hydrolyzed at rates sufficient to provide protection (Li et al., 2000; Hodgins et al., 2013). This line of research would have important practical relevance with regard to nerve agents, as shown by recent evidence of the proven use of sarin in Syria in 2013 (John et al., 2018).

Chapter 71

The role of carboxylesterases in therapeutic interventions of nerve agent poisoning

Miloš P. Stojiljković[1], Milan Jokanović[2], Dragana Lončar-Stojiljković[3] and Ranko Škrbić[1]

71.1 Introduction

Carboxylesterase, sometimes abbreviated as CarbE and sometimes, more recently, as CE, comprises an important class of hydrolytic enzymes and has the Enzyme Commission number EC 3.1.1.1. Aldridge (1953) proposed a division of all esterases into three groups: A-esterases that can metabolize organophosphorus compounds (OPCs) without being inhibited by them (Walker and Mackness, 1987), B-esterases that can simply bind and hence inactivate OPCs by removing them from blood, and C-esterases that do not react with OPCs. B-esterases include carboxylestrases (CarbE, EC 3.1.1.1), acetylcholinesterase (AChE, EC 3.1.1.7), cholinesterase (ChE, EC 3.1.1.8), and some other esterases.

Mammalian CarbEs constitute a large multigene family of α,ß-hydrolase-fold proteins involved in the metabolism of lipids, endogenous fatty acids esters, steroids, and a large number of ester-containing drugs and prodrugs, such as salicylates, clofibrate, procaine, lorazepam, cilazapril, and other angiotensin-converting enzyme inhibitors, narcotics (cocaine, heroin), capsaicin, statins, antiplatelet drugs, immunosuppressants, anticancer drugs, and antiviral agents. CarbEs also participate in detoxification of pesticides (carbofuran, pyrethroids, OPs), acrylates, mycotoxins (T2 toxin), and esters of nicotinic acid (Jokanović, 2015; Laizure et al., 2013). Of five main groups of mammalian CarbE (Satoh and Hosokawa, 1998), two, CE1 and CE2, are the most important ones in humans, with hCE1 predominantly found in the liver and hCE2 in the intestines (Laizure et al., 2013).

71.2 Enzymology of carboxylesterase

CE1 group of CarbE is the largest of the five and contains liver CarbEs of mice, rats, nonhuman primates, and humans. The influence of species on the substrate-specificity is significant and there are also within the same species more than one CarbE isoenzymes, for example, two in rat plasma and three in guinea pig plasma (Sterri and Fonnum, 1987, 1989).

All B-esterases have an active serine-moiety at their active centers that directly interacts with a molecule of an OPC. AChE, ChE, and CarbE contain a "catalytic triad" containing serine, histidine and glutamate—Ser_{200}—His_{440}—Glu_{327} (or aspartate) (Soreq et al., 1992; Cygler et al., 1993; Bajgar, 2005). Their active site is located, at least when AChE is concerned, at the bottom of a 20 Å-deep and 5 Å-wide gorge (Å = ångström = 10^{-8} m), with its walls lined with multiple conserved aromatic residues (Cheng et al., 2017). The specificity of CarbE differs from AChE and ChE in active site volume, electrostatic character, and cation-pI binding. These three enzymes all have a gorge at the active site, however, it varies in size (Sterri and Fonnum, 2015). It appears that AChE has the smallest gorge (296 D3), ChE somewhat larger (496 D3), while CarbE, has by far the largest (3014 D3 or 10 times the size of the gorge of AChE). This explains why diisopropyl fluorophosphate (DFP) cannot inhibit AChE, but it can inhibit ChE and CarbE, since the DFP molecule is too large for AChE and compliant with the ChE and CarbE gorges. In addition, ChE has seven anionic groups reacting with cationic substrates, whereas CarbE has only two. Further,

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00071-4

AChE has 14 aromatic residues lining the active site gorge, ChE has 7, and CarbE has only 2 (Ripoll et al., 1993; Shafferman et al., 1994). This explains the attraction of VX for AChE and ChE, but not for CarbE (Jokanović, 2001; Sterri and Fonnum, 2015). An additional factor that contributes to the weak reaction of VX with CarbE is its positive charge at phosphorus atoms (Jokanović, 2001).

The steps for CarbE interacting with OPC are the following:

1. The P─F bond (P−N in the case of tabun) of the OPC is attacked by the OH-group of serine.
2. The hydrogen bond between the negatively charged oxygen of a tetrahedral complex and the NH groups of glycine is stabilized by the charged phosphate oxygen of the inhibitor.
3. The P─F bond (P−N in the case of tabun) breaks and as a consequence the leaving group (F, or N in the case of tabun) diffuses away from the active center.
4. A water molecule attacks the serine-*O*-phosphoryl group on the enzyme. Then, histidine delivers a hydrogen atom to the serine-*O*-phosphoryl, which releases the phosphoryl group (Sterri and Fonnum, 2015).

A similar process happens in the case of AChE, with the difference that before the last step an intermediate reaction happens and the OPC undergoes a process known as dealkylation that makes it impossible for the phosphoryl group to leave the active center of AChE, thus rendering the enzyme permanently inhibited and resistant to asoxime (HI-6)-induced dephosphorylation (Fleisher and Harris, 1965; Worek et al., 2018). It is usually said for this dealkylated state of the enzyme−inhibitor complex that the complex was aged and hence the process described is called "aging."

The rate of aging differs when it comes to various OPCs, with soman being dealkylated with a half-time of only 2.3 min (Fleisher and Harris, 1965). Aging half-times ($t_{1/2}$) for tabun, sarin, soman, and VX are of 46 h (de Jong and Wolring, 1978), 5 h (Sidell and Groff, 1974), 1.3 min (Harris et al., 1978), and 48 h (Sidell and Groff, 1974), respectively. When human AChE is taken into account, under the same experimental conditions in human hemoglobin-free erythrocyte ghosts in vitro, the aging half-times (expressed in hours) for tabun, sarin, soman, and VX are: 19.0, 3.0, 0.04, and 36.5, respectively (Worek et al., 2004; 2005). The "aging" process does not happen in the case of CarbE, due to:

1. Different position of histidine within the active site gorge—once it is attached to the active center of the enzyme, the alkoxy group of the soman residue is farther from the histidine group (7Å in CarbE vs. 3.5 Å in AChE) (Maxwell and Brecht, 2001).
2. Very rapid spontaneous reactivation of CarbE inhibited with sarin, soman, and dichlorvos. This issue was discussed in more detail by Jokanović (2015) and in Chapter 55 on biotransformation of organophosphorus compounds in this book.

71.3 Carboxylesterase reactivation

There is a significant level of explicitness in the specificity of nerve agents for inhibition of various B-esterases. Sarin and soman have a roughly equal affinity for inhibition of all three enzymes (AChE, ChE and CarbE), while DFP equally inhibits ChE and CarbE and practically does not inhibit AChE at all (with 1000-fold less affinity than ChE and CarbE). At the same time, VX inhibits AChE 10,000-fold greater than CarbE. As mentioned earlier, the complex AChE−nerve agent ages at certain rates that depend on the inhibitor, while it does not happen with the CarbE−nerve agent complex; it even goes through hydrolysis and the CarbE molecule is recovered and ready to bind to another molecule of nerve agent. It should be noted however that the half-times of the spontaneous reactivation of CarbE is rather slow—2 h for sarin, 20 h for paraoxon, and 40 h for DFP (Jokanović, 2001, 2015; Sterri and Fonnum, 2015). Polak and Cohen (1969) have shown in rats that sarin-induced inhibition of plasma CarbE activity amounts to 50%−60% and disappears 24 h after poisoning. CarbE activity becomes reactivated even after soman poisoning—in guinea pigs, 1 h after poisoning with 0.5 median lethal dose (LD_{50}) of soman the inhibition of CarbE activity was 70%, while it became fully restored after 24 h. As a consequence, repeated administrations of sublethal doses of soman in guinea pigs led to tolerance of 5−6 acute LD_{50} of soman (Sterri et al., 1981). The same mechanism exists in the case of daily subacute intoxication of rats with 0.1−0.4 LD_{50} of tabun, where animals survived until the end of the experiment, that is, until day 28 (Stojiljković et al., 2004).

It was shown that some oximes and hydroxamic acids, like diacetylmonoxime (DAM) and monoisonitrosoacetate (MINA), can protect against sarin poisoning (Askew, 1956, 1957). DAM cannot effectively reactivate AChE, but can increase the rate of reactivation of nerve agent-inhibited CarbE. This effect of DAM is mostly present in plasma and less so in the brain, erythrocytes, and lungs of rats and mice (Myers, 1959). It is interesting that DAM caused a 50%−60% reactivation of sarin-inhibited plasma CarbE in vitro within 5 min, however this level of CarbE activity remained unchanged until 30 min (Sterri and Fonnum, 1987, 1989).

71.4 Source and induction of carboxylesterase activity

The sources of plasma CarbE are considered to be the liver and intestines (Yan et al., 1995; Sterri, 1989). Pretreatment of rats with phenobarbital 100 mg/kg i.p. for

3 days resulted in induction of CarbE activity, but significantly more in the liver (by 56%−77%) than in plasma (by 14%−22%) (Sterri et al., 1985b). In a separate experiment a 4-day phenobarbital (100 mg/kg) pretreatment in mice did not result in changes of AChE activity but resulted in 54% and 48% increases in the plasma and liver CarbE activity, respectively (Clement, 1983). In a similar experiment, 5-day-long pretreatment of rats with phenobarbital 60 mg/kg i.p. resulted in 78% and 85% increases of CarbE activities in plasma and liver, respectively (Jokanović, 1989).

It was shown that treatment of rats with propylthiouracil for 2−3 weeks can induce a hypothyroid status (Stakkestad and Bremer, 1983). Based on that, it was shown that hypothyroidism induced by feeding rats with rat chow supplemented with thiouracil 0.5% for 21 days resulted in increases in plasma BuChE and CarbE activity, by 79% and 89% in comparison with the controls, with accompanying decreased sensitivity to soman toxicity (Swisher et al., 1986). In separate experiments (Sterri and Fonnum, 2015), the effects of hypothyroidism induced by thiouracil in female and male rats, on the activity of ChE and CarbE in plasma and liver were studied (Fig. 71.1).

The esterase activities registered with ethyl butyrate as a substrate were significantly increased only in liver but not in plasma of either male or female rats, while the results obtained with 4-nitrophenyl butyrate as a substrate were inconsistent. In the same animals ChE activities of plasma and liver decreased in females and increased in males, which is in accordance with the notion that ChE activity in rat plasma and liver are sex-dependent (Leeuwin, 1966; Andersen et al., 1983; Edwards and Brimijoin, 1983; Sterri et al., 1985a). These results do not support the notion that plasma CarbE are synthesized by the liver, as it was proven that plasma ChE is undoubtedly synthesized in the liver (Augustinsson, 1948; Koelle, 1963). On the contrary, plasma CarbEs are more likely to originate from the intestine, since the two enzymes share similarly low isoelectric points (pI) of 4.0−4.8, as opposed to the 5.0−6.4 pI range of the six liver CarbE isoenzymes (Mentlein et al., 1987; Sterri, 1989). In addition, it was shown that two CarbE isoenzymes in plasma of both rats and guinea pigs and the three isoenzymes from rat small intestines can be reactivated by DAM after inhibition with soman (Sterri and Fonnum, 1987, 1989; Sterri, 1989), while all three guinea pig liver isoenzymes cannot (Sterri and Fonnum, 1987).

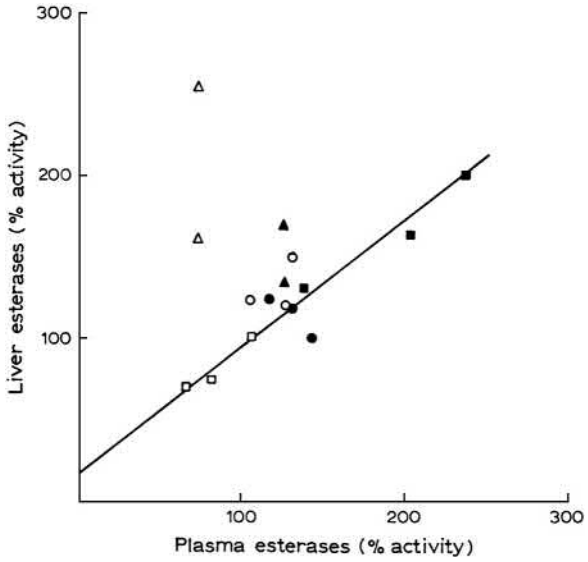

FIGURE 71.1 CarbE and ChE activities in liver versus blood plasma of thiouracil-fed rats. The animals received rat chow supplemented with 0.05% thiouracil for 22, 30, or 38 days. Methyl butyrate hydrolysis (▲△) and 4-nitrophenyl butyrate hydrolysis (●○) were measured in liver homogenate and plasma in accordance with Sterri et al. (1985b), and AChE hydrolysis (■□) by the method of Sterri and Fonnum (1978). The activities are percent of corresponding control (=100%) activities in male (*closed symbols*) and female (*open symbols*) animals fed standard rat chow.

71.5 Carboxylesterases as scavengers of nerve agents

Earlier, it was recognized that plasma CarbE represents a depot for binding sarin or soman that can be reactivated in order to decrease the nerve agent toxicity (Myers, 1959). The mechanism involves protection of AChE, not only in blood, but also in brain, from being inhibited by nerve agent (Polak and Cohen, 1969). Blood serves as a transporting medium for nerve agents and binding a portion of them by plasma CarbE decreases the amount of toxicant reaching the vital centers in the brain. This depot can be reactivated by DAM and MINA (Polak and Cohen, 1969, 1970a,b). The fact that the activity of these enzymes can be spontaneously reactivated explains the mentioned resistance of experimental animals to repeated administration of nerve agents (Stojiljković et al., 2004).

The scavenging role of CarbE is of particular importance in rodent species with large plasma CarbE activity (Myers, 1952; Aldridge, 1953; Goutier, 1956; Augustinsson, 1959; Christen and Cohen, 1969; Polak and Cohen, 1970a; Jokanović, 2001, 2015). Rat plasma is especially rich with CarbE; it was reported that the concentration of catalytic centers in rat plasma was as high as 2.8−3.2 μmol/L. Guinea pig plasma trails the rat's one, with a corresponding concentration of 0.5−0.6 μmol/L. All these active centers bind and detoxify the molecules of nerve agents (Christen and Cohen, 1969; Christen et al., 1969; Cohen et al., 1971). It was also shown that there were significant variations both in the plasma CarbE activities and in their sensitivity to inhibition with CBDP

even within the same species, that is, among the animal strains (Clement and Erhardt, 1990).

71.6 Toxicity of nerve agents and carboxylesterase

There are many proofs that a positive correlation exists between plasma CarbE activity and the LD_{50} of various OPCs and nerve agents in rodents. This means that the higher the plasma CarbE activity, the higher the LD_{50} (and the lower the toxicity) of nerve agents. Since developing young rats (i.e., until the age of 31 days) gain with time the CarbE activity, the LD_{50} of soman also increases and its toxicity proportionally decreases, with the difference between rats aged 31 days and those aged 5 days being six- to sevenfold. At the same time, ChE activity in tissues of developing rats remained fairly constant (Sterri et al., 1985a). Moreover, as a further proof of the concept, when rats aged 14 days (i.e., those ones with low CarbE activity) were treated i.v. with porcine hepatic CarbE, the resulting toxicity of soman was significantly reduced. In fact, only one of 10 animals died following inhalation exposure to soman, provided they received prophylactically a 60,000 molecular weight fraction of porcine liver CarbE (Fonnum et al., 1985). Maxwell et al. (1988) showed that in rats aged 3, 60, 90, and 120 days i.m. soman LD_{50} changes in a way that the corresponding LD_{50} values are 87, 117, 68, and 59 μg/kg, respectively, which correlates in a linear manner with the plasma CarbE activities of 3.6, 4.2, 2.5, and 1.0 μmol/L.

71.7 Carboxylesterase inhibitors

Two main CarbE inhibitors used in CarbE research are 3-*ortho*-cresyl phosphate (TOCP) (Mendel and Myers, 1953) and its metabolite 2-[*O*-cresyl]-4H-1,2,3-benzodioxa-phosphorin-2-oxide (CBDP) (Casida et al., 1961). Since TOCP needs to be activated, that is, biotransformed in liver to three metabolites, with CBDP as quantitatively the most important one, it has to be administered 24 h before poisoning with a nerve agent, with a wide dosage range of 3.5−250 mg/kg (Fonnum and Sterri, 1981; Jokanović, 1989), while the pretreatment interval for the active metabolite CBDP 35−50 mg/kg is 60−120 min (McKay et al., 1971; Bošković, 1979).

Pretreatment of rats and guinea pigs with TOCP resulted in a decrease in the value of soman LD_{50} to one-third of its control value (Fonnum and Sterri, 1981; Sterri, 1981; Sterri et al., 1981). Pretreatment with CBDP was even more effective, since it resulted in an 18-fold decrease of soman LD_{50} in mice (McKay et al., 1971; Bošković, 1979). Sarin LD_{50} was reduced by TOCP pretreatment in rats to one-fifth of the control value (Myers, 1959; Polak and Cohen, 1969). It was also discovered that inhibition of CarbE with CBDP leads to similar LD_{50} values of soman in mice, rats, and guinea pigs (Maxwell et al., 1988; Maxwell and Brecht, 2001).

Jokanović (1989) used two very different doses of TOCP for pretreatment of rats poisoned on the next day with either tabun, sarin, or soman—3.5 mg/kg that inhibited plasma CarbE by 90% and liver CarbE by 23% and 250 mg/kg that inhibited the enzyme in plasma by 100% and by 85% in liver. Relative potentiation of toxicities of tabun, sarin, and soman exerted by these two doses of TOCP were 1.1 and 1.4, 2.6 and 2.8, and 2.6 and 7.1, respectively, after s.c. injection of nerve agents, while the corresponding relative potentiations of their toxicity after i.p. administration were 1.6 and 2.2, 2.7 and 3.4, and 2.2 and 3.6, respectively. It is obvious that CarbEs have the greatest effect on soman, as the nerve agent most difficult to treat. The reason why the large TOCP dose was accompanied with twice as low impressive augmentation of soman toxicity after i.p. than after s.c. administration is the activity of liver somanases; namely only 27% of soman injected s.c. passes through the liver (Gaines et al., 1966), while all the i.p. administered soman has to pass this organ and become subject to degradation by its somanases (Bošković et al., 1988).

Jimmerson et al. (1989) pretreated rats with either of two doses of CBDP (1 and 16 mg/kg), which resulted in six- and eightfold decreases in soman LD_{50}, respectively. At the same time, the smaller dose of CBDP decreased the ED_{50} values for brain ChE inhibition and for the occurrence of soman intoxication by 10- and 7-fold, respectively. This is additional proof of the protective role of CarbE in rats, where under the conditions of their inhibition, soman attacks and inhibits ChE and AChE in the brain.

Various species have high (mice, rats), medium (guinea pigs), minor (marmosets), or zero (rhesus monkeys and humans) concentrations of plasma CarbE, respectively (Myers, 1952; Aldridge, 1953; Christen et al., 1969; Christen and Cohen, 1969; Cohen et al., 1971). This notion can afford an explanation why these species have so different LD_{50} values of soman (Dirnhuber et al., 1979; Sterri et al., 1980, 1981, 1985a).

A concept developed by Sterri and Fonnum (1989) is based on the assumption that the AChE pool in vital organs, such as brain, is relatively small and similar in several species, while the pool of plasma and liver CarbE depends on the species and may be very large (e.g., in mice) or nonexistent (e.g., in rhesus monkeys and humans) (Fig. 71.2).

This schematic presentation lists all the factors important for survival after intoxications with nerve agent: (1) AChE, (2) plasma CarbE, (3) carbamate prophylaxis, and (4) postexposure antidotes. In the case of species without plasma CarbE activity, such as humans, the

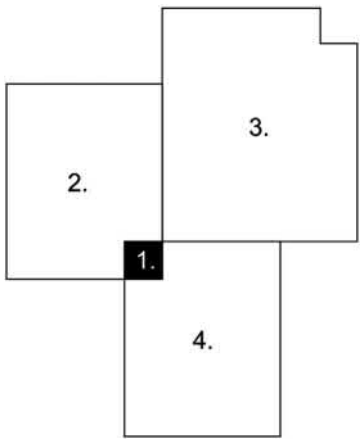

FIGURE 71.2 Visual representation of soman LD_{50} in rats as proportionally influenced by (1) target AChE, (2) plasma CarbE, (3) carbamate prophylaxis, and (4) other therapeutic regimen (at rat plasma CarbE concentration). The concentration of target AChE (1) or its enhancement by carbamate prophylaxis (3) is constant among the species, whereas the concentration of plasma CarbE (2) varies. The representation is based on the CarbE concept outlined by Sterri and Fonnum (1989) and Sterri (1989). LD_{50} decreases (and toxicity increases) when plasma CarbE (2) is decreased or absent.

segment (2) is nonexistent. This concept can be applied to the so-called G-agents tabun, sarin, and soman, while it is not applicable to VX, an OPC that does not bind to CarbE, but almost exclusively to AChE and ChE (Maxwell, 1992).

