Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

Introduction

Extremely toxic chemicals have been used for thousands of years in wars, conflicts, and extremist activities by terrorists and dictators in malicious poisonings and executions. One of the earliest forms of chemical warfare agents (CWAs) was natural toxins from plants or animals, which were used to coat arrowheads, commonly referred to as "arrow poisons." Ancient use of some CWAs and riot control agents (RCAs) dates back to the 5th century BCE during the Peloponnesian War, when the Spartans used smoke from burning coal, sulfur, and pitch to temporarily incapacitate and confuse occupants of Athenian strongholds. The Spartans also used bombs made of sulfur and pitch to overcome the enemy. The Romans used irritant clouds to drive out adversaries from hidden dwellings. In the 15th century, Leonardo da Vinci proposed the use of a powder of arsenic sulfide as a chemical weapon.

Modern use of CWAs and RCAs or incapacitating agents dates back to World War I (WWI). With advancements in science and chemistry in the 19th century, the possibility of chemical warfare increased tremendously. The first full-scale use of CWAs began in April 1915 when German troops launched a poison gas attack at Ypres, Belgium, using 168 tons of chlorine gas, killing about 5000 Allied (British, French, and Canadian) soldiers. During WWI, the deployment of CWAs, including toxic gases (chlorine, phosgene, cyanide, and mustard), irritants, and vesicants in massive quantities (about 125,000 tons), resulted in about 90,000 fatalities and 1.3 million nonfatal casualties. The majority of deaths in WWI were a result of exposure to chlorine and phosgene gases. During the Holocaust, the Nazis used carbon monoxide and the insecticide Zyklon-B, containing hydrogen cyanide, to kill several million people in extermination camps. Poison gases were also used during the Warsaw Ghetto Uprising in 1943. Again, in November 1978, religious cult leader Jim Jones murdered over 900 men, women, and children with cyanide.

Prior to, during, and after World War II, anticholinesterase organophosphate (OP) nerve agents/gases were developed in Germany, the United States, the United Kingdom, and Russia, and were produced in large volumes in many other countries. They were maximally produced and stockpiled during the "Cold War" period. These nerve agents have been used in wars and by dictators, extremists, cult leaders, and terrorist groups as chemical weapons of mass destruction (CWMD) on many occasions. In 1980, Iraq attacked Iran, employing mustard and OP nerve gases. During the period of the Iraq and Iran conflict (1980–88), Iran sustained 387 attacks and more than 100,000 troops were victims along with a large number of civilians. Thousands of these victims still suffer from long-term health effects. Shortly after the end of the Iraq–Iran war in 1988, the brutal dictator of the Iraqi regime, Saddam Hussein, used multiple CWAs against the Kurdish minorities in Halabja, killing more than 10% of the town's 50,000 residents. To date, mustards have been used in more than a dozen conflicts, killing and inflicting severe injuries in millions of military personnel and civilians.

During the Persian Gulf War, exposure to OP nerve agents occurred from the destruction of munitions containing 8.5 metric tons of sarin/cyclosarin housed in Bunker 73 at Khamisyah on March 4, 1991, and additional destruction of these nerve agents contained in rockets in a pit at Khamisyah on March 10, 1991. Although exposure levels to nerve agents were too low to produce signs of acute toxicity, military personnel serving in and around the Khamisyah area still suffer from long-term adverse health effects, most notably "Gulf War syndrome." In 1996, about 60,000 veterans of the Persian Gulf War claimed to suffer from "Gulf War syndrome" or "Gulf veterans' illnesses," possibly due to low-level exposure of nerve agents, mustard, pyridostigmine bromide, and pesticides. Exposed veterans had an increased incidence of chronic myelocytic leukemia and increased risk of brain cancer deaths compared to unexposed personnel.

In the mid-1990s, two terrorist attacks by a fanatic religious cult, Aum Shinrikyo (Supreme Truth), known as Aleph since 2000, took place in Japan (Matsumoto, 1994 and Tokyo subway, 1995). In both incidents, the OP nerve agent sarin was used as a CWA. Aum Shinrikyo in Kamikuishiki, Japan, manufactured an estimated 70 tons of sarin. Although the total fatality count involved not more than 20 civilians, injuries were observed in more than 6000 and millions were terrified. These acts of chemical terrorism were unprecedented and the impact

propagated throughout not only Japan, but the entire world. In the past few decades, many incidents have also occurred with biotoxins such as ricin and anthrax. Publicity surrounding frequent recent use due to easy access and copycat crimes increase the possibility of future use of these chemicals and biotoxins, which warrants advancement in emergency preparedness planning at the federal, state, and local government levels.

It is interesting to note that toxic chemicals have been used by governmental authorities against rebels, or civilians. In the 1920s, Britain used chemical weapons in Iraq "as an experiment" against Kurdish rebels seeking independence. Winston Churchill strongly justified the use of "poisoned gas against uncivilized tribes." The Russian OSNAZ forces used an aerosol containing fentanyl anesthetic during the Moscow theater hostage crisis in 2002. RCAs were frequently used in the US in the 1960s to disperse crowds in riot control.

Intoxications or deaths by poisoning of emperors, heads of countries, and other significant individuals have been recorded for a long time. The French Emperor Napoleon Bonaparte was poisoned with a mixture of heavy metals including arsenic and mercury. Napoleon Bonaparte died on May 5, 1821, while he was in exile on the island of St. Helena. In December 2004, during the presidential campaign, the former President of Ukraine, Viktor Yuschenko, was poisoned by a very high dose of 2,3,7,8-tetrachlorodibenzodioxin (TCDD). Ex-lieutenant of the Russian Federal Service, Alexander Litvinenko (1962−2006) died on November 23, 2006, from intoxication with polonium 210. Kim Jong-Nam, a half-brother of North Korean dictator Kim Jong-Un was poisoned with VX nerve agent at Kuala Lumpur airport in Malaysia. He died within 20 min of exposure. On March 4, 2018, the former officer of the Russian Main Intelligence Directorate, Sergey Skripal, and his daughter, Yuliya Skripal, were poisoned with Novichoks in Salisbury, United Kingdom. Following an aggressive antidotal therapy, fortunately both survived.

At present, more than 25 countries and possibly many terrorist groups possess CWAs, while many other countries and terrorist groups are seeking to obtain them, due to their easy access. Some of these agents are stockpiled in enormous quantities and their destruction and remediation are not only expensive but also associated with significant health risks. There is also the possibility of accidental release of CWAs or CWMD at their production sites, as well as during transportation, dissemination, and deployment. The intentional or accidental release of highly toxic chemicals, such as the nerve agent VX (Dugway Proving Ground, Utah, 1968), Agent Orange (Vietnam, 1961−72), PBB (Michigan, USA, 1973), dioxin (Seveso, Italy, 1976), and methyl isocyanate (Bhopal, India, 1984), has caused injuries to more than a million people, and deaths in several thousands. A 1968 accident with VX nerve gas killed more than 6000 sheep in the Skull Valley area of Utah.

After September 11, 2001, the chances are greater than ever before of the use of CWMD by extremist and terrorist groups like Al Qaeda, which presents great risks to humans, domestic animals, and wildlife in many parts of the world. On November 26, 2008, Pakistani Islamic terrorists attacked Mumbai city in India at 10 different sites, including two luxury hotels, a Jewish center, a train station, and hospitals and cafes. Approximately 200 innocent people died and about 300 people were injured by bullets and smoke. It is more likely that these terrorist groups may use toxic industrial chemicals (agents of opportunity) either as such or as a precursor for more deadly CWMD. At present, many countries have established Defense Research Institutes with two major missions: (1) to understand the toxicity profile of CWAs/CWMDs and (2) to develop strategic plans for prophylactic and therapeutic countermeasures. By the turn of the 21st century, the US established the Department of Homeland Security. Many other countries also developed similar governing branches and agencies at the state and national levels to protect people and property from terrorist attacks. Among chemical, biological, and radiological weapons, the possibility of CWMD is more likely because of their easy access and delivery system. It is important to mention that understanding the toxicity profile of CWAs/CWMD is very complex, as these chemical compounds are of a diverse nature, and, as a result, treatment becomes very difficult or in some cases impossible.

In the past, many accords, agreements, declarations, documents, protocols, and treaties have been signed at the international level to prohibit the development, production, stockpiling, deployment, and use of CWAs, yet dictators and terrorists produce and/or procure these chemicals to harm or kill enemies, create havoc, and draw national and international attention. In 1907, The Hague Convention outlawed the use of chemical weapons, yet during WWI, many countries used these chemicals. The first international accord on the banning of chemical warfare was agreed upon in Geneva in 1925. Despite the General Protocol, the Japanese used chemical warfare against China in 1930. In 1933, the Chemical Weapon Convention banned the development, possession, and use of CWAs. The document was signed and implemented by more than 100 countries. Yet, during WWI many chemicals of warfare were developed, produced, and used by several countries. In 1993, another global convention banning the production and stockpiling of CWAs was signed by over 100 countries.

The delayed health effects from CWAs used in the Iraq−Iran conflict of the 1980s, sarin subway attacks in Japan, and the First Gulf War in the 1990s are still not

well understood. Recently, the Syrian government stockpiled over 1300 metric tons of chemical agents, including sarin, VX, and sulfur mustard. In August 2013, the Syrian military repeatedly attacked civilians with chemical weapons, including sarin and chlorine. More than 1300 people died and thousands were injured. Again, on April 11−13, 2014, Syrian military forces attacked civilians in Hama province with chlorine gas, killing and injuring an unaccounted number of people. Despite warnings from many countries, the Syrian army continues to use CWAs against civilians. In the present world situation, it is highly likely that these agents will be used in wars, conflicts, terrorist attacks, and with malicious intent. In such scenarios, these extremely toxic agents continuously pose serious threats to humans, animals, and wildlife.

The first edition of this *Handbook of Toxicology of Chemical Warfare Agents* was prepared in 2009 in order to offer the most comprehensive coverage of every aspect of the deadly toxic chemicals that can be used as CWAs/CWMD. Since the publication of the first edition of this *Handbook*, concerns over the use and misuse of CWAs and BWAs have become greater than ever before. The second edition of the *Handbook of Toxicology of Chemical Warfare Agents* was published in 2015. This third edition of this *Handbook* is prepared to meet the current challenges facing academicians and lay persons alike. The format employed is user friendly and easy to understand. Standalone chapters on individual chemical and a few biological agents, target organ toxicity, biosensors and biomarkers, risks to man, animals, and wildlife, and prophylactic and therapeutic countermeasures are just a few of the many novel topics covered in this volume. The chapters are enriched with historical background as well as the latest information and up-to-date references. With 73 chapters, this book will serve as a reference source for biologists, toxicologists, pharmacologists, forensic scientists, analytical chemists, local/state/federal officials in the Department of Homeland Security, Department of Defense, Defense Research Establishments, Department of Veterans Affairs, physicians at medical and veterinary emergency care units of hospitals, poison control centers, medical and veterinary diagnostic labs, environmentalists and wildlife interest groups, researchers in the area of nuclear, chemical, and biological warfare agents, and college and university libraries.

Contributors of the chapters in this book are the most qualified scientists in their particular areas of chemical and biological warfare agents and radiation. These scientists are from around the globe and are regarded as authorities in the fields of pharmacology, toxicology, and military medicine. The editor sincerely appreciates each author for his/her dedicated hard work and invaluable contributions to this volume. The editor gratefully acknowledges Robin B. Doss and Denise M. Gupta for their technical assistance. Finally, the editor remains indebted to the editors at Elsevier (Kristi Anderson, Kattie Washington, and Kiruthika Govindaraju) for their immense contributions to this book.

Chapter 1

History of toxicology: from killers to healers

Eugenie Nepovimova[1] and Kamil Kuca[2]

[1]Department of Chemistry, Faculty of Science, University of Hradec Kralove, Hradec Kralove, Czech Republic, [2]Philosophical Faculty, University of Hradec Kralove, Hradec Kralove, Czech Republic

1.1 Introduction

The word *toxicology* comes from the Greek words *toxicon*, meaning a poison, and *logos*, meaning a scientific study. Today, the term *toxicology* refers to a scientific discipline dealing with the physical-chemical properties of toxic substances, their mechanisms of action on the body, clinical symptoms of intoxications, and the prevention and treatment of various poisonings (Klaassen, 2018). It would not be an exaggeration to claim that toxicology is almost as old as mankind. The earliest mentions of toxic substances and intoxications can be found not only in ancient scientific literature, but also in Greek myths. For example, Homer describes how Odysseus sent a warrior to Egypt to bring back traditional Egyptian poisons used for arms ammunition. In another legend, Hercules soaked his weapons in poison of the sacred Lernean hydra. Last, but not least, the myth of Helen of Troy tells how her captor died because of a wound caused by a poisoned arrow.

1.2 Ancient times

Among the oldest literary sources focused on toxicology is the Ebers Papyrus (1550 BCE) (Fig. 1.1), found in 1872 in Thebes. This 20.5 m long scroll, glued from 108 smaller sheets of papyrus, is also called "The book of preparation of remedies for all parts of the body." The oldest pharmacopoeia of the ancient Egyptians contains more than 900 prescriptions for drugs for the treatment of diseases associated with the gastrointestinal tract, respiratory tract, ear, throat, nose, eye, and skin. Such prescriptions involved substances like opium, arsenic trioxide, aconitine, cyanogenic glycosides, or a herb called Dia-Dia, currently known as mandrake (*Mandragora officinalis*, *Solanaceae*) (Hallmann-Mikołajczak, 2004). Ancient Egyptian surgeons used the juice of mandrake root for anesthesia and analgesia. Later, the art of the preparation of hypnotic and painkilling remedies isolated from the mandrake root transferred from Egypt to ancient Greece. During surgical operations, the Greeks used a sponge soaked in mandrake hot juice for anesthesia. Inhalation of the vapors of this juice resulted in a deep sleep of the patient. In the works of the Roman physician Galen, we can find passages telling about large quantities of mandrake tincture that were delivered daily to Rome. Apart from the medicinal use of mandrake, one of the Roman writers mentions mandrake wine used for war purposes, thanks to which the Carthaginians defeated the enemy. The soldiers of ancient Carthage left their camp with the mandrake wine in a conspicuous place. After returning back to the camp, they thereafter easily overpowered their sleeping enemies (Emboden, 1989; Mion, 2017).

Probably the most famous poisoning of the Hellenistic period was the execution of the Greek philosopher Socrates (470−399 BCE), who was condemned to drink the extract from hemlock (*Conium maculatum*, *Apiaceae*). His death is depicted in detail in Plato's tract *Phaedo* (Hotti and Rischer, 2017; Nepovimova and Kuca, 2019). The description of poisoning corresponds exactly to the present knowledge of coniine, the main component of hemlock.

The period of ancient Greece in world history is known for the flourishing of various scientific disciplines, including medicine. The founder of the most famous school of medicine, that was located in the Greek town of Kos, was the so-called "Father of Medicine" Hippocrates

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00001-5

FIGURE 1.1 Ebers Papyrus found in 1872 in Thebes (https://commons.wikimedia.org/wiki/File:A_page_from_the_Ebers_Papyrus,_written_circa_1500_B.C._Wellcome_M0008455.jpg).

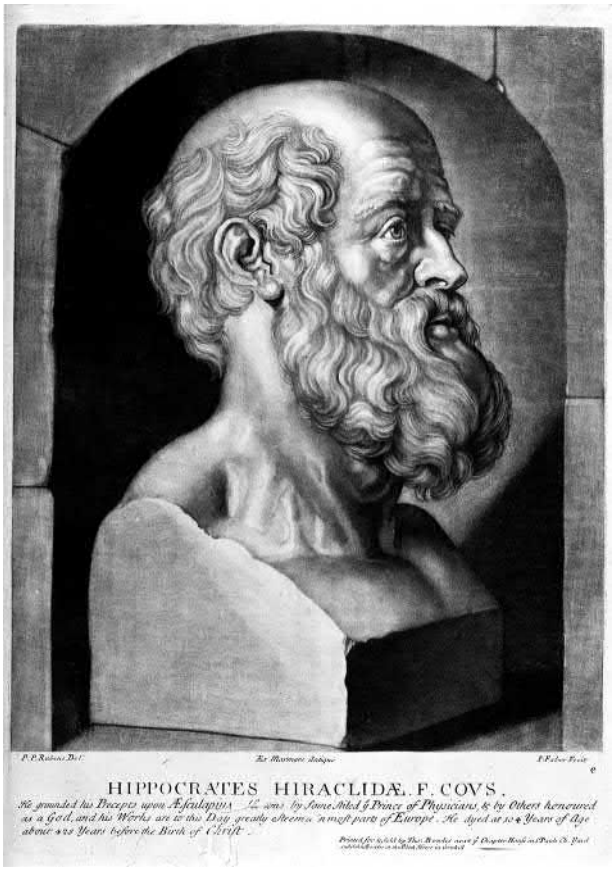

FIGURE 1.2 Father of Medicine, Hippocrates (https://commons.wikimedia.org/wiki/File:A_marble_bust_said_to_represent_Hippocrates_by_J._Faber._Wellcome_M0017663.jpg).

(460−370 BCE) (Fig. 1.2). Hippocrates rejected using poisons for removing unwanted persons. Therefore in his works, toxic substances are rarely mentioned. Some of his disciples, such as Pliny or Galen, followed the same principle, describing in their works only the antidotes. Such an informal rule has been preserved until the modern era, when young doctors, by taking the Hippocratic Oath, promise neither to administer a poison to anybody when asked to do so, nor to suggest such a course (Emery, 2013).

The ancient scientists abounded in a deep knowledge of various poisons. Usually they gained such knowledge from the observation of accidental poisonings, as well as from intentional exposure to poisons. In contrast to Eastern countries, in ancient Greece and subsequently Rome, toxic substances were quite often used as a means of killing convicts. Thus the ancient Greek poet and physician Nikander of Kolophon in his poem *Theriaca* describes clinical symptoms of intoxications by various animal toxins. In Nikander's further work *Alexipharmaca* that has survived to the present time, we find descriptions of the characteristics of plant poisons as well as methods for their treatment. As very effective therapeutic approaches he recommended invoking vomiting by drinking warm flaxseed oil or irritating the throat by simple devices made from paper or bird feathers. The majority of the knowledge reported by Nikander was based on his own experiments on convicted criminals. In addition, Nikander was by all accounts the first to describe the signs of lead poisoning (Clauss, 2012). In ancient Rome, lead was widely used in everyday life. For example, lead plates were added to wine to improve its quality. At that time, lead was very expensive and only rich people could afford it. Therefore it is not surprising that chronic lead poisoning became a scourge of the ancient Roman aristocracy (Hernberg, 2000).

From the point of view of the history of toxicology as a medical discipline, not only were poisoners and crimes committed by means of poisons important, but also searching for potent antidotes. Especially in ancient times, there was an obsession to discover a universal antidote, able to protect against most, if not all, poisons. Quite instructive is the story of King Mithridates VI of Pontus (132−63 BCE) (Fig. 1.3). Mithridates was terribly afraid of poisons, therefore, he began to study toxicology in depth—he observed the effects of various poisons on people (mostly convicts or slaves), designed antidotes, and subsequently tested their efficacy on the same groups of people. Finally, he managed to prepare a universal antidote consisting of 36 components. Such

FIGURE 1.3 King Mithridates VI of Pontus (https://commons.wikimedia.org/wiki/File:Mithridates_VI_Louvre_white_background.jpg).

an antidote even received a special designation in the Roman Pharmacopoeia—*mithridaticum.* The reputation of this antidote was excellent. It was even considered the best antidote of those times, capable of preventing the actions of aconitine, snake, scorpion, or spider toxins, etc. King Mithridates believed in his recipe so much that he decided to take this remedy daily. Acquired resistance, however, played a crucial role in his life. In old age, Mithridates attempted to commit suicide by taking a large dose of poison, but survived. Therefore he was forced to use other means (a sword) to finish this act. Based on this legend, the term *mithridatism* has been adopted into the modern toxicology indicating the increased resistance of an individual to poisons (Griffin, 1995; Valle et al., 2012, 2009).

The last wife of the Roman Emperor Claudius (10 BCE−CE 54) was his niece Agrippina the Younger (CE 15−59) (Fig. 1.4). Soon after their marriage, she decided to get rid of her husband as well as his first-born son Britannicus to make her own son, Nero, the emperor (Aveline, 2004). First, she poisoned Claudius using the toxin muscarine present in toxic mushrooms, fly agaric (*Amanita muscaria*, *Amanitaceae*), in one of his meals. The Emperor's physician, Aesculapius, tried to evoke vomiting in Claudius. However, Agrippina foresaw such a turn of events and had prepared in advance a poisoned feather. This feather was in all probability the product of the famous ancient poisoner—Locusta (Marmion and Wiedemann, 2002). After Claudius' death, Nero (CE 37−68) (Fig. 1.4) became the Emperor of Rome. Despite this, Nero's stepbrother Britannicus still constituted a threat to him (Shotter, 2008). Similarly to his mother Agrippina, Nero also asked for the help of the poisoner Locusta. In this case, she gave him a poison that was added to Britannicus' wine. After removal of his competitor, 17-year-old Nero became the only possible Emperor of Rome. Thus he decided to reward Locusta by an extraordinary right—to educate her own students. This story was one of many examples in world history where poisons were used for criminal purposes. Therefore in 81 BCE, the Roman dictator Sulla was forced to pass a special law ordering punishment, including the death penalty, for those who used poisonous substances with criminal intent (Telford, 2014).

Dioscorides (CE 40−90), the physician of the Roman Emperor Nero, in his tract *De Materia Medica* (Fig. 1.5) classified poisons based on their origin to plant, animal, and mineral. Additionally, in *De Materia Medica* we may find the methods of identification of several poisons. Such identification occurred in the scientific literature for the first time. For the next 15 centuries, Dioscorides' work was considered the "Holy Bible" of toxicology (Staub et al., 2016).

1.3 The Middle Ages

In medieval Europe, poisons were freely available in pharmacies. The first attempt to stop such a trade in poisons was made in Italy. In 1365 in Siena, apothecaries were forbidden from selling arsenic and mercury to people unknown to them. In France, a ban on toxic substances was issued in 1662, whereas in Russia this took place only in 1773 (Nepovimova and Kuca, 2019). Despite these restrictions, the question of searching for novel more potent poisons and corresponding antidotes remained relevant.

In Europe, the search for novel antidotes as well as their use in the prevention and treatment of poisoning continued until the beginning of the 18th century, and in Turkey until the beginning of the 20th century. The ancient works of Galen *De Theriaca, ad Pisonem*, *De Usu Thericae, ad Pamphilianum*, and *De Antidotis*, mainly inspired by the achievements of King Mithridates, were within the period of the Renaissance and the Middle Ages enriched with the knowledge of the Jewish physician and philosopher Moses Maimonides (1135−1204) (Fig. 1.6). His tract focused on poisons and antidotes and was published in Arabic in Cordoba (Spain) in 1198 (Rosner, 2000). This literary work constitutes a noticeable milestone in the history of toxicology, outlining the 1000-year

FIGURE 1.4 Agrippina the Younger and her son Nero (https://commons.wikimedia.org/wiki/File:Ner%C3%B3n_y_Agripina.jpg).

experience of treating various poisonings and also described the clinical picture of intoxication by poisons that were previously unknown. The first part of the tract describes intoxications as well as poisons of animal origin (bites by enraged dogs, wasps, snakes, spiders, scorpions, and other animals). As historically the first attempt, Maimonides distinguished the neurotoxic and hematotoxic symptoms of intoxication. In the second part, he focused on mineral and plant poisons. For instance, in the case of *Atropa belladonna* (*Solanaceae*) intoxication, Maimonides reported skin redness and some kind of "excitement" of the patient. As a therapeutic tool he recommended vomiting evoked by warm milk, vegetable oil, etc. (Rosner, 1968).

None of the noble families left such a significant imprint in the history of Italy and the whole world as the Spanish "holy family" of Borgia that was sadly famous for numerous murders committed by means of poisons. These Spaniards twice occupied the throne of Saint Peter—firstly as Pope Callixtus III and subsequently as Pope Alexander VI (Hibbert, 2009). "Cantarella" was the name of the poison used by the Borgias. Allegedly, Cesare Borgia (1474−1507) (Fig. 1.7), the son of the Pope Alexander VI (1431−1503) (Fig. 1.7), received the recipe for this poison from his mother. Apparently, the mystic poison contained arsenic, salts of copper, and phosphorus. According to the literary sources, the papal alchemists prepared such toxic mixtures that a drop was enough to kill a bull. Not only the poison, but also the tools containing such poison, were unique. Cesare Borgia was the owner of a ring with a huge ruby that bore the name the "Flame of Borgia." Several times he pronounced that this ring had repeatedly saved his life. Presumably, under the gemstone there was a skillfully made secret container with a poison. Cesare poured this poison into the drink of those who dared to encroach on

FIGURE 1.5 A page from Dioscorides' work *De Materia Medica* (https://en.wikipedia.org/wiki/De_Materia_Medica#/media/File:NaplesDioscuridesMandrake.jpg).

his life. The Pope himself also had a gold ring with a secret. In the process of shaking hands, a small thorn appeared on the inner side of the ring which slightly scratched the skin of the sentenced person and released a deadly drop of poison (Poole, 2010). Finally, destiny punished Pope Alexander VI, who accidentally drank poisoned wine that was intended for his victim (Hibbert, 2009).

Despite the wide use of poisons within the struggle for power, the development of toxicology in European countries in the Middle Ages was significantly hampered by the influence of religious ideologies. Medieval monks followed the principle "Like is cured by like" (*Similia similibus curantur*) (Zebroski, 2015). The exception was Swiss physician, alchemist, botanist, astrologer, and occultist of the era of the German Renaissance, Philippus Aureolus Theophrastus Bombastus von Hohenheim (1492−1541), also known as Paracelsus (Fig. 1.8). He chose this pseudonym for himself and it means "more than Celsus." Aulus Cornelius Celsus was a Roman naturalist, living more than one and half thousand years before Paracelsus (Grell, 1998). Paracelsus' groundbreaking contribution to life sciences consisted mainly in the interconnection between chemistry and medicine. Therefore it is not surprising that his life credo was: "The real purpose of chemistry is not to make gold, but to make remedies!" Paracelsus has been also considered the Father of Toxicology, since in one of his books he stated: "Dose makes the poison" (*Dosis facit venenum*). Thus substances that are taken to be toxic could be harmless in small doses, whereas normally harmless substances could be fatal if consumed excessively. This postulate still belongs among the basic pillars of modern toxicology. He was also known for his revolutionary views on the observation

of nature and man, created by himself instead of simply quoting ancient texts. Last but not least, he gave the designation to the chemical element zinc and noted that certain diseases stem from the mind of the patient (Paracelsus, 1999).

With regard to poisonings, medieval Italy and later France were considered the most powerful countries in the world. The French Queen, Catherine de' Medici (1519–89) (Fig. 1.9), also known as the Queen-Poisoner, perfectly mastered the Italian technique of poisoning to achieve her intended political goals (Kruse, 2003). Alexandre Dumas, in his historical novel "Queen Margot," wrote that Queen Catherine was involved in the death of her political rival Jeanne d'Albret by giving her an insidious present—poisoned gloves (Dumas, 1994). Within the same novel, Dumas also describes the fatal mistake of the Queen, who at the end of her life decided to remove the son of poisoned Jeanne d'Albret—Henry. She commanded he be given a poisoned book dealing with the art of hunting. Unfortunately, this book got into the wrong hands, to her own son King Charles IX. Apart from removing the competitors within the battle for the royal throne, Queen Catherine was also known for experiments with various toxic mixtures that she conducted on poor and sick people. Catherine de' Medici carefully reported each experiment, recording the velocity of the toxic response (onset of the

toxic effect), the efficacy of the toxic mixture, the strength of the toxic effect in various parts of the body (organ specificity, site of action), and the clinical picture of intoxication. Thus despite the poor reputation of the Queen-Poisoner, she can be considered the first experimental toxicologist in history (Whyte, 2001).

The development of industry in the 16th century gave rise to several highly specialized works dealing with occupational diseases. In 1556 Georgius Agricola (1494–1555), a German doctor and metallurgist, in his work "On Mining and Metallurgy" described severe occupational diseases of miners (Weber, 2002). The first real systematic contribution to occupational toxicology was made by Italian physician Bernardino Ramazzini (1633–1714). In his work "Diseases of the workers," published in 1700, where he for the first time described the diseases of workers in almost 70 professions, such as miners, gilders, chemists, plasterers, blacksmiths, etc. (Dhungat, 2017).

The Golden Age of King Louis XIV of France was not associated just with the development of the country, but also with several famous cases of poisoners—Marquis de Brinvilliers, Catherine Monvoisin, and others. Catherine Monvoisin (1640–80) (Fig. 1.10) was among the most popular poison suppliers of that time. A frequent client of Madame Monvoisin was also a hot favorite of the Sun King—Marquis de Montespan. Due to the fact that poisons were perceived as the simplest means of solving problems among the aristocratic families, King Louis XIV issued a special law, where the definition of poison was given as: "Everything that can cause a rapid death or slowly destroy human health, regardless of the fact whether it is a simple or complex substance, must be considered as a poison." To complete the story of French poisoners, Marquis de Brinvilliers, Catherine Monvoisin, and their associates were executed. Marquis de Montespan, a mother of eight illegitimate children of Louis XIV, was sent to exile in the Netherlands (Somerset, 2004).

In the late 17th–early 18th centuries, Neapolitan poisoner Teophania, more commonly known as Tophana, operated in Europe. Apparently, this Italian was responsible for the deaths of more than 600 people. Tophana was an inventor of an original product called *Aqua Tophana*. Aqua Tophana had a water-like, odorless, and colorless consistency. Allegedly, five or six drops of this magical water was enough to kill a man. The onset of the toxic effect was gradual—painless, without any sign of fever or inflammation. Death occurred due to weakness, loss of appetite, and incessant thirst. Among the most frequent customers of Aqua Tophana were women who desired to get rid of their husbands. The exact content of Aqua

Tophana remains unknown. According to one source, it was made of arsenic acid with an addition of *Herba cymbalariae* (*Scrophulariaceae*). Other sources claim that the main component of Aqua Tophana was lead acetate solution. Seniora Tophana was eventually sentenced to death and in 1709 burnt to death (Nepovimova and Kuca, 2019; Wexler, 2017).

FIGURE 1.11 The founder of toxicology Mathieu Orfila (https://commons.wikimedia.org/wiki/File:Pierre_Matthieu_Joseph_Bonaventure_Orfila._Lithograph_by_Z._Wellcome_V0004368.jpg).

At the beginning of the 19th century, the most prominent figure in toxicology was considered to be the Spanish physician Mathieu Orfila (1787–1853) (Fig. 1.11). He was the first to separate toxicology from pharmacology, clinical and forensic medicine, giving toxicology the status of an independent scientific discipline. At the age of 27, Orfila wrote a book "Treatise on poisonings," that was later published in five editions. Several years later, another work by Orfila's "A treatise on the remedies to be employed in cases of poisoning and apparent death: including the means of detecting poisons, of distinguishing real from apparent death, and of ascertaining the adulteration of wines" met with great interest from the scientific community. In his writings, the Spanish physician classified all known toxic substances, described the clinical picture of intoxications typical for various classes of poisons, and also recommended chemical methods for poison identification in biological matrices (Myers, 1961). Based on his works, it became obligatory to conduct a forensic chemical analysis for official confirmation of poisoning as the cause of the death. In addition, Mathieu Orfila gave the most general definition of poison that remains widely used "Poison is a substance, that by coming in contact with a living organism in a small amount, destroys its health and subsequently life" (Hadengue, 1987).

The 1850s could be characterized as the time of the formation of modern toxicology. The decisive influence belonged to the successes achieved in analytical chemistry and experimental analysis that won its place in theoretical medicine (Oser, 1987). The fundamental works of French scientists Francois Magendie (1783–1855) (Fig. 1.12) and his student Claude Bernard (1813–78) (Fig. 1.12) dealing with the mechanism of action of strychnine, cyanide, curare, carbon monoxide, and other poisons, served to strengthen the role of toxicology among the other scientific disciplines (Bloch, 1989). Numerous methods of

FIGURE 1.12 Francois Magendie (left) and his student Claude Bernard (right) (https://commons.wikimedia.org/wiki/File:Fran%C3%A7ois_Magendie._Lithograph_by_N._E._Maurin._Wellcome_V0003781.jpg; https://commons.wikimedia.org/wiki/File:Portrait_of_Claude_Bernard_(1813-1878),_French_physiologist_Wellcome_M0000114.jpg).

particular physiological function evaluation, such as respiration and neuromuscular conduction, proposed by Claude Bernard were preserved in experimental practice for more than 100 years. Claude Bernard was also an author of the brilliant idea that toxic substances can serve as an excellent tool in physiology research. He said: "These substances could be considered as real life reagents that are carried by the blood stream to all points of the body, act on some tissues and finally lead to the death. The mechanism of death points to the physiological role of particular tissues on which they act." This finding became a significant milestone in general physiology (Breathnach, 2014). Additionally, within his experiments with curare, Claude Bernard revealed that this poison paralyzes voluntary muscles with no effect on impulse conduction in the motor nerves as well as on contractility of the muscles. This observation led to discovery of the special sensitivity of the neuromuscular junction to curare. Several years later, these investigations served as a strong argument for the development of a theory of the neurochemical basis of excitatory transmission within the nervous system (Gomes et al., 2014).

For almost two centuries after the death of the French Emperor Napoleon Bonaparte (1769–1821) (Fig. 1.13), his demise has remained a hot topic, and the scientists continue to investigate this case. After he was sent into exile in 1820, the health status of the Corsician sharply deteriorated. Throughout his stay on the island of St. Helen, he complained about severe stomachache, weakness, and frequent attacks of nausea. Finally, on May 5, 1821, he died. According to the findings of an international group of scientists, Napoleon Bonaparte passed away due to progressive stomach cancer with metastases in the lymph nodes (Leys, 2015). However, according to conspirologists, the symptoms of the ex-Emperor's death more resemble arsenic poisoning. Moreover, recent analysis of his hair has shown an almost 40-fold increase in arsenic concentration in comparison to normal people of that time. Several theories have been formulated, explaining how Napoleon Bonaparte could have been poisoned. Among the most curious being poisonous wallpaper, or the theory claiming that Napoleon was poisoned by a mixture of heavy metals (Hindmarsh and Corso, 1998). The first hypothesis builds on the fact that adding green arsenic-based pigment into wallpaper was quite common at that time. From a chemical point of view this pigment, called Paris Green, was copper(II) acetoarsenite. The humid weather of the island promoted the proliferation of microscopic fungi which could convert inorganic arsenic in Paris Green to an organic form. It is widely recognized that organic forms of heavy metals more easily cross the biological barriers compared to their corresponding inorganic salts. Therefore this theory assumes that Napoleon was intoxicated in particular by these organic forms of

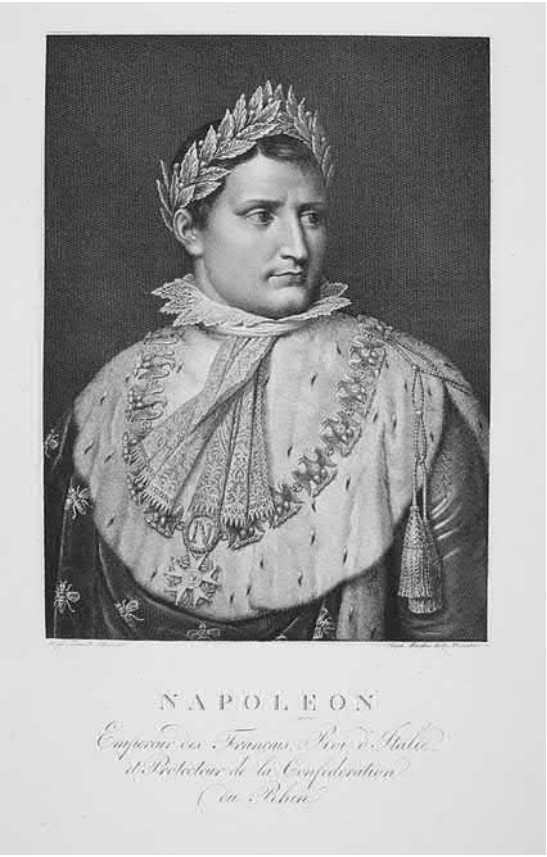

FIGURE 1.13 French Emperor Napoleon Bonaparte (https://thorvaldsensmuseum.dk/en/collections/work/E876/zoom).

arsenic. The latter theory already assumes foreign blame. According to this hypothesis, low doses of arsenic were added to Napoleon's food and drinks. The clinical picture of chronic intoxication with arsenic usually manifests as severe pain in the stomach. To relieve vomiting in Napoleon, the doctors administered him potassium tartarate of antimony. In addition to this remedy, his physicians prescribed him calomel and orgeat to combat constipation and thirst, which represent other characteristic symptoms of arsenic intoxication. The main component of orgeat is bitter almond oil, whereas calomel is a trivial name for mercury dichloride (Hg_2Cl_2). Hydrolyses of orgeat to hydrocyanic acid in the acidic gastric environment, together with calomel, gives rise to mercury cyanide. Therefore either arsenic, hydrocyanic acid, antimony, mercury cyanide, or a mixture of some or all of them could be one of the causes of Napoleon's death (Mari et al., 2004).

1.4 The modern era

The Industrial Revolution in the middle of the 19th century allowed the synthesis of natural toxins in unlimited

quantity. Moreover, novel entities derived from natural compounds were prepared. Due to all the above-mentioned events, poisons were gradually losing their mystery (Nepovimova and Kuca, 2019). At the beginning of the 20th century, the development of toxicology was strongly influenced by progress in the chemical industry. From the perspective of chemical production, Germany was among the most developed countries. Within several branches of the chemical industry, German chemists even maintained a monopoly position, for example, in dye production. One of the most famous German chemists of the time was Fritz Haber (1868–1934) (Fig. 1.14), who discovered a method of ammonia synthesis from atmospheric nitrogen. Such an invention was of high importance for the large-scale synthesis of fertilizers and explosives. Therefore in 1918, Fritz Haber was awarded the Nobel Prize (Manchester, 2002). In the history of toxicology, F. Haber is better known for another reason, he is called the "Father of Chemical Weapons" due to his longlasting reasearch in the field of weaponization of chlorine and other toxic gases in World War I (WWI). In addition, it was Haber's suggestion to use chlorine in the first chemical attack by Germans against British/French troops on April 22, 1915, near the town of Ypres (Belgium) (Charles, 2005). Subsequently, the Allies (France, Great Britain, United States, and Russia) also started to use chemicals for military purposes. During the 4 years of WWI (1914–18), about 1.3 million people were affected by chemical weapons on both sides of the conflict, of which more than 100,000 died (Tucker, 2006).

FIGURE 1.14 The "Father of Chemical Weapons" Fritz Haber (https://commons.wikimedia.org/wiki/File:Fritz_haber_1929_PI_29-C-0097.jpg).

On September 7, 1978, Bulgarian dissident Georgi Markov (1929–78), after an evening broadcast on the BBC, went around a crowded bus stop on the Waterloo Bridge in London and suddenly felt a slight sting in his leg. Looking around, the Bulgarian noticed a man picking up an umbrella from the ground. The stranger spoke with a strong accent, apologizing, and then caught a taxi and left. Due to a high fever, acute stomachache, and severe diarrhea, Markov was hospitalized that night, and a few days later he died. Fortunately, he managed to talk about the incident with the umbrella. Doctors, who performed an autopsy, found a small iridium-platinum capsule in the leg of the dissident. According to the findings of further investigations, this capsule with a diameter of less than 2 mm was filled with ricin (Crompton and Gall, 1980). Ricin is a plant toxin obtainable from the castor bean (*Ricinus communis*, *Euphorbiaceae*). By all accounts, Georgi Markov was shot by the Bulgarian special services because of his active criticism of the communist regime of Todor Zhivkov (Papaloucas et al., 2008). The killing device was an umbrella endowed with a hidden sting that shot small capsules filled with toxic ricin.

On March 20, 1995, the nerve agent sarin was used at several subway stations in Tokyo (Japan). About 10,000 people were affected, with 5000 seriously intoxicated and 12 people died. Sarin was used by the terrorists of the sect Aum Shinrikyo. They stored the nerve agent in plastic bags, which were subsequently punctured by an umbrella with a sharpened tip. The terrorists managed to puncture 10 of 11 bags. Fortunately, due to the low purity of the sarin (approximetely 30%) and the subway ventilation system, the loss of life was not as high as it might have been (Okumura et al., 2005). The question that still needs to be answered is: "Why did the sect select sarin?" There are plenty of possibilities why: (1) inspiration from the Gulf War; (2) simple synthesis; (3) starting compounds availability; and (4) low production costs (Nozaki and Aikawa, 1995). Many sect members who participated in the sarin production process claimed that they were unaware of its toxic effects. However, the handbook "Magic song of sarin," found in one of the buildings used by Aum Shinrikyo, apart from the instructions of how to synthesize the nerve agent, gave a description of its lethal effects. Therefore it was obvious that the members of the sect had lied (Kimura, 2002). The terrorist use of sarin in the Tokyo subway pointed out the serious risk of misuse of chemical warfare agents for nonmilitary purposes and highlighted the need for the development of appropriate protection including antidotal therapy.

The former President of Ukraine, Viktor Yushchenko (born 1954) (Fig. 1.15), was intoxicated by a very high dose of 2,3,7,8-tetrachlorodibenzodioxin (TCDD) in

FIGURE 1.15 Former Ukrainian President Viktor Yushchenko (https://sk.wikipedia.org/wiki/S%C3%BAbor:Viktor_Yushchenko_2006.jpg).

December, 2004. This terrible act happened during the presidental campaign. Detailed analysis revealed that Yushchenko's body contained the second highest concentration of TCDD ever detected in a human (Sorg et al., 2009). The main symptom that he suffered from was chloracne, which significantly deformed the skin on his face (Saurat et al., 2012). The same substance intoxicated thousands of Vietnamese during the war in Vietnam (1955−75).

Ex-lieutenant of the Russian Federal Service (FSB), Alexander Litvinenko (1962−2006), died in November 2006 because of intoxication with a radioactive compound. The findings of the investigators pointed to the fact that this act happened in the hotel Millennium (London, United Kingdom) during a meeting with former colleagues. Soon after the intoxication, Litvinenko's health deteriorated and, despite countless attempts by toxicologists to combat the disease, he continued to decline. On November 23, 2006, Alexander Litvinenko died (McFee and Leikin, 2009). The autopsy revealed that the cause of death was radioactive polonium 210. Among several possibilities, it was proposed that polonium had entered Litvinenko's body in tea. The ex-lieutenant died of acute heart failure. Allegedly, less than one gram of polonium 210 is enough to kill a person. After entering the body, its action is almost imposible to stop. Finally, the alpha particles of this silver powder attack the liver, kidneys, and bone marrow, resulting in gradual failure of vital organs (Harrison et al., 2007, 2017).

On February 13, 2017, a half-brother of the North Korean dictator Kim Jong-Un was poisoned. According to a video recording, Kim Jong-Nam (1971−2017) was attacked by two women at the airport in Kuala Lumpur, Malaysia. Twenty minutes later he died. His autopsy disclosed traces of an extemely toxic compound belonging to the V-group of nerve agents. Allegedly, the V-agent was in a binary form since neither of the offenders manifested any sign of intoxication (Paddock and Sang-Hun, 2017). It is highly likely that each woman was bearing a particular precursor of the binary weapon. By touching Kim Jong-Nam on the face the two precursors reacted in situ, resulting in the formation of V-agent.

On March 4, 2018, Sergey Skripal and his daughter Yuliya were intoxicated in the city of Salisbury (Great Britain). The former officer of the GRU (Main Intelligence Directorate) Sergey Skripal (*1951) had dual citizenship of Russia and Great Britain. Skripal's daughter Yuliya, a Russian citizen, had flown to London to visit her father who worked for the British Special Services. Soon afther the poisoning by a nerve agent, they were hospitalized in an uncounscious state. On April 10, 2018, Yuliya was discharged from the local hospital and taken to a hospital at a British military base. On May 18, 2019, Sergey Skripal was also discharged. British experts from Porton Down science park determined that the poison used belonged to the most recent group of nerve agents called "Novichoks," in particular, it was compound A-234. However, the scientists did not manage to reveal the origin of the compound. Later, the findings gained by British experts were confirmed by the Organization for the Prohibition of Chemical Weapons (OPCW) (Vale et al., 2018). The Novichok nerve agents were developed in the 1970s by the USSR as a reaction to the British/American invention of the VX agent. The Western world learned about the existence of the Novichoks in 1992 from a defectors who emigrated to the United States. According to the available data, these substances exert a higher or at least similar toxicity to the VX agent (Franca et al., 2019; Nepovimova and Kuca, 2018). The UK government accused Russia of an attempt to kill Sergey Skripal as well as being in violation of the Chemical Weapons Convention. Moscow categorically rejected such accusations and stated that the poisoning could have been organized by the Special Services of the United Kingdom or the United States.

1.5 Concluding remarks and future directions

This chapter points out that removal of unwanted persons via poisons was known in antiquity and is still very

popular at the present time. Almost until the 18th century, poisons were strongly associated with mystery, black magic, and occultism. Only with progress in the life sciences, including toxicology, have poisons started to be perceived differently. Such progress was accompanied by achievements in the fields of analysis and detection, chemical synthesis of novel toxic substances, and corresponding antidotes, and also the inventions of refined devices, such as in the case of the Georgi Markov assassination. Today, the most experienced toxicologists do not work in the academic field, but rather for secret services and/or military organizations. The intent for which novel poisons are prepared has also changed from mere removal of specific enemies to mass intimidation, terrorism, and false accusation. However, regardless of the intention, it is clear that toxicology as a scientific discipline will never die as new and more toxic compounds are being developing continuously.

2.1 Introduction

The employment of chemicals in war has a long history (Silvagni et al., 2002; Romano et al., 2008). Just as the use of chemicals brought about tremendous advances in society, the concept of using chemicals to help win wars has been pursued for centuries (Joy, 1997; Smart, 1997). There are many examples of the exploitation of chemicals in warfare and conflict dating back to ancient times. Primitive humans may have been the first to use chemical compounds in both hunting and battle scenarios. The use of smoke from fires to drive animals or adversaries from caves may have been the earliest use of chemical weapons. Natural compounds derived from plants, insects, or animals that were observed to cause sickness or death were likely used by our distant ancestors in attempts to gain or maintain superiority (Hammond, 1994). Natural toxins from plants or animals on arrowheads, as well as the poisoning of water or food, could increase casualties and cause fear in opposing military forces or civilian populations. These early uses of chemicals paved the way for more lethal chemical weapons. For example, in the 4th century BCE, smoke containing sulfur was used in the war between Sparta and Athens (Joy, 1997). Chinese manuscripts indicate arsenic-based compounds were used in battle (Joy, 1997). A few hundred years later, toxic smoke was employed by the Romans in Spain (Coleman, 2005). During the second siege of Constantinople, the Byzantine emperor Leo III used "Greek fire" in his quest for military victory (Coleman, 2005). During the ensuing years, there were many instances of the limited and attempted use of chemicals and toxins on the battlefield. Many of these examples may have been influenced by the intentional poisonings occurring in civilian settings (Joy, 1997; Smart, 1997; Newmark, 2004; Coleman, 2005). The earliest known treaty to ban poisons in warfare was signed between the French and Germans in the 17th century (Smart, 1997). In the siege of Groningen, European armies employed incendiary devices to release belladonna, sulfur, and other compounds. This led to the Strasbourg Agreement in 1675, which prohibited poison bullets (Smart, 1997; Coleman, 2005).

As science and chemistry advanced in the 19th century, the possibilities of chemical warfare increased exponentially. Advancements were made in industrial applications of sulfur, cyanide, and chlorine (Joy, 1997). In addition, the concept of delivering chemicals via projectiles was introduced. During the Crimean War, the British refused to use cyanide-based artillery shells against the Russians on the grounds that it was a "bad mode of warfare" (Smart, 1997). This was an early example of the ethical questions surrounding chemical use in warfare that continued into the 20th century (Vedder and Walton, 1925). During the US Civil War, both the Northern and Southern armies seriously considered using various chemicals in their pursuit of operational victories (Smart, 1997). Early attempts at international treaties met with mixed results. The United States prohibited any use of poison during the Civil War. The Brussels Convention on the Law and Customs of War of 1874 prohibited poisons or poison-related arms (Smart, 1997). The first Peace Conference at the Hague prohibited projectiles filled with asphyxiating or deleterious gases (Smart, 1997).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00002-7

The employment of chemicals as asphyxiating warfare agents was vigorously discussed there (Joy, 1997). However, some countries, including the United States, were not signatories to this agreement. Arguments again were made against chemicals based on moral grounds. However, counterarguments were made based on the assumption that chemicals lead to death without suffering (Vedder and Walton, 1925; Joy, 1997; Coleman, 2005). Individuals who advocated chemicals did not view their use as an unfair advantage; rather, it was just one of a series of technological advances which, if mastered, could provide strategic, operational, and tactical advantages on the battlefield. The second Peace Conference at the Hague, held 8 years later, prohibited both poisons and poisoned weapons (Smart, 1997). The British use of picric acid–filled shells during the Boer War and the Japanese use of arsenical rag torches in the Russo-Japanese War further illustrate that chemical warfare was considered by some a legitimate form of warfare at the turn of the 20th century (Smart, 1997). During the early 20th century, technological advancements in the chemical industry made the possibility of sustained military operations using chemicals a realistic possibility. The murder of Archduke Franz Ferdinand in Sarajevo in June 1914, which sparked World War I, set the stage for what would become the first widespread use of chemical weapons to date (Harris and Paxman, 2002).

2.2 The first sustained use of chemicals as agents of war

The talk and rhetoric of the late 19th century should have prepared the countries on both sides of World War I for chemical warfare. However, that was not the case (Smart, 1997). World War I clearly demonstrated the deadly and destructive nature of chemicals in modern warfare. Both sides of the war experimented with novel forms of warfare, including chemical weapons, and followed the lead of their adversary (Hay, 2000). It is little wonder that this war is known as the "chemist's war" (Fitzgerald, 2008). Initially, the French used gas grenades with little effect, followed by the German use of shells filled with tear gas (Joy, 1997). The Germans, capitalizing on their robust chemical industry, produced shells filled with dianisidine chlorosulfate (Smart, 1997). These shells were used in October 1914 against the British at Neuve-Chapelle, but with little effect. In the winter of 1914–15, the Germans fired 150-mm howitzer shells filled with xylyl bromide (Smart, 1997). These shells were fired on both the eastern and western fronts, with disappointing effects. Despite this inauspicious start, efforts were continued to develop new uses of chemical warfare. It would soon be evident that chemical weapons would be devastating on the battlefield (Coleman, 2005; Tucker, 2006). In late 1914, Fritz Haber, a German scientist who later won the Nobel Prize in Chemistry, proposed the possibility of releasing chlorine gas from cylinders (Joy, 1997). Chemical warfare was attractive to Germans for two reasons: the shortage of German artillery shells and the ability to defeat the trench system of the enemy (Smart, 1997). After consideration and debate, the Germans released chlorine in April 1915 at Ypres, Belgium (Coleman, 2005). The German military was not prepared for the tremendous operational advantage the chlorine release provided, however. It did not take long for the British and French forces to respond in kind to the German offensive (Vedder and Walton, 1925; Joy, 1997; Smart, 1997; Coleman, 2005). In the fall of 1915, a British officer, William Livens, introduced a modified mortar (Fig. 2.1) that could project gas-filled shells of chlorine or phosgene, the two agents of choice at that time (Joy, 1997). Both chlorine and phosgene caused extreme respiratory problems to those soldiers who were exposed to them (Vedder and Walton, 1925; Joy, 1997; Smart, 1997; Coleman, 2005; Hurst et al., 2007) (Fig. 2.2).

FIGURE 2.1 British Livens Projector, western front, World War I.

As the United States entered the war in the spring of 1917, an obvious concern of its military command was the effect of chemical warfare on standard operations. Chemistry departments at universities were tasked with investigating and developing novel chemical agents (Joy, 1997).

Protective equipment (Fig. 2.3) and basic studies of the biological effects of chemical agents were assigned to the US Army Medical Department (Joy, 1997). In the fall of 1917, the army began to build an industrial base for producing chemical agents at Edgewood Arsenal, MD (Joy, 1997). As the effects of chlorine and phosgene became diminished by the advent of gas masks (Fig. 2.4), the Germans turned to dichlorethyl sulfide (sulfur mustard) at Ypres against the British (Joy, 1997).

FIGURE 2.2 Australian infantry in trench with gas masks donned, Ypres, Belgium, September 1917.

FIGURE 2.3 US Army captain wearing a gas mask in training, 1917.

FIGURE 2.4 World War I soldier and horse, both wearing gas masks.

As opposed to the gases, sulfur mustard remained persistent in the area, and contact avoidance was the major concern (Joy, 1997). It is worth noting that almost 100 years after it was first used on the battlefield, sulfur mustard still has no effective treatment; research continues into developing effective therapeutics (Babin and Ricketts, 2000; Baskin and Prabhaharan, 2000; Casillas et al., 2000; Hay, 2000; Schlager and Hart, 2000; Hurst et al., 2007; Romano et al., 2008). It has been estimated that there were over 1 million chemical casualties (Fig. 2.5) of World War I, with almost 8% being fatal (Joy, 1997). The Russians on the eastern front had a higher percentage of fatalities than other countries in the war, primarily due to the later introduction of a protective mask (Joy, 1997). The relatively low rate of chemical deaths in World War I demonstrated the most insidious aspect of the use of such weapons—namely, the medical and logistical burden that it placed on the affected army. The eventual Allied victory brought a temporary end to chemical warfare. In 1919 the Treaty of Versailles prohibited the Germans from producing or using chemical weapons.

2.3 Initial countermeasures

The concept of a protective mask against chemical attack dates back over 500 years, to Leonardo da Vinci (Smart, 1997). By the mid-19th century, protective masks were proposed in the United States and Europe for both industrial and military use. The modern gas mask was developed by the Germans with sodium thiosulfate- and

FIGURE 2.5 British soldiers temporarily blinded by tear gas awaiting treatment at the Battle of Estaires, April 1918.

bicarbonate-soaked pads, and it was used during World War I (Joy, 1997). The French and English soon followed with their own versions of gas masks (Joy, 1997). In 1916 the Germans introduced a mask that incorporated a canister through which the soldiers breathed (Joy, 1997). Initially, the American forces in World War I used gas masks obtained from allies already fighting in the war (Smart, 1997). In 1918 the Americans introduced Richardson, Flory, and Kops (RFK) mask, a modified version of the British mask. In addition, masks were developed for the animals, such as horses, that supported the war efforts. Decontamination efforts during World War I were rudimentary and included chemical neutralization and aeration of clothing and equipment. Although the need to detect chemical agents was clearly identified, very little progress was made during World War I. Medical treatment included removal of the patient from the source, decontamination, and palliative care (Smart, 1997).

2.4 Events after World War I

By the time World War I ended, the world had been introduced to chemical warfare on an unprecedented level. While some groups thought that humanity had learned a lesson about the cruel nature of chemical warfare, others prudently went to work on improving chemical defenses (Vedder and Walton, 1925). The thoughts of many professional military officers were that future wars would be fought under the new paradigm of chemical warfare (Vedder and Walton, 1925; Vedder, 1926; Smart, 1997). New gas masks were developed, and training in chemical environments was introduced (Vedder and Walton, 1925; Vedder, 1926; Joy, 1997). Textbooks and manuals, such as those written by US Army Colonel Edward B. Vedder (Fig. 2.6), were introduced into the military medical community (Vedder and Walton, 1925). In addition, the civilian medical community gained valuable insight into toxicology from the events of World War I (Vedder, 1929; Johnson, 2007). Despite the firsthand experience with chemical warfare, some countries, including the United States, struggled to fund their offensive and defensive programs adequately during demobilization (Smart, 1997).

It did not take long for chemical warfare to appear in other conflicts. Chemical agents were used to subdue rioters and suppress rebellions. For example, the British used chemical agents to suppress uprisings in Mesopotamia in the early 1920s by dropping bombs in cities throughout the area (Coleman, 2005). The Soviet Union used chemical agents to quell the Tambov peasant rebellion in 1921, and France and Spain used sulfur mustard-gas bombs to subdue the Berber rebellion in the 1920s (Werth et al., 1999). Italy and Japan used sulfur mustard in several small regional conflicts (Joy, 1997). The Italian conflict in Ethiopia was particularly noteworthy because sulfur mustard was sprayed and dropped from planes, and some experts think that the agent's use contributed significantly to the Italian victory (Smart, 1997). This use demonstrated the contemporary belief that chemicals were viable alternatives to traditional combat.

The Japanese also used chemical weapons during the 1930s against regional foes. Sulfur mustard gas and the vesicant lewisite were released against Chinese troops and were also used in Southeast Asia (Coleman, 2005). Lewisite is an arsine that was usually produced as an oily brown liquid that was said to smell like geraniums (Spiers, 1986; Hammond, 1994). It was developed in the United

FIGURE 2.6 Captain Edward B. Vedder, the "father" of the United States Army Medical Research Institute of Chemical Defense (USAMRICD).

States by Winford Lee Lewis in 1918 and was found to be effective at penetrating clothing. The United States produced approximately 20,000 tons of lewisite but only used small quantities of the chemical in World War I (Coleman, 2005). Dimercaprol, more commonly called British antilewisite, was developed as an effective treatment for the vesicant (Goebel, 2008). In the period between the two world wars, sulfur mustard was a key part of defensive planning (Coleman, 2005). New stores of sulfur mustard were produced in many countries. Work continued on many fronts to improve protective equipment. For example, the US Chemical Warfare Service introduced the M1A2 mask, an improvement on the M1 mask (Smart, 1997). In the Geneva Protocol of 1925, 16 of the world's major nations pledged never to use gas as a weapon of warfare; however, it was not ratified in the United States until 50 years later, in 1975 (Hammond, 1994). There has long been vigorous debate on the merits of treaties with nations that balance military needs against the potential irrational concept of chemical warfare (Vedder, 1926).

2.5 World War II

In the lead-up to World War II, the Germans forever changed chemical warfare with the discovery of the organophosphorus nerve agents (Goebel, 2008). These agents inhibit cholinesterase enzymes in the nerve synapse responsible for the breakdown of the neurotransmitter acetylcholine (ATSDR, 2019). This results in the accumulation of the neurotransmitter in the synapse and overstimulation of the nervous system. This can result in subsequent respiratory failure and death (ATSDR, 2019).

In 1936 Gerhard Schrader, a German chemist working on the development of insecticides for IG Farben, developed a highly toxic organophosphate compound, which he named tabun (Hersh, 1968; Hammond, 1994). Schrader and an assistant became casualties of their discovery when a drop of the neurotoxicant was spilled in the lab, exposing both of them (Tucker, 2006). Had the amount of tabun spilled been greater, both researchers would have certainly succumbed to the effects of the poison. Tabun was the first of a series of compounds termed nerve gases (Coleman, 2005). The correct terminology, however, is nerve agents, as these substances are not gases; rather, they are liquids dispersed as fine aerosols. Tabun was extremely toxic in small amounts, and it was invisible and virtually odorless (Tucker, 2006). The compound could be inhaled or absorbed through the skin. These characteristics made it too dangerous to be used as an insecticide by farmers. German law required that any discovery having potential military applications be reported to military officials (Tucker, 2006). Schrader was not overly excited about producing chemical agents for the military; however, the Germans placed him in a secret military research facility with the emphasis on producing these nerve agents and discovering new agents (Tucker, 2006). Subsequently, Schrader and his team of researchers discovered a more lethal organophosphate compound similar to tabun, which he named sarin in honor of the team members: Schrader, Ambrose, Rudriger, and van der Linde (Coleman, 2005).

At the onset of World War II, both the Allies and the Germans anticipated that chemical agents would be deployed on the battlefield (Tucker, 2006). This expectation intensified research into the development of new agents, delivery systems, and methods of protection (Figs. 2.7 and 2.8). The Allied forces were unaware of the Germans' new nerve agent, tabun, at the beginning of the war. The German Army advanced very rapidly across Europe using their Blitzkrieg method of maneuvering. As a result, German military leaders were reluctant to use chemical weapons, fearing that their forces would lose momentum waiting for contaminated areas to clear. (Tucker, 2006). Nevertheless, the Germans produced and stockpiled large amounts of nerve agents throughout the war (Spiers, 1986). The production of these organophosphate agents was complex, required custom equipment, and was hazardous to those involved in its production (Tucker, 2006). If workers got exposed, they would be dunked in a bath of sodium bicarbonate (Harris and Paxman, 2002; Goebel, 2008). It is also interesting to

FIGURE 2.7 Gas mask production—Detroit, Michigan, 1942.

FIGURE 2.8 A private trains using protective gear during World War II.

note that some members of the German workforce were given rations containing higher percentages of fat (Harris and Paxman, 2002). This was done because authorities observed that workers with higher quality rations seemed protected against exposure to low levels of tabun. Many detainees were used in the manufacture and testing of chemical agents in Germany (Harris and Paxman, 2002; Tucker, 2006). It is not known how many chemical casualties resulted from prisoners of war being forced to work at producing nerve agents, but some fatalities were documented. The discovery of tabun and sarin was followed by the discovery of soman in 1944 by Richard Kuhn and Konrad Henkel at the Kaiser Wilhelm Institute for Medical Research (Tucker, 2006). This class of nerve agents is collectively termed "G" agents; the G stands for German, since German researchers discovered this class of compounds. A second letter is included as the specific identifier of each compound: GA (tabun), GB (sarin), GD (soman), and GF (cyclosarin) (ATSDR, 2019). These agents were mass-produced by the Nazi regime throughout the war, but they were not used (Tucker, 2006). There has been considerable debate about why the Germans did not employ their chemical weapons in World War II. While it may never be known conclusively, several possible reasons include lack of intelligence regarding the German superiority in chemical weapons, fear of retaliation, and Adolf Hitler's personal exposure to chemical agents on the battlefield in World War I (Harris and Paxman, 2002; Tucker, 2006). Other chemical agents that had been produced during and following World War I were still being produced. On December 2, 1943, German planes sank several American ships off the coast of Italy. At least one of the ships contained sulfur mustard, which was to be used in retaliation if the Germans unleashed a large-scale chemical weapons attack (Tucker, 2006). Many casualties resulted from exposure to the sulfur mustard, some of which included civilian merchant seamen (US Navy, 2019). The presence of the agent on the ship was classified, resulting in physicians incorrectly treating many of the victims (Tucker, 2006).

2.6 Post–World War II

By the conclusion of World War II, both the Allies and Germany had stockpiled large amounts of chemical agents (Tucker, 2006). The Allied forces divided up the stockpiles of agents discovered in German facilities. Following the end of the war, many of the Allied countries continued to conduct research on the German nerve agents. The rise of the Soviet Union as a power and adversary prompted the United States and other countries to continually search for novel chemical and biological warfare agents (Tucker, 2006). The research and resources that were allotted for these efforts were not trivial, even though they were often overshadowed by the research and development of thermonuclear weapons (Hersh, 1968; Goebel, 2008).

The post–World War II era ushered in the nuclear age. Some felt the age of chemical warfare was over (Smart, 1997), but subsequent events would prove this to be a hasty conclusion. In the United States, research on the G-series agents and medical countermeasures against these agents was accomplished by the late 1940s. Research and intelligence gathering were further hastened by the impressive gains that the Soviet Union made in

chemical warfare capability in the years after World War II. By the early 1950s, production of sarin had been initiated in the United States (Smart, 1997). At nearly the same time, Ranajit Ghosh, a chemist at the British company Imperial Chemical Industries plant, developed a new organophosphate compound to use as a potential insecticide (Tucker, 2006). Like with Gerhard Schrader, this compound was deemed too toxic to be used in the field as a pesticide. The compound was sent to researchers in Porton Down, England, synthesized, and developed into the first of a new class of nerve agents, the V agents (Goebel, 2008). Like the G agents, the V agents have a second letter designation: VE, VG, VM, and VX (Coleman, 2005). Of these, VX was the most common. The V series of agents are generally more toxic than the G agents (ATSDR, 2019). In a deal brokered between the British and US governments, the British traded the VX technology for the thermonuclear weapons technology of the United States (Tucker, 2006). The United States produced and stockpiled large quantities of VX after that (Hersh, 1968; Hammond, 1994).

Throughout the 1950s and 1960s, advancements were made in the production and delivery of chemical weapons to include sarin and VX (Smart, 1997). While work on improving masks continued, a renewed concern was the inability to detect nerve agents. Several prototypes were developed in the mid-1950s. Great advancements were made in the therapeutics of agents that inhibited the enzyme acetylcholinesterase (Taylor, 2006; Gupta, 2008; Klaassen, 2008). Atropine was introduced in the early 1950s. Oximes were added as an adjunct to speed up reactivation of the enzyme (Smart, 1997). The autoinjector was developed to overcome user fear of self-injection of atropine. Major advances were made in the use of chemical weapons in artillery (Fig. 2.9). For example, the United States developed both short- and long-range rockets filled with chemical agents. But it disposed of stockpiles of its chemical weapons in the late 1960s in an operation termed CHASE (which stood for "cut holes and sink 'em") in the sea (Coleman, 2005). In 1969 nerve agent stockpiles were discovered in US depots in Japan after several US military members became ill while doing maintenance (Tucker, 2006). This stockpile, which had been kept secret from the Japanese, created an uproar that later resulted in the disposal of the agents in the Johnston Atoll in the Pacific Ocean.

Defensive equipment, such as improved field alarms and drinking tubes for gas masks, were introduced in the 1960s (Smart, 1997). Great strides were also made in collective protection during the 1960s and 1970s. Although not used extensively since World War I, chemical agents have nonetheless been used for military purposes. The Egyptians allegedly used sulfur mustard and possibly nerve agents in the North Yemen Civil War in the 1960s

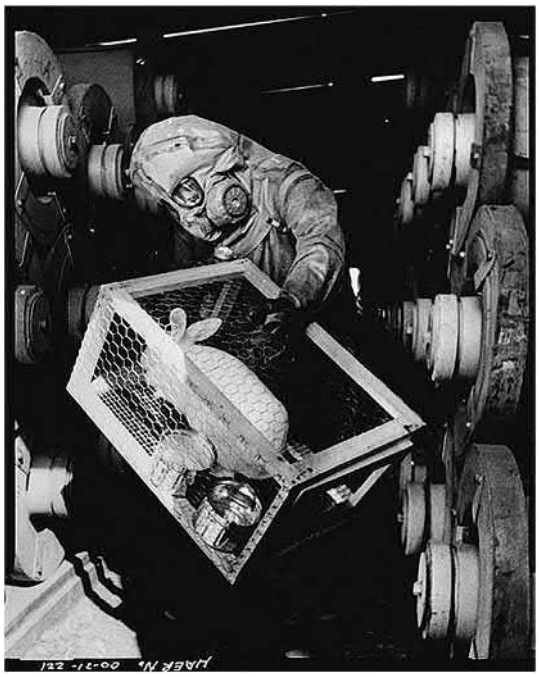

FIGURE 2.9 Testing for leaks at a sarin production plant, 1970.

(Joy, 1997; Smart, 1997). This was the first reported use of nerve agents in armed conflict. There were allegations that chemical agents were used by the Vietnamese in Laos and Kampuchea in the late 1970s (Coleman, 2005). In the Vietnam War, the United States used defoliants and tear gas, and the Soviet Union was accused of using chemical agents in their war in Afghanistan (Joy, 1997).