71.8 Carboxylesterase and prophylactic/therapeutic interventions

The area of segment (3) denoting protection offered by pyridostigmine prophylaxis is 30-fold larger than the area symbolizing the target AChE activity. As a consequence, the protective ratio (PR) in species that have a large pool of plasma CarbE (e.g., mice, rats, guinea pigs) can be calculated as the ration between (1) + (2) + (3) (i.e., LD_{50} in pyridostigmine-protected animals) and the same, but without carbamate prophylaxis (1) + (2). Since (2) is large in these species, the obtained PR is low. On the contrary, in rhesus monkeys the field (2) does not exist and the PR is calculated as the ratio between (1) + (3) and (1), which is around 30. This is why a similar level of pyridostigmine protection is to be expected in humans too, since they, like rhesus monkeys, lack plasma CarbE activity. Indeed, pyridostigmine prophylaxis along with atropine assured PRs against soman of 15 and 28 in marmosets, a species with low plasma CarbE activity and rhesus monkeys, a species completely without it, respectively (Dirnhuber et al., 1979).

The same applies to postexposure therapy, with or without carbamate protection—(1) + (2) + (3) + (4) or (1) + (2) + (4), respectively. In both cases the PRs are relatively modest in species with a large plasma CarbE pool and high in those with low (marmosets) or absent plasma CarbE activity (rhesus monkeys, humans).

71.9 Stoichiometric and catalytic scavengers of organophosphorus compounds

Indeed, it was later shown that the PRs obtained by prophylactic and/or postexposure antidotes in various species are similar in rats, guinea pigs, rabbits, and nonhuman primates, but only when their plasma CarbEs were previously inhibited by CBDP (Maxwell and Brecht, 1991; Maxwell et al., 1993). All these findings have important implications in further development of antidotal regimens against nerve agents in humans, since only the effects obtained in species with a naturally low level of CarbE or in those where the CarbE activity was rendered low by TOCP- or CBDP-induced pretreatment can be directly extrapolated to humans. A good example is use in such experiments of CarbE knockout mice (Duysen et al., 2012; Marrero-Rosado et al., 2018).

The idea of sequestration of nerve agents by an enzyme originated from the notion that CarbE, and especially that in plasma, can bind OPCs. For these purposes intravascular prophylaxis with CarbE, AChE, and BuChE of various origins became a new and promising field of research (Fonnum et al., 1985; Wolfe et al., 1987; Raveh et al., 1989, 1997; Broomfield et al., 1991; Maxwell et al., 1991, 1992; Doctor et al., 1993). In all these experiments B-esterases were used as stoichiometric scavengers, meaning that one molecule of an esterase neutralizes one molecule of an OPC. This approach has its limitations, such as the need for administration of large quantities and volumes of these esterases. In addition, in some experiments on wild-type human CarbE (hCE1) a spontaneous reactivation of the enzyme could be obtained only after adding sarin, but not when soman or cyclosarin were the inhibitors (Hemmert et al., 2010).

For these reason, A-esterases that decompose molecules of OPCs without being inhibited themselves—catalytic scavengers—are being intently investigated. Human paraoxonase-1 (PON-1) is certainly one of them, although it possesses only a moderate affinity to bind OPCs and has a slow turnover rate, meaning that it takes some time before this enzyme becomes ready to bind another OPC molecule. It is therefore not likely that the prophylactic use of native human PON-1 can result in significant protection against nerve agents (Lenz et al., 2007). For this reason, further efforts are being undertaken in order to develop mutants of human PON-1 (Yeung et al., 2004; Aggarwal et al., 2016). Although the results of the initial

efficacy experiments are promising (Worek et al., 2014), their immunogenicity and plasma half-lives in humans have yet to be determined (Lenz et al., 2007).

There are also reports on engineering a slightly modified molecule of human CarbE1, where histidine was introduced instead of valine (V146), and glutamate instead of leucine (L363). Charges of valine and glutamate positioned on the opposite sites of the CarbE active center direct a water molecule toward the hydroxyl group of serine and thus alleviate CarbE reactivation. The resulting molecule retained the same affinity for binding the OPCs, with the spontaneous reactivation time being much shorter (Hemmert et al., 2011).

71.10 Concluding remarks and future directions

CarbE proved to be very important for species-dependent detoxification of nerve agents tabun, sarin, and especially soman. Experimental models for their induction with barbiturates and inhibition with TOCP or its metabolite CBDP enable direct extrapolation of the protection experiments from rodent species (with abundant CarbE plasma activity) to humans (with absence thereof). CarbEs can be used as effective stoichiometric scavengers against nerve agents, but with long spontaneous reactivation times. Further research is warranted to investigate the possibility to develop a modified CarbE molecule with unchanged affinity to bind nerve agents, but with a significantly shorter turnover time.

Chapter 72

Catalytic bioscavengers: the second generation of bioscavenger-based medical countermeasures

Patrick Masson[1] and Sofya V. Lushchekina[2]

[1]*Neuropharmacology Laboratory, Kazan Federal University, Kazan, Russian Federation,* [2]*Emanuel Institute of Biochemical Physics of Russian Academy of Sciences, Moscow, Russian Federation*

Abbreviations

AChE	acetylcholinesterase
BChE	butyrylcholinesterase
CaE	carboxylesterase
ChE	cholinesterase
CRISPR	clustered regularly interspaced short palindromic repeats
CVX	Chinese VX
DFP	diisopropylfluorophosphate
DFPase	diisopropylfluorophosphate hydrolase
GF	cyclosarin, cyclohexylsarin
GST	glutathione *S*-transferase
HPBP	human phosphate binding protein
MD	molecular dynamics
NA	nerve agent
NTE	neuropathy target esterase
OP	organophosphorus compound
OPAA	organophosphoric acid anhydrolase
OPAH	organophosphorus acid anhydride hydrolase
OPH	OPase organophosphate hydrolase
PAF-AH	platelet-activating factor acetylhydrolase
PI	penta-coordinated intermediate
PLL	phosphotriesterase-like lactonase
PON-1	paraoxonase 1
PROL	prolidase
PTE	phosphotriesterase
QM/MM	quantum mechanics/molecular mechanics
SMP	senescence marker protein
TCP	tricresyl phosphate
TMPP	trimethylolpropane phosphate
VX	ethyl ({2-[bis(propan-2-yl)amino]ethyl}sulfanyl)(methyl) phosphinate
VR	Russian VX

72.1 Introduction

Organophosphate thio/oxo-esters (OPs) were discovered in the middle of the 19th century. They are mostly pesticides (parathion, malathion, chlorpyriphos, dichlorvos), and some of them have been used as drugs or prodrugs (echothiophate, metrifonate, cyclophosphamide), flame retardants, and antiwear agents (tricresyl phosphate, TCP). Other OPs are potent chemical warfare agents (G agents: tabun, sarin, soman, cylclohexyl-sarin, and V agents: VX, VR, CVX). The fourth-generation NAs, called "novichoks" (A-230, A-232, A-234), are phosphoramidates supposedly 10 times more toxic than V agents (Tucker, 2006; Mirzayanov, 2009; Hosseini et al., 2016; Carlsen, 2018; Nepovimova and Kuca, 2018; Franca et al., 2019; Kuca and Nepovimova, 2019). Highly toxic OPs may be formed by cytochrome P450-mediated metabolic oxidation of thiono-phosphoesters, for example, paraoxon from the parent compound parathion (Foxenberg et al., 2007), or 2-(*o*-cresyl)-4H-1,3,2-benzodioxaphosphoran-2-one (CBDP or cresyl-saligenin phosphate, CSP) by cyclization of tri-*ortho*-cresyl phosphate (TOCP), a TCP isomer (Eto et al., 1962). High-temperature pyrolysis of synthetic oils may lead to toxic OPs, such as trimethylolpropane phosphate (TMPP) (Masson, 2012). Most of these compounds are potent irreversible inhibitors of cholinesterases (ChEs) (Fig. 72.1) (Costa, 2006), and of many other serine hydrolases. However, TMPP is not an inhibitor of ChEs; it is a GABA antagonist, so toxic that it has been called "the poor man's nerve agent."

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00072-6

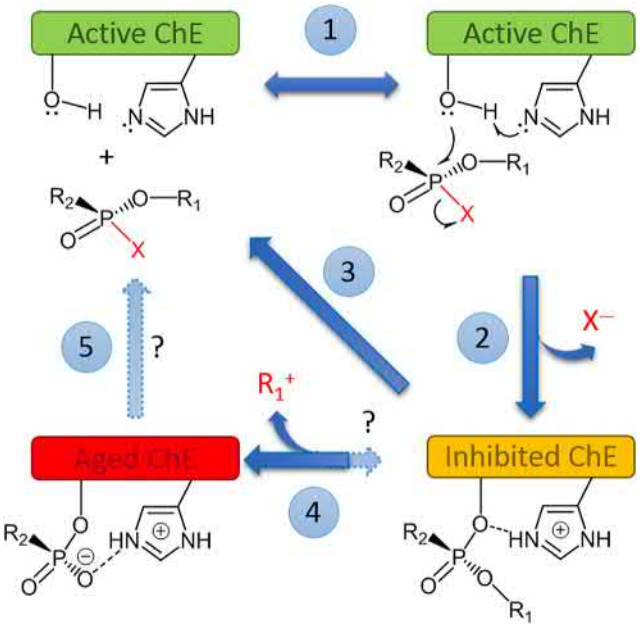

FIGURE 72.1 Mechanism of inhibition of cholinesterases by OPs. After formation of reversible complex between ChE and OP (step 1), the active serine (esteratic site, E-OH) is phosphylated; the reaction leads to release of leaving group X (step 2). The phosphylated enzyme can be reactivated by nucleophilic agents, such as quaternary oximes [2-PAM (contrathion or pralidoxime), TMB-4, MMB-4 (methoxime), Obidoxime (toxogonin), HI-6, Karboxim (carboxim)], used as antidotes in emergency treatment of OP poisoning (Lundy et al., 2006; Worek et al., 2007; Worek and Thiermann, 2013) (reaction 3); water is a too weak nucleophile for fast spontaneous reactivation of phosphylated ChE. The phosphyl–ChE conjugate may undergo a spontaneous dealkylation through alkyl-oxygen bond scission ("aging") (Kovach, 2004; Masson et al., 2010), resulting in irreversibly inactivated ("aged") enzyme (step 4). The dealkylation reaction can be very fast ($t_{1/2} = 3$ min at 37°C for human AChE phosphonylated by soman). Drug-mediated reactivation to E-OH through realkylation (R_1) of aged ChE (reverse reaction 4 and subsequent reaction 3, called "resurrection" or "resuscitation") was recently demonstrated to be possible (Zhuang et al., 2018). Direct displacement of the aged adduct (reaction 5) is still thought to be impossible.

There are two types of ChEs, acetylcholinesterase (AChE; EC 3.1.1.7) and butyrylcholinesterase (BChE; EC.3.1.1.8). AChE plays a major role in the cholinergic system terminating the action of the neurotransmitter acetylcholine. Inhibition of AChE leads to accumulation of acetylcholine in synapses, and blockade of cholinergic transmissions in the peripheral and central nervous systems. Inhibition of AChEs is the main cause of acute toxicity of OPs (Maxwell et al., 2006). Irreversible inhibition of other enzymes, including various serine hydrolases plays a role in subacute toxicity and noncholinergic toxicity of OPs (Casida and Quistad, 2004, 2005). Phosphylation of serine, tyrosine, lysine, and other residues in numerous proteins is also involved in chronic toxicity of OPs (Onder et al., 2018; Schopfer and Lockridge, 2019).

Significant progress has been made in the past 25 years in emergency treatments of acute poisoning and management of poisoned casualties (Eyer et al., 2007; Thiermann et al., 2007; Wetherell et al., 2007; Eddleston et al., 2008; Moshiri et al., 2012; Masson, 2016). However, classical pharmacological approaches are reaching their optimum limit. Recent attacks in Syria, where nerve agents (NAs) were employed, revealed the limitations of current medical treatments (Dolgin, 2013). In addition, due to accumulation of OP in depot sites and subsequent slow release from these stocks, blood and tissue ChEs may remain inhibited for long periods of time. Therefore, persistence of certain OPs in the body after initial exposure complicates treatments. This is particularly well documented for severe intoxications by parathion (Willems et al., 1993).

Endogenous enzymes are involved in natural defenses against OP toxicity. The presence of detoxifying enzymes in skin contributes to reduce the OP dose that penetrates the body (Schallreuter et al., 2007). Numerous secondary targets of OPs present in various tissues are detoxifying enzymes and they play a role in the natural defenses against OPs (Wang et al., 1998; Nomura et al., 2005, 2008). The presence of endogenous OP-hydrolyzing enzymes has been regarded as the first line of defense against OP poisoning (Satvik Iyengar et al., 2015).

Liver enzymes play an essential role in detoxification. In particular, oxidases, such as glutathione *S*-transferases (GSTs), play a role in degradation of alkyl/aryl chains (Casida and Durkin, 2013). However, as mentioned above, liver cytochrome P450 enzymes activate phosphorothioates and lead to oxon forms much more toxic than parent compounds, but cytochromes P450 also dearylate aryl-containing OPs and participate in detoxification of OPs (Furlong, 2007; Ellison et al., 2012). Natural blood bioscavengers significantly contribute to reduce the amount of OP molecules reaching physiological targets. It has been shown that animal species in which the concentration in paraoxonase-1 (PON-1; EC 3.1.8.1) or in carboxylesterase (CaE; EC 3.1.1.1) is high are relatively resistant to OPs (Kaliste-Korhonen et al., 1996). Conversely, *knockout* mice for PON1 are very sensitive to OPs (Shih et al., 1998). Albumin displays a low esterase activity, and slowly reacts with carbamyl- and phosphoryl-esters. However, its concentration in blood and lymph is so high (≈ 0.6 mM) that it likely plays a role in detoxification of carbaryl at toxicologically relevant concentrations (Sogorb et al., 2007). Thus, plasma albumin could also play a role in the detoxification of certain OPs (Tarhoni et al., 2007; Li et al., 2008).

Toxicity of OPs can be countered by reducing skin absorption and lowering OP concentration in the blood compartment, thus preventing the transfer of OP molecules toward cholinergic synapses and other biological

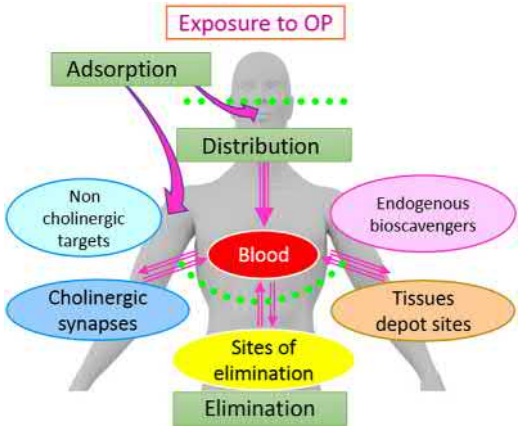

FIGURE 72.2 Biological fate of organophosphorus compounds in human.

Routes of penetration of OPs are absorption through the skin, eyes, and/or respiratory tract (NAs, pesticides), or ingestion (self-poisoning). OP molecules distribute from the blood compartment into tissues, including depot sites, biophase (cholinergic synapses and secondary targets) and sites of elimination (liver and kidneys). Cholinesterases are the main biological targets (acute toxicity); reaction with secondary targets (carboxylesterases, serine-amidases, peptidases, and other proteins) may be responsible for noncholinergic sublethal effects of OPs and chronic toxicity at low-dose exposure (Costa, 2006; Bigley and Raushel, 2013).

targets (Fig. 72.2). Neutralization of toxicant molecules can be achieved by using stoichiometric traps or catalysts acting on exposed surfaces (e.g., active topical skin protectants, TSPs) or in the bloodstream (bioscavengers). The concept of bioscavengers and developments of this approach in prophylaxis and postexposure treatment of OP poisoning have been exposed in several reviews (Masson and Rochu, 2009; Masson and Lockridge, 2010; Nachon et al., 2013; Masson and Nachon, 2017).

72.2 Stoichiometric scavengers

The first molecules that were studied for the purpose of making stoichiometric scavengers were cyclodextrins (Desire and Saint-Andre, 1986), neutralizing antibodies (Glikson et al., 1992), and activated charcoal. Though the interest in charcoal is much debated, hemodialysis on a charcoal cartridge was successfully used on a Tokyo casualty who was resistant to the classical treatment of sarin poisoning (Yokoyama et al., 1995). Transfusion of human plasma has been used for treating OP poisoning. The effects of fresh frozen plasma (plasmapheresis) on cholinesterase levels and outcomes in OP-poisoned patients have been evaluated (Güven et al., 2004; Qiu et al., 2011). An in vitro study also suggests that plasma (freshly prepared and fresh frozen plasma) therapy may be an effective adjunctive treatment method against G agents (Wille et al., 2014). Plasma BChE, and possibly other abundant OP-scavenging proteins in plasma (e.g., albumin, PON-1), may have contributed to these results. At this point, it must be noted that unlike plasma of most model animals, human plasma does not contain carboxylesterases (Li et al., 2005; Napon et al., 2018).

At the end of the 1980s, research on scavengers mostly focused on enzymes that specifically react with OPs. Cholinesterases (Wolfe et al., 1987) and carboxylesterases (Redinbo and Potter, 2005; Fleming et al., 2007; Hemmert et al., 2010) have been proposed as stoichiometric scavengers. Human BChE has proved to be an effective stoichiometric bioscavenger for pre- and postexposure treatment of NA and OP pesticide poisoning (Allon et al., 1998; Doctor and Saxena, 2005; Lenz et al., 2007; Saxena et al., 2008a,b; Mumford et al., 2013; Rosenberg et al., 2013, 2014; Rice et al., 2016; Reed et al., 2017). Human plasma-derived BChE was granted Investigational New Drug (IND) status by the FDA in 2006 for protection against nerve agents (Lenz et al., 2007). Clinical trials on volunteers (phase I) were then performed. However, enzymatic stoichiometric neutralization of several OP LD_{50} needs administration of huge amounts of enzyme, about 3 mg/kg of highly purified plasma BChE (Ashani and Pistinner, 2004), that is, 200−300 mg for humans against $2 \times LD_{50}$ of soman. This enzyme must be free of contaminants, for example, coagulation factors, bacterial toxins, viruses, and bacteria. Large-scale production of enzymes, in particular human plasma BChE, under GMP conditions at a reasonable cost has been the subject of intense research in the past 10 years. However, although several thousand tons of outdated human plasma or Cohn fraction IV are available in the United States for preparing the enzyme, 1 L of human plasma provides less than 1 mg of GMP BChE tetramer.

Several industrial GMP processes have been proposed for mass production of human BChE. The first is purification of the natural enzyme from human plasma (Cohn fraction IV). This process was initially developed by Saxena et al. (2008a,b) and Baxter Healthcare Corporation (www.baxter.com). The second method was developed by Nexia (www.nexiabiotech.com), and uses the recombinant human enzyme produced in milk of transgenic goats. Several grams of enzyme can be secreted in 1 L of milk. This enzyme has been named Protexia. Pharmatheme (www.pharmathene.com), in 2005, developed Protexia PEGylated derivatives of this enzyme (Huang et al., 2007) and fusion proteins (Huang et al., 2008). However, production of recombinant human BChE in milk of transgenic mammals has been discontinued due to high cost and pharmacokinetics problems. Therefore, Pharmatheme and other companies are working on large-scale production of recombinant human BChE expressed in human cells or in CHO cells (Rosenberg et al., 2010). Production of tetrameric human BChE in transgenic tobacco (*Nicotiana benthamiana*) has

also been made possible (Geyer et al., 2010; Larrimore et al., 2013; Alkanaimsh et al., 2016). PlantForm in Canada (www.plantformcorp.com) has been engaged in the development of recombinant human BChE in tobacco that mimics the stability and pharmacokinetics of plasma-derived enzyme. In Russia, expression of human BChE in horseradish has been undertaken with mixed results (Martirossian et al., unpublished). After years of failure, functional expression in bacteria of both human AChE (Goldenzweig et al., 2016) and human BChE (Brazzolotto et al., 2017) is now possible. Even functional expression of thermally stable human BChE dimer in *Escherichia coli* has recently been possible (Cai et al., 2019). However, this approach implies introducing a large number of mutations in the protein structure. This enzyme redesign may impair further mutagenesis of the enzyme, for example, for making OP-degrading ChEs.

The recent introduction of Hupresin for affinity chromatography of recombinant or human plasma has made it possible to speed up purification of cell cultures, Cohn fraction IV, or transgenic plant extracts (Lockridge et al., 2018; Alkanaimsh et al., 2019; Schopfer et al., 2019), even at a preindustrial scale (Schopfer et al., 2019).

Certain secondary targets of OPs are potential bioscavengers. In particular, owing to the high number of amino acid residues in human serum albumin that covalently bind OP molecules (five tyrosines and two serines) (Ding et al., 2008), it may be hypothesized that reactivity of these residues could be enhanced by genetic engineering and/or upon specific chemical modification. However, direct tyrosine nitration (to lower the pK_a of tyrosine) did not lead to the expected improvement in reactivity, possibly because of steric hindrance (Masson et al., unpublished). Engineered albumins could lead to a new generation of stoichiometric bioscavengers. However, conversion of albumin into a catalytic bioscavenger would need to increase its catalytic efficiency by several orders of magnitude, a challenge that seems to be unrealistic (Li et al., 2008).

Low-molecular-weight stoichiometric scavengers could be an economic alternative to enzyme-based stoichiometric scavengers. Several serine- and tyrosine-containing hexapeptides from a random library of peptides have been selected because they form a phosphoester bond with a fluorescent analog of sarin (Landry and Deng, 2008; Zhu et al., 2008). However, the reactivity of these molecules is not yet sufficient. Finally, a way to increase the endogenous stoichiometric bioscavenger capacity could be to enhance the endogenous expression of BChE and AChE. This could be achieved by administration of proline-rich polypeptides derived from ChE collagenic tail peptide (ColQ, PRAD) or peptides derived from RAPH-1 or transmembrane anchor (PRIMA) that promote folding, tetrameric assembly, and exportation of the enzymes from cells (Rotundo, 2011). The recent resolution of the tetrameric structure of natural human BChE (Leung et al., 2018; Boyko et al., 2019) and information about the structural organization of the C_5 variant of hBChE, composed of the BChE tetramer linked to a polyproline protein of 50 kDa (Schopfer et al., 2017) are expected to help to make more stable ChE-based bioscavengers with longer residence time in the bloodstream. Human umbilical cord perivascular cells secrete a BChE tetrameric form related to the C_5 variant. Cultures of these cells could be developed to produce wild-type or engineered BChE (Braid et al., 2019).

72.3 Pseudocatalytic bioscavengers

Since the main limitation of the stoichiometric bioscavenger approach is the cost of the huge dose of enzyme to be administered for challenging the OP molecules, a way to circumvent this problem is to in vivo reactivate the administered enzyme, turning the stoichiometric bioscavenger into a pseudocatalytic bioscavenger.

Certain ChE mutants sensitive to OPs do not "age" after phosphylation, they are fully reactivatable (cf. Fig. 72.1, reaction 3). Such ChE mutants, for example, the human AChE mutant Y337A/F338A (Cochran et al., 2011) when associated with oximes (e.g., 2-PAM, HI-6), act as pseudocatalysts in displacing the OP moiety bound to the enzyme. These enzyme−reactivator coupled systems could lead to a new family of pseudocatalytic bioscavengers (Kovarik et al., 2007, 2008; Taylor et al., 2007; Mazor et al., 2008). Study with wild-type human BChE showed that the geometry of oxime function access to the phosphorus atom of conjugate is an important criterion for fast reactivation (Semenov et al., 2020). Several libraries of positively charged and uncharged molecules have already been made by in silico design or click chemistry and tested with success in vitro against human ChE inhibited by paraoxon, tabun, soman, and VX (Kovarik et al., 2013; Radic et al., 2013; Renou et al., 2013; Katalinic et al., 2016, 2018).

The success of this approach in vivo requires implementation of new oximes, displaying higher affinity for phosphylated ChEs (lower K_D), higher reactivation constant (k_r), and a long circulation time in the bloodstream. However, for reactions under optimal conditions, the pharmacokinetic profiles of enzymes and reactivators must be similar. Though enzymes can be chemically modified for long residence times in the bloodstream, pharmacokinetics of oximes is in general fast. To circumvent this problem, oximes can be either encapsulated into nanocontainers for prolonged release (Pashirova et al., 2018) or both enzyme and encapsulated oximes incorporated into

circulating nanoreactors where coupled reactions of bioscavenger phosphylation and oxime-mediated reactivation take place (Masson et al., unpublished).

72.4 Catalytic scavengers

Catalytic scavengers are second-generation bioscavengers. They are enzymes or artificial catalysts capable of degrading OPs with a turnover. These catalysts detoxify OPs by hydrolyzing the phosphoester [organophosphorus acid anhydride hydrolase (OAAH) activity also called "phosphotriesterase" (PTE) activity, OP hydrolase (OPH, OPase) activity]. Other catalytic bioscavengers lead to less toxic compounds by degrading their alkyl/aryl chains through oxidation. Several recent reviews deal with this second generation of bioscavengers (Masson and Lushchekina, 2016; Worek et al., 2016; Masson and Nachon, 2017; Goldsmith and Ashani, 2018). In particular, the last one discusses the recent in vivo outstanding protective results obtained with evolved PTEs.

The catalytic bioscavenger concept is based on the idea of continuously trapping and degrading OPs in the bloodstream before OP molecules reach their central and peripheral neuronal and neuromuscular targets. Then, prophylactic injection of enzymes capable of hydrolyzing OP quickly (alone or in association with current prophylactic countermeasures, i.e., pyridostigmine bromide, PANPAL, and other reversible ChE inhibitors and anticholinergic drugs) (Masson, 2016), would allow first responders, firemen, explosive ordnance disposal technicians, and medical personnel, to operate safely in contaminated environments on contaminated casualties. Intravenous or intramuscular administration of bioscavengers to chemical casualties is expected to greatly improve the efficacy of implemented pharmacological countermeasures (Ashani et al., 1998; Saxena et al., 2006).

These enzymes could be also used for protection of skin (Fischer et al., 2005), and for decontamination of skin, mucosa, and open wounds (LeJeune and Russell, 1999; Gill and Ballesteros, 2000). Genetically engineered bacteria producing OPHs could be introduced in water effluents of decontamination units that could purify contaminated water before recycling or washing up in the environment (Chen and Mulchandani, 1998).

Research on catalytic antibodies has made some progress (Jovic et al., 2005; Smirnov et al., 2013). In particular, resolution of the 3D structure of a "reactibody" fragment with an OP (Smirnov et al., 2011) has opened the possibility of rational design of more active catalytic antibodies (Kurkova et al., 2012). However, the turnover rate of catalytic antibodies is still extremely slow, and antibody specificity remains too narrow for practical interest as medical countermeasures.

Research on artificial enzymes acting as catalytic scavengers, for example, functionalized β-cyclodextrins, is promising. Cyclodextrin derivatives bearing a nucleophilic group such as isodozobenzoic acid or an oxime were made (Ramaseshan et al., 2006; Estour et al., 2013; Kalakuntla et al., 2013; Bierwisch et al., 2014; Letort et al., 2016; Sambrook et al., 2017). These compounds display very interesting catalytic properties against certain NAs, in particular cyclosarin (Muller et al., 2013). However, engineering (computer design and/or directed evolution) of enzymes capable of degrading OPs remains the most promising short-term research field.

72.5 Requirements

The general requirements for the use of enzyme-degrading OPs as medical countermeasures against OP poisoning are as follows. These enzymes must have a large activity spectra, and ideally, enantioselectivity for toxic stereoisomers. Their mass production under GMP conditions must be realizable at a reasonable cost. Long-term storage without activity loss (in solution, lyophilized, or adsorbed/bound on a matrix) must be possible under field conditions. Conformational stability can be optimized by chemical modification or addition of stabilizers likes polyols. Otherwise, thermostable phosphotriesterases from hyperthermophilic bacteria (Merone et al., 2005; Elias et al., 2008) expressed in *E. coli* or mutated/evolved highly stable enzymes from mesophilic bacteria are promising alternatives.

Other conditions depend on the method of administration, delivery system, or galenic formulation of these enzymes. Enzymes can be injected intravenously or intramuscularly. Other routes have been considered such as the intranasal method against aerosolized or gaseous NAs. For instance, pretreatment of macaques with aerosolized forms of BChE have been shown to provide long-term protection against aerosolized paraoxon (Rosenberg et al., 2013, 2019). For parenteral administration, the toxicant concentration in blood has to be considered. Even in the most severe case of poisoning, this concentration, [OP], is always very low. For example, the sarin concentrations in serum of casualties after Matsumoto and Tokyo chemical attacks have been estimated between 1.5 and 30 nM, 14 h postexposure (Polhuijs et al., 1997). Therefore, the [OP] concentration in plasma is always well below the K_m of the enzyme for OP substrates. This determines first-order kinetics for hydrolysis of OP in blood (Masson et al., 1998, 2008) as described by Eq. (72.1):

$$v = k_{cat}/K_m \cdot [E] \cdot [OP] \qquad (72.1)$$

In Eq. (72.1), the product of the bimolecular rate constant (k_{cat}/K_m) and the enzyme active site concentration ([E]) is the first-order rate constant. The amount of

enzyme to be injected for degradation of toxic molecules in a very short time depends on the enzyme efficiency, that is, k_{cat}/K_m. The higher the catalytic efficiency, the lower the enzyme dose to be administered. The enzyme concentration needed to drop the OP concentration to a nontoxic concentration in time t is:

$$[E] = \frac{X}{k_{cat}/K_m \cdot t} \tag{72.2}$$

X is the factor by which [OP] is reduced ($X = \mathrm{Ln}[OP]_0/[OP]_t$) (Masson et al., 2008). In this equation, it is assumed that the stability and pharmacokinetics of the administered enzyme have been optimized, and that the enzyme concentration, [E], does not decrease during the time-course of the reaction with OP. The efficiency and stereospecificity of a given enzyme can be increased by several orders of magnitude by mutagenesis or chemical engineering (Griffiths and Tawfik, 2003; Hill et al., 2003; Gupta et al., 2011; Tsai et al., 2012; Goldsmith et al., 2017; Goldsmith and Ashani, 2018). Engineering strategies to increase k_{cat}/K_m have been theorized (Goldsmith and Tawfik, 2017).

The second constraint is to maintain the bioscavenger concentration, [E], in the bloodstream as high as possible for a long time. [E] is controlled by the enzyme pharmacokinetics/pharmacodynamics and/or the frequency of repeated administrations (sustained pharmacokinetics). Increasing the size of the enzyme by polymerization, conjugation to other proteins (e.g., albumin, antibody fragments) or to biodegradable polymers such as XTEN polypeptides (Podust et al., 2016), decreasing glycosylation microheterogeneity, and chemical modifications of solvent-exposed surface ("capping") improve the biological life of injected enzymes (Cohen et al., 2006). Fast clearance of glycoproteins is often due to glycosylation defects; fast clearance of nonglycosylated enzyme may result from their too small size (Jackson et al., 2010). Glycosylation defects can be corrected either by chemical modifications such as PEGylation (Chilukuri et al., 2005), polysialylation of purified expressed enzyme (Ilyushin et al., 2013), or by selection of an appropriate expression system (Chitlaru et al., 1998), including overexpression of an additional glycosylation enzyme that increases the sialylation content of the expressed glycoprotein (Schneider et al., 2014). Size defects can be corrected by conjugation to polyethylene glycol, dextran, other macromolecules, or fusion to albumin (Huang et al., 2008). Tetramerization of recombinant human BChE expressed in CHO cells was shown to considerably increase the residence time of the enzyme in mouse bloodstream (Terekhov et al., 2015). All modifications reduce renal clearance and increase plasma retention. Finally, like many detoxifying enzymes (Liu et al., 2015), nanoencapsulation of bioscavengers into nanocarriers ("nanoscavengers") may greatly increase their residence time in the bloodstream (Zhang et al., 2019) and suppress potential adverse effects such as immunoreactivity.

Administration of homologous enzymes does not induce an immunologic response following a second injection (Sun et al., 2009). On the other hand, immunotolerance of injected heterologous enzymes is a major issue. Bacterial enzymes and heterologous mammalian enzymes are not suitable for use in humans, but conjugation to dextran or polyethylene glycol (PEGylation) is often sufficient to reduce antigenicity and to slow down clearance following multiple injections (Novikov et al., 2010; Trovaslet-Leroy et al., 2011; Sun et al., 2013). Nanoencapsulation of nonhuman enzymes is another strategy to cheat the immune system and to increase residence time in the bloodstream (Liu et al., 2015; Zhang et al., 2019). However, enzyme-containing nanocontainers must be completely sealed to prevent leaks. This implies sophisticated design of decorated and cross-linked multilayer nanoparticles.

Therapeutic plasma exchange has proven to be effective in patients with severe intermediate syndrome resulting from severe poisoning by pesticide OPs (Yilmaz et al., 2013). Alternatively, extracorporeal removal of toxicants can by performed by hemodialysis (Borkan, 2002; de Pont, 2007; Monaghan and Acierno, 2011). Extracorporeal dialysis has been successfully implemented in a patient for blood decontamination after the Tokyo subway attack (Yokoyama et al., 1995). Moreover, it was postulated that charcoal hemoperfusion associated with infusion of lipid emulsions could be used for the treatment of severe OP pesticide poisoning (Zhou et al., 2010). Also, incorporation of OP-degrading enzymes in the medical dialysis system could greatly improve the efficiency of hemodialysis. Enzymes can be immobilized on dialysis cartridges (Klein and Langer, 1986). Accessibility of OP molecules to an enzyme active center must not be altered by the immobilization method or by matrix effects. The enzyme concentration per surface unit has to be maximized to reduce diffusion constraints. In that case, both the reactive surface of the matrix and k_{cat}/K_m would have to be as high as possible and the flow rate reduced to increase the efficiency of the reactor. First-order degradation kinetics takes place under the particular conditions of immobilized enzymes in a continuous-flow system. Immunocompatibility problems are theoretically suppressed, thus permitting the use of unmodified nonhuman enzymes. However, implementation of this approach needs blood derivation through peristaltic pump systems. The above-mentioned nanoreactor approach could be an alternative to extracorporeal immobilized enzyme-cartridges.

Lastly, in situ transient production of enzymes, if the need arises, will be possible by gene therapy in the future.

Promising results have been published using short-induction gene vectors (adenoviral systems) for human PON-1 (Cowan et al., 2001; Bradshaw et al., 2005; Fu et al., 2005; Miyoshi et al., 2007; Guns et al., 2008; Duysen et al., 2011), human AChE (Li et al., 2006), human BChE (Chilukuri et al., 2009; Parikh et al., 2011), mutated human BChE that displays high cocaine esterase (Gao et al., 2013), and human prolidase (Aleti et al., 2013).

Enzymes in skin and eye lotions, immobilized in foams and on tissues for skin and eye decontamination (Gordon et al., 2003), or in TSPs (Braue et al., 2002), act under conditions where local OP concentrations can be very high. In these cases, enzyme reaction order in [OP] tends to zero, so that the reaction rate is close to maximum velocity:

$$v \rightarrow V_{max} = k_{cat} \cdot [E] \qquad (72.3)$$

The enzyme efficiency depends on its concentration and its catalytic constant k_{cat}. Thus, for external use, enzyme preparations have to be highly concentrated with high molecular catalytic activity. Coimmobilization of different enzymes could be an easy way to extend the spectra of agents to be degraded. This should allow simultaneous detoxification of G and V agents, as well as other potential chemical warfare agents, pesticides and so-called "nontraditional nerve agents." Indeed, exposure to multiple agents has to be considered. In this view, it should be remembered that during the war between Iran and Iraq, tabun and other OPs were combined with mustard gas in some attacks (UN Reports, 1984, 1987). In asymmetric conflicts, eschatological and mafia-like terrorisms, the most extreme scenarios have to be taken into account.

72.6 Potential enzymes

72.6.1 Phosphotriesterases

72.6.1.1 Bacterial phosphotriesterases

Bacterial phosphotriesterases (PTEs; EC 3.1.8.1) detoxify OPs (Ghanem and Raushel, 2005; Theriot and Grunden, 2011). These enzymes have been isolated from numerous sources. Four enzyme families showing different folds or topologies can be described: TIM-barrel fold, β-lactamase fold, pita bread fold, and β-propeller fold (Bigley and Raushel, 2013). They are encoded by the organophosphate degradation (*opd*) gene found in species of *Brevundimonas diminuta* (formerly *Pseudomonas diminuta*), *Flavobacterium* sp., *Agrobacterium radiobacter* (Horne et al., 2002), and *Pseudomonas pseudoalcaligenes* (Gotthard et al., 2013), and genes similar to *opd* were also located in archaea (Merone et al., 2005). PTEs belong to a superfamily of amidohydrolases (Holm and Sander, 1997; Bigley and Raushel, 2013).

B. diminuta PTE is a 72 kDa dimeric bimetallic enzyme with Zn^{2+} involved in the catalytic process (Carletti et al., 2009). Substitution of the native Zn^{2+} ions in the active site with Mn, Co, Ni, or Cd ions results in almost full retention of catalytic activity. Following the first determination of the three-dimensional structure of *P. diminuta* PTE (Benning et al., 1994) (Fig. 72.3A), a

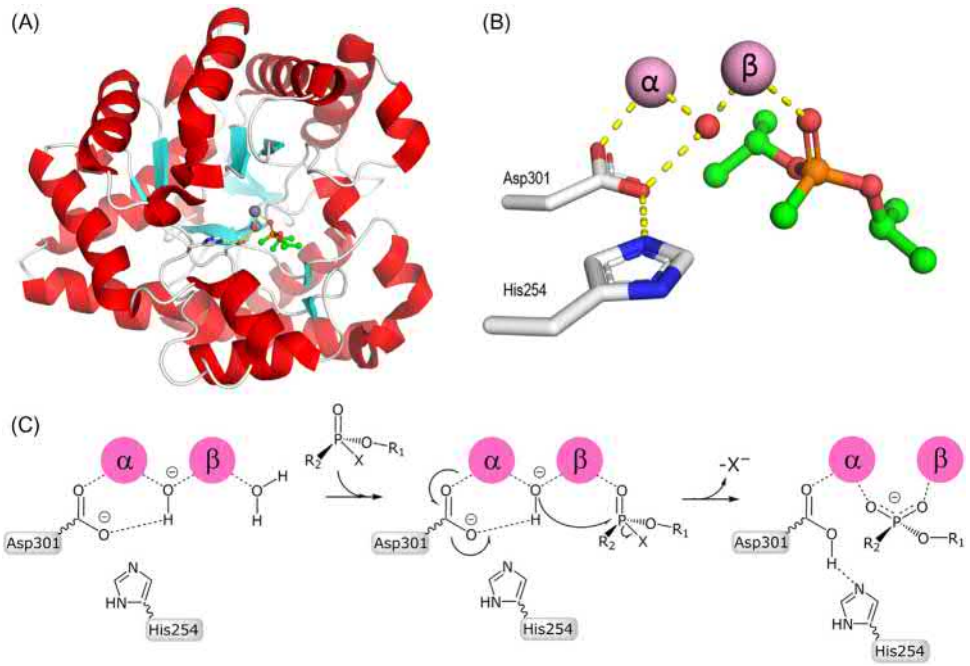

FIGURE 72.3 X-ray structure *Brevundimonas diminuta* PTE [PDB ID 1EZ2, (Benning et al., 2000)], (A) overall view and (B) close view on metal center with bound substrate analog diisopropyl methyl phosphonate. (C) Scheme of hydrolysis reaction described in Bigley and Raushel (2019).

series of crystal structures, kinetic, and spectroscopic experiments were described. Oxygen atom seen in X-ray structures, coupled with two metal cations (Fig. 72.3B), is thought to be in a hydroxyl form, because the structure is pH-dependent, protonation of the hydroxyl leads to loss of coupling (Samples et al., 2005). Nevertheless, the enzyme mechanism of bacterial PTEs is still debated and the functional roles of divalent metal cations and amino acids in the active center are not yet fully understood (Aubert et al., 2004; Jackson et al., 2006, 2008; Chen et al., 2007; Samples et al., 2007; Wong and Gao, 2007; Bigley and Raushel, 2013).

The mechanism proposed by Bigley and Raushel (Bigley and Raushel, 2013, 2019) suggests that OP hydrolysis by bacterial PTE occurs through direct attack of hydroxyl-group bridging divalent metal cations on P atom (Fig. 72.3C). As a result, formation of products is accompanied by inversion of phosphorus atom stereoconfiguration. Product is bound to cations in a bidentate manner. Surrounding residues have a supplementary role, accepting proton from the hydroxyl-group upon formation of negatively charged product. There are kinetic (Samples et al., 2005), crystallographic (Kim et al., 2008), EPR spectroscopy (Samples et al., 2007), NMR (Bigley et al., 2016), and computational (Wong and Gao, 2007; Zhang et al., 2009) supports for this mechanism.

These promiscuous enzymes are primarily lactonases, now called phosphotriesterase-like lactonases (PLL). The lactonase activity plays a role in bacterial communication (*quorum* sensing) (Dickschat, 2010). Virulence and formation of biofilms are regulated by concentration of lactones (*N*-acetyl-homoserine lactones) in the medium. Thus, the lactonase activity by hydrolyzing lactones acts as a *quorum* quencher, which in turn inhibits bacterial communication (Amara et al., 2011). The PTE activity of these enzymes is believed to have evolved from lactonases (Afriat et al., 2006; Elias et al., 2008; Afriat-Jurnou et al., 2012; Hiblot et al., 2012).