2.7 Incapacitants and toxins

Incapacitating agents have long been considered an intermediate between chemical and traditional warfare. The Germans investigated the military use of lacrimators in the 1880s followed shortly thereafter by the French (Smart, 1997). The English and French considered using lacrimators in World War I (Smart, 1997). Japanese forces used tear gas against the Chinese in the late 1930s. The US Army used riot control agents and defoliants in the Vietnam War (Smart, 1997). The defoliant known as Agent Orange was later potentially linked to several forms of cancer (Stone, 2007). During the 1950s and 1960s, the United States had an active incapacitant program (Smart, 1997). These agents were thought of as more humane than traditional chemical agents because the intent was not to kill. These agents were designated K agents and included tetrahydrocannabinol and lysergic acid (Smart, 1997). One of the most extensively studied incapacitating agents was 3-quinuclidinyl benzilate, designated BZ by the US Army (Ketchum, 2006). Like many incapacitating agents, BZ was not adopted due to

difficulty producing reproducible effects, unwanted side effects, latency in its effects, and difficulty in producing a dissemination that was free of smoke (Smart, 1997; Ketchum, 2006).

There have been multiple attempts to use the toxins from plants and living organisms to develop viable weapon systems. Two that are noteworthy are ricin and botulinum toxin. Ricin, a very potent toxin derived from the castor bean plant, has been recognized as a potential biological weapon since World War I. While the British were developing the V agents, US military researchers patented a procedure for purifying ricin (Harris and Paxman, 2002). The development of a method of disseminating ricin as a chemical weapon proved problematic, which made its use very limited. In 2003 ricin was detected on an envelope processed in a postal facility in Greenville, South Carolina. Postal workers did not develop symptoms of ricin exposure, and the individual who mailed the letter remains at large (Shea, 2004). The development and use of botulinum neurotoxin as a biological weapon was initiated at least 60 years ago (Smart, 1997; Arnon et al., 2001). In the 1930s, during Japan's occupation of Manchuria, the Japanese biological warfare group Unit 731 purportedly fed cultures of *Clostridium botulinum* to prisoners, killing them. The US Army biological weapons program produced botulinum neurotoxin during World War II in response to Germany's biological weapons program (Coleman, 2005). In fact, more than 100 million toxoid vaccine doses were prepared in time for the D-Day invasion of Normandy (Arnon et al., 2001).

2.8 Recent experience

The 1980s proved to be a very significant time for the employment of chemical weapons on the battlefield. In 1980 Iraq invaded Iran (Smart, 1997). The Iraqi armed forces, advised by the Soviet Union, possessed chemical agents and were trained in their use. The war was unequivocally barbarous, and neither side gained an advantage. In many ways, this war had similarities to World War I. By 1983, Iran formally protested to the United Nations (UN) about the Iraqi use of chemical agents. The general consensus was that Iraq used sulfur mustard agents and possibly tabun in this war (Fig. 2.10). It is estimated that 5% of Iranian casualties, totaling approximately 45,000, can be attributed to chemical agents; the Iraqi Army used chemical agents against the Kurdish minority in northern Iraq as well; and Libya was suspected of using chemical agents when it invaded Chad in 1986 (Smart, 1997).

The late 1980s also saw improvements in defensive equipment, such as the M40 gas mask developed by the United States (Smart, 1997). Other advancements were made in collective protection, decontamination, and detection. In 1984 US President Ronald Reagan issued a statement calling for an international ban on chemical weapons (Tucker, 2006). Subsequently, on June 1, 1990, President George H.W. Bush and Soviet leader Mikhail Gorbachev signed a treaty banning the production of chemical weapons and initiated the destruction of the stockpiles of both nations (Tucker, 2006). In 1993 the Chemical Weapons Convention was convened and signed, and it was implemented in 1997 (Hammond, 1994). As of 2008, the vast majority of UN member states had joined the Chemical Weapons Convention (OPCW, 2008).

In 1990 the Iraqi Army invaded neighboring Kuwait. Subsequently, the United States, at the request of Saudi Arabia, led a coalition to send forces to the area (Smart, 1997). These forces were the largest to operate in a potential chemical environment since World War I. They were provided with atropine autoinjectors, an acetylcholinesterase reactivator, and a nerve agent pretreatment

FIGURE 2.10 Aftermath of Iraqi chemical weapon attack (1980s).

(pyridostigmine bromide). Fortunately, chemical weapons apparently were not used in this conflict, although multiple false alarms were reported. The failure of the Iraqi military to use chemical weapons could be attributed to fear of retaliation, breakdown of communication, changing wind patterns, the surprising speed of the coalition attack, or the fact that Iraqi chemical infrastructure was attacked during the initial portion of the conflict. Since the conflict ended, many coalition veterans have reported a myriad of symptoms that have been commonly referred to as Gulf War syndrome. The etiology of this syndrome is unclear despite multiple epidemiological studies (Coleman, 2005). The most recent example of chemical weapons use is the ongoing Syrian Civil War (Pellerin, 2013). Both sarin and sulfur mustard have been reportedly been used in this conflict (Sezigen, 2019; Kilic et al., 2018).

2.9 Terrorist use

One of the reasons why chemical weapons have been used relatively infrequently in combat over the past century is the fear of retaliation by opposing countries. In less organized asymmetrical conflicts, this fear is not as dangerous. At the same time, the potential exploitation of chemical weapons by terrorists is of great worldwide concern (Kilic et al., 2018). The appeal of these weapons to terrorists lies largely in the fact that many of these chemical agents are cheap and relatively easy to produce, transport, and release. These characteristics, along with the fear associated with the idea of a chemical attack, make chemicals an ideal weapon for terror attacks (Romano and King, 2001). In 1974 Muharem Kurbegovic attacked several public buildings with firebombs in California and claimed to have developed sarin and some other nerve agents (Tucker, 2006). The search of his home resulted in the discovery of various precursor materials for chemical agents and a large amount of sodium cyanide. In 1994 the Aum Shinrikyo, a Japanese religious cult, carried out several attacks both in the subway and in residential areas using sarin produced by the cult's members (Tucker, 2006). A total of 19 people were killed, and over 6000 received medical attention, some of which suffered long-term neurological and behavioral deficits (Yokoyama et al., 1998). Some of those who sought medical attention may have done so due to a fear of exposure. Psychological stress is a common aftermath of a chemical or biological attack (Romano and King, 2001). In the 21st century, chemicals that once had been used exclusively by the military have reemerged as contemporary threats. In the fall of 2006, Al Qaeda and associated groups used chlorine combined with traditional car and truck bombings to spread panic in Iraq (Garamone, 2007). These attacks were followed by similar incidents in the subsequent months. There have also been reports of state-sponsored terrorist activities to eliminate individuals using chemical weapons as agents (Hersman and Pittinos, 2018) such as the use of the nerve agent, VX, to assassinate Kim Jong Nam, the brother of North Korean leader Kim Jong Un, at Kuala Lumpur international airport in 2017 (Bradley, 2017) and the use of a Novichok agent (an extremely toxic organophosphate nerve agent) in the poisoning of former Russian double agent Sergei Skripal and his daughter Yulia in England in 2018 (Peplow, 2018).

2.10 Concluding remarks and future directions

So long as there are legitimate uses for chemicals in our society, the risk of chemical agents in conflict and terrorist activity will always be present. Research continues across the globe for better detection, protection, and treatment of chemical agents. While many countries have denounced and are signatories to various treaties to limit the use and production of chemical warfare agents, nonstate and terror organizations are under no such restrictions. Luckily, chemical weapon use has been limited in both warfare and less formal conflicts. As we progress into the 21rst century, the use of established chemical warfare agents is a real possibility. The potential use of legitimate industrial chemicals (e.g., the Iraqi burning of petroleum fields in the first Gulf War) and the potential synthesis of new agents should also be recognized (Kilic et al., 2018). History has demonstrated that chemicals have been used in both organized and asymmetrical conflicts, and preparations for defense and therapy for such encounters is prudent. Despite the progress made during the past 100 years, chemicals represent a unique force multiplier that simply cannot be ignored in the 21st century.

3.1 Introduction

The threat of chemical weapons (CWs), used either by states or parties to the Chemical Weapons Convention (CWC; Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction) or by terrorists, has never attracted so much public attention as it has in the past 10 years. Despite the existing legal documents dealing with the prohibition of CWs, for example, Geneva Protocol 1925 and CWC, some incidents of the use of CWs in different conflicts and terrorist attacks have been observed. Moreover, the alleged use of CWs has been noted during the period from 1925 to the present. It must be emphasized that the theoretical and practical basis for production, storage, and use of CWs still exists. Also, it must be clearly stated that CWs are applicable at any time, in any place, and in large quantities.

CWs consist of chemical warfare agents (CWAs) and the means them to deliver to the target. They are characterized by high effectiveness for use against large targets and are known as area weapons or silent weapons. They are relatively low cost and it is possible to achieve destruction of everything that is living while avoiding the destruction of materials and buildings. They are also called the nuclear weapons of poor countries—a "poor man's nuclear weapon." It should be pointed out that the use of CWs is connected with the use or release of toxic chemicals; thus chemical warfare can be considered part of generally observed situations in which toxic chemicals are used or released and influence the environment and humankind.

A number of causal reasons for these events exist but, apart from accidents connected with the release of toxic chemicals from a natural source (e.g., volcanoes), the factors shown in Fig. 3.1 or their combinations can be involved.

For military purposes a number of chemicals were tested, but only a few are contained in military arsenals. However, according to the definition used by the CWC, any toxic chemical intended for military use must be considered a CW; in other words, the aim is to limit the designation of the compound in question for use as a CW. However, it is possible for terrorists to choose any chemicals with high toxicity.

3.2 Background

The use of toxic chemicals against humankind is as old as warfare. The use of the poisoned arrow against humans—not animals—can be considered as the beginning of chemical warfare and is characterized as the intentional use of chemicals.

At the very beginning, chemical warfare was more closely connected with fire. "Greek fire" was an excellent naval weapon because it would float on water and set fire to wooden ships. There are other examples from history; for example, toxic smoke was used in China in 2000 BCE. In Thucydides' *History of the Peloponnesian War* (the 5th century BCE war between Athens and Sparta), we find the first description of chemical warfare—the formation of toxic sulfur oxide by burning sulfur. In the year 184 BCE, Hannibal of Carthage used baskets with poisonous snakes against his enemy. Both Socrates and Hamlet's father were poisoned with coniine. Aqua Toffana containing arsenic was also a known poison in ancient Italy. Leonardo da Vinci proposed a powder of arsenic sulfide in the 15th century. There are many more

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00003-9

examples of the use of CWAs (Bajgar et al., 2007b). Modern history shows us that terrorists have used other chemicals, such as ricin (the Bulgarian, G. Markov, was poisoned in 1978) or dioxin (the President of Ukraine, Viktor Andriyovych Yushchenko, was poisoned in 2004).

In a region of Bohemia, a "form" of CW was used as early as 600 years ago. It was in 1422 that the castle of Karlstein, the property of King Charles IV, was besieged and 1822 kegs containing matter from the cesspools of the streets of Prague were hurled into the castle. Allegedly, the stench in the castle was unbearable. According to historical sources, the castle defenders were probably intoxicated with hydrogen sulfide released from the contents of the cesspools and therefore they showed typical symptoms of poisoning (Bajgar, 2006).

There were some attempts to prohibit CWs by international agreement or law. Most early attempts were bilateral or unilateral agreements directed at the use of poisons. These included the 1675 agreement between France and Germany, signed in Strasbourg, to ban the use of poison bullets.

The first international attempt to control chemical and biological weapons took place in Brussels in 1874, when the International Declaration was signed and included a prohibition against poison and poisoned arms. Despite the first and second Brussels and Hague Conventions (1899 and 1907 signatories agreed not to use projectiles that could spread asphyxiating or deleterious gases), the world witnessed the application of chemicals during warfare to an unprecedented extent during World War I (WWI). A brief summarization of the events connected with the use/release of toxic chemicals is given in Table 3.1.

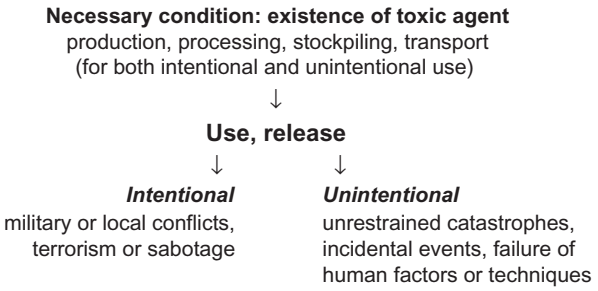

FIGURE 3.1 Possible reasons for release/use of toxic chemicals.

TABLE 3.1 Some milestones related to the use/release of CWs and toxic chemicals.

Year(s)	Event
2000 BCE	Toxic smoke in China inducing sleep
4th century BCE	Spartacus—toxic smoke
184 BCE	Hannibal—baskets with venomous snakes
1168	Fustat (Cairo)—use of "Greek fire"
1422	Bohemia region—cesspools (H_2S)
1456	Belgrade—rats with arsenic
19th century	Admiral Dundonald—proposed the use of chemicals in war
1914–18	WWI—start of chemical war
1918–39	Development of new CWs and protective means
June 17, 1925	Geneva Protocol
December 23, 1936	Lange and Kruger—synthesis of tabun
1940–45	Concentration camps—cyanide
1943	Synthesis of sarin
1943	Hoffmann and Stoll—synthesis of LSD-25
1945	Kuhn—synthesis of soman
1950	V agents are invented

TABLE 3.1 (Continued)

Year(s)	Event
1962	BZ was introduced into military arsenals
1970	Bicyclic phosphates considered as potential CWAs
1976	Seveso—release of dioxin
1980	Some rumors on intermediate volatility agent
1984	Bhopal incident—release of methylisocyanate
1985	Decision on production of binary CWs
1986, 1987	Demonstration of US CWs (Tooele) and Soviet Union CWs (Shikhany) to the CD in Geneva
1987	Production of binary CWs
1988	Halabja—use of mustard
1980–90	Rumors of new nerve agent Novichok
1989	Conference on chemical disarmament, Paris
1991	Persian Gulf War—veteran's syndrome
1992	BZ military stocks of the United States were destroyed
1992	Finalization of the rolling text of the CWC at the CD—Geneva
1993	Signing CWC in Paris
1993	Preparatory Commission on OPCW
1994	CWs of Iraq were destroyed
1994	Aum Shinrikyo—sarin attack in Matsumoto
1995	Aum Shinrikyo—sarin attack in Tokyo
April 29, 1997	CWC—entry into force; establishment of OPCW in The Hague
2000	Research on nonlethal weapons intensified
2002	Moscow theater—fentanyl derivatives used against terrorists
April 29, 2012	CWs of the state parties to the CWC to be destroyed but it was prolonged; this period varies from 2015 to 2023 years
August 2013	Syria—use of sarin
February 2017	Kim-Chang Nam assassination by V-type agent at Kuala Lumpur airport
March 2018	Skripal and his daughter, percutaneous intoxication by Novichok, Salisbury
September 2018	Destruction of Russian CWs completed

3.3 Military use of chemical weapons

The intentional use of CWs for military purposes can be found in both global and local conflicts. A typical example is the warning "Gas! Gas!" This was common in WWI and it is well known from the E.M. Remarque novel *All Quiet on the Western Front* in which Remarque describes a chemical attack with chlorine.

During WWI, many chemicals were used, including mustard and asphyxiating and irritant agents. Approximately 45 types (27 more or less irritating and 18 lethal) of toxic chemicals were used. During the latter part of 1914, irritants were used by Germany and France; the effect was insubstantial. In late 1914, Nobel Prize winner Fritz Haber of the Kaiser Wilhelm Physical Institute in Berlin (chemical synthesis of ammonium in 1918) came up with the idea of creating chlorine, although this idea of using toxic chemicals in war was expressed by Admiral Dundonald as early as 1855. Chemical warfare really began in 1915, when German troops launched the first large-scale poison gas attack at Ypres, Belgium, on April 22, using 6000 cylinders to release 168 tons of chlorine gas, killing 5000 British, French, and Canadian soldiers. This date is recognized as

"the birthday of modern chemical warfare," and thereafter the belligerent parties frequently used chemical gases against each other. Phosgene was introduced by Germany in late 1915. Soon after the first chlorine attack, the Allies used primitive emergency protective masks. In May 1916, the Germans started using diphosgene, while the French tried hydrogen cyanide 2 months later and cyanogen chloride the same year. The first time mustard gas was used by German troops was July 12, 1917. After its use near Ypres, it was also called yperite.

By the end of WWI, approximately 124,200 tons of CWAs (chlorine, phosgene, mustard, etc.) had been released, causing at least 1.3 million casualties, of which more than 90,000 were fatal. The threat of the use of CWAs led to the development of protective means not only for humans but also for horses and dogs. The effectiveness of CWs in comparison with classic munition was evident: 1 ton of classic explosives caused 4.9 casualties; 1 ton of chemical munitions caused 11.5 casualties; and 1 ton of yperite caused 36.4 casualties (Bajgar, 2006).

3.4 The period between World War I and World War II

The terrible casualties from the CWs used during WWI and the dangerous consequences for humans and the environment led to the signing of the "Geneva Protocol for the Prohibition of the Use in War of Asphyxiating, Poisonous and other Gases and Bacteriological Methods of Warfare" on June 17, 1925. This is recognized as one of the unique and famous international treaties on the prohibition of CWs. However, it neither comprises provisions for effective verification nor prohibits the development, stockpiling, and transfer of CWs. Moreover, no definition of CWs was included. Despite the provisions of the Geneva Protocol, during 1935–36 Italian troops used CWs during their invasion of Abyssinia (Ethiopia). This first major use of CWs after WWI came after October 3, 1935, when Mussolini launched an invasion of that country. Despite the Geneva Protocol (Italy had ratified in 1928), the Italians used mustard gas with horrible effects. Later, CWs were used between Japan and China during 1937–45. The Japanese attacked Chinese troops with mustard gas and lewisite. The Japanese, in addition to their biological program, had an extensive CWs program and were producing agents and munitions in large quantities by the late 1930s.

3.5 World War II

Despite the storing and stockpiling of CWs by the great powers engaged in World War II (WWII), these fatal weapons were not significantly used (except small examples) during WWII (probably because of the fear of massive retaliatory use of CWs). An example of intentional use, but not during military conflict, was the killing of prisoners in concentration camps in Nazi Germany. The agent first used in the camps was carbon monoxide, followed by the more "effective" hydrogen cyanide released from Zyklon B. Some experiments with aconitine-impregnated shells and some other toxic compounds including biological agents were tested on prisoners.

However, during WWII, an important step in the preparation of the most dangerous CWA was observed in Germany. In Schrader's group, organophosphates (Ops) were synthesized, primarily with the aim of obtaining more effective insecticides. Between 1934 and 1944, Schrader's team synthesized approximately 2000 Ops, including two well-known OP compounds, parathion and paraoxon. As early as 1935, the government of Nazi Germany insisted that Schrader switch the primary aim from OP insecticides to CWAs. Presently, Ops are widely used in agriculture, medicine (human and veterinary), and industry. These compounds also include nerve agents (the most toxic compounds of the OP group). Nerve agents such as sarin, tabun, soman, and VX are the main compounds of CWAs. The Germans were also the greatest producers of nitrogen mustard and produced approximately 2000 tons of HN-3.

This part of history is well known (Koelle, 1963, 1981; Bajgar, 2006; Tuorinsky and Lenhart, 2008; Klement et al., 2013). The first synthesis of OP was described in the second half of the 18th century. For a long time the first OP (its toxicity was described later) was considered to be TEPP, which was synthesized by Clermont (1854–55). Philippe de Clermont was a well-known chemist in Sorbonna. Charles Adolph Wurtz dedicated his work to the synthesis of esters of pyrophosphoric acid. These data were specified by Petroianu (2008), and thus he contributed to the discovery that the first synthesis of this OP—TEPP—was performed by Vladimir Moshnin of Moscau. These data are depicted in the work of Patočka (2010). New trends in the synthesis of nerve agents have been described by Halamek and Kobliha (2011).

Tabun was synthesized in 1936, followed by others (sarin at the end of WWII, followed by soman), and production of these agents for the military in large quantities and their stockpiling were recognized after WWII in Dyhernfurth, Poland (e.g., stocks of tabun and some quantities of sarin). The technology was subsequently transferred to Russia, and research and development of new OP nerve agents was continued. During this period, British and American scientists were evaluating the toxic properties of DFP.

3.6 The period after World War II, and the Cold War

At the end of WWII, many Allied nations seized the German CWs. Most of the CW manufacturing plants in

Germany were taken over and moved to new sites in Russia, such as the military area of Shikhany. This "take-over" prompted other states to begin even more research into CWs. Despite the Allies' own research into CWs, very important technologies and "know-how" were obtained from Nazi Germany for both the United States and the former Soviet Union.

The interest in CW technology was probably one reason for the change to the future border: according to Churchill's history of WWII, the proposed future boundary between Poland and Germany had been primarily agreed to consist, in part, of the Oder River flowing to the Baltic Sea, and its tributary, the Neisse River. Before their confluence, the Neisse consisted of two branches, the East Neisse and the West Neisse. The East Neisse should be the boundary, resulting in slightly more territory for Germany. Stalin held for the West Neisse and progress was delayed. No one knows why Stalin was so insistent in this matter. The reason was probably very simple: the small town of Dyhernfurth (now Brzeg Dolny), a few kilometers north of Breslau (Wroclaw) in the disputed territory, contained a factory for the production of nerve agents. It was estimated that when Dyhernfurth was captured it contained stockpiles of 12,000 tons of tabun, 600 tons of sarin, and an unknown amount of soman. Presumably, the factory was dismantled and, along with their stockpiles, transported to the Soviet Union (Koelle, 1981). It has been documented that the Soviets were ready to conduct a chemical attack and their research and development of CWs were intensified.

In the United States, during the 1950s, the chemical corporations concentrated on the weaponization of sarin. At the same time, they became interested in developing CWs that incapacitated rather than killed the targets. Mescaline and its derivatives were studied but without practical output. Five years later, the new project "Psychochemical Agents" (later K-agents) was established. The objective was to develop a nonlethal but potent incapacitant. Nonmilitary drugs like LSD-25 and tetrahydrocannabinol were also examined. None of these agents was found to be of military importance. The first and only incapacitant was BZ, developed in 1962; however, its stocks were destroyed in 1992, as declared by the US delegation to the Conference on Disarmament in Geneva (Document of CD, 1991). These agents, intended not to kill but to induce incapacity, are covered under the class of nonlethal weapons (Hess et al., 2005).

In the former Soviet Union as a whole, during 1940–45, approximately 110,000 tons of first-generation toxic chemicals were produced, and most of these were yperite, lewisite, and irritating agents. Second-generation CWs were composed of nerve agents such as sarin, soman, V agents, and, to a lesser degree, tabun. The development of new third-generation CWs comprised traditional and nontraditional CWs, for example, blister and irritant agents and nerve gases, including new types such as Novichok 5, whose exact chemical structure is unknown, although some assessments have been made (Bajgar, 2006). It could be a nerve agent having high toxicity, and its effects are difficult to treat using common antidotes.

An example of the unintentional use of CWs has also been observed. In March 1968, thousands of dead sheep were discovered in the Skull Valley area in Arizona in the United States. This area was adjacent to the US Army's Dugway open-air testing site for CWs. Nerve gas had drifted out of the test area during aerial spraying and killed the sheep. One year later, on July 8, 1969, the Army announced that 23 US soldiers and one civilian had been exposed to sarin in Okinawa during the clearing of sarin-filled bombs (Sidell et al., 1997).

There are a number of examples of localized conflicts during which CWs have been intentionally used but cannot be verified: from 1951 to 1952 during the Korean War; in 1963 the Egyptians used mustard bombs against Yemeni royalists in the Arabian peninsula; during the Indo-China War (see Vietnam War); in 1970 in Angola, antiplant agents were almost certainly used; and in the former Yugoslavia, there were rumors of the use of psychotomimetic agents.

3.7 Iraq–Iran War and the Afghanistan War

On September 22, 1980, Iraq launched its invasion of Iran. There has been mention of the large-scale use of CWAs in the Iran–Iraq war. In November 1983, Iran informed the United Nations that Iraq was using CWs against Iranian troops. Soon after, the use of CWs was unleashed; in addition, mustard and tabun were used. It is well known that the Iraqi government used these agents against its own citizens, more conspicuously at Halabja in March 1988. This CW attack was the largest against a civilian population in modern times. More than 100,000 Iranians were poisoned with CWAs; sulfur mustard was the most frequently used and induced a number of delayed complications in Iranian veterans (pulmonary, dermal, ocular, immune system depression, reproduction, malignancy, etc.) (Afshari and Balali-Mood, 2006). Other localized conflicts involving alleged use of CWs are described in detail in an extensive review (Robinson, 1971).

The Soviet Union probably used mustard (and nerve gas) in Afghanistan. The Afghanistan War was considered the Soviet Union's "Vietnam." The use of CWs was described by Sidell et al. (1997). The use of CWs by Soviet forces was also significant and has been confirmed

against unprotected subjects. Despite the use of CWs, the withdrawal of Soviet troops from Afghanistan began at the start of 1989.

3.8 Vietnam War

After WWII, the main use of CWs was recorded during 1961–72, when the US Army used defoliants. The herbicide Agent Orange was used during the Vietnam War and led to the injury of more than 1 million Vietnamese and Americans. Agent Orange (a mixture of 2,4-dichlorophenoxy acetic acid and 2,4,5-trichlorophenoxy acetic acid) contained the chemical contaminant dioxin as an impurity that caused many deaths on both sides. There were also other herbicide mixtures, such as Agent White (2,4-D and picloram) and Agent Blue (cacodylic acid). The biological effects of dioxin were described by Sofronov et al. (2001). The first major operation of this type was conducted over the Ca Mau peninsula during September–October 1962. The areas sprayed with defoliants were 5 times larger and 10 times larger in 1965 and 1967, respectively. The scale of the use of defoliants was approximately in proportion to the overall involvement of US troops. In 1970 herbicides and defoliants were used in tens of tons, especially 2,4,5-T. The area sprayed grew from 23 km^2 in 1962 to 22,336 km^2 in 1969. The area exposed to spraying was assessed to be 58,000 km^2 and the number of people exposed was assessed to be more than 1 million; there were more than 1000 deaths. In addition to defoliants used to destroy vegetation concealing the North Vietnamese, the United States used tear gas for clearing tunnels and bunkers. The irritants CS, CN, and DM were reported to have been used. The total CS procured was approximately 7000 tons from 1963 to 1969.

3.9 Development of VX agent

VX was synthesized in the 1960s on the basis of the results of Tammelin and Aquilonius (Tammelin, 1957; Aquilonius et al., 1964). The manufacturing of VX began in the United States in 1961. Construction of the United States' VX agent production plant at Newport, Indiana, was completed in 1961, when the first agent was produced. The production facility only operated for 7 years and was placed on standby in 1968 (Smart, 1997).

During the same period, Soviet scientists developed the so-called Russian VX (VR, RVX, R 033) (Kassa et al., 2006; Kuca et al., 2006). The chemical structure of VX was unknown for a long time. Therefore some attempts to resolve this question have been made (Bajgar, 1968). Because of these ambiguities and difficulties in synthesis, model V agent [EDMM, *O*-ethyl *S*-(2-dimethylaminoethyl) methylphosphonothioate] was initially used in the Eastern Bloc to study antidotal treatment. Another structural analog of VX, known as Chinese VX (CVX), was also developed and studied (Eckert et al., 2006).

A very important step in the development of CWs has been the production of "binary munitions," in which the final stage of synthesis of the agent from precursors is performed in the munition (bomb, shell, or warhead) immediately before or during delivery to the target. In the 1950s, armed forces had begun looking at binary weapons. Until this time, CWs were unitary—the toxic agent was filled in the munition and then stored ready to be used. The binary concept—mixing or storing two less toxic chemicals and creating the nerve agent within the weapon—was safer during storage. The production of binary projectiles began on December 16, 1987, at the Pine Bluff Arsenal in Arkansas.

3.10 Persian Gulf War

On August 2, 1990, Saddam Hussein sent Iraqi troops into Kuwait, allegedly in support of Kuwaiti revolutionaries who had overthrown the emirate. Iraq was known to have a large stockpile of CWs during its conflict with Iran and confirmed that they would use CWs.

President George H.W. Bush ordered US forces to be sent to Saudi Arabia at the request of the Saudi Government (Operation Desert Shield); this was the build-up phase to the Persian Gulf War. As a consequence, in 1996, almost 60,000 veterans of the Persian Gulf War claimed certain medical problems related to their war activities. Some were caused by exposure to nerve agents (released after the bombing and destruction of the sarin production facility). Unexplained "Gulf War syndrome" with low-dose exposure to CWAs was suggested as a possible cause. Extensive research failed to find any single cause of the problem. However, some health effects, including alterations to the immune system 3 months after exposure to low concentrations of sarin, were demonstrated (Kassa et al., 2001, 2003). In the desert, during the autumn and winter of 1990–91, the threat of chemical warfare became very real to allied military personnel. It was demonstrated by the UN Commission that major Iraqi agents included mustard, tabun, sarin, and cyclosarin. Mustard agent was relatively pure, but nerve agents were a complex mixture of the agent and degradation products. During the period from June 1992 to June 1994, the Commission's Chemical Destruction Group destroyed 30 tons of tabun, 70 tons of sarin, and 600 tons of mustard, which were stored in bulk and in munitions.

Suddenly, it became clear to the whole world that there were countries with CWs and biological weapons, and there were other countries that might obtain or produce them.

3.11 Syria

The conflict in Syria has been the most recent conflict in which the use of CWs was confirmed by the UN Mission (UN, 2013). Nerve agent sarin was used in an attack on the Ghouta area of Damascus (August 21, 2013). It is not the intention of this chapter to evaluate political situations; however, it was not possible to decide exactly who used sarin (current government or FSA) against civilian victims. The first complex reactions were published in October 2013 in the CBRNe World (Higgins, 2013; Johnson, 2013; Kaszeta, 2013; Winfield, 2013). For the Mission, these were not ideal conditions: difficult political situation, chaotic scene, and timing that was not ideal. However, the report was well-structured and conclusions were clear: sarin was present in some samples and rocket remains, and selected survivors showed symptoms supporting sarin exposure (Johnson, 2013).

There are different data regarding the number of victims, initially varying from hundreds to thousands. The Syrian Observatory for Human Rights reported more than 500 deaths and thousands of patients displaying "neurotoxic symptoms," including civilians and children. Medicine Sans Frontiers said at least 3600 patients had these symptoms and, of those patients, 355 had died. The UN Mission selected 36 of 80 survivors who met the criteria established by the Mission. Symptoms consistent with organophosphate intoxication were observed: decreased consciousness (78%), dyspnea (61%), blurred vision (42%), eye irritation or inflammation (22%), lacrimation (8%), miosis (14%), salivation (22%), vomiting (22%), and convulsion (19%). Johnson (2013) did not mention the postmortem samples or data regarding dead persons. The treatment of victims and the course of poisoning, including laboratory results, have not been specified. However, laboratory examinations would be useful, as in the case of Tokyo victims (Polhuis et al., 1997). It would be possible to use other methods of laboratory diagnoses of nerve agent intoxication, as described previously (Noort et al., 2009; Schans van der and Gupta, 2009; Bajgar, 2013). Autopsies of victims were not conducted but would have been useful, as would postmortem examinations of dead animals. Regarding CWs in Syria, they will be destroyed under the supervision of the Organization for Prohibition of Chemical Weapons (OPCW) (for Syria, CWC entered into force on October 14, 2013) and with international assistance.

3.12 Unintentional use of toxic chemicals

There have been two main accidents connected with the release of toxic chemicals. In July 1976, in Seveso, Italy, more than 40,000 people were exposed to dioxin, a persistent and highly toxic chemical. The first signs were skin lesions appearing on children, and after some months there was evidence of chloracne. Health consequences have been observed from that time to the present. The Seveso accident was possibly the most systematically studied dioxin contamination incident. A similar contamination of one building of the Spolana company in Neratovice (a town in the former Czechoslovakia) was also observed (Bajgar et al., 2007a; Pelclová et al., 2011). Another example, the Bhopal accident, is probably the greatest industrial disaster in history. In 1984 on December 2 and 3, water inadvertently entered the methylisocyanate storage tank (containing approximately 40 tons of this chemical). As a result, methylisocyanate was released into the surrounding area. There was no warning. Many people who inhaled high concentrations of toxic gas asphyxiated because of extensive lung damage. Approximately 150,000 people were intoxicated (50,000 seriously poisoned) and more than 2500 people died (Bajgar, 2006).

3.13 Terrorist use of chemical weapons

Terrorists have expressed an interest in nerve agents and have deployed them in attacks on unprotected civilians (Rotenberg and Newmark, 2003). A Japanese religious cult, Aum Shinrikyo, independently manufactured numerous chemical and biological agents. The first such attack with sarin occurred in Matsumoto in 1994 and in the Tokyo subway in 1995. Thousands of people were affected and dozens of people died (Ohtomi et al., 1996; Nagao et al., 1997; Okomura et al., 1998; Yokoyama et al., 1998). In Matsumoto (1994), 600 people were poisoned and hospitalized, and seven died (Morita et al., 1995; Nakajima et al., 1997; Yoshida, 1994). The attack in the Tokyo subway (1995) resulted in 5500 people seeking hospital evaluation and 12 deaths (Bajgar, 2006). An interesting terrorist act was described by Tsuchihashi et al. (2005)—a fatal intoxication with VX administered percutaneously.

Nerve agents belong to the group of OPs. These compounds in the form of pesticides are commercially available and are used in agriculture, which can lead to professional, suicidal, or accidental intoxication. The mechanism of action, diagnosis, and treatment of intoxication with OP pesticides and nerve agents are very hot topics at present. Moreover, some principles of the effects, diagnosis, and therapy are very similar for OP and highly toxic nerve agents; therefore the principle of action and effective treatment can also be applied in general for the civilian sector.

The use of these chemicals was observed in Moscow in 2002. A Moscow theater hostage crisis resulted in the seizure of a crowded theater on October 23, 2002, by approximately 40 armed Chechen militants who claimed

allegiance to the separatist movement in Chechnya. They took 850 hostages and demanded the withdrawal of Russians from Chechnya and an end to the war in Chechnya. The leader of the terrorists was 22-year-old Movsar Baraev. After 2.5 days of waiting, Russian forces used an unknown gas that was pumped into the ventilation system. Officially, 39 terrorists and at least 129 of the hostages (nine of them foreigners) were killed. Some estimates have put the civilian death toll at more than 200. It was thought that the security services used an aerosol of a CWA, first assessed as BZ, but later it was specified that an aerosol anesthetic of the fentanyl type was used (Bajgar and Fusek, 2006).

In hospitals, the survivors were cut off from any communication with the outside world and their relatives were not allowed to visit them. An incorrect list of hospitals for victims was released. The main problem was the lack of information about those dealing with the identification and characterization of the chemical used and the unavailability of known antidotes (e.g., naloxon) by medical staff treating the victims (Bajgar et al., 2007a). It appeared from this event that there were compounds not explicitly enumerated in the CWC and therefore not controlled by this Convention. Fentanyl can be considered as a nonlethal weapon (a group of so-called calmatives) and these chemicals can also be used to incapacitate animals; of course, its use against humans is not excluded (Bajgar, 2006; Hess et al., 2005).

3.14 Negotiations

Although the Cold War was continuing, the political situation led to increased activities in international negotiations. At the Conference on Disarmament in Geneva, some attempts to negotiate a ban of CWs were begun, first as an ad hoc Working Group, and later as an ad hoc Committee on Chemical Weapons with the mandate to negotiate the text of a convention banning CWs.

The discussions in Geneva were more intensive from 1987 and, in 1992, the elaboration of the so-called rolling text of future CWCs was finished. During these negotiations, the text of future Conventions ("rolling text") was enlarged: the final report (CD/342) of February 2, 1983, contained 23 pages; the same report of August 23, 1985 (CD/636), had 46 pages; and CD/952 of August 18, 1989, contained 134 pages. Simultaneously with the Geneva negotiations, in September 1989, the Memorandum of Understanding between the Governments of the United States and the USSR regarding a bilateral verification experiment and data exchange related to the prohibition of CWs, otherwise known as the Wyoming Meeting, started negotiations between the two main possessors of CWs. These countries also contributed to the negotiations in Geneva: they demonstrated their CWs to the Conference on Disarmament in the United States in November 1986 (Tooele) and in the USSR in October 1987 (Shikhany). The final document of the Convention is approximately 200 printed pages. The Convention was then agreed on in New York at the UN General Assembly and signed in Paris in 1993. The CWC (Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction) entered into force on April 29, 1997, 180 days after the deposit of the 65th instrument of ratification of the Convention by Hungary. At this time, 87 countries ratified the CWC and became original state parties to the Convention. Simultaneously, the OPCW in The Hague started its work of supervising the destruction of CW stocks and monitoring the world's chemical industry to prevent future misuse. There are many activities of the OPCW, for example, training of inspectors for control of destruction of CWs including their medical protection, research, and supported activities, solving problems due to practical implementation of the CWC, control of chemical and military facilities, and other activities. Russia and the United States were unlikely to meet the final stockpile destruction deadline of April 29, 2012. By the middle of 2008, 183 signing states and 194 recognizing states had adhered to the Convention (Davey, 2008). However, there are still states that are nonsignatories to the Convention. CWs have a long and ancient history. A lack of CW use in WWII suggested that "gas warfare" had ended. However, further development and the utility of chemicals in Vietnam and in terrorist attacks have maintained the military interest in CWs.

Current information of OPCW provides the status of the destruction of CWs. April 29, 2012, was suggested to be the prolonged period for CW destruction. Seven state parties declared they possessed CWs (Albania, India, Iraq, South Korea, Libya, Russia, and the United States). The stocks of Albania, India, and South Korea were destroyed. To this date, 73.72% of all declared CWs (a total of 71,195.086 tons) had been destroyed (Streda, 2013). On the basis of the Conference of the State Parties (16th Session, December 2011), the destruction period was prolonged for Russia (2015), Libya (2016), and the United States (2023). Simultaneously, CW-producing facilities were also destroyed or dismantled—13 state parties declared 70 of these facilities (Bosnia and Herzegovina, China, France, India, Iraq, Iran, Japan, South Korea, Libya, Russia, Serbia, Great Britain, and the United States) and 43 of these objects were destroyed and 21 were dismantled for peaceful purposes.

It is clear that the use (incidental or otherwise) of toxic chemicals has impacts on different spheres of human existence, such as state structures and infrastructure, economics, psychic and public behavior, and the environment. Toxic chemicals are a great consumer of

natural sources, both renewable and nonrenewable. They also consume raw materials and energy and, as a consequence, cause pollution of the environment and lead to a deficiency of raw materials throughout the world and therefore an unequal distribution of the world's natural sources. The impact on the psychology of humankind is also important, following either chemical wars (both global and local) or use of these chemicals by terrorists. The development of new technologies is equally important because they influence, positively and negatively, further human development. Research in this direction not only can contribute to "improvement" of chemicals to obtain more effective CWAs but also can improve our knowledge of basic sciences (toxicology, neuropharmacology, etc.) and allow us to better understand physiological functions in general. It is appropriate to recall the history of cholinesterases and their inhibitors. The existence of cholinesterases was predicted by H.H. Dale in 1914, 14 years before acetylcholine was demonstrated as a natural constituent of animal tissues. This research approach was changed during WWII and cholinesterases acquired a special significance in the context of chemical warfare and nerve agents (Silver, 1974). Another publication in this area (Koelle, 1963) can be considered as the first to deal with anticholinesterase agents including CWAs—nerve agents. One can only hope that in the future the only physiological and pharmacological research will be performed in a nonmilitary framework, but that may not be the case.

3.15 Concluding remarks and future directions

The threat of the use (either military or terrorist) of CWAs (and other toxic chemicals) still exists. The military use of these agents is limited, but their terrorist use is unlimited. The spectrum of these agents is very large and the ability to be prepared against the use of toxic chemicals is necessary.

Acknowledgment

This work was supported by a grant from the Ministry of Defense (Czech Republic) called "A long-term organization development plan 1011." Also supported by the UHK long-term development project.

Chapter 4

Sarin attacks in Japan: acute and delayed health effects in survivors

Chapter 4.1

Part 1 Sarin attacks in Japan: acute and delayed health effects in survivors of the Matsumoto incident

Tamie Nakajima

Department of Life and Health Sciences, Chubu University, Kasugai, Japan

4.1.1 Introduction

Sarin, isopropyl methylphosphonofluoridate, is an organophosphate agent which is highly toxic and considered to be a lethal chemical warfare agent. It was infamously used against the Kurdish community in Iraq, which was substantiated by analysis of samples obtained from ruptured munitions from the mountainous region of northern Iraq (Black et al., 1994; Black, 2009).

4.1.2 Matsumoto sarin incident

On the night of June 27, 1994, 9 months before the Tokyo subway incident, a terrorist released 12 L of high-purity sarin vapor in a residential area of Matsumoto City, Japan, using a heater and fan and a remodeled truck (Nakajima et al., 1998a; Morita et al., 1995). It was rainy with a 0.6−1.8 m/s wind from the southeast in the area. Seven persons who lived near the district where sarin was released died, with another dying later, but many victims were hospitalized and consulted doctors. Common features among these victims were a decrease in miosis and decreased serum acetylcholine esterase (S-AChE) level, which are symptoms often observed in exposure to organophosphorus chemicals. Six days after the incident, the causative agent was reported to be sarin.

Questionnaire surveys were conducted for 2052 persons living around the sarin-released area and rescue team 3 weeks after the sarin incident (Nakajima et al., 1997, 1998a). There were 1743 respondents (84.9%), and the follow-up questionnaire study for this cohort was conducted at 4 months, 1, 3, and 5 years after the sarin incident (Nakajima et al., 1999). The first study revealed that 76% of sarin victims were inhabitants in the block separated by postal code where sarin was released; the prevalence was broken down by region with 44%−47% in the north, 72% in the northeast, 47% in the east, and 35% in the south locations. There were an estimated 600 victims, including eight who died (five men and three women). All victims were distributed in an area of 800 m north to south and 570 m east to west, including the point of sarin release. The majority (80%) of victims were located in an elliptical area with a 400-m long axis northeast of the site. All eight persons who died, and all hospitalized victims, were located in this area. Thus, sarin was distributed according to the wind direction. Other victims were distributed outside of the elliptical area, but experienced only minimal symptoms not requiring medical consultation.

Distribution by the time of onset of sarin symptoms was bimodal: the first peak was between 11:00 and 12:00 p.m. on the 27th of June, and the second peak was between 8:00 and 9:00 a.m. the next day (Fig. 4.1.1). Compared to the second peak, sarin victims who felt the symptoms during the first peak were younger and with more severe symptoms, all required hospitalization, a higher percentage were outpatients, and all lived in the elliptical area with a 400-m long axis. Victims in the second peak did not feel severe symptoms like the hospitalized ones, but no significant difference was observed between the numbers of victims and the distance of their home from the site where sarin was released.

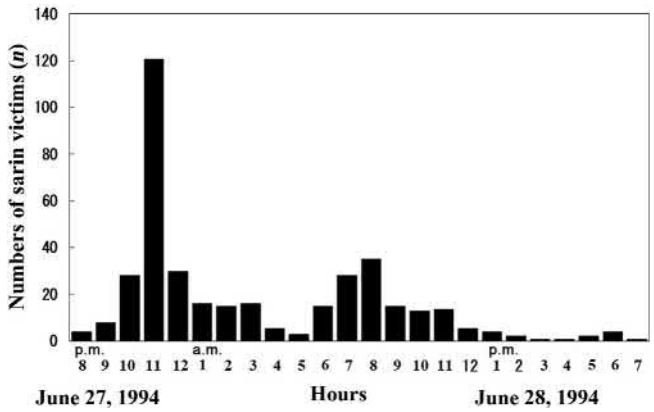

FIGURE 4.1.1 Distribution by time of the symptoms onset in sarin-exposed victims. Abscissa axis represents the time of symptom onset and spindle axes represents the number of victims reporting first onset of symptoms.

One month after the sarin incident, a medical checkup survey was conducted for applicants (155 persons: 68 men and 87 women) who requested it in the first questionnaire survey. In this survey, S- and E-AChE activities were also measured. The pupil diameter in sarin victims was smaller compared with persons who had not suffered from sarin intoxication, even 4 weeks after exposure. S- and E-AChE activities were also lower in sarin victims than nonvictims. Significant differences were also observed in both test results among inpatients, outpatients, and patients without a medical consultation. Therefore, pupil diameter and AChE activity, especially E-AChE activity, are excellent biomarkers to determine the severity of sarin poisoning.

4.1.3 Acute impacts

In the early stage after the sarin attack, victims felt symptoms which disturbed the nose and respiratory organs, such as sneezing, rhinorrhea, nasal voice, sore throat, coughing, dyspnea, and eye abnormalities such as darkness and narrowing of the visual field, flickering of vision, ocular pain, increased lacrimation, blurriness of vision, and diplopia (Fig. 4.1.2). These symptoms were caused by the muscarinic effects of sarin. In addition to these symptoms, the more severely affected victims were inpatients who felt headache, nausea, vomiting, dizziness, dysesthesia of the extremities, muscle cramp, gait disturbance, paresis of perioral muscle, dysphagia, and fatigue. The symptoms of dysesthesia of extremities, gait disturbance, and fatigue were reported to be caused by the nicotinic effects of sarin (Sidell, 1974).

The frequency of early symptoms associated with sarin poisoning decreased over time. Three weeks after the exposure, symptoms caused by muscarinic effects of sarin quickly resolved, and the most prominent complaint was dysesthesia of the extremities, suggesting that sarin affects the peripheral nervous system. However, this symptom was not observed 4 months after exposure, and none of the victims showed any abnormalities in nerve conduction studies. Symptoms reported immediately after sarin intoxication in victims resolved 4 months later. Contrary to these phenomena, the complaint of asthenopia began to occur in victims with lowered E-AChE activity at 4 weeks after intoxication. It is noteworthy that the frequencies of this complaint further increased at 4 months after intoxication and it was still present after 1 year, although E-AChE activity had returned to normal levels. The symptoms of fatigue increased again and new reports of asthenia rose after 1 year.

4.1.4 Long-lasting complaints

A questionnaire survey of sarin exposure-related symptoms was conducted for the first survey cohort at 3 ($n = 1237$, 60.3%; victims = 318; nonvictims = 919) and 5 years after the sarin incident ($n = 838$, 40.8%; victims = 169; nonvictims = 669) (Nakajima et al., 1999). E-AChE activity 4 weeks after the sarin incident was compared between persons who had and did not have symptoms associated with sarin exposure after 1 year. The E-AChE activity in those exhibiting symptoms of fatigue, asthenia, and asthenopia were lower than those who were asymptomatic; this suggests that these symptoms were observed in persons who had more severe sarin intoxication. The locations of subjects who were symptomatic 1 year after sarin exposure were mapped by postal code. Almost all symptomatic people were located in an elliptical area with a 400-m axis northeast of the sarin release site.

Three years after the sarin incident, 46 (27.2%) victims had one or more symptoms, whereas only 36 (5.4%) nonvictims had one or more symptoms, indicating that there were more symptomatic individuals in the victim

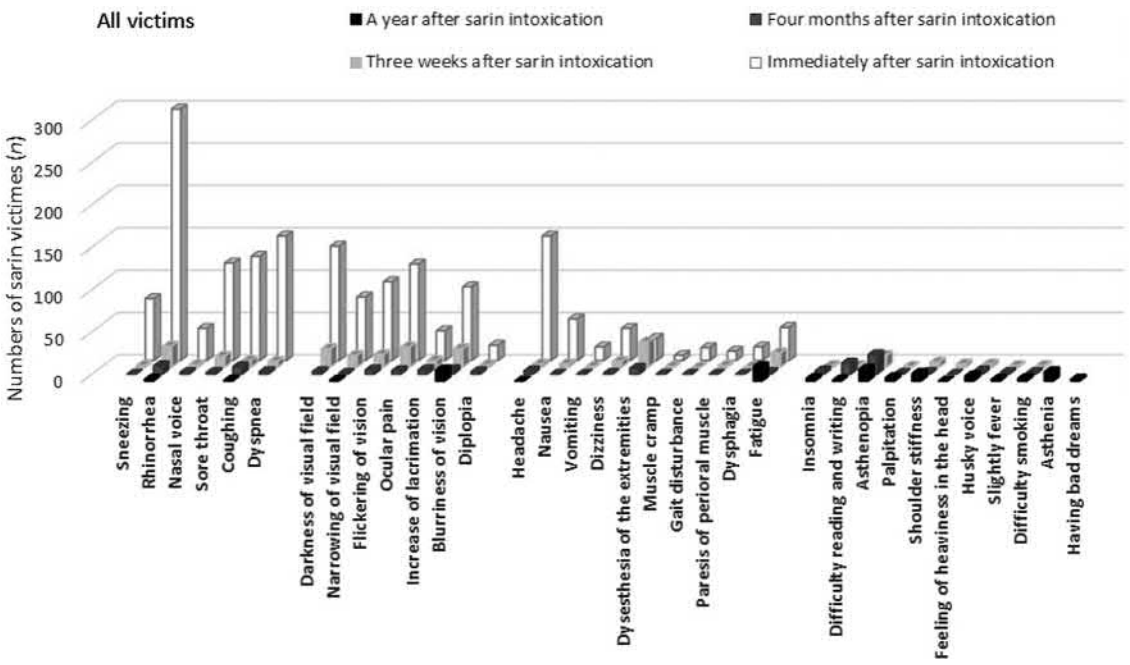

FIGURE 4.1.2 Transition of each symptom immediately, at 3 weeks, at 4 months, and 1 year after sarin exposure. The vertical axis shows the number of people who had each symptom.

group. Of these victims, 40 (24.0%) complained of asthenopia, 25 (15.0%) complained of fatigue, 18 (10.8%) complained of blurred vision, 15 (9.0%) complained of shoulder stiffness, and 14 (8.4%) complained of asthenia and headache. Conversely, among the nonvictims, 21 (3.1%) complained of asthenopia, 22 (3.3%) complained of fatigue, 13 (1.9%) complained of blurred vision, 25 (3.7%) complained of shoulder stiffness, 11 (1.8%) complained of asthenia, and 7 (1.0%) complained of headache. The percentages of these symptoms were greater in victims than in nonvictims. The percentage of victims having slight fever was slightly greater than that of nonvictims. In agreement with these findings, the odds ratios of these symptoms were greater in the victim group given their exposure to sarin. No significant differences between nonvictims and victims were noted in symptoms of bad dreams, insomnia, narrowing of the visual field, difficulty in smoking, husky voice, and palpitations. The odds ratios for each symptom after standardizing for age did not differ from those mentioned above.

The prevalence of victims with symptoms both 1 and 3 years after the sarin incident (victims with consistent symptoms) was compared with that of nonvictims. Significant differences were observed in the prevalence of symptomatic subjects or those with symptoms of blurred vision and asthenopia between victims and nonvictims. Similarly, odds ratios for symptomatic subjects or those with both symptoms were also higher in the victims than in nonvictims.

Taken together, symptoms of asthenopia, fatigue, blurred vision, shoulder stiffness, asthenia, and headache are later-manifested sequelae of sarin poisoning because (1) these complaints broke out in a dose-dependent manner; (2) the prevalence of these symptoms was significantly greater in victims compared with nonvictims; and (3) some of these complaints persisted after sarin exposure until 5 years, with the odds ratios of these symptoms clearly higher in the victim group.

In the additional medical checkup survey and clinical investigation conducted 3 years after the incident, seven of 31 admitted patients were diagnosed with sequelae of sarin: four showed epileptic electroencephalographic changes, three showed arrhythmia and sensory polyneuropathy with reducing sensory nerve conduction velocity, and one continued to have visual field constriction at a year postexposure, but 2 years after the poisoning, this was resolved completely (Sekijima et al., 1997). These victims responded to every questionnaire survey with complaints of asthenopia, fatigue, asthenia, blurriness of vision, headache, and/or slight fever.

The urinary sarin metabolites isopropylmethylphosphonic acid (iPMPA) and methylphosphonic acid (MPA) were measured in an unconscious severely ill victim who was brought into the hospital (Nakajima et al., 1998b). iPMPA was detected until 156 h after sarin exposure, but MPA was not detected at that time point. Therefore, this suggested that sarin metabolites were excreted into the urine within 1 week, even in those severely affected. The total excretion

amounts of iPMPA and MPA were 2.1 mg and 0.45 mg, respectively. When all the sarin inhaled was excreted within a week (as determined by these two metabolites), the victim was considered to have been exposed to 2.79 mg (0.05 mg/kg) sarin during the incident. This shows that sarin inhaled by humans is quickly metabolized, and this chemical and its metabolites are excreted from the body within 1 week, even in lethal doses. The later sequelae may be due to irreversible effects of acute exposure and chronic exposure to the chemical or its metabolites.

4.1.5 Psychological impacts

Psychological problems associated with posttraumatic stress disorder (PTSD) have been noted after accidents such as the Tokyo subway sarin poisoning incident (Ohbu et al., 1997) and earthquakes (Najarian et al., 1996; Goenjian et al., 1997). Five years after the sarin incident in Matsumoto, psychiatric symptoms were investigated for the follow-up cohort using a questionnaire survey at the same time as the later sequelae investigation of sarin intoxication. The questionnaire consisted of three clusters: (1) arousal ("sleep disturbances," "strong fear," "unease and frustration," and/or "lack of concentration, frequent errors, and mistakes"); (2) re-experiencing ("distressing dreams," "flashbacks to the sarin attack," and/or "distressing reminders when approaching the sarin attack site"); and (3) avoidance ("avoidance of sarin attack-related news and/or conversation," "apathy," "poor memory," "loss of memory toughness, becoming depressed," and/or "physical tension such as shoulder stiffness and sweaty hands"). In the survey, a person with one or more symptomatic subjects in each cluster was judged to have "symptomatic arousal," "symptomatic re-experience," and "symptomatic avoidance." There was no difference noted in PTSD-related symptoms between male victims and nonvictims. However, the odds ratios of symptomatic arousal, re-experiencing, and avoidance were significantly higher in female victims compared with female nonvictims.

4.1.6 Ten years after the sarin incident

The final questionnaire survey was conducted 10 years after the sarin incident. The questionnaire was distributed to 1813 inhabitants, which was similar to the follow-up cohort, but differed slightly because of a population inflow and outflow phenomenon. In total there were 727 (40.1%) responses. Of these responses, 668 persons agreed to complete the survey. There were 511 valid responses to the question regarding if the respondent felt sarin-related symptoms. There were 99 (19.4%) original Matsumoto sarin victims from 10 years previously and 412 (80.6%) nonvictims. The crude odds ratio (95% confidence interval, CI), unadjusted for age and sex, of symptoms of asthenopia at a slight-intermediate level for all victims was 4.11 (2.26−7.49), and that at considerable to very high levels was 7.22 (3.35−15.57), that of fatigue was 2.40 (1.41−4.07) and 4.45 (2.10−9.43), that of blurred vision was 2.54 (1.48−4.37) and 3.93 (1.74−9.00), that of asthenia was 2.63 (1.58−4.36), and 2.66 (1.01−7.02) and that of headache was 2.61 (1.49−4.57) and 3.32 (1.01−10.93), respectively (Table 4.1.1) (Report on health surveys of the Matsumoto sarin attack, 2015). It was obvious that many victims still had complains of eye abnormalities, especially "asthenopia" and "blurred vision." However, there was a significant difference between victims and nonvictims in other awareness observed as sequelae after 5 years.

With regard to PTSD symptoms, although a cluster analysis was not conducted in the 10-year survey, the odds ratio of each symptom was analyzed. In female victims, crude odds ratios (CI) of "sleep disturbance," "distressing dream," "flashbacks to the sarin attack," "unease and frustration," "lack of concentration, frequent errors and mistakes," "apathy," and "physical tension such as shoulder stiffness and sweaty hands" were 2.35 (1.14−4.86), 2.50 (1.09−5.73), 5.35 (2.49−11.50), 2.70 (1.13−6.41), 2.29 (1.06−4.98), 2.47 (1.10−5.41), and 2.18 (1.00−4.75), respectively, at slight-intermediate levels (Table 4.1.2). In male victims, the odds ratio of "sleep disturbance," "flashbacks to the sarin attack," "unease and frustration," "loss of mental toughness, becoming depressed," and "physical tension such as shoulder stiffness and sweaty hands" were 3.39 (1.44−7.72), 3.76 (1.49−9.49), 4.92 (1.59−15.73), 2.35 (1.04−5.30), and 2.44 (1.08−5.50), respectively, at slight-intermediate levels. In contrast, frequencies of symptoms of "distressing reminders when approaching the sarin attack site" and "poor memory" were significantly higher in female victims than female nonvictims, and the odd ratios (95% CI) both at slight-intermediate levels and at considerable to very high levels were 3.77 (1.72−8.27) and 6.72 (1.07−42.21), and 2.42 (1.16−5.04) and 4.58 (1.23−17.10), respectively. No such findings were observed in male victims. The PTSD symptoms observed at considerable to very high levels alone were "avoidance of sarin attack-related news and/or conversations" (odds ratio, CI: 15.13, 1.63−140.05) and "loss of mental toughness, becoming depressed" (3.76, 1.01−14.02) in female victims; "distressing dream" (13.56, 1.36−135.37), "avoidance of sarin attack-related news and/or conversation" (14.08, 1.41−140.75), and "poor memory" (3.07, 1.04−9.08) were observed in male victims. Thus, the psychological impact of sarin appears to be generally stronger in women than in men, which is similar to the effects on PTSD found after 5 years. The odds ratio of "avoidance of sarin attack-related news and/or conversation" was highest in both men and women at considerable to very high levels.

TABLE 4.1.1 **Typical subjective symptoms in sarin victims and nonvictims (all responders) at 10 years after the sarin incident.**

CI, Confidence interval; *Ref*, reference.

The symptoms reported in the 10-year survey were cross-referenced to receiving medical consultation: whether he/she was an inpatient, outpatient, or other. The crude odds ratios of "asthenopia," "unease and frustration," and "loss of mental toughness, becoming depressed" were significantly higher in inpatients and outpatients compared with the others group.

Ten years after the attack, many victims still complained of physical and psychological disorders. Many of these symptoms were dependent on the severity of sarin poisoning at immediately after the attack.

4.1.7 Conclusion

Sarin exposure acutely affected the human body with so-called muscarinic and nicotinic effects, and also caused long-term effects on physical and mental status. Symptoms of asthenopia, fatigue, blurred vision, shoulder stiffness, asthenia, and headache were manifested as later sequelae. In particular, the crude odds ratio of asthenopia was extremely high compared with other complaints. Psychological disorders were also observed 10 years after sarin intoxication. The impact of sarin on psychological disorders was greater in women than men.

Chapter 4.2

Part 2 Tokyo sarin attack: acute health effects

Tetsu Okumura, Toshiharu Yoshioka, Takemi Yoshida, Yukio Kuroiwa and Tetsuo Satoh

Japan Poison Information Centre, Tsukuba, Japan

4.2.1 Overview of the Tokyo subway sarin attack

This attack took place during the morning rush hour, at about 8 a.m. on March 20, 1995, the day before the Spring Equinox holiday. The attack was carried out by members of a cult known as Aum Shinrikyo to distract police from carrying out a raid on the group's headquarters. The terrorist target was government buildings in Kasumigaseki in the heart of Tokyo. Most offices in Kasumigaseki open for business at 9:30 a.m., but the early-morning rush hour was unusually heavy because it was a Monday. Some believe that the time of 8 a.m. was chosen because some cult members had inside information about the government offices. Police suspected, based on an undercover investigation that they were conducting, that Aum Shinrikyo was manufacturing sarin for use in a terror attack, but few people, even within the police department, were aware of this fact. The police did not have personal protective equipment (PPE), which meant that they had to borrow PPE and receive training on use of the equipment from the Self-Defense Forces. Members of the Self-Defense Forces were alerted to some of Aum Shinrikyo's planned activities, but the general public, including healthcare providers and fire department personnel, knew nothing of these activities (Fig. 4.2.1). According to a subsequent police report, the terrorists placed sarin in five subway trains in the following way.

Approximately 600 g of sarin at a concentration of 33% was mixed with hexane and *N*,*N*-diethylaniline and placed in a nylon/polyethylene bag. Five terrorists then wrapped the bags in newspaper, punctured the bags with the tips of their umbrellas, and left the bags on the trains. In this way, the sarin seeped out of the bags and vaporized, but no other active means of dispersal were used. In this sense, as well as the relatively low number of deaths, the Tokyo subway sarin attack was not considered a full-scale attack.

Of the bags of sarin used in the attack, two bags were not punctured. These bags were returned to the police laboratory for analysis. At Kasumigaseki, one of the subway stations on the Chiyoda subway line, two station employees collapsed and died on the platform after they cleaned and removed one of the bags that didn't get punctured, even though they were wearing gloves. The number of victims of this attack varies depending on the source, but all known information confirms that 13 people died in the attack, and it is generally believed that at least 5500 victims suffered mild to serious injuries. Firefighting agencies estimate 5642 victims, and the police, 3796 victims, while official figures released by the subway company put the total number of victims at 5654. This includes the 12 who died (10 passengers, 2 employees), those hospitalized (960 passengers, 39 employees), and those treated for minor injuries (4446 passengers, 197 employees).

Thus, the way in which we use the lessons learned from this attack will affect our ability to deal adequately with future terrorist attacks using sarin, which could be even greater and more serious with respect to the number of victims. Can we really assume that only 12 of the approximately 5500 victims died because the Japanese

FIGURE 4.2.1 Scene from a sarin attack at Tsukiji station.

medical system was particularly well prepared for such an eventuality? Probably not. It is more likely that the relatively small number of fatalities was due to the low concentration of sarin and the passive means of dispersing it. From this perspective, the Matsumoto sarin attack 1 year earlier was more aggressive than the Tokyo subway sarin attack. In a trial after the Matsumoto incident, it was revealed that a 70% concentration of sarin was actively volatilized using an electric heater and dispersed using an electric fan. A total of seven victims died and 660 were injured, and one victim died 14 years after sarin exposure. In other words, if the Tokyo subway sarin attack had been conducted using the same means as those employed in the Matsumoto sarin attack, the number of fatalities may have been 50 or 60. So humanity has not yet experienced the effects of a full-scale sarin attack in a major city.

Even if it did not rise to the level of a major attack, this incident was the first chemical terrorist attack in a large city. There were few first-responders who could even have conceived of such an attack, let alone be prepared to rapidly evacuate victims from the subway stations. Many passengers who had difficulty walking rushed out of the trains and onto the subway platform and fell down, which would have increased their exposure to the sarin permeating the stations. In addition, the site to which many of the victims were finally evacuated at ground level, where they could lie down, was close to an air exhaust vent from the subway below, so the exposure continued.

The first call for an ambulance came 9 min after the 8 a.m. attack, with the first report of a "victim with seizures at Kayabacho Station." By 8:15 a.m., the reports of victims started to increase. Around this time, the fire department received a report from Tsukiji Station stating that "an explosion occurred and several people were injured." Calls for ambulances eventually came from 19 subway stations, and after 8:30 a.m., victims began to pour into local clinics and hospitals. According to the Tokyo Fire Department, 5493 people were treated at 267 medical institutions in Tokyo, and 17 people were treated at 11 medical institutions outside Tokyo. Among the victims, 53 were seriously injured (Ieki, 1997). Another source states that a total of 6185 people were treated at 294 medical institutions (Chigusa, 1995). The discrepancy in the number of victims reported by different agencies attests to some of the confusion at the time. St. Luke's Hospital received the largest number of victims (640 on the day of the attack), probably because of its close proximity to the Hibiya line, where a large number of victims were located, and because of a report on television stating that "St. Luke's Hospital has the antidote for treatment."

4.2.2 Emergency treatment of sarin toxicity

The standard treatment for sarin toxicity includes (1) maintaining the airway, (2) assisting breathing, and (3) supporting circulation. Endotracheal intubation was performed frequently in victims of the Tokyo subway sarin attack. However, in the Matsumoto sarin attack, endotracheal intubation was more difficult to carry out in many victims because of airway hypersecretion and bronchospasm. This difference in symptoms is attributable to the 70% concentration and the active means by which the sarin was dispersed at Matsumoto, as opposed to the

much lower 33% concentration and passive means of dispersal employed in Tokyo. Dr. Frederick Sidell, an expert on chemical terrorism in the United States, advocated decontamination, drugs, airway, breathing, and circulation (DDABC) as the basic treatment for nerve agent poisoning. Even if the advised emergency treatment is followed, initial efforts to achieve adequate ventilation may be in vain. Efforts to achieve adequate ventilation should be made after at least initial administration of atropine to control the buildup of airway secretions and bronchoconstriction (Sidell, 1997). If healthcare professionals learn from the Matsumoto attack, they can better recognize early parasympathetic nervous symptoms, including miosis, hypersecretion, and rhinorrhea, as common indications of chemical terrorism due to nerve agents, and will therefore be able to institute appropriate treatment with antidotes in time. In large-scale disasters with many victims, treatment is often deferred in those with cardiopulmonary arrest (CPA; so-called black tag). However, at St. Luke's Hospital, one in three persons with CPA and two patients with respiratory arrest made a full recovery and were discharged. This high rate of recovery and return to the community is unlike that seen in other types of disasters. Therefore, if medical resources are available, all victims of a sarin attack should be aggressively treated, including cardiopulmonary resuscitation (CPR) when necessary.

The global standard for the treatment of sarin toxicity is the administration of (1) atropine, (2) an oxime agent like 2-PAM, and (3) diazepam (Medical Letter, 2002).

Recommended doses of atropine are 2 mg in patients with mild symptoms that are primarily ocular, but without respiratory symptoms or seizures; 4 mg in patients with moderate symptoms, including respiratory symptoms such as dyspnea; and 6 mg in patients with severe symptoms, including seizures and respiratory arrest. The standard administration route should be intramuscular. As mentioned previously, intravenous administration of atropine in the treatment of severe symptoms such as hypoxemia can induce ventricular fibrillation; thus, intramuscular administration is advised. Oxime agents, such as 2-pralidoxime methiodide (2-PAM) or 2-formyl-1-methylpyridinium iodide oxime, should also be given. The recommended dose for 2-PAM in moderate and severe cases of inhalation, or for liquid exposure to a nerve agent, is 1 g by intravenous infusion over 20–30 min. Further continuous administration of 500 mg/h may also be required in severe cases. Since the rate of aging of the nerve agent–enzyme bond is correlated with time until 2-PAM is administered, if the aging half-life of sarin is 5 h, then 2-PAM must be administered before this time. The oxime of choice for sarin and VX is 2-PAM, but asoxime chloride (HI-6) should be used for soman and obidoxime for tabun. Seizures are treated with diazepam. This three-drug combination (atropine, 2-PAM, and diazepam) is the global recommendation for sarin toxicity, and autoinjectors are available in several countries (Vale et al., 2006) (Fig. 4.2.2).

After the Tokyo subway sarin attack, St. Luke's Hospital, which treated 640 victims, used about 700 ampules of 2-PAM and 2800 ampules of atropine (Okumura et al., 1998). This calculates out to 550 mg of 2-PAM and 2.2 mg of atropine per victim. The route of administration was intravenous in all cases, with a total dose of 1.5–9 mg of atropine in severe cases (Okumura

FIGURE 4.2.2 Sarin victims at St. Luke's International Hospital.

et al., 1996); this range of dose reflects the low concentration and passive means of sarin dispersal used in the Tokyo attack.