Whereas the catalytic efficiency of *B. diminuta* PTE for hydrolysis of paraoxon, the best substrate identified so far, is approaching the diffusion-controlled limit, it is slow against OP NAs (Table 72.1). Meanwhile, directed evolution of *B. diminuta* PTE showed that only three amino acid changes dramatically enhanced the catalytic efficiency for an analog of soman by about three orders of magnitude (Hill et al., 2003). Further studies combining rational design and directed evolution led to randomized libraries of mutants and selection of variants with greatly improved catalytic activity against S_p enantiomers of NA chromogenic analogs, including VX and VR analogs, and racemic real NAs (Table 72.1) (Tsai et al., 2010, 2012). This strategy has recently led to multiples variant with k_{cat}/K_m values up to four orders of magnitude higher than that of wild-type PTE against V agents (Bigley et al., 2019; Bigley and Raushel, 2019). Though a recent theoretical study suggests that enzymatic hydrolysis of novichok agents would be possible (Lyagin and Efremenko, 2019), it appears to be a very difficult challenge, owing to the presumed phosphoramidate structure of A-230, 232, and 234. There have been numerous studies highlighting the potential of this enzyme for decontamination or skin protection in addition to OP-detection (LeJeune and Russell, 1999; Gill and Ballesteros, 2000; Ghanem and Raushel, 2005; Letant et al., 2005; Karnati et al., 2007). Administration of PTE before or after OP exposure was shown to improve pretreatment and current treatment of OP intoxication (Doctor and Saxena, 2005). However, in order to prevent abnormally fast pharmacokinetics and/or immunological response due to injection of a bacterial enzyme, PTE could be PEGylated (Jun et al., 2007) or encapsulated. The first attempts at using PTE encapsulated within sterically stabilized liposomes were promising, providing protection of rats from multiple LD_{50}s of OP pesticides (Petrikovics et al., 2004). An alternative route could be the blood detoxification by extracorporeal circulation through a cartridge containing PTE immobilized in hollow fibers (unpublished results). PTEs possibly could also be used for skin protection as active components of TSPs or covalently coupled to the cornified layer of epidermis (Parsa and Green, 2001).

B. diminuta PTE was also entrapped in additives for latex coating of biodefensive surfaces. Such PTE-based additives for paints and coatings were shown to retain catalytic parameters and stability of the enzyme (McDaniel et al., 2006). For decontamination of OPs in the environment and remediation, an alternative approach, phytodegradation by transgenic plants (e.g., tobacco) expressing a bacterial PTE, has been considered as a potentially low-cost, effective, and environmentally friendly method (Wang et al., 2008a,b). It should be mentioned that His-tagged PTE (Efremenko et al., 2009) was reported to degrade NAs, including VX, at a high rate. Since the enzyme was not genetically modified, it is suggested that the presence of the His tag plays a role in this amazing activity. Though neither 3D structure nor molecular dynamics (MD) studies are available for this enzyme, it can be hypothesized that the His tag may increase the enzyme flexibility, which in turn should increase the enzyme capability to accommodate numerous OP molecules and improve its catalytic activity.

Highly stable promiscuous lactonases/phosphotriesterases from hyperthermophilic archaea have been isolated in hot springs and volcano *solfatare*. The three-dimensional structures, evolution, stability, and catalytic properties of several PTEs have been determined (Elias et al., 2008; Hiblot et al., 2012, 2013a,b; Zhang et al., 2012; Gotthard et al., 2013; Porzio et al., 2013). These enzymes have been conveniently expressed in *E. coli* and

mutated (site-directed mutagenesis and directed evolution) to improve their catalytic properties against OPs (Merone et al., 2010; Hiblot et al., 2012, 2013a,b; Jacquet et al., 2017; Restaino et al., 2017) (Table 72.1). Owing to their high stability that allows long-term storage at room temperature, fieldable uses for decontamination are possible. Other extremophile PTEs have been isolated from halophilic bacteria (*Alteromonas*), such as the OPAA (organophosphorus acid anhydrolase) and from radio-resistant bacteria, *Deinococcus radiodurans* and *A. radiobacter*. The 3D structure and catalytic mechanism of these enzymes have also been determined and used for structure-based random mutagenesis rational design to improve their catalytic efficiency against OPs (Hawwa et al., 2009; Jackson et al., 2009; Ely et al., 2010). Recent mutagenesis of OPAA generated new mutants against G agents, one of these mutants displays the highest activity against soman (Bae et al., 2018). New fluorimetric screening methods allow identification of highly active PTEs in microorganisms from various biotopes (Santillan et al., 2016).

72.6.1.2 Human paraoxonase

The human paraoxonase-1 (PON-1) is a 45 kDa calcium-dependent plasma enzyme bound to high-density lipoprotein (HDL) particles, in association with other apolipoprotein partners. PON-1 shows a genetic polymorphism; the most prominent allele determines the Q192R allozyme, which can have a substantial impact on PON-1 activity against OPs and arylesters (Smolen et al., 1991; Dardiotis et al., 2019) (Table 72.1). The enzyme was shown to be involved in the protection against atherosclerosis (Watson et al., 1995; Shih et al., 1998) and thus became a player in vascular physiology. Albeit its primary function is a lipophilic lactonase (Khersonsky and Tawfik, 2005; Ben-David et al., 2013), PON-1 displays two promiscuous activities, PTE and arylesterase (Blaha-Nelson et al., 2017).

Abundant biochemical, biological, and toxicological information has been collected in the past two decades, leading to partial characterization of the enzyme function (Costa and Furlong, 2002; Mackness et al., 2008), but recurrent attempts at solving the 3D structure of human PON-1 failed. Through chemical modification and site-directed mutagenesis studies, some amino acid residues have been identified as essential for activity (Josse et al., 1999). Finally, molecular modeling (Fokine et al., 2003; Yeung et al., 2004) and crystal structure of a hybrid rPON-1 (a synthetic construct issued from shuffling of rabbit, mouse, rat, and human PON-1 genes expressed in *E. coli*) (Harel et al., 2004) showed that human PON-1 is a six-bladed β-propeller protein with a structure very similar to that of *Loligo vulgaris* DFPase (Katsemi et al., 2005). Differences in substrate preference between PON-1 and DFPase reflect the molecular evolution of these related enzymes (Zhang et al., 2018).

A catalytic mechanism for DFPase, a calcium-dependent PTE, was described (Blum et al., 2006; Bigley and Raushel, 2013). This mechanism involves a calcium-coordinated aspartate residue as the nucleophile that attacks the OP phosphorus atom. Alternatively, a more realistic mechanism involves the activation of a water molecule into a hydroxide ion that attacks the phosphorus center (Elias et al., 2013). This mechanism is consistent with the common mechanism that has been proposed for PON-1 (Ben-David et al., 2013), PTEs (Aubert et al., 2004), and PLLs (Elias et al., 2008). Lastly, a unified mechanism for eukaryotic PTEs was recently proposed (Grunkemeyer et al., 2018). This mechanism considers that the water molecule is activated by a calcium cation. Hydroxyl ion either directly attacks the substrate (carbonyl or phosphoryl group, depending on the type of substrate), or activates another nearby water molecule. Surrounding residues play an important role in modulating activity, but mutagenesis results suggest that they are not involved directly (Grunkemeyer et al., 2018). This mechanism is close to the above-mentioned mechanism for bacterial PTEs containing two divalent metal cations (Bigley and Raushel, 2019) (Fig. 72.3C).

As a naturally occurring enzyme present in plasma, human PON-1 has been considered as the most promising catalytic bioscavenger candidate for pretreatment and therapy of poisoning by OP (La Du, 1996; Rochu et al., 2007a; Worek et al., 2014). Thus, the enzyme has been the focus of intensive research to improve its efficacy and functionalization. To provide a valuable medical countermeasure against intoxication by NAs, the catalytic efficiency of PON-1 has to be enhanced by only one or two orders of magnitude. Chimeric PON-1 mutants obtained by directed evolution and exhibiting enhanced OP-hydrolase activity (Amitai et al., 2006; Ashani et al., 2011; Worek et al., 2014) show this goal to be reasonably achieved soon. However, instability of PON-1 mutants could impinge on their biotechnological development. Indeed, as a HDL-bound protein, PON-1 requires association to apolipoprotein partners to retain its stable active conformation (James and Deakin, 2004; Gaidukov and Tawfik, 2005; Rochu et al., 2010) and long residence time in the bloodstream (Valiyaveettil et al., 2012). Highly purified human plasma PON-1 was found to be associated to human Phosphate Binding Protein (HPBP) (Rochu et al., 2007b). HPBP is an apolipoprotein that binds inorganic phosphate in blood. HPBP was serendipitously discovered (Morales et al., 2006). This protein belongs to the family of DING proteins (Berna et al., 2009). Its three-dimensional structure and complete amino acid sequence were solved (Morales et al., 2006; Diemer

et al., 2008). The conditions found to separate HPBP and PON1 in vitro indicated that HPBP is strongly associated with PON-1 (Renault et al., 2006). Moreover, stabilization of the active form(s) of human PON-1 by HPBP suggests that HPBP could be a functional chaperone for PON1 (Rochu et al., 2007b,c; Clery-Barraud et al., 2009). Biotechnological difficulties encountered with plasma-derived human PON-1 have been overcome by expressing the enzyme in a stably *Drosophila* S2 cell line. The recombinant human PON-1 was fused to the human immunoglobulin Fc domain to improve stability and purification (Yun et al., 2017a,b).

A gene issued from the HPBP amino acid sequence was synthesized (Diemer et al., 2008), and the protein was expressed in *E. coli*. However, attempts at cocrystallization of the PON-1−HPBP complex have failed so far. Yet this crucial phase is the first step of the staircase leading to the design and development of stable human PON-1 mutants with enhanced catalytic efficiency against toxic OP stereoisomers (S_p) of G NAs.

Site-directed mutagenesis of human PON-1 based on molecular modeling has led to double mutants capable of hydrolyzing G and V NAs (Kirby et al., 2013). However, the catalytic efficiency of these mutants is modest and enantioselectivity is not changed compared to the wild-type enzyme. A directed evolution strategy has been more successful in producing chimeric PON-1 capable of degrading toxic isomers of coumarinyl NA analogs as well as real G-NAs. In particular, enantioselectivity of evolved PON-1 was completely reversed. For instance, the activity against S_p-cyclosarin was enhanced 10^5-fold (Ashani et al., 2011; Gupta et al., 2011; Goldsmith et al., 2012). The most active evolved PON-1 mutant, IIG1 (Table 72.1), administered at a dose of 1 mg/kg was shown to prevent $2 \times LD_{50}$ cyclosarin systemic toxicity in the guinea pig (Worek et al., 2014). This mutant was also shown to detoxify most G-NAs at a high rate under first-order conditions, but was ineffective against VX even under second-order conditions (Goldsmith and Ashani, 2018).

Gene therapy could also be considered to challenge OPs by using a mutated PON-1 gene coding for an enzyme with high OPH activity against NAs. Several approaches with different gene-delivery vectors in mice showed increased PON-1 level serum that reduced or even prevented the entry of OP into the brain, and reduced atherosclerosis signs (Cowan et al., 2001; Bradshaw et al., 2005; Fu et al., 2005; Guns et al., 2008; Duysen et al., 2011; Hodgins et al., 2013). Local delivery of PON-1 gene using Sendai virus vector inhibited neonatal hyperplasia after arterial balloon-injury in rabbits fed a high-fat diet (Miyoshi et al., 2007). However, wild-type human PON-1 does not have sufficient catalytic efficiency against NAs to provide in vivo protection against $2 \times LD_{50}$ of G agents. Thus, enhanced expression of mutated PON-1 by gene therapy could be beneficial for the different functions of the enzyme. Meanwhile, the complex and defectively identified PON-1 activity makes it apparent that the strategy for repetitive administration of high concentrations in humans must be undertaken cautiously.

72.6.2 Other enzymes

Other enzymes are involved in biodegradation of OPs; including hydrolases, for example, prolidases, senescence marker protein (SMP), and platelet-activating factor (PAF-AH); others are oxidases, such as cytochromes P450, GSTs, laccases, and peroxidases.

72.6.2.1 Other mammalian phosphotriesterases

Prolidases (EC 3.4.13.9, PROL) were first isolated from halophilic bacteria (*Alteromonas haloplanktis* and *Alteromonas* sp. JD6.5). This bacterial metallo-enzyme (binuclear Mn^{2+} center) has a "pita bread" structure (Vyas et al., 2010). Prolidase from *Alteromonas* sp. JD6.5 is an OPAA that displays high activity against soman ($k_{cat} = 3100\ s^{-1}$), but it is inactive against VX (Cheng et al., 1999). Thermostable prolidases from hyperthermophilic archaeas *Pyrococcus furiosus* (Theriot et al., 2010) and *Pyrococcus horikoshii* (Theriot et al., 2011) hydrolyze P−F and P−O bonds in NAs. Evolved mutants of these enzymes capable of degrading OPs over wide temperature ranges, as engineered hyperthermophilic PLLs do, should have a future for biodecontamination under mild conditions. PROL was also isolated from human liver, kidney, erythrocytes, and skin and expressed in *E. coli* (diTargiani et al., 2010; Costante et al., 2012; Chandrasekaran et al., 2013). This enzyme displays a catalytic activity against sarin and soman (Wang et al., 1998; diTargiani et al., 2010) and exhibits sequence homology with the *A. haloplanktis* prolidase (Wang et al., 2006). First engineered human PROL showed that mutants A265R and P365R have a slightly improved activity against DFP (Yun et al., 2017a,b). Also, gene-delivered human liver PROL using adenovirus produced a high level of active enzyme, but protected mice only against $1 \times LD_{50}$ of DFP (Aleti et al., 2013).

SMP-30 was isolated first from rat liver (Kondo et al., 2004). It is a six-bladed-β-propeller metallo-lactonase structurally close to PON-1 and DFPase with a promiscuous PTE activity (Chakraborti and Bahnson, 2010). The human and mouse enzymes display a modest PTE against G-agents (diTargiani et al., 2010; Belinskaya et al., 2012). Engineering of this enzyme is still at the early stages.

PAF-AH is a group of 45 kDa lipoprotein (HDL and LDL)-associated phospholipases A2. In human, they are present both in plasma and brain. These enzymes that

react with numerous OPs are structurally related to NTE (Karasawa et al., 2003; Quistad et al., 2003, 2005; Epstein et al., 2009). Site-directed mutagenesis of human plasma PAF-AH for making an OPH with the purpose of NA detoxification has been undertaken (Kirby et al., 2012). However, research on these enzymes as possible catalytic bioscavengers is still in its infancy.

72.6.2.2 Oxidases

GSTs (EC 2.5.1.18) are 20–30 kDa enzymes that catalyze glutathione conjugation (nucleophilic attack of the thiol group) to electrophilic substrates. They are involved in cellular detoxification processes of endogenous compounds and of numerous xenobiotics, and their role in insect resistance to insecticides is well established. OP detoxification by GSTs results from a regioselective dealkylation of the alkyl or aryl side chain (Maturano et al., 1997). These enzymes exhibit wide genetic polymorphism. Some GST allelozymes from the flies *Drosophila melanogaster* and *Musca domestica*, highly active against OP insecticides, have been cloned and expressed in *E. coli* (Fournier et al., 1992). There is evidence that GSTs contribute to OP detoxification in humans (Fujioka and Casida, 2007).

Laccases (EC 1.10.3.2) are fungal phenol oxidoreductases that have been used for detoxification of numerous xenobiotics, including dyes and pesticides (Richardt and Blum, 2008). The laccases from *Pleurotus ostreatus* and *Chaetomium thermophilium* were found to rapidly degrade VX and VR in the presence of 2,2′-azinobis(3-ethylbenzthiazoline-6-sulfonate) (ABTS) as a mediator (Amitai et al., 1998). Laccases from *Trametes versicolor* and *Coriolopsis polyzona* with ABTS display similar properties against V agents (Trovaslet-Leroy et al., 2010). The heme-containing chloroperoxidase (EC 1.11.1.X) from *Caldaromyces fumago*, with peroxide as cosubstrate, is another efficient VX-degrading enzyme (Amitai et al., 2003). A bacterial laccase from *Pseudomonas* sp. S2 produced in a bioreactor was found to oxidize OP pesticides in a short time (Chauhan and Jha, 2018). This enzyme could at least be used for decontamination.

These enzymes are promising for the destruction of chemical weapons stockpiles, soil remediation, and the decontamination of materials, protective equipment, and water polluted by pesticides and NAs (Russell et al., 2003). In particular, phosphorothiolates such as VX are almost resistant to PTEs. Thus, oxidative cleavage of the P–S bond could be achieved by oxidases like laccases. These enzymes could be used in association with other OP-degrading enzymes for skin decontamination or in topical skin protection formulations. Though no work has been performed on the combined action of oxidases and hydrolases, oxidation of P-bonded alkyl/aryl chains by oxidases is expected to alter the enantioselectivity of PTE for parent OPs. Therefore, biopharmaceutical formulations of combined oxidases and PTEs may improve the efficiency of PTE-based catalytic bioscavengers.

72.6.3 Engineered cholinesterases and carboxylesterases

As seen in Fig. 72.1, OPs may be regarded as pseudo-substrates of cholinesterases and carboxylesterases. When ChEs and CaEs react with carboxyl-ester substrates, the acyl-enzyme intermediate is a transient, the acyl group being rapidly displaced by a water molecule. On the contrary, in the case of phosphyl-esters, the stereochemistry of the phosphyl-enzyme intermediate restricts the accessibility of water to the phosphorus atom. Thus, hydrolysis of the phosphylated intermediate is very slow, and the enzyme remains inhibited (Järv, 1989). It was postulated that introduction of a second nucleophile pole in the active center could activate a water molecule. This water molecule could subsequently attack the phosphorus atom on the back face, leading to breakage of the P-serine bond.

The determination of the three-dimensional structure of AChE from *Torpedo californica* (Sussman et al., 1991) opened the way to rational redesign of ChEs. Then, the possibility to convert a ChE into an OPH was demonstrated a few years later by Millard et al. (1995). Human BChE was chosen as the model enzyme because its active center is larger (500 $Å^3$) and less stereospecific than that of AChE (300 $Å^3$) (Saxena et al., 1997). Molecular modeling based on the structure of the *Torpedo* AChE model was used for making the first mutants of human BChE. The second nucleophile pole was created in the oxyanion hole of the active center; a glycine residue was replaced by a histidine. The first mutant, G117H, was capable of hydrolyzing paraoxon, sarin, echothiophate, and VX (Millard et al., 1995; Lockridge et al., 1997) (Fig. 72.4). However, this mutant was irreversibly inhibited by soman because the "aging" process of the conjugate was faster than the dephosphonylation reaction (Fig. 72.1, reaction 4). Mutation of E197 into D, Q, or G considerably reduced the rate of aging. As expected, the double mutant G117H/E197Q was capable of hydrolyzing soman (Millard et al., 1998). However, the catalytic activity of this mutant was too slow to be of pharmacological interest.

Construction of transgenic mice *knockout* for AChE and carrying the G117H mutant of human BChE were found to be less sensitive to OP than wild-type animals (Wang et al., 2004). Though transgenic mice expressed G117H mutant in all organs, unlike resistance of the bow fly, their resistance to OP cannot be explained by OP

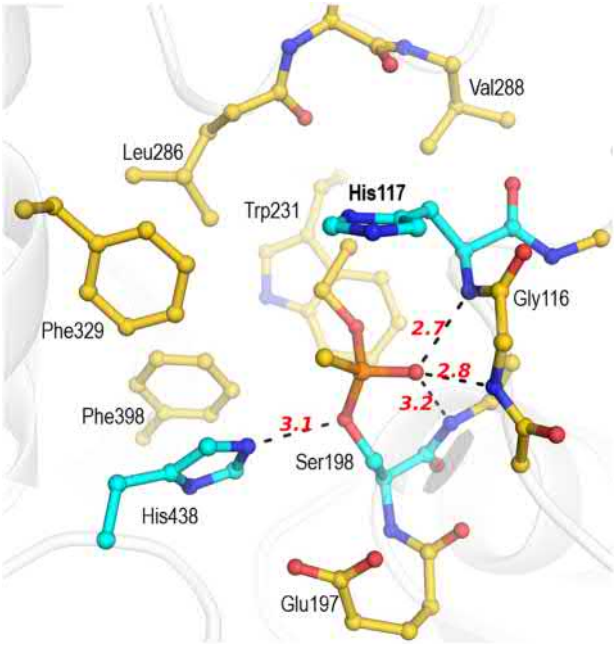

FIGURE 72.4 X-ray structure of the active center of G117H mutant of human butyrylcholinesterase conjugated with VX at 2.1 Å resolution (Nachon et al., 2011).
The enzyme was phosphorylated by soaking the crystal into 1 mM VX for 2 min. X-ray data were collected at European Synchrotron Research Facility (ESRF, Grenoble, France). Two catalytic triad residues, active serine (S198) and histidine (H438), and the mutated residue (H117) in the oxyanion hole are shown as sticks as well as other active center important residues.

hydrolysis that was too slow, but rather by hydrolysis of excess acetylcholine in cholinergic synapses.

More than 60 double or triple mutants based on G117H were made (Schopfer et al., 2004; Lushchekina et al., 2018), certain mutants were eventually designed using the X-ray structure of human BChE (Nicolet et al., 2003). At the same time, mutants of human AChE and *Bungarus fasciatus* AChE were made, using the same strategy (Poyot et al., 2006). Unfortunately, none of these muteins was more active than the G117H mutants. Actually, there is evidence that mutations at position G117 cause dislocation and loss of functionality of the oxyanion hole (Masson et al., 2007). For a historical review of this quest, see Masson et al. (2008).

The crystal structure of the G117H mutant conjugated to echothiophate and VX was solved (Nachon et al., 2011) (Fig. 72.4). Despite numerous works, the mechanism of dephosphylation of this mutant is still debated (Amitay and Shurki, 2011; Lushchekina et al., 2011; Nachon et al., 2011; Yao et al., 2012; Masson and Lushchekina, 2016; Lushchekina and Masson, 2018). However, computer-assisted design of new OPH mutants of BChE is conceivable (Lushchekina et al., 2010, 2018; Grigorenko et al., 2019). This new approach called "intelligent" directed mutagenesis design is based on simulation of the reaction mechanism. Simulation of the reaction pathway approach was already successfully applied to the design of other BChE mutants. Using the three-dimensional structure of human BChE, modeling of intermediate and transition state structures with QM and QM/MM calculations along deacylation reaction coordinates allowed highly active mutants against (−)-cocaine to be made (Zheng and Zhan, 2008; Liu and Zhan, 2012; Zhan et al., 2014). A computational strategy for developing OPH BChE mutants, more active than G117H, aims at optimizing the dephosphylation reaction pathway in the following ways: (1) lowering the energy barrier, that is, the energy level of transition states of the reactions to accelerate kinetics of the process; (2) stabilizing the intermediate and products to favor thermodynamics of the process; and (3) creating an intermediate configuration more favorable for a dephosphylation reaction rather than dealkylation (aging).

Structurally, this is based on the principles, initially used for creation of G117H mutant (Järv, 1989). (1) Accessibility of the phosphylated serine by water molecules. The environment of the phosphylated adduct is highly hydrophobic, it is surrounded by F398, F329, W231, L286 (Fig. 72.4). Natural BChEs, capable of spontaneous self-reactivation [bovine BChE (Dafferner et al., 2017) and porcine BChE (Brazzolotto et al., 2015; Nachon et al., 2019)] have substitutions in the acyl-binding loop compared to the wild-type human enzyme. In addition, in bovine BChE, a bulky aromatic residue, F398, is replaced by I, a smaller aliphatic residue. MD simulations showed that mutations in the acyl-binding loop increase its mobility. This improves the accessibility of phosphylated serine by water molecules (Brazzolotto et al., 2015; Dafferner et al., 2017). Creating-space replacements, like F398I and F329E, alone do not lead to self-reactivation; the self-reactivating effect results from its coupling to mutations in the acyl-binding loop (Lushchekina et al., 2018). (2) Activation of the water molecule by general base (nucleophile pole) can be performed either by residues present in the active site of native BChE (H438, E197), or by introduction of new residues instead of "inert" ones. Additional mutations can be introduced to facilitate proton transfer in the course of water activation, and thus, stabilize the resultant intermediate. The water-activating potency of residue strongly depends on its protonation state in the active site (Lushchekina and Masson, 2018). (3) Orientation of the water molecule can be changed by introduction of general bases in corresponding positions. For the pentavalent phosphorus conjugates there are four possibilities. Choice of direction determines both the route of nucleophilic attack and the configuration of the penta-coordinated intermediate (PI), and consequently, the results of

competition between reactivation and aging reactions. Therefore, understanding mechanisms of interactions between ChEs and OPs is the foundation for the design of novel mutants. The development of structural and computational methods led to ample amount of works, describing all processes, as shown in Fig. 72.1. The different mechanisms are summarized in Lushchekina and Masson (2018),

72.6.3.1 Inhibition of cholinesterases by organophosphates

The formation of a reversible complex between enzyme and inhibitor (Fig. 72.1, step 1) can be accompanied by conformational changes (Bennion et al., 2015); this is well documented in the case of bulky noncovalent inhibitors. In the case of OPs, orientation of the OP molecule in the active site determines the mechanism of covalent reaction (Fig. 72.1, step 2). There are three possible mechanisms of phosphyl transfer between two nucleophiles: concerted (A_ND_N), dissociative ($D_N + A_N$), and addition-elimination or associative ($A_N + D_N$) (Allen and Dunaway-Mariano, 2004). However, for inhibition of ChEs by OPs, the addition-elimination mechanism with formation of stable penta-coordinated intermediate is considered the most probable (Kovach, 1988; Wang et al., 2008a,b; Field and Wymore, 2014; Sirin and Zhang, 2014). Upon formation of PI, the proton of the catalytic serine is transferred to the catalytic histidine. Within the addition-elimination mechanism, there are two possible pathways, depending on orientation of the OP molecule during the nucleophilic attack (Fig. 72.5). (1) leaving group in apical position to the catalytic serine (Fig. 72.5, route A and Fig. 72.6A). After backside nucleophilic attack, and formation of PI, the leaving group departs in anionic form. The catalytic histidine remains protonated in the phosphylated enzyme. This mechanism leads to inversion of configuration of the chiral phosphorus atom for OPs with different substituents. (2) Leaving group in side orientation (Fig. 72.5, route B and Fig. 72.6B), with respect to catalytic residues. The leaving group departs in protonated form with proton abstracted from the catalytic histidine during dissociation of PI. In this case, the stereoconfiguration of the phosphorus atom is retained.

In general, nucleophilic substitution for pentavalent phosphorus proceeds with inversion of configuration via the backside mechanism (Kolodiazhnyi and Kolodiazhna, 2017). However, echothiophate, one of the most popular OP models with a nonchiral phosphorus atom, has the same thiocholine-leaving group as thioster substrates (acetyl/butyryl-thiocholine) (Fig. 72.6C). In enzyme−substrate complexes, the thiocholine moiety is bound to the cation-binding pocket formed by W82 and E197. For echothiophate, such a position for the leaving group leads to a sideway attack and inhibition reaction according to mechanism Fig. 72.4B.

The mechanism with a leaving group in the apical position from serine was elaborated by Kovach and her coworkers (Kovach, 1988, 2004; Qian and Kovach, 1993; Kovach et al., 1997), similar schemes are presented in Beck and Hadad (2010), Field and Wymore (2014), and Bennion et al. (2015). Docking of VX into AChE showed that the leaving group is opposite to the catalytic serine, while it is in side orientation in BChE (Bennion et al.,

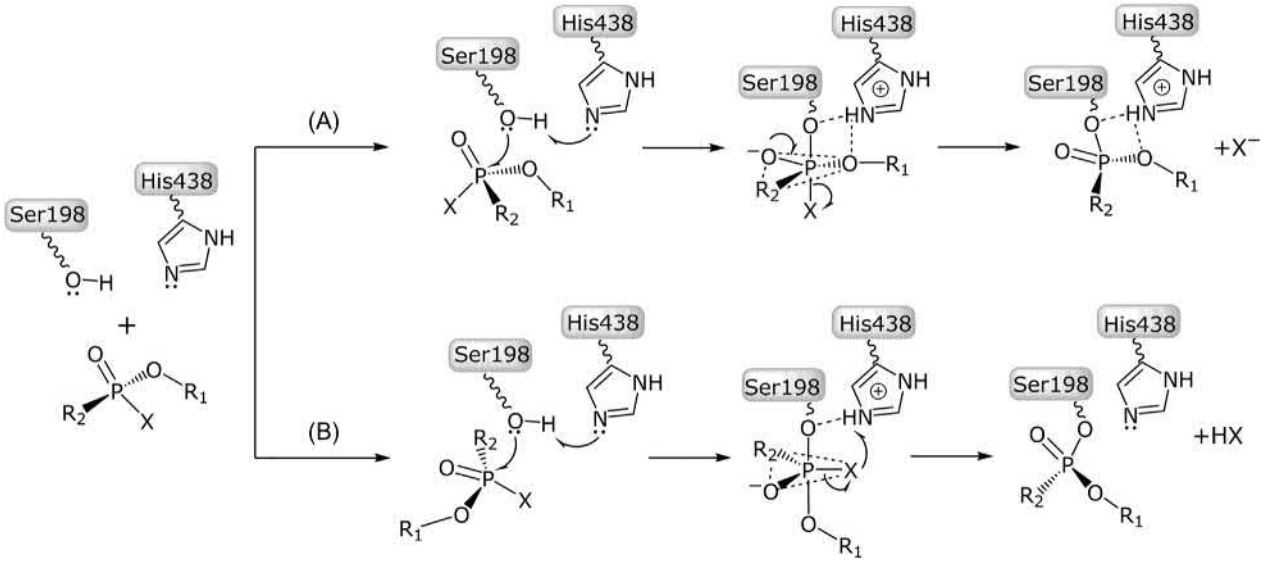

FIGURE 72.5 Mechanism of ChE inhibition by OPs. (A) Binding of inhibitor with its leaving group opposite to the catalytic serine leads to protonated histidine in phosphylated adduct. (B) Binding of inhibitor with the leaving group aside from catalytic serine and histidine suggests that histidine may be deprotonated after departure of protonated leaving group.

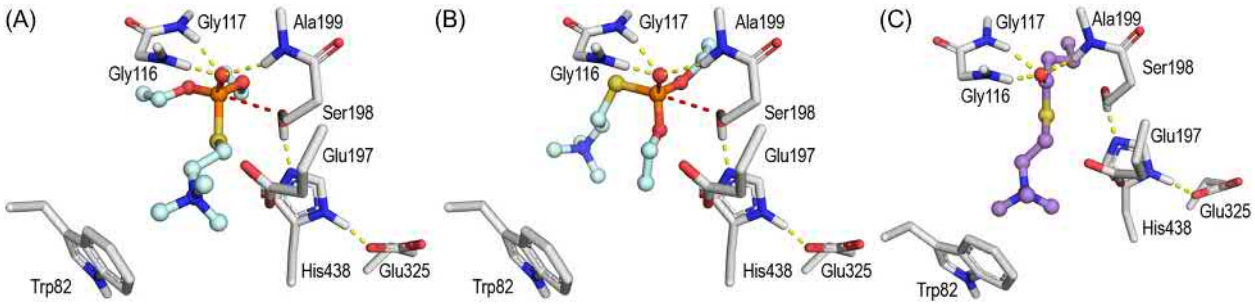

FIGURE 72.6 Possible positions of echothiopate in BChE active site in enzyme inhibitor complex for: (A) backside nucleophilic attack, and (B) side attack. (C) Enzyme−substrate complex BChE/butyrylthiocholine.

2013). This suggests a mechanism backside nucleophilic attack for AChE and a side attack for BChE. Detailed reaction schemes of AChE phosphorylation (Liu et al., 2009; Quinn et al., 2017) specifically show the leaving group in protonated form and histidine deprotonated, implying the side position of the leaving group.

Recent computational studies (Zlobin et al., 2018a,b; Grigorenko et al., 2019) directly compared these two mechanisms, taking into account the different OP conformations. These studies indicate that the leaving group is in an apical position outside the cation-binding site, an orientation different from substrate in the active center, and more favorable for inhibition reaction. This is consistent with inversion of the configuration of the phosphorus chiral center for reaction of BChE as observed with optically pure VX enantiomers (Wandhammer et al., 2011) and with early observations about reactions of OPs with AChE (Ashani et al., 1973). This establishes that in inhibited enzyme catalytic histidine is protonated, and hence cannot activate water for a dephosphylation/delakylation reaction, but rather orients this water molecule, unless a proton transfer events take place.

72.6.3.2 Proton transfer wires

The protonated state of the catalytic histidine in phosphorylated conjugate suggests that the noncatalytic glutamic acid is the nucleophilic pole, activating a water molecule for spontaneous reactivation or aging reactions. This statement is supported by the fact that mutation of E197 into D, Q, or G considerably reduces the rate of aging (Masson et al., 2008). However, another point of view that E197 (E199 in *Tc*AChE, E202 in hAChE) is protonated has been persistent in the literature since the X-ray structure of *T. californica* AChE was solved (Soreq et al., 1992). E197 is coupled with E441 through bridging of a water molecule. Lack of proton between E197 and E441 may lead to artifacts in modeling due to electrostatic repulsion between two negatively charged amino acids and unsaturated hydrogen bonding. In MD simulations of di-isopropyl-phosphorylated BChE, E441 was considered protonated (Masson et al., 1997), some further MD simulations of BChE and its mutants followed this approach (Sun et al., 2001; Suarez and Field, 2005). EVB modeling of the catalytic reaction in G117H BChE mutant (Amitay and Shurki, 2009) suggested that protonation of E197 reduces the reaction energy barrier. It was observed that AChE in MD simulations is more stable when one or two of these residues are protonated (Wiesner et al., 2010). Detailed QM/MM study of the protonation state of E202 during oxime-mediated reactivation of VX-inhibited ACHE was published recently (Driant et al., 2017); referring to this work further studies mention the unusually high pK_a of E197 in human BChE (Rosenberry et al., 2017) and E202 in human AChE (de Koning et al., 2017; Rosenberry et al., 2017). Later, the possibility of protonated E197 was rediscovered in an MD study of the tacrine−BChE complex (Wan et al., 2018).

QM/MM calculations of proton transfer processes in diethylphosphorylated BChE showed that protonated catalytic histidine may transfer its proton to E197 through a chain of water molecules. Proton may be transferred from E197 to E441 and back, through bridging water molecule, depending on the charge distribution in the active site (Lushchekina and Masson, 2018) (Fig. 72.7). Hence, both H438 and E197 may serve as a general base activating and orienting water molecules for reactivation and aging reactions.

72.6.3.3 Mechanism of aging

Possible mechanisms of aging (Fig. 72.1, step 4) of soman-aged ChEs were actively debated before resolution of the X-ray structure of AChE (Kovach, 1988), shortly after (Kovach et al., 1993), and in the following years, with new crystallographic and kinetic data for various mutants (Shafferman et al., 1996, 1997; Kovach et al., 1997; Viragh et al., 1997; Saxena et al., 1998a,b). Later, when the X-ray structures of aged and nonaged forms of soman-inhibited *Tc*AChE were obtained, the aging mechanism was clarified (Sanson et al., 2009), and QM/MM modeling of this reaction was performed (Sirin et al.,

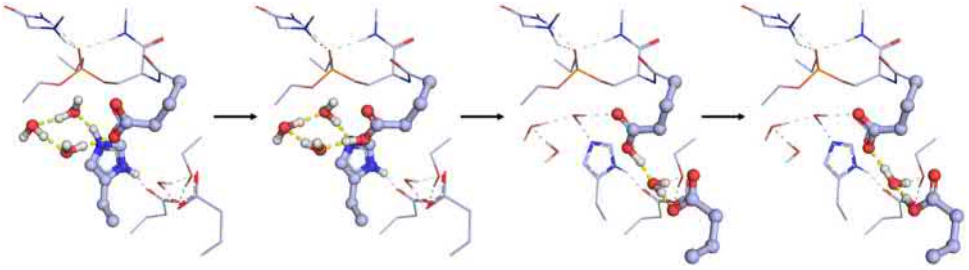

FIGURE 72.7 Concerted proton transfer from protonated H438 to E197 through surrounding water molecules and to E441 through bridging water molecule.

2012). Markedly, it was found that this reaction is favorable when E199 is protonated. Generally, aging of soman-inhibited AChE is thought to occur through formation of planar pinacolyl carbenium ion, which undergoes rearrangement into a mixture of 2,3-dimethyl-2-butanol, 2,3-dimethyl-1-butene, and 2,3-dimethyl-2-butene.

Something rather different was observed in the X-ray structure of echothiophate-inhibited human BChE (Nachon et al., 2005a,b). The resolved water molecule is able to form hydrogen bonds with H438 and E197. Assuming H438 protonated, the water molecule is activated by E197, and vice versa. After formation of penta-coordinated intermediate aging is induced via breaking either a C−O bond or a P−O bond (Fig. 72.8). Mass-spectrometry analysis of BChE aged after phosphorylation by echothiophate in the presence of H_2O^{18}, suggested that aging proceeds through C−O bond cleavage for different OPs (Li et al., 2007).

72.6.3.4 Spontaneous reactivation

There are numbers of crystallographic and theoretical studies on oxime-assisted reactivation (Fig. 72.1, step 3), while studies of spontaneous reactivation of phosphylated ChEs are few. For most OP adducts, self-reactivation is much slower than aging, or it cannot be recorded experimentally. However, molecular modeling can be used to force a system through an energetically unfavorable pathway to examine the possible reaction mechanism. Such an approach allows comparison of energy barriers for wild-type enzymes and suggests mutations for designing novel ChE-based catalytic bioscavengers.

Suggested aging mechanisms through P−O bond cleavage can also be applied for spontaneous reactivation mechanisms with PI dissociation through proton transfer from H438 to S198 oxygen atom (Fig. 72.8).

The X-ray structure of the G117H BChE mutant was published in 2011 (Nachon et al., 2011). Four possible mechanisms for the role of H117 in self-reactivation were discussed according to crystallographic data. Activation of a water molecule by H117 was a dominating idea, but the X-ray structure revealed that there is not enough room for water molecules to approach the phosphorus atom from the side of H117. It was concluded that the role of H117 in catalytic reactivation is mostly to cause geometric disturbance in the oxyanion hole and phosphoryl adduct. In computational studies of the spontaneous reactivation mechanism for diethylphosphorylated G117H BChE mutant, discussed below, energy profiles for the same reaction in wild-type were computed, with either protonated H438 (Kulakova et al., 2015; Masson and Lushchekina, 2016; Nemukhin et al., 2016) (Fig. 72.8A) or not protonated (Yao et al., 2012) (Fig. 72.8B).

One of the emerging questions is the fate of the proton from the water molecule attached to the phosphorus atoms. Usually, in simulations of the reactivation reaction, it is left in hydroxyl group form. However, the product of diethylphosphorylated ChE reactivation is diethyl phosphoric acid with $pK_a = 1.39$ (Kumler and Eiler, 1943); and the product of reactivation of VX-inhibited ChE is ethyl methylphosphonate, $pK_a = 2.16$ (Richardson et al., 2006). Therefore, this proton has to be transferred either to catalytic histidine, or to a water molecule, forming a hydronium ion. For comparison, the mechanism of OP hydrolysis by bacterial PTE, discussed above, includes proton transfer to one of the vicinal residues upon hydrolysis product formation (Bigley and Raushel, 2019).

72.6.3.5 New routes of reactivation

Activation of the water molecule by H438 or E197 present in native BChE is only one of the possible directions of nucleophilic attack of the water molecule on the phosphorus atom. Other directions have been discussed in a recent work (Lushchekina et al., 2018). Residues L286, F329, F398, and W231 surrounding phosphylated serine (Fig. 72.4) are perspective places for replacement with a nucleophilic pole, for example, histidine. The histidine pK_a value is higher than the pK_a of aspartic and glutamic acids. Therefore, histidine can be protonated more easily, while those carboxy-acids remain options. This creates new directions for attack of a water molecule from three other sides (Fig. 72.9).