However, in Tokyo, no one was saved by administration of 2-PAM; conversely, no one died because they did not receive it. In other words, if the victims' survival was the ultimate goal, there was no clinical evidence that 2-PAM was effective. The only reported finding was a more rapid return of plasma pseudocholinesterase levels to normal in patients who received 2-PAM, as compared to those who did not. But in terms of long-term prognosis, this does not rule out the effectiveness of oxime therapy. Ideally, detailed studies are needed to evaluate the efficacy of 2-PAM, including for long-term prognoses. To date, however, there has been no sophisticated study of the Tokyo subway sarin attack in this vein.

One piece of evidence supporting the efficacy of 2-PAM to treat sarin toxicity has been the clinical benefit associated with it when treating toxicity due to organophosphorus pesticides. However, some experts now doubt whether such a benefit really exists. For example, Peter et al. (2006), using meta-analytic techniques, reevaluated the effects of oxime therapy in organophosphate poisoning. Not only did they find no beneficial effects, they reported possible adverse effects. The Cochrane Reviews for clinical evidence-based medicine (Buckley et al., 2005) reported no risk/benefit evidence supporting the use of oxime agents in organophosphate poisoning, but they did conclude that further detailed investigations are necessary.

According to reports about Iranian physicians who treated sarin toxicity during the Iran–Iraq war (Newmark, 2004), 2-PAM was not available on the front lines, and atropine alone was used for treatment. The doses of atropine used were considerably higher than those used in the Tokyo subway sarin attack, or that are generally recommended in the United States (Medical Letter, 2002). The Iranian protocol called for initial administration of 4 mg intravenously. If no atropine effects (improvement in dyspnea or decrease in airway secretions) were seen after 1–2 min, 5 mg was then administered intravenously over the next 5 min while the heart rate was monitored. A rise in heart rate of 20–30 beats per minute was diagnosed as an atropine effect. In severe cases, 20–200 mg was given. Regardless of the dose, the key to saving lives, according to this protocol, was how soon the atropine was administered.

Thus, treatment without the use of an oxime agent is possible. Of course, in countries where this is economically possible, treatment should use the combination of atropine, an oxime agent like 2-PAM, and diazepam. In addition, the use of autoinjectors for administration is also helpful. Unfortunately, terrorist attacks using sarin are also carried out in less economically developed countries; and even if the drugs are available, performance relative to cost needs to be considered. In this sense, preference should be given to the availability of atropine and diazepam. In other words, unless it is economically feasible, funds should be used to obtain atropine and diazepam rather than oxime agents, whose cost–benefit ratio is still inconclusive.

Based on data from 627 victims treated at St. Luke's Hospital (Okumura et al., 1998), the symptoms, listed in order of prevalence, were miosis (pupillary constriction; 90.5%), headache (50.4%), visual impairment (37.6%), eye pain (37.5%), dyspnea (29.2%), nausea (26.8%), cough (18.8%), throat pain (18.3%), and blurred vision (17.9%). Cases were categorized as severe if they involved seizures or respiratory arrest requiring mechanical ventilation, moderate for respiratory distress or fasciculations, and mild for eye symptoms only. Of 640 cases reported by St. Luke's Hospital, the degree of intoxication was severe in five victims, moderate in 107, and mild in 528, with nicotinic effects observed in those with moderate or severe symptoms.

In the Tokyo subway sarin attack, decontamination was not performed on site, and first-responders and healthcare workers initially did not wear PPE. As a result, of 1364 firefighting personnel, 9.9% became secondary victims. At that time, TV and newspapers reported on the sarin attack daily, and many people in Japan became scared of the sarin incident affecting them. At St. Luke's Hospital, 23% of hospital staff became secondary victims (Okumura et al., 1998). The percentage of secondary victims by hospital occupation was as follows: nursing assistants (39.3%), nurses (26.5%), volunteers (25.5%), doctors (21.8%), and clerks (18.2%). Thus, increased contact with a primary victim increased the risk of becoming a secondary victim. The percentage of secondary victims by hospital location were the chapel (45.8%), the intensive care unit (38.7%), the outpatient department (32.4%), the general ward (17.7%), and the emergency department (16.7%). The high rate of secondary victims in the chapel was attributed to poor ventilation and the large number of victims sheltered there. Because it was during winter, victims entered the chapel fully clothed. When they removed their coats, and every time they moved thereafter, some of the sarin trapped inside the clothing probably escaped, causing secondary exposure. Fortunately, none of the secondary victims died. However, if a higher concentration of sarin and more effective means of dispersion had been employed in the Tokyo attack, as had been done in the Matsumoto incident, then it is likely that some of the secondary victims would have died.

Within the context of risk communication, the so-called worried-well, who were concerned about having been exposed to the nerve agent, and those complaining of symptoms even though actual exposure was unlikely, also flocked to hospitals seeking treatment (Bloch et al., 2007). As previously mentioned, among patients treated at St. Luke's Hospital on the day of the attack, 90.5% had

miosis, an objective finding due to sarin exposure, but the remaining 9.5% were considered to be worried-well patients.

The reason or reasons for the small number of worried-well patients in the Tokyo subway sarin attack are unclear. Given the extensive coverage by the news media, who mentioned that victims were crowding into St. Luke's Hospital, persons without definitive symptoms, or those who were unsure whether they had been exposed but who did not want to add to the confusion, likely avoided going to that hospital, which created a kind of natural selection process. Another contributing factor may have been that the target of the attack was the government buildings in Kasumigaseki in the heart of Tokyo, which meant that many of the victims were probably well educated. Conversely, unfamiliarity with sarin and toxic gases in general may also have contributed to the low number of such patients. In either case, these observations should be reviewed from the perspective of risk communication.

4.2.3 Laboratory findings in sarin toxicity

According to inpatient records from St. Luke's Hospital, the most common laboratory finding related to sarin toxicity was a decrease in plasma cholinesterase (ChE) levels in 74% of patients. In patients with more severe toxicity, plasma ChE levels tended to be lower, but a more accurate indication of ChE inhibition is the measurement of erythrocyte ChE, as erythrocyte acetylcholinesterase (AChE) is considered "true ChE" and plasma ChE is "pseudo-ChE." However, erythrocyte ChE is not routinely measured, whereas plasma ChE is included in many clinical chemistry panels; thus, it can be used as a simple index for ChE activity. In both the Matsumoto and Tokyo subway sarin attacks, plasma ChE served as a useful index of sarin exposure. In 92% of hospitalized patients, plasma ChE levels returned to normal on the following day. In addition, inpatient records from St. Luke's Hospital showed elevated creatine phosphokinase and leukocytosis in 11% and 60% of patients, respectively. In severe cases such as the Matsumoto attack, hyperglycemia, ketonuria, and low serum triglycerides due to the toxic effects of sarin on the adrenal medulla were observed (Yanagisawa et al., 2006).

Acknowledgments

We wish to thank the many people who have devoted their lives to the research into treating exposure to chemical weapons since the Tokyo subway sarin attack and who provided valuable advice in preparing this chapter. This chapter is dedicated to the memory of Dr. Frederick Sidell at the United States Army Medical Research Institute.

Chapter 4.3

Part 3 Structural changes in the human brain related to sarin exposure

Hidenori Yamasue

Department of Psychiatry, Hamamatsu University School of Medicine, Hamamatsu city, Japan

The chemical sarin (*o*-isopropyl methylphosphonofluoridate) is a highly poisonous organophosphate (Lee, 2003). The main mechanism of acute sarin toxicity is irreversible inhibition of acetylcholinesterase. A single exposure to sarin causes chronic brain damage in animals, especially

in the hippocampus (Kadar et al., 1995; Chebabo et al., 1999; Abdel-Rahman et al., 2002); however, the long-lasting brain damage caused by a single exposure to sarin in human is poorly characterized. A number of studies have, however, explored a possible link between exposure to organophosphorus chemical weapons during the Gulf War and long-lasting medical problems, including changes in brain morphology (Haley et al., 1997, 2000; Couzin, 2004; Chao et al., 2010, 2011, 2014, 2015; Figueiredo et al., 2018). The compound was also deployed during the Iraq−Iran war and on Kurdish people in northern Iraq. In 2013, sarin was dropped in Damascus, killing more than 1400 Syrians including 426 children (Dolgin, 2013).

In the 1995 Tokyo subway sarin attack (TSSA), approximately 5500 civilians were exposed to sarin, 12 of whom died (Suzuki et al., 1995). The patients with acute sarin intoxication presented various symptoms, including muscle weakness and dyspnea. Almost all patients exhibited miosis and related symptoms, such as headache, blurred vision, ocular pain, and visual darkness, which are all typical symptoms of sarin intoxication (Lee, 2003; Ohbu et al., 1997). Approximately one-half of the patients exhibited abnormally low serum cholinesterase (ChE) levels a few hours after the exposure, which is also consistent with sarin exposure (Ohbu et al., 1997). However, longitudinal observations showed that various somatic complaints, ocular symptoms, and cognitive dysfunctions remained even 5 years after the sarin attack, despite ChE levels having returned to within the normal range (Kawana et al., 2001). The cause of these long-lasting medical problems has not been fully elucidated (Chen, 2012).

Yamasue and colleagues employed voxel-by-voxel whole-brain analyses of magnetic resonance images (MRI) to explore whether acute single-dose sarin intoxication in TSSA victims caused persistent morphological changes (Yamasue et al., 2007). The relationships between regional brain morphology, low serum ChE levels on the day of exposure, and current severity of somatic symptoms and cognitive dysfunctions were also explored in the TSSA victims to indicate a neurobiological basis of these long-lasting symptoms (Yamasue et al., 2007).

One hundred and ninety-one of the 582 TSSA victims, who were treated in the emergency room for acute sarin poisoning at St. Luke's International Hospital on March 20, 1995, had participated in a previous epidemiological study at the hospital in 2000 (Kawana et al., 2001). Of these 191 subjects, 38 right-handed victims agreed to participate in a neuroimaging study in 2000−2001, approximately 5−6 years after the TSSA. These subjects included 36 victims who participated in a study examining the effect of posttraumatic stress disorder (PTSD) on brain morphology (Yamasue et al., 2003). Nine of the 38 victims were diagnosed as having PTSD because of the attack. Seventy-six healthy volunteers matched for age, gender, handedness, and self and parental socioeconomic status also participated in the study.

Serum ChE levels, both on the day of the sarin attack and on the day of MRI scanning, were available for 22 victims. All of these 22 victims showed a decrease in serum ChE level on the day of the attack (117 ± 40, mean $\pm$ SD) compared with that on the day of the MRI scan (308 ± 62, $P < .001$). The percent reduction of serum ChE level on the day of the attack relative to that on the day of MRI scanning ranged from 42 to 81% (62 ± 12). The TSSA victims completed a self-reported questionnaire (Kawana et al., 2001), and of the 38 victims who participated in the neuroimaging study, 29 reported somatic complaints, 33 reported ocular symptoms, and 21 perceived forgetfulness, although memory function assessed with Wechsler Memory Scale-Revised (Wechsler, 1987) was observed to range from 100 to 119.

The 38 participants underwent MRI scanning and high-spatial resolution three-dimensional T1 images were acquired. Voxel-based morphometry (VBM) image processing, a fully automatic technique for computational analysis of differences in regional brain volume throughout the entire brain, was conducted. Statistical comparison between the TSSA and control groups was performed using an analysis of covariance model. To account for global anatomical variations, the intracranial volume was treated as a confounding covariate. Age and gender were also treated as confounding covariates because these measures can influence brain structure (Good et al., 2001a, 2001b). Small volume correction for multiple comparisons was used for regions that were predicted to be affected from animal studies of sarin intoxication, such as bilateral hippocampus (Kadar et al., 1995; Chebabo et al., 1999; Abdel-Rahman et al., 2002).

Although there was no group difference in total gray matter, total white matter, total CSF, or intracranial volume between the victims and the controls, the VBM revealed significantly reduced regional gray matter volume in the right insular and temporal cortex in the victims. A significant regional gray matter volume reduction in the left hippocampus was also detected with small volume correction. Moreover, the victims were also associated with significant regional white matter volume reduction in the left temporal stem close to the insular cortex (corrected $P < .05$). The regional white matter volumes in the right temporal stem and frontal lobe were also decreased in the victims, although the significance level was marginal ($.05 <$ corrected $P < .1$) (Fig. 4.3.1A).

To detect the effect of exposure to sarin, the subsequent analysis treated intracranial volume, age, and gender as confounding covariates, and the serum ChE level on the day of the attack and/or severity of clinical

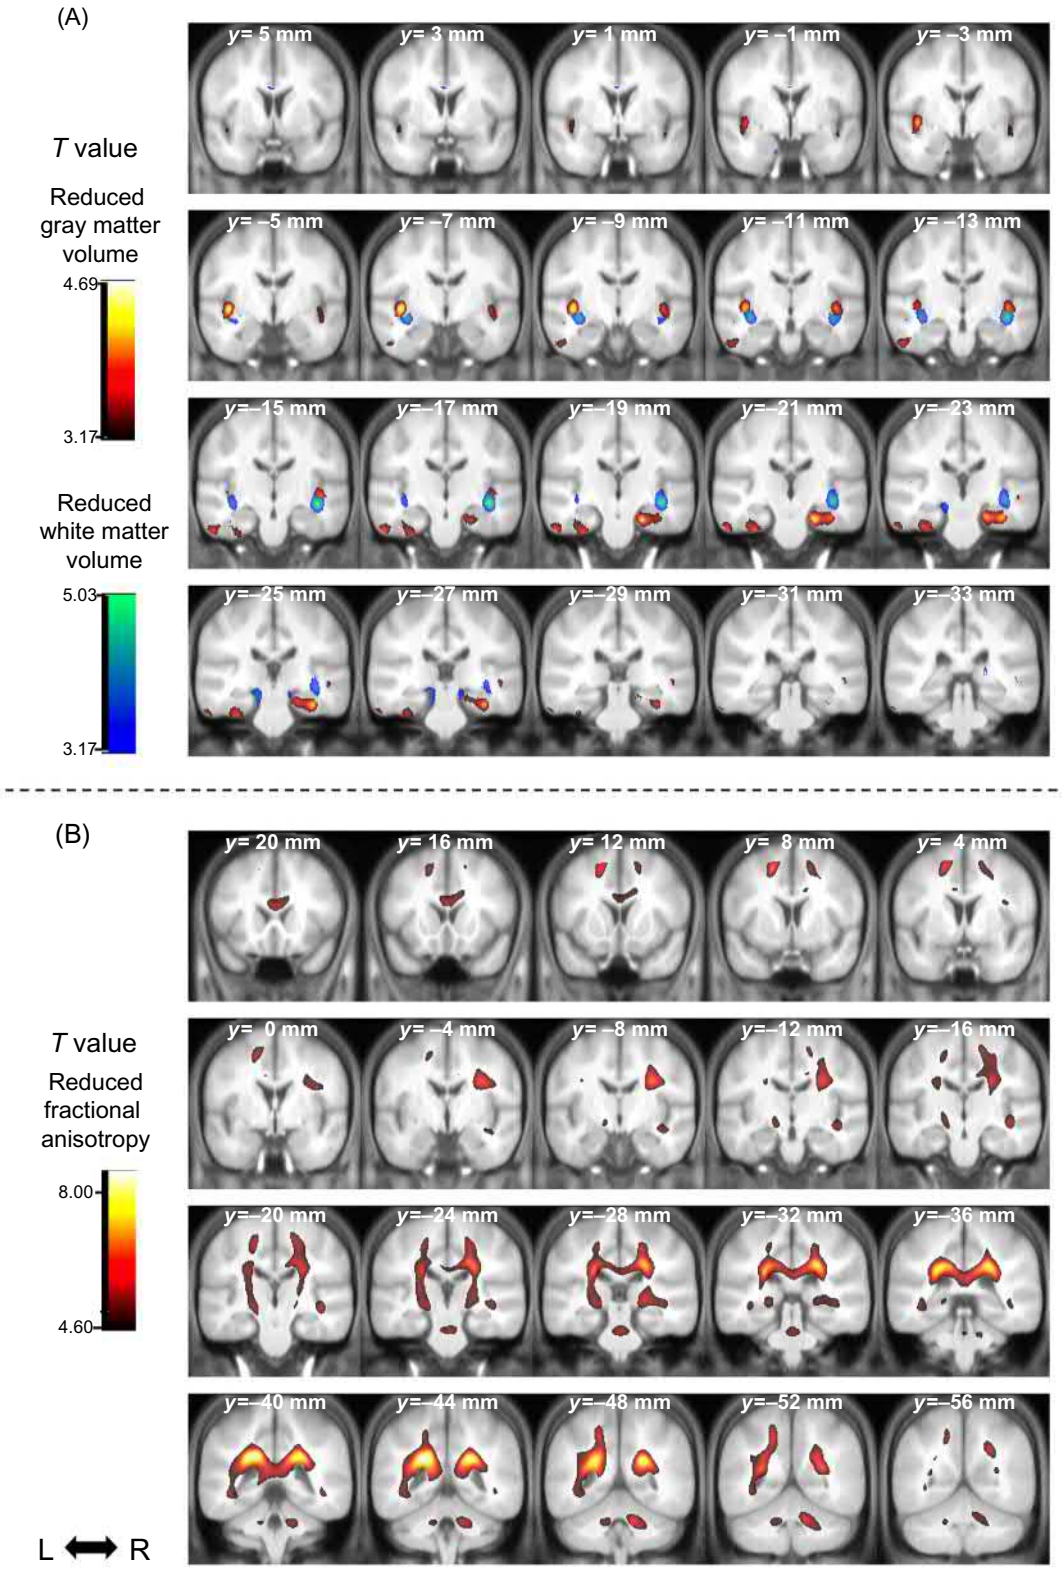

FIGURE 4.3.1 Regional brain morphology in sarin intoxication victims.
(A) Significant reductions in regional gray matter (*red-yellow*) and white matter (*blue-green*) volumes in the victims exposed to sarin compared with the controls are rendered onto the averaged image of the whole study sample ($n = 114$) (voxel threshold: uncorrected $P < .001$). The y-coordinate for each coronal slice in the Montreal Neurological Institute space is given in millimeters. (B) The regions showing a significant fractional anisotropy (FA) reduction in the victims exposed to sarin compared with the controls are rendered onto the averaged image of the whole sample ($n = 114$) (voxel threshold: corrected $P < .05$). The *y*-coordinate for each coronal slice in the Montreal Neurological Institute space is given in millimeters. *L*, left; *R*, right. *From Yamasue, H., Abe, O., Kasai, K., et al., 2007. Human brain structural change related to acute single exposure to sarin. Ann. Neurol. 61, 37–46.*

symptoms (somatic complaints, ocular problems, and forgetfulness) as the covariate of interest. An important difference between the victims of sarin intoxication and the control subjects, apart from the exposure to sarin, is a history of psychological stress. The region related to psychological stress was explored within the cluster, where the group comparison analysis showed regional volume reduction in victims compared with controls. A significant positive association with the serum ChE level at the time of the incident was found for the left subinsular white matter region, which was close to the temporal stem where the volume reduction was found in the group comparison (Fig. 4.3.2A). The serum ChE level at the time of the incident also showed positive correlations with the regional white matter volume in right frontal and left superior temporal regions with a trend toward significance ($.05 <$ corrected $P < .1$). There were no significant associations between regional gray matter volume and ChE indices. Furthermore, a significant negative correlation between the reduced regional white matter volume in the left temporal stem and the severity of the chronic somatic complaints was found in the victims (Fig. 4.3.2B). The severity of the somatic complaints was correlated with neither the severity of PTSD nor serum ChE level; therefore, the correlation between the somatic complaints and the left temporal stem cannot be attributed to these indirect effects. There were no other significant correlations between the severity of the ocular symptoms or forgetfulness and brain structure in the victims. The F-tests covering both ChE levels and somatic symptoms to address dependencies among these causal variables showed significant effects in the regional volume of the left subinsular white matter (corrected $P = .004$) and left temporal stem (corrected $P = .04$). The locations and statistical values of these effects are close to those of T-tests on the ChE levels but not on the somatic symptoms (subinsular: corrected $P = .007$; temporal stem: corrected $P = .002$); therefore, the correlations between the somatic symptoms

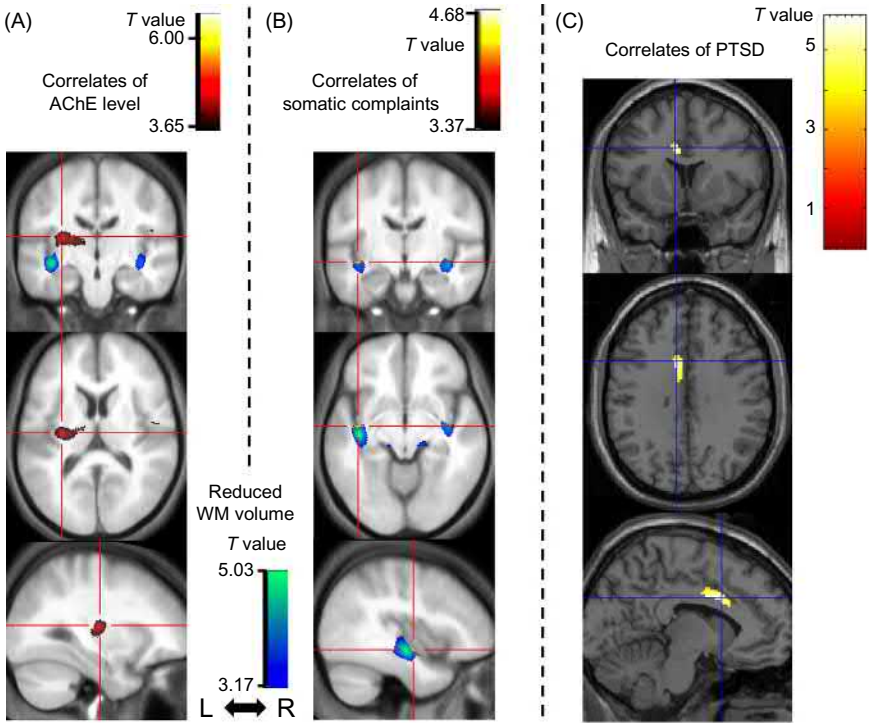

FIGURE 4.3.2 Neuroanatomical correlates of the decline in serum ChE level, somatic complaints, and posttraumatic stress disorder in sarin intoxication victims.

(A) The white matter (WM) region showing significant correlation with the effect of depressed cholinesterase (ChE) level was rendered onto the averaged image of the whole sample (*red-yellow*) ($n = 114$). (B) The white matter region showing a significant association with the somatic complaints was rendered onto the averaged image (*red-yellow*). The cluster, where the regional volume showed a significant association with the severity of somatic complaints, is included in the cluster, where victims had significantly smaller volumes than controls. (A, B) For comparison purposes, the regions showing significantly reduced regional white matter volume in the victims compared with the controls are overlaid and colored in blue (voxel threshold: uncorrected $P < .001$). (C) Regional differences between the victims with and without PTSD. Areas significantly reduced in the victims with PTSD compared with those without PTSD were confined to the anterior cingulate cortex and were rendered onto orthogonal slices of the normal template MR images. *L*, left; *R*, right. *From Yamasue, H., Kasai, K., Iwanami, A., et al., 2003. Voxel-based analysis of MRI reveals anterior cingulate gray-matter volume reduction in posttraumatic stress disorder due to terrorism. Proc. Natl. Acad. Sci. U.S.A. 100, 9039–9043; Yamasue, H., Abe, O., Kasai, K., et al., 2007. Human brain structural change related to acute single exposure to sarin. Ann. Neurol. 61, 37–46.*

and regional volume are independent from those between ChE levels and regional volume. In contrast, there were no brain voxels showing a significant correlation between an effect of psychological stress and the reduced regional brain volume in the victims within the regions showing group difference between the victims and controls, even when a liberal screening significance threshold of uncorrected $P < .001$ was utilized. Areas that were significantly reduced in the victims with PTSD compared with those without PTSD were confined to the anterior cingulate cortex (Fig. 4.3.2C) (Yamasue et al., 2003). Consequently, it can be concluded that the reduced regional volume in the right insular cortex, right temporal cortex, left hippocampus, and left temporal stem are related not to psychological stress but to the exposure to sarin.

All the subjects also underwent diffusion tensor imaging (DTI) in the same scanner and at the same time as 3D-T1. The voxel-by-voxel analysis of the fractional anisotropy (FA) maps created from DTI showed an extensive bilateral reduction in regional FA in the parietal and temporal lobes of the victims. Of note, the regional FA in the left temporal stem, where the VBM showed a significantly reduced white matter volume in the victims, was significantly reduced in the victims compared with controls. Furthermore, a regional FA in the brain stem, where a previous MR-spectroscopy study reported neurochemical abnormality in Gulf War veterans exposed to chemical nerve agent (Haley et al., 2000), was also significantly decreased in the victims (Fig. 4.3.1B). Furthermore, the decreased FA in the bilateral temporal stem and left subinsula significantly correlated with the more severe physical symptoms in the victims.

The crucial finding of the neuroimaging study by Yamasue et al. (2007) was a significant decrease in regional gray matter volume in the right insular and right temporal cortices, in the left hippocampus, and in regional white matter volume of the left temporal stem in the victims of sarin exposure compared with the matched controls not exposed to sarin. The regional volume of the left subinsular white matter showed a significant positive correlation with serum ChE levels at the time of the incident. Furthermore, reduced regional white matter volume of the left temporal stem was significantly related to the severe long-lasting somatic complaints in the victims. The DTI analysis showed that microstructural white matter integrity was significantly disrupted in widespread bilateral brain regions, including the parietal lobe, temporal stem, and brain stem, in the victims compared with the controls. It seems remarkable that the decreased FA was found in an area that also showed a significantly decreased white matter volume in the victims because these overlapping regional effects were inferred on the basis of independent data.

The victims included in the study demonstrated both a remarkable decrease in serum ChE levels and the presence of acute sarin intoxication symptoms. All of the victims were treated in the emergency room for acute sarin intoxication and showed a significant decrease in serum ChE levels; therefore, the severity of exposure to sarin was estimated to be at least intermediate (Brown and Brix, 1998). Most of the victims also suffered from various long-lasting somatic and cognitive symptoms, which is consistent with exposure to sarin at or above the intermediate level. Although most of the 38 victims suffered from various long-lasting symptoms, including somatic complaints, ocular symptoms, and forgetfulness, neuropsychological and occupational impairments were relatively mild.

The victims had significantly smaller regional volumes in the right insular cortex, right temporal cortex, left hippocampus, and left temporal stem than control subjects. Moreover, the regional volume in the left subinsular white matter, which was close to the left temporal stem where the significant volume reduction was found, showed a positive correlation with the serum ChE level at the time of sarin exposure. A limited number of previous studies have evaluated brain morphology of human subjects exposed to sarin, although animal studies have repeatedly reported dose-dependent (Abdel-Rahman et al., 2002) and progressive (Kadar et al., 1995) neuropathological change subsequent to sarin exposure (Chebabo et al., 1999). However, a limited number of studies using other research modalities have reported functional or chemical brain abnormalities in victims of sarin intoxication. Murata et al. (1997) reported significantly prolonged P300 auditory event-related potentials and P100 visual-evoked potential latencies in the TSSA victims. Matsuda et al. (1998) detected products of sarin hydrolysis in postmortem brain tissue of victims who died in the TSSA, although this analysis was limited to four individuals. Morphological changes in the brain have also been reported in Gulf War veterans. Haley et al. (2000) reported a reduced *N*-acetylaspartate-to-creatine (NAA/Cr) ratio in the putamen and brain stem of Gulf War veterans who had perceived chemical nerve agent exposure during wartime. Chao et al. (2010, 2011) reported a significant reduction in total gray and white matter volume in veterans with low-dose sarin and cyclosarin exposure (Chao et al., 2010, 2011). Significant reductions in the CA2 and CA3/dentate gyrus subfields of the hippocampus were reported in individuals exposed to low-dose chemical warfare agents (Chao et al., 2014), and remodeling of the white matter is suspected in the temporal stem, corona radiata, superior/inferior cingulum, internal and external capsule, inferior and superior fronto-occipital fasciculus, and nine superficial white matter areas located between the cortex and deep white matter (Chao et al., 2015).

Furthermore, animal studies show that ChE inhibitors have various delayed neurological and behavioral effects,

even at subtoxic doses (Scremin et al., 2003). The neuroimaging study that demonstrated regional brain volume reduction in victims of a single toxic sarin dose is partly consistent with these previous studies. Although overstimulation of muscarinic receptors and neuronal cell death induced by glutamate overflow subsequent to sarin exposure have been observed (Solberg and Belkin, 1997), the mechanism by which acute sarin exposure induces brain damage has yet to be clarified.

MRI examination (Yamasue et al., 2007) also showed a significant association between smaller regional white matter volume in the left temporal stem and more severe somatic complaints. Interestingly, the location of the neuroanatomical correlate of the somatic complaints was close to the insular cortex. Critchley et al. (2004) reported that activity and gray matter volume in the right insular cortex predicts individual variability in interoceptive awareness. Information concerning the internal state of the body is conveyed through a dedicated lamina-1 spinothalamocortical pathway that converges, with vagal afferents, to "interoceptive centers" in the insular cortex (Craig, 2002). The disruption of connections to the insular cortex thorough subcortical white matter fibers is linked to alterations in perceptions of internal bodily status (Manes et al., 1999). Furthermore, patients with insular stroke have more anergia, reduced activity, and tiredness than patients without insular lesions (Augustine, 1996). In summary, the insular cortex plays a crucial role in awareness of internal bodily status, such as pain, visceral, olfactory and gustatory sensations, and tiredness, especially in the emotional context (Augustine, 1996). Thus, the correlation found in this study indicates that regional volume reduction in this region related to sarin intoxication chronically influences subjective feeling states, such as tiredness, palpitations, and bodily pain among the victims.

The analysis utilizing DTI also revealed an FA reduction in a wider area than that showing volume reduction in the victims, in addition to associations between reduced FA and somatic complaints. DTI has been used to quantify the magnitude and directionality of tissue water mobility in three dimensions. Lower FA indicates less directionality and more random movement of water in all directions measured (Beaulieu, 2002). Previous studies have reported FA decreases without volumetric reduction in neuropsychiatric disorders (Kalus et al., 2005); therefore, FA may be more sensitive in finding morphological abnormalities than volumetric measurements. In addition to cerebral regions, the study by Yamasue et al. (2007) also found reduced FA in the brain stem. Haley et al. (2000) reported corroborating findings: Gulf War veterans exposed to organophosphorus chemical weapons and who exhibited mild cognitive and occupational impairment showed reduced *N*-acetylaspartate measured with 1H MR-spectroscopy, a marker of neural integrity.

The neuroimaging study (Yamasue et al., 2007) had limitations. First, the cross-sectional nature of the MRI examination and the absence of MRI scans and psychological assessments at the time of the incident cannot directly determine the etiology of the structural brain change. Second, the possible effects of psychological trauma on brain structure (MceEwen, 1999) cannot be totally ruled out, although a previous study indicated that smaller than normal hippocampal volume in patients with PTSD is likely to be a pre-existing vulnerability indicator rather than an acquired effect after traumatic events (Gilbertson et al., 2002). A bidirectional modulation of genes that regulate acetylcholine availability after stress and blockade of ChE has been observed (Kaufer et al., 1998), indicating possible synergy between the deleterious effects of ChE inhibitors and stress (Sapolsky, 1998). Third, a previous study reported the relationship between serum ChE levels and psychological stress in a sample overlapping that of the current study (Tochigi et al., 2002). Therefore, it is difficult to completely differentiate the effects of sarin intoxication from psychological stress. In this study, however, regional brain volume reduction showed a significant correlation with serum ChE levels but not with psychological symptoms, arguing against the possibility that psychological stress was a serious confound.

In conclusion, the MRI study of the TSSA victims (Yamasue et al., 2007) demonstrated in vivo evidence of a relationship between an acute single exposure to sarin and long-lasting morphological changes in specific brain regions. Furthermore, the findings also indicate that the increased sensitivity to internal bodily status in the victims is related to morphological brain damage, including in the insular and neighboring subcortical white matter: the "interoceptive centers." Therefore, these findings shed light on the neural background of unexplained somatic problems.

Acknowledgments

This study was supported by the Special Coordination Funds for Promoting Science and Technology from the Ministry of Education, Culture, Sports, Science and Technology of the Japanese Government. We thank Dr. S. Ishimatsu and Prof. H. Shimizu for their help with the recruitment of subjects. We thank Jeremy Allen, PhD, from Edanz Group (www.edanzediting.com/ac) for editing a draft of this manuscript.

Chapter 5

Early and delayed effects of sulfur mustard in Iranian veterans after the Iraq–Iran conflict

Mahdi Balali-Mood

Medical Toxicology Research Centre; Department of Clinical Toxicology; Imam Reza Hospital, Faculty of Medicine Mashhad University of Medical Sciences, Mashhad, IR, Iran

5.1 Introduction

5.1.1 Brief chemistry

Sulfur mustard (SM), which is bis(2-chloroethyl) sulfide and is also known as mustard gas, was first synthesized in 1822 by Despretz. SM is an oily liquid that is colorless if pure, but it normally ranges from pale yellow to dark brown. Iranian veterans have described it as having a slight garlic or horseradish odor. It has a density of 1.27 g/mL, a melting point of 14.4°C, and a boiling point of 217°C. SM is only 0.05% soluble in water (Kikilo et al., 2008; Pechura and Rall, 1993).

SM is generally regarded as a "persistent" chemical agent because of its low volatility. In cool weather there is little vapor; however, mustard's evaporation increases as the temperature increases. At higher temperatures, such as those in the Middle East during the hot season (38°C–49°C), mustard vapor becomes a major hazard (Pechura and Rall, 1993; Sidell et al., 1997; Kikilo et al., 2008).

5.1.2 Summarized historical uses

SM has been the most widely used chemical warfare agent (CWA) of the past century. It was first used extensively in World War I (WWI) between 1914 and 1918. Despite the Geneva Protocol in 1925 on the prohibition of CWA, SM was used by Italian troops in Ethiopia (1935–36) and by Egyptian forces in Yemen (1963–67). The greatest military use of SM was by the Iraqi Army against the Iranian soldiers and even civilians in Sardasht and Halabjah between 1983 and 1988, resulting in more than 100,000 chemical casualties (Balali-Mood and Hefazi, 2005; Salem et al., 2008).

5.2 Types and routes of exposure

Based on the situation involved, several types of exposure including single, multiple, secondary, subclinical, and chronic may occur. Most human cases of SM poisoning have occurred during armed conflicts and most accidents involved a single exposure (Pechura and Rall, 1993; Sidell et al., 1997; Balali-Mood and Hefazi, 2005; Kikilo et al., 2008; Salem et al., 2008). Multiple low SM exposures occurred occupationally, during WWI and in the Iran–Iraq conflict (Balali-Mood and Hefazi, 2005; Salem et al., 2008). First aid workers and nursing and medical staff who cared for SM casualties in the field clinics and hospitals during the Iraq–Iran War without proper personal physical protection have become intoxicated. Some of them (between 5% and 25%) are now suffering from the delayed toxic effects of SM and have disabilities (Balali-Mood and Hefazi, 2005).

Low-level SM exposure with or without symptoms but with delayed or long-term health effects has been described in detail (Mandel and Gibson, 1917; Hurst et al., 2001; Balali-Mood et al., 2005a,b; Balali-Mood et al., 1986a). Subclinical exposure to SM in some Iranian combatants induced delayed toxic effects (Ghanei et al., 2004a,b,c). Chronic SM exposure is usually occupational. Some factory workers in Japan and in the United Kingdom were reported to have had SM poisoning and even malignancies attributable to SM (Brown, 1949; Nishimoto et al., 1970).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00005-2

Inhalation is the major route of exposure that induces respiratory and systemic toxicity after absorption across the lung surface (Sidell et al., 1997; Balali-Mood and Hefazi, 2005; Hefazi et al., 2005). However, SM is a vesicant or blistering agent that has direct toxic effects on the skin, producing erythema, blistering, epidermolysis, and necrosis. It is a lipid-soluble compound and thus can be readily absorbed across the skin (Balali-Mood and Hefazi, 2005; Hefazi et al., 2006).

The eyes are the organs most sensitive to SM. This marked susceptibility is attributed to ocular features, including the aqueous−mucous surface of the cornea and conjunctiva as well as the high turnover rate and intense metabolic activity of the corneal epithelial cells (Pickard, 1919; Etezad-Razavi et al., 2006).

SM may also enter the body via oral ingestion. Some Iranian combatants were observed during the Iran−Iraq War who had ingested food contaminated by SM and subsequently became intoxicated. They experienced nausea, vomiting, hematemesis, abdominal pain, and dyspnea. SM may also be absorbed through the lower gastrointestinal (GI) tract (Balali-Mood and Hefazi, 2005). Injection is a very rare route of SM intoxication and has not been reported in humans.

5.3 Human toxicity

Exposure to very high doses of SM in the field may induce convulsions and death in less than 1 h (World Health Organization, 1970; Balali-Mood et al., 1986a; Sidell et al., 1997; Balali-Mood and Hefazi, 2005). Such observations have not been reported during the Iran−Iraq War. Acute toxic effects generally appear after variable periods of latency depending on the dose, mode of exposure, the environmental temperature, and the individual (Anslow et al., 1946; World Health Organization, 1970; Balali-Mood et al., 1986; Pechura and Rall, 1993; Balali-Mood and Hefazi, 2005).

Subacute exposure occurred during the Iran−Iraq War and in the workers in SM munitions factories. However, this type of exposure may present as mild acute SM intoxication, as a complication in the respiratory tract, or even as malignancy (Balali-Mood, 1986; Easton et al., 1988).

Delayed toxic effects of SM have been documented. The first report of delayed toxic effects in Iranian veterans was reported in 1986 (Balali-Mood, 1986). Several articles on the delayed toxic effects and complications of SM in Iranian veterans have since been published (World Health Organization, 1970; Balali-Mood, 1986; Ghanei et al., 2004a,b,c; Balali-Mood et al., 2005a,b; Hefazi et al., 2005; Etezad-Razavi et al., 2006; Hefazi et al., 2006).

The workers who were chemically exposed to mustard agents in British and Japanese munitions factories developed chronic respiratory effects, including chronic bronchitis, bronchiectasis with progressive emphysema, and narrow attenuated bronchioles (Brown, 1949; Nishimoto et al., 1970; Easton et al., 1988).

5.4 Main mechanisms of toxicity

The monofunctional mustards have one alkylating site and, therefore, can attack and break the DNA at specific nucleotides. Although SM reacts with RNA, proteins, and phospholipids, the general consensus is that a DNA alkylate plays an important role in delayed toxic effects (Walker, 1971; Ball and Robert, 1972). The major alkylating site of nucleic acids of mammalian origin is the nitrogen residue of guanine (Wheeler, 1962). Cell death from DNA cross-linking is delayed until the cell replicates its DNA or undergoes division. At higher cellular exposures, however, mechanisms other than DNA cross-linking become important and produce more rapid cell death. The acute damage to the cornea, mucous membranes, and skin seen after SM exposure is probably generated by one or more of these other mechanisms. One mechanism that may be involved in acute damage is nicotinamide adenine dinucleotide depletion. Other potential mechanisms of cell death are related to rapid inactivation of sulfhydryl containing proteins and peptides, such as glutathione. These sulfhydryl compounds are critical in maintaining the appropriate oxidation reduction state of cellular components. Glutathione is also thought to be critical in reducing reactive oxygen species in the cell and preventing peroxidation and loss of membrane integrity (Rankin et al., 1980; Eklow et al., 2004). Tumor necrosis factor-α is involved in SM-induced skin lesions (Worsmer et al., 2005).

5.5 Target organs and acute clinical features

Acute toxic effects of SM are mostly observed in the eyes, respiratory tract, and skin. These organs are thus known as the target organs, because their involvement is more prominent here than in the other organs. However, neuropsychiatric symptoms and signs and digestive and cardiovascular dysfunctions were also observed. Frequencies of clinical features of acute SM intoxications in 233 Iranian patients treated in Mashhad, Iran, are shown in Fig. 5.1.

Eyes are the organs that are most sensitive to SM. The first symptoms of SM exposure usually occur in the eyes. The Iranian patients with SM exposure reported itching and burning sensation of the eyes, leading to acute conjunctivitis, blepharospasm, and even keratitis. In the acute stage, the limbal region frequently presents a marbled appearance in which porcelain-like areas of ischemia are

surrounded by blood vessels of irregular diameter. Later, the vascularized scars of the cornea often contain deposits of cholesterol, calcium, and fat (Giraud, 1917; World Health Organization, 1970; Balali-Mood et al., 1986a,b; Balali-Mood et al., 1986; Balali-Mood and Hefazi, 2005).

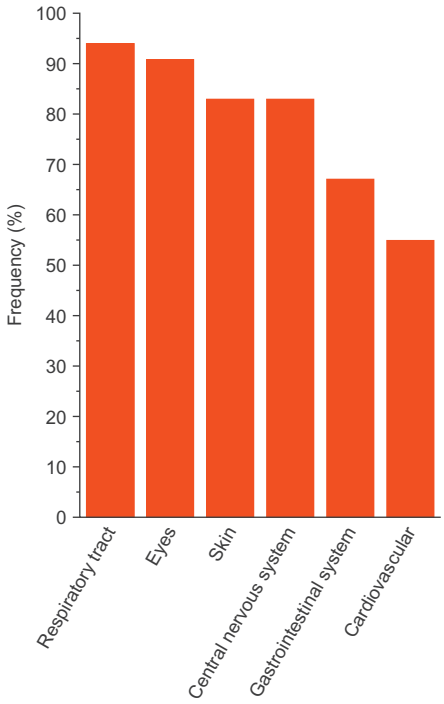

FIGURE 5.1 Frequency of clinical features of acute SM poisoning in different organs of 233 Iranian patients treated in Mashhad, Iran, a few days after exposure.

Respiratory effects occur in a dose-dependent manner from the nasal mucosa to the terminal bronchioles (World Health Organization, 1970; Balali-Mood et al., 1986a,b). Acute pulmonary effects commence with a tracheobronchitis, followed by bronchopneumonia, adult respiratory distress syndrome, and even pulmonary emboli in severely intoxicated patients, which may lead to death, mostly during the second week after SM exposure. Chest X-ray (CXR) of the Iranian SM-intoxicated patients revealed fewer abnormalities than the clinical manifestations. However, the severely intoxicated patients showed abnormal CXR results. CXRs of an Iranian patient with bronchopneumonia caused by acute SM poisoning before and after treatment in 1985 are shown in Fig. 5.2.

Direct toxic effects of SM on the skin are the main apparent effects that lead to it being called a vesicant or a blistering agent. Erythema and blisters are the most common skin manifestations caused by SM exposure. A soldier who had a separate suit and face mask suffered from skin erythema and blisters on his neck 3 days after SM exposure, as shown in Fig. 5.3.

A German and an Iranian medical toxicologist (first author) classified the cutaneous mustard gas lesions as described under the clinical manifestations (Helm and Balali-Mood, 1988).

GI effects after SM exposure have been documented in some studies. Destruction of the mucosa and shedding of the epithelial elements, however, begin days after exposure, resulting in the loss of large volumes of fluid and electrolytes (Papirmeister et al., 1991). Acute gastroduodenitis with hemorrhagic erosions, acute desquamative enteritis, and severe hemorrhagic necrotic colitis were

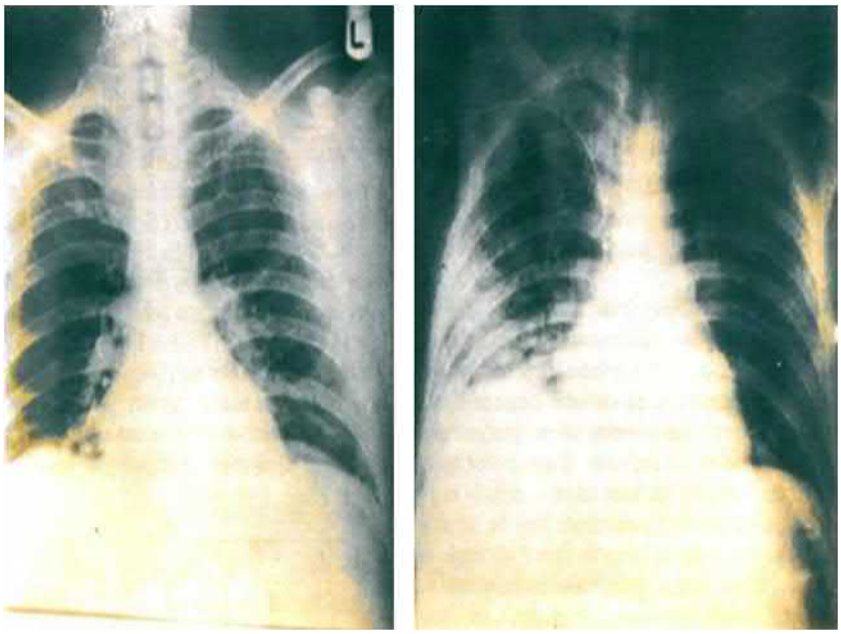

FIGURE 5.2 Chest X-rays of an Iranian patient with bronchopneumonia due to acute SM poisoning before (right) and after (left) treatment 8 and 19 days after exposure in 1985.

FIGURE 5.3 A soldier who had a separate suit and face mask revealed skin erythema and blisters on his neck 3 days after SM exposure in 1985.

reported in WWI veterans (Canelli, 1918) but were not observed in the Iranian veterans.

Extremely heavy exposure to SM can cause central nervous system (CNS) excitation, leading to convulsions in animals (Anslow et al., 1946). Balali-Mood et al. (1986a,b) reported convulsions in six Iranian veterans who were hospitalized during the early stages of their intoxication (Balali-Mood et al., 1986a,b). Most casualties from WWI and from the Iran–Iraq conflict, however, revealed mild and very nonspecific neurological effects, such as headache, anxiety, restlessness, confusion, and lethargy (Canelli, 1918; Balali-Mood et al., 1986a,b). A frequent long-term complication in patients exposed to SM is delayed neuropathic toxicity, which was underrepresented in most previous studies (Thomsen et al., 1988).

5.6 Hematoimmunological complications

SM, as an alkylating agent, is particularly toxic to rapidly proliferating cells such as lymphoid and bone marrow cells. Leukocytosis is common within the first few days after exposure. White blood cell (WBC) counts then begin to decrease starting from the third or fourth day after exposure and reach their minimum level at approximately the ninth day. This leukopenia is followed by a decrease in megakaryocytes and, finally, in the erythropoietic series (Willems, 1989; Tabarestani et al., 1990; Balali-Mood et al., 1991). Bone marrow biopsies have shown hypocellular marrow and atrophy involving all elements (Tabarestani et al., 1990). If cytopenia is not marked and there are still remaining stem cells, then recovery will occur as the patient recovers (Krumbhaar and Krumbhaar, 1919; Tabarestani et al., 1988; Tabarestani et al., 1990; Balali-Mood et al., 1991; Mahmoudi et al., 2005). The bone marrow studies reveal a severe decrease in cellularity and fat replacement and also nuclear changes, such as budding, binuclear, and karyorrhexis in erythrocyte precursors. The toxic effects of SM on the hematopoietic system are dose-dependent, and it is concluded that SM causes aplastic or ineffective hematopoiesis (Tabarestani et al., 1988). Severe leukopenia, however, is an ominous sign, leading to secondary infections and higher mortality rates in these patients. SM victims with WBC counts of 200 cells/mL or less died during their initial admissions (Willems, 1989).

SM poisoning could result in the impairment of both humoral and cellular immune functions (Dayhimi et al., 1988; Zandieh et al., 1990; Ghotbi and Hassan, 2002). Along with the appearance of clinical disorders, both C3 and C4 titers showed an increase, followed by a gradual decrease, over 1 year. The majority of SM-exposed patients had increased levels of IgG and IgM during the first weeks and up to 6 months after exposure (Ghotbi and Hassan, 2002).

A decrease of cell-mediated immunity has been observed in Iranian veterans 1, 2, and 3 years after exposure (Zandieh et al., 1990). Natural killer (NK) cells, which are known to be one of the most important components of cellular immunity, have been found to be significantly lower in patients with severe respiratory complications 10 years after exposure (Ghotbi and Hassan, 2002).

Hematological and immunological complications of 40 patients 16–20 years after severe SM intoxication in comparison with 35 controls were reported (Balali-Mood et al., 2005a,b; Mahmoudi et al., 2005). Total WBC and red blood cell (RBC) counts and hematocrit (HCT) levels were significantly higher in the patients than in the control group. The percentages of monocytes and $CD3^+$ lymphocytes were significantly higher, and the percentage of CD16 + 56 positive lymphocytes (NK cells) was significantly lower in patients than in the control group. Other hematological and flow-cytometric parameters did not show any significant difference between the two groups. Serum IgM and C3 levels were significantly higher in the patients in comparison with the controls. Other immunoglobulins and complement factors did not show any significant difference between the two groups, as shown in Table 5.1.

5.7 Delayed clinical complications

The main target of the long-term complication of SM poisoning is the respiratory system. In a study of incidence of common late complications of SM poisoning in lungs, eyes, and skin in 34,000 Iranians, the lungs were found to be the most affected organ (Khateri et al., 2003). In another study, the most common clinical complications of SM in different organs of 40 Iranian veterans 16–20 years after exposure showed that the respiratory tract was

TABLE 5.1 Hematological and immunological changes in 40 patients, 16–20 years after severe SM intoxication comparing with 35 healthy subjects.

Parameters	Patient mean SD	Control mean SD	*P*-Value
WBC (1000/mm^3)	7.24 ± 1.90	5.79 ± 1.12	.025

Peripheral neuromuscular	30	75
Skin	29	72.5
Eyes	27	67.5

involved in 95% of the patients, as shown in Table 5.2 (Balali-Mood et al., 2005a,b).

5.8 Respiratory tract

Respiratory complications are the greatest cause of long-term disability among people with SM exposure. A pulmonologist who investigated the pulmonary complications in Iranian veterans in 2007 named it mustard lung (Ghanei and Adibi, 2007).

A triad of cough, expectoration, and dyspnea has been found to be present in more than 80% of Iranian veterans 3 years after their initial exposure (Balali-Mood, 1992; Balali-Mood et al., 1986a). Hemoptysis (mainly streaky), chest tightness, chest pain, and nocturnal dyspnea are also frequent. The main objective clinical findings are generalized wheezing (the most common sign), crackles, decreased lung sounds, clubbing, and cyanosis (Balali-Mood, 1992; Balali-Mood et al., 1986a,b; Ghanei and Adibi, 2007).

Pulmonary function testing has revealed more obstructive patterns than restriction, and approximately half of these obstructive spirometric results are reversible in response to inhaled bronchodilators. FVC, FEV1, and FEV1/FVC (FEV1%) have all been found to be significantly lower in SM-intoxicated veterans in comparison with healthy nonexposed subjects and CWA survivors who had used a gas mask at the time of attack (Balali-Mood, 1992; Balali-Mood and Hefazi, 2005; Balali-Mood et al., 2005a,b; Ghanei and Adibi, 2007).

Abnormal spirometric findings in general and restrictive patterns in particular tend to increase over time (Balali-Mood and Hefazi, 2005; Balali-Mood et al., 2005a,b; Ghanei and Adibi, 2007). A study of 77 subjects who were present in a contaminated area and had no acute signs and symptoms at the time of exposure, but who now have respiratory disorders, indicates that subclinical exposure to SM can be responsible for the occurrence of delayed respiratory complications such as bronchiectasis and bronchiolitis obliterans (Ghanei et al., 2004a,b,c).

CXR findings in patients with late respiratory complications of SM have been described as increased bronchovascular markings, hyperinflation, bronchiectasis, pneumonic infiltration, and radiologic evidence of pulmonary hypertension (Balali-Mood et al., 2005a,b; Ghanei and Adibi, 2007). However, CXR is not sensitive enough for the detection of respiratory complications in these patients and high-resolution computed tomography of the chest may be required as the diagnostic imaging procedure of choice (Bagheri et al., 2003; Balali-Mood et al., 2005a,b; Bakhtavar et al., 2008). A study of 197 Iranian veterans 10 years after a single heavy exposure to SM revealed the development of a series of delayed destructive pulmonary sequelae, such as chronic bronchitis (58%), asthma (10%), bronchiectasis (8%), large airway narrowing (9%), and pulmonary fibrosis (12%). Each of these complications is described in more detail (Emad and Rezaian, 1997).

5.8.1 Chronic bronchitis

Several studies have reported chronic bronchitis as the most common late complication of the respiratory system resulting from war exposure to mustard gas (Balali-Mood, 1992; Emad and Rezaian, 1997; Ghanei et al., 2004a,b,c, 2005, 2006a,b; Balali-Mood et al., 2005a,b). Hypoxemia and hypercapnea are commonly observed in moderate to severe cases, leading to cor pulmonale and respiratory failure in the final stages of the disease (Emad and Rezaian, 1997; Balali-Mood and Hefazi, 2005; Balali-Mood et al., 2005a,b). Infection of the respiratory tract, resulting in bronchopneumonia, is also a common problem that is often complicated by septicemia (Balali-Mood et al., 1986a,b, 2005a,b; Balali-Mood and Hefazi, 2005).

5.8.2 Asthma

Airway hypersensitivity, manifested as typical attacks of breathlessness, wheezing, and nocturnal cough, as well as a reversible obstructive pattern on pulmonary function tests, have been reported between 4 weeks and 20 years after SM inhalation. Patients with chronic bronchitis may also have some degree of bronchospasm, which does not respond to bronchodilators. Attacks of bronchospasm are characteristically triggered by respiratory infections, environmental allergens, and cold weather (Emad and Rezaian, 1997; Bijani and Moghadamnia, 2002; Ghanei et al., 2004a,b,c, 2005, 2006a,b; World Health Organization and Perry-Robinson, 2004; Balali-Mood et al., 2005a,b). New techniques, such as impulse oscillometry (IOS), have been used for evaluation of airway dysfunction. However, it was found to be less sensitive than spirometry in spotting small airways obstructions. IOS is a good diagnostic method in the detection of pulmonary involvement in uncooperative patients (Ghanei et al., 2004a,b,c).

5.8.3 Bronchiectasis

Direct effects of SM on the bronchial wall mucosa and more recurrent respiratory infections after inhalation of SM are known to be responsible for the development of bronchiectasis. Both the severity and frequency of bronchiectatic lesions tend to increase over the long-term, as evidenced by a study of 40 Iranian veterans with severe late complications of SM poisoning. These lesions usually begin bilaterally in the lower lobes and then progress toward the middle lobe and the lingula.

In severe cases with extensive bronchiectatic lesions, pulmonary hypertension and, ultimately, cor pulmonale may occur (Sohrabpour, 1992; Hosseini, 1998; Aslani and Cheraghali, 2000; Ghanei et al., 2004a,b,c; Balali-Mood et al., 2005a,b).

5.8.4 Large airway narrowing

Airway narrowing, attributable to scarring or granulation tissue, is late sequelae of acute injuries to the trachea and large bronchi, usually developing 2 years after exposure (Aslani and Cheraghali, 2000; Sohrabpour, 1992; Ghanei et al., 2004a,b,c). A study of 19 Iranian veterans with large airway narrowing caused by SM revealed stenosis in the trachea (seven cases), main bronchi (eight cases), and lobar bronchi (four cases) (Ghanei et al., 2004a,b,c). In contrast to stenosis caused by prolonged intubations, there is no predilection in the right main bronchus (Balali-Mood et al., 2005a,b). The major problem in these patients is the recurrence of the lesion, which usually occurs 6 months after treatment (Aslani and Cheraghali, 2000).

5.8.5 Pulmonary fibrosis

Late-onset pulmonary fibrosis has been reported in several Iranian veterans with combat exposure to SM (Aslani and Cheraghali, 2000; Balali-Mood et al., 2005a,b). The analysis of bronchoalveolar lavage fluid from patients with mustard gas inhalation showed that these patients

have an ongoing local inflammatory process of the lower respiratory tract, resulting in the development of pulmonary fibrosis years after the initial exposure. Histopathological examination of transbronchial lung biopsy (TBLB) samples of SM-exposed veterans revealed variegated fibrosis, diffuse fibrosis, and an absence of fibrosis in 86%, 4%, and 10% of the patients, respectively. Usual interstitial pneumonitis accounted for 97% of all cases of fibrosis (Emad and Rezaian, 1997). In another study, electron microscopic examination of seven TBLB specimens was performed in a WHO research center in Japan. Abnormal findings included: (1) proliferation, desquamation, and degeneration of the bronchial epithelial cells; (2) interstitial fibrosis or fibrosing alveolitis; and (3) increased type I and type II alveolar epithelial cells as well as hyperplasia of ciliated and goblet cells (Sohrabpour, 1992). Inflammation and fibrotic processes in the lung tissue of SM-exposed patients may be progressive (Ghanei et al., 2004a,b,c). Diffusing lung capacity could be used as an objective monitor of the degree of fibrosis and also as a good predictor for prognosis (Emad and Rezaian, 1997).

5.9 Peripheral neuromuscular complications

Electromyography (EMG) and nerve conduction velocity (NCV) of 40 Iranian veterans with severe late manifestations of SM poisoning revealed abnormalities in the peripheral nervous system of 77.5% of the patients. NCV disturbances were more common in sensory nerves compared with motor nerves and were more prevalent in the lower extremities than in the upper extremities. EMG recordings revealed a normal pattern in 24 (60%) patients, incomplete interference with normal amplitude in 6 (15%) patients, and incomplete interference with low amplitude in 10 (25%) patients. NCV and EMG disturbances in both upper and lower extremities were mostly symmetric (Ghanei et al., 2004a,b,c; Balali-Mood et al., 2005a,b).

5.10 Dermal delayed effects

The occurrence and persistence of lesions after SM exposure are directly related to the duration and severity of exposure. Injury that results in erythema and edema without vesicle formation is almost always followed by complete healing and nonresidual effects (Chiesman, 1944; Balali-Mood and Hefazi, 2005). Blistering and necrotic wounds, however, cause permanent residual effects. The first report of delayed toxic effects of SM poisoning in 236 Iranian veterans 2 years after exposure revealed late skin effects such as hyperpigmentation (34%), hypopigmentation (16%), and dermal scarring (8%) (Balali-Mood et al., 1986a,b). The most common skin symptom among these patients was itching, followed by a burning sensation and desquamation. These symptoms are basically caused by dryness of the skin and become worse in dry weather and after physical activity. A more recent study of 40 Iranian veterans who were heavily exposed to the gas 16–20 years previously revealed the most common cutaneous lesions to be hyperpigmentation, erythematous papular rash, dry skin, multiple cherry angiomas, atrophy, hypopigmentation, and hypertrophy. These lesions were found on the genital areas (48%), the back (48%), the front thorax and abdomen (44%), lower extremities (mainly inguinal) (44%), upper extremities (mainly auxiliary) (41%), and the head and neck (15%). Dry skin was more prominent in the extremities. Hyperpigmentation in some patients had the appearance of pigmented xerodermoid, which is a diffuse hyperpigmented area with superimposed macular hypopigmentations and hyperpigmentations (Balali-Mood et al., 2005a,b; Hefazi, et al., 2006).

In another study, the cutaneous lesions of 500 SM-exposed Iranian veterans were compared with 500 unexposed veterans. An association was found between SM exposure and late skin lesions such as severe dry skin, hyperpigmentation and hypopigmentation, localized hair loss, eczema, and chronic urticaria. There was also a higher incidence of vitiligo, psoriasis, and discoid lupus erythematosus among SM-poisoned patients. This could be attributable to the immunological basis of these disorders and to the fact that SM has adverse long-term effects on the immune system. Previously injured sites have been reported to be sensitive to subsequent mechanical stimulation and showed recurrent blistering after mild injury (Fekri and Janghorbani, 1992).

Histopathological examination of skin biopsy samples has revealed nonspecific findings including epidermal atrophy, keratosis, and basal membrane hyperpigmentation. Nonspecific fibrosis and melanophages have also been observed within the dermis (Fekri and Janghorbani, 1992; Balali-Mood et al., 2005a,b; Hefazi et al., 2006). Occupational exposure to SM has been demonstrated to cause a variety of skin changes, including pigmentary disorders, skin ulcers, and cutaneous cancers (Khehr, 1984).

5.11 Ophthalmologic complications

In less than 1% of patients with battlefield exposure to SM, a delayed type of ulcerative keratopathy may develop, leading to late-onset blindness (Hughes, 1942; Blodi, 1971; English and Benett, 1990; Pleyer et al., 1999; Javadi et al., 2000). The maximum delayed toxic effects usually occur 15–20 years after initial exposure, although latency periods as long as 40 years or as short as 6 years have also been reported (Solberg et al., 1997;

Javadi et al., 2000; Etezad-Razavi et al., 2006). Patients are usually symptom-free for an indefinite number of years when delayed keratitis develops, characterized by photophobia, lacrimation, and failing vision (Pleyer et al., 1999). Vascularized scars of the cornea are covered with crystal and cholesterol deposits, leading to a worsening of the opacification, recurrent ulcerations, and sometimes corneal perforation. Opacification of the cornea is seen predominantly in the lower and central portions, whereas the upper part is often protected by the eyelid (Solberg et al., 1997; Pleyer et al., 1999). Surprisingly, lesions even recur after corneal transplantation (Javadi et al., 2000). The exact pathogenesis of this condition is unknown, but degenerative processes and immune reactions against corneal proteins (collagen−mustard compound) have been suggested as the cause of long-term damage (Solberg et al., 1997). Unfortunately, there has been no report of any long-term studies of mustard gas workers to determine their ocular status after prolonged occupational exposure.

5.12 Psychiatric complications

Casualties from WWI and from the Iran−Iraq conflict were noted to be long-term mood and anxiety disorders, as well as posttraumatic stress disorder (Balali-Mood, 1986a,b; Tabatabaee, 1988; Hashemian et al., 2006). Debility, loss of vitality, impaired concentration, sensory hypersensitivity, diminished libido, weakened potency, neuralgic symptoms, and disorders in autonomic regulation are common manifestations. Neuropsychiatric evaluation of 1,428 Iranian veterans 3−9 years after exposure to SM revealed anxiety (15%), depression (46%), personality disorders (31%), convulsions (6%), and psychosis (3%) (Tabarestani et al., 1988). Disorders of consciousness (27%), attention (54%), emotion (98%), behavior (80%), thought process (14%), and memory (80%) were studied in 70 patients 3−5 years after SM exposure (Balali-Mood, 1986a,b). Depression and posttraumatic stress in Iranian survivors of chemical warfare, mostly SM exposure, were also reported (Javadi et al., 2000). In another study, decreased libido and impotence were recorded in 52% and 9% of patients, respectively. Quite interestingly, 10% of the patients revealed an increased libido. Functional photophobia and aphonia and effort syndrome have also been reported (Balali-Mood et al., 2005a,b).

5.13 Carcinogenicity

SM is genotoxic because of its reactions with DNA, which is an important first step in carcinogenesis. Although most cells possess effective DNA repair mechanisms, these are not always effective in the case of SM damage. Alkylation of *O*6-guanine by SM seems to be critical. *O*6-ethylthioethylguanine is a poor substrate for the DNA repair enzyme *O*6-alkylguanine-DNA alkyltransferase (Ludlum et al., 1986). Therefore, this *O*6 lesion may be the most important mutagenic lesion. However, only limited data are available regarding the specific mutations produced by SM. Mutations in a tumor suppressor or an oncogene gene can favor a proliferate advantage of a clonal cell. Notably, alterations in the p53 tumor suppressor gene have been described in Japanese mustard gas workers (Takeshima et al., 1994). However, most of the lesions in this population were similar to smoking-related mutations. Mutations in lymphocytes at the hypoxanthine phosphoribosyltransferase (hprt) gene locus have also been reported (Yanagida et al., 1988).

5.14 Reproductive complications

The effects of SM exposure during pregnancy are unknown. Data addressing the productive toxicities of SM in human models are both lacking and contradictory (Azizi et al., 1995).

5.15 Cardiovascular complications

Cardiovascular complications such as myocardial perfusion abnormalities and coronary ectasis have recently been observed in some patients (Gholamrezanezhad et al., 2007). Further, more detailed studies of larger groups of veterans and controls are now being undertaken, especially in regard to cardiovascular complications.

5.16 Recent advances in sulfur mustard poisoning and its complications

Because there are still several hundred Iranian veterans suffering from the long-term complications of SM poisoning, research of these patients is continuing. Attaran et al. (2010) have found a significant positive correlation between interleukin-6 and airflow limitation in SM-exposed patients with chronic obstructive pulmonary disease (Attaran et al., 2010). Another Iranian research group (Abolghasemi et al., 2010) has demonstrated a significant association between overall frequency of physical abnormalities in children and paternal SM exposure. They have concluded that SM exposure may have a lasting and important effect on generations to come (Abolghasemi et al., 2010).

Razavi et al. (2012) published a systematic review of the delayed complications of SM poisoning in Iranian veterans. They have reported numerous late complications among the victims and listed a wide range of respiratory, ocular, dermatological, psychological, hematological, immunological, GI, and endocrine complications, all which influence the quality of life of the exposed veterans. Although the mortality rate

attributable to SM poisoning was 3%, morbidity was high, with variety and chronicity of toxic effects and complications (Razavi et al., 2012).

Karami et al. (2013) studied the effects of delayed complications of SM poisoning on the mental health of Iranian veterans 25 years after exposure and found a wide range of psychiatric complications, including neurotic and psychotic disorders. They have recommended that psychological state should be considered more often in SM-exposed veterans and that it is important to provide more mental health centers for these patients (Karami et al., 2013).

Unfortunately, there is no antidote or effective treatment for SM poisoning. Poursaleh et al. (2012) studied the treatment of SM poisoning in Iranian veterans and have found that mustard lung has an ongoing pathological process and is an active disorder even years after exposure. They concluded that there are no curative modalities for mustard lung; therefore, primary prevention and, if injury has occurred, secondary prevention for SM victims should be considered. They recommended studies that investigate underlying physiopathology and pharmacokinetics of drugs, as well as those that conduct more surveys and controlled clinical trials to obtain more effective treatments (Poursaleh et al., 2012).

Despite two centuries of research on SM in experimental animals and in humans, the animal studies are still ongoing. Mishra et al. (2010) showed that dermal SM exposure in euthymic hairless guinea pigs induced infiltration of both $CD4^+$ and $CD8^+$ T cells into the exposed skin. They also found strong upregulated expression of pro-inflammatory cytokines and chemokines (TNF-α, IFN-γ, and IL-8) in distal tissues such as the lung and the lymph nodes. They claimed to report for the first time that SM induced a specific delayed-type hypersensitivity response that is associated with splenomegaly, lymphadenopathy, and proliferation of cells in these tissues. Their results suggest that dermal exposure to SM leads to immune activation, infiltration of T cells into the SM-exposed skin, delayed-type hypersensitivity response, and molecular imprints of inflammation in tissues distal from the site of SM exposure (Mishra et al., 2010). These immunological responses may contribute to the long-term sequelae of SM toxicity, as evident in many reports of the SM-exposed Iranian veterans (Krumbhaar and Krumbhaar, 1919; Dayhimi et al., 1988; Tabarestani et al., 1988; Zandieh et al., 1990; Ghotbi and Hassan, 2002; Mahmoudi et al., 2005).