Direction A, adjacent to the serine residue, corresponds to the above-discussed mechanisms of aging and reactivation in wild-type and G117H BChE. Direction B from the apical position (opposite to the serine residue) can be realized with certain geometrical strains through

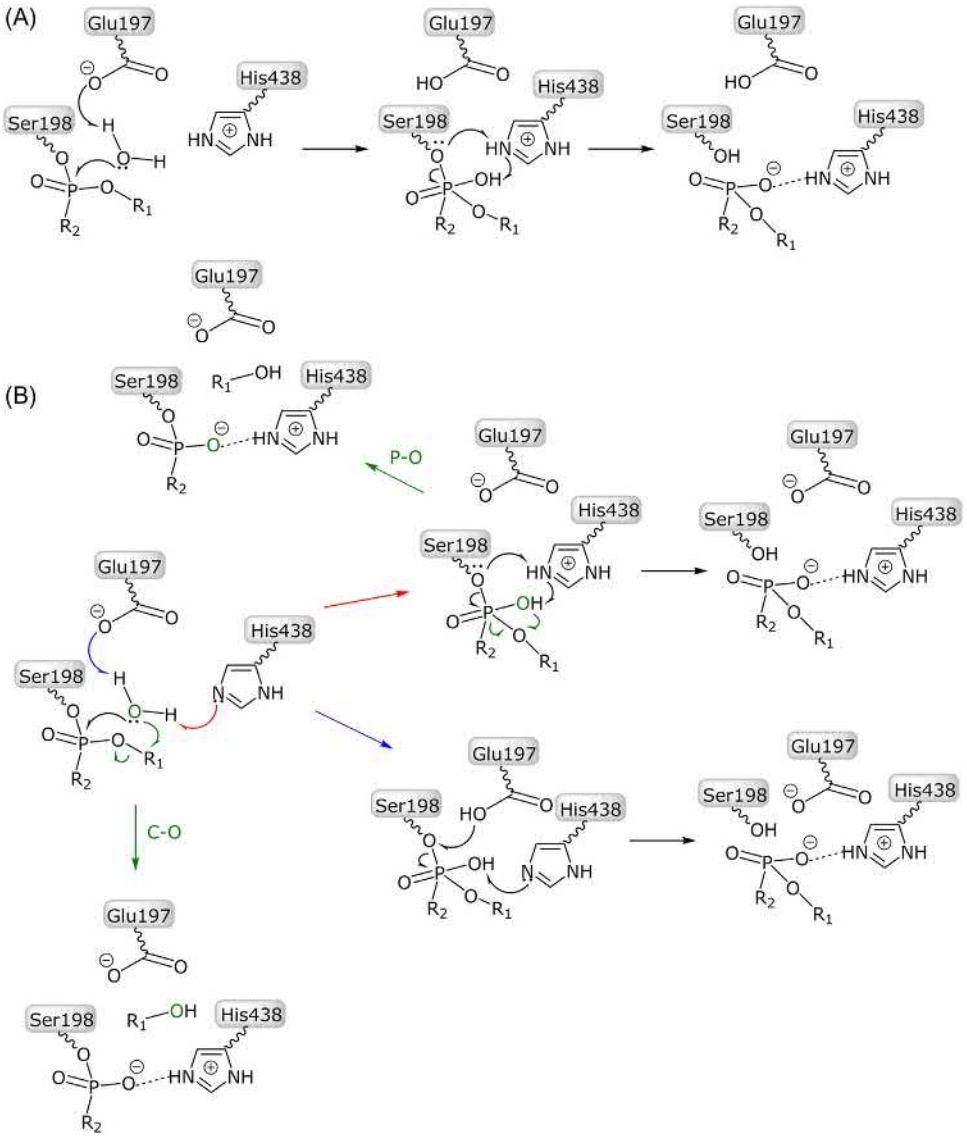

FIGURE 72.8 Possible mechanisms of spontaneous reactivation and aging: (A) with protonated catalytic histidine; (B) with nonprotonated histidine, red arrow—catalytic histidine activates water molecule, blue arrow—not catalytic glutamic acid activates the water molecule and transfers proton to release catalytic serine. Green arrows show aging mechanisms through P−O and C−O bond cleavage. Green oxygen atom shows position of O^{18} for the two pathways, studied by NMR in Li et al. (2007).

introduction of a histidine into position 286 of the acyl-binding loop. In the resulting PI, protonated H286 would form a hydrogen bond with an oxy-ethyl group from the diethylphosphate, suggesting strong competition between reactivation and aging processes. Direction C can be realized by introducing a histidine in position 398 and/or 329. Direction D can be achieved by replacement of W231, but might be ineffective alone due to poor accessibility for the water molecule.

Mutation L286H resulted in reactivation at a low rate ($k_3 \sim 0.0032\ \text{min}^{-1}$) (Schopfer et al., 2004; Lushchekina et al., 2018). QM/MM calculations show that the energy barrier for this mutant is slightly lower than that for G117H, but the PI is unstable because W231 hinders the shift of the diethylphosphate oxy-ethyl group in the trigonal bipyramid plane (Fig. 72.9). Replacement of the neighboring rigid P285 with a more flexible residue improves the orientation of H286. Also, QM/MM calculations show that the energy barrier for the aging reaction in this case is very close to reactivation (Lushchekina et al., 2018). More mutations in the acyl-binding loop generated by the combinatorial approach (Terekhov et al., 2017) slightly improved the rate of self-reactivation ($k_3 \sim 0.006\ \text{min}^{-1}$), but calculated energy levels for the reaction pathway show that the intermediate remains unstable (Zlobin et al., 2018a,b).

For comparison, self-reactivating bovine BChE (Dafferner et al., 2017) and swine BChE (Brazzolotto et al., 2015; Nachon et al., 2019) carrying mutations in the acyl-binding loop, but not a new nucleophile pole, have higher rates of reactivation: $k_3 \sim 0.023\ \text{min}^{-1}$ for bovine BChE with chlorpyrifos oxon (the same

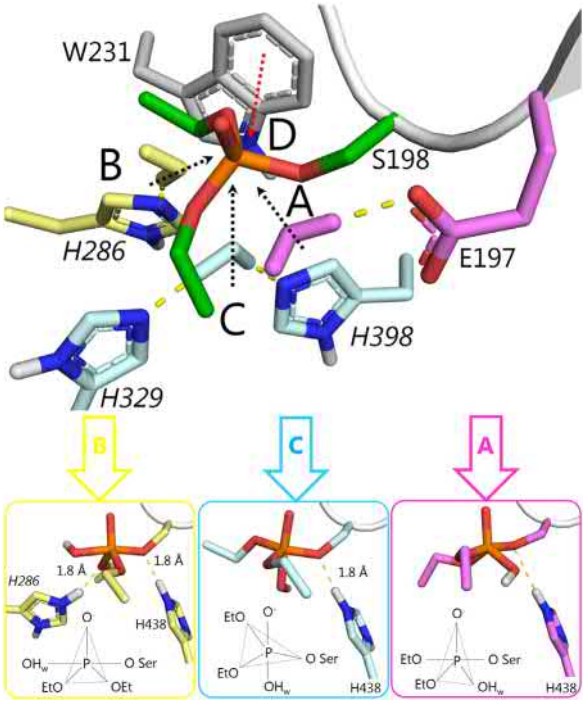

FIGURE 72.9 Possible directions for nucleophilic attack of a water molecule on the phosphorus atom of diethylphosphorylated serine with corresponding configurations of the resulting PI. 2D schemes indicate vertices of trigonal bipyramids. Carbon atoms of the activating histidines and water molecules are colored according to the direction of the attack: direction A, magenta; direction B, yellow, direction C, blue.

phosphylated adduct as for echothiophate) (Dafferner et al., 2017). For swine BChE, only reaction rates with VX have been reported so far (Brazzolotto et al., 2015).

Thus, introduction of a nucleophilic pole in the acyl-binding loop has certain drawbacks: low stability of resulting PI with geometry favorable not only for reactivation, but also for the competing aging reaction.

Another option for nucleophilic attack by a water molecule is direction C (Fig. 72.9). This construct results in PI configuration unfavorable for aging. In this scenario, a pair of mutations, F329H and F398H, suppresses the hydrophobic pocket, creates enough space for a water molecule, and orients the water molecule in a proper position to facilitate hydrolysis of the diethylphospho-adduct. Introduction of two histidines also helps to solve the above-mentioned problem of proton transfer from the PI hydroxyl-group during its dissociation. On other hand, saturation of the active site with histidine residues may result in binding of metal divalent cations, affecting the desired catalytic properties.

Further improvement in the efficiency of nucleophilic attack could be achieved by introduction of amino acids that facilitate protonation of the histidine during activation of the water molecule. This would stabilize the resulting intermediate. Pairs like Glu-Ser, Asp-Ser hydrogen-bonded with histidine mimic the catalytic triad. The role of an acidic residue in such a system is to stabilize the orientation and protonation state of the introduced histidine, increase its pK_a, and cause charge stabilization of an ion pair between the imidazolium cation and the negatively charged PI. Addition of a polar residue like Ser, Thr, Gln, and Asn aims at an additional stabilization of the hydrogen-bonded chain. QM/MM calculations support that such approach is perspective (Lushchekina et al., 2018). However, for that result, multiple mutations are required, what may significantly impair protein stability and lead to partial or complete unfolding. There are reported cases when point mutations led to complete loss of activity (Delacour et al., 2014a,b) due to rearrangement of the hydrogen-bonding network and/or changes in protein dynamics. Changes in the hydrogen-bonding network outside the active side of BChE could reduce conformational stability, but maintain catalytic activity (Grigorenko et al., 2019). This can lead to unexpected catalytic complexities such as slow establishment of steady state (Legler et al., 2014), allosteric effects, and changes in inhibitor sensitivity (Larrimore et al., 2017). Computationally, MD methods, supported by new methods of analysis like principal component analysis and Markov chain models help to explore such issues before making functional expression of proposed mutants.

To summarize, the main approaches to create new BChE-based catalytic bioscavengers are: (1) identification of a geometrically favorable position for a new nucleophile and direction of attack by this nucleophile on the adduct phosphorus; (2) introduction of additional mutations for charge stabilization of intermediates and products; (3) suppression of the competing aging reaction by proper choice of nucleophilic attack direction; and (4) maintenance of overall enzyme stability. The effects of mutations on both the stability and catalytic activity of mutants may be assessed by computational methods: energetic aspects by QM/MM methods, structural and dynamical aspects by MD simulations. However, folding problems that may occur during protein biosynthesis and glycosylation remains an issue to be addressed experimentally after expression.

Then enzyme mutagenesis and expression of computer-designed mutants may lead to new generation of BChE mutants capable of hydrolyzing OPs at high rate. Directed evolution of ChEs could be an alternative to computer-based methods. However, functional expression of ChEs is difficult in yeast, and heavy engineering for bacterial functional expression may lead to misfolded enzymes, thus impairing the desired functionalities of novel ChE mutants.

Bioavailability and biological stability of mutated ChEs for injection is an important issue. The first pharmacokinetic studies of highly purified human BChE injected

to the rat showed that the half-time ($t_{1/2}$) of the enzyme in the bloodstream depends on sialylation of the carbohydrate chains (Douchet et al., 1982). It is well known that rapid elimination of asialoglycoproteins from the circulation is due to their capture by specific receptors located on the surface of hepatocytes. These receptors recognize galactosyl residue, the carbohydrate that precedes sialic acid at the terminus of complex glycans. Studies with other natural and recombinant ChEs confirmed the importance of sialic acid (*N*-acetylneuraminic acid) residues ending glycans (Kronman et al., 1995, 2007; Saxena et al., 1998a,b; Cohen et al., 2007). It was found that $t_{1/2}$ is inversely proportional to the number of unoccupied attachment sites of sialic acid (Kronman et al., 2000). To increase the $t_{1/2}$ of administered recombinant ChEs, all galactosyl residues have to be sialylated. Full sialylation of recombinant enzymes can be achieved using an expression system capable of synthesizing glycans similar to natural human glycoprotein glycans and adding inhibitors of sialidase in the cell culture medium. Coexpression of the enzyme of interest and sialyltransferase in HEK 293 cells was found to lead to fully sialylated recombinant human AChE (Kronman et al., 2000). Alternatively, in vitro sialylation of purified enzymes is possible with a sialyltransferase or using a chemical method (Gregoriadis et al., 1999) and even by cross-linking polysialic acid chains (Ilyushin et al., 2013; Meng et al., 2018). PEGylation has also been proven to be an effective chemical modification for increasing the circulatory half-life of administered recombinant ChE (Cohen et al., 2007; Kronman et al., 2007; Huang et al., 2008). A 150 kDa recombinant fusion protein of human albumin−human BChE showed substantially improved pharmacokinetics when administered to juvenile pigs, $t_{1/2} \approx 32$ h against ≈ 3 h for recombinant 70%-tetrameric BChE (Huang et al., 2008).

Engineering of carboxylesterases to make enzymes capable of hydrolyzing NAs has made progress. In fact, the discovery of a blowfly (*Lucilia cuprina*) resistant to OPs because it carries a mutated carboxylesterase (CaE; LcαE7), G137D, at a position homologous to G117, stimulated research on G117H-based mutants of BChE. Though the OPH activity of the G137D is low, it is balanced by the abundance of the enzyme in the insect organs (Newcomb et al., 1997). The 3D structure of this enzyme was recently solved (Jackson et al., 2013). Knowledge of this structure is a good starting point for engineering of mutants of LcαE7 with improved catalytic activity against OPs. Another interesting CaE is the human CaE1. The 3D structure of human CaE1−NA conjugates (with soman, tabun, sarin, and cyclosarin) was solved (Bencharit et al., 2003; Hemmert et al., 2010). The enzyme was shown to reactivate spontaneously after phosphonylation by the most toxic P_s stereoisomer of sarin (Hemmert et al., 2010). These results guided the computer-modeling design of the first CaE1 mutants displaying OPH activity against soman and cyclosarin (Table 72.1), and enhanced the rate of spontaneous dephosphonylation following sarin inhibition (Hemmert et al., 2011). Thus, CaEs can be reasonably considered as novel catalytic bioscavenger candidates.

72.7 Concluding remarks and future directions

Identified enzymes that neutralize or degrade OPs can be purified from natural sources, for example, human plasma. Recombinant enzymes can be produced using prokaryotic expression systems (*E. coli*), eukaryotic expression systems (yeast, insect, mammalian cell cultures), transgenic animals (worm, rabbit, goat), or transgenic plants (tomato, potato, tobacco, horseradish), and also acellular biosynthetic systems. The goal of current research in protein engineering is to improve mass production of stable and effective muteins at low cost. Regarding OPHs, improvement of in vitro and in vivo catalytic properties toward NAs and pesticides is still the main issue. In addition, improvement of thermodynamic stability (storage stability in solution or in dry forms) and in vivo operational stability, improvement of immunotolerance and bioavailability are other goals. For this purpose, the different strategies of enzyme engineering have been implemented. They consist of research into new natural enzymes, in particular in collections of bacterial strains (Otto et al., 2013) and in extreme environments (Ferrer et al., 2007) or identification of such enzymes from genomic sequences of extremophiles, followed by expression of the synthetic gene in a mesophilic bacterial host, characterization of catalytic properties, and X-ray structure determination (Hiblot et al., 2013a,b). Potential extremozymes, PLL and PROL, have been discovered in halophilic, hyperthermophilic, piezophilic, radioresistant bacteria and archaeas. Research into potential enzymes by computational structure mining in the PDB database is also promising (Jacob et al., 2016). Other enzymes of interest are in insects resistant to OP pesticides, and among secondary targets of OPs in human. Site-directed mutagenesis and directed evolution approaches in combination with chemical modifications and medium manipulations have been used with success to improve the desired properties, in particular stereo-selectivity, high k_{cat}/K_m, and broad spectrum of activity of PTEs (Bershtein and Tawfik, 2008; Goldsmith et al., 2012; Bigley et al., 2013). Computational redesign (molecular modeling and transition state simulations) of known enzymes is another promising strategy. It has already been successfully implemented: the active site of mouse

adenosine deaminase, a zinc enzyme, was redesigned for hydrolysis of OPs. After maturation using directed evolution, the novel enzyme displayed a k_{cat}/K_m activity greater than 10^7-fold the activity of the wild-type enzyme against R_p model OP (Khare et al., 2012). Lastly, pharmacokinetics, toxicokinetics, and immunological studies on animal models are needed to validate the different enzymes of interest.

Catalytic bioscavengers will be part of the arsenal of medical countermeasures for prophylaxis and postexposure treatments of OP poisoning in the very near future. Multiple enzyme associations (enzyme cocktails) will extend the activity spectrum of injected catalytic bioscavengers as well as the efficacy of active components in TSPs, chemical protective clothing suits, and decontamination tools.

Next, gene therapy will offer the possibility of transitory production of human or humanized OP-degrading enzymes in the body. However, the road to gene therapy is still long. In regard to ethical issues, further works are needed to engineer safe vectors that do not produce toxic viral proteins and/or induce immune response. The CRISPR/Cas9 technology offers new possibilities for the development of this approach under safe conditions (Lino et al., 2018; Li et al., 2019).

Chapter 73

Rapid decontamination of chemical warfare agents from skin

Edward D. Clarkson[1] and Richard K. Gordon[2,*]

[1]Medical Toxicology Branch, Analytical Toxicology Division, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Grounds - Edgewood Area, MD, United States, [2]US Army Medical Research and Material Command, Ft. Detrick, MD, United States

Abbreviations

AChE	acetylcholinesterase
BChE	butyrylcholinesterase
CWA	chemical warfare agent
DS2	decontamination solution 2
FDA	Food and Drug Administration
GA	tabun, ethyl *N,N*-dimethyl-phosphoramidocyanidate
GB	sarin, isoproppyl-methylphosphonofluroidate
GD	soman, 1,2,2-trimethylpropyl methylphosphonofluoridate
H	impure mustard
HD	distilled sulfur mustard
HTH	high test hypochlorite
L	lewisite
LD_{50}	median lethal dose
RBC	red blood cell
RSDL	Reactive Skin Decontamination Lotion
VX	*o*-ethyl S-[2-(diisopropylamino)ethyl] methylphosphonothiolate

73.1 Background: the nature of human skin

Human skin, the largest organ in man, developed as a physical barrier to the environment (keeping things out); on the other hand, it also maintains the aqueous nature of the human body (keeping things in). Mammalian skin consists of three major layers: stratum corneum, epidermis, and dermis. The stratum corneum, the thin outer layer of keratin-filled dead cells (corneocytes) bounded by densely cross-linked protein and embedded in crystalline lamellar lipids, represents the major barrier protecting the body from loss of internal components and entry of undesirable external materials. The epidermis, the layer underneath the stratum corneum, contains cells that change from viable keratinocytes to corneocytes (which are anucleated cells without cytoplasmic organelles) as they migrate from the dermis to the stratum corneum. It also contains a large number of specialized dendritic cells. Smaller amounts of specialized cells are integral to the epidermis, including the pigmentation melanocytes, the immunological Langerhans cells, and the sensory Merkel cells. Throughout the epidermis sebaceous glands, sweat glands, and hair can be found. The next inward layer, the dermis, contains hair follicles with associated sebaceous glands, ecrine sweat glands and ducts, dendritic cells, and a vascular network including subepidermal capillaries, vascular plexi associated with the sweat glands, and dermal papillae associated with the hair follicles. Capillaries are responsible for transporting any chemicals that enter the skin systemically. Recent reviews of the skin structure and permeation are available (Menon, 2002; Hadgraft and Lane, 2005; Godin and Touitou, 2007; Wester and Maibach, 2000).

The stratum corneum, composed of keratinized dead cells that are continually being replaced, is the first major barrier to chemical agents. The barrier qualities of the stratum corneum depend on a number of factors, including its location on the body, which affects thickness and how much hair is present. Thus, hair follicles and sweat glands can either provide channels through the stratum corneum, and thereby bypass its barrier attributes, or at least provide increased surface area for penetration of compounds, since a number of compounds were shown to penetrate faster in hair follicle-rich areas (Illel et al., 1991). Maibach studied three radiolabeled pesticides, parathion, malathion, and carbaryl, for their permeability

* Published posthumously.

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00073-8

at 13 different anatomical sites in humans (Maibach et al., 1971). Variations in percutaneous penetration were observed; higher penetration of the pesticides occurred at the abdomen and dorsum of the hand.

Because it is often difficult to determine which specific nerve agent was used, most poisoning from pesticides or chemical warfare agents will initially be treated in a general supportive manner and not by administering a specific antidote. Thus decontamination is the most important early intervention (Simpson and Schuman, 2002). Although Maibach et al. (1971) present relatively recent human in vivo studies, most testing of decontamination products is performed either in vivo with animal models (Braue et al., 2011a, b; Clarkson et al., 2012) or in vitro using human skin samples (Mircioiu et al., 2013).

The lipid matrix is another feature important for the barrier function in the epidermis. The arrangement of lamellar-like sheets yields a barrier to hydrophilic compounds and transcutaneous water transport. Extraction of those lipids from skin with organic solvents reduces barrier function (Hadgraft, 2001). The lamellae, which have little phospholipids as they are catabolized, ultimately contain mainly ceramides, cholesterol, and fatty acids (Wertz and Downing, 1989; Bouwstra and Ponec, 2006). The resulting matrix is composed of nonpolar compounds enriched in cholesterol that are adapted to protect the dermis from water loss. While extraction of these lipids may increase the penetration of aqueous moieties, in the case of organophosphates (note the organic-like nature of the chemical warfare agents, as described below), the hydrophobic nature of skin likely facilitates partition of these chemical agents through the lipid matrix, which then enter the subepidermal capillaries for dissemination throughout the body. Further insight into the barrier properties of skin can be observed in disease states including psoriasis, where an increase in epidermal cell replication yields an irregularly stacked stratum corneum and abnormal capillaries in the dermis. This leads to an increase in drug penetration, such as hydrocortisone (Kranz et al., 1977). No studies have evaluated pesticide or chemical warfare agent penetration in psoriasis.