5.17 Concluding remarks and future directions

A wide range of early and delayed toxic effects of SM can be categorized into two major groups: (1) direct toxic effects on the skin, eyes, and respiratory system with subsequent long-term complications such as chronic obstructive pulmonary disease (COPD), bronchiectasis, pulmonary fibrosis, large airway narrowing, hypopigmentation and hyperpigmentation of the skin, chronic conjunctivitis, and delayed keratitis and (2) systemic toxicities, particularly the immunohematopoietic complications, that are believed to be responsible for the increased risk of infections and malignancies in these patients. However, there are still major gaps in SM literature and further studies of human subjects who have been exposed to the agent are required. Immunological and psychological dysfunctions, as well as the relationship between SM exposure and carcinogenesis and teratogenesis, are important fields that need further investigation. Recent findings of cardiovascular complications in some of these patients also require further investigations, particularly on a molecular basis to discover the mechanisms of early and delayed toxic effects of SM in humans. Future experimental and human studies may lead to a better understanding of SM poisoning and more effective treatment.

Chapter 6

Epidemiology of chemical warfare agents

Linda A. McCauley
Nell Hodgson Woodruff School of Nursing, Emory University, Atlanta, GA, United States

6.1 Introduction

While chemical warfare agents have been used in military conflict for over a century, it is only in the last three decades that increased attention has been paid to the acute and chronic health effects of these substances. Reports of poorly defined illnesses in veterans following the 1991 Gulf War—and the recent news coverage of Syrian sarin attacks—have focused international attention on the capacity of chemical agents to cause death and human suffering.

Other than investigations following the Iranian conflict in the 1980s and the Japanese terrorist attacks of the 1990s, little objective research is available on the health effects of chemical warfare agents. In particular, studies on this topic are limited by difficulties in correctly determining participants' exposures. This chapter discusses the major studies on populations exposed to chemical warfare agents and summarizes methodological issues in the literature base.

6.2 Pre-World War II

The first full-scale deployment of chemical agents occurred when Germany used them against French, Canadian, and Algerian troops in 1915 during World War I. Casualties were relatively heavy, though few deaths resulted from this initial attack. Over the course of the war, however, chemical weapons directly accounted for about 1,176,500 nonfatal casualties and 85,000 fatalities. Official records indicate that a total of 50,965 tons of pulmonary, lachrymatory, and vesicant agents were collectively deployed by both the Allies and Central Powers, including chlorine, phosgene, and mustard gas (Heller, 2005).

In 1925, 16 nations signed the Geneva Protocol, pledging never to utilize gas in warfare again; though reports of its use did follow shortly thereafter. In 1935, Italy unleashed mustard gas when invading Ethiopia during the Second Italo-Abyssinian War, resulting in 15,000 chemical casualties. While chemical agents were widely used in this and subsequent wars, there was neither formal data collection involving exposed populations, nor any systematic attempt to accurately describe the epidemiology of exposures until the 1970s.

Eventually, a longitudinal follow-up study was conducted in 1975 involving three samples of World War I veterans. Researchers sought to determine if a single exposure to mustard gas with respiratory injury increased lung cancer risk in later life (Norman, 1975). Veterans Administration death records men who served in WWI and were born between 1889 and 1893. Of these men, 2718 had been exposed to mustard gas, 1855 had been hospitalized with pneumonia in 1918, and 2578 had sustained extremity wounds rather than chemical exposures (control group). There were 4136 deaths reported across the study groups, which was 95% of that expected. Observed deaths from lung cancer numbered 69 (2.5%) for the mustard gas group, 33 (1.8%) for the pneumonia group, and 50 (1.9%) for the control group. The risk of lung cancer death among men who were gassed relative to risk for the control group was estimated at 1.3, with 95% confidence limits of 0.9−1.9.

6.3 World War II

German scientists discovered the chemical structure of sarin nerve gas in 1938 before learning the structure of soman, also a nerve agent, in the spring of 1944 (Schmaltz, 2006). Yet chemical warfare agents were not extensively used by Axis forces in battle, due in part to fear of a devastating Allied retaliation. There was, however, one account of mustard gas exposure in 1943 when Germany sunk several US ships. One of the US ships had been carrying mustard gas intended for retaliation in case of chemical hostilities by the Germans. Because the

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00006-4

presence of the gas had been highly classified, authorities treating casualties ashore had no idea that they were seeing the effects of mustard gas. They prescribed improper treatments as a result. This incident was not uncovered for many years, though declassified records now show that 628 of the hospitalized casualties suffered from mustard gas exposure and 69 deaths were due, in whole or in part, to this cause (US Naval Historical Center, 2016). It was common during WWII for the impacts of gas exposures among armed and civilian populations not to be disclosed or accurately recorded. Reasons for this included military secrecy and difficulties discerning the effects of gas exposures from other types of injuries.

During the Holocaust, the Nazis used insecticide Zyklon B, containing hydrogen cyanide, to kill several million people in extermination camps. The Nazis also conducted experiments on camp prisoners using mustard gas and phosgene, and reportedly released poison gases during the Warsaw Ghetto Uprising in 1943.

A 1994 US Senate report titled, *Is Military Research Hazardous to Veterans' Health? Lessons Spanning a Half Century*, states that US military personnel were used as human subjects in 1940s chemical tests. They were exposed, without informed consent, to two agents: mustard gas and a similar compound called lewisite. The testing was reportedly done to determine how to best protect troops from the effects of chemical warfare (Pechura and Rall, 1993). This secret research, completed during WWII, involved up to 4000 men across numerous experiments. Researchers required participants to wear gas masks and clothing that had been treated to keep gases from reaching the skin. Some men were sealed in a test room for 1−4 h; others were tested in the field, restricted to an area that had been bombed with mustard gas anywhere from 1 h to 3 days prior.

In 1992, the US Department of Veterans Affairs (VA) began to allow compensation for seven conditions that can result from mustard gas exposure: laryngitis, chronic bronchitis, emphysema, asthma, chronic conjunctivitis, chronic keratitis, and corneal opacities. However, the VA expanded this list when the National Academy of Sciences published a report addressing the nonvoluntary nature of the 1940s chemical tests. It described how certain exposures were severe enough to cause burns and highlighted the lack of long-term monitoring for affected veterans. The VA updated its compensation list to include respiratory cancers (nasopharyngeal, laryngeal, and lung except for mesothelioma), skin cancer, chronic obstructive pulmonary disease, and acute nonlymphocytic leukemia (Pechura and Rall, 1993).

Bullman and Kang (2000) conducted a 50-year mortality follow-up study involving World War II Navy veterans who had experienced low-level nonlethal exposures to mustard gas. Subjects were male veterans who had participated in chamber tests at Bainbridge, MD, between 1944 and 1945; they had been wearing protective clothing and masks at the time of exposure. A control group consisted of 2663 Navy veterans who had served at the same time and location as the exposed men, but who had not participated in chamber tests. Investigators found no excess of any cause-specific mortality associated with varying doses of mustard gas that had been sufficient enough to cause skin reactions upon exposure. A strength of Bullman and Kang's study was that long-term dose—response analysis was made possible by detailed data from the original experiments; length of time in the chamber, dose of exposure, and documentation of observable acute effects were available for all subjects.

Another matter of concern was the possibility of posttraumatic stress disorder (PTSD) among chamber test participants. After randomly sampling, from the VA registry, 363 male veterans who had participated in testing, Schnurr et al. (2000) found 32% of mustard gas-exposed men to have full PTSD and 10% to have partial PTSD. Prevalence varied as a function of risk and protective factors, including volunteering, physical symptoms during the tests, and prohibited disclosure. Veterans with full PTSD reported poorer physical health, higher likelihood of several chronic illnesses and health-related disability, greater functional impairment, and higher likelihood of healthcare usage than those with no PTSD.

In a prior study, Schnurr et al. (1996) postulated that some of these diagnoses might have involved elements of "contamination stressor," in which information about the exposure—or a lack of information—acted as the stressor, rather than the incident itself. Receiving little or no information upon exposure, and then notification of potential consequences decades later could have led to vague or diffuse fear among chamber test participants. Contamination stressors often promote a future orientation—a worry about problems that might develop as a result of a past event, which can contribute to PTSD.

6.4 Post-World War II

The decades post-World War II were characterized by the development and testing of other chemicals, such as the *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX) nerve agent. By 1961, the United States was producing large amounts of VX and investing in research on the health effects of nerve agents. Military testing continued between 1951 and 1969, with various chemical and biological agents being trialed at the Dugway Proving Ground in Utah.

A large testing program took place from 1962 to 1973, when more than 5800 military personnel participated in a series of experiments on the vulnerability of warships to biological and chemical attacks. Only some of the

involved personnel consented to these tests. Many experiments involved chemical stimulants, which were thought to be harmless at the time, but are now known to have the potential for toxic effects. Test results were reported in a series of classified documents called *The SHAD Report*. In 2000, the US Department of Defense (DoD) released information about this testing along with the names of participants. This led the Institute of Medicine (IOM) to undertake a 2002 study on the potential long-term health effects of these exposures. The IOM team assembled a control group, conducted a health survey by phone, and examined mortality records. Their primary outcomes of interest were general health, medical conditions, and mortality.

The team divided SHAD participants into four groups:

- Group A consisted of 3000 participants whose exposure had been limited to either *Bacillus globigii* (BG) or methylacetoacetate (MAA).
- Group B consisted of 850 participants whose only potential exposure had been to trioctyl phosphate (TEHP); this group contained a large number of Marines.
- Group C consisted of 720 participants who had taken part in tests where active chemical warfare agents were used.
- Group D consisted of 850 subjects potentially exposed to simulants who were not in groups A, B, or C.

Control groups were assembled for comparison with each of the above groups. Of the nearly 12,500 Navy and Marine subjects, 9600 were assumed alive (i.e., no evidence of death in available records) and contacted for survey. Response rates were 60.8% for SHAD participants and 46.6% for controls. Researchers observed no differences in all-cause mortality between SHAD participants and controls, though SHAD members had a higher risk of death due to heart disease, which was statistically significant. A lack of data on participants' cardiovascular risk factors makes this difference difficult to interpret. SHAD members also reported worse overall health than controls (also statistically significant), but no specific illness patterns were identified.

Group C, the only group with potential exposure to active chemical or biological agents, reported the smallest differences in overall health compared to controls. Small differences in memory, attention, and somatization were observed among Group C versus controls. Group C participants also had higher levels of neurodegenerative conditions. There were no significant differences in self-reported hospitalizations.

The SHAD I study was significant in that it was the first epidemiological investigation of a military population with documented exposure to multiple chemical agents or stimulants. The survey was, however, conducted 30 years after the exposure and, with the exception of mortality records, was limited to self-reported measures of health. A mortality follow-up study of the SHAD cohort was published by Kang and Bullman (2009). In this study, cause-specific mortality of 4927 SHAD veterans was compared to that of 10,927 nonexposed Navy veterans of the same era. The SHAD cohort was found to have a greater risk of overall mortality, primarily from heart disease; but this heightened risk was not attributed to exposure to active chemical or biological warfare agents. This research was limited by its lack of information on participants' other potential exposures, particularly to Agent Orange (a defoliant used in Vietnam), and the possibility of error due to exposure misclassification.

In 2012, the IOM was commissioned to conduct a second epidemiological study comparing the health of SHAD veterans with that of a control population. The SHAD II study expanded on the initial investigation by reflecting a longer follow-up period and incorporating diagnostic data from Medicare and the VA. A retrospective cohort study, SHAD II involved men identified by the DoD from ship logs and personnel diaries as having been present during some portion of at least one SHAD test. The comparison population consisted of individuals who had served on ships (or a unit) of a similar class, crew complement, operating area, and home port at the time of the exposures. A small number of SHAD participants had served on five light tug boats with about 9–12 men per boat; no comparison vessels could be named for these.

The committee generated hypotheses on potential long-term health effects associated with substances used in the SHAD tests. Substance-specific exposure groups were created, including a sarin group. In addition, a broader exposure classification group was constructed to include "any chemical exposure." These groups were not mutually exclusive—a SHAD participant might have fallen into any or all of the exposure classifications. Researchers conducted a subanalysis for three distinctive groups: the crew of the *USS George Eastman*, which had participated in tests with live agents like sarin, members of the SHAD technical staff, which included persons on the light tugs, and a third group that had received unique exposure to trioctyl phosphate (TOF). TOF is an agent that was once used as a stimulant, but has come under increased scrutiny for possible carcinogenic and pulmonary effects. Each man underwent a detailed cumulative exposure assessment by the committee.

Health outcomes analyzed in relation to potential sarin exposures included systemic neurological effects (both central and peripheral nervous systems), specific neurological effects such as hearing loss, and psychological symptoms (depression, anxiety). The committee evaluated all causes of death in the study population since the 1960s, along with diagnoses assigned at hospital and

outpatient visits. Records from Medicare (1999 through 2011) and the VA Health System (late 1997 through 2011) were used to gather these data. Cause of death information was obtained from the National Death Index and death certificates found in state vital statistics offices. Ninety-one percent of the study population was identified as deceased, and 83% of SHAD participants presumed living were 65 years or older at the time of analysis.

The committee did not find any overall differences in all-cause morbidity and mortality between SHAD veterans and comparison groups. The association with heart disease mortality described in the SHAD I study was not present in this study. In fact, no notable differentials in health outcomes were identified between exposure and control groups in this extensive analysis.

The SHAD II study encountered several methodological challenges. Because of the lengthy time between the SHAD tests and this follow-up study, it was difficult to account for factors beyond the exposures that might have influenced health outcomes. Of significance, the study could not control for potential exposures to Agent Orange. The committee assumed that risk of Agent Orange exposure was similar between the SHAD and comparison groups based on evidence from VA data. Furthermore, researchers neither had access to classified data on the concentration of test substances, nor did they know ship location data for individuals, meaning exposure doses could not be estimated.

6.5 Iran–Iraq War

Iraq attacked Iran in 1980, employing mustard gas and tabun, in a war that would last 8 years. Saddam Hussein, then President of Iraq, had received chemical weapons from many countries, including the United States, West Germany, the Netherlands, the United Kingdom, France, and China (Lafayette, 2002). A total of five percent of all Iranian casualties were directly attributable to the use of such chemical agents, with Iran sustaining approximately 387 chemical attacks throughout the war (Shemirani et al., 1993). About 100,000 Iranian soldiers became chemical warfare victims, along with a significant number of civilians. In fact, nerve gas killed about 20,000 Iranian soldiers instantly during fighting. In the closing days of the war, in 1988, the Iraqi Kurdish village of Halabja was bombed with mustard gas and sarin, resulting in the death of 10% of its 50,000 residents.

Iranian scientists have produced a large volume of well-designed epidemiological studies on the health effects of chemical warfare in the decades since. Hashemian et al. (2006), for example, conducted a cross-sectional, randomized survey of 153 civilians in three towns exposed to military conflict in northwestern Iran: Oshnaviveh (low-intensity conventional warfare), Rabat (high-intensity conventional warfare), and Sardasht (both high-intensity conventional warfare and chemical weapons). The surveys measured full or partial PTSD and symptoms of anxiety and depression. Compared with those exposed to low-intensity warfare, people exposed to both high-intensity warfare and chemical weapons were at greater risk for:

- Lifetime PTSD [odds ratio (OR) 18.6; 95% confidence interval (CI), 5.8–59.4];
- Current PTSD (OR 27.4; 95% CI, 3.4–218.2);
- Increased anxiety symptoms (OR 14.6; 95% CI, 6.0–35.6);
- Increased depressive symptoms (OR 7.2; 95% CI, 3.3–15.9).

Exposure to high-intensity warfare, but not to chemical weapons, was also significantly associated with lifetime PTSD (OR 5.4; 95% CI, 1.7–17.6), compared with exposure to low-intensity conventional warfare. Further, compared with those exposed to high-intensity warfare alone, people exposed to both high-intensity warfare and chemical weapons had a greater risk of lifetime PTSD (OR, 3.4; 95% CI, 1.5–7.4), current PTSD (OR, 6.2; 95% CI, 2.0–20.1), increased anxiety symptoms (OR, 5.6; 95% CI, 2.5–12.6), and increased depressive symptoms (OR, 3.7; 95% CI, 1.8–7.2).

In a separate 2013 study, an excess of psychological symptoms were found to have persisted for Iranian victims 20 years after exposure. Roshan et al. assessed the mental health of 367 civilians who had been exposed to sulfur mustard. When compared to 128 age-matched controls, exposed people had significantly higher rates of somatization, obsessive-compulsion, depression, anxiety, hostility, and global distress indices. Another report published in 2019 described a secondary data analysis of chronic mental and physical conditions among exposed Iranian male veterans (Safi-Aghdam et al., 2019). Compared to nonexposed veterans, those who had experienced chemical attacks showed significantly elevated odds of PTSD, hypertension, coronary heart disease, and diabetes.

Sulfur mustard is rated by the International Agency for Research on Cancer (IARC) as a human carcinogen and is a known risk factor for occupational lung cancer (Nishimoto et al., 1987; Ghanei and Vosoghi, 2002). Zafarghandi et al. (2012) described the incidence of cancer in 7570 Iranian sulfur mustard-exposed veterans, versus 7595 unexposed subjects in a 25-year follow-up study. Cancer incidence was significantly higher among the sulfur mustard group, with a cancer incidence rate ratio of 1.81 (95% CI, 1.15–2.34), though no increased risk of site-specific cancer was found. The hazard ratio of cancer occurrence was 2.02 (95% CI, 1.41–2.88).

Affected Iranians have reported lasting health effects from sulfur mustard and nerve agents, even 25 years post exposure. A 2013 study by Behravan et al. substantiated these reports by revealing higher levels of DNA damage, as measured by comet assay in 25 sulfur mustard-exposed veterans, compared to controls. In 2018, these same researchers demonstrated that telomere lengths (associated in laboratory studies with aging and tumor development) in 40 sulfur mustard-exposed Iranian veterans were shorter than those observed in 40 nonexposed healthy volunteers.

The long-term respiratory effects of sulfur mustard were explored in the Sardasht-Iran Cohort Study, which included 372 exposed individuals from Sardasht and 128 nonexposed individuals from Rabat (Ghazanfari et al., 2009). As part of this research, Ghanei et al. (2010) studied pulmonary complications and found that blistering at the time of exposure was associated with more respiratory symptoms and worse lung function over time, according to computed tomography (CT) of the thorax. Blistering upon exposure was not, however, associated with air trapping, bronchiectasis, or mosaic parenchymal attenuation. Boskabady et al. (2012) built upon this research by comparing the pulmonary function of 142 exposed victims with 120 controls. A full 100% of exposed people in their sample reported respiratory symptoms. The exposed group performed worse on pulmonary function tests and also experienced respiratory symptoms with greater severity than the control group.

A possible link between sulfur mustard and cardiovascular toxicity was reported by Karbasi et al. (2013). This case-control study involved 200 consecutive patients undergoing angiographic assessment due to coronary artery disease, 100 with a history of sulfur mustard exposure and 100 without. Significantly different coronary findings were noted between the exposed and nonexposed groups, suggesting the need for more studies on the cardiovascular effects of sulfur mustard. Khosravi et al. (2018) described long-term right ventricular changes in patients exposed to sulfur mustard. As part of their study, exposed ($n = 23$) and nonexposed ($n = 19$) veterans of the Iran–Iraq War underwent echocardiographic measurements of right ventricular size and function. Pulmonary artery pressure was found to be higher and right ventricular strain lower in the exposed group. This highlights the need for more studies evaluating a possible link between sulfur mustard and cardiotoxicity.

The dermatological effects of sulfur mustard and nerve agents also have been studied among survivors of the Iran–Iraq War. Emadi et al. (2012) tracked late cutaneous complications between two exposure groups: 154 people with a history of sulfur mustard exposure and 175 people with a history of nerve agent exposure. Only 18.1% of the mustard-exposed group was asymptomatic, compared to 62.4% of the nerve agent group. Numerous mustard-induced dermatologic lesions were reported, including scars, intertrigo, xerosis, cherry angioma, hyperpigmentation, pilar keratosis, poikiloderma, and malignant tumors.

Children were exposed to toxic chemicals during this war as well. Talabani et al. (2018) were the first to evaluate the long-term health outcomes for affected children. Seventy percent of exposed children (now adults) who they surveyed reported chronic health problems, compared to 3.3% of the nonexposed population. The most common chronic problems affecting this group were visual impairments, chronic dermatological issues, and respiratory conditions, such as asthma and chronic bronchitis. The authors noted greater prevalence of these issues among people exposed during childhood than among those exposed during adulthood (determined by comparing their data with existing reports).

6.6 1991 Gulf War

Given his history of using chemical weapons against Iraqi citizens, there was much international attention that Saddam Hussein would employ these weapons against Coalition Forces. Yet the only known Gulf War exposures to anticholinesterase warfare agents did not take place during battle. Rather, one occurred during the detonation of munitions containing 8.5 metric tons of sarin/cyclosarin housed in Bunker 73 at Khamisiyah, Iraq, on March 4, 1991. The second involved the destruction of sarin/cyclosarin rockets in a pit at Khamisiyah on March 10, 1991. The US DoD reported that exposure levels were too low to activate chemical alarms or to cause symptoms at the time of detonation. However, several studies have since been conducted to assess the long-term health effects of these events. The DoD, for example, modeled the air plume that resulted from the detonation to estimate the extent of troops potentially exposed to the plume.

McCauley et al. (1999) completed a computer-assisted telephone survey of 2918 Gulf War veterans to evaluate the prevalence of self-reported medical diagnoses and hospitalizations among those potentially exposed. Respondents included veterans living in Oregon, Washington, California, North Carolina, and Georgia who had been deployed to the Southwest Asia Theater. The comparison group consisted of veterans living in the same states who had been deployed to different locations during the war. Troops reported to have served within 50 km of the Khamisiyah site did not differ from other deployed troops in terms of reported medical conditions. Hospitalization rates among exposed and nonexposed troops did not differ 9 years postwar either. Exposed troops were, however, significantly more likely than nonexposed troops to report diagnoses of high blood pressure (OR = 1.7), heart disease (OR = 2.5), slipped disk or pinched nerve (OR = 1.5), PTSD (OR = 14.9),

hospitalizations for depression (OR = 5.1), and periodontal disease (OR = 1.8). Exposed veterans also reported more diagnoses of any cancer (OR = 3.0).

Another study explored the postwar morbidity of Gulf War veterans, contrasting the health of those possibly exposed to low levels of nerve agents at Khamisiyah to that of veterans unlikely to have been exposed (Smith et al., 2003). Cox regression modeling was performed for hospitalizations from all causes, as well as hospitalizations from 15 specific diagnoses, among those on active duty from March 10, 1991 through December 31, 2000. Veterans possibly exposed to nerve agents were not found to be at greater risk for hospitalization from most chronic diseases nearly 10 years later. Only 2 of 37 models suggested that personnel possibly exposed to subclinical doses of nerve agents might be more prone to hospitalization from circulatory diseases, specifically hospitalizations due to cardiac dysrhythmias.

Bullman et al. (2005) published a mortality study of troops exposed to chemical warfare agents based on air plume models that were developed post detonation. Cause-specific mortality of 100,487 exposed US Army Gulf War veterans was compared to that of 224,480 nonexposed veterans. Most disease-related mortality rates were similar between groups. However, exposed service members had an increased risk of brain cancer death (relative risk = 1.94; 95% CI, 1.12, 3.34). This increased risk was highest among veterans who were exposed for 2 or more days versus only 1 day.

This same team conducted a separate study to examine the association between Khamisiyah plume exposure and subsequent self-reported morbidity (Page et al., 2005). Their sample included 1056 Gulf War Army veterans who had responded to the National Health Survey of Gulf War Era Veterans in 1995, and who were resurveyed in 2000. Half of the subjects had been notified of potential exposure to chemical warfare agents. Comparing notified and nonnotified subjects, there were no statistically significant differences with respect to bed days, activity limitations, clinic visits, or hospital visits. This suggested that receiving information about the potential exposure did not increase self-reports of illness and clinic visits.

Page et al. (2005) published a similar study investigating whether possible chemical warfare exposure might be associated with morbidity among Army Gulf War veterans, using data for 5555 individuals. Their analysis incorporated responses to 86 self-assessed health measures, as reported in the 1995 National Health Survey of Gulf War Era Veterans. The authors found little association between potential exposure and health outcomes after adjusting for demographic variables. They concluded that potential exposure to sarin or cyclosarin at Khamisiyah did not seem to have adversely affected self-perceived health status, as evidenced by a wide range of health measures.

The Fort Devens Cohort, part of the VA Boston Healthcare System, is one of the largest Gulf War cohorts studied to date. These veterans were initially assessed just days after their return from deployment and at additional points over the past 19 years. Reports from the early 1990s revealed excess joint pain, headaches, memory and attention difficulties, skin rashes, gastrointestinal symptoms, and sleep disorders (Krengel, 2013; Proctor, 1998; Wolfe et al., 2002). A 2019 study by Zundel et al. compared the prevalence of self-reported chronic medical conditions in the Devens Cohort ($n = 448$) to the population-based National Health and Nutrition Examination Survey (NHANES) Cohort (also self-reported). This was the fifth survey of the Devens Cohort since its inception in 2013. Participants that reported exposure to war-related chemical agents also experienced higher rates of hypertension, diabetes, arthritis, and chronic bronchitis. The authors acknowledged that while this self-reported information is useful in describing health patterns among Gulf War veterans, direct linkages could not be drawn between health status and CWA exposures.

Several neurological studies have been conducted on subgroups of the Devens Cohort. Heaton and colleagues (2007) examined the association between modeled estimates of various levels of sarin/cyclosarin exposure and volumetric measurements of gross neuroanatomical structures in 1991 Gulf War veterans. A total of 26 individuals recruited from the Devens Cohort participated (13 exposed and 13 nonexposed). Veterans underwent magnetic resonance images (MRIs) of the brain, which were analyzed using morphometric techniques. Researchers produced volumetric measurements of white matter, gray matter, right and left lateral ventricles, and cerebrospinal fluid. Volumetric data were then analyzed against exposure estimates obtained from refined models of the presumed exposure hazard area in Khamisiyah. Researchers observed no differences in volumetric measurements of discrete brain tissues between the 13 exposed and 13 nonexposed veterans. However, linear trend analyses showed a significant association between higher levels of estimated sarin/cyclosarin exposure and both reduced white matter volume (adjusted parameter estimate = 4.64, $P < .0001$) and increased volume of the right lateral ventricle (adjusted parameter estimate = 0.11, $P = .0288$) and left lateral ventricle (adjusted parameter estimate = 0.13, $P < .0001$). These findings suggest subtle, but persistent central nervous system pathology in Gulf War veterans potentially exposed to low levels of sarin/cyclosarin.

This investigative team also studied neurobehavioral performance results collected prior to the notification of veterans potentially exposed during the Khamisiyah detonation (Proctor et al., 2006). They hypothesized that exposure to sarin and cyclosarin would be associated with poorer performance on objective neurobehavioral tasks in

specific functional domains (particularly visuospatial abilities and psychomotor functioning) in a dose-dependent manner. They found that sarin and cyclosarin were significantly associated with less proficient neurobehavioral functioning on certain tasks 4–5 years after exposure. Specifically, potentially exposed veterans performed tasks requiring fine psychomotor dexterity and visuospatial abilities with less proficiency. The authors concluded that findings suggest a dose–response association between low-level sarin and cyclosarin and specific central nervous system effects.

Investigators from the University of California, San Francisco, published several additional studies on a second group of Gulf War veterans with suspected sarin/cyclosarin exposure (Chao et al., 2010). They compared the neurological health of 40 Gulf War veterans categorized as having been exposed at Khamisiyah to that of a control group with 40 nonexposed veterans. After obtaining MRI brain scans, researchers calculated volumetric measurements of gray matter, white matter, cerebrospinal fluid, and the hippocampus. They also performed a series of cognitive function tests. Exposed veterans had reduced total gray matter and hippocampal volumes compared to controls ($P < .01$). No group differences on measures of cognitive function or total white matter volume were observed. However, the authors did report significant positive correlations between total white matter volume and measures of executive function and visuospatial abilities in exposed veterans. This effect on visuospatial functioning was also displayed in a larger sample ($n = 136$) of Gulf War veterans recruited from the San Francisco area. Chao (2016) again revealed that self-reported frequency of hearing chemical alarms in theater was inversely associated with performance on a visuospatial task.

Based on these initial findings of possible low-dose sarin/cyclosarin effects, Chao and colleagues continued to examine hippocampal changes in Gulf War veterans. However, in a 2011 follow-up study, Chao et al. were not able to replicate hippocampal findings in 64 service members with possible sarin/cyclosarin exposure (Chao et al., 2011). Suspecting that imaging technique may have led to these negative findings, in a 2014 report, Chao et al. used a new technique called the automatic segmentation of hippocampal subfields to quantify hippocampal subfields in 56 exposed Gulf War veterans. (The control group included 56 nonexposed veterans). While this study revealed no difference in total hippocampal volume, differences were noted in certain subfields. The authors continued to explore potential links between chemical warfare agents (based on DoD exposure models) and hippocampal function. In 2017, they published a study on 113 Gulf War veterans who had not participated in previously published studies of hippocampal function (Chao et al., 2017). This research found exposed veterans to have smaller total hippocampal and subarea volumes compared to unexposed veterans, controlling for genetic and clinical variables. Memory performance was positively correlated with hippocampal volume.

Continuing to focus on hippocampal structural changes and neurological function, Chao et al. (2017) tested 126 previously nonstudied veterans to describe whether volume changes were accompanied with microstructural alterations of the hippocampus. Significant associations between exposure and mean diffusivity of the hippocampus were noted, and this diffusivity was related to verbal memory learning performance. These papers have been important in exploring the mechanism by which low-dose exposure to chemical warfare agents may be related to long-term and chronic alteration in hippocampal function.

6.7 Syrian War

The ongoing Syrian War, which began in 2011, has featured the use of deadly force by Bashar al-Assad's regime against dissident groups and civilians located in dissident-held territories. The use of chemical weapons against civilians. While the Syrian government denies ever having used chemical weapons, initial tests on samples from two attack sites detected chlorinated organic chemicals. Following a 2017 attack on the rebel-held area of Khan Sheikhoun, experts reported with confidence that sarin was used in the attack, which reportedly killed more than 80 people.

The most recent attack occurred in April 2018 with an estimated 1700 casualties. Citizens seen in emergency departments were described as having respiratory distress, central cyanosis, excessive oral foaming, corneal burns, and the emission of a chlorine-like odor (BBC News, 2018). Due in part to the ongoing conflict, little is known about the long-term effects these exposures might be having on targeted populations. Rodriguez-Llanes et al. (2018) applied descriptive epidemiological techniques to characterize the victims of attacks from 2011 to 2017. The authors estimated a total of 1206 direct deaths, with 1084 of those deaths resulting from five major attacks. Civilians comprised the vast majority of these deaths (97.6%), and children accounted for 13%–14% of fatalities.

In a 2015 correspondence, Hakeem and Jabri described adverse birth outcomes among women exposed to the 2013 Moadamyah chemical attacks. They reviewed the medical records of 211 pregnant women who visited the Al Ghouta Hospital in September, October, and November 2014. There were 110 women who had a self-reported exposure to the attack and 101 who had not been exposed. The miscarriage rate was 45% in the exposed group, compared to 14% in the nonexposed group.

The exposed group also had four premature births and three stillbirths, compared to none in the nonexposed group. Congenital anomalies were observed among the births, including cardiac abnormalities and multiple malformations of the head and spinal cord. The authors point to the need to closely monitor maternal records of exposed pregnant women, given their particular susceptibility and the susceptibility of their offspring.

6.8 Terrorism

Two sarin-based terrorist attacks took place in Matsumoto and Tokyo, Japan, in 1994 and 1995 respectively. These attacks killed 19 people and injured more than 6000. Morita et al. (1995) described the acute effects of the attacks, including instantaneous death by respiratory arrest in four Matsumoto victims. In Tokyo, two people died in station yards, and another 10 died in hospitals within hours to 3 months after poisoning. A total of six victims with serum cholinesterase (ChE) below 20% of the lowest normal levels were resuscitated from cardiopulmonary arrest (CPA) or coma with generalized convulsion. Of those, five recovered completely and one remained in a vegetative state due to anoxic brain damage. Electroencephalogram (EEG) abnormalities were observed for up to 5 years in some victims. Miosis and copious secretions from the respiratory and gastrointestinal tracts (muscarinic effects) were common in slightly to severely affected individuals. Weakness and muscle twitches (nicotinic effects) appeared in severely affected people. Neuropathy and ataxia impacted a small number (less than 10%) of victims; these symptoms disappeared after between 3 days and 3 months. Leukocytosis and high serum creatine kinase (CK) levels were also common. Hyperglycemia, ketonuria, low serum triglycerides, and hypokalemia were observed among those severely affected; these abnormalities were attributed to damage to the adrenal medulla.

The Matsumoto government assembled a committee of city officials, local hospital personnel, and physicians from Shinsu University to monitor immediate and long-term exposure outcomes. Their work represents the most comprehensive epidemiological studies on the acute and residual effects of chemical warfare agents to date. Three weeks after the attack, residents living within 850−1000 m of its location ($n = 2052$) were surveyed and categorized as "severely affected" if they had been admitted to the hospital, "moderately affected" if they had been treated in outpatient clinics, and "slightly affected" if they had experienced symptoms, but did not seek medical attention. At the time of the survey, 28% of affected residents remained symptomatic (69% of those severely affected, 42% of those moderately affected, and 14% of those slightly affected). The most common persistent symptoms were fatigue, dysesthesia of extremities, and ocular pain. Visual problems persisted in about 10% of severely affected victims (Yanagisawa et al., 2006).

In the Tokyo subway attack, 640 victims were seen within hours of the incident. Of these people, five were critically injured and required mechanical ventilation; another 107 were moderately injured with systemic symptoms and signs of respiratory, digestive, or neurological damage, in addition to ocular problems. A large majority (528 people) had eye damage or ocular symptoms only and were released after several hours of observation (Yanagisawa et al., 2006).

Yokoyama et al. (1998a) followed up with 18 sarin-exposed victims 6−8 months after the attack and found their mean plasma ChE to be 72.1 (normal range = 100−250 IU/L). In neurobehavioral testing, this group scored significantly lower on the Digit Symbol Substitution Test, a timed, paper-and-pencil cognitive test, than the control group. Exposed people were also more likely to have higher scores on both the General Health Questionnaire, an indication of psychological distress, and fatigue measures than controls; their PTSD scores were also greater. Furthermore, victims displayed poorer postural balance, suggesting their integration of visual input might have been impaired (Yokoyama et al., 1998b). P300 and VEP (P100) latencies were significantly prolonged for sarin victims compared with matched controls (Murata et al., 1997). Additionally, CVRR (electrocardiographic R−R interval variability) among victims was significantly related to serum ChE levels measured immediately after sarin exposure. While people exposed to sarin had high PTSD scores, those scores were not significantly associated with any specific neurophysiological data. These findings suggest that asymptomatic aftereffects from sarin, rather than PTSD, persist in the higher and visual nervous systems beyond the turnover period of ChE.

The National Police Academy in Japan (1999) conducted a survey of 1247 Tokyo residents who had reported a sarin exposure to police at the time of the incident. In the survey, more than half complained of physical symptoms, such as asthenopia and decreased visual acuity; 17% reported lasting psychological trauma from the event. Fourteen percent remained unable to ride on subways 3 years after the incident.

There have been several follow-up studies describing residual effects from the Tokyo subway exposures. Ohtani et al. (2004) followed 34 victims for 5 years after the event. Not only PTSD, but also nonspecific mental symptoms, continued to affect them at high rates. A total of 11 victims were diagnosed with current or lifetime PTSD. Those with PTSD showed higher anxiety levels and greater degrees of visual memory impairment.

Yamasue et al. (2007) conducted a study 5 years post exposure to identify persistent morphological changes in

Tokyo subway attack survivors. In this study, 38 people who had been treated in the emergency department for sarin intoxication and 76 control subjects underwent weighted and diffusion tensor MRIs. Researchers compared victims' present-day ChE levels to their levels immediately after the attack. Voxel-based morphometry exhibited smaller-than-normal regional brain volumes in the insular cortex and neighboring white matter, as well as in the hippocampus. Reduced regional white matter volume correlated with both decreased serum cholinesterase levels and the severity of chronic somatic complaints related to interoceptive awareness. Furthermore, voxel-based analysis of diffusion tensor MRIs demonstrated a significantly lower-than-normal fractional anisotropy in the victims. These findings suggest that sarin intoxication might be associated with structural changes in specific brain regions.

Attention also has been paid to rescue and safety workers who responded to the Tokyo attack. Nishiwaki et al. (2001) looked at 27 male rescue team members and 30 police officers 3–45 months after the event. The subjects showed decreased performance on the Digit Span Test, a measure of short-term memory retention. However, they noted no effects on participants' stabilometry or vibration perception thresholds. In another study, Li et al. (2004) followed 27 male firefighters and 25 male police officers 3 years after the attack for genotoxic effects. They found an elevated frequency of sister chromatid exchanges in the victims' lymphocytes, which were related to the percentage of ChE inhibition observed just after the attack.

6.9 Concluding remarks and future directions

This chapter described the major epidemiological studies of populations exposed to chemical warfare agents. Many of the studies involving military populations took place decades after the exposure and suffer from inaccurate exposure assessment, as well as a lack of clinical data. However, in the past two decades, studies surrounding terrorist attacks and the Iran–Iraq War have provided comprehensive data on the scope of health outcomes associated with warfare chemicals. Emerging reports of chronic disease in the years post exposure point to the need for long-term follow-up studies involving victims of such events. As more women participate in military forces and public safety units, studies are needed to document gender-related health effects. Chemical warfare exposure continues to be a threat in the current Civil War in Syria. More studies are needed to determine the effects of these agents on vulnerable populations, such as children and pregnant women.

7.1 Introduction

After the September 11, 2001 (9/11) terrorist attacks in the United States, the high risk of possible attacks with chemical weapons (CWs), especially by groups linked to jihadist terrorism, has been perceived. Before 9/11, in 1994 and 1995, Aum Shinrikyo, a religious organization in Japan, used sarin (a nerve agent) in attacks in Matsumoto and on the Tokyo subway, causing a large number of casualties. These terrorist attacks had a large impact on the international chemical defense and intelligence communities, but not on other circles, perhaps because a chemical attack by a religious organization in Japan seemed something far removed from the reality of the rest of the world. But this changed after 9/11, when the mailing of letters containing *Bacillus anthracis* spores accompanied by images of the attacks on New York City's World Trade Center towers increased the concern about weapons of mass destruction (WMD) attacks, including attacks with CWs.

In this chapter, information is analyzed from open sources regarding the possible use of CWs by terrorist groups, especially by those affiliated with the jihadist terrorism network. As religious terrorist groups, Al Qaeda and Daesh do not fit the assumption made by Brian Jenkins in 1975 that "terrorists want a lot of people watching and a lot of people listening, and not a lot of people dead" (Jenkins, 1975). This statement fits better with secular terrorist groups. But for religious terrorist groups, "divine duty" results in disappearance of moral restraints that would justify "a lot of people dead" in their terrorist attacks, such as the 9/11 attacks. And if CWs are part of the WMD concept because they can cause a large number of casualties, they could be very good tools for jihadist terrorist groups to achieve their goals.

7.2 Chemical weapons for terrorist actions

7.2.1 "Classical" chemical warfare agents: vesicants and nerve agents

The two main chemical warfare agents (CWAs) are vesicants and nerve agents (Table 7.1). The first chemicals used as weapons in World War I included toxic industrial chemicals (TICs) that were widely available in the chemical industry. These included lung-damaging agents like chlorine and phosgene, as well as cyanides that were named "blood agents." When these agents proved to be effective at the tactical level, research and development programs of CWAs started (Pita, 2008). These programs tried to obtain chemicals that would be effective in battle because of their physicochemical and toxicological properties, although they had no use in the industrial field.

First, sulfur mustard, a vesicant warfare agent, was produced and used in World War I. Mustards alkylate a wide range of biologically important molecules producing cytostatic, mutagenic, and cytotoxic effects. In 1936, just before the start of World War II, tabun was synthesized and then produced as the first nerve CWA. Nerve agents inhibit acetylcholinesterase (AChE) throughout the body, causing an accumulation of acetylcholine (ACh), which produces overstimulation at muscarinic and nicotinic receptors in the peripheral and central nervous systems.

Vesicant agents (sulfur mustards, nitrogen mustards, and lewisites) and nerve agents (tabun, sarin, soman, and VX, among others) are included in the Chemical Weapons Convention (CWC) Schedule 1 of chemicals for the application of verification measures. This schedule features chemicals that have little or no use in the industry and have been developed, produced, stockpiled, or used

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00007-6

TABLE 7.1 Some potential chemical agents for terrorist actions.

Vesicants	Sulfur mustards
	Nitrogen mustards
	Lewisites
Nerve agents	Tabun (GA)
	Sarin (GB)
	Soman (GD)
	VX
	"Novichok" agents
Incapacitating agents	BZ
	Opioids
Riot control agents	CS
	CN
	CR
	Capsaicin
Toxic industrial chemicals	Chlorine
	Phosgene
	Cyanides
	Phosphine
	Hydrogen sulfide
Toxins	Ricin

as CWs. Other nerve agents include intermediate volatility agents (IVAs) like GV, as well as those allegedly developed in the Foliant program of the former Soviet Union during the Cold War, commonly known as Novichok ("Newcomer") (Nepovimova and Kuca, 2018a; Pita, 2008). One of the most interesting properties of the Novichok agents is that they were not included until 2020 in the CWC's schedules for the application of verification measures. Most of the public information available about Novichok agents comes from Vil Mirzayanov, an analytical chemist who worked in the Foliant program. In his book *State Secrets*, Mirzayanov (2008) published for the first time the chemical structures of some of the agents developed.

Nerve agents can be considered as the most important CWAs because of their high toxicity and their high versatility for tactical use. This high versatility is attributable to the fact that although all nerve agents are liquid at room temperature, some can be considered persistent agents (e.g., VX) because of their low volatility, whereas others can be considered nonpersistent (e.g., sarin) because their volatility is higher. Persistent agents would be useful against targets with no occupational interest that would be contaminated for a certain period of time. In contrast, nonpersistent agents would evaporate faster and would be the choice against targets that need to be occupied.

Toxicological and physicochemical properties of nerve agents would also make this group the CWs of choice for terrorist groups. However, the synthesis process requires some level of expertise and is far more complex than the recipes featured in the "do it yourself" (DIY) manuals available on the Internet (Fig. 7.1). Even Aum Shinrikyo—which had excellent financial resources and personnel with the required expertise and performed their attacks before the entry into force of the CWC—had some difficulties in synthesizing sarin (Tu, 2002).

7.2.2 Incapacitating agents

Incapacitating agents are chemicals that produce a disabling condition that persists for hours to days after exposure has occurred. These were studied during the Cold War when it was assumed that incapacitating the enemy would cause damage not only because casualties would become unavailable for duty but also because they would need to be evacuated and would consume more logistical resources (Pita, 2008). Incapacitating agents include depressants and stimulants of the central nervous system (CNS). The main incapacitating agent is BZ (3-quinuclidinyl benzilate), a CNS depressant included in Schedule 2 of the CWC because it is produced in small commercial quantities for biomedical purposes.

Opioids have also been studied as incapacitating CWAs. In October 2002, a fentanyl derivative was used by Russian Special Forces to end a hostage crisis during which Chechen terrorists had taken approximately 800 hostages at a Moscow theater (Wax et al., 2003). The dissemination of this opioid through the theater ventilation system killed approximately 130 people and injured more than 600. The fact that medical services did not have information about the identity of the chemical resulted in a lack of antidotal treatment of the poisoned hostages.

7.2.3 Riot control agents

Riot control agents (RCAs), popularly referred to as "tear gas" or "pepper spray," should not be confused with incapacitating agents. Unlike the latter, RCAs are local irritants with disabling effects that disappear within a short time after the exposure. Most important, RCAs do not act at the CNS level; therefore, they have lower toxicity and a wide margin of safety when compared with incapacitating agents. RCAs are not listed in the CWC schedules. Although the Convention prohibits its use as a method of warfare, it does not prohibit its use for law enforcement purposes.

FIGURE 7.1 A jihadist manual dealing with the production of CWs available on the Internet.

7.2.4 Toxic industrial chemicals

TICs are of special interest in the chemical terrorism context because they are widely available in large quantities. An attack against a chemical plant or transport vehicle may result in a release with potentially catastrophic consequences, like the release of methyl isocyanate in Bhopal (India) in 1984.

The importance of TICs is reflected in the fact that the CWC features a schedule that includes chemicals that may be produced in large commercial quantities for industrial purposes, but that have been produced, stockpiled, or used as CWs. Schedule 3 includes phosgene, a lung-damaging agent, and some cyanides. Cyanides are commonly named "blood agents," something that may cause confusion, leading one to think that cyanides affect the oxygen transportation in the blood. The reason for calling cyanides blood agents was because chlorine and phosgene were toxic chemicals with local effects in the respiratory tract, whereas cyanides had to be absorbed in the lungs and passed to the blood to produce systemic effects. Although cyanides produce cellular asphyxiation at the mitochondrial level, it is not rare to see them as "blood agents" when mentioned in the CWs or chemical terrorism context.

7.2.5 Toxins

Toxins are chemical substances of biological origin, although synthesis procedures for some nonprotein toxins that have been studied as weapons are widely available (Jacobi et al., 1984; Tanino et al., 1977). Toxins are included in the CWC because it covers toxic chemicals "regardless of their origin or of their method of production." Actually, two toxins, ricin and saxitoxin, are explicitly included in Schedule 1 of the CWC. However, toxins are also included in the Biological and Toxin Weapons. For these reasons, toxins can be considered CWs, biological weapons, or mid-spectrum agents.

7.3 Tampering with chemical weapons

Throughout history, there have been extortion tampering cases where toxic chemicals have been used. For example, at the end of 1982, there were seven fatal cases of cyanide poisoning after the ingestion of acetaminophen-tampered capsules (Dunea, 1983; Wolnik et al., 1984). McNeil Consumer Products had to destroy approximately 22 million units and changed the production from capsules to tablets that were more difficult to tamper with. Those responsible were never identified, and some imitators in the US started contaminating medicines and food products with toxic chemical substances.

In some cases, blackmailers have even attacked governments. For instance, on March 2, 1989, an anonymous person called the United States and Japanese embassies in Santiago, Chile, alerting them that cyanide had been injected in fruit destined to be exported to those countries (Grigg and Modeland, 1989; Spiers, 2000; Wilkening, 1999). Although countermeasures were not taken initially, after a second call to the US embassy on March 17, the US Food and Drug Administration (FDA) decided to start inspections at the Philadelphia port, the port of entry of

approximately 80% of the fruit from Chile. After an extensive search, only two grapes that had been injected with a small quantity of sodium cyanide were found. However, as a preventive measure, on March 13, all fruit coming from Chile was placed on quarantine. Subsequent searches did not find more tampered fruit and the quarantine ended on March 17. Although the event ended without any poisoning cases, it meant losses of approximately $300 million for Chile's fruit export market.

Europol's 2018 terrorism situation and trend report mentions that between 2013 and 2017 anarchist organizations in Greece and Italy threatened to intentionally contaminate food or water (Europol, 2018). These threats were part of campaigns to target multinational corporations in order to produce loss of revenue.

7.4 State terrorism

CWs have also been used in the assassination of selective targets by secret services. The defection of the KGB's Capt. Nikolai Khohhlov in February 1954 brought to light some of the devices created for this type of attack. In fact, Khohhlov defected in the middle of a mission to assassinate Georgi Okolovich, a Soviet dissident living in West Germany, by using a cigarette pack that concealed a hydrogen cyanide ampoule (Andrew and Gordievsky, 1990). Similar cases include the killing of two Ukrainian exiles in Munich in 1957 and 1959 by a KGB agent who used a special gun device to disperse hydrogen cyanide. According to Vadim Birstein, since the 1920s and at least until the late 1970s, different laboratories in the Soviet Union were in charge of the development of assassination devices for their Secret Services (Birnstein, 2001).

One of the most bizarre stories of assassination is the murder of Georgi Markov, a Bulgarian journalist exiled in the United Kingdom, with an umbrella that delivered ricin (Crompton and Gall, 1980; Knight, 1979). The umbrella was allegedly modified to fire a small pellet filled with approximately 500 μg of ricin. On September 7, 1978, Markov was waiting for a bus on Waterloo Bridge when he felt a strong puncture in the back of his right thigh. When he turned around, a man with an umbrella apologized. The next day he was hospitalized with fever, vomiting, speaking difficulties, and a white cell count of 10,600/mm^3 that increased to 33,200/mm^3 3 days later. On September 11, Markov died of cardiac failure. The autopsy revealed the presence of a small spherical pellet with a diameter of 1.53 mm that had two holes of 0.34 mm. Days before Markov was attacked, on August 26, another Bulgarian exiled in Paris (France), Vladimir Kostov, also felt a puncture in his back and had to be hospitalized for 12 days, although he finally recovered. On September 26, a similar pellet—spherical, of 1.52 mm diameter, with two holes of 0.34 mm—was extracted from his back.

No public reports about the identification of ricin have been published. The ricin link was made based on the differential diagnosis by the UK's Ministry of Defense scientists (they even administered ricin to a pig to compare the clinical signs of the poisoning with those observed in Markov), histopathological findings that were similar to those found in different *in vivo* tests with animal models, and intelligence regarding a ricin program in the Soviet Union and perhaps other Warsaw Pact nations (Birnstein, 2001; Waller et al., 1966).

Years later, former KGB members stated that the umbrella was provided by the KGB to the Bulgarian Secret Services, and that previous attempts to kill Markov had been unsuccessful (Andrew and Gordievsky, 1990; Kalugin, 1994). Because Bulgarian documents about the Markov case appear to have been destroyed, only future KGB document releases would disclose more information about this murder (Carus, 2002).

More recently, on March 4, 2018, former Russian double agent Sergei Skripal and his daughter were found unconscious in Salisbury (UK) and transported to hospital where they were treated for nerve agent poisoning (Vale et al., 2018). A police officer who responded to the incident and visited Skripal's house was also poisoned and received similar treatment. The three patients survived and were eventually discharged from hospital. Analyses of environmental and biomedical samples by Porton Down's Defence Science and Technology Laboratory (DSTL) and by the Organization for the Prohibition of Chemical Weapon (OPCW)'s designated laboratories, identified a Novichok nerve agent of high purity (Bristow, 2018; Johnson, 2018; Sedwill, 2018; Wilson, 2018). Russia's ambassador to the UK leaked the agent identity as "A-234" (Faulconbridge and Holden, 2018). The highest concentrations were found in samples taken from the handle of Skripal's front door, indicating that most probably exposure was caused by dermal contact with a liquid agent applied to the handle. After the analyses results were made public, the British government stated that based on capabilities and motivations, it was "highly likely" that Russia was responsible for the attack (Bristow, 2018; Johnson, 2018; Sedwill, 2018). The Russian authorities denied any involvement in the Salisbury incident and the existence of a chemical program that developed Novichok agents (Embassy of the Russian Federation to the United Kingdom, 2019).

On June 30, a man and a woman from Amesbury (about 7 miles north of Salisbury) were hospitalized and treated for nerve agent poisoning after handling a perfume bottle they had found at Queen Elizabeth Gardens in Salisbury. The man was subsequently discharged from

hospital, but the woman died on July 7. The same Novichok agent was identified in biomedical and environmental samples analyzed by Porton Down's DSTL and OPCW's designated laboratories (OPCW, 2018). The analysis of the fake Nina Ricci perfume bottle content showed a concentration of 97%–98%. Therefore, the perfume bottle had most probably been used in the attack on Skripal and then discarded.

In early September, British authorities announced that they had identified two suspects who were linked to the Russian military intelligence service (GRU) (Bellingcat Investigation Team, 2018a,b,c,d,e). The Salisbury incident, as well as the 2004 dioxin poisoning of Viktor Yushchenko, former Ukrainian president, and the 2006 polonium-210 poisoning of Alexander Litvinenko show that assassination of selected targets with CWAs is not something of the past (le Polain de Waroux et al., 2011; Sorg et al., 2009).

The former Warsaw Pact Secret Services were not the only ones to perform such CW programs, as seen during the appearances of CIA officials in the Senate Committee known as the Church Committee, which took place during September 16–18, 1975. Former CIA Director William Colby explained that the CIA had an incapacitating agents' program (known as MKULTRA) and provided documents detailing the CIA stock of CWs at that time, which included small quantities of BZ, toxins, and cyanide pills, among others (USS, 1976).

On February 13, 2017, Kim Jong-nam, half-brother of North Korea's leader, Kim Jong-un, was killed at Kuala Lumpur International Airport (Malaysia) by two women who applied VX to his face (Nakagawa and Tu, 2018; Nepovimova and Kuca, 2018b). It is still not clear if VX or a binary system was used for the attack. The North Korean intelligence service was blamed for the assassination, although North Korea has denied responsibility (Swenson, 2017).

7.5 Nationalist and separatist terrorist groups

Secular terrorist groups have not shown significant interest in CWs, perhaps thinking that its use may be rejected by their own followers (although many of them have performed terrorist attacks with conventional explosives that produced a high number of casualties). There are some reported cases indicating that nationalist and independent groups have used chemical substances in sabotage actions. For example, in 1992 the Kurdistan Workers' Party (PKK) allegedly contaminated several water tanks with sodium cyanide in an air base near Istanbul (Karasik, 2002). The attack was aborted when the recipients of 25 kg of potassium cyanide were found next to the tanks.

Another example can be found in the Liberation Tigers of Tamil Eelam (LTTE) in Sri Lanka. Although the LTTE was a secular terrorist group, their members showed a level of veneration for their leader, Velupillai Prabhakaran, akin to that of a religious cult, and even used tactics used by jihadist terrorist groups. LTTE members were known to carry sodium cyanide capsules that were to be used to commit suicide in case of capture. There are also some reports about the use of sodium cyanide against Sri Lanka's economic interests (Carus, 2002; Wilkening, 1999). The first report was from 1986, which mentions attempts to sabotage tea exporting by informing different embassies that some lots had been contaminated with cyanide. US authorities analyzed different lots but did not find anything suspicious. The second report was from December 1996, when potassium cyanide was allegedly applied to stamps used by the Sri Lanka Army. However, the most important LTTE chemical attack occurred in June 1990, when drums of chlorine were used against a military camp located in east Kiran, although there is no information about the number of casualties (Hoffman, 2009).

7.6 Left-wing terrorist groups

In May 1975, the Baader-Meinhof Gang, also known as the Red Army Faction (RAF), a left-wing terrorist group based in West Germany, threatened to use sulfur mustard in Stuttgart and other cities in Germany if imprisoned members were not freed. However, in-depth studies of this incident have found no evidence of the RAF having access to sulfur mustard (Claridge, 2000). The terrorist organization was taking advantage of media reports indicating that old sulfur mustard containers from World War I had disappeared from a CW destruction facility.

Colombian guerrillas (initially left-wing terrorist groups but today considered to be narcoterrorism groups because of their association with organizations that deal with the illicit traffic of drugs of abuse) have performed small attacks with CWs. On December 2, 2001, members of the Revolutionary Armed Forces of Colombia (FARC) attacked a police station in San Adolfo (Huila), probably with cyanogen chloride, killing four policemen (Pita, 2008). Since then, munitions charged with cyanide have been found in raids against FARC camps. In fact, in November 2007, Colombia's National Police showed their concern after finding a clandestine FARC laboratory near the frontier with Ecuador that was working on the filling of rockets with toxic chemicals. The chemicals included ammonia, chlorine, and cyanide compounds.

7.7 Right-wing terrorist groups and lone actors

Koehler and Popella (2017) consider the possibility that far-right domestic terrorism may be tempted to use WMD in what could be considered as a competition with jihadist terrorism to gain public and media attention. In fact, it is not uncommon to find criminal activities using CWs linked with right-wing groups or sympathizer lone actors. The two most common agents used have been cyanides and ricin. In fact, hydrogen cyanide production and ricin extraction procedures are commonly found in "cookbooks," publications that are popular among members of white supremacist groups and in "amateur terrorist" circles. Some of these titles include *Assorted Nasties*, *The Poisoner's Handbook*, *The Preparatory Manual of Chemical Warfare Agents*, and *Silent Death*.

Although hydrogen cyanide gas (boiling point at 760 mmHg, 25.7°C; vapor pressure at 20°C, 600 mmHg) is easy to obtain by mixing the right cyanide salt and acid, transporting and mixing the reagents without being discovered constitutes one of the biggest hurdles to terrorist attacks. Regarding the ricin extracted with procedures included in cookbooks, it is not able to achieve a product capable of causing a large number of casualties by any exposure route, mainly because of the low content of toxin in the final extracts (Pita et al., 2004).

In the mid-1980s, a group named the Covenant, the Sword, and the Arm of the Lord obtained potassium cyanide to contaminate water supplies in different US cities (Stern, 2000). In a raid that took place on one of their facilities, authorities found a drum with 30 gal of potassium cyanide. When one of its members was told that the attack would kill not only those he considered enemies (Jews and "mud-people") but also other people, including members or sympathizers of the group, his reply was: "We felt that God would take care of this [and] that those who were meant to die would be poisoned" (Stern, 2000). And when he was told that 30 gal were not enough to obtain a toxic concentration in the city's water reservoir he answered: "God would... make sure the poison got to the town" (Stern, 2000). He even explained that they had decided to act because there were signs of the arrival of the Armageddon: "You get tired of waiting for what you think God is planning" (Stern, 2000). These statements make it clear that terrorist groups with religious motivations often have no moral restraints in performing attacks that could cause a large number of casualties. In fact, Christian-identity right-wing groups and lone actors have also carried out terrorist attacks that have caused a large number of casualties, such as the April 19, 1995, bombing of the Alfred P. Murrah Federal building in Oklahoma that caused 168 fatalities and more than 500 nonlethal casualties.

In 1991, four members of the Minnesota Patriots Council, an antigovernment right-wing group, obtained a kit called "Silent Tool of Justice" that contained approximately one dozen castor plant seeds and a toxin extraction procedure that one of the members followed (Tucker and Pate, 2000). The plan was to mix the toxin with dimethyl sulfoxide (DMSO) and *Aloe vera* gel and apply it on doorknobs of different individuals that were considered enemies of the group. The four members were arrested in 1994.

Cases of lone actors with intentions of using CWs are not rare. For example, in the mid-1970s, authorities found 25 pounds of sodium cyanide at the apartment of Muharem Kurbegovic, the "Alphabet Bomber" (Simon, 2019). Other chemicals and documents found showed a special interest in CWs. Kurbegovic had threatened to use nerve agents, but he did not have any when arrested. A good example of a lone actor linked to right-wing groups is Thomas Leahy (Carus, 2002). In 1997, an enforcement officer in Wisconsin responded to a report of spousal abuse made by Leahy's wife. When the officer arrived, the wife opened the door wearing a mask and explained the reason to the officer: "Because my husband is in the basement making poison gas" (Gurr and Cole, 2000). Among the items found in the laboratory were some cookbooks, ricin extracts, and three spray bottles with a mix of nicotine and DMSO. Also, in 2004, an arms trader with white supremacist group connections was sentenced to 11 years in prison (Kosal, 2006). In April 2003, authorities had raided his Texas warehouse arsenal and found that he was building an improvised chemical device (ICD) based on the mixing of sodium cyanide and an acid.

7.8 Apocalyptic cults: Aum Shinrikyo

Aum Shinrikyo's sarin and VX attacks are detailed in Chapter 4, Sarin attacks in Japan: acute and delayed health effects in survivors. This Japanese cult is a clear example of how difficult it is to produce a CWA and use it as a weapon with an efficient dissemination system, especially considering that they had adequate financial resources and technological means. The cult also benefited from the 1951 Religious Corporation Law that grants tax exemptions to religious organizations in Japan and protection against possible interference of the state in their activities. This advantageous situation allowed Aum Shinrikyo, when it started its chemical, biological, and toxin programs, to enjoy a position that would be similar to that within a proliferating state—where there is no need to hide these activities from the security forces because the program is integrated within government activities—rather than a terrorist organization.

But sarin and VX were not the only CWs used by the cult. After the Tokyo sarin terrorist attacks in 1995, Aum Shinrikyo cult members tried an attack with hydrogen cyanide. On May 5, they used an ICD in Shinjuku's Tokyo subway station that consisted of two plastic bags, one with sodium cyanide suspended in 2 L of water and another with 1.5 L of a sulfuric acid solution (Dolnik and Gunaratna, 2008; Tu, 2002). The activation system consisted of two condoms, one with sodium chlorate and another with sulfuric acid, so when the latter destroyed the latex the fire produced would break the plastic bags and allow the mixing of the cyanide salt and the acid, producing hydrogen cyanide. However, the quantities were not well-calculated, and the fire destroyed the ICD. On July 4 and 5, another two attacks occurred in Tokyo, this time using an ICD in which the activation of an electrical device with blades would break the plastic bags. One ICD failed, while the other only produced one case of mild poisoning.

7.9 Jihadist terrorism: Al Qaeda, Daesh, and the Global Jihad Movement

7.9.1 Weapons of mass destruction intentions

There are three phases in the statements of Al Qaeda members related to WMD. In the first phase, Al Qaeda tended to justify the acquisition and possession of these weapons from the point of view of deterrence. This phase goes as far back as 1998, when Osama bin Laden had stated that acquiring WMD was a "religious duty" (Pita, 2007). This and similar statements were made by bin Laden in different interviews after the US attack on the Al Shifa Pharmaceutical Industries factory in Khartoum on August 20, 1998. This attack was part of Operation Infinite Reach in retaliation for the bombings of the US embassies in Kenya and Tanzania on August 7, 1998, for which the bin Laden terrorist network was blamed by US officials. The Al Shifa target was justified in the finding of *O*-ethyl methylphosphonothionate, a precursor of the nerve agent VX, in soil samples outside the factory, and in the financial contributions of bin Laden to the production of CWs. Soon after 9/11 and the mailings of envelopes with *B. anthracis* spores in the United States, bin Laden was interviewed again. When asked about reports claiming that he was trying to acquire WMD, he answered: "We have the weapons as deterrent" (Pita, 2007).

The second phase of statements of Al Qaeda members related to WMD began soon after the overthrow of the Taliban regime in Afghanistan. Al Qaeda's reasoning was that the Coalition Forces had used conventional weapons (e.g., missiles) that had caused a large number of casualties and destruction, and for this reason these weapons could be considered WMD. This interpretation justified the use of chemical, biological, radiological, and nuclear (CBRN) weapons as retaliation for similar attacks. The most well-known statement in this second phase was made by Suleiman Abu Gheith, Al Qaeda's spokesman, who wrote in his 2002 electronic article "In the Shadow of the Lances" that based on this reasoning they had the "right to kill four million Americans—two million of them children—and to exile twice as many and wound and cripple hundreds of thousands" (Pita, 2007).

The third phase started in May 2003, when Nasir bin Hamad Al Fahd, a Saudi cleric who supports the global jihad movement, issued a fatwa justifying and authorizing the use of WMD (Paz, 2005). Al Fahd used arguments based on reciprocity, stating that the US had used weapons that caused a large number of casualties and mass destruction. But what was new in this fatwa was that Al Fahd's arguments were also based on Islamic texts that supposedly justify that it is permissible to use WMD if those engaged in jihad decide there is benefit in using them. And this is the case of Al Qaeda's influential strategist Mustafa Setmarian Nasar, better known as Abu Musab Al Suri, who posted a letter on the Internet in December 2004 stating that the use of WMD was "a necessity." Al Fahd's arguments were recovered in 2008, when Ayman Al Zawahiri published "Exoneration." Moreover, in 2015 Al Fahd allegedly pledged allegiance to Abu Bakr Al Baghdadi, leader of Daesh (Dean et al., 2018; Johnson, 2015).

Al Qaeda's speech about WMD has been adopted in Daesh's doctrine, which is not strange because of the link between these terrorist organizations. In fact, Al Qaeda in Iraq (AQI), founded by Abu Musab Al Zarqawi, can be considered the embryo of Daesh. Al Zarqawi was heavily influenced by Abu Abdullah Al Muhajir, an Egyptian who was the head of Al Qaeda's Religious and Scholarly Committee (Abu Hanieh and Abu Rumman, 2015; Dean et al., 2018; Winter and Al-Saud, 2016). Al Muhajir wrote *The Jurisprudence of Blood*, copies of which started circulating in AQI training camps in Iraq in 2004 (Dean et al., 2018). In this book, the use of WMD is justified as a more effective tactic than suicide bombings to cause mass casualties (Al Ansari, 2018). The book also justifies killings of noncombatants, beheadings, and hostage operations, among others. Al Zarqawi used its texts to justify AQI indiscriminate killings in Iraq. *The Jurisprudence of Blood* is still considered a key publication in Daesh and it is used for ideological indoctrination purposes (Al Ansari, 2018; Townsend, 2018).

Jihadist terrorism's interest in WMD may also be based on their important psychological effects. An objective of using these weapons in a military scenario is not only to cause physical casualties but also to demoralize troops. Similarly, in a terrorist attack on civilians, one of

the primary goals is to create a general sense of panic and fear, resulting in psychological trauma and disruption to economic and social activities (Zanders, 2003). For these reasons, WMD can also be regarded as "weapons of mass *disruption*." For instance, it is frequently asserted that the Aum Shinrikyo sarin subway attack caused more than 5000 casualties, but only approximately 1000 patients had clinical signs of sarin exposure (Woodall, 1997). That means that approximately 4000 people who sought attention in medical facilities were mainly psychological casualties with psychogenic symptoms. Based on a book by Abu Walid Al Misri, editor of a magazine for the Taliban, quoted in Peter Bergen's book *The Osama bin Laden I Know* (2006), Al Qaeda has been aware of the psychological effects of WMD since they first thought about acquiring them.

7.9.2 Chemical weapon capabilities

7.9.2.1 Al Qaeda

The first information of Al Qaeda's CW programs came from Jamal Ahmed Al Fadl (an Al Qaeda member who defected and became a United States government informer in 1996), who claimed that in the early 1990s he and other Al Qaeda members discussed the start of a manufacturing program of CWs with a Sudanese army officer (Bergen, 2001; Clarke, 2004; Tucker, 2006). In fact, the Al Shifa facility would have been part of this program.

Since October 2001, reporters and military forces in Afghanistan found written and electronic documents with rudimentary procedures for the production and use of toxic chemicals (Pita, 2007). These procedures are similar and, in some cases, word-for-word translations from those included in the cookbook publications mentioned previously. Two well-known cookbooks were found in Afghanistan, *Assorted Nasties* and *The Poisoner's Handbook*. This material came mostly from the Abu Khabab camp located in the Darunta training camp complex that specialized in explosives, but also in toxic chemicals (Dean et al., 2018; Gunaratna and Acharya, 2006). This camp was named after the man who ran it, the Egyptian Midhat Mursi, commonly known as Abu Khabab Al Masri, who was killed in a US air strike on the Pakistan−Afghan border in July 2008.

Ahmed Ressam, an Algerian arrested by US authorities for carrying explosives that he intended to use in a bombing against the Los Angeles International Airport, explained in court in July 2001 that he had been trained in the Darunta training camp complex in 1998 to prepare hydrogen cyanide by mixing a cyanide salt and sulfuric acid (Pita, 2007). He was told to release it near the air intake vents of buildings and even participated in live training exercises using dogs. In August 2002, CNN aired several Al Qaeda videotapes obtained in Afghanistan that revealed experiments with chemical agents on dogs. One of those tapes showed several men—apparently after having mixed several chemical reagents—rushing out of an enclosure, inside which was a tied-up dog. Soon, a white vapor appeared and a few moments later the dog started showing the first clinical signs of exposure. The quality of the images was not good enough to identify a toxidrome, but the videotape was reminiscent of what Ahmed Ressam said about his training with hydrogen cyanide in Afghan camps. These experiments were allegedly recorded by Abu Khabab in the Darunta training camp complex.

In November 2006, a book published by Nasiri (2006), the pseudonym of an alleged informer of the British and French intelligence services, explained his participation in experiments with animals using cyanide at the Khalden training camp. Nasiri also describes the failed attempts to develop sulfur mustard munitions in Khalden. He states that after many trials, finally the camp members celebrated when the shell produced a "thick cloud of smoke." However, this does not mean that the munition was effective in disseminating sulfur mustard.

More recently, Aimen Dean, a former MI6 spy inside Al Qaeda who was trained and worked with Abu Khabab between 1997 and 1999, confirmed the animal experiments in Darunta, especially with cyanides, but also with chlorine, nicotine, phosgene, and phosphine (Dean et al., 2018). Khabab obtained chemicals for his camp through the university of Jalalabad. Dean's description of his work at the camp fits with the crude procedures detailed in cookbooks. He even mentions that Khabab was aware of his limitations for producing more complex chemicals like nerve agents. Dean also mentions that he helped Khabab develop an ICD, known as the Al Mubtakkar, that solved the problem of mixing the cyanide salt and acid just before launching the attack.

Basically, the Al Mubtakkar device works as a crude binary munition (a binary chemical munition is one in which chemical substances held in separate containers react when mixed or combined as a result of being fired, launched, or otherwise initiated to produce a CW) (Pita, 2015). It produces hydrogen cyanide when a barrier that separates the cyanide salt (potassium cyanide) and the acid (hydrochloric acid) is broken. Potassium permanganate is also included for the device to potentially produce a mix of hydrogen cyanide, cyanogen chloride, and chlorine. The device can be activated manually or by using the explosive triacetone triperoxide (commonly known as TATP) and a detonator. The detonator can be activated remotely or with a temporizer, allowing terrorists to escape but, if it is not well-regulated, the explosion will inactivate the chemical reagents and obviate production of the cyanogen agent.

One of the most relevant discoveries in Afghanistan regarding the chemical and biological weapons program was made by *Wall Street Journal* reporter Alan Cullison, who obtained two computers from a looter who allegedly stole them from Al Qaeda's central office in Kabul on November 12, 2001 (Cullison, 2004; Cullison and Higgins, 2001). The looter told Cullison he had found the computers in the office of Al Qaeda's military commander Muhammad Atef (aka, Abu Hafs), a strong supporter of Al Qaeda's acquisition of WMD, who was killed in a US air strike that same month. Computer files included information of Al Qaeda's effort to start a chemical and biological weapons program code-named "Al Zabadi" ("Yogurt") in May 1999 with an initial budget of only $2000−4000. Based on Cullison's analysis of the computer files, Ayman Al Zawahiri—Al Qaeda's second-in-command at that time—and Abu Hafs (assisted by Abu Khabab) started the program after studying different books and articles from biomedical journals.

According to former CIA Director George Tenet, Al Qaeda became interested in chemical and biological weapons after Aum Shinrikyo's 1995 sarin attack on the Tokyo subway (Tenet and Harlow, 2007). However, an electronic message sent by Al Zawahiri to Hafs in 1999 stated that it was "the enemy" who brought these weapons to his attention, possibly US Secretary of Defense William Cohen (Leitenberg, 2004, 2005). In November 1997, Cohen appeared on television showing a 5-pound sugar package and saying that if it were to contain spores of *B. anthracis* and were spread over Washington, DC, half the city's population would die. A photograph of Cohen holding the 5-pound sugar package was allegedly also found in Afghanistan (Leitenberg, 2004).

No public report of sophisticated CBRN means or production facilities found in Afghanistan was made. Only a centrifuge and an "oven" found near Kandahar were presented by the US Department of Defense as the equipment Al Qaeda intended to use to produce chemical and biological weapons (Miller, 2002). This material was part of a laboratory that was being built to produce *B. anthracis* spores (Pita and Gunaratna, 2009).

Based on intelligence assembled from collected documents, detainee interviews, and reconnaissance of Al Qaeda facilities during Operation Enduring Freedom, the Commission on the Intelligence Capabilities of the US Regarding Weapons of Mass Destruction concluded in its unclassified report that Al Qaeda did not have large-scale chemical and biological weapons capability (US WMD Commission, 2005). Still, past and current chemical and biological programs are said to be not fully understood, especially because of difficulties in penetrating the terrorist network and, therefore, in collecting human intelligence (HUMINT).

7.9.2.2 Daesh

Since 2014, the occupation of territories in Iraq and Syria by Daesh allowed it to exploit the production capabilities of industrial facilities and institutions working with chemicals, not only to improve the production of explosives and improvised explosive devices (IEDs) but also to develop the use of TICs as weapons. Daesh's chemical program is a continuity of Al Qaeda's program developed in Afghanistan. In fact, it is known that Abu Musab Al Zarqawi visited Abu Khabab's camp in 1999 (Dean et al., 2018). He showed interest not only in explosives but also in Khabab's developments in toxic chemicals.

There have been different reports of Daesh's use of IEDs with chlorine cylinders, and munitions filled with TICs as well as sulfur mustard in Iraq and Syria (Binder et al., 2018; Chivers, 2015; Hart, 2016, 2017; Kilic et al., 2018; Said and Lister, 2015; Sezigen et al., 2019; Strack, 2018). Moreover, the OPCW-UN Joint Investigative Mechanism (JIM) in Syria, which operated from August 2015 to November 2017, concluded that Daesh was responsible for at least two sulfur mustard attacks in Syria, one with artillery shells at Marea on August 21, 2015 (Sezigen et al., 2019; UNSC, 2016), and another with mortar rounds at Umm Hawsh on September 15−16, 2016 (UNSC, 2017).

The first reports of the use of sulfur mustard by Daesh in Iraq and Syria initially suggested that supplies from the Syrian government's chemical weapons stock had fallen into the terrorist organization's hands, or that they had even used remains from Iraq's old chemical weapons program of the 1980s that were either abandoned or had escaped Iraqi government control (Doornbos and Moussa, 2016; Entous, 2015). However, the results of the investigations of the JIM in Marea, as well as the information obtained by the OPCW in the attacks against the Kurdish peshmerga in Makhmur (Iraq), also in August 2015, suggested instead the use of low-quality sulfur mustard with a high level of polysulfides, synthesized by the so-called Levinstein procedure (UNSC, 2016).

The required chemical reagents for sulfur mustard production would be available from chemical plants, especially petrochemical plants and academic institutions, seized in the occupied territories (Gareth, 2017; Warrick, 2019). In addition, Daesh would have had access to personnel with chemical engineering knowledge, or with links to chemical weapons programs. One example is Sulayman Dawud Al Bakkar—also known as Abu Dawud—who was captured by American troops in February 2016 in the city of Tal Afar, some 60 kilometers west of Mosul (Cooper and Schmitt, 2016; Parrish, 2016; Robert, 2016). Al Bakkar was presented by the US Department of Defense as the person primarily in charge of Daesh's chemical weapons program. His experience

came from working in the former chemical weapons program of Saddam Hussein at the Iraqi Military Industrial Commission. Daesh's access to these material and human capabilities would have allowed them to start the production of sulfur mustard to load into mortar grenades, rockets, and artillery shells.

Nevertheless, the poor quality of the sulfur mustard and its use in conventional munitions, not specifically designed for the dispersion of toxic chemicals, mitigated the impact of the chemical attacks and limited the number of casualties (Dorrian, 2017). In an attempt to improve efficacy, trials were made with solid matrices, in the form of very small particles, into which the chemical agent could be absorbed to increase its persistence (Blau, 2016). Due to the limitations of the available sulfur mustard, most of the chemical attacks combined conventional ammunition with a small amount loaded with sulfur mustard. While conventional weapons were the main cause of casualties and material damage, these attacks also took advantage of the psychological effect produced by sulfur mustard which, despite its poor quality, caused blisters on the skin of those coming into contact with it.

Interrogation of captured members of Daesh involved in the chemical program allowed for the identification and bombing of many sites related to the production and storage of Daesh's sulfur mustard during the 2016 Mosul Offensive (Hart, 2016, 2017, 2018; Strack, 2018; Warrick, 2019). While Daesh's chemical capability was degraded, some small-scale attacks took place during the Battle of Mosul in late 2016 and 2017 (Browne and Starr, 2017; Hart, 2018). Although there were reports about a relocation of chemical production capabilities to the Syrian border, between the towns of Mayadin and Al Qaim in the Euphrates River Valley, most probably these attacks were made with the remains of the old production (Browne and Starr, 2017; Strack, 2018). Abandoned munitions that tested positive for sulfur mustard were found by Coalition Forces in the retaking of Mosul (Hart, 2018).

7.9.2.3 Trends

After the disappearance of the Afghan training camps and with the fall of the Daesh bastions of Mosul and Raqqa, training electronic resources have acquired more relevance in the jihadist terrorism network. Jihadist websites and social media channels are important tools providing autonomous cells and lone actors with training manuals as well as lessons learned from previous attacks (Fig. 7.2). These electronic training manuals include information and procedures about toxic chemicals like those found in training camps, that is, similar to the information included in cookbooks. Some of these websites offer scanned copies of these cookbooks.

In 2018, Europol reported that the number of online jihadist propaganda messages and tutorials proposing easy-to-implement scenarios for small-scale CW attacks had increased when compared to previous years (Europol, 2018). It also alerts to the threat of foreign terrorist fighters returning from combat zones, with the possibility that some of them may have experience with toxic chemicals which they may try to use in other countries.

7.9.3 Plots with chemical weapons

A detailed study of incidents with CWs linked to Al Qaeda shows that cyanides, ricin, and TICs have been the main choices of jihadist terrorists (Pita, 2007). Nerve agents also seem to be of interest, especially because of their toxicological and physicochemical properties, which make them ideal for tactical use in terrorist attacks. However—and as previously mentioned—the synthesis process requires some level of expertise and is far more complex than the recipes featured in jihadist manuals.

7.9.3.1 Nerve agents

Open sources have reported jihadist cells planning terrorist attacks with nerve agents and showing interest in these CWAs. In any case they had the chemical agent or proved that they had acquired the capability to produce it.

The *Daily Telegraph* (London) reported that members of an Al Qaeda cell based in the United Kingdom were arrested while planning to release sarin in the European Parliament building in Strasbourg in February 2001, although no actual evidence of sarin was found (Bamber et al., 2001). Also in February 2001, the *Daily Telegraph* reported that British police had foiled a plot involving sarin against the London underground (Hastings and Bamber, 2001). Once again there was no evidence of the actual presence of the nerve agent. Both incidents seemed to be linked and related to a transnational network of Al Qaeda cells in the United Kingdom, Germany, Italy, Belgium, France, and Spain. What these cells had in common was that their key members had been trained in Afghan camps in the mid to late 1990s. The network was planning terrorist attacks with conventional weapons and chemical substances. In a conversation on March 13, 2001, that was bugged, a member of the Italian cell mentioned "an extremely efficient liquid that suffocates people," suggesting it could be placed in tomato cans, exposing people when the cans were opened (Finn and Delaney, 2001). Referring to the German cell, he mentioned, "They arrested them while they were preparing the gas." The chemicals this cell possessed were acquired in 48 separate purchases at pharmacies but were intended to be used in IEDs, not in nerve agent production (Finn, 2002; Finn and Delaney, 2001; Pita, 2007).

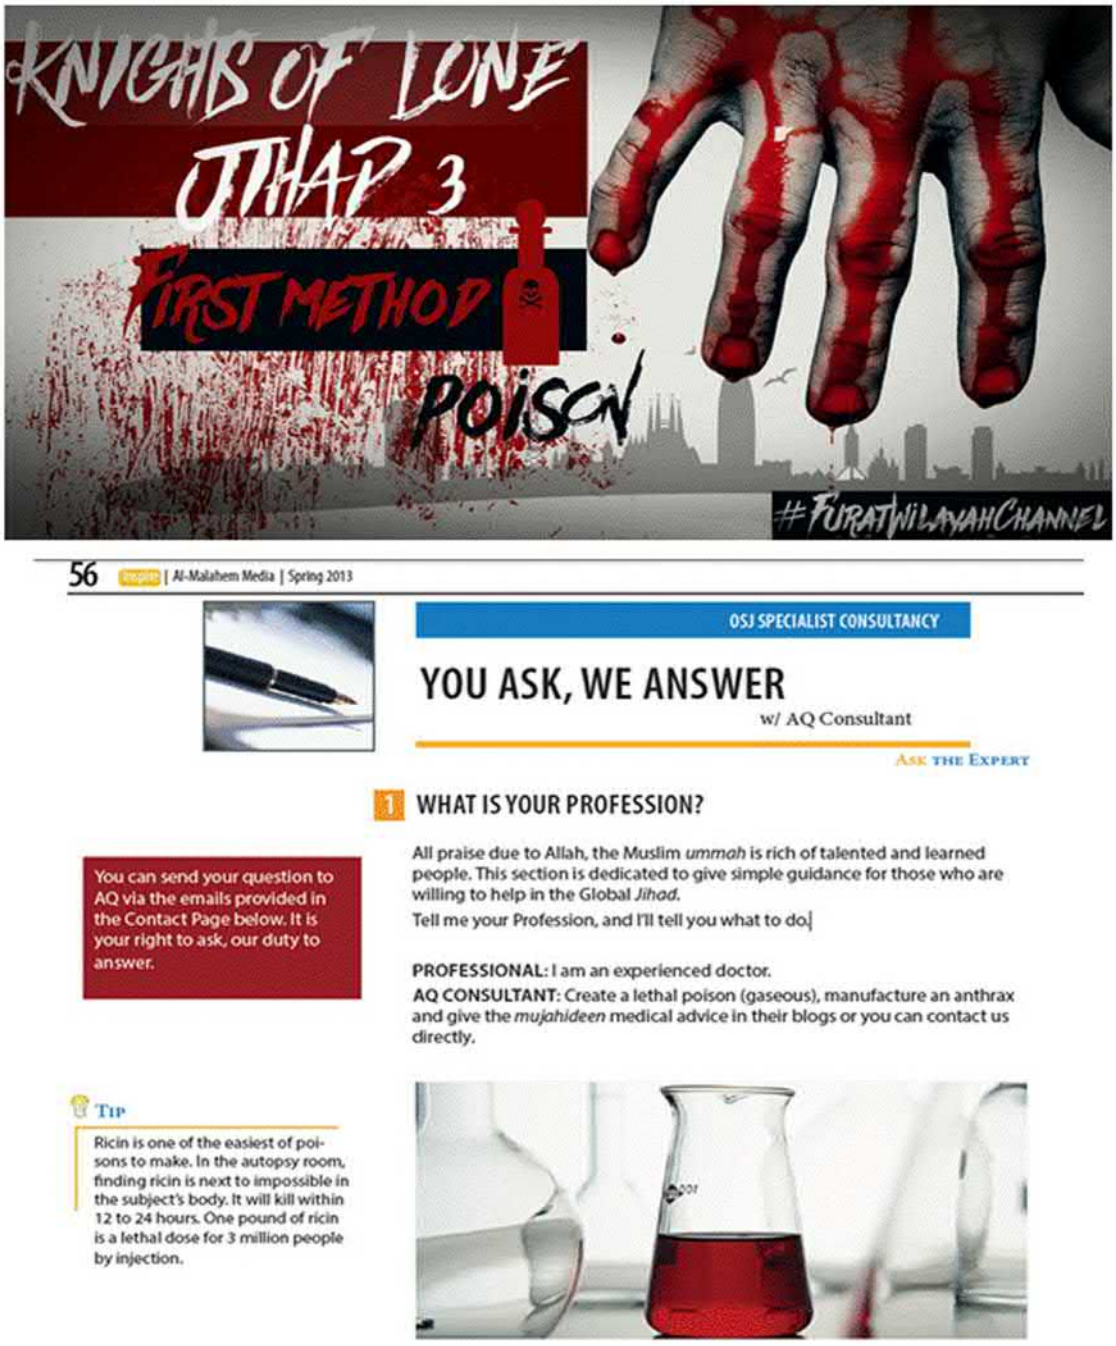

FIGURE 7.2 Jihadist electronic publications that address the use of toxic chemicals by lone actors.

On November 14, 2003, the following headline appeared in the Spanish newspaper *La Razón* (Madrid): "The FBI believes that the Salafists intended to mix napalm with sarin gas" (Arnuero, 2003). This was in reference to the chemical substances found in possession of a supposed Al Qaeda-related cell whose members were arrested in Barcelona in January 2003. However, sarin was not present among the chemicals, nor were any of its precursors. Later, it was made public that the Spanish cell, helped by other cells based in France and the United Kingdom, was planning a chemical attack against a naval base in Rota (Spain), used jointly by Spain and the United States (Martínez and Muñoz, 2005).

On September 30, 2004, the Special Advisor to the Director of Central Intelligence on Iraq's WMD reported that the Al Abud network (a network of Iraqi insurgents) attempted to produce tabun, nitrogen mustard, and ricin from late 2003 to mid-2004 (Duelfer, 2009;

Iraq Survey Group, 2004). These attempts failed, but nine mortar rounds were filled with malathion, an organophosphate insecticide.

Based on an internal British police document and on information disclosed by a UK senior officer, the *Sunday Times* (London) reported in August 2005 that Scotland Yard had thwarted an Al Qaeda attack on the House of Commons with "chemicals, a dirty bomb, and sarin gas" (Leppard and Winnett, 2005). The report mentioned that the plot was discovered after decoding encrypted e-mail messages in 2004, but there was no mention of the actual presence of the agents. This report was presumably linked to the arrest of eight men in August 2004 in the United Kingdom who were charged with conspiracy to commit public nuisance using "radioactive materials, toxic gases, chemicals, and/or explosives" (Pita, 2007). No chemicals were found, although one of the arrested men, Dhiren Barot, had two notebooks with information of explosives and toxic chemicals, as well as reconnaissance information of financial facilities in the United States. Later, Barot was reported to have been a trainer in Afghanistan camps in the late 1990s.

In June 2013, the Iraqi Defense Ministry said that they foiled a plot by an Al Qaeda cell to use remote-controlled toy planes to disseminate CWs, including sarin and sulfur mustard (Roggio, 2013). The cell was allegedly planning to execute the attacks in the Middle East, Europe, and North America. However, when the five cell members were arrested, they had not yet been able to produce any CWAs.

7.9.3.2 Cyanides

The first case of an Al Qaeda terrorist attack linked to chemical terrorism was the February 1993 World Trade Center bombing, as it is commonly believed that the explosives were mixed with a cyanide compound. The reason being that during the trial the judge stated: "You had sodium cyanide around, and I'm sure it was in the bomb. Thank God the sodium cyanide burned instead of vaporizing. If the sodium cyanide had vaporized, it is clear what would have happened is the cyanide gas would have been sucked into the north tower and everybody in the north tower would have been killed. That to my mind is exactly what was intended" (Parachini, 2000).

This was based on the idea that the terrorists considered the tactic of using a toxic chemical in the attack and the fact that the FBI found a small bottle of a sodium cyanide solution in a storage shed. However, hydrogen cyanide was never detected in the attack and even a detailed case study of this event concludes that no toxic chemical was mixed with the explosives (Parachini, 2000).

In December 1999, Jordanian authorities arrested 16 people with links to Al Qaeda who were planning attacks with explosives on New Year's Eve (Tenet and Harlow, 2007). It was later discovered that the plans also included the dissemination of hydrogen cyanide in a cinema in Amman.

On February 19, 2002, four Moroccans, members of the Salafi Group for Preaching and Combat (GSPC, now Al Qaeda in the Islamic Maghreb) were arrested in Rome (Pita, 2007). They had approximately 4 kg of potassium ferrocyanide that they intended to use to contaminate the water supplies near the US embassy. Nevertheless, this substance is widely used as a food additive (E 536) and, because of its toxicological properties, was probably not the best choice to use in a chemical attack.

Based on information in Ron Suskind's *The One Percent Doctrine* (2006), an Al Qaeda cell in Saudi Arabia planned an attack on the New York City subway with Al Mubtakkar devices in 2002. This was confirmed in 2018 by Aimen Dean, who was asked to train four cell members in Morocco on how to build the device before traveling to the United States (Dean et al., 2018). Surprisingly, Al Zawahiri decided to cancel the operation. Suskind's book claims that this decision was made just 45 days before the intended attack. One of the members of the Saudi cell had the blueprints for the Al Mubtakkar in a laptop when they were arrested in February 2003. Later, security services also found large quantities of chemicals in the desert of Riyadh, where the cell had tested the device (Dean et al., 2018). Dean was again contacted in 2004 to build Al Mubtakkar devices to attack nightlife centers frequented by US military personnel in Bahrain (Dean et al., 2018). The plot was thwarted when Dean informed the MI6 and Bahraini authorities arrested the cell members.

7.9.3.3 Ricin

Ricin was reported to have been detected in January 2003 in an apartment in the north of London where North African Al Qaeda sympathizers were living (Pita, 2007). The raid took place when the United Kingdom received a tip-off from the Algerian intelligence services indicating that "poison" had been prepared there. This ricin finding turned out to be a false positive, because subsequent analyses of samples by the British reference laboratory did not identify ricin (Leitenberg, 2005). However, 20 *Ricinus communis* seeds and a written ricin extraction procedure—copied from a cookbook and downloaded from the Internet—were found (Stenersen and Lia, 2007). The alleged plot was to use ricin on door handles (perhaps with DMSO). The fingerprints on the material and the handwriting analysis identified Kamal Bourgass, an Algerian refugee who had applied for asylum in the United Kingdom in 2000. Of all the arrested men, only Bourgass was convicted, on April 8, 2005, of conspiring

to commit a public nuisance using poisons and/or explosives. At an earlier trial in 2004, he had been convicted of killing a police officer during his capture in an apartment in Manchester on January 14, 2003.

Intelligence reports from 2010 mentioned that Al Qaeda in the Arabian Peninsula was trying to acquire large quantities of *R. communis* seeds in Yemen to produce ricin (Schmitt and Shanker, 2011). No further information about this has been made public.

Sief Allah H., a Tunisian with links to Daesh, was arrested in Cologne (Germany) on June 12, 2018, after he had prepared 84.3 mg of a ricin extract from 3150 *R. communis* seeds (Flade, 2018). Although the product found was described as "potentially lethal," results of the analyses about the content of ricin in the 84.3 mg extract have not been made public yet. The *R. communis* seeds were obtained by mail through an online store and the recipe for ricin production was an online video, which had also been found when two Egyptians were arrested in Paris (France) the previous month.

7.9.3.4 Toxic industrial chemicals

On March 30, 2004, antiterrorism police in the UK arrested eight alleged sympathizers of Al Qaeda who were supposedly planning to use osmium tetroxide against Gatwick Airport, the London subway, and other enclosed high-traffic areas, although they did not have the chemical when arrested (Baker and Kosal, 2004). Osmium tetroxide is often used as a stain in biology laboratories. One month later, Jordanian authorities announced that they had defeated an Al Qaeda plot to use explosives and large quantities of TICs such as sulfuric acid, cyanide salts, and pesticides against the US embassy in Amman, the Jordanian prime minister's office, and the headquarters of the Jordanian General Intelligence Department (Levitt and Sawyer, 2004).

From October 2006 until mid-2007, AQI suicide terrorists in Iraq detonated vehicle-borne improvised explosive devices (VBIEDs) carrying chlorine cylinders (Pita, 2012). This new tactic clearly showed that the use of TICs is an option that may yield better results than following the crude and rudimentary procedures of jihadist terrorism-related publications to produce CWs. However, the chlorine attacks in Iraq were still rudimentary in their means of delivery. In most of the attacks, casualties were not caused by chlorine exposure, but rather because of the mechanical and thermal effects of the explosion. Also, in some attacks, chlorine was not released because the low mechanical effect of the explosion was not enough to break the cylinders. Reports of Daesh's use of chlorine, chlorine-based chemicals, and phosphine, in Iraq and Syria were frequent until 2017 (Binder et al., 2018; Chivers, 2015; Hart, 2016, 2017; Said and Lister, 2015; Strack, 2018).

At the end of July 2018, two people were arrested in Australia, accused of attempting to place an IED in an aircraft at Sidney airport (Pita and Domingo, 2017; Westbrook and Barrett, 2017; Williams, 2017). The mounting of the IED, disguised as a meat mincer, was undertaken following the direct instructions of Daesh through social networks and other electronic communications media. In fact, Australian police stated that contact with the terrorist organization was established in April since the brother of one of those arrested was a high-ranking member of Daesh in Syria. This was, therefore, a "remote-controlled" operation in which the suspects even received the components of the IED by air from Turkey. Finally, the explosive device did not even make it through airport security control, apparently because of excessive baggage weight. This caused one of the arrested to leave the airport without detonating the IED.

With the failure of this attempt, the terrorist cell began another operation, also in consultation with Daesh in Syria, to manufacture an ICD. Such a device would allow the combination of two precursors for the production and dispersion of hydrogen sulfide, a toxic chemical in gaseous state at room temperature that, once inhaled, acts upon the organism via a toxicological mechanism similar to that of cyanides producing cellular asphyxiation.

7.10 Concluding remarks and future directions

Nerve agents are the most important CWs because of their high toxicity and versatility in tactical use. However, production difficulty seems to be their most important drawback. Amateur production of CWAs or extraction of toxins using cookbooks and jihadist-related manuals has commonly been overrated, leading to supposedly catastrophic consequences of terrorist attacks. In fact, CWs are frequently described as "the poor man's atomic bomb," but this description was used at the end of World War II to explain that for a state actor trying to acquire WMD capability, chemical and biological weapons would be a more feasible option than nuclear weapons, which require more complex technical resources.

An additional problem for terrorists is the need to have a reliable delivery system. Effective dissemination may be even more difficult than obtaining the agent, especially if the objective is to cause a large number of casualties. The "art" of CWs includes the research and development of special munitions that, among other things, do not inactivate the agent by the thermal effect of the explosion. Aerosolization dispersal systems are another option. Luckily, another gap in the information in jihadist-related publications and cookbooks is the often-inaccurate information regarding delivery systems.

Despite the difficulties in obtaining and effectively disseminating toxic chemicals, the evolution of CWs in Iraq and Syria suggests that jihadist terrorism is aware of the important psychological and media effects that would be produced by the mere attempt to use them. This idea can be summarized in a message that appeared in a jihadist forum linked to Daesh in June 2016: "Of course it is not easy to get anthrax or real poison, but the mere suspicion (of its presence) will provoke within the enemy an attack on their nerves, undermining their work." Therefore, it is likely that attempts to use CWs will continue.

Advances in science and technology should also be considered. Some of the drawbacks in the production of CWs and dissemination systems may disappear in the future, making re-evaluation of threat assessments necessary. The lack of adequate procedures and programs to produce CWs may explain why, until now, jihadist terrorists have not been capable of achieving an effective chemical attack outside the conflict areas of Iraq and Syria. However, they are both interested in achieving a CW capability and are actively trying to obtain it. For this reason, it should not be dismissed that options other than self-production may also be attempted, for example, resorting to sponsoring states or black-market arms trafficking networks.

The ready access to TICs in the chemical industry makes them attractive to nonstate actors. Minimizing access to "dual-use" materials by increasing security measures in academic and industrial facilities is one of the main elements addressed in different nations' strategies for countering terrorists' efforts to use WMD. The threat of insiders who work with toxic chemicals and whose integrity may be compromised by terrorist groups is one of the main concerns of intelligence services today. Insiders who decide to participate in chemical terrorism could have a variety of motivations, from ideological to financial. Advances in science and technology have also increased the number of people working with toxic "dual-use" chemicals and with the explicit and tacit knowledge that could be used for terrorist purposes.

Analysis of the chemical terrorism threat shows how important it is that medical personnel considers CWA poisoning in the differential diagnoses in cases of suspected terrorist attacks. The excellent performance of the medical personnel involved in the Novichok incidents in the United Kingdom is a good example of the importance of training in the medical aspects of CWAs.

Chapter 8

Organophosphate nerve agents

Robert A. Young and Annetta Watson
Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States

8.1 Introduction

It is unfortunate that the organophosphate (OP) nerve agents maintain a high profile among chemical warfare (CW) agents due to their use by terrorist groups and militant states. In the 1980s, both sarin and tabun were used by the Iraq military against Iranian soldiers (Balali-Mood and Balali-Mood, 2008). In 1988, thousands of civilians died when the Kurdish city of Halabja was attacked with sulfur mustard and nerve agents (Hay and Roberts, 1990). There were deliberate releases of the nerve agent sarin at lethal concentrations in the Japanese cities of Matsumoto (1994) and Tokyo (1995) by a Japanese domestic terrorist group. Unfortunately, the use of nerve agents for malicious intent by radical groups or by militant states continues. In 2013, sarin was deployed during an attack in Ghouta near Damascus, Syria (Dolgin, 2013; John et al., 2013; Rosman et al., 2014). Sarin was used in a 2017 attack on Khan Sheikhoun, Syria (UNSC, 2017a,b), and VX was used in the assassination of Kim Jong-nam at Kuala Lumpur International Airport in 2017. Historically, OP nerve agents were used by military authorities of several nations to develop munitions (e.g., Germany during the Nazi era, the United States, the former Soviet Union).

This chapter addresses the OP nerve agents tabun (GA), sarin (GB), soman (GD), cyclosarin (GF), and VX. All of these are, or have been, part of the US domestic munitions inventories (Carnes, 1989; Opresko et al., 1998; NRC, 1999). Russian VX (often represented as VR) is evaluated in Chapter 10 by Rembovskiy et al. (2015). Other less well-characterized nerve agents such as compound GE, VG (Amiton), or V_x are evaluated as data allow.

The OP nerve agents are potent anticholinesterase compounds that were deliberately formulated to induce debilitating effects or death. They are notably more potent than OP pesticides. US military stockpiles of CW munitions manufactured as a Cold War deterrent decades ago are undergoing destruction at designated stockpile sites and have been the subject of extensive emergency preparedness and response planning. Additional planning has been necessary at other current and formerly used military sites where containers and buried munitions have been inventoried (the "nonstockpile" sites) (Opresko et al., 1998; NRC, 1999, 2003). More recent global events necessitate continued attention on the potential threat of chemical terrorism, especially at transportation hubs (Tucker and Raber, 2008). The Matsumoto (1994) and Tokyo (1995) incidences affirm that such attacks are a reality that require advance emergency preparedness planning (Morita et al., 1995; Okumura et al., 1996, 2007; Sidell, 1996; Cannard, 2006; Yanagisawa et al., 2006; Tu, 2007). Information provided on agent toxicity, risk assessment, treatment options, and other related topics will be useful to communities and facilities developing and updating emergency preparedness plans for accidental or intentional release of nerve agents; this information can also be used to support environmental decision making where nonstockpile material and military gear have been found. In response to various public laws and international agreements such as the Chemical Weapons Convention (PL 99−145, 1986; PL 102−484, 1993), existing emergency guidance and military policy documents currently reflect the identified criteria and information (OASA, 1999; CSEPP, 2003, 2006a,b; NRT, 2008).

Although there are different applications for the information provided in this evaluation, in general the toxicological focus for emergency preparedness and response applications is that of acute exposures associated with a one-time release. Typically, the scenarios considered include a single-source airborne release from either an intentional terrorist attack, or an accident involving an agent container or munition from a military site. It is widely recognized that vapor inhalation is the exposure route of greatest concern for such an event (Sidell et al., 1997; ATSDR, 2007). In contrast, the toxicological focus

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00008-8

of environmental site remediation plans for military installations and formerly used defense sites where buried CW agent residues may occur, requires consideration of long-term release and potential incidental ingestion of media such as soil particles or water with relatively low levels of contamination. To reflect these critical applications and information needs, the current evaluation will also primarily focus on:

- single-source, one-time nerve agent releases and exposure routes involving agent vapor inhalation or direct ocular vapor exposures;
- long-term (chronic or subchronic) exposure from residual nerve agent contamination.

It is acknowledged that there exists a rich and valuable body of repeat-exposure studies using serial vapor or serial injection exposures for the nerve agents soman (GD), sarin (GB), and VX (see recent excellent reviews and analyses by Shih et al., 2006; McDonough et al., 2008; and experimental studies by Dabisch et al., 2005, 2007a). The interested reader is encouraged to examine these and related resources, because the current evaluation does not highlight experiments that apply serial exposure protocols.

8.2 Background

8.2.1 Development of organophosphate formulations as chemical warfare agents

The G-series nerve agents evaluated are all ester derivatives of phosphonic acid containing either a cyanide (GA) or a fluoride (GD, GE, GF) substituent and are commonly termed "nerve" agents as a consequence of their anticholinesterase properties as well as their effects on both the peripheral nervous system (PNS) and central nervous system (CNS). The "G" series military nomenclature used by NATO member nations has been historically considered to be an abbreviation for "German," with the second letter of the code ("A," "B," and so on) identifying the order in which these compounds were found and analytically identified by Allied forces investigating materials found in captured German military facilities at the close of WWII (Sidell et al., 1997). Alternately, the G designation is also attributed to **G**erhard Schrader, a German chemist often considered to be the "Father of Nerve Agents" in reference to his work on insecticide development and subsequent synthesis of tabun (agent GA) in 1936 (Lopez-Muñoz et al., 2008). Agent VX, a phosphonic acid ester with a sulfur substituent, was industrially synthesized in the United Kingdom in the early 1950s; the code letter "V" is a reported reference to "venom or venomous" (Sidell et al., 1997). Other, less well-characterized V-series compounds include Vx, VE, VM, and VG (trade name Amiton when commercially introduced as a miticide in the mid-1950s).

As Cold War deterrents, nerve agents began to be manufactured and weaponized by the United States in the 1950s. When the US CW agent production program was terminated by the Nixon presidential "Statement on Chemical and Biological Defense Policies" of November 1969 (National Security Decision Memorandum 35), the US stockpile of unitary munitions included bulk ("ton") containers, underwing spray tanks, projectiles, rockets, bombs, land mines, and rockets (Carnes, 1989; Sidell et al., 1997). Nerve agent unitary munitions contained GA, GB, or VX.

8.2.2 Destruction of nerve agent stockpiles

The Organization for Prohibition of Chemical Weapons (OPCW), the implementing body for the Chemical Weapons Convention (CWC), oversees the global endeavor to permanently and verifiably eliminate chemical weapons. The OPCW was awarded the 2013 Nobel Peace Prize for its extensive work in eliminating chemical weapons (OPCW, 2019a). As of April 30, 2019, 96.99% of the world's declared chemical weapons stockpiles (all chemical weapons including nerve agents) had been destroyed (OPCW, 2019b).

Consistent with this effort, US CW agent munition stockpiles have been undergoing destruction. As of 2019, the remaining stores of nerve agent in the United Sates are at Blue Grass Amy Depot, KY. Destruction of nerve agent at the Blue Grass Chemical Agent-Destruction Pilot Plant will use neutralization followed by supercritical (high temperature and pressure) water oxidation. Operations are expected to begin in 2019 with scheduled completion by 2023 (PEOACWA, 2019).

8.2.3 Physical and chemical properties of nerve agents

The G-agents are all viscous liquids of varying volatility (vapor density relative to air between 4.86 and 6.33) with faint odors ("faintly fruity" or "spicy," "odor of camphor"). Agent VX is an amber-colored liquid with a vapor density of 9.2, and is considered odorless. Thus, nerve agent vapors possess little to no olfactory warning properties (Table 8.1).

The vapor pressures and acute toxicity of these agents are sufficiently high for the vapors to be rapidly lethal. Within the G-series, GB is considered to present the greatest vapor hazard (order of vapor hazard approximates GB > GD > GF > GA). Agent VX was deliberately formulated to possess low volatility; VX is approximately 2000-times less volatile than nerve agent GB (DA, 1990a,b). As a consequence, agent VX is considered a persistent

"terrain denial" military compound with the potential to be a contact hazard or generate off-gas toxic vapor concentrations over a period of days after surface application, particularly under cold weather conditions or when bulk-release quantities of liquid agent are involved. Although not readily volatile, VX vapors (if allowed to accumulate) are nevertheless considered more acutely potent than those of agent GB or the other G-series agents (Mioduszewski et al., 1998).

As a consequence of the volatilities exhibited by G-series nerve agents (Table 8.1), the most likely exposure route (and source of primary hazard) is via direct vapor exposure to the eyes and upper respiratory tract tissues and vapor inhalation (with consequent systemic absorption) (Cannard, 2006; Dabisch et al., 2008a); G-agents are considered "nonpersistent" as per definitions used by the US Department of Defense (DOD, 2008). Nerve agent VX is widely considered to present a greater threat from the percutaneous exposure route (when compared with the G-series agents) as well as a vapor inhalation threat at elevated ambient temperatures (e.g., >40°C) (Craig et al., 1977; Sidell et al., 1997; Benton et al., 2005, 2006a).

Nerve agent V_x exhibits volatility (76.4 mg/m^3 at 25°C) intermediate to that of agents GA and VX, and a vapor density (7.3) intermediate to that of agents GF and VX; V_x is also considered "persistent." There are few data from which to characterize nerve agents VE (*O*-ethyl-*S*-[2-(diethylamino) ethyl]ethylphosphonothioate, CAS No. 21738-25-0) or VM (*O*-ethyl-*S*-[2-(diethylamino)ethyl]methylphosphonothioate, CAS No 21770-86-5).

8.2.4 Mode of action and clinical signs

All of the OP nerve agents under consideration are cholinesterase inhibitors that phosphorylate acetylcholinesterase (AChE), thereby preventing the inactivation of the neurotransmitter acetylcholine (ACh) at neural synapses and neuromuscular junctions (NMJs). Depending on the route of exposure and amount absorbed, the PNS and/or CNS can be affected. The result is prolonged stimulation of muscarinic and/or nicotinic receptors. The mnemonic, SLUDGE, refers to muscarinic-mediated effects of *S*alivation, *L*acrimation, *U*rination, *D*efecation, *G*astrointestinal distress, and *E*mesis. An abbreviation (MTWTF) referring to days of the week refers to nicotinic receptor-mediated responses of *M*iosis, *T*achycardia, *W*eakness, Hypertension/Hyperglycemia, and *F*asciculations. OP nerve agent interaction with other esterases may also occur, and direct effects to the nervous system have been reported.

In addition to the previously noted array of effects and mediated by similar mechanisms, exposure to acutely toxic concentrations of nerve agents may cause paralysis, loss of consciousness, convulsions, depression of respiratory centers, and death (Grob and Harvey, 1953; Grob, 1956; Sidell et al., 1997; Yanagisawa et al., 2006; Marrs et al., 2007a; Okumura et al., 2015). Minimal effects observed at low vapor concentrations include miosis (contraction of the pupils of the eye, with a subsequent decrease in pupil area), tightness of the chest, rhinorrhea, and dyspnea (Dunn and Sidell, 1989; Dunn et al., 1997). Pupillary contraction, resulting in varying degrees of miosis characterized by measures of pupil diameter, is consequent to local inhibition of ocular AChE activity with pupillary sphincter contraction (Dabisch et al., 2007b, 2008a,b; Dabisch et al., 2010).

Using social media (YouTube), Rosman et al. (2014) provided a unique and informative analysis of the Damascus area attack in 3013 that killed 1400 civilians in Syria. The observations were consistent with signs of toxicity consistent with OP nerve agent exposure. An objective analysis by physicians who were chemical, biological, radiological, and nuclear specialists analyzed 67 videos that met various inclusion criteria. These videos showed 130 casualties, 119 of which were evaluated as having moderate injuries or worse. Clinical signs of dyspnea, diaphoresis, and loss of consciousness were observed in 53%, 48.4%, and 40.8%, respectively, of the casualties. Miosis was observed in 13.8% of victims, hypersalivation in 32.3%, and convulsions in 18.5% of victims.

Reactivation of inhibited cholinesterase by dephosphorylation is not possible once the nerve agent−cholinesterase complex undergoes "aging," which is thought to be the consequence of the loss of an alkyl or alkoxy group. Agent GD ages very rapidly when bound to red blood cell cholinesterase (RBC−ChE), with a $t_{½}$ (time required for 50% of the enzyme to become resistant to reactivation) of 1.3 min (Harris et al., 1978). The aging half-time for agent GA with RBC−ChE is 46 h (calculated; De Jong and Wolring, 1978), and the $t_{½}$ for agent GB with RBC−ChE is 5 h (Sidell and Groff, 1974). The complex formed between RBC−ChE and agent VX does not age significantly (half-life of approximately 48 h) (Sidell and Groff, 1974; Dunn et al., 1997).

8.2.5 Direct nervous system effects

Nerve agents exert toxic effects on the CNS and PNS indirectly through AChE inhibition (Koelle, 1981; Koelle et al., 1975), but may also affect nerve impulse transmission by additional mechanisms at NMJs (see reviews by Somani et al., 2001; Marrs et al., 2007a; Gupta et al., 2010) and at neurotransmitter receptor sites in the CNS (Myhrer et al., 2010; Weissman et al., 2010). Rao et al. (1987) reported that VX caused an increase in ACh release at NMJs in the frog by an interaction with the nicotinic ACh receptor−ion channel complex. Aas et al. (1987) reported alterations in muscarinic receptors in rat

bronchi and lung tissue after subacute inhalation exposures to agent GD. In the CNS, nerve agents may act directly on muscarinic, nicotinic, and glutamate receptors in manners unrelated to cholinesterase inhibition (Bakry et al., 1988; Chebabo et al., 1999; Lallement et al., 1991a, b; Rocha et al., 1998, 1999). Chebabo et al. (1999) reported that 0.3−1 nM of agent GB reduced the amplitude of GABA-mediated postsynaptic currents (GABA; neurotransmitter γ-aminobutyric acid), but had no effect on the amplitude of glutamatergic-mediated postsynaptic currents; this selective reduction in action potential-dependent release of GABA might account for GB-induced seizures. Lallement et al. (1991a,b) had suggested that GD-induced overstimulation of glutamatergic receptors contributed to maintenance of seizures.

Although these electrophysiological data indicate that nerve agents may have direct effects on the nervous system unrelated to AChE inhibition, the data do not provide a means of determining a dose conversion to an integrative whole-body endpoint such as lethality or qualitative/quantitative comparisons directly relevant to adverse effects.

It should be further noted that the effects of nerve agents on GABAergic transmission in the CNS may have implications for behavioral effects in laboratory animals and humans, and may also contribute to the induction of convulsions at higher doses (Bakshi et al., 2000). Nevertheless, given the present undefined application of noncholinergic data to whole-body estimations, reliance on the primary assumption of AChE action is consistent with recognized opinion (Bakshi et al., 2000).

8.2.6 Binding with blood cholinesterases

The activity levels of RBC−ChE, and plasma cholinesterase (plasma−ChE, plasma butyrylcholinesterase or BuChE), have been used to monitor exposure severity as well as recovery from anticholinesterase pesticides and OP nerve agents. There is some historical evidence that RBC−ChE can be as sensitive as brain−ChE to the anticholinesterase effects of nerve agents. Grob and Harvey (1958) reported that in vitro concentrations producing 50% activity depression of brain−ChE and RBC−ChE were equivalent in the case of GA (1.5×10^{-8} mol/L), and comparable in the case of GB (3.0×10^{-9} vs 3.3×10^{-9} mol/L). The in vivo animal studies conducted by Jimmerson et al. (1989) disagree, which is further supported by the fact that blood ChE activity may not always be correlated with exposure or with signs and symptoms of toxicity (Holmstedt, 1959; Sidell and Somani, 1992; Sidell et al., 1997) (Table 8.2). This was also observed during clinical treatment of cases after the Matsumoto and Tokyo chemical terrorist incidents of GB exposure to the public (Nozaki et al., 1997; Yanagisawa et al., 2006).

It is generally considered that systemic effects in humans after acute nerve agent exposures are likely when RBC−ChE is inhibited by 75%−80% (e.g., to 20%−25% of normal activity levels) (Sidell and Somani, 1992). Nevertheless, it is well-known that local signs and symptoms of the eyes and nose in humans and animals (e.g., miosis, rhinorrhea) can occur in the absence of any measurable change from baseline ChE activity in the blood after vapor or aerosol nerve agent exposure (Harvey, 1952; Craig and Woodson, 1959; Sidell and Somani, 1992) and are attributable to the local and direct effects of the agent on tissues of the eyes and upper respiratory tract (Grob, 1956; Dabisch et al., 2008a) (Table 8.2). When systemic exposure (e.g., other than direct ocular or direct nasal) occurs, miosis and rhinorrhea are not usually observed as the first noticeable effects (NRC, 2003; Dabisch et al., 2008a).

EPA science policy guidelines regarding the use and application of cholinesterase activity inhibition data generally consider blood ChE activity inhibition to be an imperfect measure, and there appears to be no fixed percentage of blood ChE activity change that can distinguish adverse from nonadverse effects (Storm et al., 2000; USEPA, 2000). A number of investigations have noted the poor association between blood (RBC and plasma) cholinesterase activity and nerve agent intoxication (Rubin and Goldberg, 1957; Sidell and Somani, 1992; Sidell et al., 1997; Koelle, 1994; Mioduszewski et al., 2002a; Cannard, 2006; Yanagisawa et al., 2006); minimal blood ChE activity has been observed in association with normal tissue function (Sidell and Somani, 1992). In a clinical situation, measurement of blood ChE activity has forensic utility and is helpful as a measure of recovery but is not a quantitative measure of absorbed dose (Cannard, 2006).

8.2.7 Binding with other enzymes

Nerve agents also interact with detoxification enzymes such as carboxylesterases (CarbE) and A-esterases (e.g., arylesterase and paraoxonase), and the degree of such interaction can alter the magnitude and extent of the toxic cascade after AChE inhibition (Gupta et al., 1991; Pope, 1999; Pope and Liu, 2002; Fonnum et al., 2006) as well as species-specific characteristics. Observed spontaneous reactivation of soman-inhibited plasma CarbE in the rat indicates that "aging" does not occur for the GD−plasma CarbE complex (in contrast to that observed for GD and RBC−ChE) (Dunn et al., 1997), and further suggests that endogenous plasma CarbE may be a principal functional scavenger for agent GD (Maxwell and Brecht, 2001). Recent studies indicate that full characterization of the OP-protective capabilities of CarbEs requires assessment not only of the amount, but also of the affinity exhibited

TABLE 8.2 Human experimental data for single exposures to GB vapor.

Concentration (mg/m^3)	Exposure duration	Ct ($mg\ min/m^3$)	Signs and symptoms	References

by CarbEs for the inhibitor, as well as the total CarbE activity unlikely to be inhibited (inhibitor-resistant esterase activity) (Chanda et al., 2002). The detoxification potential of CarbEs is multifaceted and is an area requiring further experimental characterization (Fonnum et al., 2006, 2015).

8.3 Toxicity

8.3.1 Effects

Nerve agents are toxic anticholinesterase compounds by all routes of exposure and exhibit a steep dose−response curve. Detailed descriptions of nerve agent toxicity may be found in reviews by Munro et al. (1994), Sidell et al. (1997), Mioduszewski et al. (1998), Opresko et al. (1998), NRC (1999, 2003), Bakshi et al. (2000), Somani et al. (2001), Marrs et al. (2007a), Weissman et al. (2010), and Hulet et al. (2019). The toxic responses to nerve agents generally involve inhalation of and direct contact (especially for ocular effects) with vapors and aerosols. Especially with regard to aerosol exposures, it is also possible that some ingestion of the agents will occur that will result in direct effects on the gastrointestinal tract. The following sections provide an overview of key studies on OP nerve agent toxicity but are not intended to be an exhaustive encyclopedic review of the subject.

Anticholinesterase effects of nerve agent exposure can be characterized as muscarinic, nicotinic, or CNS. Muscarinic effects occur in the parasympathetic system and, depending on the amount absorbed, can be expressed as conjunctival congestion, miosis, ciliary spasm, nasal discharge, increased bronchial secretion, bronchoconstriction, anorexia, emesis, abdominal cramps, sweating, diarrhea, salivation, bradycardia, and hypotension. Nicotinic effects are those that occur in the somatic (skeletal/motor) and sympathetic systems, and can be expressed as muscle fasciculations and paralysis. CNS effects may be manifested as confusion, reflex loss, anxiety, slurred speech, irritability, forgetfulness, depression, impaired judgment, fatigue, insomnia, depression of central respiratory control, and death (Sidell and Groff, 1974; Sidell and Somani, 1992; Sidell et al., 1997; Opresko et al., 1998; Bakshi et al., 2000). Minimal effects observed at low concentrations in human subjects include miosis, a feeling of "tightness" in the chest, rhinorrhea, and dyspnea (Dunn and Sidell, 1989) (Table 8.2).

RBC−ChE inhibition in the blood is considered an operationally acceptable surrogate for CNS inhibition. Plasma ChE is more labile and is a less reliable reflection of enzyme activity change at neuro-effector sites (Young et al., 1999; USEPA, 2000). Assays to assess nerve agent exposure are continually being improved. Mathews et al. (2017) reported on a high-confidence mass spectrometry assay for OP nerve agent adducts to human butyrylcholinesterase. A variety of assays are available for assessing cholinesterase activity and have been summarized in Benedict et al. (2019).

In the whole-body agent vapor exposure studies of Mioduszewski et al. (2002a; SD rat single exposures to GB vapor) and Benton et al. (2006a; SD rat single exposures to VX vapor), miosis was usually not correlated with or accompanied by reductions of circulating AChE, BuChE, or CarbE. For the VX vapor exposure study of Benton et al. (2006a), and among those rats exhibiting only one sign (either whole-blood AChE activity inhibition or miosis), miosis developed in the absence of blood AChE activity depression "90% of the time." The findings of Mioduszewski et al. (2002a) for SD rats are consistent with those for human volunteers exposed to GB vapor in the study by Rubin and Goldberg (1957). These results further document the fact that miosis alone, and in the absence of signs such as ChE or CarbE activity inhibition, is a local effect and reflects an exposure much less than that required for the generation of systemic clinical effects. Thus, consideration of a local effect such as miosis as a critical endpoint for decision criteria and exposure guideline determination allows a useful margin of protection against the potential for agent exposures sufficiently large to generate systemic effects.

8.3.2 Minimal potential for delayed neuropathy

A continuing area of public concern regarding nerve agent exposure is the possibility of chronic neurological effects, particularly delayed neuropathy, given that neuropathic effects have been observed after high levels of occupational exposure to the lipophilic agricultural pesticides. Exposure to some OP anticholinesterase compounds results in delayed neurotoxic effects (ataxia, distal neuropathy, paralysis), which are collectively described as organophosphate ester-induced delayed neuropathy (OPIDN). OPIDN is characterized by myelin sheath and axon degeneration and was once thought to be the consequence of inhibition and aging of neuropathy (or neurotoxic) target esterase (NTE) (Abou-Donia, 1993; Ehrich and Jortner, 2002; Gupta et al., 2012). With greater knowledge and recent data pointing out that NTE-knockout mice may also develop OPIDN (Abou-Donia, 2003; O'Callahan, 2003; Winrow et al., 2003), the NTE theory has been replaced with one involving a noncholinergic, proteolytic mechanism involving cytoskeletal proteins found in neurofilaments (De Wolff et al., 2002). The resulting proteolysis, accompanied by perturbed ionic gradients, cellular edema, and myelin debris, can generate neuropathy.

A number of well-conducted studies using USEPA guidelines for experimental determination of delayed neurotoxicity (USEPA, 1998) have been performed for the G-agents and agent VX (Gordon et al., 1983; Willems et al., 1984; Goldman et al., 1988; Wilson et al., 1988). The USEPA protocol requires toxicological testing with the domestic hen, an OPIDN-sensitive laboratory animal. In general, exposure to the standard threat nerve agents (e.g., GA, GB, GD, GF, VX) is not considered neuropathic in

humans (Marrs et al., 2007a) given that agent VX is not neuropathic in standard challenge tests with hens and that G-agent concentrations necessary to induce OPIDN would be supralethal, and human survival would be highly unlikely.

8.3.3 Long-term effects following exposure to nerve agents

Although delayed OPIDN has not been demonstrated for the organophosphate nerve agents, assessments of casualties from recent civilian subversive activity and military attacks have provided evidence for long-term neuropsychological and neurobehavioral effects. Analyses of these events lack exposure terms which prevents an accurate determination of an exposure concentration−effect relationship. Exposures are typically defined by the severity of initial effects and the level of medical intervention required for immediate treatment. In a systematic review of studies addressing the long-term neurological effects of acute exposure to sarin, the National Toxicology Program concluded with a moderate level of confidence that acute exposure of humans to sarin is suspected of having long-term (≥1 year after exposure) adverse effects on learning and memory. Further, a cross-sectional study and one case report of Tokyo subway attack victims noted evidence for morphological and histopathological changes in the nervous system in the years following exposure to sarin (NTP, 2019). The report also stated that additional and more refined analyses should address areas of low confidence and inconsistencies in topics of concern such as visual and ocular effects, and long-term effects on cholinesterase. Talibani et al. (2018) reported a wide range of long-term neurological sequelae in about one-third of individuals in a study group who had been exposed during the attack on the Kurdish city of Halabja. Long-term effects of exposure to OP nerve agents have been reviewed by Figueiredo et al. (2018) and are discussed in greater detail in other chapters in this volume.

8.3.4 Evaluation of other potential effects

Animal data from vapor, oral, and injection exposure studies for the G-series nerve agents and agent VX indicate that these agents do not induce reproductive or developmental effects in mammals (Van Kampen et al., 1970; Denk, 1975; Schreider et al., 1984, 1988; Laborde and Bates, 1986; Goldman et al., 1988; Bates et al., 1990; Bucci et al., 1993; LaBorde et al., 1996). Incidental data from the Tokyo subway incident (Ohbu et al., 1997) documenting the birth of healthy children to women who had received exposures to toxic GB concentrations at 9−36 weeks of gestation support this finding.

Neither agent GB nor agent VX was genotoxic in a series of microbial and mammalian assays (Crook et al., 1983; Goldman et al., 1987, 1988), whereas agent GA has been reported to be weakly mutagenic in similar cellular assays (Wilson et al., 1994). Experimental results indicate that agents GB, GA, and VX have no carcinogenic potential (Weimer et al., 1979; Goldman et al., 1988; Bucci et al., 1992a,b).

8.3.5 Inhalation/ocular toxicity in controlled experiments with human subjects

It is noted that the most complete experimental data set for the nerve agents evaluated in all species is that for agent GB. The following analysis reflects that emphasis (Table 8.2). Human study reports evaluated have been previously judged by the US Environmental Protection Agency National Advisory Committee for Acute Exposure Guideline Levels for Hazardous Substances and the National Research Council (NRC) Committee on Toxicology to be consistent with acceptable criteria and procedures regarding informed consent and appropriate clinical supervision (NRC, 2001, 2003).

8.3.5.1 Agent GB

Fairley and Mumford (1948) exposed 16 male volunteers to 0.3 mg GB/m^3 for 0.5 min. Nine of the test subjects reported that they could detect the agent by smell, seven reported tightness of the chest and 16 reported rhinorrhea. McKee and Woolcott (1949) evaluated the effects of low concentrations of agent GB on 14 male volunteers. A single exposure to 0.6 mg GB/m^3 for 1 min or 0.06 mg GB/m^3 for 40 min resulted in miosis and slight tightness of the chest; within 24 h, signs and symptoms resolved in subjects exposed for 1 min, whereas more than 48 h was required for resolution in subjects exposed for 40 min.

In a study reported by Harvey (1952), 128 adult male volunteers were exposed in a chamber to GB concentrations ranging from 0.05 to 3.0 mg/m^3 for 2−20 min. The corresponding cumulative exposures ranged from 1.0 to 6.0 mg min/m^3. The most common signs and symptoms resulting from the GB exposures were headaches, eye pain, rhinorrhea, tightness in the chest, cramps, nausea, and concentration difficulties.

When evaluating data from the Harvey (1952) study, Johns (1952) reported on the occurrence of miosis in exposed individuals. Regression analysis of 150 observations, including 55 controls, indicated that the concentration at which a 50% decrease in pupil diameter would be attained was approximately 4.1 mg min/m^3, with 90% confidence limits of approximately 2.7 and 5.7 mg min/m^3. Johns (1952) defined “mild miosis” as a “decrease of 1−2 mm” in pupil diameter, which usually disappeared

within 24 h. Although mild miosis as defined was observed in some subjects at the lowest Ct tested ($Ct = 1.0$ mg min/m^3), other subjects exhibited mean maximal pupil decreases of less than 1 mm, indicating attainment of a response threshold at this level of exposure. Untreated controls exhibited a pupil diameter decrease of 0.33 mm or more; Johns (1952) attributed this difference to observer bias and pointed out that there was still a relative difference between the control group and the exposed groups.

Oberst et al. (1968) conducted inhalation studies in which 125 volunteers were exposed to low concentrations of GB vapor to measure levels of GB retention and changes in RBC−ChE activity. In one series of tests in which resting subjects were exposed to GB for 2 min, the calculated retained dose was 3.4−3.8 μg/kg and the percent inhibition of RBC−ChE activity was 39%−63% (average 49%). In a second series of tests in which exercising men were exposed to GB for 2 min, the calculated retained dose was 3.2−4.0 μg/kg and the percent inhibition of RBC−ChE activity was 29%−58% (average 47%). The reported 2 min ChE_{50} dose for all 125 subjects (grouped data) was 3.95 μg GB/kg. From these data, the 2 min EC_{50} for cholinesterase inhibition can be estimated as approximately 21 mg/m^3 for resting men breathing approximately 7 L/min and approximately 4 mg/m^3 for exercising men breathing approximately 50 L/min.

Baker and Sedgwick (1996) exposed eight human volunteers to 0.5 mg GB/m^3 for 30 min in a chamber; test subjects walked at a rate of 96 paces per minute while breathing normally. The exposure resulted in a 60% inhibition of RBC−AChE activity; subjects exhibited miosis, some photophobia, and mild dyspnea. Respiratory symptoms resolved within minutes and the ocular effects within 48 h after exposure. There were no clinical neuromuscular signs or symptoms; however, small and nonclinical changes in single-fiber electromyography (SFEMG) of the forearm were measured at 3 h and 3 days after exposure; SFEMG changes were not detectible 15−30 months after exposure.

The results of agent GB vapor exposure studies conducted with human volunteers indicate that the threshold for miosis and other minimal toxic effects is in the range of 0.05−0.5 mg/m^3 for 10−30 min exposures (Table 8.2 and summaries). Rubin et al. (1957) evaluated the effects of agent GB on the visual threshold of three adult volunteers. The test individuals were exposed to 2 mg GB/m^3 for 2 min with the eyes exposed or protected. With the eyes unprotected, the exposure resulted in moderate miosis with no other obvious signs of cholinesterase activity inhibition, but with a significant elevation of the absolute visual threshold in the dark-adapted eye.

Callaway and Dirnhuber (1971) evaluated the "miotogenic potency" of GB vapor in humans (62 miosis responses in 26 human volunteers). Exposure time periods ranged from 10 min to 5 h. Callaway and Dirnhuber reported 50% and 90% decrements in pupil area (Table 8.2). There are acknowledged weaknesses in the protocol and data of Callaway and Dirnhuber (1971), such as limited 1970s-era capabilities for measuring agent vapor concentrations, semisubjective protocols for measuring miosis in human eyes, and incomplete documentation of miosis incidence.

Based on human and animal data, McNamara and Leitnaker (1971) estimated that the EC_{50} for miosis in humans would be 0.0083 mg/m^3 for 8 h exposure duration or 0.0028 mg/m^3 for 24 h exposure duration. McNamara and Leitnaker (1971) did not expect miosis to occur at 0.001 mg/m^3 for 8 h or 0.0003 mg/m^3 for 24 h.

8.3.5.2 Agents VX and Vx

No experimental data are available for direct characterization of acute VX vapor toxicity in humans after inhalation exposure. Based on lethality data for several animal species, Bide and Risk (2000, 2004) estimated the 10 min LCt_{50} value for a VX aerosol to be 7 mg min/m^3 for a 70-kg man breathing 15 L/min for 10 min.

One of the few experimental attempts to evaluate human exposure to VX vapor for durations longer than a few minutes is the historically important study of Bramwell et al. (1963), in which eight individuals were exposed to VX vapor concentrations ranging from 0.23 mg/m^3 to 5 mg VX/m^3 for durations ranging from 2.25 s to 24 min ($Cts = 0.7−25.6$ mg min/m^3). The Bramwell et al. (1963) study is not considered credible because of its seriously flawed exposure protocol; both C and t were varied (resulting in no replicate cumulative exposures), and the organic solvent benzene was used to help disperse the agent in the exposure (carrier solvent may have altered agent absorption) (Reutter et al., 2000).

Koon et al. (1959) evaluated the minimum odor detection limits of VX in 16 volunteers. Each subject sniffed the agent both during the morning and afternoon on 2 successive days (presumably only one sniff at each time point). The estimated total doses for the four exposures ranged from 0.01 to 0.13 μg/kg. No significant changes in RBC or plasma ChE activity were observed in the test subjects. Three subjects reported headaches the evening of the last test, and three other subjects reported slight chest tightness, dryness of the mouth, and nasal irritation for 30 min after the test.

Recent multiservice (Army, Marine Corps, Navy, and Air Force) guidance on agent-specific exposure limits estimates the VX ECt_{50} for mild toxicity in humans (miosis, rhinorrhea) to be 0.10 mg VX-min/m^3 for 2−360 min exposures (DA, 2005). The inhalation/ocular ECt_{50} for severe effects in humans (i.e., muscular weakness,

tremors, breathing difficulty, convulsions, paralysis) was estimated to be 10 mg min/m^3 for 2−360 min exposures for a respiratory minute volume of 15 L/min (DA, 2005).

Agent Vx is considered toxic via inhalation exposure or direct contact with the eye and/or skin (DA, 2005) but has been poorly studied. Because of lack of data suitable for analysis, DA (2005) has determined that no toxicity estimates for Vx can be developed at this time.

8.3.6 Inhalation/ocular toxicity in laboratory species

8.3.6.1 G-series agents

8.3.6.1.1 Lethal levels

Data regarding the acute lethality of G-series agents for short-term exposures are summarized in Table 8.3 (see also NRC, 2003, for a detailed review). In studies conducted by Mioduszewski et al. (2001, 2002a), acute lethality of agent GB to male and female SD rats was evaluated for time periods of 10, 30, 60, 90, 240, and 360 min in a whole-body dynamic chamber. GB concentrations ranged from approximately 2 to 56 mg/m^3, and lethality was assessed at 24 h and at 14 days after exposure. Female rats were reported to be significantly ($P < .01$) more sensitive than males to GB vapor toxicity over the range of exposure concentrations and durations studied.

In studies conducted by Bide and Risk (2004), male CD1 strain mice were exposed to whole-body GB for time periods ranging from 20 to 720 min. LC_{50} values for 3−12 h were progressively higher (toxicity lower) than that predicted by either Haber's rule or the Ten Berge relationship (Ten Berge et al., 1986). In studies conducted by Anthony et al. (2004), male and female SD rats were exposed to whole-body agent GF for 10, 60, or 240 min, and lethality was assessed 24 h and 14 days after exposure (Table 8.3). Females were more sensitive than males.

Hulet et al. (2006b) exposed male and female Göttingen minipigs to whole-body lethal concentrations of agent GF vapor for 10, 60, or 180 min (Table 8.3). No significant gender differences were observed in the GF lethality values.

In the latter years of WWII, agent GE underwent acute inhalation toxicity characterization at a number of research facilities managed by the Office of Scientific Research and Development (National Defense Research Committee). These results, for which the research protocols and exposure concentrations are not available for comparison, were summarized by Gates and Renshaw (1946) and are provided in Table 8.3 as LCt_{50} values.

8.3.6.1.2 Sublethal levels

A consistent endpoint for sublethal effects determination is miosis. This information is summarized in Table 8.4.

Van Helden et al. (2003, 2004a,b) exposed male and female marmosets (*Callithrix jacchus*, Harlan, UK) (whole-body) to mean GB vapor concentrations of 0.27−0.91 μg/m^3 and male Dunkin−Hartley guinea pigs to 0.02−0.43 μg/m^3 for 5 h. The lowest cumulative exposure at which the internal dose became measurable (based on fluoride-regenerated GB from blood BuChE) was 0.04 ± 0.01 mg min/m^3 in marmosets and 0.010 ± 0.002 mg min/m^3 in guinea pigs.

Miosis, EEG effects, and visual-evoked response (VER) were examined after 5 h exposures at concentrations ranging from 7.5 to 150 μg GB/m^3. Significant miosis (as measured by the ratio of pupil diameter to iris diameter; $P < .05$) was attained for marmosets and guinea pigs (Table 8.4) (Van Helden et al., 2003, 2004a). Significant ($P < .05$) threshold change in EEG parameters for marmosets occurred at 0.2 mg min/m^3, whereas significant threshold VER changes occurred at 25 mg min/m^3 (Van Helden et al., 2004b).

Mioduszewski et al. (2002a,b) exposed young adult (8- to 10-week-old) male and female Sprague−Dawley (SD) rats to whole-body GB vapor concentrations of 0.01−0.48 mg/m^3 for three exposure periods of 10, 60, and 240 min in a dynamic airflow inhalation chamber. Rat pupil diameters were assessed and blood samples were also collected for RBC−AChE, BuChE, and plasma carboxylesterase (CarbE) activity determinations. Animals were also observed for development of clinical signs during a 7-day postexposure period; EC_{50} values for miosis were reported (Table 8.4; miosis EC_{50} points defined as the statistical concentration required for postexposure pupil diameters of 50% or less of the pre-exposure pupil diameter in 50% of the exposed population) (Mioduszewski et al., 2002a,b). Gender differences (females more susceptible) were observed. Whole-body exposure to GB vapor did not result in significant activity inhibition for any blood enzyme monitored (RBC−AChE, plasma−BuChE, or CarbE) for any GB vapor concentration and duration tested. Mioduszewski et al. (2002a,b) concluded that clinical signs associated with whole-body GB vapor exposure were limited to miosis.

Kassa et al. (2001) exposed male albino Wistar rats for 60 min in an inhalation chamber once, or repeatedly to GB concentrations of 0.8, 1.25, or 2.5 mg/m^3. Animals exposed to the lowest concentration (level 1) were asymptomatic based on clinical and laboratory measurements. Animals exposed to the second concentration (level 2) were asymptomatic based on clinical signs but experienced significant inhibition of RBC−AChE activity

(by 30%). The highest test concentration (level 3) was reported to be a nonconvulsive symptomatic exposure. Three months after exposure, control and exposed animals were evaluated for GB-induced effects using biochemical, hematological, neurophysiological, behavioral, and immunotoxicological methods. None of the exposed animals showed any clinical signs of intoxication; their body weight did not differ significantly from control values, and there were no changes in hematological or biochemical parameters, including blood and brain cholinesterase activity. The only significant effect ($P < .05$) observed in rats exposed once to 1.25 mg GB/m^3 (level 2) was an increase in stereotypical behavior. In a continuation of these studies, Kassa et al. (2004) reported that at 3 months after exposure, the level 3 animals showed significant increases in two biochemical markers of stress, plasma corticosterone, and liver tyrosine aminotransferase activities. The latter was also significantly increased in level 2 test animals. In spatial discrimination tests, animals tested at all three GB concentrations showed significant increases in reaction time up to 2 h after exposures. In the level 3 animals, the effects lasted for 3 weeks.