Aging contributes to decreased lipid barrier protection, decreased intercellular cohesion, and increased absorption of toxic material. This barrier is also complicated by environmental effects such as exposure to sun, disease, and other aging processes that include many changes to the structure of the skin. Examples of such changes are decreased amounts of collagen, loss of melanocytes, decreased number of glands and hair follicles, reduced blood flow (Yates and Hiley, 1979), and the loss of lipid content in the stratum corneum (Elias and Ghadially, 2002). Another study found that 11 of 14 pesticides showed different rates of skin penetration in aged rats compared to young rats (Shah et al., 1987). Generally, decreased absorption occurred in studies of aged skin (Fisher et al., 1992; Farage et al., 2007).

Percutaneous absorption in vivo leads to the delivery of the chemical or drug to the microcirculation in the dermis. The period of time that it takes for entrance to the blood supply and circulation throughout the body depends on the diffusion parameters and the interaction with the lipid matrix (Roberts, 1997). Thus, chemicals exhibiting a longer lag time through the skin should be less toxic if quickly removed compared to rapidly penetrating compounds. Another aspect of percutaneous absorption is the number of exposures to the chemical. Some chemicals, such as azone (1-dodecylazacylohepan-2-one), alter the organization of the skin so that an increase in absorption or a synergistic effect is observed with each exposure (Ademola et al., 1993). Chemicals that do not alter the skin's structure would not be likely to increase their bioavailability and absorption, but rather provide an additive response (Bucks et al., 1985).

73.2 Background: nerve agents

Nerve agents are among the most toxic of the known chemical agents. Nerve agents are organophosphates that bind irreversibly to acetylcholinesterase (AChE) (Taylor et al., 1999) and to the bioscavenger butyrylcholinesterase (BChE) (Wolfe et al., 1992) in both the peripheral and central nervous systems. AChE is responsible for terminating the action of the neurotransmitter acetylcholine by hydrolysis. Organophosphate-inhibited AChE results in an excess of acetylcholine and the overstimulation of muscarinic and nicotinic receptors. Characteristic signs of nerve agent poisoning and cholinergic overload include hypersecretion and respiratory distress. When the nerve agent is transported past the blood−brain barrier, convulsions can lead to coma and death. Organophosphates pose a hazard in both their vapor and liquid states. Notably, AChE inhibitors are used not only as a therapy for treating glaucoma, myasthenia gravis, Alzheimer's disease, and atropine poisoning, but also in potentially hazardous ways as pesticides to kill insects and as chemical warfare agents by terrorists and in warfare to kill humans (Sidell, 1997; Leikin et al., 2002; Martin and Lobert, 2003). The use of nerve agents by the Syrian military in 2013 demonstrates that large numbers of fatalities are not only possible but probable when unprepared civilian populations are attacked (Chai et al., 2017).

The nerve agents include the G-type agents GA (tabun, ethyl *N,N*-dimethyl-phosphoramidocyanidate), GB (sarin, isoproppyl-methylphosphonofluroidate), and GD (soman, 1,2,2-trimethylpropyl methylphosphonofluoridate), and V-type agents such as VX (*o*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothiolate). The V-type nerve agents are several orders of magnitude less

volatile than the G-type agents and act primarily as a liquid via the percutaneous route; for example, VX is several orders of magnitude more lethal percutaneously than GB (Reutter, 1999; Braue et al., 2011a) or GD (Clarkson et al., 2012; Braue et al., 2011b).

Log *P* data (octanol:water partition coefficients and a reflection of lipid solubility) of nerve agents were used to both predict absorption through the skin and determine the distribution of organophosphate compounds in tissues, and were then correlated with toxicity as measured by the onset time of fasciculation in guinea pigs. An excellent correlation ($r = 0.95$) was established between the measured log *P* value and the time local fasciculations were visually observed (Czerwinski et al., 2006). The authors suggest the log *P* data can be used to estimate absorption in the skin, penetration to blood, and dissemination to muscle tissue throughout the animal (Czerwinski et al., 2006).

Maxwell and Lenz reported that AChE is more reactive with cationic nerve agents such as VX when compared to neutral agents that contain less than two bulky groups (e.g., GA, GB, and GD) (Maxwell and Lenz, 1992). Investigations by Tammelin revealed that organophosphates containing quaternary choline-like side groups were about 1000 times more reactive with AChE than their tertiary counterparts (Tammelin, 1958). In general, since AChE has a smaller active site than BChE, the size and ionic character of the active sites determine the specificity of these esterases for the agents. The estimated ranked percutaneous nerve agent LD_{50}s are VX > GD > GA > GB, which corresponds to their volatility. The ranked volatility for these agents is VX < GA < GD < GB.

Using parathion as a model simulant for the nerve agent VX, the in vitro percutaneous absorption through unprotected human skin and clothed and uniformed skin was determined. The percent parathion dose absorbed through the unprotected skin was significantly greater than that observed through dry uniformed skin, while absorption was higher through the wet (sweat) uniform. These results suggested that military uniforms and clothing worn in public places provide protection to this simulant and by analogy to VX; but absorption through cloth and skin quantitatively occurred more readily with wet clothing than dry. Thus, even with clothing, immediate responses and decontamination of skin and clothing are required (Wester et al., 2000).

In conclusion, because of the extreme toxicity of nerve agents, the search for medical decontamination countermeasures to organophosphates is of paramount importance. Two recent assassination attempts, the successful assassination of Kim Jong-Nam (Chai et al., 2017) and the unsuccessful assassination attempt of Sergei Skripal and his daughter, Yulia (Chai et al., 2018), have increased interest in the study of dermal absorption of nerve agents and demonstrated the need for effective decontamination. Rapid removal from the skin would prevent penetration to the general circulation and the resulting decrements of cholinergic toxicity, which ultimately leads to seizure and/or death in untreated individuals. In the development of medical decontamination countermeasures to nerve agent poisoning, different nerve agent administration routes are acknowledged to likely have different requirements for effective treatment. The window of opportunity for decontamination treatment following agent exposure is limited (Joosen et al., 2017). The signs of poisoning develop within minutes, and if decontamination is delayed, toxic levels of the nerve agents are likely to be disseminated via the bloodstream after the agent has been absorbed. Decontamination will prevent continued absorption of the agent, reducing the need for further medical management (Table 73.1) (Hamilton et al., 2004; Clarkson et al., 2004, 2012).

TABLE 73.1 VX applied to pig skin (ear).

73.3 Background: vesicating agents (distilled sulfur mustard, HD; impure sulfur mustard, H; Lewisite, L)

Sulfur mustard (HD), a synthetic vesicating agent, was a major chemical warfare agent during World War I and continues to be a modern-day threat (Reutter, 1999; Ghanei and Harandi, 2007; Bismuth et al, 2004; Sezigen et al, 2019). Sulfur mustard's simple and cheap chemical synthesis makes it readily accessible to terrorists and for use by the military. Sulfur mustard is an alkylating agent that causes its damage by disrupting nucleic acids and proteins, impairing cell homeostasis and eventually causing cell death, although the significance of the multiple pathways is unclear (Smith et al., 1995). Whole-body exposure results in cutaneous (liquefaction necrosis of the epidermis), respiratory (injury to the laryngeal and tracheobronchial mucosa), and ocular effects (severe conjunctivitis). In contrast to HD agents, there is no delay

with lewisite (L), which produces immediate burning of the skin and eyes. Compared with the G-nerve agents, sulfur mustard has a relatively low acute lethal toxicity; that is, its toxicity as an incapacitating agent is of much greater concern than its capacity to kill. Furthermore, HD is persistent in the soil and other materials for hours to weeks (Devereaux et al., 2002).

The skin is an important port of entry for vesicating agents. The agent's lipophilic nature and the propensity of skin to exclude aqueous compounds but not lipophilic substances make the skin an unwitting transport system. An increase in ambient temperature causes increased penetration (which was used effectively in World War I, where mustard was mostly disseminated at night and warmed in the early morning sun). It has been estimated that 80% of liquid mustard evaporates and 20% penetrates the skin. Of this 20%, 12% is retained in the skin matrix, while 8% is absorbed systemically, so only large dosages of mustard will produce significant systemic toxicities (Cullumbine, 1947; Dacre and Goldman, 1996).

Mustard skin lesions first present as erythema followed by blisters (Somani and Babu, 1989). Erythema usually begins 2–24 h after contact, followed by acute itching, which diminishes as the characteristic blisters appear. Blisters initially appear as small vesicles within the area of erythema 18 h after contamination; these vesicles then coalesce to form the characteristic pendulous blisters containing large volumes of clear but yellow fluid. Blisters are not painful per se, but they may be uncomfortable and may feel tense. Warm, moist areas such as genitalia and axilla are more likely to exhibit bullous lesions. By 48 h postexposure, blistering is clearly evident and a new round of blisters appears. As the skin layer is disrupted, the large blisters break, leading to erosions and full-thickness skin loss (in which subcutaneous fat may be visible but bone, tendon, or muscle are not exposed), and ulceration, necrosis and, 72 h postexposure, formation of an eschar. The eschar sloughs in a 4- to 6-day time period, finally leaving a pigmented scar (Reid et al., 2000, 2007). The burn caused by blister agents is much slower to heal in comparison with a thermal burn, likely because of the multiple mechanisms by which the agent affects biological tissue, as known from World War I and reestablished in Iranian casualties from the Iran–Iraq War. The site of healed mustard burns is hypersensitive to mechanical trauma. In a comparison of cutaneous lesions in 500 mustard-exposed Iranian veterans and 500 unexposed veterans, a correlation was observed between exposure and skin lesions and severe dry skin, hyper- and hypopigmentation, local hair loss, eczema, and chronic urticaria. Histopathological examination of skin biopsies has revealed nonspecific findings, including epidermal atrophy, keratosis, and basal membrane hyperpigmentation (Balali-Mood and Hefanzi, 2006).

73.4 Model systems to measure absorption, removal, and decontamination

73.4.1 Rats

Many different animal models have been used to assess the percutaneous absorption of toxic chemicals. There is little question that while in vivo human studies are best for predicting the absorption of percutaneously applied chemical warfare agents, ethics preclude conducting such studies. Rats have been widely used in the study of skin contamination, wounds, and healing and the efficacy of different decontamination modalities (Wester and Maibach, 2000; Shah et al., 1987; Baynes et al., 1997).

73.4.2 Guinea pigs

While rats are often selected for their availability, low cost, small size, and thorough biological characterization, rats are not the ideal chemical warfare agent model because they contain a high amount of carboxylesterase, a potential hydrolytic enzyme for organophosphates (Sweeney and Maxwell, 2003). Unlike rats, humans have small amounts of this enzyme relative to AChE and BChE. To overcome this limitation, the guinea pig, which exhibits low carboxylesterase, has been developed as a model for chemical warfare agent exposure (Fonnum et al., 1985). Guinea pigs have been evaluated for skin damage from burns and are often used as a wound-healing model for sulfur mustard (Ramos et al., 2008), as well as for skin irritation to toxic industrial chemicals (Kennedy, 2007; Weaver et al., 2003). Guinea pigs have also been used to study absorption of chemical warfare agents through the skin (Dalton et al., 2006; Wormser et al., 2002) and uptake of radioactive sulfur mustard through the skin (Logan et al., 1999), as well as an animal model for evaluating pretreatment regimens to protect against chemical warfare agents (Wetherell et al., 2006) and for assessing cholinesterase activity responses (Haigh et al., 2005) to GD exposure and organophosphate-induced seizures (Harrison et al., 2004).

For evaluating the decontamination of guinea pig skin, Clarkson et al. (2012) sedated and clipped guinea pigs which were then cutaneously exposed to neat nerve agents on their sides. Animals had their fur removed using Oster brand clippers (model: Golden A5) with a #4 blade CryogenX blade instead of being shaved with shaving cream and a razor blade, as previous work showed that shaving caused razor burn and increased the rate and amount of agent absorbed. One minute after the exposure, a sponge wrapped around a pair of forceps was moved across the guinea pig's side; then the forceps were rotated 180 degrees so that the clean surface of the sponge was

pointed at the animal. Three more passes were taken from the rear toward the front. An identical procedure was used when the protocol required an additional second sponge to decontaminate the animal. Similarly, guinea pigs were used for studies on the decontamination of sulfur mustard. In this case, 24 h after neat HD exposure and decontamination, animals were injected with trypan blue and then euthanized. The skin covering the backs of the animals was removed. In addition, skin punches were taken from each of the exposure sites (control, exposed, and decontaminated sites) (Gordon et al., 1999; Gordon and Doctor, 2003).

73.4.3 Swine

Pig skin has long been a valuable model for human skin (Meyer et al., 1978; Riviere and Monteiro-Riviere, 1991) as it expresses a sparse hair covering, epidermis, and an arrangement of dermal collagen and elastic fibers similar to that of human skin. Again, many investigations have used the porcine skin model to study cutaneous toxicology of HD (Gold et al., 1994). Pig skin, because of its similarity to human skin, with respect to hair covering, apocrine sweat glands, and other morphological similarities (Reifenrath et al., 1991), is an attractive model for cutaneous absorption and toxicology studies of organophosphate chemical warfare agents (Hamilton et al., 2004). Cutaneous absorption studies show that pig skin permeability, compared to that of the rat and rabbit, most closely resembles that of human skin (Bartek et al., 1972) with a variety of test agents. Because porcine skin can be easily mounted on static skin diffusion cells and the penetration of radiolabeled agent quantified, this model is currently widely in use (Matar et al., 2019). Therefore the pig is a good model in which to assess the effects of extraneous material or chemicals during the early events of exposure. The downside is that pigs are large animals, are difficult to house, are more costly, and require special cages to maintain them in comparison to rodents. Their size creates a serious caging issue when neat chemical warfare agents are applied to skin, because the animals are required to remain in the chemical fume hood until the agent has off gassed or been neutralized by decontamination. This process can take several days, which creates not only logistical problems but also animal welfare problems since strict guidelines govern how long an animal can be kept in a cage small enough to fit in the hood.

73.5 Decontamination requirements

Medical decontamination requires removal and/or neutralization of chemical warfare agents, which upon penetration of the skin produce vesication or, with organophosphates, enter the systemic circulation and poison cholinesterases. The most important process for the exposed soldier or civilian is to remove the chemical agent from the skin as quickly as possible. The soldier, under harsh conditions, must use the product quickly to minimize transdermal penetration. A decontaminant that inactivates the chemical agent prevents its penetration through the skin and potentially protects a medical worker or buddy from suffering a second-hand exposure.

Another criterion for the decontaminating system and reagents is that it be as universal as possible and protect against the various classes of chemical agents (as well as radiochemicals and biological agents, although the latter compounds are not discussed here). In other words, the soldier has a limited amount of space and weight to carry, and cannot carry multiple decontamination schemes. Furthermore, a soldier is unlikely to be able to determine the type of agent with which he is contaminated in the absence of symptoms.

In addition, proven efficacy of a decontamination product would have to meet Food and Drug Administration (FDA) guidelines and approval, assuring the safety of the product for the soldier. The product should be environmentally safe to use by itself and render the chemical/biological agent environmentally safe, to prevent cross-contamination. Logistics would preclude decontamination products that require freezing or refrigeration, since they would not be available in the field. Last, application of the product needs to be simple so that the soldier can easily use the product under stressful conditions, thereby reducing the probability of failure. Products like the M291 Skin Decontamination Kit (SDK) (see below) are used by simply wiping the contaminated skin and do not require significant training. However, the M291 SDK has some drawbacks, such as a black, irritating dust that must not be allowed to contact the eye. The ideal decontaminating product should be nonirritating and nonallergenic and should not have an offensive odor (as some potential mercapto compounds exhibit) (Shi et al., 2008); otherwise, the product will be hesitantly used.

Methods for decontamination, neutralization, and removal of chemicals, such as organophosphorus and organosulfur compounds, herbicides, and insecticides, are discussed in the literature (Hurst, 1997; Houston and Hendrickson, 2005; Rosenberg, 2005; Baker, 2004). The compositions and devices utilized for medical purposes are markedly different from nonmedical devices; the latter are not compatible with the skin or other sensitive tissues because they can be corrosive, flammable, toxic, difficult to make and store, composed of two-component systems, and limited in their shelf-life. For example, DS2, a standard decontamination agent, is comprised of 70% diethylenetriamine, 28% ethylene glycol monomethyl ether, and 2% NaOH by weight (Modec, 2003). Although DS2 is effective, it is corrosive upon exposure to air. DS2 as well

as any matter resulting from its use is classified and regulated as hazardous material. After an application, the DS2 must stand for 30 min before rinsing the treated area with water. Additionally, DS2 comprises a teratogen. Clearly, this is not a better method for neutralizing, detoxifying, decontaminating, and cleaning personnel exposed to chemical warfare compounds.

73.6 Decontamination schemes

Organophosphorus nerve agents are a serious threat to military and civilian personnel, but not just from exposure during warfare or a terrorist event; with these agents the possibility exists that exposed individuals could cross-contaminate the medical personnel treating them. Several medical decontamination schemes, each exhibiting advantages and disadvantages, are described below. While the ideal candidate does not exist, the final product must be field deployable for the individual—that is, for personal use in a rapid, deployable manner. Simple materials such as bleach and complex products such as organophosphate-degrading immobilized enzymes sponges are described. Inexpensive and readily available household materials were tested for pesticide decontamination of fabric materials over 20 years ago (Easter and DeJonge, 1985). The household products provided only marginal decontamination efficacy.

73.6.1 Classical liquid: sodium hypochlorite (bleach)

Decontamination methods employing hypochlorite formulations have some corrosive and toxic side effects. A Chlorox (hypochlorite) solution is composed of household bleach, which is about 5% sodium hypochlorite. Thus, for a 0.5% solution, bleach is mixed with nine parts water, although even this diluted solution is contraindicated for use in or on a number of anatomical areas including the eye.

Undiluted bleach is not used because it is toxic to the skin and may create more damage than no decontaminant. Hairless guinea pigs were exposed to sulfur mustard in wounds and the surrounding intact skin, and then decontaminated with water, 0.5%, or 2.5% bleach. No significant differences were observed among wounds decontaminated with the three solutions. Unexpectedly, the skin surrounding nondecontaminated (but exposed) control animals showed the least visual pathology. The lesions observed after decontamination might be due to the mechanical flushing of sulfur mustard onto the perilesional skin, by chemical damage of the skin induced by the solution, enhanced penetration of the agent, or interaction of sulfur mustard with the decontaminating solutions (Gold et al., 1994). In a study evaluating decontamination of GB from skin, rabbits that received GB but were not decontaminated were observed to neither convulse nor die. In contrast, when decontaminated with 5% bleach, symptoms and death increased, suggesting that 5% bleach perturbed the protective barrier of the skin or facilitated GB transport through the skin (Kondritzer et al., 1959). Since diluted bleach (0.5%) is a nonirritant to human skin, it is preferred (Racioppi et al., 1994).

In contrast, the effectiveness of diluted bleach has been demonstrated. This study measured the rate of sulfur mustard disappearance from the skin after topical application of the vesicant, which rapidly penetrates the skin because of its hydrophobicity. Three swabbing treatments of undiluted HD-exposed skin with gauze pads soaked in 0.5% hypochlorite caused a 68% reduction in skin HD content and a 64% reduction when hypochlorite was replaced by water (Wormser et al., 2002). The effectiveness of 0.5% hypochlorite with water for decontaminating sulfur mustard on guinea pigs was also evaluated. However, the gauze pads soaked with the bleach contained microgram quantities of HD when water was used but no detectable HD levels when 0.5% bleach was used. Thus, the neutralizing effect of 0.5% bleach occurred after the agent was removed from the skin and away from the lipophilic structures of the skin where the 0.5% hypochlorite could react with and reduce the levels of the agent.

Similar to bleach's oxidative iodine properties, topical povidone-iodine at 15 and 30 min postexposure to sulfur mustard exhibited protective effects. Severity of the dermal parameters, acute inflammation, and dermal necrosis were significantly reduced, and reduced skin damage was observed in areas adjacent to treated sites (Brodsky and Wormser, 2007).

The impact of this work using 0.5% bleach has been significant (Wormser et al., 2002). US Navy warships are equipped to operate in a chemical, biological, or radiological warfare environment where their exterior surfaces may become contaminated while the interior is kept clean. Most of these ships have decontamination facilities accessible from the ship's deck. Thus, in a contaminated environment, patients would be brought to the ship's facilities by personnel wearing protective gear. Next, contaminated clothing would be removed and contaminated skin washed with 0.5% bleach. Because of space considerations this 0.5% bleach solution is made by dissolving High Test Hypochlorite (HTH). HTH is a dangerous corrosive powder that contains a chlorine concentration of 65%−70%. After washing with 0.5% bleach, the patients are rinsed with warm water and monitored to determine if it is safe to bring the decontaminated personnel into the interior of the ship for treatment (National Academy of Sciences, 2004).