Walday et al. (1991) exposed male Wistar rats to 0.05 or 0.2 mg GD/m^3 for a single 40 h period. No clinical signs of toxicity were seen during the exposures. AChE, BuChE, and CarbE activities were significantly inhibited in airway and lung tissue at both doses. Brain BuChE and CarbE activity exhibited significant effects at either dose; brain AChE activity did not significantly change from baseline at 0.05 mg GD/m^3, but did so at 0.2 mg GD/m^3.

Genovese et al. (2004) evaluated cognitive and general performance effects of GB on adult male SD rats. The test animals received a single whole-body exposure for 60 min once at 1.7−4.0 mg GB/m^3. Cognitive and behavioral performance testing began 48 h after inhalation exposure and was conducted during 55 sessions occurring over approximately 11 weeks after exposures. Single exposures did not significantly affect performance and no delayed performance onset was observed.

Genovese et al. (2008) characterized the miosis EC_{50} for sarin in a nonhuman primate (African green monkey; *Chlorocebus aethiops*) after 10 min exposures (Table 8.4). Evaluation of potential behavioral change by performance on a serial probe recognition test indicated no change from baseline for all subjects. No other clinical sign was observed.

Genovese et al. (2006) also evaluated cognitive and general performance effects of GF on adult male SD rats using the same protocol as that for GB. The test animals were exposed for 60 min to 0, 1.6, 3.7, or 5.2 mg GF/m^3. The highest test concentration resulted in a significant decrease in the response rate in the behavioral task for the first two postexposure sessions; however, the deficit was not persistent and recovery occurred rapidly. None of the exposures to GF caused a significant effect on completion time in the maze (cognitive) task.

In tests conducted by Allon et al. (2005), freely moving male albino SD rats were exposed to whole-body 34.2 ± 0.8 μg GB/L for 10 min, after which electrocardiograms of exposed and control animals were monitored every 2 weeks for 6 months. One and 6 months after exposure, rats were challenged with epinephrine under anesthesia and the threshold for cardiac arrhythmia was determined. Surviving treated rats displayed agitation, aggression, and weight loss compared with nonexposed rats, and approximately 20% experienced sporadic convulsions. GB-challenged rats with severe signs demonstrated QT segment prolongation during the first 2−3 weeks after exposure. Epinephrine-induced arrhythmias appeared at a significantly lower blood pressure in the

treated group during the first month after exposure and lasted for up to 6 months.

Callaway and Dirnhuber (1971) evaluated the miotogenic potency of GB vapor in rabbits exposed to GB under goggles (43 miosis responses in 10 albino rabbits). Exposure time periods ranged from 10 min to 5 h (Table 8.4).

Bartosova-Sevelova and Bajgar (2005) exposed rats to agent GB vapors for 4 h at four different concentrations (0.30, 0.43, 0.58, and 0.82 mg/m^3) in a whole-body exposure chamber. Convulsions and hypersalivation were observed in one animal exposed to 0.82 mg/m^3. There was a significant decrease in blood AChE activity in all but the low-dose test groups and the controls. AChE activity in the brain was significantly decreased only in animals exposed to 0.58 mg/m^3, and only in the pontomedullar area. No significant alterations in AChE activity were seen in the frontal cortex or in the basal ganglia. AChE activity in the pontomedulla was lowest at the greatest dose (0.82 mg/m^3), but the data were too variable for statistical significance.

Sekowski et al. (2004) evaluated gene and protein level changes in the brains of male and female SD rats exposed to low-level doses (0.004−0.033 mg/m^3) of aerosolized agent GB and GF via whole-body inhalation for 4 h. Preliminary results indicate that exposure to nerve agents results in differential expression of a number of neuronal genes, including a group that affects cellular processes critical to neurological injury and regeneration, and gender-associated differences in the level and type of gene expression response were significant.

Whalley et al. (2004) exposed adult male and female SD rats to a series of whole-body agent GF vapor concentrations for 10, 60, or 240 min. Miosis (defined as a 50% reduction in pupil area compared with baseline) measured approximately 30 min after exposure indicates that females were significantly more sensitive than males ($P < .05$) (Table 8.4).

In studies conducted by Hulet et al. (2006a,c, 2007), male and female Göttingen minipigs were exposed to whole-body agent GB or GF for 10, 60, or 180 min (Table 8.4). Male minipigs were significantly ($P = .022$) more sensitive to the effects of GF exposure than females.

Conn et al. (2002) exposed male F344 rats to 0, 0.2, or 0.4 mg GB/m^3 for 1 h/day for 1 or more days. Animals were maintained at either 25°C or 32°C to evaluate the effects of heat stress. Body temperature and activity were monitored by telemetry continuously during exposure and for 1 month after the exposures. Although RBC−ChE activity was reduced in the exposed animals (quantitative data not provided), the test protocol did not significantly alter temperature regulation or locomotive activity of the rats.

8.3.6.2 Agent VX

8.3.6.2.1 Lethal levels

Benton et al. (2006b, 2007) experimentally determined the LCt_{50} and LC_{50} in male and female adult SD rats exposed to whole-body VX vapor for 10, 60, and 240 min in a dynamic exposure chamber (Table 8.3); the study protocol was similar to that for agent GB in the studies conducted by Mioduszewski et al. (2001, 2002a). Experiments testing the role of decontamination less than 24 h after exposure provided clear evidence for percutaneous toxicity induced by whole-body vapor exposure to the persistent nerve agent VX. For severe and lethal VX vapor exposure effects, females were not more susceptible than males for the exposure durations examined.

Bide and Risk (2000) exposed outbred male CD1 (SD) BR rats, outbred male CD1 (ICR) BR mice, and outbred male (HA) BR guinea pigs to NaCl aerosols containing entrained VX in a nose-only inhalation system for an exposure time of 12 min. Observed LCt_{50} values are summarized in Table 8.3.

Bide and Risk (2000, 2004) also cite several previous studies in which LCt_{50} values for mice, guinea pigs, rabbits, hamsters, and dogs were reported (Table 8.3).

For exposure to VX vapors, Koon et al. (1960) reported 10 min LCt_{50} values for mice with exposure to either whole-body or head only, as well as for goats. Carroll et al. (1957) also reported female mouse LCt_{50} values for nose-only and whole-body protocols. However, Carroll et al. (1957) reported that the concentration of VX in the exposure chamber was not measured directly but was estimated from the mortality level, which was correlated with the LD_{50} for i.v. injection.

8.3.6.2.2 Sublethal level

Benton et al. (2005, 2006a, 2007) have characterized miosis as well as severe effects (severe tremors and/or prostration, convulsions, and/or gasping) in male and female SD rats exposed to whole-body VX vapor (0.00037−0.016 mg VX/m^3) under study protocols similar to those for agent GB in the studies conducted by Mioduszewski et al. (2001, 2002a). Miosis EC_{50} endpoints were derived for VX vapor exposure durations of 10, 60, and 240 min (Table 8.4). At the highest VX concentrations tested for each exposure duration, significant (>99.9% confidence) differences between control and experimental whole-blood AChE activity were observed; no other signs (e.g., tremors, salivation) were observed and delayed pupil effects were minimal. For the miosis endpoint, female rats are considered more susceptible than males to VX vapor exposure.

For severe effects (tremors, prostration, etc.), the ECt_{50} values (mg min/m^3) reported by Benton et al. (2007) were

as follows: 10 min, 40.9 (female) and 35.2 (male); 60 min, 30.0 (female) and 31.2 (male); and 240 min, 31.5 (female) and 29.9 (male). EC concentrations were not reported.

After single 60 min VX vapor exposures in the range of 0.016–0.45 mg VX/m^3, Genovese et al. (2007) examined blood AChE activity, dose estimation by regeneration assay, transient miosis, and behavior parameters in adult male SD rats. Behavioral evaluation included a radial maze task and a variable-interval schedule-of-reinforcement task. At all concentrations tested, transient miosis and AChE activity inhibition were observed and some subjects exhibited transient ataxia and slight tremor. After 3-month postexposure evaluations of behavior, the authors concluded that performance deficits were minor and transient at these concentrations. Further, no delayed effects were observed.

8.4 Risk assessment

Application of standard risk assessment methods by numerous authorities and agencies to the toxicological data summarized has generated exposure guidelines that provide objective and health-based foundations for responsible and efficient responses after nerve agent release, as well as a basis for site recovery and decontamination decision criteria. The health-based nerve agent exposure guidance summarized here has been derived in an open and transparent manner and judged scientifically valid and protective (Opresko et al., 1998, 2001; NRC, 1999, 2001, 2003; Krewski et al., 2004; Watson et al., 2006a,b; see also www.epa.gov/oppt/aegl/). Although initially developed to facilitate disposal of the US stockpile of CW munitions and to support remediation or closure at sites where CWs were historically processed, nerve agent exposure guidance became a subject of interest for homeland defense applications after the events of September 2001.

For reasons described previously, the air exposure pathway has been a primary focus of risk assessment activity for nerve agents (NRC, 2003; Cannard, 2006; ATSDR, 2007; Dabisch et al., 2008a). In situations where long-term agent release is a concern, and where agent residuals may be found, potential exposure to relatively low levels of ingested agents is a priority.

In all cases, it is important to appropriately safeguard public health without defaulting to overly conservative actions (e.g., to "nondetect") that would divert limited resources without significant benefit. The following sections summarize toxicological support and developmental rationale for the two primary criteria of interest to community decision-makers managing response to an intentional or accidental release of nerve agent(s) to the environment.

8.4.1 Acute exposure guideline levels

Credible short-term nerve agent exposure limits, designed to aid state and local government agencies in developing emergency response plans in the event of accidental or deliberate atmospheric release, have been derived. These short-term values have also proved useful in deployed force health protection, and in establishing health-based CWA performance goals for detection system development (USACHPPM, 2004, 2008).

Acute exposure guideline levels (AEGLs; expressed in units of mg/m^3 or ppm) are vapor exposure guideline values for numerous hazardous compounds (primarily toxic industrial compounds) that have been published by the National Academy Press (e.g., NRC, 2003, 2007). For each hazardous compound, guideline levels are developed for vapor exposure durations of 10 and 30 min, 1, 4, and 8 h, as well as for three gradations of toxic effect severity. AEGL-1 concentrations are the mildest effect category, whereas AEGL-3 concentrations represent the most severe effect category (NRC, 2001). The point above the AEGL-3 concentration at which level 3 effects would initiate for any given human exposure duration is not identified in the AEGL assessment protocol.

Typically, the AEGL concentration established for any given effect level is often less than the known experimental concentration at which such toxicological effects occur. This protective nature of the AEGL process and values was demonstrated for each of the nerve agents, where observed human thresholds for reversible effects occur at air concentrations greater than AEGL-1 levels (Watson et al., 2006a,b).

Selection protocols for critical effects and studies, AEGL derivation, time scaling, use and selection of uncertainty and modifying factors, and a description of the lengthy and deliberative review process used are all described in NRC (2001) as well as in recent articles by Krewski et al. (2004) and Bruckner et al. (2004). Development of AEGL values includes consideration of uncertainty factors as well as the need for any modifying factors. Because exposure–response data are usually not available for each AEGL-specific exposure duration (NRC, 2001), temporal extrapolation is used in the development of values for some AEGL-specific time periods. The concentration–exposure time relationship for many systemically acting vapors and gases may be described by $Cn \times t = k$, where the exponent n ranges from 0.8 to 3.5 (Ten Berge et al., 1986; NRC, 2001). Some investigators refer to the Ten Berge extrapolation as the "toxic load model" and n as the "toxic load exponent" (Sommerville et al., 2006; Dabisch et al., 2008a). The excellent data collected by investigators at Edgewood Chemical Biological Center (Aberdeen Proving Ground, MD), characterizing nerve agent vapor exposure miosis and lethality

endpoints for multiple agents and species, has allowed agent-specific determination of *n* (summarized in Dabisch et al., 2008a). In the case of swine exposed to G-agents and rats exposed to VX, the experimentally determined *n* values for these endpoints are 1.6 or less, which are less than the *n* of 2 assumed during AEGL development for these same compounds in 2001–2003 (NRC, 2003), and based on then-available data for SD rats exposed to agent GB (Mioduszewski et al., 2002a,b). It thus appears that G-agent and VX dose response for the miosis and lethality endpoints are less steep than previously indicated and that the published nerve agent AEGL values (Table 8.5) are more protective than originally considered (NRC, 2003; Watson et al., 2006a,b).

For comparison, it is useful to consider other common guideline sources applicable to short-term nerve agent release events. The US Department of Energy, in their development of 1 h Protective Action Concentrations/Temporary Emergency Exposure Levels (PAC/TEELS), has chosen to replicate the published nerve agent-specific 1 h AEGL-1, AEGL-2, and AEGL-3 values as tier 1, tier 2, and tier 3 PAC/TEEL values, respectively (http://hss.energy.gov/HealthSafety/WSHP/chem_safety/teel.html).

8.4.1.1 Application of AEGL values

The AEGL process does not include specific implementing or application guidance, and specific approaches for using the values are left to the discretion of risk managers and appropriate authorities (NRC, 2001). Nevertheless, AEGL application is already broad and continues to expand.

The utility of AEGL values for CW agent emergency preparedness planning was recognized by the Chemical Stockpile Emergency Preparedness Program (CSEPP), when FEMA and US Army representatives adopted final nerve agent AEGL concentrations to replace previous agent toxicity criteria for emergency response decision making (CSEPP, 2003). As of February 2003, standing CSEPP policy guidance for each of the communities hosting agent demilitarization facilities in the US, recommends application of AEGL-2 concentrations as the protective action level for evacuation or shelter-in-place, and application of AEGL-1 concentrations as notification levels (CSEPP, 2003). Since publication of final AEGL levels by NRC (2003) and enactment of the CSEPP Policy Paper (CSEPP, 2003), multiple stockpile states and counties have incorporated the Policy Paper

recommendations into their individual community emergency response plans, and used them in making regulatory decisions permitting agent munition disposal operations (CSEPP, 2006a,b).

In February 2008, the US National Response Team (NRT) posted Quick Reference Guides for the G-series nerve agents and VX for public access on its website (www.nrt.org) (NRT, 2008). These Quick Reference Guides are useful summaries of agent characteristics and advisories and are provided as national guidance. While acknowledging that site-specific clean-up decision criteria will be the result of multiagency agreements and site-specific factors, the NRT considers that attainment of agent-specific air concentrations less than 8 h of AEGL-1 is an acceptable criterion for verification of site decontamination.

In general, agent concentrations less than AEGL-2 are considered to be in a range that poses relatively negligible health consequences for acute exposures. Other AEGL applications performed or recommended include use as hazard assessment plume modeling criteria for the US Nonstockpile Chemical Material Program and Homeland Defense scenarios, as testing criteria for personal protective equipment intended for use by first responders in a single weapon-of-mass-destruction scenario, as detection performance goals for advanced equipment acquisition and development, and as a tool for assessing potential exposures during military missions such as peacekeeping (USACHPPM, 2008).

8.4.2 Estimated oral reference doses

Development of nerve agent-specific reference dose estimates is critical to remediation and restoration at existing and closing military sites, which is a priority activity for the Department of Defense (DOD) (Opresko et al., 1998, 2001). A reference dose (RfD; mg/kg/day) was originally designed for estimating noncancer health risks at CERCLA (Comprehensive Environmental Response, Compensation, and Liability Act of 1980) Superfund sites (USEPA, 1989). As such, it is an essential component of the site risk assessment used to assess potential long-term exposures to contaminated media such as soil, where RfDs address the pathway of incidental ingestion of soil particles (USEPA, 1989; Dourson et al., 1994; Cicmanec et al., 1996; Abernathy et al., 2004).

Methods used to derive oral RfDs for nerve agents follow standard USEPA protocols (USEPA, 1989; Dourson et al., 1994), use appropriate toxicological data and uncertainty factors, and have undergone review for consistency by the National Research Council (Opresko et al., 1998, 2001; NRC, 1999; Bakshi et al., 2000). Because the EPA has not officially verified the derived values for nerve agents, they are identified as estimated RfDs (RfDe) (Table 8.6).

These criteria are selected by the Office of the Army Surgeon General as the most appropriate oral toxicity reference values for use in environmental risk assessments and represent the Army's position (Opresko et al., 2001). The RfDe values have been put in to USEPA risk models along with accepted chronic vapor exposure limits (as cited in Watson and Dolislager, 2007) to generate agent-specific Health-Based Environmental Screening Levels (HBESLs). These HBESLs are endorsed by military policy as criteria to assess potentially contaminated soils (Table 8.6) (USACHPPM, 1999; OASA, 1999; Watson and Dolislager, 2007).

8.4.3 Management of exposure to nerve agents

The continued use of nerve agents by terrorists and militant states necessitates the need for further effort in the management of exposure to these agents. This entails decontamination of exposure sites, prophylactic measures, and medical intervention to treat both immediate and longer-term effects of nerve agents. Although briefly considered here, these topics are addressed more fully in later chapters of this volume.

8.4.4 Critical role of decontamination

Before discussion of antidotes and treatment regimens, it is noted that affected individuals should be removed from the site of agent exposure as quickly as possible, and undergo rapid decontamination to remove potential for continued personal exposure and to prevent secondary exposure to responders, healthcare workers, medical transport vehicles, and treatment facilities (Sidell et al., 1997; Cannard, 2006; ATSDR, 2007; Okumura et al., 2007; Pulley et al., 2008; Chilcott et al., 2019). Decontamination efforts generally focus on removing agent from the skin and limiting further contact from agent-contaminated clothing and other contaminated materials. It is imperative that decontamination of the skin be rapid, efficacious and, especially for those involved in armed conflicts, easily performed. Over the years, decontaminants have included the M291 Skin Decontamination Kit (SDK), Reactive Skin Decontamination Lotion (RSDL), soapy water, and dilute sodium hypochlorite among others.

8.4.5 Signs and symptoms guiding medical management

Depending on the concentration and duration of exposure, cases of nerve agent intoxication can exhibit a dose-dependent "constellation" of clinical signs and symptoms representing a variety of parasympathetic effects, functional change at NMJs, and altered CNS function (Cannard, 2006). As a consequence, critical care personnel and others responsible for developing and administering treatment protocols should take into account the totality of the case presentation. A good example is drawn from observations made by medical personnel treating subway passengers presenting at Tokyo area hospitals and clinics on day 1 of the sarin release incident. In decreasing order of frequency, the following clinical signs and symptoms were noted: miosis (observed in most patients), headache, dyspnea, nausea, vomiting, muscular weakness, cough, rhinorrhea, chest oppression, muscular fasciculations, and psychological disturbances such as anxiety (Lillibridge, 1995). Similar distributions were observed among subway passengers treated at St. Luke's International Hospital (Okumura et al., 1996, 2007) as well as residents affected in the Matsumoto incident of 1994 (Yanagisawa et al., 2006), and are consistent with classic descriptions of nerve agent intoxication (Sidell et al., 1997; Leikin et al., 2002; Cannard, 2006). Miosis was found to be a more responsive exposure index than RBC−ChE activity inhibition (Nozaki et al., 1997) or serum cholinesterase activity (Yanagisawa et al., 2006) in cases of sarin vapor exposure during the Tokyo and Matsumoto incidents, respectively (Okumura et al., 2015).

Yanagisawa et al. (2006) classified individuals exhibiting a pupil diameter larger than 3.0 mm as without miosis and not affected by nerve agent vapor exposure given that simultaneous serum ChE activity measurements taken during treatment of the Matsumoto cases displayed no inhibition (e.g., largely $\geq 100\%$ of normal serum ChE activity with two cases exhibiting activity $<90\%$ of normal). This, and additional miosis data from Matsumoto, can be used in determining appropriate treatment for individuals without known or confirmed nerve agent vapor exposure (Cannard, 2006; Yanagisawa et al., 2006); for these individuals, examination, observation without treatment, and discharge are appropriate actions and were successfully implemented during medical responses to the Tokyo subway incident (Lillibridge, 1995; Okumura et al., 2015).

8.4.6 Nerve agent antidotes

Advances in medical countermeasures for OP nerve agents are a continuing area of research. The choice of a specific treatment regimen depends on the agent as well as the extent and route(s) of exposure. Very mild exposure to nerve agent vapor may necessitate only decontamination and observation; severe exposure to vapor or liquid requires immediate decontamination, antidote administration, artificial respiration, monitoring, and supportive therapy over hours to multiple days (Sidell et al., 1997; ATSDR, 2007; Vale et al., 2007; Pulley et al., 2008). Convenient triage classifications have been developed by ATSDR (2007) in collaboration with the US Army Medical Research Institute of Chemical Defense.

In cases of massive inhalation exposure, immediate care is vital to prevent death from respiratory failure and because the agent−AChE complex becomes resistant to reactivation by oxime-type antidotes. "Aging" is compound-specific; aging half-times range from minutes (agent GD) to days (agent VX) (Sidell and Groff, 1974; Sidell et al., 1997). Standard antidotes clinically available in the United States are atropine (anticholinergic) and pralidoxime (Protopam or 2-PAM-Cl). In addition, CNS active drugs such as diazepam (Valium) are strongly recommended if convulsions occur; anticonvulsant

treatment is critical for protection against lethality and brain pathology (Shih et al., 2003). If administered soon after exposure, benzodiazepine anticonvulsants reduce seizures and improve recovery but may also increase the risk of seizure recurrence (Figueiredo et al., 2018).

Individuals exposed to vapor and exhibiting miosis only or miosis and rhinorrhea only do not usually require antidote treatment and will resolve without medical intervention (Cannard, 2006; ATSDR, 2007), but they should be observed. If rhinorrhea is problematic in these vapor-only cases, then ATSDR (2007) advises intramuscular atropine (0.05 mg/kg pediatric; 2.0 mg adult) to relieve signs, followed by patient discharge. If eye pain/headache or nausea is problematic in vapor-only cases, then ATSDR (2007) further advises administration of topical atropine or homatotropine to the eye for relief, eye protection from bright light, and discharge.

If liquid/droplet exposure is known or suspected in an individual exhibiting miosis only or miosis and rhinorrhea only, it is recommended that the individual receive no antidote treatment but be closely observed for at least 18 h, because toxic effects of liquid percutaneous exposure may not manifest for several hours (Sidell et al., 1997; Cannard, 2006). Toxic effects from vapor-only exposure usually occur quickly (within minutes) (Sidell et al., 1997). Current medical management guidelines and recommended medication protocols are summarized in ATSDR (2007), Vale et al. (2007), and Pulley et al. (2008). The ATSDR antidote treatment protocol for civilian emergency management is summarized in Table 8.7. The reader may also wish to consult the National Institute for Occupational Safety and Health (NIOSH) (CDC, 2019) for antidote information. Additional information regarding medical management protocols is discussed in Chapters 67, 68, and 71 of this volume.

8.4.7 Ongoing antidote development

The development of medical countermeasures to OP nerve agents continues to receive significant attention. Given that termination of seizure activity protects against the development of neuropathological lesions (especially neuronal necrosis) in brain tissues of experimental animals (Martin and Doebler, 1985; Shih et al., 2003; Marrs et al., 2007b), focus on anticonvulsant therapy is critical. Reduced potential for permanent brain damage in human cases by preventing or limiting the duration of status epilepticus is a primary goal. In challenge tests against multiple LD_{50} doses of agents GA, GB, GD, GF, VX, and VR in guinea pigs, the anticonvulsants midazolam and trihexyphenidyl were more effective than diazepam for seizure control, and midazolam was the most rapidly effective (Shih et al., 2003). The diazepam pro-drug avizafone is also effective (Lallement et al., 2000, 2004) and is available via autoinjector administration (as is diazepam). For more rapid seizure control during acute treatment phases, Marrs et al. (2007b) recommend midazolam administered intramuscularly because of its more rapid intramuscular absorption.

Although pralidoxime is an effective and well-tolerated reactivator, its potency is limited. The search has thus continued for oximes that would combine high reactivator effectiveness against nerve agents but have low toxicity and good chemical stability. Initially, several promising drugs (the oxime HI-6; trimedoxime, or TMB-4; and obidoxime, or LüH-6) emerged but are not equally effective against all agents and forms of exposure (Dawson, 1994; Marrs et al., 2006; Antonijevic and Stojiljkovic, 2007; Eyer et al., 2007; Wetherell et al., 2007; Kuca et al., 2009; Kassa et al., 2010). Marrs et al. (2006) point out that, in the absence of pyridostigmine pretreatment, there are at present "no clinically important differences" between the standard oxime pralidoxime and the alternative oximes HI-6 and obidoxime in the treatment of nerve agent intoxication. These pyridinium oximes, however, are unable to effectively penetrate the blood−brain barrier and, therefore, are ineffective at reactivating OP-inhibited AChE in the brain (Shih et al., 2012). Ongoing research with novel brain-penetrating oximes (substituted phenoxyalkyl pyridinium oximes) and a sarin surrogate (nitrophenyl isopropyl methylphosphonate) or paraoxon (the active metabolites of the OP pesticide parathion) have shown these oximes to be effective reactivators of OP-inhibited brain AChE (Chambers et al., 2012; Chambers and Meek, 2016; Chambers and Meek, 2019; Dail et al., 2019). These are further discussed elsewhere in this volume.

As a combinatorial drug with atropine, galantamine has been effective and safe in counteracting lethal GD and GB doses in the guinea pig (Albuquerque et al., 2006; Pereira et al., 2008); galantamine also protects against neurodegeneration at doses of LD_{50} or more in the guinea pig, and it shows promise as a pretreatment before GD or GB exposures. Lethality was prevented by treatment with nasal atropine (atropine methyl nitrate), and postexposure treatment with atropine methyl bromide instillation, in combination with pulmonary therapeutic surfactants or liquevents in guinea pigs exposed to approximate LC_{50} concentrations of VX aerosol (Nambiar et al., 2007).

The use of bioscavengers has been considered for both the prevention and treatment of nerve agent-induced toxic effects and research on these continues (Nachon et al., 2013; Masson and Nachon, 2017; Goldsmith and Ashani, 2018). Pretreatment with an anticholinesterase carbamate, such as pyridostigmine bromide (PB), was shown to reversibly sequester (and thereby protect) a fraction of AChE from bonding with circulating nerve agents. The

TABLE 8.7 Recommended antidote protocol for emergency nerve agent exposure therapy.

Patient age	Antidotes		Other treatment
	Mild/moderate signs and symptoms[a]	Severe signs and symptoms[b]	
Infant (0–2 years)	Atropine: 0.05 mg/kg i.m. or 0.02 mg/kg i.v.	Atropine: 0.1 mg/kg i.m. or 0.02 mg/kg i.v.	Assisted ventilation as needed. Repeat atropine (2 mg i.m. or 1 mg i.m. for infants) at 5–10 min intervals until secretions have diminished and breathing is comfortable or airway resistance has returned to near normal. Phentolamine for 2-PAM-induced hypertension (5 mg i.v. for adults; 1 mg i.v. for children). Diazepam for convulsions (0.2 to 0.5 mg i.v. for infants up to 5 years; 1 mg i.v. for children > 5 years; 5 mg i.v. for adults).
	2-PAM-Cl: 15 mg/kg i.v. slowly	2-PAM-Cl: 15 mg/kg i.v. slowly	
Child (2–10 years)	Atropine: 1.0 mg i.m.	Atropine: 2.0 mg i.m.	
	2-PAM-Cl: 15 mg/kg i.v. slowly	2-PAM-Cl: 15 mg/kg i.v. slowly	
Adolescent (> 10 years)	Atropine: 2.0 mg i.m.	Atropine: 4.0 mg i.m.	
	2-PAM-Cl: 15 mg/kg i.v. slowly	2-PAM-Cl: 15 mg/kg i.v. slowly	
Adult	Atropine: 2.0–4.0 mg i.m.	Atropine: 6.0 mg i.m.	
	2-PAM-Cl: 15 mg/kg (1 g) i.v. slowly	2-PAM-Cl: 15 mg/kg i.v. slowly	
Elderly, frail	Atropine: 1.0 mg i.m.	Atropine: 2.0 mg i.m.	
	2-PAM-Cl: 5–10 mg/kg i.v. slowly	2-PAM-Cl: 5–10 mg/kg i.v. slowly	

[a] *Mild/moderate signs and symptoms include localized sweating, muscle fasciculations, nausea, vomiting, weakness, dyspnea.*
[b] *Severe signs and symptoms include unconsciousness, convulsions, apnea, flaccid paralysis.*

carbamate moiety spontaneously hydrolyzes from the AChE molecule within hours and allows AChE to again become available for normal physiological function. Such a pretreatment concept and drug enhances the effectiveness of atropine and oximes in treating lethal doses of GA, GB, and VX (Gall, 1981; Inns and Leadbeater, 1983). US combat units already supplied with atropine and pralidoxime have been equipped with 30 mg PB tablets for oral administration every 8 h; the current maximum pretreatment period is 21 days (Sidell et al., 1997; Scott et al., 2007). A related carbamate, physostigmine, was shown to protect animals against not only nerve agent lethality but also incapacitation (Leadbeater et al., 1985). When co-administered with hyoscine, physostigmine effectively reduced incapacitation and prevented death in guinea pigs exposed to agent GD (Wetherell, 1994), and prevented lethality and reduced or prevented incapacitation in guinea pigs exposed to GA, GB, GD, GF, and VX (Wetherell et al., 2002). Transdermal patch administration of physostigmine and hyoscine, or physostigmine alone, in the guinea pig has protected against GD intoxication (Meshulam et al., 1995).

Other developmental pretreatment options included NMDA receptor antagonist memantine in combination with atropine sulfate (Gupta and Dettbarn, 1992; McLean et al., 1992), pre-exposure loading with an excess of

circulating ChE or BuChE (Bajgar et al., 2007; Lenz et al., 2008; Podoly et al., 2008; Saxena et al., 2008; Van der Schans et al., 2008; Masson and Gupta, 2015), or CarbEs (Maxwell et al., 1987) to bind the nerve agent before the agent can reach tissue AChE sites.

Research on the use of bioscavengers such as organophosphate hydrolases is promising for the development of prophylactic measures as well as postexposure treatment of OP nerve agent-induced intoxication (Trovaselet-Leroy, et al., 2011; Masson and Nachon, 2017; Goldsmith and Ashani, 2018). Bioscavengers may interact with OP nerve agents (and OP pesticides) stoichiometrically or catalytically before the OP agents can reach their acetylcholinesterase target. The stoichiometric bioscavengers are proteins that sequester the OP agents while the catalytic bioscavengers bind to and subsequently hydrolyze the OP nerve agent. Multiple examples of these bioscavengers are being investigated individually or as a combination therapeutic measure against OP nerve agent effects. Bioscavengers may offer the potential for pretreatment where the threat of nerve agent exposure exists.

8.5 Concluding remarks and future directions

Stockpiles of OP nerve agents have already been destroyed or are scheduled for destruction in the near future. However, attacks with OP nerve agents by terrorist organizations or by rogue militant states necessitate continued work on protection prior to suspected exposure as well as postexposure medical countermeasures. Medical management of casualties in the event of an attack with OP nerve agents is relevant not only for immediate emergency response but also for longer-term follow up. The latter is being assisted by continued research focusing on identifying and understanding health effects beyond the initial cholinergic crisis syndrome.

Technical advances in precision detection of OP nerve agents further direct attention toward responsible consideration of the consequences for transient presence of residual, low-level agent concentrations in a number of scenarios. Having a transparent, robust, and data-supported framework within which to evaluate likely consequences of potential low-level nerve agent exposure will greatly aid in emergency planning and emergency response operations, and for reducing the magnitude of disruption to affected communities and facilities.

Acknowledgments

Some of the analysis contained in this evaluation was originally prepared for two agencies of the US Department of the Army: the US Army Center for Health Promotion and Preventive Medicine under Interagency Agreement 2207-M135-A1, and the US Army Environmental Command under Interagency Agreement 2134-K006-A1. The Oak Ridge National Laboratory (ORNL) is managed and operated by UT-Battelle, LLC, for the US Department of Energy.

9.1 Introduction and background

One of the most abundant and most toxic agents in the chemical arsenals of the United States and former Soviet Union were VX and VR (Russian VX), respectively, whose development in the middle of the 20th century indicated the peak of warfare chemistry. V-gases are low-volatile liquids with high boiling points, so they are much more persistent than the higher-volatility organophosphorus nerve agents, such as sarin and soman. V-series compounds are more toxic that other organophosphates (OPs). For example, in comparison with sarin (GB), VX is estimated to be approximately twice as toxic by inhalation, 10 times as toxic by oral administration, and approximately 170 times as toxic by skin exposure (Munro et al., 1994). V-series nerve agents are quite effective when exposed through skin contact (especially as tiny drops) and commonly cause death. Poisoning occurs regardless of exposure method, specifically: inhalation; ingestion of vaporous and liquid agents through intact or injured skin or eye mucosa; and contact with contaminated surfaces.

The name *VX* relates to a group of *O,S*-diesters of methylphosphonic acid $ROPO(CH_3)S(CH_2)_2N(R1)_2$. *O*-isobutyl *S*-2-(diethylamino)ethyl methylphosphonothioate (R = *i*Bu, R1 = Et), produced since 1972 exclusively in the former Soviet Union, was generally referred to as *Russian VX* or *VR* (CAS #159939-87-4). The synonyms for this substance are as follows:

- VA;
- Phosphonothioic acid methyl-, *S*-[2-(diethylamino)ethyl] *O*-(2-methylpropyl) ester;
- *O*-isobutyl *S*-2-(diethylamino)ethyl methylthiophosphonate;
- *O*-isobutyl *S*-(*N,N*-diethylaminoethyl) methylphosphonothioate;
- Russian V-gas.

The brutto formula of VR is $C_{11}H_{26}NO_2PS$ (MW 267.368). The structural formula of VR is presented in Fig. 9.1.

VR is a colorless transparent liquid resembling glycerol in mobility, with a boiling point of 300°C, melting point of 35°C, ρ^{20} of 1.0083 g/cm^3, and volatility of C_{max}^{20} 0.0105 mg/dm^3. The agent is poorly soluble in water (less than 5% at 20°C) and highly soluble in organic solvents. Technical products can be colored from yellow to dark brown and smell like fried sunflower seeds.

Research into the environmental behavior of highly toxic chemicals is an important branch of analytical toxicology. We take the word *behavior* to mean the persistence, mechanisms of possible transformation, composition of such transformation products, and toxicity of these substances. Among known toxicants, V-series compounds tend to undergo perhaps the most varied transformations due to their unique structure. Possessing both high reactivity and polyfunctionality, these compounds incorporated into multicomponent matrices are capable of concurrently reacting with several components. Therewith, the reactions may involve different active centers within the same molecule. The routes and results of such reactions cannot be predicted in advance. The situation is even more complicated by the fact that active components of a natural or technogenic matrix are not always known. In view of this, research aimed at identifying transformation products of VX or VR in various media is of particular importance. The degradation of such compounds is suggested to be initiated by electron addition to phosphorus via reaction with anionic nucleophiles (Yang, 1999), such as hydroxide ions, water, alcohols, amines, or unsaturated organic compounds. The problem of determination of VR in complex matrices and identification of

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00009-X

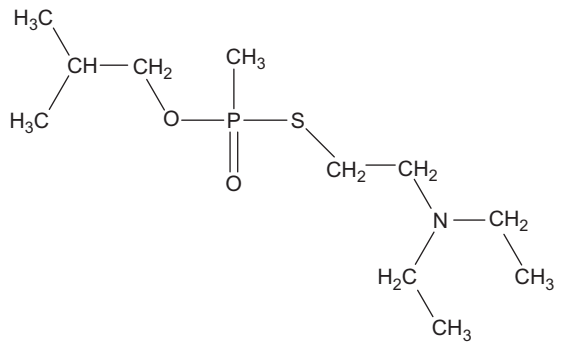

FIGURE 9.1 Structural formula of VR (Russian VX).

VR transformation products is still more complicated by the scarcity of available reference information.

9.2 Monitoring of Russian VX

A group of measures for assessing levels of toxic chemicals in the environment is termed *ambient monitoring*. The possible objects of ambient monitoring are air, water, soil, food, wastes, building materials, and other media through which toxicity factors can be delivered to the human organism. Biomonitoring is based on sampling and analysis of body fluids and tissues and is an indicator of internal dose that provides a measurement of exposure to a toxic chemical. It is quite understandable that toxicological studies are mainly focused on biomonitoring rather than on the levels of toxic compounds in environmental media. At the same time, ambient monitoring is the only tool for revealing sources of toxic pollutants affecting an organism.

9.2.1 Ambient monitoring of Russian VX

The composition of VX degradation products and admixtures has been studied in detail by hybrid chromatography–mass spectrometry (MS) methods. The objects of admixture studies were the contents of containers in which VX had been stored for a long time. Dozens of admixtures and stabilizers could be identified. There has been much work on the identification of admixtures in VX and its degradation products. A systematic review of VX transformation products is presented by Munro et al. (1999), but there are no such systematic data for VR. The degradation of VR in various media always produces complex mixtures of products that commonly contain dozens of both volatile and nonvolatile organic compounds. The prevalent volatile products are phosphorus-free alkyl diethylaminoethyl mono- and polysulfides. The electron impact (EI) mass spectra of these compounds are quite similar to each other and most commonly contain a single strong peak at *m/z* 86, formed by the $[(Et)_2NCH_2]^+$ ion. Among phosphorus-containing products, methylphosphonic acid (MPA) and its monoisobutyl and diisobutyl esters (iBuMPA and iBu_2MPA) are usually detected in certain quantities. These compounds are also present as admixtures in technical VR samples in varied amounts (from tenths of a percent to several percent). The P–S bond cleavage in VR forms diethylamino ethanethiol and iBuMPA. The latter slowly hydrolyzes to form MPA.

The most hazardous known VX hydrolysis products are persistent bis[2-(diisopropylamino)ethyl] disulfide, and highly toxic and persistent *S*-[2-(diisopropylamino) ethyl] methylphosphonothioate. The decomposition of VR gives rise to structural analogs of the above products: bis [2-(diethylamino)ethyl] disulfide and *S*-[2-(diethylamino) ethyl] methylphosphonothioate. Systematic data on the behavior of these products in the environment, as well as on their acute and chronic toxicity to humans and mammals and ecotoxicity, are lacking. Components of the complex mixture of VR decomposition products present as low-informative EI mass spectra; therefore, these compounds are barely possible to identify solely on the basis of mass spectral data. Chemical-ionization (CI) mass spectra are much more characteristic, but CI mass spectra—in view of their irreproducibility and lack of databases—are of limited use for identification. Like VX, VR does not possess a strong electron-acceptor center favoring decomposition but still is not a complete analog of VX in this respect. In dilute aqueous solutions, VR proved to be much more persistent: a half-life of 12.4 days as opposed to 4.8 days for VX (Crenshaw et al., 2001). The mechanism of the neutralization of VX and VR with an equimolar amount of water was first described by Yang et al. (1996). It was found that autocatalytic hydrolysis is possible exclusively in V-series nerve agents since it should involve the protonated amino group.

We performed experimental research on the stability assessment of VR and identification of its transformation products under the action of equimolar or excess amounts of water. The method for analysis was gas chromatography–electron ionization mass spectrometry (GC-EIMS). In a dilute aqueous solution (10 mg/mL) in the presence of 5% phosphoric acid, the concentration of VR after exposure for 20 days at room temperature without stirring was 2.7 mg/mL, or 27% of the initial amount. Since among VR hydrolysis products both volatile and nonvolatile compounds could be expected, we chose three schemes for sample preparation: (A) evaporation to dryness followed by silylation with bis-(trimethylsilyl)trifluoroacetamide (BSTFA); (B) organic solvent extraction; and (C) silylation of the extract obtained by procedure (B).

Table 9.1 lists the principal products of VR hydrolysis with excess water in an acid medium, along with specified

TABLE 9.1 Products of VR hydrolysis with excess water in an acid medium.

RT (min)	Compound	Formula	Fraction	Content in the reaction mixture[a] (%[b])
6.709	*N,N*-Diethylformamide	$HCONEt_2$	**B**[c]	1

analytical fractions with the highest content of each compound. Fractions A, B, C listed in Table 9.1 are in correspondence with A, B, C schemes for sample preparation. It should be noted that even after 100-day exposure, about of 1% of the initial amount of VR in the solution was detected, which implied a uniform hydrolytic degradation.

Experiments on VR hydrolysis with an equimolar amount of water were performed as follows. A mixture of 74 μL of VR and 5.6 μL of water was exposed at room temperature for 3.5 months without stirring. An ash-gray thick homogenous material formed after hydrolysis and completely dissolved in 5 mL of acetonitrile. The solution was diluted 100 times with acetonitrile and analyzed by GC-EIMS (scheme B). An aliquot of this sample was mixed with an equal volume of BSTFA, and the mixture was heated at 70°C for 30 min and then analyzed by GC-EIMS (scheme C). The autocatalytic hydrolysis of VR was almost complete by the end of the experiment, since the VR content in the sample was no more than 0.01%. Qualitatively, the reaction mixture in the latter case was much poorer than in the hydrolysis with excess water. Among the volatile hydrolysis products, the following were detected by GC-EIMS: 2-(diethylamino)ethanethiol (4%), diisobutyl methylphosphonate (2%), bis[2-(diethylamino)ethyl] sulfide (2%), VR (<0.01%), and bis[2-(diethylamino)ethyl] disulfide (80%). Of nonvolatile products in sample, MPA (3%) and isobutyl ester of MPA (isobutyl MPA) (96%) were identified as trimethylsilyl ester. Isobutyl MPA, which catalyzes VR degradation, was detected as the major component of the reaction mixture. As the second most abundant component we expected 2-(diethylamino)ethanethiol, according to Yang et al. (1996), but we found instead that it was almost completely converted into bis[2-(diethylamino)ethyl] disulfide. This result seems feasible since once the autocatalytic degradation of VR was complete, nothing would prevent thiol from being converted into disulfide. In a dilute aqueous solution of VR, this conversion occurs less rapidly, and even after 100 days the solution contains much less [2-(diethylamino)ethanethiol than bis(2-diethylamino)ethyl] disulfide.

The safe levels of VR content on surfaces of various types and in the waste of building materials were established during the period of the chemical weapon destruction (CWD) program and were 2×10^{-6} mg/dm^2 for surfaces and 5×10^{-5} mg/kg for waste, respectively. In order to monitor compliance with these standards, in addition to biochemical methods, more selective gas chromatography techniques have been developed. Under standard GC analysis conditions, a direct determination of VR with a detection limit that meets hygiene standards is not achieved. Therefore, the conversion of VR to fluorohydride on a tablet impregnated with silver fluoride is used, followed by thermal desorption of fluorohydride into a gas chromatograph from a sorption tube. This approach was taken as the basis for the development of all official Russian methods for determining VR in swabs of the surfaces and in-depth samples by GC with mass

spectrometric, thermionic, flame-photometric, and pulsed flame-photometric detectors. VR was extracted from solid matrices by treating the ground material with a mixture of solvents in a Soxhlet apparatus followed by re-extraction of VR into acidified water (pH 4). The aqueous sample was alkalinized to pH 9 with borate buffer solution and VR was extracted into dichloromethane, followed by concentration of the extract to the required volume. When developing official methods, we focused on the use of gas chromatographs, since there were no HPLC instruments at the CWD facilities. In research laboratories equipped with modern instrumental techniques, including HPLC-MS/MS, methods for the direct determination of VX and VR, which excludes the stage of conversion to fluorohydride, were developed. Bell et al. (2001) reported on the directions of fragmentation when VX and VR were directly introduced into the electrospray ionization ion trap mass spectrometry (ESI/ITMS). It was found that in the electrospray ionization mode, different directions of fragmentation are characteristic for VX and VR. The main direction of fragmentation of the VX precursor ion is the loss of C_4H_8 alkene. For VR, a priori also expected loss of alkene, but it turned out that the predominant direction is the loss of the phosphorus-containing fragment. The peculiarity of VR fragmentation is apparently explained by the higher acidity of the proton at the quaternary carbon atom of the isobutyl group of VR compared to the methyl proton of the ethyl group of VX.

To determine VR and the main products of its conversion, the HPLC-MS/MS method was developed, implemented on a Shimadzu LC-20AD instrument equipped with an autosampler and a Shimadzu LCMS-8050 mass selective detector with electrospray ionization at atmospheric pressure. Within the framework of the complex procedure, the VR and four products of its conversion were simultaneously determined: *S*-2-(diethylaminoethyl) methylphosphonothioate, bis (2-diethylaminoethyl) disulfide, as well as mono- and di-isobutyl methylphosphonates. Paraoxon was used as an internal standard, a solution of which in acetonitrile was applied to a tampon in the case of washing analysis or added to a weighed sample of crushed material in the case of analysis of solid samples. Model samples of materials contaminated with VR were prepared in the laboratory. The analytes were extracted from tampons or crushed solid samples with methanol. The components were separated on a Gemini-NX 3μ C18 110A (Phenomenex) column 150×2 mm $\times 3$ μm in the gradient mode. Characteristics of the substances to be determined are presented in Table 9.2.

Detection was carried out in the mode of selected reaction monitoring (SRM, MS/MS): registration of product ions formed during fragmentation of the precursor ion during positive or negative ionization was carried out in accordance with the parameters presented in Table 9.3.

Mass spectrometric detection conditions:

- Mass spectrometric detector: Shimadzu 8050;
- Flow rate of the gas dryer: 10 dm^3/min;
- Auxiliary gas flow rate: 10 dm^3/min;
- Flow rate on the sprayer: 3 dm^3/min;
- Interface temperature: 300°C;
- Temperature of the desolvation line: −250°C;
- Heater temperature: 400°C;
- Voltage on the capillary: 3500 V.

Optimization of the parameters was carried out so that the maximum sensitivity was achieved for VR. When implementing the technique, the detection limits of VR make it possible to monitor its content on surfaces and in deep samples with limits of determination of 3.3×10^{-7} mg/dm^2 for surfaces and 4×10^{-5} mg/kg for the crushed solid samples. VR and/or *S*-2-(diethylaminoethyl)methylphosphonothioate identification in the comtaminated samples should be confirmed by repeated analysis of the sample and reference samples using either high-resolution HPLC-MS/MS with an UltiMate 3000 liquid chromatograph (Thermo, USA) and mass Thermo Scientific Q-Exactive selective detector with electrospray ionization at atmospheric pressure, or similar equipment, in accordance with the parameters presented in Table 9.4.

High selectivity of the technique ensures its unified application in the analysis of the environmental objects with various matrix compositions. In the course of model experiments, it was found that various materials are capable of irreversibly retaining VR and its conversion products to varying degrees. Thus, only free (extractable) forms of these compounds can be analytically determined.

9.2.2 Biomonitoring of Russian VX

The following biomarkers are usually considered in the biomonitoring of VR and toxicokinetic studies:

- Inhibited AChE and BChE of red blood cells and blood plasma;
- Free (intact) VR;
- Isobutyl methylphosphonic acid, a product of hydrolysis of VR;
- *O*-isobutyl methylfluorophosphonate, the reactivated product from the adducts with blood proteins under the action of an excess of fluoride ions;
- Phosphorylated serum albumin.

VR adducts with cholinesterase are not susceptible to rapid aging and, therefore, can be reactivated for a sufficiently long time, both spontaneously and induced by the action of reactivators (Koryagina et al., 2014). On the other hand, VR adducts with albumin are not susceptible to both aging and reactivation, so they are the most reliable biomarkers confirming exposure to this substance. Recently, the successful determination of VR adducts with albumin in dry blood plasma spots has been

TABLE 9.2 Formulas and molecular weights of analytes in the monitoring of laboratory samples contaminated with VR.

demonstrated (Koryagina et al., 2018). Using the HPLC-MS/MS method, rapid and reliable determination of the VR hydrolytic metabolite, isobutylmethylphosphonic acid, was achieved (Koryagina et al., 2016). The same as with other nerve agents, abundant excretion of isobutylmethylphosphonic acid with urine occurs during the first 2 days after a single exposure to VR, but in the next 2−3 weeks, detection of this urinary metabolite is still possible in order to establish the fact of exposure. Isobutylmethylphosphonic acid is usually found in the blood and tissues when renal excretion is impaired or discontinued. In postmortem analysis, after exposure to lethal doses, this biomarker is found in almost all bio-fluids and tissues of laboratory animals. Recently, the kinetics of alkyl methylphosphonic acids in plant tissues has been investigated (Sarvin et al., 2019). Garden grass was grown using hydroponics with solutions of alkyl methylphosphonic acids, including isobutyl methylphosphonic acid, a VR marker. After replacing the solution of alkyl methylphosphonates with pure water, alkyl methyl phosphonic acids could be detected in the roots and leaves for at least 5 weeks. Such a high retrospectiveness of the analysis was ensured by the stability of alkyl methylphosphonic acids in biomatrices, as well as by the high sensitivity of HPLC-MS/MS determination. Detection and identification of biomarkers when exposed to nonlethal doses of VR for significant intervals after exposure (up to several weeks) are implemented on the basis of modern chromatographic spectral technologies. Tandem mass spectrometry and high-resolution mass spectrometry proved to be the most effective analytical methods (Savel'eva et al., 2014).

The direct highly sensitive determination of V-agents in biological samples by HPLC-MS/MS made it possible to study the toxicokinetics of not only biomarkers (metabolites) formed in the body when exposed to V-agents (Reiter et al., 2008). In a number of studies, the possibility of direct highly sensitive determination of intact VR in blood plasma was confirmed, the lifetime of which in the body was longer than in VX (Cuquel et al., 2015; Reiter et al., 2015). When studying the molecular and stereoselective aspects of VX and VR in in vitro experiments, it turned out that the enantiomer (−)VR has a cholinesterase inhibition constant that is four times higher than the constant for (−)VX. VR showed a more pronounced stereoselectivity compared to VX. The ability to reactivate acetylcholinesterase inhibited by racemates or pure (−) enantiomers was found to be comparable for both agents. The differences in the toxicodynamic profiles of VX and VR are apparently caused by steric factors, in particular by the presence of the isobutyl group in VR. The toxicokinetics of the intact agent was studied at the molecular level by subcutaneous administration of VR to pigs. In this case, special attention was paid to the absorption mechanism. For cutaneous application of VX and VR at doses of $3 \times LD_{50}$, first-order absorption constants were determined for all enantiomers VX and VR. Four hours after exposure, significant differences were found in the rates of elimination of VX and VR; elimination of the latter being much slower. Furthermore, spontaneous reactivation of VR-inhibited AChE was observed to be faster than in the case of VX.

The expansion of the authority of the OPCW (the Organization for the Prohibition of Chemical Weapons) and the endowment of its attributive function, initiated studies aimed not only at identifying toxic substances but also at establishing their origin by identifying precursors and impurities, in order to establish the source of the prohibited substance. The first studies in this area were devoted to the attribution of VR (Holmgren et al., 2018; Jansson et al., 2018; Williams et al., 2018). In the cited works, the possibility of attribution is based mostly on statistical studies, though an extensive experimental material was obtained using the most advanced analytical technologies.

9.3 Mechanisms of action and principles of therapy

Three types of damage induced by OPs have been identified: acute poisoning; the so-called intermediate syndrome (IS); and OP-induced delayed polyneuropathy (OPIDP) (Ray and Richards, 2001). The IS symptoms and signs usually occur after apparent recovery from the acute cholinergic syndrome, but before OPIDP develops (Karalliedde et al., 2006). OPIDP also occurs almost exclusively in patients with preceding acute cholinergic toxicity related to severe acute exposure to an OP compound; neuropathy target esterase (NTE) is considered to be the principal molecular target for OPIDP (Lotti and Moretto, 2005). However, there are no data to indicate that VX has any potential at high or low doses for the induction of OPIDP in its classic manifestation in humans or other species, either with acute or long-term exposure. The reason could be that the ability of VX to inhibit NTE is nearly 1000-fold less than that of GB (Vranken et al., 1982; Gordon et al., 1983). Single i.m. injections of VX at 5 LD_{50} in atropine-protected chickens produced neither inhibition of NTE nor histological or behavioral evidence of OPIDP (Wilson et al., 1988a). There was no ability of VX at subchronic exposure (0.04 mg/kg for 90−100 days) to induce OPIDN in antidote-protected chickens (Wilson et al., 1988b). According to other data, NTE activity in brain areas and soleus muscles of rats was significantly depressed after they were subacutely exposed to VX in the absence of supporting therapy for 14 days at doses at the LD_{50} level and higher, and surviving animals exhibited muscle myopathy in the soleus muscles (Lenz et al., 1996). Blood AChE activity was depressed to zero throughout the experiment, so there is no contradiction on the lack of clear OPIDP signs under severe intoxication with VX.

9.3.1 Acute intoxication with Russian VX

A contributing factor to the high toxicity of VX may be its preferential reaction with AChE. Moreover, unlike the G agents, VX depresses AChE activity significantly more than BChE in humans (Sidell and Groff, 1974); the result is that more VX is available to react specifically with the target enzyme, AChE. In addition, indirect primary (connected with AChE inhibition) and secondary (not connected with AChE inhibition) effects of VR have also been described. Development of after-intoxication immunodeficient or immunotoxic states relate to the first group of effects (Germanchuk and Zabrodskii, 2005). In experiments with rats that were administered VR at a dose of 0.75 LD_{50}, a suppression of immune reactions was found: Th-1 cells significantly lost their functions and T-dependent immune reactions were depressed. In addition, an optimal balance of cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) in lymphocytes necessary for their proliferation and differentiation was disturbed (Zabrodskii et al., 2007). On the other hand, after a severe intoxication of laboratory rats with VR (2 LD_{50} with therapeutic treatment), there were no after-effects concerning the capability of the central nervous system (CNS) to produce conditioned reflex reactions, neither in the early post-intoxication period (2 weeks) nor at remote terms (1−6 months) (Novikova et al., 2007). Four different effects of RVX were ascribed to the second group (Prozorovskii and Chepur, 2001): (1) sensitization and desensitization of cholinoceptors to acetyl choline that is characteristic of M-cholinoceptors; (2) influence on acetyl choline release by nerve terminals: an inhibition after stimulation of M-cholinoceptors and facilitation after stimulation of N-cholinoceptors; (3) direct interaction with cholinoceptors, mainly with nicotinic ones, leading either to their activation or inactivation; and (4) interaction with ionic channels, mainly with that of N-cholinoceptors.

Hypoxic syndrome is one of the principal clinical manifestations under acute intoxication with VR, as well as other V-agents. It is triggered by disturbance of ventilation, which in its turn is caused by bronchospasm, bronchorrhea, convulsions, and central deregulation of respiration. A series of pathological mechanisms leads to reduction of circulating blood volume, decrease of blood vessel tone, and deregulation of vessel wall permeability. Abnormalities of blood rheology, caused by the loss of body fluids (salivation, bronchorrhea, etc.), and aggregation of blood cells significantly increase the dynamic viscosity of blood and aggravate disturbances of microcirculation. Disturbances of oxygen transport and its delivery to tissues induce secondary metabolic disorders and involvement in a pathological process of related biological systems that facilitates oxygen utilization by the tissues (Shestova and Sizova, 2005). An imbalance of electrolytes has also been described: in blood plasma under acute intoxication there was a decrease in sodium and potassium, the latter being more expressed than the former (Rybalko et al., 2005). Indirect secondary effects of OP agents, including VR, can be induced by excessive amounts of ACh in blood, with its action on cells having no cholinergic innervations. This can lead to deformation of red blood cells and endothelial cells, activation of basophils, and degranulation of mast cells (Prozorovskii and Chepur, 2001). In this context, one should keep in mind that endothelial cells have all the attributes of autonomic cholinergic regulation. Not only *M*-cholinoceptors but also *N*-cholinoceptors have been revealed (Hsu et al., 2005), as well as activity of AChE (Carvalho et al., 2005; Santos et al., 2007), the system of synthesis of acetylcholine (cholinacetyl transferase), and vesicular system of ACh transport out of the cells (Kirkpatrick et al., 2003).

9.3.2 Delayed effects: chronic and subchronic intoxication with Russian VX

The difficulty of diagnosis of delayed effects and chronic intoxication with VR relates to polymorphism of the clinical manifestations (Savateev et al., 2001). Long-term monitoring of personnel staff engaged in production of VR revealed slowly progressing signs of chronic intoxication (Gur'eva et al., 1997). The clinical signs of this may consist of functional and organic disorders of the CNS together with vegetative dysregulations, such as peripheral angiodystonic syndrome, vegetosensory polyneuropathy, or complex motor-sensory-vegetative pathology of axonopathic or myelinopathic type. Neuromuscular effects, visual and gastrointestinal disorders, immunodeficiency, and metabolic disorders have also been described (Gur'eva et al., 1997; Yanno et al., 2000). Cessation of contact with VR does not lead to involution of the clinical picture of chronic intoxication. Along with nervous, gastrointestinal, and motor disorders, there can be visual and cardiovascular diseases. Moreover, the chronic occupational pathology of the former workers of the facilities may develop in 3–6 years, even though they were exposed to no more than 10 times the maximum allowable concentrations of RVX and had no acute intoxications in their anamneses (Filippov et al., 2005). Taking into consideration various and mostly indefinite clinical manifestations of delayed and chronic effects of VR, an experimental search was undertaken to seek new possible mechanisms of the pathogenesis and novel functional signs of intoxication. To model chronic intoxication in experiments with animals, VR was dissolved daily in drinking water to concentrations of 5×10^{-8}, 5×10^{-7}, and 5×10^{-6} g/100 mL. A group of five rats consumed 20 mL of VR aqueous solution daily. During the 3-month test, animals of the first group consumed daily VR with drinking water in a dose of 10^{-5} mg per 1 kg body weight (I), animals of the second group consumed a dose of 10^{-4} mg (II), and those of the third group consumed 10^{-3} mg (III). Measurement of AChE activity in red blood cells (RBC-AChE) was performed by Ellman's method, and the functional activity of platelets was investigated by a low-angle light-scattering technique that allows all stages of the platelet transformation to be assessed (Mindukshev et al., 2005). Investigation of monosynaptic myotatic reflex and conduction rate through the peripheral nerve fiber was conducted with *n. tibialis.* Comparative analysis of biochemical and physiological parameters studied is indicative of the complete absence of significant changes of RBC-AChE activity in rats of all three groups relative to the control, after exposure to the VR doses given above (not shown in this chapter). Conversely, platelets of test animals exposed to VR differed from the control by their pronounced instability, an indication of which was development of their spontaneous activation and aggregation (Fig. 9.2).

After 3 months of intoxication, two kinetic parameters of aggregation (namely: normalized maximal rate U_{max}; and effective concentration EC_{50}) were significantly increased in groups II and III. Two months after cessation of the chronic intoxication with VR (i.e., the rehabilitation period), significant differences of both kinetic parameters were found only for group III. Groups I and II showed significant increases of EC_{50}, but only a tendency ($P < .1$) to increase U_{max}. The final estimation of kinetic parameters of aggregation, made 6 months after rehabilitation, showed a significant decrease of U_{max} in group III and an increase of EC_{50} in all three intoxicated groups (Fig. 9.3). A significant increase of U_{max} suggests the sensitization of platelets with the primary activation of signaling ways via protein kinases, the action of which tends to increase the expression of GPIIb/IIIa receptors (Shattil et al., 1998). The increase of the EC_{50} parameter with further elevation of U_{max} points to a partial desensitization of $P2X_1$ and $P2Y_1$ receptors, as does the growing activity of the above-mentioned kinases.

Stimulation of the peripheral nerve trunk of intact animals leads to generation of muscle action potentials of three types. According to the duration of latent periods, they fall into the following order: (1) M-response (the result of the direct stimulation of α-motoneuron axons); (2) H-response (the monosynaptic response); and (3) polysynaptic responses with the variable latent period from 8–12 up to about 40 ms. In test animals of the III group, the changes of temporal parameters refer mainly to the latent period and duration of M-response (Table 9.5). Polysynaptic responses occur at all intensities of excitation and have a more pronounced character than in intact rats. A marked level and more distinct differentiation of the peaks of the complex action potential were noted.

The results obtained after examining the rats in group II differ from the control group more significantly. Along with normal action potentials (of the "spike" type), there were slow waves of depolarization of up to 30 ms duration. Another significant difference is the absence of the "subthreshold border"; that is, graduation of the increase of the amplitude of the action potential when the irritation stimulus enhances (Fig. 9.4). Such an event usually takes place in newborn animals and is caused by a slight differentiation of motor neurons (Bursian, 1983). The latent period of M-response, the rate of rising action potentials, and their duration increased significantly. The results of testing the rats of group I did not differ from the control. At the same time, some animals had the entire spectrum of pathologic reactions observed in rats of groups II and III: fasciculations, the presence of slow (local, depolarized) potentials, and paradoxical discharges. The opposite character of the changes in velocity of nerve impulse

conduction within groups II and III could be caused by different intensities of demyelinization of nerve fibers with different diameters.

9.3.3 Delayed effects: embryo- and gonadotoxicity, mutagenesis, and carcinogenesis

To study the embryotoxicity of VR, it was administered to pregnant female rats per orally at a dose of 1/100 LD_{50} (Kiryukhin et al., 2007). VR had a toxic effect in the females judged by a decrease in their RBC-AChE activity; at the same time, AChE activity in tissues of fetoplacental complex complied with age-specific control levels. These results may be regarded as evidence for impossibility (or at least low probability) of transplacental transfer of VR from the maternal organism to the fetus. However, manifestation of intoxication symptoms by pregnant rats indicates that VR can induce an embryotoxic effect, which is apparent from disorders of prenatal and postnatal ontogenesis (Tochilkina and Kiryukhin, 2007). It should be mentioned that embryotoxicity of VX to rat fetuses was also shown after single LD_{50} doses to the mother (Guittin, 1988), and after repeated doses of 0.005 mg/kg (near 1/5 LD_{50}) at varying times during fetal development (Guittin et al., 1987). On the other hand, no teratogenic potential of VX was found in sheep, rats, or rabbits (Van Kampen et al., 1970; Goldman et al., 1988).

Gonadotoxicity of VR was investigated in chronic experiments for different methods of introduction. Dermal exposure of male rats to VR demonstrated that general toxic effects were the governing factor of gonadotoxicity. There were no gonadotoxic effects at the level of threshold dose, which was estimated to be 4×10^{-6} mg/kg (Maslennikov and Kiryukhin, 2003). Other research has not revealed changes in the weight parameters of left and right testicles and epididymis, nor their total and specific weight parameters (Shabasheva et al., 2007). It has been concluded that VR poses no danger concerning the

TABLE 9.5 Electrophysiological parameters of the peripheral nervous system of rats after 3 months of VR chronic exposure.

development of specific disorders of male reproductive function, and this agrees with available data on VX: neither acute nor chronic VX exposure had deleterious effects on reproductive potential (Van Kampen et al., 1970). Studies of mutagenicity of VR in the Ames test revealed no point mutations in the indicative bacteria. However, studies conducted by a micronuclear test have demonstrated that a single intragastric introduction of VR at a dose of 1/10 LD_{50} stimulated in rats an enhancement of frequency of polychromatophilic erythrocytes with extranuclear inclusions. In cases where the cytotoxic effects were absent, these alterations could be interpreted as being of a mutagenic nature (Maslennikov and Ermilova, 2005). At the same time, the threshold dose of general toxic effect of VR had neither mutagenic nor embryotoxic nor gonadotoxic effects. Therefore, the delayed effects of VR can appear at doses exceeding those that induce general toxic effects, indicating the nonspecific character of its action. In the available literature, we could not find experimental data on the carcinogenicity of VR. Nevertheless, epidemiologic data on tumor and pretumor diseases of people that were engaged in production of VR did not reveal an increase in oncological morbidity compared to a control group of human subjects (Fedorchenko et al., 2003). In agreement with this, McNamara et al. (1973) reported that there was no association of increased cancer in personnel working daily with VX.

9.3.4 Principles of therapy

Acute toxicity of OPs in general and VR in particular has been much more extensively investigated than chronic toxicity, so it is not surprising that an effective therapy has been developed for acute intoxications only. The most effective antidote complex for treating acute VR intoxications consists of an antagonist of M-cholinoceptors, a reversible inhibitor of ChE, and a reactivator of ChE; in addition, anticonvulsants can be used in cases where convulsions occur. In experiments with guinea pigs, they were pretreated with pyridostigmine (0.026 mg/kg, i.m.), and then immediately after VR intoxication ($2 \times LD_{50}$) animals were given pralidoxime chloride (25 mg/kg, i.m.) and atropine sulfate (2, 8, or 16 mg/kg, i.m.); diazepam (5 mg/kg, i.m.) was administered to animals that displayed seizures and convulsions (Chang et al., 2002). It was also shown that in cases of acute intoxication with VR, higher doses of atropine should be administered compared to those for VX. Of several oximes (pralidoxime, obidoxime, and HI-6), the most effective was HI-6, as was the case for VX, sarin, cyclosarin, and soman poisonings (Kassa et al., 2006).

When developing therapies to treat chronic, low-dose VX intoxication, one should keep in mind that the VX-AChE complex has been found to undergo a significant degree of spontaneous reactivation in humans (at a rate of about 1%/h over the first 70 h after i.v. administration of VX). Another feature of VX toxicity is the lack of aging or stabilization of the VX-AChE complex and the relative ease of reactivation of VX-poisoned enzymes by oxime antidotes in humans (Sidell and Groff, 1974). Because there are no major differences in the reactivation process of VX- and VR-inhibited cholinesterase (Kuca et al., 2006), natural inactivation with plasma and liver paraoxonase (PON1) of VR, VX, and other warfare agents could play a greater role in prophylactic therapy of acute and chronic intoxications and their delayed effects (Costa et al., 2005).