73.6.2 Powder decontamination material: M291 SDK (Fig. 73.1)

In the 1990s, the product provided to the US soldier for field use was the M291 SDK. For 15 years, the US military fielded the M291 SDK, but in the late 2000s the US began to replace it with the Reactive Skin Decontamination Lotion (RSDL). However, throughout the world, many decontamination facilities continue to use the M291 SDK, and therefore it is important to discuss it in detail here. In the M291 SDK three main components are incorporated into individual pouches: a fiber pad (six to a pouch), an absorbent activated charcoal, and a reactive resin (Ambergard XE-555). Each component serves a unique purpose. First, the cotton pad provides structural integrity for use on a finger. Second, the carbon incorporated into the pad absorbs organic material such as organophosphates and HD. Third, the ion-exchange resin binds chemical agents and very slowly detoxifies them. The soldier takes the M291 SDK pad and rubs the area that needs to be decontaminated. The goal is to rapidly bind chemical agents still on the surface of the skin and prevent their penetration through the stratum corneum. The M291 SDK is precluded from use in the eye because its particulate nature is irritating, but it can otherwise be used on the face and around wounds. Much of the black powder from the M291 SDK remains on the skin, which has been a deterrent to its use. The presence of the black powder is an indication to the soldier that the area has been decontaminated. However, since ion-exchange resin binds chemical agents and very slowly detoxifies them, for maximum effectiveness it is best to brush off excess black powder as this powder can contain agent that has not been inactivated.

Efficacy of the M291 SDK has been evaluated in a number of animal models for organophosphate poisoning (DO49 Technical Report, 1987). In an early report, rabbit skin was shaved (to mimic human skin without fur) and then the skin exposed to GD and VX for 2 min. Decontamination with the M291 SDK yielded higher LD_{50}s [of more than 10- and 20-fold, respectively (Hobson et al., 1985)], in comparison to control (nondecontaminated) animals. In another study, with rabbits under similar conditions, the penetration of the organophosphate VX was measured by red blood cell AChE inhibition. The M291 SDK increased the amount of VX required to inhibit AChE by 50% (Joiner et al., 1988). Thus, the M291 SDK neutralized and/or removed VX so that less penetrated through the skin to be systemically delivered as indicated by RBC AChE inhibition.

Three recent reports examined the effectiveness of the M291 SDK in treating GD and VX, using an animal model of anesthetized clipped-hair guinea pigs (Braue et al., 2011a,b; Clarkson et al., 2012); the LD_{50}s were determined at 24 h. Clarkson et al. (2012) reported that decontamination with the M291 SDK 1 min after neat (undiluted) exposure to GD increased the LD_{50} from 11.6 to 76.9 mg/kg, yielding a protective ratio of 6.6. Decontamination with the M291 SDK 1 min after neat exposure to VX increased the LD_{50} from 0.10 to 0.87 mg/kg, yielding a protective ratio of 8.7. In contrast, Braue et al. (2011a,b) reported that decontamination with the M291 SDK 2 min after neat exposure to GD increased the LD_{50} from 11.0 to 30.0 mg/kg, yielding a protective ratio of 2.7, and decontamination after neat exposure to VX increased the LD_{50} from 0.13 to 0.14 mg/kg, yielding a protective ratio of 1.1. The untreated LD_{50}s in the studies discussed here were similar, while the difference in protective ratio for GD can be explained by the time difference in decontamination (1 vs 2 min). GD penetrates skin faster, so the additional minute delay can have a significant impact on dissemination of the nerve agent systematically compared to the slower penetrating VX, which is reflected in the decreased protective ratio. The difference in protective ratios for VX is more difficult to explain, as VX does not penetrate to the systemic circulation as rapidly as GD.

The M291 SDK is also efficacious in rabbits against the vesicating agents HD and L. The shaved dorsal skin of rabbits was exposed to neat HD and then decontaminated after 1 min. Vesicant-induced histopathology determined after tissue staining was reduced over 20-fold compared to nondecontaminated control rabbits.

FIGURE 73.1 M291 SDK (www.defenselink.mil).

73.6.3 Liquid decontamination material: Sandia foam (Fig. 73.2)

Sandia National Laboratories decontaminating foam (licensed to Modec Inc., Denver, Colorado) is a solution (MDF-100) composed of two parts: part a is a solution of 6.6% *N,N,N,N′,N′*-penta-methyl,-*N′*-tallow alkyl 1,3-propanamine diammonium, 2.6% tallow pentamethyl propane quaternary ammonium compounds, benzyl-C12-18 alkyl dimethyl, and 1% isopropyl alcohol; part b is a solution of 8% hydrogen peroxide. Mixing the two parts results in a foam-like product which lasts for up to 30 min. The mixture was tested in the guinea pig model, where fur was clipped on the side of the animal 1 day before exposing the skin of the anesthetized animals to neat GD or VX (Lukey et al., 2004; Clarkson et al., 2012). The animals were decontaminated 1 min later with sterile gauze soaked in the combined solution in a defined manner: the contaminated side was wiped across the exposure site in the direction of the shaved fur once and then rotated so that a clean surface of the gauze could be used to wipe the skin for three additional passes. Next, the organophosphate-exposed area was similarly dried with a second piece of gauze. The exposed area was wiped a total of eight times. Twenty-four hours later, survival was determined. Control nondecontaminated animals yielded an LD_{50} of 11.6 mg/kg for GD, while animals decontaminated with the mixture yielded an LD_{50} of 412 mg/kg, a 36-fold protective ratio. For VX, cutaneous neat exposure and decontamination with Sandia foam yielded an LD_{50} of 10.4 mg/kg compared to the control animals' LD_{50} of 0.10 mg/kg, a 104-fold protective ratio.

FIGURE 73.2 Sandia foam.

Despite its efficacy, Sandia foam has a number of drawbacks for field use by the soldier. First, it must be stored as separate components, which would require a rapid, personal, on-site mixing chamber for combining the two solutions. Second, the presence of hydrogen peroxide, a strong oxidizing agent, precludes its use near the eye, and would create much discomfort if used in a wound (Watt et al., 2004). To partially address these concerns, Sandia developed the formulation DF-200, which in part, contains less hydrogen peroxide and surfactant.

73.6.4 Liquid decontamination material: Diphotérine

Diphotérine is a product for chemical spatters on the eye and skin. Prevor Laboratory in France manufactures this odorless, colorless liquid dispensed as an eye wash or skin decontamination spray. It is composed of an aqueous solution to wash many chemical families and pull hydrophilic chemical agents away from the surface of tissues, an amphoteric solution that acts on acids and bases and restores the tissue physiological pH, and a hypertonic solution that stops penetration of corrosive chemicals into tissues. The pH is slightly alkaline (pH 7.2−7.7) and sterile. Although not classified as a medical device in the United States, it is classified as such in Europe, Canada, Australia, and Brazil (www.prevor.com).

Diphotérine's action on more than 600 chemical compounds was reviewed (Hall et al., 2002). These chemicals included acids, alkalis, oxidizing and reducing agents, irritants, lacrimators, solvents, alkylating agents, and radionuclides. In the literature, there is one abstract describing the decontamination of sulfur mustard (Gerasimo et al., 2000). In this report, radiolabeled sulfur mustard was placed on human skin for 5 min in vitro. The skin was then treated with Diphotérine, water and soap, or saline at different time periods after sulfur mustard exposure, and Diphotérine was reported to be significantly better at removing sulfur mustard. No reports could be found in the literature for organophosphate decontamination, although Hall et al. (2002) also state that Diphotérine is suitable for decontamination of organophosphate pesticides.

Evaluation of Diphotérine has occurred mainly in the European workplace, where it has been reported to be nonirritating to normal human eyes or skin. No adverse effects have been observed in ongoing postmarketing surveillance in European industrial facilities (Hall et al., 2009). Diphotérine is nontoxic in guinea pigs and does not sensitize their skin (Mathieu et al., 2007). The product has prevented or decreased the severity of chemical eye/skin burns from 96% sulfuric acid, 100% acrylic acid, 50% acrylamide, solid sodium hydroxide flakes, and

dimethylethylamine; 24 workers in a German metallurgy facility who were exposed to weak or strong acids and bases and obtained immediate Diphotérine decontamination did not require further medical or surgical burn treatment nor did eye/skin burns develop (Nehles et al., 2006). Clearly, Diphotérine's potential is intriguing and needs to be critically evaluated for decontamination and detoxification of chemical warfare agents.

73.6.5 Liquid and sponges: Reactive Skin Decontamination Lotion (Fig. 73.3)

RSDL was developed for cutaneous decontamination of chemical warfare agents. It was developed for topical use by the Defense Research Establishment in Suffield, Canada, with broad-spectrum decontamination properties for chemical agent cutaneous threats. The RSDL solution is composed of 1.25 M potassium 2,3-butanedione monoximate in polyethylene glycol monoethyl ethers of average molecular weight 550 daltons ($MPEG_{550}$) with 10% w/w water (pH 10.6). The pads consist of a sponge-like plastic foam, Opcell, which is lightweight and easy to store. It is used instead of a cotton pad, and the Opcell holds more of the decontaminating solution for spreading on the skin.

The toxicological profile of this formulation was determined by the US military prior to FDA (Food and Drug Administration) clearance (Tonucci et al., 2004). The Army tested the product's safety by conducting skin irritation, sensitization, and photo-irritation studies in more than 300 people. Its effectiveness was also tested by treating animals that had been exposed to chemical agents. On March 28, 2003, the product was approved by the FDA to remove or neutralize chemical warfare agents and T-2 fungal toxin from the skin (but not other biological threat agents or radiological contaminants).

The efficacy of RSDL has been demonstrated. RSDL was selected as the Joint Service (Army, Navy and Air Force) Personnel Decontamination System (JSPDS) in March 2007. It is also an approved medical device for nerve agent decontamination in the EU, Australia, and Canada. The efficacy of RSDL to remove and decontaminate chemical warfare agents was demonstrated in vivo with guinea pigs and in vitro with chick embryos.

The in vitro work by Sawyer et al. (1991) involved primary cultures of chick embryo neurons to test the efficacy of the RSDL. By relating the anticholinesterase activity in these cultures of the organophosphate/RSDL mixture to that of pure organophosphate standards, a sensitive measure of the value of the RSDL in inactivating tabun, sarin, soman, and VX was obtained. Data from experiments with all four nerve agents in this in vitro system correlated well with the in vivo data, and also indicated that the inactivation process was time- and agent-dependent and was related to the ratio of organophosphate to RSDL. The authors showed that RSDL is also effective in decontaminating GD and VX in cutaneously exposed guinea pigs (Table 73.2; Gordon, unpublished observations). The protective ratios reported in Table 73.2 are in agreement with the protective ratios reported by Braue et al. (2011a,b).

The product was also compared to Fuller's earth in a pig model. The potency of the RSDL/sponge was statistically better than Fuller's earth against skin injury induced by sulfur mustard, observed 3 days postexposure. RSDL was more efficient than Fuller's earth in reducing the formation of perinuclear vacuoles and inflammation processes in the epidermis and dermis. The potencies of the RSDL/sponge and Fuller's earth were similar to severe inhibition of plasma cholinesterases induced by VX poisoning. Both systems completely prevented cholinesterase inhibition, which indirectly indicates a prevention of toxic absorption through the skin (Taysse et al., 2007).

FIGURE 73.3 Reactive Skin Decontamination Lotion (RSDL; www.nbcdefence.net).

However, there are some caveats for the use of RSDL. The application of RSDL directly to open wounds impaired wound strength and decreased collagen content in the early phases of wound healing. This may have clinical implications for the treatment and outcomes of chemical casualty combat trauma (Walters et al., 2007). RSDL is also reported to be flammable.

73.6.6 Polyurethane sponge (Fig. 73.4)

At the Walter Reed Army Institute of Research, an enzyme-immobilized polyurethane foam sponge to decontaminate the skin of chemical warfare agents in a wide variety of environmental conditions is being developed (Munnecke, 1979; Wood et al., 1982; Havens and Rase, 1993). A porous polyurethane foam formed in situ from water-miscible hydrophilic urethane prepolymers has been combined with enzymes such as ChEs to produce immobilized enzyme sponges (Gordon et al., 1999; Gordon and Doctor, 2003; Ember, 1997; Medlin, 1998). In this method, the enzyme becomes an integral part of the solid support. Some of the advantages of this technique include retention of similar kinetic characteristics as the soluble form of the enzyme. Most important, the immobilized enzyme retains high activity after prolonged storage and is resistant to the detrimental effects of low and high temperatures and to long exposure to the environment. In addition, the enzymes are covalently attached to the polyurethane, so they will not leach from this polymer support.

To increase the organophosphate/enzyme stoichiometry, polyurethane-immobilized enzymes were combined with oximes (enzyme reactivators such as HI-6; Peter et al., 2007) so that the catalytic activity of organophosphate-inhibited AChE (or BChE) is rapidly and continuously restored before irreversible aging of the enzyme−organophosphate complex can occur. Thus, the organophosphate is continuously detoxified. A reusable immobilized-enzyme sponge of cholinesterases and oximes for organophosphate decontamination is the envisioned product. Next, it was demonstrated that the organophosphates diisopropylfluoro-phosphate (DPF) or MEPQ [7-(methyl-ethoxyphosphinyloxy)-1-methylquinolinium iodide] inhibited the activity of ChE-sponges, as was observed for nonimmobilized ChE in solution. The oxime HI-6 restored activity of the AChE-sponge until the molar concentration of MEPQ reached approximately 1000 times that of the cholinesterase active site. However, the AChE-sponge could be recycled many times by rinsing the sponge with HI-6 in the absence of OP. In this case, most of the original ChE activity would be restored to the sponge. Therefore, the bioscavenger approach could be used externally: the sponge would soak up organophosphate, decontaminating the contaminated skin (Caranto et al., 1994). Then the ChE sponge and oxime would detoxify the OP in the sponge. We found that the ability of the immobilized enzymes and HI-6 to detoxify the organophosphate MEPQ was dependent upon the efficiency of the sponge to decontaminate particular surfaces including plastic and guinea pig skin.

Characteristics of polyurethane immobilized enzymes: The longevity of sponges composed of immobilized cholinesterases is greater than 5 years at room temperature (not shown). The immobilized enzymes are also very stable in aqueous environments. One significant

none	0.14	n/a

[a]*Protective ratio.*

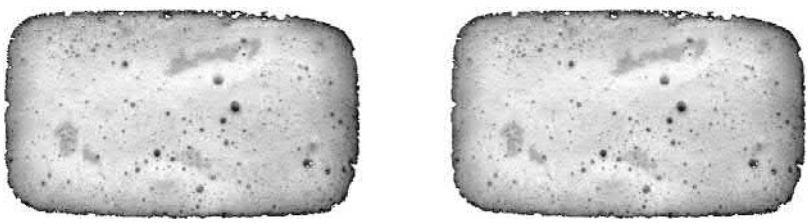

FIGURE 73.4 Polyurethane sponge.

difference and advantage that the immobilized enzymes have compared to the soluble cholinesterases is that immobilized enzymes do not dissociate (leach) from the sponge. Therefore, the immobilized enzymes can be left in the liquid or other environments. For instance, the AChE activity in the immobilized sponge was stable for more than 60 days in continuous immersion in aqueous samples including Allegheny River fresh water or brackish water (Gordon et al., 2002). Since the results were identical for autoclaved and untreated water, the immobilized enzymes were also resistant to microbial-induced proteolytic degradation. Also, note that the same sponge was assayed multiple times over many days, so it is evident that the immobilization process confers dramatic stability to covalently coupled cholinesterases and that the enzymes do not leach from the polyurethane matrix.

Organophosphate removal by the sponge and formulation: The capacity of sponges to remove GD or organophosphates from guinea pig skin was determined using a back-titration method, where removed organophosphate in the sponge was added to a known amount of cholinesterase. Inhibition of the exogenously added cholinesterase permits quantitation of the organophosphate concentration. From these studies, it was determined that additional components when added to the sponge improved the sponge's efficacy by leaching out the chemical warfare agents. In this case, we settled on tetraglyme, which has a propensity to dissolve organic-like materials, including organophosphates (and sulfur mustard, see below). In part, the inability of sponge-tetraglyme to remove all the GD likely reflects the rapid penetration of GD through skin and the inability of tetraglyme to extract this fraction. It also points to the requirement for as rapid a decontamination as possible. These results clearly demonstrate that the sponge not only removed organophosphate from the skin of the guinea pigs, but also in the presence of oxime effectively and completely detoxified the organophosphates within hours. Thus, these sponges would not pose any additional cross-contamination hazard.

Protective ratios of the sponge: It proved to be impossible to modify the prepolymer since currently there is no formulation with an increased hydrophobic nature that might be expected to absorb the organophosphates more effectively. Instead, we utilized additives described above to provide the additional ability to remove soman from the skin, protecting guinea pigs significantly better than the M291 SDK (Table 73.2). A comparison with RSDL is also shown. Compared to the LD_{50} values of 9.9 and 17.7 mg/kg for untreated animals (nondecontaminated) and the M291 SDK, respectively, the sponge provided an LD_{50} of 290. This combination is also effective against VX-contaminated guinea pigs: the sponge increased the LD_{50} from 0.14 to 21 mg/kg, yielding a protective ratio of 150. RSDL provided a protective ratio of 150.

Sulfur mustard decontamination and formulation: The sponge was used to wipe guinea pig skin contaminated with neat sulfur mustard. The following day, the animals were injected with trypan blue. Those areas representing vesicant injury take up the dye. It was observed that the neat HD-exposed tissue (positive control) had a significant dye uptake, while the area decontaminated by the sponge had only a slight uptake of the dye. The control had no dye uptake. In addition, the amount of HD taken up and removed by the sponge was measured over time. While neat mustard remained after 15 min in water, the corresponding amounts were destroyed in the matrix of the sponge and additives. Histopathology of the HD-exposed skin specimens after 24 h demonstrated microvesicles, coagulation at the dermal interface, and in the most severe cases, dermal coagulation. Overall, HD-exposed areas decontaminated with the sponge exhibited characteristics associated with reduced exposure (microvesicles). Thus, these sponges could reduce the damage that HD produces. Cholinesterases may provide sinks as alkylation sites for the sulfur mustard and account for some of the reduced toxicity of the agent upon sponge decontamination. Another feature demonstrated was that the tetraglyme leaches from skin not only organophosphates, but also the organic-like sulfur mustard, thereby reducing its ability to alkylate skin proteins. Finally, the formulation of the sponge was modified to include nucleophilic additives to act as a reactive moiety for the sulfur mustard in place of skin proteins. Taken together, the polyurethane sponge was shown to decontaminate and detoxify guinea pig skin exposed to two classes of chemical warfare agents: organophosphates such as GD and alkylating compounds such as HD.

73.6.7 Immobilized enzyme badges (Gordon et al., 2002)

The sponge can incorporate a detection system for organophosphates and alkylating agents—a unique attribute not present in current decontamination methods. The immobilized enzymes provide a detector and a rapid field system capable of identifying the type of organophosphate. In addition to organophosphate detection, a coupled enzyme reaction provides a rapid colorimetric or electrochemical indication of mustard. With the constant threat of chemical warfare or terrorist acts, the development of alternative means of protecting and decontaminating individuals from exposure to CWAs is critical.

Like Diphotérine, which has been evaluated only for sulfur mustard decontamination, the polyurethane enzyme-immobilized sponge is a novel technology that has demonstrated efficacy for organophosphate and sulfur mustard cutaneous poisoning, but is only now

undergoing evaluation for decontamination of biological warfare agents (T-2 mycotoxin, botulinum toxin) and radionucleotides (Gordon et al., 2006). Another advantage of cholinesterases over general reacting additives is that the cholinesterases are the direct target for current or future warfare agents, and therefore countermeasures that incorporate cholinesterases should not require major reformulation. These new technologies likely will provide more efficacious solutions for the soldier in the future.

73.7 Concluding remarks and future directions

Organophosphorus nerve agents are a serious threat to military and civilian personnel. These agents are some of the most potent toxic agents and are specific inhibitors of cholinesterases. Organophosphate nerve agents can exist as a vapor and be inhaled, as a liquid they can contaminate skin, or they can be ingested if food or water is contaminated. Vesicating agents such as sulfur mustard cause irreversible cell damage as a result of rapid alkylation, and were an agent of terror during World War I and more recently in Iran and Iraq. Another serious problem that may be encountered while caring for personnel contaminated with chemical warfare agents is the possibility of cross-contamination of medical providers. In addition, during combat or terrorist acts, individuals might be exposed to chemical toxins before they don their protective gear. Decontamination postexposure has the potential to be an important, integral, and therefore necessary step for medical countermeasures against chemical warfare agents. The products described here must meet several criteria to be effective personal decontaminants and detoxifiers of chemical warfare agents for the soldier, although there is room for improvements; thus novel technologies have been discussed. However, any product must be lightweight for individual use, yet be shelf-stable under environmental conditions found in the field. Decontamination and detoxification products must be readily available and work quickly because of the rapidity with which CWAs cause damage: organophosphates penetrate skin in less than 5 min, and mustard produces irreversible cell damage as a result of alkylation equally rapidly. The product should also be environmentally friendly. In the future, one product should incorporate chemical, biological, and radiological decontamination and, when possible, detoxification. With the constant threat of chemical warfare, terrorist acts, or spills of pesticides, the development of alternative means of protecting and decontaminating individuals from exposure is critical.