9.4 Toxicometry and hygienic regulations

In countries dealing with destruction of CWAs, control limits for exposure via surface contact of drinking water are needed, as are detection methods for their low levels in water, soil, or foodstuffs. Some of the toxicity parameters of VR for humans and animals are available in the *Textbook of Instructive and Technical Documentation on*

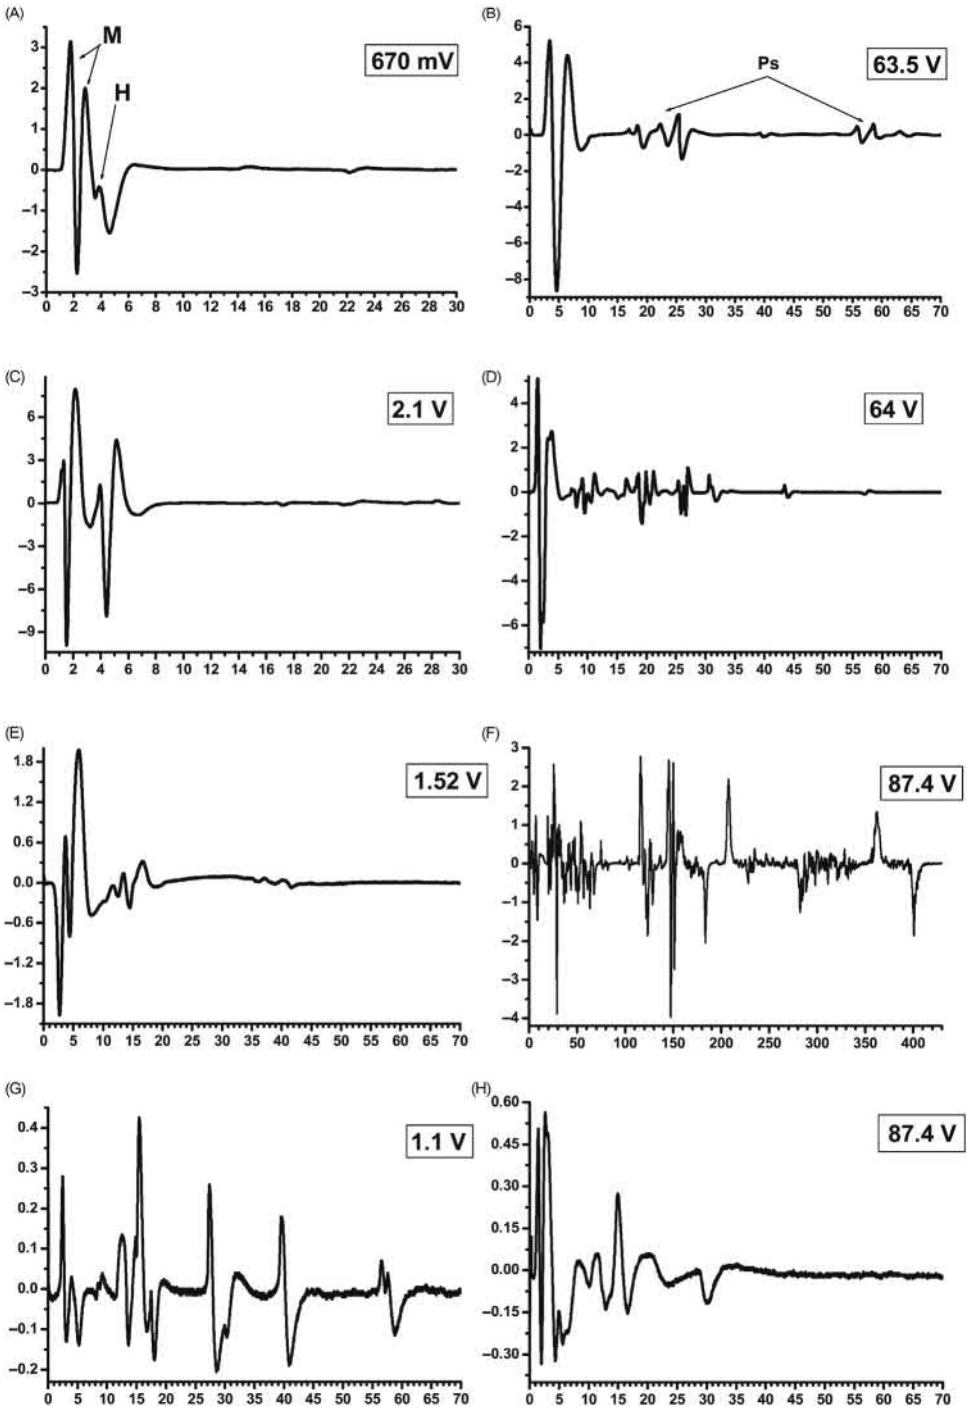

FIGURE 9.4 Action potentials of the rat gastrocnemius muscle under stimulation of *n. tibialis*: Effect of direct stimulation of the muscle (M-response, M), mono- (H-response, H), and polysynaptic (Ps) responses of control rats (A, B), rats of groups III (C, D), II (E, F), and I (G, H). Ciphers within frames indicate value of the stimulus. The *x*-axis shows the time of registration in ms; the *y*-axis shows the amplitude of action potential in mV.

the Problem of Chemical Weapon Destruction (Anon, 2001) and are given in Table 9.6.

In the event of possible contact of human skin with contaminated fabric of a protective suit, toxicometric parameters of VR have been experimentally estimated with laboratory rats (Zhukov et al., 2007): $LD_{50} = 0.55 \pm 0.09$ mg/kg, or 6.9×10^{-3} mg/cm^2; Lim ac (integr.) $= 0.056 \pm 0.001$ mg/kg, or 7.0×10^{-4} mg/cm^2; Lim ac (sp) $= 0.0051 \pm 0.001$ mg/kg, or 6.4×10^{-5} mg/cm^2; Lim ch $= 4.75 \times 10^{-5}$ mg/kg, or 5.9×10^{-7} mg/cm^2. The maximum concentration limit of VR for the fabric of protective suits has been estimated to be 3.1×10^{-8} mg/cm^2, taking into consideration the reserve coefficient, average body weight, and total area of the skin covered.

For the purposes of sanitary regulations, it has been estimated that VR within the range of concentrations

0.01–1.0 mg/L has no negative influence on the natural purification of aquatic reservoirs, on growth and decay of saprophytic and pathogenic microflora, and on nitrification processes. The noneffective dose of VR has been estimated to be 1×10^{-7} mg/kg, the threshold dose 1×10^{-6} mg/kg, and the effective dose 1×10^{-5} mg/kg (Maslennikov and Ermilova, 2006). Studies on VR effects on soil microflora have revealed that actinomyces and micromycetes proved to be the most vulnerable, whereas *Nitrobacteria* was the least vulnerable species (Gorbunova and Maximova, 2003). The hygienic regulations for VR are presented in Table 9.7.

9.5 Concluding remarks and future research

In this chapter, the principal products of VR hydrolysis with excess water in an acid medium have been presented. It has been shown that after 3 months of exposure, nearly 1% of the initial amount of VR in the solution could be detected. According to data on VR hydrolysis with an equimolar amount of water, the autocatalytic hydrolysis of VR was almost completed after 3 months since the VR content in the sample was no more than 0.01%. Moreover, the reaction mixture was much poorer than in the case of hydrolysis with excess water. Isobutyl MPA, which catalyzes VR degradation, was detected as the major component of the reaction mixture.

The extremely low recoveries of VR from materials of various natures can be explained by both irreversible sorption and degradation. A summarized list of compounds isolated from samples of building materials has been presented, which were taken from some areas of a former VR production facility and might have contacted VR. A brand-new approach is presented for the determination of VR and its conversion products in samples taken at former CWD facilities for possible reprofiling. The toxicological features of VR have not been fully clarified. On the one hand, pathogenesis of acute intoxication has been described, and toxicometric parameters and hygienic regulations have been developed. On the other hand, mechanisms of nonspecific effects, chronic intoxication, and the pathogenesis of delayed manifestations need further clarification. That is why there is a lack of effective prophylactic and therapeutic means of treating the delayed effects of VR. Our data support the existence of a key role for nonsynaptic mechanisms in developing effects under chronic exposure to VR. The morphofunctional changes at the level of the microcirculatory bed that influence the functional state of platelets may prove to be significant factors in the etiology of delayed effects of chronic intoxication. An adequate interpretation of the experimental data would lead to a proper understanding of the therapeutic approaches, which could prevent or even reverse the development of delayed effects of VR and other warfare OPs.

TABLE 9.6 Parameters of VR toxicity for animals and humans.

Parameter	Rout of exposure	Dose
LCt_{50} (human)	Inhalation	0.04 mg/min/dm^3
CL_{50} (mouse)	Inhalation	$1.8–4.5 \times 10^{-5}$ mg/kg
LCt_{50} (mouse)	Inhalation	0.011 mg/min/L
LD_{50} (rabbit)	Percutaneous	0.014 mg/kg
LD_{50} (cat)	Percutaneous	0.01 mg/kg
LD_{50} (dog)	Percutaneous	0.0157 mg/kg
LD_{50} (mice)	Percutaneous	0.016 mg/kg
LD_{50} (human)	Percutaneous	0.1–0.01 mg/kg

TABLE 9.7 VR safety standards in the Russian Federation (Uiba et al., 2007).

MAC for working air (mg/m^3)	5×10^{-6}
MAC for reservoir water (mg/dm^3)	2×10^{-6}
TSEL for ambient air (mg/m^3)	5×10^{-8}
MPL for equipment surface (mg/dm^2)	2×10^{-6}
MPL for human skin (mg/dm^2)	3×10^{-8}
MAC for soil (mg/kg)	5×10^{-5}
EEL for ambient air (mg/m^3)	
After 1 h	1.6×10^{-5}
After 4 h	4.1×10^{-6}
After 8 h	2.0×10^{-6}
After 24 h	6.6×10^{-7}

EEL, Emergency exposure limit; *MAC*, maximal allowable concentration; *MPL*, maximal permissible level of pollution; *TSEL*, tentative safety exposure level.

In conclusion, we outline some present and future areas of study on the analytical chemistry, biochemistry, and toxicology of VR:

- Improvement of the methodology of chemical and biochemical monitoring in environmental objects and human organisms;
- Development of prognostic modeling for probable risk assessment in case of elevation of the allowable levels of VR in various media;

- Studies on the quantitative relations dose−effect, time−effect, and dose−time−effect for cholinesterase and noncholinesterase effects, for both acute and chronic exposures to VR;
- Studies on novel molecular and functional effects under acute and chronic exposures to VR;
- Studies on mechanisms of development of delayed effects after intoxication with VR;
- Development of novel effective means for prophylaxis and treatment of delayed effects of intoxications with VR.

Fulfillment of these studies would surely contribute to fundamental and applied knowledge well beyond the toxicology of VR.

10.1 Historical overview

After World War I, the idea of chemical warfare gained a firm position in the military doctrines of all developed countries around the world, without exception. Great Britain and France started with the improvement of known chemical warfare agents (CWAs) as well as an increase in the number of production capacities. According to the Versailles Treaty, defeated Germany was forbidden from possessing CWAs. Finally, the United States, having the most powerful chemical military potential, surpassed Great Britain and France in the production of toxic agents (Halámek and Kobliha, 2011; Klement, 2011).

In 1934, German chemical and pharmaceutical conglomerate I.G. Farben initiated a project focusing on synthetic insecticides. Otto Bayer was behind this development and handed over this research branch to Gerhard Schräder (Nepovimova and Kuca, 2018). In 1936, Schräder turned his attention toward organophosphorus (OP) compounds. This group of compounds had been well known since the beginning of the 20th century. However, Schräder's research opened the way for targeted synthesis of these biologically active substances. One of the first recognized OP compounds with a systemic effect was ethyl dimethylphosphoramidocyanidate, more commonly known as tabun (GA; Trilon, 83), synthesized by Lang and Krüger on December 23, 1936 (Klement, 2011; Szinicz, 2005). The success with tabun led to the establishment of a factory in Dyhernfurth (today, Brzeg Dólny, Poland). Of 3000 employees of this factory, several hundred were injured and several dozen died as a result of their employment. From 1942 to 1945, this plant produced up to 30,000 tons of tabun, of which 12,000−15,000 tons were filled into ammunition (Klement, 2011). In 1939, Schräder and his team found an OP compound that was similar to tabun—propan-2-yl methylphosphonofluoridate (GB; Trilon 46). This compound got its name from that of the team itself, that is, it was called sarin after Schräder, Ambros, Ritter, and Van der Linde (Coleman, 2005). After 1935, any invention that could in any capacity be used by the military had to be reported to the German Ministry of War, as per an official decree. In 1937, sarin and tabun were both sent to the German Army Weapons Office (Wa Prüf 9), and all patent applications that were related to such compounds were declared secret (Szinicz, 2005). A code name Trilon was created to carefully guard these compounds. After sarin and tabun were discovered, next in line was sarin's pinacolyl analogue, soman (GD; 3,3-dimethylbutan-2-yl methylphosphonofluoridate), discovered by Richard Kuhn and Konrad Henkel in 1944 (Tucker, 2006). The name was allegedly chosen from a Greek word that translates into "to sleep" (Kloske and Witkiewicz, 2019). All three of the compounds in question are essentially nerve agents (NAs) that fall under the collective title of G-agents, where G is an abbreviation for German. This is because they were all found by German researchers (Gupta, 2015).

Despite the mass production of G-agents by the Nazis, NAs have rarely been used on a mass scale in chemical warfare (Halámek and Kobliha, 2011). Additionally, the factory in Dyhernfurth even complicated the Yalta Conference in February 1945. Winston Churchill in his writings about World War II described how one of the last points in their discussion in Yalta was the border between Poland and Germany. According to the preliminary agreement, the border should have led along the river Oder and its tributary Neisse. However, by looking at map, it can be seen that Neisse has two tributaries—the Eastern and the Western. President Roosevelt suggested choosing the Eastern one, whereas Premier Stalin insisted on the Western. This disagreement delayed the negotiations for almost a day. Finally, the factory in Dyhernfurth fell to the Russians. Almost immediately after the end of

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00010-6

WWII the factory was dismantled and all the reserves as well as the equipment were taken to the then Soviet Union and used for further development and production of toxic substances (Klement, 2011; Paxman and Harris, 2011; Pitschmann, 2014; Tucker, 2006).

As the Nazi regime was defeated, the Soviet and Allied forces—who were working together to defeat the Germans—took over NA production hubs. In addition, they also took over the research that the Germans had conducted on the subject. Thereafter, the Soviets as well as the Allies almost immediately started to develop and stockpile their own supplies of compounds (Wiener and Hoffman, 2004). In the 1950s, British chemist Ranajit Ghosh within his work on the development of novel organophosphorus (OP) pesticides, discovered a novel group of OP esters derived from thiocholine. Similar to G-agents, the existence of these compounds had to be reported to the British Chemical Warfare division due to their high toxicity and possible utilization by the military. The agent VX (*S*-{2-[di(propan-2-yl)amino]ethyl} *O*-ethyl methylphosphonothioate) has been labeled a promising agent within the set (Gupta, 2015; Szinicz, 2005). Within the military exchange program between the United States and the United Kingdom, the UK interchanged VX tech for thermonuclear weapons from the United States. Thereafter, large-scale synthesis of VX was launched in the 1960s in the United States (Tucker, 2006). At the same time, an isomer of VX—Russian VX (VR, RVX, substance 33, *S*-[2-(diethylamino)ethyl] *O*-(2-methylpropyl) methylphosphonothioate)—was created in the USSR. Later this compound became a prototype for A-agents. Another isomer of VX known as Chinese VX (CVX, *O*-butyl *S*-[2-(diethylamino)ethyl] methylphosphonothioate) was created and tested in a battery of experiments (Gupta, 2015). These are a class of NAs known as "V-agents." According to various sources, the *V* stands for "venomous," "victory," "virulent," or "viscous" (Gupta, 2015; Kloske and Witkiewicz, 2019).

During the Cold War, some long-term research programs were triggered in the USSR. Two of these, Fluorine and Phosphorus, were of particular interest in terms of not only the economy, but also in terms of the military sector. Special emphasis was placed on substances that had a significant biocidal impact (Halámek, 2008; Vásárhelyi and Földi, 2007).

At the same time, problems associated with the stability of Russian VX led to the start of a highly secretive program known as Foliant which ran from 1973 to 1976. The information acquired from the previous two programs was included in this new one. The idea behind it was to develop novel CWAs that would: (1) not be detectable through standard chemical detection tools being implemented by NATO member forces, (2) be able to penetrate the body of the enemy irrespective of what protective measures were in play, (3) be safer than previous iterations within the process of stockpiling, and (4) not be listed (also the precursors) in the Chemical Weapon Convention (CWC) (Vásárhelyi and Földi, 2007; Halámek, 2008; Halámek and Kobliha, 2011; Kloske and Witkiewicz, 2019). The endeavor associated with this program gave birth to a minimum of three unitary pieces of chemical weaponry, A-234, A-232, and A-230 (Fig. 10.1). Officially, the structures of the agents in questions have never found their way into scientific literature. Within the last couple of years, the data on these agents show that they are created from dihaloformaldoxime. The presumption is rooted in the scientific contributions of Soviet chemists that were likely a part of Foliant (Martynov et al., 1969; Petrov et al., 1967; Razumova et al., 1968; Kruglyak et al., 1972a,b; Malekin et al., 1972). It is interesting to note that a few decades before the discovery of A-agents the first acetylcholinesterase (AChE, E. C. 3.1.1.7) reactivators bearing an oxime functional group were published (Hobbiger, 1957). Later, however, it was disclosed that phosphorylated/phosphonylated oximes are formed as side products immediately after the reactivation process. These substances, instead of decreasing the toxic effect of OPs towards AChE activity strongly, inhibit the enzyme (Andersen, 1978; Fossier et al., 1983).

According to available data, "the A-agents faced the same issue as Russian VX," that is, low stability in the environment (Karev, 2009). To address this particular drawback, a binary form of A-agents was developed, passing the requirement of stability of their precursors. Finally, at least five precursors were developed under the code name Novichok (Karev, 2009). According to S.L. Hönig, the crucial moiety of Novichoks is 2-fluoro-1,3,2-dioxophospholane (Fig. 10.2) (Hoenig, 2007). The first mention of Novichoks appeared after the closing of the Foliant program (Petrov et al., 1967; Razumova et al., 1968; Martynov et al., 1969; Kruglyak et al., 1972a,b; Malekin et al., 1972; Mirzayanov, 2009).

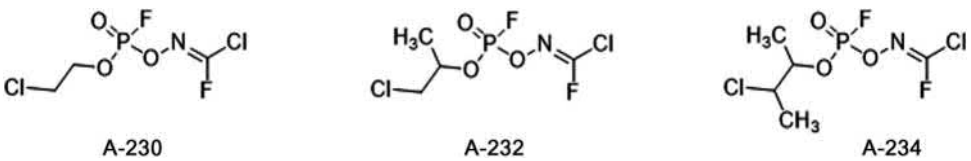

FIGURE 10.1 Possible chemical structures of A-agents (Nepovimova and Kuca, 2018).

In September 1992, a newspaper article revealing the existence of Novichoks was published on the eve of the ratification of the Chemical Weapon Convention by Russia (Mirzayanov, 1992). Vil Mirzayanov, an analytic chemist connected to the State Research Institute of Organic Chemistry and Technology authored the article. After the article was published, Vil Mirzayanov was arrested. However, due to an enormous public outcry, he was released after a couple of months. He then exiled himself to the United States (Halámek, 2008; Karev, 2009). Today, the data on the agents in question, alongside Novichoks, is still shrouded in mystery. The only available data come from the interviews and articles of Mirzayanov, Uglev, Zheleznyakov, and Fyodorov (Karev, 2009). The end of the Novichok program was probably associated with the ratification of CWC by the Russian Federation (Table 10.1) (Halámek, 2008).

10.2 Synthesis

The synthesis of compounds leading to the production of A-agents consists of three steps (Fig. 10.3) (Ellison, 2016; Halámek and Kobliha, 2011). The first two reactions of phosphorus trichloride with an appropriate diol and the subsequent nucleophilic substitution of a chlorine atom by fluorine should by all accounts lead to synthesis of the precursors to A-agents, known as Novichoks (Novichok ?, Novichok 5, Novichok 7). Finally, 2-fluoro-1,3,2-dioxaphospholanes react with dichloro(fluoro)nitrosomethane, a compound structurally resembling the choking agent, chloropicrin. According to S.L. Hoenig, the stability of formed products is temperature-dependent. At low temperature (−40°C), they are stable but when the temperature rises the nucleophilic attack by the chloride anion is facilitated, resulting in a phospholane ring opening (Hoenig, 2007; Halámek and Kobliha, 2011).

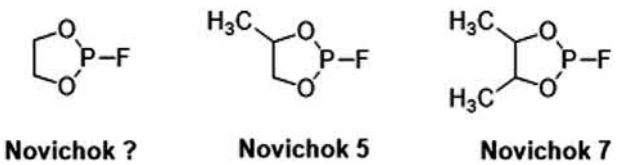

FIGURE 10.2 Plausible chemical structures of A-agent precursors—Novichoks (Nepovimova and Kuca, 2018).

From these data, the following findings are observed:

1. Although A-agents resemble fluorophosphates, they lack a C−P bond. Compounds without a C−P bond are out of CWC's scope.
2. The secondary alkoxy side chains, not methyl, ethyl, propyl, or isopropyl, are also outside the CWC scope.
3. CWC makes no mention of compounds with P−O−N linkage.
4. The precursor fluorodichloronitrosomethane does *not* fall under the regulation of CWC, even though its derivative chloropicrin does (Nepovimova and Kuca, 2018; "Organization for the Prohibition of Chemical Weapons," n.d.).

10.3 Physicochemical properties

Due to the scarcity of information and data pertaining to the physicochemical properties of A-agents and Novichoks, this section is presented in table form (Table 10.2) (Hoenig, 2007; Karev, 2009; Mirzayanov, 2009; Halámek and Kobliha, 2011; Pitschmann, 2014).

Considering the high volatility and low persistency of G-agents, as well as the low volatility and high persistency of V-agents, chemists from the military—who focused on third-generation NAs—looked at synthesizing compounds with properties that had a balance of the physical and chemical elements at play. This included aspects such as the density, volatility, and also stability in terms of moisture and light. As per the data outlined above, one can suppose that several drawbacks

characteristic of the first two generations of NAs were removed.

10.4 Mechanism of action

The mechanism of action of A-agents is irreversible inhibition of AChE (Hoenig, 2007). Once the A-agent reaches the bottom of the active site gorge, the nucleophilic attack of the phosphorus atom by the hydroxyl group of serine occurs (Mercey et al., 2012). This reaction is accompanied by a simultaneous cession of the fluoride ion and formation of phosphorylated enzyme (Fig. 10.4). The covalent bond shared by the phosphorus atom and serine constitutes a catalytic site of AChE, and substantially slows down spontaneous hydrolysis, varying from hours to days (Mercey et al., 2012).

Rapid hydrolysis of the $=N-O-$ bond within the A-agent–AChE complex may result in an aged form of

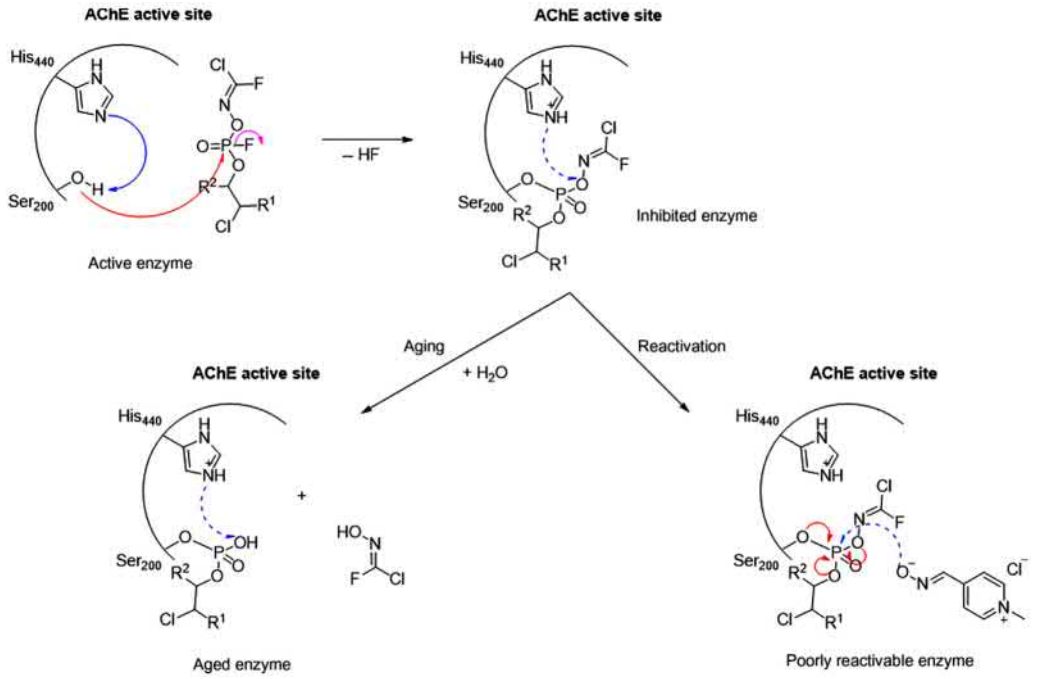

FIGURE 10.4 Mechanism of AChE inhibition by A-agents, aging, and reactivation by oximes (Nepovimova and Kuca, 2018).

TABLE 10.3 Toxicological parameters of G-, V-, and A-agents.

A-232	6–10	1–2
A-234	7	5

AChE where the phosphonic oxyanion forms a salt bridge with the protonated histidine that strongly stabilizes the conjugate (Fig. 10.4). Aged enzyme is permanently inactivated and no reactivator can restore its function (Mercey et al., 2012; Sharma et al., 2015). According to the available data, the aging half-time of A-230 and soman are relatively similar (2–4 min) (Worek et al., 2004; Karev, 2009).

Reactivation of inhibited AChE by A-agents appears to be relatively difficult. This is true not just due to rapid aging, but also because of the phosphorus atom's debilitated partial positive charge, which is attacked by the oximate of the available reactivators (Fig. 10.4). Thus, the only effective treatment approaches seem to be symptomatic therapy (combination of an anticholinergic drug and an anticonvulsant) or administration of so-called bioscavengers, such as butyrylcholinesterase (BChE, E. C. 3.1.1.8). Such exogenous enzymes would detoxify A-agents entering the patient's circulation. Thereafter, toxic substances would not reach AChE and evoke clinical signs of intoxication (Bajgar et al., 2009). Generally, bioscavengers are considered a prophylactic approach. However, in the case of A-agents poisoning when causal therapy is ineffective, they can be used ex post. Additionally, bioscavengers should be able to detoxify all types of NAs, thus representing a universal approach.

10.5 Toxicity

Available sources claim that A-agents display a higher or the same level of toxicity as VX. Exact toxicological

parameters of A-agents, as well as of representatives of G- and V-agents, are summarized in Table 10.3.

If the victim survives the acute phase of intoxication by the A-agent, the delayed neurotoxicity marked by serious nerve system disruption manifesting as paralysis, taking place at 1−3 weeks subsequent to intoxication, could occur (Gupta, 2015). One of the scientists working on A-agents development, Andrey Zheleznyakov, suffered exposure to A232. He experienced multiple health issues including epilepsy, cirrhosis, and trigeminal neuritis and died 5 years after his exposure (Karev, 2009).

10.6 Concluding remarks and future directions

Although many years have passed since the disclosure of the Novichok program, exact reliable data do not exist. If even a small part of the information holds true, it is imperative that the risk that such lethal weapons holds be acknowledged. It is important to strengthen global verifications and regulations. The priority should be inclusion of A-agents, alongside their precursors, to the CWC. After this, a small amount of the agents should be synthesized to discern how efficient a possible antidote could be to deter its side effects and/or to create impactful detection strategies.

Chapter 11

Blister agents

Robert A. Young[1] and Cheryl B. Bast[2]

[1]Senior Research Staff (Retired), Environmental Sciences Division, Oak Ridge National Laboratory, Oak Ridge, TN, United States, [2]Keller and Heckman LLP, Washington, D.C, United States

11.1 Introduction

As their name implies, blister agents (also referred to as vesicants) cause blistering lesions in the skin (Anslow et al., 1947; Graef et al., 1948). The respiratory tract and eyes, however, are more sensitive targets of toxicity. Respiratory tract effects are the primary cause of acute lethality. The mode of action of blister agents is complex and continues to be a focal point for research. These cytotoxic alkylating agents were initially developed as chemical weapons used to induce ocular, dermal, and respiratory damage that results in immediate casualties, reduction in fighting efficiency, and demoralization. Depending on the exposure, injury may be local or systemic. This chapter focuses on sulfur mustards, nitrogen mustards, and lewisite. Although occasionally classified as a vesicant due to its action as a skin, eye, and respiratory tract irritant, phosgene oxime (CX) is more appropriately considered a urticant, or nettle agent, and is not discussed here. Extensive information regarding the chemistry and toxicology of vesicants is available in several publications (Papirmeister et al., 1991; Somani, 1992; USACHPPM, 1996; ATSDR, 2003; Romano et al., 2008). In response to a request by the US Department of Veterans Affairs (VA), a panel of experts extensively reviewed and evaluated the medical and scientific literature on mustard agents and lewisite, as well as the military testing programs relative to these agents (IOM, 1993).

Although generally associated with World War I, the Organization for the Prohibition of Chemical Weapons (OPCW) documented the use of sulfur mustard in Umm Hawsh, Syria, in 2016 (UNSC, 2017). Blister agents were also deployed by Iraq against Iranian forces and Kurdish citizens of Iraq during the Iran−Iraq war in the 1980s (Haines and Fox, 2014).

The term *sulfur mustard* may refer to distilled mustard [bis(2-chloroethyl)sulfide; HD, sesqui mustard (SM)], Levenstein mustard (H), agent HT [a mixture of HD and bis (2-chloroethylthioethyl)ether], or a sulfur mustard−lewisite mixture (HL). Distilled mustard (HD) is relatively pure (97%) bis(2-chloroethyl)sulfide and results from the vacuum distillation of HD. Generic references to sulfur mustard usually mean HD. Levenstein mustard (H) is a mixture of HD and sulfur impurities (generally in a 70:30 ratio), and, as its name implies, it was produced by the Levenstein process, which involves reacting ethylene with sulfur chloride. Agent H may contain sulfur impurities imparting a yellowish color and sweet, garlic-like odor.

Agent HT is generally a mixture of 60% HD and 40% bis(2-chloroethylthioethyl)ether (T), although this ratio may vary. Agent HL is a mixture of sulfur mustard (HD) and lewisite (L) that was developed for cold weather or high-altitude use due to its lower freezing point. SM is 1,2-bis(2-chloroethylthio) ethane and is considered a more potent vesicant than HD, but its very low vapor pressure limits its effectiveness as a warfare agent. This condition is remedied by combining it with HD to form agent HQ. The removal of one chlorine from sulfur mustard results in "half-mustard" (2-chloroethyl ethyl sulfide, or CEES), a monofunctional sulfur mustard analog. Although retaining some alkylating properties, half-mustard is not as highly regulated as sulfur mustard and is frequently used in sulfur mustard research. Most of the discussion of sulfur mustards in this chapter will be about distilled sulfur mustard (HD).

Nitrogen mustards include HN1 [bis(2-chloroethyl) ethylamine], HN2 (2,2′-dichloro-*N*-methyldiethylamine), and HN3 [tris(2-chloroethyl)amine hydrochloride]. As will be discussed later in this chapter, some of these were used in therapeutic arenas rather than in warfare.

Lewisite [L or L-1; dichloro(2-chlorovinyl) arsine] is an arsenical vesicant developed early in the 20th century. Lewisite occurs as *cis*- and *trans*-isomers, the typical ratio

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00011-8

being 10:90. Several impurities, including bis(2-chlorovinyl)chloroarsine (L-2) and tris(2-chlorovinyl)arsine (L-3), are typically present. The chemical and physical properties of *cis*- and *trans*-isomers are similar.

11.1.1 Sulfur mustards

Sulfur mustards are capable of causing severe skin and eye damage at very low concentrations. Table 11.1 shows the chemical name, synonyms, identification codes, chemical formula, and structural formula for sulfur mustard.

Although frequently referred to as "mustard gas," the chemical is a liquid at normal ambient temperatures. Due to its oily consistency and low aqueous solubility, sulfur mustard is persistent in the environment. Information on the half-life of HD in air is unavailable. As previously noted, impurities may impart a garlic-like odor to sulfur mustard. Odor thresholds ranging from 0.15 to 0.6 mg/m^3 have been reported for sulfur mustard (Dudley and Wells, 1938; Bowden, 1943; Fuhr and Krakow, 1945; Ruth, 1986).

Watson and Griffin (1992) have summarized information on the distribution of unitary chemical weapon stockpiles in the United States. The chemical and physical properties of sulfur mustard (agent HD) are shown in Table 11.2.

The water solubility of sulfur mustard has been reported as 0.092 g/100 g water at 22°C (DA, 1974), and 5×10^{-3} M at room temperature (MacNaughton and Brewer, 1994). In dilute aqueous solutions, sulfur mustard hydrolyzes almost completely to thiodiglycol and hydrochloric acid (Papirmeister et al., 1991). For dissolved HD, the hydrolysis half-life ranges from about 4 to 15 min for temperatures of 20°C–25°C. Bulk HD may persist in water for up to several years (Small, 1984). It has been estimated that it takes 15 days for the mass of a 1-cm droplet of HD in quiescent water to decrease by half (Small, 1984). The Henry's law constant for HD has been estimated to be 2.1×10^{-5} atm m^3/mol (MacNaughton and Brewer, 1994), indicating a moderate potential for evaporation from water.

The persistence of sulfur mustard in soil depends on the soil type, pH, moisture content, and whether the agent is at the soil surface or buried. Small (1984) reported that HD applied to the soil surface volatilized and would likely be the main route of HD loss (with a half-life of about 30 min). In wet soil, however, hydrolysis would be the primary loss pathway. When sprayed onto soil, a vesicant action may persist for about 2 weeks, but when the agent continually leaks into the soil, vesicant action may be present after 3 years (DA, 1974). Rosenblatt et al. (1995) state that the persistence of sulfur mustard in soil is due to the formation of oligomeric degradation products that coat the surface of the mustard agent and that are resistant to hydrolysis. This may greatly enhance the environmental persistence of sulfur mustard. Sulfur mustard has a log K_{ow} of 1.37 and a K_{oc} of 133, indicating that binding to soil organics would limit transport through soil to groundwater (MacNaughton and Brewer, 1994). MacNaughton and Brewer (1994) also calculated a leaching index of 7.2 for HD (i.e., the number of leachings required to reduce the HD soil concentration to one-tenth of the original amount, assuming that for each leaching, 1 kg of soil is in equilibrium with 1 L of water).

11.1.2 Nitrogen mustards

Nitrogen mustards are tertiary bis(2-chloroethyl)amines with vesicant activity (NDRC, 1946). Tables 11.3 and 11.4 summarize the nomenclature and chemical and physical properties of HN1, HN2, and HN3. Due to their toxicity and various physical–chemical properties, initial interest in these chemicals as warfare agents developed shortly before and during World War II. Although HN2 and HN3 were specifically developed as military agents, HN1 was originally developed as a pharmaceutical. HN2 (mechlorethamine) later found use as an antineoplastic agent. Nitrogen mustards and derivatives such as melphalan, chlorambucil, and cyclophosphamide are alkylating agents used as cancer therapeutic agents (Somani, 1992).

11.1.3 Lewisite

Lewisite is composed of *cis*- and *trans*-isomers in the ratio of 10:90 and several impurities including bis(2-chlorovinyl)chloroarsine (L-2) and tris(2-chlorovinyl) arsine (L-3) (Rosenblatt et al., 1975). The chemical and physical properties of the *cis*- and *trans*-isomers are similar. The nomenclature and chemical and physical properties of L-1, L-2, and L-3 are presented in Tables 11.5 and 11.6, respectively. In pure form, lewisite is colorless and odorless, but it usually occurs as a brown oily liquid with a distinct geranium-like odor. Gates et al. (1946) reported an odor threshold of 14–23 mg/m^3 for lewisite.

Information regarding the atmospheric transformation of lewisite is limited. MacNaughton and Brewer (1994) reported that some photodegradation may take place and that hydrolysis may also occur in the gas phase. Lewisite is only sparingly soluble in water; 0.5 g/L (Rosenblatt et al., 1975). Hydrolysis of lewisite results in the formation of lewisite oxide and HCl, and this may occur rapidly. The hydrolysis of lewisite is complex and includes several reversible reactions (Epstein, 1956; Rosenblatt et al., 1975; Clark, 1989; MacNaughton and Brewer, 1994). Under slightly acidic conditions, lewisite initially undergoes rapid and reversible conversion to dihydroxy arsine, 2-chlorovinyl arsine oxide, and two equivalents of hydrogen chloride:

$$Cl-CH=CH-AsCl_2 + 2H_2O \rightarrow Cl-CH=CH-AsCl_2 + 2HCl$$

The production of two equivalents of chloride occurs within 3 min at 20°C; at 5°C, the reaction is 90% complete within 2 min, and completion of the reaction requires several hours. The hydrolysis rate constant is reported as 1 min^{-1} at 20°C. Hydrolysis of 2-chlorovinyl arsine oxide is slower, resulting in lewisite oxide (chlorovinyl arsenous oxide) and polymerized lewisite oxide:

$$Cl-CH=CH-As(OH)_2 + H_2O \rightarrow Cl-CH=CH-AsO + (Cl-CH=CH-AsO)_n$$

The forward reaction is favored because lewisite oxide and polymerized lewisite oxide are insoluble. In a basic

TABLE 11.5 Nomenclature, chemical formulae, and chemical structures of lewisite.

Lewisite (L)	
Synonyms	2-Chlorovinyldichloroarsine; (2-chlorovinyl)arsenous dichloride; beta-chlorovinyldichloroarsine; dichloro(2-chlorovinyl) arsine; chlorovinylarsine dichloride; EA 1034
CAS No.	541-25-3
Chemical formula	$ClCH{=}CHAsCl_2$
Chemical structure	L-2	
Synonym	Lewisite-2
CAS No.	40334-69-8
Chemical formula	$(ClCH{=}CH)_2AsCl$
Chemical structure	L-3	
Synonym	Lewisite-3
CAS No.	40334-70-1
Chemical formula	$(ClCH{=}CH)_3As$
Chemical structure	
TABLE 11.6 Physical and chemical properties of lewisite.

	Value	References
Lewisite		
Physical state	Oily, amber brown liquid	Lindberg et al. (1997)
Molecular weight	170.08	USACHPPM (1996)
Boiling point	190°C	Trammell (1992)
Freezing point	−18°C; varies depending on purity	Watson and Griffin (1992)
Vapor pressure (mmHg)	0.34 mmHg at 25°C; 0.22 mmHg at 20°C	USACHPPM (1996)
Water solubility (g/L)	0.5 g/L in water; soluble in most organic solvents	USACHPPM (1996)

solution, the *trans*-lewisite isomer is cleaved by the hydroxyl ion to give acetylene and sodium arsenite; this reaction may occur even at low temperatures (Rosenblatt et al., 1975; Clark, 1989). *Cis*-lewisite heated to over 40°C reacts with sodium hydroxide to yield vinyl chloride, sodium arsenite, and acetylene (Rosenblatt et al., 1975). In aqueous solution, the *cis*-isomer undergoes a photoconversion to the *trans*-isomer (Rosenblatt et al., 1975). Epstein (1956) reported that the toxic trivalent arsenic of lewisite oxide in standing water is converted to the less toxic pentavalent arsenic.

Lewisite in soil may rapidly volatilize or may be converted to lewisite oxide due to moisture in the soil (Rosenblatt et al., 1975). The low water solubility suggests intermediate persistence in moist soil (Watson and Griffin, 1992). Both lewisite and lewisite oxide may be slowly oxidized to 2-chlorovinylarsonic acid (Rosenblatt et al., 1975). Possible pathways of microbial degradation in soil include epoxidation of the C═C bond and reductive dehalogenation and dehydrohalogenation (Morrill et al., 1985). Due to the epoxy bond and arsine group, toxic metabolites may result. Additionally, residual hydrolysis may result in arsenic compounds. Lewisite is not likely to bioaccumulate. However, the arsenic degradation products may bioaccumulate (Rosenblatt et al., 1975).

11.2 History and background

11.2.1 Sulfur mustards

Sulfur mustard was synthesized and its biological activities first characterized in the 1800s (Guthrie, 1860; Niemann, 1860; Despretz, 1992). By the early 1900s, its synthesis was further refined and its use as a warfare agent had been established when used as Levenstein mustard during World War I. More recent use occurred during conflicts in the Middle East. Its oily nature makes it persistent on surfaces it makes contact with. Because sulfur mustard exerts toxic effects following dermal, ocular, and inhalation exposure, its use necessitated full body protection which, in turn, required the development of protective clothing and significant changes in warfare operations.

Minute quantities of sulfur mustard are used by various military and contract laboratories for defense research purposes, and for verification of Chemical Weapons Convention compliance. Bulk quantities of sulfur mustard are no longer manufactured in the United States. Military stockpiles of sulfur mustard are awaiting destruction or are in the process of being destroyed. Some sulfur mustard may also be found buried or abandoned at former defense sites. Sulfur mustard was frequently loaded into artillery shells and aerial bombs (often with lewisite). Various quantities of sulfur mustard also exist in other countries. Large amounts of sulfur mustard have been disposed of at sea.

Outside of military conflicts, exposure to sulfur mustard has occurred or may occur in work environments that involve chemical weapon materials (e.g., storage depots, demilitarization facilities, and research laboratories), during emergency response operations or remediation and decontamination activities, or during treaty verification activities in support of the Chemical Weapons Convention. Chemical weapons such as vesicants are still considered potential military threats and terrorist targets. The most likely route of exposure to sulfur mustard is via aerosol/vapor exposure of the skin, eyes, and respiratory tract.

11.2.2 Nitrogen mustards

Due to the toxicity and various physical−chemical properties of nitrogen mustards (which are structurally similar to sulfur mustard), initial interest in these chemicals as warfare agents began shortly before and during World War II. Like sulfur mustard, all are alkylating agents. This chapter only discusses the nitrogen mustards referred

to as HN1, HN2, and HN3; selected chemical and physical properties of these substances are summarized in Tables 11.3 and 11.4. Although HN2 and HN3 were initially investigated as military agents, HN1 was originally developed as a pharmaceutical. HN2 (mechlorethamine) later found application as a pharmaceutical. Nitrogen mustards and derivatives such as melphalan, chlorambucil, and cyclophosphamide are alkylating agents used as cancer therapeutic agents (Somani, 1992). HN1 and HN3 are among the chemical agents found in Chemical Agent Identification Sets (CAIS), which are considered a component of nonstockpiled material. Generally, nitrogen mustards have not had the interest or high profile that sulfur mustard and lewisite have.

11.2.3 Lewisite

Lewisite, an organoarsenic compound, was developed in an attempt to create a more effective blister agent than sulfur mustard. Its development is generally credited to Winford Lewis at the Catholic University, Washington, DC, and is based upon a thesis by Julius Nieuwland, who described the synthesis of lewisite from arsenic trichloride, acetylene, hydrochloric acid, and mercuric chloride. Early on, the compound was frequently referred to by the vividly descriptive term "Dew of Death." Like sulfur mustard, it is both a vesicant and a systemic poison with target tissues not limited to the skin. In an attempt to develop an antidote to lewisite, British anti-lewisite (BAL), also known as dimercaprol, was developed (Peters et al., 1945), which later became invaluable in the treatment of arsenic poisoning. Late in World War I and into World War II, large quantities of lewisite were manufactured by Germany, the United States, Italy, the Soviet Union, and Japan (reviewed by Trammell, 1992). Large amounts of lewisite were manufactured (up to 2 tons/day by Japan) and stored prior to and during World War II (Tanaka, 1988; Trammell, 1992). Lewisite was frequently a component (often mixed with sulfur mustard) of artillery shells and aerial bombs (often mixed with sulfur mustard). Like sulfur mustard, there are reports of large amounts of the compound being disposed of at sea (Spiers, 1968). With the possible exception of its use against Iranian soldiers during the Iran–Iraq conflict (Perera, 1985), there has been little or no use of lewisite in battle. Goldman and Dacre (1989) have reviewed the chemistry and toxicology of lewisite.

11.3 Toxicokinetics

11.3.1 Sulfur mustards

Due to its lipophilicity, toxicologically relevant amounts of sulfur mustard are absorbed in epithelial tissue (Papirmeister et al., 1991). Dermal absorption depends on the thickness of the epidermis and on the presence of moisture, which enhances penetration. Absorption tends to be greater at the base of hair shafts and in the hair follicle, where the epithelial tissue is thinner than the surrounding surface area (Papirmeister et al., 1991). Approximately 20% of sulfur mustard applied to skin may be rapidly absorbed, while 12%–50% of this may react and remain at the application site (Somani and Babu, 1989). About 12% of the absorbed material remains at the contact site; the rest enters the circulation (Renshaw, 1947). Renshaw (1947) noted that the rate of penetration is 1–4 $\mu g/cm^2$/min at 75°F.

For dermal exposure, penetration rates over 2–8 h ranged from 2.9% to 6.7% and rates of absorption ranged from 1.2% to 4.0% following application of 400 μg of radiolabeled sulfur mustard per cm^2 of isolated perfused porcine skin (Riviere et al., 1995). The average total recovery of the radiolabel was 9.3% (3.8%–17.7%), suggesting substantial loss due to volatilization.

Contrary to dermal absorption, little is known about absorption in the respiratory tract. Cameron et al. (1946) calculated the absorption of sulfur mustard vapor in the noses of rabbits and rhesus monkeys. The concentration of the agent in the nasal passages was 10%–30% of the chamber concentrations (40, 100, and 500 mg/m^3), implying an absorption of approximately 70%–90%.

Several studies using radiolabeled sulfur mustard have shown that sulfur mustard and its metabolites may be widely distributed in the body after percutaneous or intravenous exposure. Maximum levels of radioactivity were detected in the kidneys, lungs, and livers of rabbits following intravenous administration (Boursnell et al., 1946). At 15 min following percutaneous exposure of rats, sulfur mustard-derived radioactivity was found in all examined tissues except the eyes (Young et al., 1944). Similarly, Clemedson et al. (1963) noted uniform distribution of radioactivity in mice after either percutaneous or intravenous exposures, with most radioactivity occurring in the nasal region, kidneys, liver, and intestine. Hambrook et al. (1993) reported on the uptake and distribution of radiolabeled sulfur mustard in the skin and blood of rats after cutaneous application. It was found that much of the agent entering the blood binds to hemoglobin and, to some extent, with glutathione (GSH). Results of studies with rabbits showed that sulfur mustard was concentrated in the cornea and, to a lesser extent, in the iris, lens, and conjunctiva within 5 min after application (Axelrod and Hamilton, 1947).

The biotransformation of sulfur mustard after intravenous or intraperitoneal injection of radiolabeled compound in rats has been examined. Following intravenous injection, the major urinary metabolite was GSH-bis-chloroethyl sulfide conjugates (45% of total urinary radioactivity) and smaller amounts of sulfone conjugates (7%)

and thiodiglycol and its conjugates (14.4%) (Davison et al., 1961). Roberts and Warwick (1963) found the major urinary product of cysteine-bis-(β-chloroethyl)sulfone after intraperitoneal injection of sulfur mustard in rats. Papirmeister et al. (1991) concluded that hydrolysis to thiodiglycol and reaction with GSH are the most important routes of detoxification. This is supported by human data showing that thiodiglycol is present in the urine for 1 week or more after exposure (Wils, 1987).

11.3.2 Nitrogen mustards

The effects of time, temperature, and humidity on the vapor penetration of HN1 and HN3 into the forearm skin of human male volunteers were reported by NDRC (1945). Results of this research showed similar effects of temperature and humidity as observed for sulfur mustard (e.g., greater absorption with increased temperature and humidity). The penetration of HN1 and HN3 was found to be linear with time (5−20 min for HN1 and 30−60 min for HN3). At 71°F−72°F and 50%−52% relative humidity, the HN1 penetration rate was 2.8 μg/cm^2/min; for HN3, it was 0.18 μg/cm^2/min at 72°F−73°F and 45%−48% relative humidity. At 86°F−87°F and 47%−49% relative humidity, the HN1 penetration rate increased to 5.2 μg/cm^2/min, and the HN3 penetration rate increased to 0.3 μg/cm^2/min at 85°F and 47%−48% relative humidity. Excretion via the urine is likely a major route of elimination, especially due to the water solubility of the immonium ion (see Section 11.4).

11.3.3 Lewisite

Little information is available regarding the toxicokinetics of lewisite. It is readily absorbed by mucous membranes and, because of its lipophilicity, dermal absorption is significant (HSDB, 2019). Dermal absorption reportedly occurs faster for lewisite than for sulfur mustard (Hurst et al., 2008). Axelrod and Hamilton (1947) reported that radiolabeled (^{74}As) lewisite applied to a 0.43 cm^2 area of human skin was primarily fixed on the epidermis and that very little was found in the dermis; most was detected in hair and hair follicles. In experiments with guinea pigs, histological examination revealed that lewisite applied to skin entered the epidermis within 2 min and penetrated the dermis within 10 min (Ferguson and Silver, 1947). Only trace amounts were detectable in the dermis at 24 h postapplication.

11.4 Mode of action

11.4.1 Sulfur mustards

Sulfur mustard is a lipophilic bifunctional alkylating agent that efficiently enters tissue upon contact. The mode of action of sulfur mustard is multifaceted and complex, and has been reviewed by Papirmeister et al. (1991), Hurst et al. (2008), Smith et al. (2008), Shakarjian et al. (2010), and Ghanei and Harandi (2011). Efforts to understand the mechanisms of sulfur mustard toxicity are ongoing. Basically, sulfur mustard disrupts the interface of the epidermis and basement membrane causing blistering between the epidermis and dermis. Both immediate (immediate cell membrane damage) and delayed phases [secondary effects resulting from inflammatory responses, deoxyribonucleic acid (DNA) damage, and vascular leakage] have been described for sulfur mustard-induced dermal effects (Somani and Babu, 1989). Sulfur mustard may initiate intramolecular and intermolecular cross-links that provide many targets, including proteins, nucleic acids, and lipids. Many of the toxic effects of sulfur mustard also appear to be attributed to oxidative stress resulting from the disruption of normal cellular metabolism.

The sulfur mustard toxidrome is likely the result of multiple mechanisms including: (1) thiol depletion leading to intracellular calcium imbalance and subsequent cell death, (2) the alkylation of DNA and other cellular macromolecules resulting in necrosis and apoptosis, and (3) sulfur mustard-induced glutathione depletion and subsequent lipid peroxidation; and induction of inflammatory responses.

A key component of sulfur mustard toxicity is the formation of a sulfonium ion and resulting episulfonium intermediate that may react with sulfhydryl-containing macromolecules. Damage may include Ca^{2+} translocases (Ca^{2+}-stimulated, Mg^{2+}-dependent ATPase), which depend on thiol groups to maintain cellular Ca^{2+} homeostasis, and microfilamentous proteins. The resulting increase in intracellular calcium levels ultimately causes a decrease in cellular integrity and induction of apoptosis. Oxidative stress in sulfur mustard toxicity has been reviewed by Smith et al. (2008).

The role of DNA alkylation and the poly(ADP-ribose) polymerase (PARP) hypothesis theory for sulfur mustard toxicity has been reviewed by Papirmeister et al. (1991) and Debiak et al. (2001). In this mechanism, DNA is the initial target of the mustard agent. Alkylated DNA purines are enzymatically depurinated, creating apurinic sites that are cleaved by apurinic endonucleases, resulting in DNA strand breaks. The accumulation of DNA breaks leads to activation of the chromosomal enzyme PARP, which, utilizing NAD^+, causes a severe reduction in cellular NAD^+. Depletion of NAD^+ results in the inhibition of glycolysis, and stimulation of the nicotinamide adenine dinucleotide phosphate ($NADP^+$)-dependent hexose monophosphate shunt, ultimately resulting in the induction and secretion of proteases and subsequent cellular changes. Kehe et al. (2009) have reviewed dermal toxicity mechanisms of sulfur mustard. Sulfur mustard-induced apoptosis and activation of inflammatory mediators such

as various interleukins (ILs) such as IL-1alpha, IL-1beta, IL-6, IL-8, as well as tumor necrosis factors, also appear to be involved in the toxic response to sulfur mustard.

Papirmeister et al. (1991) noted that sulfur mustard-induced cytotoxicity is dose-dependent and that DNA appears to be more sensitive to mustard-induced alkylation than are other cellular constituents. The low-dose effects of sulfur mustard are characterized by genotoxicity and inhibition of mitosis. The loss of cellular reproduction may be due to bifunctional alkylation that ultimately prevents normal DNA replication. It was hypothesized that monofunctional DNA damage might be responsible for low-dose mutagenic and possibly carcinogenic effects.

Sulfur mustard-induced lipid peroxidation is a function of GSH depletion. For this mechanism, depletion of GSH results in an accumulation of reactive oxygen species via hydrogen peroxide-dependent processes (Miccadei et al., 1988). The oxygen radicals react with membrane phospholipids, forming lipid peroxides that alter membrane structure, causing it to break down.

Additional work has focused on the identification of possible biomarkers of sulfur mustard exposure and injury (Buxton et al., 2000, 2001; Danne et al., 2000). More recently, the role of metalloproteinases and collagen degradation (Gerecke et al., 2005), platelet-activating factor (Clark et al., 2005, 2006), and interaction with cytochrome P450 processes (Brimfield and Hodgson, 2005; Brimfield et al., 2006; Mancheco and Brimfield, 2006) is being investigated relative to the mechanism of action of sulfur mustard.

11.4.2 Nitrogen mustards

Similar to sulfur mustard, a key component of nitrogen mustard toxicity is the formation of a cyclic onium cation. This occurs in the presence of polar solvents such as water (Somani, 1992). The immonium ion may react with nucleophiles (such as nitrogen) in the base components of nucleic acids and with sulfhydryl groups in proteins and peptides. The precise mechanism of nitrogen mustard activity is unclear, but several have been proposed: DNA/RNA alkylation and resultant effects, effects on GSH, membrane effects (protein cross-linking, ion transport effects), and cytoplasmic effects (release of lysosomal enzymes). The possible mechanisms of nitrogen mustard have been reviewed by Gray (1989). Results of preliminary work by Elsayed and Omaye (2006) in mice given HN2 intraperitoneally showed pulmonary alterations indicative of oxidative stress and impaired detoxification processes that are consistent with the aforementioned mechanisms.

11.4.3 Lewisite

Dermal or intravenous exposure to lewisite leads to local skin edema and pulmonary edema due to increased capillary permeability. The increased capillary permeability results in blood plasma loss and resultant physiological responses collectively referred to as *lewisite shock*. Lewisite shock may be likened to shock observed in severe burn cases. It has been hypothesized that functional changes in the lungs, kidneys, respiratory tract, and cardiovascular and lymphatic systems may be the result of a disturbance of osmotic equilibrium (Goldman and Dacre, 1989).

Lewisite-induced vesicant and systemic toxicity are likely due in part to interactions with thiol groups (Goldman and Dacre, 1989). The interaction with enzyme sulfhydryl groups may cause inhibition of enzyme by the formation of stable cyclic structures with arsenic. These thiol interactions result in energy depletion, leading to cell death (Young, 1999).

To investigate the mechanism of lewisite-induced ocular effects, Tewari-Singh et al. (2016, 2017) evaluated the pathophysiology of corneal injury in New Zealand White rabbits exposed to lewisite vapor at a concentration of 0.2 mg/L for 2.5 or 7.5 min, followed by a postexposure observation period of up to 28 days. An increase in total corneal thickness was noted starting at day 1 postexposure and epithelial degradation starting at day 3 postexposure, with maximal effect at day 7 postexposure, followed by recovery at later time points. Lewisite also induced an increase in the number of blood vessels and inflammatory cells and a decrease in keratocytes with maximum effects at day 7 postexposure. A significant increase in epithelial−stromal separation was observed at days 7 and 14 following the 7.5 min exposure. Lewisite also caused an increase in the expression levels of cyclooxygenase-2, IL-8, vascular endothelial growth factor, and matrix metalloproteinase-9 at all the study time points, indicating their involvement in lewisite-induced ocular effects.

More recently, Srivasta et al. (2018) identified a molecular mechanism underlying lewisite-induced acute kidney injury. Following cutaneous exposure to lewisite, renal tubular damage was noted in mice. The effect was characterized by loss of brush border in proximal tubules and tubular cell apoptosis accompanied by increases in serum creatinine, neutrophil gelatinase-associated lipocalin, and kidney injury molecule-1. Production of reactive oxygen species in the kidney was noted and resulted in the activation of autophagic and DNA damage response signaling pathways. Scavenging reactive oxygen species by cutaneous postexposure application of the antioxidant *N*-acetyl-L-cysteine, decreased the lewisite-induced autophagy and DNA damage.

11.5 Toxicity

11.5.1 Sulfur mustard

Anslow et al. (1947) and Graef et al. (1948) provided basic information on the clinical pathology and complex

toxicology of sulfur mustards and nitrogen mustards. Subsequently, sulfur mustard toxicity in humans and animals has been extensively reviewed by Sidell et al. (1992), Somani (1992), Watson and Griffin (1992), IOM (1993), ATSDR (2003), NRC (2003), Romano et al. (2008), and Ghanei and Harandi (2011). Sulfur mustard affects the skin, respiratory tract, and eyes. The acute effects include edema, ulceration, and necrosis of epithelial tissue. Systemic toxicity may also occur and is characterized by nausea and vomiting, fever, and malaise. There is evidence of systemic toxicity (gastrointestinal tract) following dermal exposure only (Dacre and Goldman, 1996). Delayed effects include conjunctivitis and blindness following ocular exposure and chronic bronchitis following inhalation exposure. Affected tissues may have an increased susceptibility to secondary infections, and possibility of carcinogenicity of the skin and respiratory tract. However, the often-observed latency between acute exposure and late-onset tissue damage is not fully understood. Of the approximately 100,000 casualties of sulfur mustard exposure during the Iran−Iraq war (1983−88), approximately 45,000 were still experiencing long-term effects of exposure over 20 years later (Ghanei et al., 2010). Similarly, Isono et al. (2018) reported significant long-term autonomic nervous system issues and neuropsychological effects among 44 individuals accidentally exposed to a mixture of sulfur mustard and lewisite in Qiqihar, northeast China, in August 2003. Medical follow-up of the victims was carried out between 2006 and 2014. Various medical issues were detected in 30%−63% of the subjects.

Ambient temperature and humidity govern the degree of toxicity of sulfur mustard; in hot and humid conditions, lower mustard concentrations are required to produce debilitating effects. The severity of sulfur mustard effects is also greater in areas of the body with greater moisture (e.g., the axilla, groin, and eyes). Information regarding the toxic effects of long-term exposure to low levels of sulfur mustard that are not acutely toxic is limited. Ghanei et al. (2010) have reviewed the acute and long-term cutaneous effects of sulfur mustard.

Available data suggest that the location and severity of damage resulting from exposure to sulfur mustard are concentration-dependent and a function of the highly reactive nature of sulfur mustard (Papirmeister et al., 1991). The eyes are generally considered to be the most sensitive and rapidly responding target (Reed, 1918; Reed et al., 1918; Anderson, 1942). For low exposures, sulfur mustard-induced injury appears to be limited to the upper respiratory tract (Eisenmenger et al., 1991) and eyes (Reed, 1918; Reed et al., 1918; Guild et al., 1941; Anderson, 1942). In work with informed volunteer subjects, Anderson (1942) reported that Ct values of 60−75 mg-min/m^3 would result in conjunctivitis, photophobia, and ocular irritation, while Ct values of 75−90 mg-min/m^3 would cause a high proportion of casualties, as determined by more severe ocular damage requiring several weeks of treatment. A chronic ocular injury known as *mustard gas keratopathy (MGK)* has been identified in some individuals following moderate- to high-level exposure. The corneal damage may be recurrent many years following initial exposure. A weak positive correlation between severity of ocular and pulmonary involvement was found in a study of 292 Iran−Iraq conflict veterans (Ghasemi et al., 2012). McNutt et al. (2013) provided insight into the progression and pathophysiological correlates for this injury.

At exposure concentrations higher than those causing ocular damage, pulmonary effects would be expected (Eisenmenger et al., 1991). Regardless of the target tissue, there is a latency period between initial exposure and development of effects. The eyes and respiratory tract appear to have the shortest latency period, with effects appearing within hours depending on the exposure level. Later-onset lung injury is often referred to as mustard lung (ML) because the injury differs somewhat from more typical chronic obstructive pulmonary disease. In a review of the mechanisms of sulfur mustard-induced lung injury, Ghanei and Harandi (2011) found that oxidative stress and apoptosis may be more relevant mechanisms regarding ML than for other chronic obstructive pulmonary diseases.

In addition to the acute toxic effects on the eyes, skin, and respiratory tract, both acute and longer-term neuropsychiatric effects [e.g., depression, anxiety, neurasthenia, insomnia, and posttraumatic stress syndrome (PTSD)] have been documented for individuals exposed to sulfur mustard (Romano et al., 2008). Many of these effects have been documented for individuals exposed during noncombat conditions (e.g., those of munitions plant workers) and are not always the result of high-level exposure that result in serious overt effects. Longer-term effects, such as chronic bronchitis, have been associated with occupational exposures that included episodes of acute toxicity, and delayed or recurrent keratitis may occur 8−40 years after a severe vapor exposure. Sulfur mustard-induced immunosuppression resulting in greater susceptibility to infections has also been reported.

Results of a recent study by Dachir et al. (2017) showed that a 10-minute whole-body exposure of male rats to sulfur mustard at concentrations of 135, 145, or 155 μg/L produced effects typical of sulfur mustard exposure. These included ocular and upper respiratory tract damage within 24−48 h. Examinations of animals euthanized at various times up to 14 days postexposure revealed a progression of ocular and respiratory tract effects as well as alopecia, transient body weight, and aggressive behavior. The remaining rats were euthanized at 12 weeks after exposure. At 4 weeks, clinical signs had resolved. Histopathology of the respiratory tract showed

focal areas of damage and continuation of inflammatory processes. Ocular damage (corneal erosion, abnormal epithelia, and severe edema) continued and remained at study termination.

Additional acute lethality data in animals are summarized in Table 11.7. Based upon the animal data, interspecies variability in the lethal response to sulfur mustard vapor is less than an order of magnitude. For nonlethal effects, the animal data suggest that test species exhibit signs of toxicity that are qualitatively similar to humans when acutely exposed to sulfur mustard vapor. Ocular and respiratory tract irritations are clearly evident in studies using dogs, rats, mice, rabbits, and guinea pigs.

Effects of orally administered sulfur mustard in rats were studied by Sasser et al. (1996a). Repeated gavage administration of sulfur mustard in sesame oil produced epithelial hyperplasia of the forestomach at the highest dose tested, but no deaths and no other treatment-related pathological lesions or changes in clinical chemistry or hematological parameters.

Results of a multigenerational study in rats given sulfur mustard by gavage showed no significant adverse effects on reproductive parameters at any dose level, but revealed dose-related lesions of the squamous epithelium of the forestomach (acanthosis and hyperplasia) (Sasser et al., 1996b). It is likely that the forestomach lesions were a function of the treatment regimen, whereby the bolus dose in an oil vehicle (sesame seed oil) would enhance the effects of sulfur mustard having direct contact with the forestomach tissue. Studies by Hackett et al. (1987) in which rabbits were gavage-dosed with sulfur mustard were equivocal regarding reproductive/developmental effects, due in part to the dose regimen and overt maternal toxicity.

Developmental and reproductive effects of sulfur mustard have been reviewed by the National Research Council (NRC, 1999, 2003). Acute exposures resulting in systemic uptake may have effects on reproductive organs, including inhibition of spermatogenesis. Fetal anomalies were observed in tests with rats given sulfur mustard during gestation, but only at maternally toxic doses.

TABLE 11.7 Acute lethality of sulfur mustard in laboratory species following inhalation exposure.

Species	Lethality value	Concentration (mg/m^3) and exposure duration (min)	References
Rat	2 min LCt_{50}: 1512 mg-min/m^3	756 mg/m^3 (2 min)	Fuhr and Krakow (1945) (not verified)
	30 min LCt_{50}: 990 mg-min/m^3	33 mg/m^3 (30 min)	
	60 min LCt_{50}: 840 mg-min/m^3	14 mg/m^3 (60 min)	
Mouse	2 min LCt_{50}: 4140 mg-min/m^3	2070 mg/m^3 (2 min)	Fuhr and Krakow (1945) (not verified)
	30 min LCt_{50}: 1320 mg-min/m^3	44 mg/m^3 (30 min)	
	60 min LCt50: 860 mg-min/m^3	14.3 mg/m^3 (60 min)	
	60 min LCt_{50}: 42.5 mg/m^3	42.5 mg/m^3 (60 min)	Vijayaraghavan (1997)
Monkey	10 min LCt_{50}: 800 mg-min/m^3	80 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Dog	10 min LCt_{50}: 600 mg-min/m^3	60 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Cat	10 min LCt_{50}: 700 mg-min/m^3	70 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Goat	10 min LCt_{50}: 1900 mg-min/m	190 mg/m^3 (10 min)	Rosenblatt et al. (1975)
Guinea pig	5 min LCt_{50}: 800 mg-min/m^3	160 mg/m^3 (5 min)	Langenberg et al. (1998)
	10 min LCt_{50}: 1700 mg-min/m^3	170 mg/m^3 (10 min)	Rosenblatt et al. (1975)

The genotoxicity of sulfur mustard is well documented as demonstrated by DNA cross-linking, mutations following replication or repair errors, chromosomal breaks, and chromosomal aberrations. Occupational exposures have been associated with increased frequencies of somatic cell mutations, sister chromatid exchanges, and chromosome abnormalities. Studies with rats indicate that subchronic inhalation or oral exposures can produce dominant lethal effects.

The carcinogenicity of sulfur mustard in animals has been reviewed in IARC (1975), Watson et al. (1989), IOM (1993), NRC (1999), and USACHPPM (2000). McNamara et al. (1975) studied the potential carcinogenicity of sulfur mustard in rats, mice, rabbits, guinea pigs, and dogs exposed via inhalation for up to 1 year. No tumors were detected in the mice, rabbits, guinea pigs, or dogs, but skin tumors (i.e., basal and squamous cell carcinomas, trichoepitheliomas, and keratoacanthomas) were associated with sulfur mustard exposure at the highest exposure tested (0.1 mg sulfur mustard/m^3 for 6.5 h, followed by 0.0025 mg sulfur mustard/m^3 for 17.5 h/day, 5 days/week). An increased incidence of pulmonary tumors in Strain A mice was observed following intravenous injections (four doses over 2 days) of sulfur mustard (Heston, 1950), and an increase in injection-site tumors in mice given subcutaneous injections of sulfur mustard over a 6-week period (Heston, 1953).

In a cohort study reported by Easton et al. (1988), there was a significant excess of laryngeal, pharyngeal, upper respiratory tract, and lung cancers in workers at a sulfur mustard manufacturing facility during World War II. A study of the Iranian military veterans exposed to sulfur mustard under battlefield conditions during the Iran–Iraq conflict at levels sufficient to cause severe signs of toxicity indicated a potential increased incidence of chronic myelocytic leukemia (CML). In several earlier studies on World War I veterans who were exposed to sulfur mustard, leukemia was not identified as a possible effect, although it is unclear if examination for CML had ever occurred in those populations. Confounders, such as exposure to benzene or radiation, which complicate the analysis, have not yet been ruled out in the ongoing epidemiologic study of Iranian veterans. Two cases of CML were reported for Japanese workers exposed to sulfur mustard (Shakil et al., 1993) but the incidences of CML in the entire population of sulfur mustard-exposed workers and in an unexposed control population were not reported. Studies in animals provide supporting evidence for the carcinogenicity of sulfur mustard, although the results of some studies are compromised by insufficient exposure durations and injuries resulting from caging situations.

11.5.2 Nitrogen mustards

Information regarding the toxicity of nitrogen mustards is less extensive than that for sulfur mustard. Limited lethality data in animals are summarized in Table 11.8. Like sulfur mustard, exposure to nitrogen mustards may cause skin blistering, as well as respiratory tract injury and ocular damage. Response data from tests with informed human volunteer subjects (NDRC, 1944) suggested a

TABLE 11.8 Lethality of nitrogen mustard (HN2).

Route	Species	Dose (mg/kg)	Exposure time	Effect	References
Oral	Rat	10–85	–	LD_{50}	NDRC (1946)

TABLE 11.9 Estimated effect thresholds in humans exposed to nitrogen mustard vapors.

HN1	HN2	HN3	Effect
–	0.012 mg-min/m^3	–	No observable effect level during therapeutic use of HN2 (Van Vloten et al., 1993)
90 mg-min/m^3	70 mg-min/m^3	42 mg-min/m^3	Moderate but reversible ocular effects (Porton Report, 1942a,b, 1943a,b,c,d; U.S. Army Med. Div., 1945a,b; NDRC, 1946)
>21,170 mg-min/m^3	5800 mg-min/m^3	1800 mg-min/m^3	Median blistering Ct (10 or 20 min exposure) for normal skin
		31,300 mg-min/m^3	Median blistering Ct (20 min exposure) for sweating skin (NDRC, 1944)

relative potency of HN3 > HN1 > HN2 for vesicant effects, although the differences were minor. Like sulfur mustard, dermal effects were enhanced by moisture (as from sweating). Estimated thresholds for skin blistering and ocular injury are summarized in Table 11.9. Ocular injury (irritation resulting in compromised operational effectiveness of military personnel) was detected at exposures much lower than those causing dermal effects. All of the toxic effects of nitrogen mustard appear to involve a latency period of several hours for ocular responses and several days for dermal blistering. Nitrogen mustards are alkylating agents with known mutagenicity, but there are no animal cancer bioassays and no human carcinogenicity data.

Nitrogen mustard and its hydrochloride salt have been shown to be teratogenic in mice and rats. Intraperitoneal administration of HN2-hydrochloride/g to mice during gestation resulted in serious teratogenic effects (Danforth and Center, 1954). Haskin (1948) and Murphy et al. (1958) reported similar findings in rats given HN2-hydrochloride/kg subcutaneously during gestation.

Nitrogen mustards are bifunctional alkylating agents that produce a carcinogenic response (primarily lung tumors and lymphomas) in mice following subcutaneous, intraperitoneal, and intravenous administration, as well as by skin painting (IARC, 1987). Intravenous administration of nitrogen mustard to rats produced tumors in multiple organs (IARC, 1987). Information in humans is limited to reports of squamous cell carcinomas of the skin following therapeutic application of nitrogen mustard in the treatment of mycosis, fungoides, and psoriasis (IARC, 1987).

11.5.3 Lewisite

The toxicology of lewisite has been reviewed by Goldman and Dacre (1989), Trammell (1992), Watson and Griffin (1992), Hurst et al. (2008), and NRC (2013). Because lewisite L-2 and L-3 are of lower volatility than L-1, occur in lesser amounts, and are toxicologically similar to L-1, the discussion of toxicity is limited to lewisite (NRC, 2013). Its characteristic geranium-like odor is detectable at 14–23 mg/m^3 (Gates et al., 1946). Lewisite may be lethal to humans following inhalation, dermal, or oral exposure. It is reportedly immediately highly irritating at estimated concentrations of 6–8 mg/m^3. Gates et al. (1946) estimated an LC_{50} of 3300 mg/m^3 for 30 min for lewisite vapor absorption through the bare skin and an inhalation LC_{50} of 120 mg/m^3 for 10 min and 50 mg/m^3 for 30 min. Inhalation of 10 mg/m^3 lewisite for 30 min may result in severe intoxication and incapacitation lasting for several weeks, and inhalation of 10 mg/m^3 for 15 min caused inflammation of the eyes and swelling of the eyelids (Franke, 1977). Like sulfur mustard, moist tissues are particularly sensitive to lewisite. The eyes exhibit the greatest sensitivity (IOM, 1993).

The vesicant properties of lewisite result from direct contact with the skin. Signs of dermal toxicity (pain, inflammation) may be experienced within a minute after exposure. Acute lethality is usually the result of pulmonary injury. Ocular exposure may result in corneal necrosis. Due to its lipophilicity, percutaneous absorption of lewisite is rapid and, at a sufficient exposure, may be associated with systemic toxicity characterized by pulmonary edema, diarrhea, agitation, weakness, hypothermia, and hypotension (IOM, 1993). The threshold for severe systemic toxicity in humans following dermal exposure to lewisite has been estimated at 10 mg/kg (9.1–13.4 mg/kg) (Sollman, 1957).

Eldridge (1923) conducted tests on human volunteers to assess the effects of dermal exposure to lewisite vapor. The arms of men (1–7 men with previously determined average sensitivity to lewisite) were exposed to varying concentrations of lewisite vapor for periods ranging from 10 min to 3 h for the purpose of determining the concentration of lewisite required to create blistering. The resulting dermal responses ranged from reddish discoloration to a clear, watery blister over the entire burned area, accompanied by reddening, swelling, and hardening of the surrounding skin. The burns reached maximum severity in

36–48 h, and healing was complete in 6 days to 2 weeks. The men also reported that the healed skin remained sensitive for several weeks after the healing was complete.

It has been hypothesized that fatalities following dermal exposure to lewisite may be due to blood plasma loss resulting from extensive capillary damage (lewisite shock; Cameron et al., 1946). Sollman (1957) estimated that an oral dose of as little as 2 mL in an adult human (equivalent to 37.6 mg/kg) may be fatal within several hours. The target tissues and organs for systemic toxicity of lewisite include the liver, gallbladder, urinary bladder, lungs, and kidneys (Cameron et al., 1946; Snider et al., 1990). Generally, there is a data deficiency regarding definitive exposure–response data for lewisite.

In studies with rats, Silver and McGrath (1943) found little difference in the acute lethality of *cis*- or *trans*-lewisite exposed for 10 min. Ten-minute mouse LC_{50} values for the *cis*- and *trans*-isomers were 190 and 200 mg/m^3, respectively. All mice exposed to 240 mg/m^3 lewisite for 10 min died. Clinical signs in dogs exposed for 7.5 or 15 min included immediate continual eye blinking, followed by excessive nasal secretion, lacrimation, and sneezing (Armstrong, 1923). Ocular inflammation and vomiting also occurred in some dogs by the end of the 7.5- and 15-min exposures. Dogs exposed for 30 min or longer exhibited frequent retching, vomiting, extreme salivation, labored breathing, and inflammation of the entire respiratory tract. Necropsy revealed a thick membrane in the nostrils, larynx, and trachea, which was accompanied by purulent bronchitis, hemorrhage, pneumonia, edema, and congestion of the lungs.

Similar to the work on sulfur mustard, Sasser et al. (1989a) conducted experiments in rats given lewisite by gastric intubation (in sesame oil) at doses of 0.01, 0.1, 0.5, 1.0, or 2.0 mg/kg, 5 days/week for 13 weeks. A dose-related response was observed for lethality (deaths in the three highest dose groups) and frequency and severity of forestomach lesions. The forestomach lesion incidence and severity were due, at least in part, to the bolus of dosing and the sesame oil vehicle.

Multigeneration reproductive studies in rats (Sasser et al., 1989b) and teratology studies in rats and rabbits (Hackett et al., 1987) given lewisite by gastric intubation were negative or compromised by concurrent maternal toxicity.

The carcinogenic potential of lewisite is not well understood. In a long-term follow-up study, Krause and Grussendorf (1978) reported the formation of a malignant lesion at the site of contact 8 years following a single, acute dermal exposure of a German soldier accidentally exposed to liquid lewisite on his lower right leg in 1940. The lesion was diagnosed as malignant 8 years later, and 38 years after exposure, the area of contact remained ulcerated and diagnosed as Bowen's disease (an intradermal squamous cell carcinoma). Bowen's disease was also diagnosed in workers at a Japanese lewisite production facility (Inada et al., 1978). Findings in these workers were not conclusive due to concurrent exposure to diphenylcyanoarsine and sulfur mustard. Furthermore, no quantitative estimates of dose or exposure rates were available (Inada et al., 1978).

Increased incidences of cancer mortality (respiratory tract: 14%; digestive tract: 9.6%) in workers from the Okuno-Jima poison gas factory were reported by Wada et al. (1968). When cancer rates were correlated with job classifications, the frequency of respiratory and gastrointestinal tract neoplasms was highest in workers who were involved in the production of sulfur mustard or lewisite, followed by those who worked indirectly with sulfur mustard or lewisite. The lowest frequency occurred in the group having no direct contact with the vesicant agents (Yamakido et al., 1985). Similar to the Bowen's disease findings, the cancer incidences were confounded by the fact that workers were also exposed to sulfur mustard, hydrocyanic acid, diphenylcyanoarsine, chloroacetophenone, and phosgene.

11.6 Risk assessment

Although stockpiles of sulfur mustard are being destroyed, the possibility of its use by militant states and terrorists remains. Encountering blister agents in buried munitions has also occurred and the potential for such encounters remains, as do accidents in handling contaminated material. These activities necessitate the need for health-based exposure values for use in emergency planning and emergency response activities.

11.6.1 Sulfur mustards

11.6.1.1 Noncancer

Various standards and guidelines have been developed for sulfur mustard. These values are applicable to occupational exposures, emergency planning and response efforts, and remediation efforts. Airborne exposure limits (AELs) and health-based environmental screening levels (HBESLs) for sulfur mustard have been developed by the US Army (USACHPPM, 1996, 2000). Most health-based criteria for sulfur mustard vapor exposure are based upon protection of the eyes and respiratory tract, which are the most sensitive targets.

Acute exposure guideline levels (AEGLs) for sulfur mustard have been developed for emergency planning and emergency response applications (NRC, 2003; US EPA, 2012). The AEGLs represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h (Table 11.10). The AEGLs for nitrogen mustards are interim status

TABLE 11.10 Inhalation standards and guidelines for sulfur mustard.

Guideline	Exposure duration				
	10 min	30 min	1 h	4 h	8 h
AEGL-1[a]	0.06 ppm	0.02 ppm	0.01 ppm	0.003 ppm	0.001 ppm
AEGL-2[a]	0.09 ppm	0.03 ppm	0.02 ppm	0.004 ppm	0.002 ppm
AEGL-3[a]	0.59 ppm	0.41 ppm	0.32 ppm	0.08 ppm	0.04 ppm
Dept. of the Army/Civilian Occupational WPL[b]					0.0005 ppm (24 h)
Dept. of the Army/Civilian GPL[c]					$1.5 \times 10 \times 10^{-5}$ ppm (24 h)
CDC-CSEPP[d]					0.3 ppm

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. The AEGL-1 values for sulfur mustard are based upon minor ocular irritation in informed human volunteers (Anderson, 1942). AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. The AEGL-2 values for sulfur mustard are based on marked conjunctivitis, edema, photophobia, and eye irritation in informed human volunteers (Anderson, 1942). AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 values for sulfur mustard are based on a lethality threshold estimated in mice (Kumar and Vijayaraghavan, 1998).

[a]*AEGL (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects.*

[b]*Worker population exposure limit (DA, 1991, 1997; DHHS, 1988), 8-h TWA, 5 days/week.*

[c]*General population limit (no observable effects), 24-h TWA, 5 days/week.*

[d]*Recommended acute effect levels for determining emergency evacuation distances in the Chemical Stockpile Emergency Preparedness Program (CSEPP); no specified exposure duration.*

values that have not undergone final review and publication by the National Research Council/National Academy of Sciences. Provisional Advisory Levels (PALs) are developed by the US Environmental Protection Agency (EPA) as public emergency exposure limits for three severity levels (PAL 1, PAL 2, and PAL 3) and for exposure durations of 24 h, 30 days, 90 days, and 2 years for both oral and inhalation exposure (Young et al., 2009). Oral PALs for sulfur mustard are not recommended due to insufficient data and because of the chemical nature of sulfur mustard (Bast et al., 2013). Inhalation PAL 1 values for sulfur mustard are 0.00083 mg/m^3 for 24 h and 0.00010 mg/m^3 for 30 days, 90 days, and 2 years. Inhalation PAL 2 values are 0.0042 mg/m^3 for 24 h, 0.0029 mg/m^3 for 30 days, and 0.00097 mg/m^3 for 90 days and 2 years. PAL 3 values are 0.088 mg/m^3 for 24 h, but are not recommended for longer durations (Bast et al., 2013).

An interim reference dose (RfDi), an estimate of a daily dose to humans that is likely to be without appreciable risk of deleterious health effects during a lifetime, of 7×10^{-2} mg/kg/day has been developed for sulfur mustard (NRC, 1999).

Inhalation standards and guidelines for sulfur mustard are summarized in Table 11.10. Other standards and guidelines for sulfur mustard have been summarized by ATSDR (2003).

11.6.1.2 Cancer

The International Agency for Research on Cancer (IARC) classified sulfur mustard as a Group 1 carcinogen (carcinogenic to humans) (IARC, 1987). The National Toxicology Program (NTP) considers mustard gas to be a substance "known to be a human carcinogen" (DHHS, 1988). These assessments are based upon human and animal data.

Studies of occupational exposures to sulfur mustard indicate an elevated risk of respiratory tract and skin tumors following long-term exposure to acutely toxic concentrations. Overall, several factors are important regarding the assessment of the carcinogenicity of sulfur mustard. Increased cancer incidence in humans appears to be associated only with exposures that caused severe acute effects, and occupational exposures tended to involve repeated exposures and repeated injury of the same tissues. Although numerous individuals have suffered sulfur mustard-induced injuries in various conflicts over the years, incidences of skin cancer are rarely reported (Firooz et al., 2011). Evidence for lung cancers resulting from sulfur mustard exposure are well documented, with most cases associated with long-term exposures, although there is emerging evidence for the involvement of acute and short-term exposure (Ghanei and Harandi, 2010). Because the therapeutic use of the sulfur mustard analog nitrogen mustard is associated with an increased incidence of CML,

the reports of CML in HD-exposed individuals appear to be relevant to the carcinogenicity of sulfur mustard.

Cancer slope factors and unit risk values for sulfur mustard have been summarized by ATSDR (2003).

11.6.2 Nitrogen mustards

11.6.2.1 Noncancer

Very few standards and guidelines are available for nitrogen mustards. AEGL values for the nitrogen mustards (HN1, HN2, and HN3) have been developed and are based upon ocular irritation in human volunteers (AEGL-2) and lethality in rodents (AEGL-3), as shown in Table 11.11. Data were insufficient for derivation of level AEGL-1 values. The AEGL values are currently awaiting finalization. The US Army (USACHPPM, 1996, 2004) has developed worker population limit (WPL) values and general population limit (GPL) values for nitrogen mustard (USACHPPM, 1996, 2004).

11.6.2.2 Cancer

Data are not available with which to quantitatively assess the cancer risk from nitrogen mustards. However, IARC (1987) considers nitrogen mustard a Group 2A carcinogen based upon limited evidence in humans and sufficient evidence in animals.

11.6.3 Lewisite

11.6.3.1 Noncancer

The US Army has developed HBESLs for lewisite (USACHPPM, 1999). Additionally, a chronic oral reference dose (RfD) of 1×10^{-4} mg/kg/day is available (NRC, 1999; USACHPPM, 1999), as are inhalation and dermal RfDs (USACHPPM, 1999). Acute exposure guideline levels (AEGLs) have been developed for lewisite (NRC, 2013), and are presented in Table 11.12. Inhalation PAL 1 values are not recommended for lewisite. Inhalation PAL 2 and 3 values for 24-h exposure durations are 0.01 and 0.037 mg/m^3, respectively (Bast et al., 2013). Exposure values for longer PAL-specific durations (30 days, 90 days, and 2 years) are not recommended.

11.6.3.2 Cancer

Data regarding the potential carcinogenicity of lewisite are anecdotal and insufficient for a quantitative assessment. Although quantitative data are lacking, the position maintained by the Centers for Disease Control and Prevention (CDC) (DHHS, 1988) is that some evidence suggests that lewisite may be a carcinogen. For environmental exposure and remediation concerns, the arsenic component and/or arsenic-containing degradation products, however, are relevant.

Although the carcinogenicity of lewisite is equivocal and a quantitative assessment is not feasible, several lewisite degradation products are known carcinogens. Combustion products of lewisite include the inorganic arsenicals, arsenic trichloride, arsenic trioxide, and vinyl chloride. Inorganic arsenic is carcinogenic in humans and animals and is classified as a Group A carcinogen by the US EPA (2008). Arsenic trioxide and vinyl chloride are both considered Group A carcinogens by the US EPA (1984) and Group 1 carcinogens by IARC (1987).

11.7 Treatment

11.7.1 Sulfur mustards

Medical management of sulfur mustard exposure begins with preventing exposure. As previously noted in this chapter, the military use of sulfur mustard necessitated

TABLE 11.11 AEGLs for nitrogen mustards (HN-1, HN-2, HN-3).

Guideline	Exposure duration				
	10 min	30 min	1 h	4 h	8 h
AEGL-1[a]	NR	NR	NR	NR	NR
AEGL-2[a]	0.13 mg/m^3	0.044 mg/m^3	0.022 mg/m^3	0.0056 mg/m^3	0.0028 mg/m^3
AEGL-3[a]	2.2 mg/m^3	0.74 mg/m^3	0.37 mg/m^3	0.093 mg/m^3	0.047 mg/m^3

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. No AEGL-1 values for nitrogen mustards are currently recommended due to insufficient data. AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. A threshold for ocular irritation in informed human volunteers is the basis for the AEGL-2 values for nitrogen mustards. AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 values for nitrogen mustards are based on an estimated lethality threshold in rats.

[a]*AEGL (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects.*

TABLE 11.12 AEGLs for lewisite.

Guideline	Exposure duration				
	10 min	30 min	1 h	4 h	8 h
AEGL-1[a]	NR	NR	NR	NR	NR
AEGL-2[a]	1.3 mg/m^3	0.47 mg/m^3	0.25 mg/m^3	0.070 mg/m^3	0.037 mg/m^3
AEGL-3[a]	3.9 mg/m^3	1.4 mg/m^3	0.74 mg/m^3	0.21 mg/m^3	0.11 mg/m^3

AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. No AEGL-1 values for lewisite are currently recommended due to insufficient data. AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. A threefold reduction of the AEGL-3 values for lewisite were considered an appropriate and defensible estimate for the AEGL-2 values (NRC, 2013). AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 values for lewisite were based upon an estimated LC_{01} in dogs (Armstrong, 1923).

[a]*AEGL (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels—AEGL-1, AEGL-2, and AEGL-3—are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects.*

full body protection. As a result, considerable effort has been expended in the development and evaluation of protective clothing and equipment (Schier et al., 2005). In general, these include air-purifying and atmosphere-supplying respirators and chemical-protective clothing (e.g., chemical and vapor impermeable coverings and clothing treated with adsorbing or neutralizing chemicals).

Following exposure, rapid decontamination is essential and may include removal of contaminated clothing and removal or neutralization of the agent. Developing medical management strategies for mustard-induced cutaneous damage is an ongoing effort (Graham et al., 2005, 2009; Tewari-Singh and Agarwal, 2016). The use of possible antidotes such as antioxidants has been reviewed by Smith et al. (2008) and Laskin et al. (2010).

Polyurethane sponges containing detoxification additives were developed and evaluated for decontamination and detoxification (Gordon et al., 2006). Using ^{14}C-labeled sulfur mustard and porcine skin, Matar et al. (2019) found that itaconic acid. *N*,*N*'-methylenebisacylamide, 2-trifluoromethylacrylic acid, Fuller's earth, and Fast-Act were effective in reducing the amount of radiolabel absorbed into the skin at 24 h postapplication. A wide range of antiinflammatory drugs and scavengers of reactive oxygen species also continue to be examined.

Ocular exposure requires rapid removal of the agent from the eyes by flushing with water. Symptomatic treatment with analgesics, antiinflammatory agents, and antibiotics is generally appropriate. Jadidi et al. (2014, 2015) reported that topically applied cyclosporin A was useful in treating sulfur mustard-induced superficial eye injuries.

Vapor exposure will also target the respiratory tract and will necessitate respiratory support. Medical management has traditionally relied on prevention, decontamination, and palliative treatment of signs and symptoms. Keyser et al. (2014) reviewed the use of antiinflammatory compounds, antioxidants, protease inhibitors, and antiapoptotic agents. The importance of preventing cell death with the antiapoptotic compounds was emphasized. Veress et al. (2015) found that intratracheal administration of tissue plasminogen activator eliminated mortality and improved morbidity in rats exposed to lethal levels of sulfur mustard vapor. Development of medical countermeasures has been reviewed by Munro et al. (1990), Keyes et al. (2005), Laskin et al. (2010), and Keyser et al. (2014).

11.7.2 Nitrogen mustards

Medical management of nitrogen mustard exposure is similar to that for sulfur mustard. It involves preventing exposure and, where exposure has occurred, decontamination and support therapy. The use of antioxidants in the treatment of nitrogen mustard toxicity is under investigation (Hardej and Billack, 2006).

11.7.3 Lewisite

Similar to the mustard agents, exposure prevention is the first line of defense against lewisite. Rapid decontamination is especially relevant to lewisite exposure due to the rapid development of pain (1−2 min) associated with lewisite exposure. Unlike other vesicants, an effective antidote for lewisite toxicity exists in the form of BAL (2,3-dimercaptopropanol), which binds with arsenicals, thereby countering the lewisite-induced damage. Such chelation therapy is associated with notable side effects (e.g., renal effects) and requires careful medical management. More effective analogs of BAL have been developed that have less significant side effects.

Mouret et al. (2013) reported that for the SKH-1 hairless mouse model, topical applications of dimercapto-chelating agents, such as BAL and meso-2,3-dimercapto-succinic acid (DMSA), were more effective than subcutaneous administration in the attenuation of lewisite vapor-induced injury. Although both agents reduced neutrophil infiltration, wound size, and necrosis of the skin barrier, BAL was found to be more effective than DMSA.

In spite of extensive research efforts, effective therapies for lewisite-induced ocular corneal injuries are not currently available. Goswami et al. (2016) have developed primary human corneal epithelial cell and rabbit corneal organ culture models that may lead to the development of therapies against lewisite-induced ocular effects.

11.8 Concluding remarks and future directions

Vesicants continue to receive attention with respect to the destruction of agent stockpiles, remediation of contaminated sites, the documented and speculated use of these agents in regional conflicts, and their potential use in subversive/terrorist activity. This elevated interest profile has resulted in summaries of older toxicological data, generation of new data, and a greater understanding of the effects of these agents on biological systems. Application of these data is invaluable in the development of various health-based criteria, standards, and guidelines for use in remediation efforts, risk planning, and emergency response.

In accordance with the Chemical Weapons Convention, the United States is destroying (via chemical neutralization followed by biotreatment or supercritical water oxidation) its stockpile of sulfur mustard munitions stored at the Pueblo Army Depot (PEO ACWA, 2019). In the United States, sulfur mustard occurs in artillery projectiles and mortar rounds. As of April 1, 2019, 25% of this stockpile has been destroyed with a completion deadline of December 31, 2023. Continuing research efforts are focusing on additional in-depth understanding of the mechanism of action of these agents through the development of experimental models for vesicant-induced injury, and development of therapeutic measures for the prevention and treatment of vesicant-induced injury.

Chapter 12

Riot control agents

Jaroslav Pejchal

Department of Toxicology and Military Pharmacy, Faculty of Military Health Sciences, University of Defence, Hradec Kralove, Czech Republic

12.1 Introduction

Nonlethal agents are a broad class of compounds intended to produce transient incapacitation of an individual or individuals. Incapacitating agents and riot control agents (RCAs) are separate classes of nonlethal agents. Although the two classes share the characteristic to incapacitate, a distinction must be drawn between these two types of agents. RCAs differ from incapacitating agents in several respects. RCAs are potent irritants of peripheral chemosensors. They possess relatively short onset and limited duration of action. These substances induce short-term toxic effects that subside within minutes after termination of the exposure. Modern RCAs have also a very high safety ratio compared with incapacitating agents and first-generation RCAs. Compared with RCAs, incapacitating agents are represented by centrally acting neuropharmacological compounds. Many incapacitating agents were developed during the Cold War and produced either limited lethality and/or prolonged morbidity. Consequently, incapacitating agents have been banned by international treaties recognized by the United States, including the Chemical Weapons Convention (CWC). Specifically, the CWC has placed a ban on the development, production, and possession of any chemical weapon intended to cause death or "temporary incapacitation." The United States considers these broad incapacitating agents as chemical warfare agents (CWAs). However, the United States does not recognize RCAs as CWAs; therefore, US policy considers them to be legal for use by civilian police or the military. The CWC does prohibit their use in times of war.

Although the field of nonlethal agents is diverse and interesting, we limit our discussion to only those agents considered to be RCAs. The goal of RCAs is to temporarily incapacitate through irritating the skin and mucosal membranes of the eyes, airways, and digestive tract. As a result of their short-term toxicity, they are used by military and law enforcement personnel to disperse crowds, clear buildings, and quell riots. Whereas RCAs are often thought of as "tear gas" or pulmonary irritants, they encompass more than this terminology would suggest. They are neither gases nor exclusively pulmonary irritants. Historically, RCAs were categorized as lacrimators, sternutators, and vomiting agents based on their predominant toxicity in the eyes, lungs, or digestive tract. This nomenclature is outdated because modern RCAs affect a wide variety of organ systems. This fact will be clearly evident in the subsequent discussion concerning their mechanism of action and toxicity. Today, RCAs comprise a diverse array of chemical compounds with similar toxic effects because of their introduction to the battlefield in the early part of the 20th century. Opinions, interpretations, conclusions, and recommendations are those of the author and are not necessarily endorsed by the US Food and Drug Administration.

12.2 History

The Chinese were perhaps the first to use pulmonary irritants with their stink bombs (Smart, 1996). The smoke emanating from them was a primitive sternutator designed to harass the enemy. RCAs were used during the Peloponnesian War in the 5th century BC when the Spartans used smoke from burning coal, sulfur, and pitch to temporarily incapacitate and confuse occupants of Athenian strongholds (Thoman, 2002). During antiquity, the Romans used irritant clouds to drive out their Spanish adversaries from hidden dwellings (Robinson, 1971). Almost all of these examples involved the use of incapacitating agents as an offensive tactical weapon as opposed to controlling crowds for defensive purposes.

The first modern RCA ever deployed was bromoacetone (BA) to control riots in Paris in 1912 (Swearengen, 1966). World War I (WWI) marked the modern age of CWAs (Fig. 12.1). During WWI, both German and

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00012-X

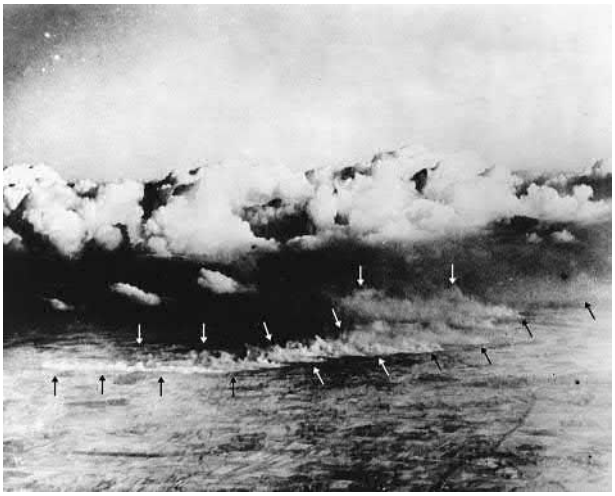

FIGURE 12.1 The birth of CWAs in WWI. The photograph depicts the initial chlorine gas attack by Germany at Ypres, Belgium, on April 22, 1915. The German Army released chlorine gas from cylinders to form a poisonous cloud (indicated by black and white arrows) directed toward the French lines by the prevailing winds.

French forces used a wide variety of irritating agents, such as acrolein (papite), chloropicrin (PS), and diphenylaminearsine (DM; Adamsite); however, BA was the most widely used lacrimator agent at that time. At the end of WWI, the US military investigated the use of chloroacetophenone (CN) as a chemical irritant. First developed by Graebe in 1869 and formulated as Chemical Mace, CN was the most widely used RCA until World War II (Olajos and Stopford, 2004). Two chemists, Corson and Stoughton (1928), synthesized 2-chlorobenzylidene malononitrile (CS); however, it was not adopted by the military as an official RCA until 1959. As a more chemically stable compound and having a greater potency with less toxicity than CN, it gradually replaced CN as the preferred RCA. CS was widely used during the Vietnam War to flush the Viet Cong out of the labyrinth of underground tunnels and bunkers throughout Southeast Asia (Fig. 12.2). In the years following the Vietnam War, other militaries adopted CS. Saddam Hussein's forces used it against Iran during the Iran–Iraq War of the 1980s. Today, CS is commonly used by law enforcement agencies and militaries for riot control training, respirator training in boot camps, temporary incapacitation of an assailant, and civil disturbances. A famous case of RCA use by the US Federal government involved CS dissemination on the Branch Davidian cult members in 1993. Because of its high flammability rating, CS was believed to be a large contributor to the inferno that burned down the Waco, TX, compound and killed its inhabitants. Even before fire broke out and destroyed the compound, CS concentrations supposedly ranged from five to 60 times the amount required to deter individuals (Bryce, 2000).

FIGURE 12.2 (Top) US Army Engineers unpack and test a Mighty-Mite blower in the jungles of Vietnam. The Mighty-Mite aerosolized and disperse smoke, CS powder, or other RCA as a means of tunnel denial. (Bottom) American soldiers ("tunnel rats") wearing M28 protective masks just before entry into underground tunnels previously saturated with CS. *Photograph (Top) Courtesy US Army Engineer School, Fort Belvoir, VA.*

During the 1980s and 1990s, the use of CS gas was rapidly on the decline and slowly being replaced by oleoresin capsicum (OC) spray. OC, an extracted resin from *Capsicum* pepper plants, was first developed in the 1970s as an alternative to CN and CS agents. Commercially available OC sprays used by the public are approximately 1% capsaicin, whereas formulations used by law enforcement agencies can contain up to 15% capsaicin. Most recently, a synthetic form of capsaicin called nonivamide, marketed as Captor, gained popularity as a defensive aerosol in the early 1990s (Olajos and Stopford, 2004).

Under the CWC of 1997, RCAs were banned from use as a method of warfare because in high concentrations RCAs are toxic chemicals with the potential to incapacitate individuals for prolonged periods, produce long-term sequelae, and cause death. The CWC allows RCAs to be used in domestic riot control as well as for enforcement

of domestic law and "extraterritorial law enforcement activities undertaken by military forces" (Rosenberg, 2003). These boundaries and definitions, although vague, were clarified in 2003 by President George W. Bush (Schmitt, 2003). Bush authorized the use of tear gas against Iraqi troops for defensive purposes as allowed in Executive Order 11850 of 1975. Many experts believed this would violate the CWC (which was not signed by Iraq) and give Saddam Hussein the power to use chemical agents against the United States under the authority of the Geneva Protocol (Schmitt, 2003). In the end, the use of RCAs by US military and multinational forces remained limited to rioting prisoners at detention centers during the postinvasion phase (Giovanello, 2012).

Currently, the utilization of RCAs for law enforcement purposes is widespread. In 2018, of the 193 states committed to the CWC, 127 declared holding of CS, 68 of CN, 50 of capsaicinoids, 14 of CR, and 17 of "other types" of RCAs (OPCW, 2019).

12.3 Background

12.3.1 The agents and their physicochemical properties

Unlike the majority of chemical agents that are liquid at room temperature, modern RCAs are crystalline solids with low vapor pressure (see Table 12.1). RCAs are typically administered as fine particles, aerosol sprays, or in solutions; therefore, they are not true gases. The inhalation toxicity of RCAs, as well as CWAs, is often indicated by the expression *Ct*. This term is defined as the product of concentration (*C*) in mg/m^3 multiplied by exposure time (*t*) in minutes ($mg\ min/m^3$). LCt50 and ICt50 are conventional terms used to describe airborne dosages that are lethal (L) or incapacitating (I) to 50% of the exposed population. The intolerable concentration (mg/m^3), ICt50, and minimal lethal concentration (mg/m^3) of the most common RCAs are provided in Table 12.1. The ocular irritancy threshold (minimal irritant or minimal effective dose), estimated human LCt50, and safety ratio are provided in Table 12.2 for these same RCAs. The modern RCAs are characterized by a high LCt50, low effective Ct50, low ICt50, low minimal irritating concentration, and large safety index ratio (LCt50/irritancy threshold). As a rule of thumb, clinical signs and symptoms from RCA exposure generally subside within 30 min but may persist, depending on the dose and duration of exposure (Blain, 2003). CN and CS are the classic representative agents of this class of compounds. The toxicity of both is discussed in depth because of the vast volume of literature available for these compounds.

12.3.1.1 Chloroacetophenone

CN is a crystalline solid with a strong, pungent odor (Fig. 12.3). It is dispersed as a smoke, powder, or liquid formulation from grenades or other devices. It is perhaps better known under the trade name Chemical Mace and was once used widely for self-protection. It was also the standard tear gas used by the military (Fig. 12.4) and police personnel. It has been replaced in favor of the less toxic CS for riot control and capsaicin pepper spray for self-defense.

CN exhibits the greatest toxicity among RCAs in use today. Consequently, it has been replaced by compounds with higher safety ratios. CN is 3- to 10-fold more toxic than CS in rats, rabbits, guinea pigs, and mice (Ballantyne and Swanston, 1978). Pathological findings in the lungs tend to be more severe and CN causes far greater edema. CN typically causes an acute, patchy, inflammatory cell infiltration of the trachea, bronchi, and bronchioles, in addition to early bronchopneumonia. CN not only demonstrates greater irritation to the skin than CS but also is a more potent skin sensitizer (Chung and Giles, 1972). Patients frequently exposed to CN are at high risk for development of allergic dermatitis (Penneys, 1971).

12.3.1.2 Ortho-chlorobenzylidene malononitrile

The term CS was adopted after the two chemists, Corson and Stoughton, who synthesized the compound. CS is a white, crystalline powder with a pepper-like odor and low vapor pressure (Fig. 12.5). It exists in three forms: CS, CS1, and CS2. CS identifies the compound in pure form, which is rapidly hydrolyzed after contact with water. CS1 is a micronized powder of crystalline agent containing 5% silica gel characterized by improved dissemination by an explosive burst or dusting apparatus. In CS2 form, the agent is microencapsulated with silicone to increase its weather resistance and flow properties (WHO, 1970).

CS is the most widely used RCA today, although many countries are switching to even less toxic compounds. CS is used by the US Armed Forces for gas discipline training exercises to help new recruits learn the importance of donning their protective masks quickly (Fig. 12.6). It was also used by the United States during the Vietnam War for tunnel denial and crowd control (Fig. 12.7) and by police forces for dispersing violent protests and incapacitating assailants.

12.3.1.3 Dibenz(b,f)-1:4-oxazepine

Dibenz(*b*,*f*)-1:4-oxazepine (CR) (Fig. 12.8) is a potent sensory irritant with less toxicity than CS or CN (Ballantyne, 1977). CR causes an immediate and effective irritation of the eyes, nose, and skin without persistent

TABLE 12.1 Physical characteristics and toxicity data for the common RCAs.

Agent	Discovered in	Physical characteristics			Toxicity data			
		Solubility	Vapor pressure (mmHg at 20°C)	Vapor density	Onset	Intolerable concentration (mg/m^3)	ICt50 (mg min/m^3)	Minimal lethal concentration[a] (mg/m^3)
CS	1928 (Corson and Stoughton)	Insoluble in water Soluble in organic solvents	0.00034	6.5	Immediate	5	3–10	2500
CN	1869 (Graebe)[b]	Poorly soluble in water	0.0054	5.3	Immediate	35	20–40	850–2250
DM	1915 (Wieland)[c] and 1918 (Adams)[d]	Insoluble in water Poorly soluble in organic solvents except acetone	2×10^{-13}	9.6	Delayed with long recovery period	5	22–150	1100–4400
CR	1962 (Higginbottom and Suschitzkey)	Sparingly soluble in water Stable in organic solvents	0.00059	6.7	Immediate	1	1	10,000
Bromobenzyl cyanide (CA)	1881 (Riener)[e]	Insoluble in water Soluble in organic solutions	0.12	4.0	Immediate	0.8	30	1100

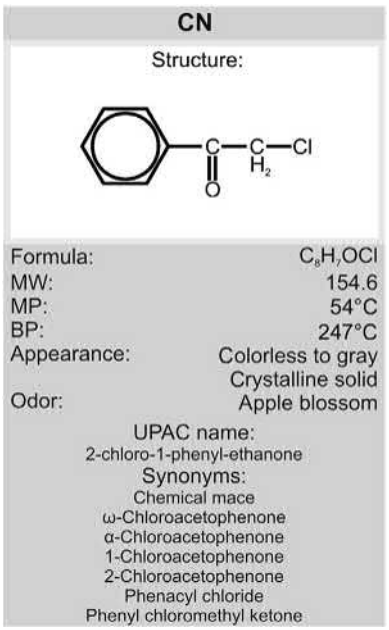

FIGURE 12.3 Chemical structure and physicochemical properties of chloroacetophenone (CN).

effects in these target organs. The irritation associated with CR is more transient compared with other RCAs. It is 5–10 times greater in potency than CS; therefore, a smaller concentration is needed to cause irritation (low minimal irritant concentration or dose) and incapacitation (low ICt50) (Tables 12.1 and 12.2). CR has a favorable safety ratio; it is safer than other RCAs based on its higher LCt50 (Table 12.1) and greater LCt50/irritancy

FIGURE 12.4 US soldier in protective clothing disseminating CN aerosol using the M33A1 disperser.

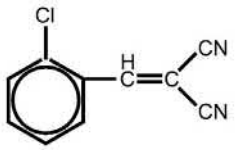
threshold (safety ratio). In humans, the effects caused by CR are identical to CS. The LCt50 for humans is estimated at $>100{,}000\ mg\ min/m^3$. Despite its reduced toxicity in humans, CR is not entirely without risk. CR is fairly stable, resists weathering, and persists in the environment (Sidell, 1997), therefore, enhanced toxicity may occur with prolonged exposure.

12.3.1.4 Diphenylaminechlorarsine

DM (Fig. 12.9) or Adamsite is a pro-emetic agent used in WWI. DM has greater toxicity than other RCAs and has been abandoned in favor of compounds with less toxicity and greater safety ratios. Although toxicity is typically

CS

Structure:



Formula:	$C_{10}H_5N_2Cl$
MW:	188.6
MP:	93°C
BP:	310°C–315°C
Appearance:	White, crystalline solid
Odor:	Pungent, pepper-like

UPAC name:
2-[(2-chlorophenyl) methylidene] propanedinitrile

Synonyms:
2-(2-Chlorobenzylidene) malononitrile
(ortho-Chlorobenzal)malononitrile
2-(Chloro-phenyl)methylenemalononitrile
(2-Chlorophenyl)methylenepropanedinitrile
β,β-Dicyano-ortho-chlorostyrene

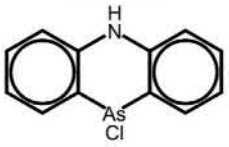
DM

Structure:



Formula:	$C_{12}H_9AsClN$
MW:	277.5
MP:	195°C
BP:	405°C–415°C
Appearance:	Yellow-green, crystalline solid
Odor:	No distinct odor, but irritating

Synonyms:
Adamsite
5-Aza-10-arsenaanthracene chloride
10-Chloro-5,10-dihydroarsacridine
10-Chloro-5,10-dihydrophenarsazine
Dibenzo-1-chloro-1,4-arsenine
Diphenylaminochloroarsine
Phenarsazine chloride

FIGURE 12.9 Chemical structure and physicochemical properties of diphenylaminechlorarsine (DM).

delayed with DM exposure, toxic signs and symptoms can occur within minutes after exposure. Systemic toxicity may also be more pronounced and prolonged. Symptoms often subside hours after exposure. Because DM is an antiquated RCA, this compound is irrelevant today and will not be discussed further.

12.3.1.5 Oleoresin capsicum

OC is an oily resin derivative from capsicums and is composed of several related compounds. Capsicums are solanaceous (nightshade species) plants from the genus *Capsicum*. More than 20 species fall within the genus. Capsaicinoids are considered the active ingredients of OC. These active compounds are endocrine products of

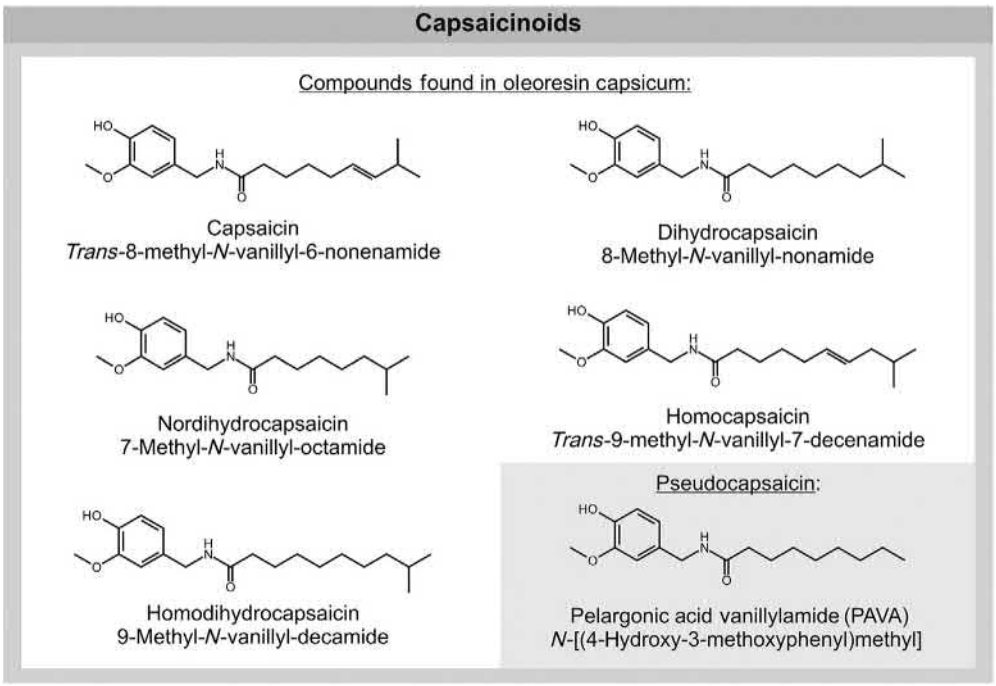


FIGURE 12.10 Chemical structures of the most common capsaicinoids found in OC.

glands found in the plant placenta and are a mixture of two unsaturated and three saturated homologs (Fig. 12.10). Capsaicinoids are isolated through a volatile solvent extraction of the dried, ripened fruit of chili peppers. The capsaicinoids are distilled, dried, and compounded together. The final oleoresin contains several branched-chain alkyl vanillylamides, in addition to capsaicin, the major component in OC. The predominant capsaicinoid components of OC are capsaicin (70%), dihydrocapsaicin (20%), norhydrocapsaicin (7%), homocapsaicin (1%), and homodihydrocapsaicin (1%) (Salem et al., 2006) (Fig. 12.10).

Capsaicinoids cause dermatitis as well as nasal, ocular, pulmonary, and gastrointestinal effects in humans. OC gained popularity in the 1990s as a defensive weapon for civilians and law enforcement agencies because they produce immediate, temporary immobilization and incapacitation when sprayed directly into the face or eyes. It is important to note that hand-held pepper spray formulations can contain OC by themselves or a mixture of OC and CS.

12.3.1.6 Pelargonic acid vanillylamide

Other capsaicinoids are available. Pelargonic acid vanillylamide (PAVA or nonivamide), shown in Fig. 12.10, is a "synthetic" form of capsaicin. Nonivamide was first synthesized by Nelson (1919). Nonivamide was originally found to be a minor component in *Capsicum annum* peppers (Constant et al., 1996); however, the majority of PAVA is derived from synthesis rather than by extraction from natural plant sources. As a result, the composition and concentration of PAVA can remain consistent (Haber et al., 2007).

For PAVA to work, it must be directed at the subject's eyes. The pain in the eyes is reported to be greater than that caused by CS tear gas (ACPO, 2006; Smith et al., 2004). The effects are immediate but will subside 15–20 min after exposure to fresh air. PAVA does display disadvantages. Although PAVA has a high rate of effectiveness, it has proven to be ineffective against those under the influence of alcohol (ACPO, 2006). Additionally, the Smith et al. (2004) study mentions a number of cases in which PAVA was used without effect. The effect of PAVA was also reported to be almost instantaneous, with the undesirable effect that recovery was also immediate. PAVA is commercially available in two forms, captor I and captor II. Captor I contains 0.3% PAVA with a solvent of equal parts of ethanol and water. Captor II contains 0.3% PAVA with propylene glycol, water, and ethanol (COT, 2007).

12.3.1.7 New potent compounds

Identification of CS, CN, and CR as agonists of transient receptor potential ankyrin 1 (TRPA1) implicated in inflammatory pain-related signals in 2008 (Brône et al., 2008) revived scientific interest in RCAs. Since then, new agonists and antagonists have been synthesized. Among them, several morphanthridine and CR derivatives show stronger agonism toward TRPA1 than conventional RCAs

(Gijsen et al., 2010). Their physicochemical properties as well as toxicities are not known. Nonetheless, the substances could provide a higher safety ratio than CR.

12.4 Mechanism of action

The mechanisms of action through which RCAs act are not completely understood. RCAs interact with neurons in afferent nociceptive fibers and target receptors within transient receptor potential (TRP) family of cation-selective channels. Currently, seven different subfamilies can be recognized within this family.

CS, CN, and CR are potent activators of TRPA1, the only member of the ankyrin subfamily found in mammals. These receptors are expressed in neurons and in some non-neuronal cell types, such as keratinocytes, melanocytes, fibroblasts, smooth muscle cells, and glial or endothelial cells (Viana, 2016). TRPA1 is best known as a sensor for environmental irritants, cold, and stretch (Annas et al., 2015). Genetic ablation or pharmacological inhibition of TRPA1 dramatically reduces acute pain behavior in mice after CS, CN, and CR exposure, confirming the essential role of TRPA1 in their sensory detection (Bessac et al., 2009). In human studies, CS, CN, and CR affinity to TRPA1 clearly correlates with their perceived irritancy (Lindsay et al., 2015). CS, CN, and CR are electrophilic alkylating compounds (Brône et al., 2008). From the chemical point of view, the electrophilic activators of the TRPA1 receptor bind to reactive cysteines within the intracytoplasmic N-terminus of the receptor in a covalent fashion by the mechanism known also as the Michael addition (Kádková et al., 2017).

Capsaicinoids selectively interact with transient receptor potential vanilloid 1 (TRPV1) receptor. The receptor is one of six members of the TRPV subfamily named for chemicals with a vanillyl moiety in its structure that activate this channel (Caterina et al., 1997). TRPV1 is coexpressed on the vast majority of TRPA1-expressing sensory nerves as well as on non-neuronal cells. Both receptors integrate a variety of noxious stimuli. TRPV1 is particularly responsive to diverse physical and chemical stimuli, including heat ($>43°C$), low pH (<6.0), or capsaicinoids (Fernandes et al., 2012). TRPV1 knockout mice exposed to capsaicin display significantly reduced pain-related behavioral responses, underscoring the important role of this ion channel (Caterina et al., 2000). Capsaicin interacts with its receptor following the traditional Fischer lock-and-key principle, which was demonstrated using high-resolution cryo-electron microscopy structures of TRPV1 in its apo and capsaicin-bound states (Yang et al., 2018).

Binding of RCAs to TRPA1 or TRPV1 causes channel opening, influx of Ca^{2+}, Na^{+}, and K^{+}, depolarization of the neuron, activation of signaling pathways, alteration of cyclooxygenases, and release of neuropeptides (Liu et al., 2016; Martling, 1987; Yamamoto et al., 2015; Zhang et al., 2007). TRPA1- and TRPV1-expressing sensory neurons release active substances, such as neurokinin A, substance P, and calcitonin gene-related peptide that produce changes in the airway mucosa and induce neurogenic inflammation of the respiratory epithelium, airway blood vessels, glands, and smooth muscle. This is associated with bronchoconstriction, increased vascular permeability, edema of the tracheobronchial mucosa, elevated mucosal secretion, and neutrophil chemotaxis (Tominack and Spyker, 1987). In addition, proinflammatory mediators, including bradykinin, prostaglandins, histamine, purines, and proteases upregulate expression of both channels (Bessac and Jordt, 2010). This positive feedback may explain increased sensitivity of asthmatics to RCA exposure, as well as exacerbation of asthma and inflammatory skin conditions after RCA exposure (Dimitroglou et al., 2015; Watson and Rycroft, 2005).

Additional mechanisms might be involved in toxicity of RCAs. CS, CN, and CR contain chloride atoms in their structure. Production of hydrochloric acid through reduction of chloride ions on mucosal membranes may help explain the marked, focal irritation and burns on the skin resulting from exposure to CS (Anderson et al., 1996; Worthington and Nee, 1999).

CS, CN, and CR are also SN_2 alkylating agents (Ballantyne and Swanston, 1978; Cucinell et al., 1971); in contrast, the vesicant mustard is an SN_1 alkylating agent. The SN_2 moniker describes direct reaction of the agent with nucleophilic compounds in a bimolecular fashion. In particular, they react with intracellular thiol or SH-containing enzymes, thereby inactivating them (Ballantyne et al., 1977). Mackworth (1948) first showed that CN and other first-generation lacrimators used during WWI (bromoacetophenone, ethyl iodoacetate, chloropicrin, and bromobenzyl cyanide) strongly inhibited thiol-containing succinic dehydrogenase and pyruvic oxidase, major players of crucial metabolic pathways. Some suggest that lactic dehydrogenase is completely insensitive to lacrimators (Mackworth, 1948), but only lacrimators from the iodoacetate family were ever studied by this group. Another group reported that lactic dehydrogenase is, in fact, strongly inhibited by CS (Cucinell et al., 1971). CS also reacts with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase system (Olajos and Salem, 2001). Alteration in dihydrolipoic acid biochemistry can lead to decreased acetyl CoA levels, resulting in cellular injury. Inactivation of these metabolic enzyme systems is, however, transient because the enzymes can be rapidly reactivated if exposure is terminated (Beswick, 1983). Less is known regarding the action of CR on thiol-containing molecules. But according to Brône et al. (2008) both CS and CR rapidly form adducts with benzylmercaptane in vitro.

The metabolism of CS to cyanide (see Section 12.5) was once thought to be responsible for agent-induced lethality in animals (Cucinell et al., 1971; Jones and Israel, 1970). Despite reports of alleged fatality cases, mortality in humans after CS administration has not been authenticated (Ballantyne et al., 1977; Olajos and Salem, 2001). CS has been demonstrated to cause death in dogs (Cucinell et al., 1971). CS is hydrolyzed to malononitrile and 2-chlorobenzaldehyde (Brewster et al., 1987). Further metabolism of malononitrile yields two potential cyanides, which could interact with sulfur thiols to yield thiocyanate. Cyanide typically causes death immediately, but animals administered CS by inhalation far more than the lethal *Ct* do not die immediately; death occurs 12−24 h after exposure. In fact, death seems to be attributable to airway and lung damage (Ballantyne and Swanston, 1978). Studies to ascertain cyanide production after CS exposure in humans showed negligible levels of plasma thiocyanate (Leadbeater, 1973). Another study revealed low levels of cyanide production in mice administered with ^{14}C-labeled CS (Brewster et al., 1987). In short, cyanide is not liberated in sufficient quantities from CS metabolism to become toxic enough to cause death. It may however alter an array of biochemical interactions, including lipid peroxidation (Johnson et al., 1987), neuronal calcium homeostasis (Johnson et al., 1986), and phospholipid hydrolysis (Sakaida et al., 1992), and amplify resulting tissue damage.

Additional mechanisms of action have been also identified in capsaicin-treated models. TRPV1-independent pathways were suggested to block complexes I and III of the respiratory chain, leading to the impairment of mitochondrial potential (Skrzypski et al., 2014). Moreover, capsaicin suppresses the plasma membrane NADH-oxidoreductase electron transport chain (Gonzales et al., 2014; Sánchez et al., 2007). Both mechanisms disrupt cellular redox homeostasis, stimulate ROS overproduction, and contribute to the cytotoxic effect. Interestingly, Thomas et al. (2011) demonstrated in normal and immortalized bronchial epithelial cells that there is a concentration threshold (∼200−250 μM), at which capsaicinoid analogs become cytotoxic independent of TRPV1 expression or function. Capsaicin TRPV1-independent mechanisms were also implicated in the regulation of voltage-gated potassium channels (Yang et al., 2014), lipopolysaccharide-induced fever (Mahmoud et al., 2007), or glycinergic neurotransmission in hypoglossal motor neurons (Thakre and Bellingham, 2019).

12.5 Toxicokinetics

The uptake, distribution, and metabolism of CS, CR, and capsaicins have been well characterized. In contrast, toxicokinetics of CN has been poorly characterized despite numerous investigations reporting its toxicity.

12.5.1 Uptake, distribution, and metabolism of ortho-chlorobenzylidene malononitrile

CS is rapidly absorbed and distributed throughout the body after inhalation exposure. Pharmacokinetic studies show that CS is removed from circulation quickly with first-order kinetics after inhalation exposure. CS half-life is just less than 30 s (Olajos et al., 2004). Short half-lives in the circulatory system are also demonstrated for the major CS metabolites (2-chlorobenzyl malononitrile and 2-chlorobenzaldehyde) (Leadbeater, 1973). The absorption of CS from the digestive tract in cases of exposure by ingestion is unknown at this time. Systemic toxicity has been noted after ingestion of CS pellets (Solomon et al., 2003).

In mammalian species, CS rapidly hydrolyzes to form 2-chlorobenzaldehyde and malononitrile (Leadbeater, 1973). The malononitrile intermediate is further metabolized from two cyanide moieties, which are converted to thiocyanate (Cucinell et al., 1971). The aldehyde intermediate undergoes oxidation to 2-chlorobenzoic acid or reduction to 2-chlorobenzyl alcohol. In rats, these metabolites are conjugated and excreted in the urine (80%−95%) and feces (Brewster et al., 1987). 2-Chlorohippuric acid was demonstrated to be the major CS metabolite. Its urinary concentration correlates with CS concentration during exposure and urine sampling time, showing the potential to be an effective retrospective indicator of CS in future biomarker developments (Buchanan et al., 2017).

12.5.2 Uptake, distribution, and metabolism of dibenz(*b,f*)-1:4-oxazepine

Absorption of CR after aerosol inhalation is rapid, with a plasma half-life of 5 min, this is consistent with half-life estimates after intravenous administration (Upshall et al., 1977) and gastrointestinal uptake (French et al., 1983). Corneal tissue has been demonstrated to take up CR and metabolize it to the lactam derivative (Balfour, 1978).

A number of studies have investigated the bioconversion, fate, and elimination of CR in various animal species (Balfour, 1978; French et al., 1983). Human metabolic studies of CR have not been performed because of the high degree of sensitivity of human tissues to CR. The maximum tolerated dosage is far too low to allow for detection in metabolic studies (Olajos et al., 2004). The lactam derivative dibenz[*b*, *f*]1:4-oxazepin-11-(10H)-one is a primary metabolic product of metabolism and a direct precursor of the urinary hydroxylated metabolites. In rats, the lactam, a dihydro-CR metabolite, an amino alcohol of

CR, and an arene oxide are metabolites in CR degradation. In the rat, the major mechanism for elimination is sulfate conjugation and biliary excretion to a limited extent. Phase I metabolism by microsomal mixed-function oxidases involves reduction of CR to the amino alcohol, oxidation to form the lactam ring, and hydroxylation to form the hydroxylactams. Phase II conjugation reactions sulfate the hydroxylactam intermediates for renal elimination. Amino alcohol intermediates are conjugated with glucuronide for biliary secretion.

12.5.3 Uptake, distribution, and metabolism of capsaicin

Capsaicin is well absorbed when administered topically or orally. Gastrointestinal absorption reaches up to 94%–98% (Leelahuta et al., 1983; Suresh and Srinivasan, 2010). The estimated plasma half-life varies from 0.4 to 1.6 h (Babbar et al., 2009; Chaiyasit et al., 2009). Capsaicin and capsaicinoids undergo phase I metabolic bioconversion to catechol metabolites via hydroxylation of the vanillyl ring moiety (Miller et al., 1983). Metabolism involves oxidative, in addition to nonoxidative, mechanisms. An example of oxidative conversion involves the liver mixed-function oxidase system to convert capsaicin to an electrophilic epoxide, a reactive metabolite (Olajos et al., 2004). Surh and Lee (1995) have also demonstrated the formation of a phenoxy radical and quinine product; the quinine pathway leads to formation of a highly reactive methyl radical (Reilly et al., 2003). Capsaicin dimers are known to be produced by the coupling of phenoxyl and/or carbon-centered radical intermediates (Surh and Lee, 1995). The alkyl side chain of capsaicin also undergoes rapid oxidative deamination or hydroxylation (Reilly et al., 2003) to hydroxycapsaicin as a detoxification pathway. An example of nonoxidative metabolism of capsaicin is hydrolysis of the acid–amide bond to yield vanillylamide and fatty acyl groups. Phase II involves formation of glutathione and *N*-acetylcysteine conjugates that are primarily excreted in the urine (Reilly et al., 2013).

12.6 Toxicity

RCAs produce a wide variety of physiological effects in humans. Fig. 12.11 illustrates toxic signs and symptoms

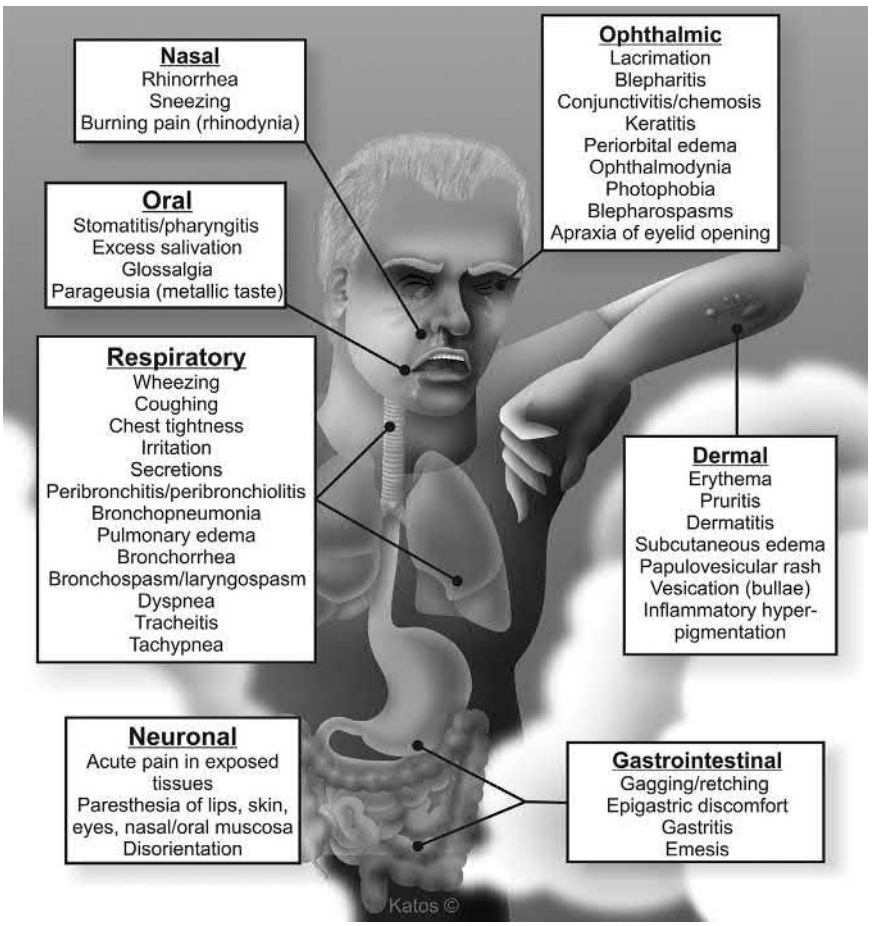

FIGURE 12.11 Physiological effects of riot control agents. *Illustrated, copyright protected, and printed with permission by Alexandre M. Katos.*

of exposure. The clinical effects in the figure are representative of those encountered after CN or CS exposure. CR causes effects qualitatively similar to those caused by CS, except it has greater potency. The predominant anatomical regions affected include eye, lung, and skin. RCAs also cause nasal, oral, neuronal, and gastrointestinal effects.

12.6.1 Ophthalmological effects

The eyes are a major target for the short-lived toxic effects of RCAs. Eye findings from RCA toxicity can range in severity from conjunctival erythema to ocular necrosis. Lacrimation, conjunctival erythema/edema, blepharitis, and erythema are the most typical findings after exposure to all RCAs. Toxic signs may further include periorbital edema (Yih, 1995), blepharospasm or spasms during eyelid closure (Blain, 2003; Grant, 1986), apraxia of eyelid opening, ophthalmodynia, corneal injury, and ocular necrosis (Grant, 1986). Fig. 12.12 illustrates and summarizes the common toxic ophthalmological signs and symptoms associated with RCA aerosol exposure. It is important to note that eye findings tend to be more severe in RCA exposure victims if they are wearing contact lenses (Solomon et al., 2003). The degree of the injury is also higher if eyes were anesthetized prior to the exposure (MacLeod, 1969).

12.6.1.1 Ortho-chlorobenzylidene malononitrile

After exposure to CS, the latency period for the development of ocular signs varies from immediate/few minutes to less than 24 h. Dimitroglou et al. (2015) reviewed 25 studies covering 90 cases of CS exposure. The ocular symptoms were present in 57% of cases and most frequently included lacrimation, eye irritation, conjunctivitis, and stinging of the eyes. There were also reports of

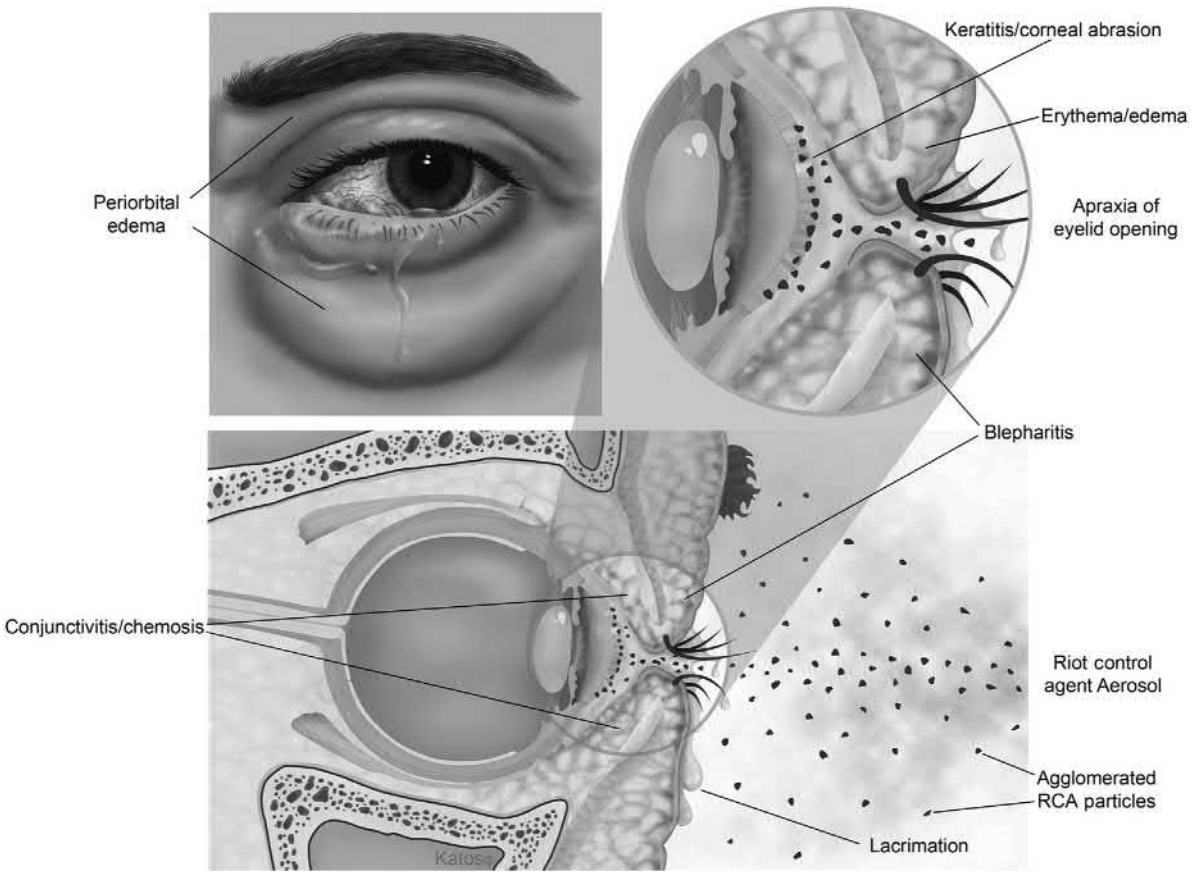

FIGURE 12.12 Exposure of the eye to CS aerosol. (Top left panel) External view of left eye immediately after exposure to CS aerosol, showing scleral injection, periorbital edema, and lacrimation. (Bottom panel) Penetration of CS aerosol into the eye, sagittal view. Following exposure to CS, the eye responds with inflammation, edema (chemosis), lacrimation, erythema, eye pain, and eyelid closure. (Top right panel) Close-up of the eye and eyelids, sagittal view. Inflammation of the eyelids (blepharitis), conjunctivae (conjunctivitis), and cornea (keratitis) are apparent. The eye, in turn, responds with spasms of eyelid closure (blepharospasms) followed by an inability to open the eyelids (apraxia of eyelid opening). Agglomerated CS particles can penetrate the eye on initial contact and cause corneal abrasions. *Illustrated, copyright protected, and printed with permission by Alexandre M. Katos.*

blepharospasm with excessive blinking of the eyes, keratitis, and transient reduction of vision. Recovery is typically complete within 15–30 min after exposure, but a few signs such as erythema of the lid margins and photophobia may persist up to 48 h (Ballantyne et al., 1974), depending on the concentration and duration of exposure (Blain, 2003). The conjunctivae may appear injected or even progress to fulminant conjunctivitis and blurred vision after some RCAs, including CS (Euripidou et al., 2004).

In studies involving human exposure (Rengstorff and Mershon, 1969a,b), CS (0.1% or 0.25% in water; 1.0% in triocyl phosphate) sprayed or administered as ophthalmic drops onto the eyes caused apraxia of eyelid opening with blepharospasm on eyelid closure for 10–135 s. It also caused a transient conjunctivitis but no corneal damage on further inspection with a slit lamp. Rabbit eyes contaminated with CS as a solution (0.5%–10% in polyethylene glycol), as a solid, or thermally dispersed as a smoke (15 min at 6000 mg/m^3) showed greater toxicity with solution. CS in solution caused profuse lacrimation, conjunctivitis, iritis, chemosis, keratitis, and corneal vascularization at concentrations of 1% or more. The lesions tended to be more severe and have a greater duration at higher doses. Histologically, the cornea appeared with patchy denudation of the epithelium and infiltration of neutrophils to the site of injury (Ballantyne et al., 1974).

The eyes are also affected by a CS agent without direct contact between the agent and the eye. In one report, seven patients were exposed to oral ingestion of a juice drink contaminating CS pellets (Solomon et al., 2003). In addition to mild headache and gastrointestinal irritation, they reported ocular irritation and lacrimation. The majority of symptoms resolved within 24 h.

12.6.1.2 Chloroacetophenone

CN causes a similar constellation of ocular signs and symptoms as CS, but CN toxicity is likely to be more severe in the eyes and skin. CN sprayed into the eyes from a distance causes lacrimation, edema of the corneal epithelium and conjunctivae, and reversible epithelial defects of the cornea (Leopold and Lieberman, 1971). Toxic signs in the conjunctivae from CN Mace exposure can include conjunctivitis, sloughing, limbal ischemia, and symblepharon formation (adhesion of the eyelids to the eyeball) (Scott, 1995). Permanent eye injury is unlikely, except after exposure to high concentrations of CN Mace (Grant, 1986). Although permanent eye damage is uncommon, increased intraocular pressure from edema may precipitate acute angle closure glaucoma if left untreated.

Because RCAs are solids, it is possible for a particle to clump or agglomerate, causing penetration into corneal or conjunctival tissues (Fig. 12.12). Agglomerated CN particles can penetrate eye tissue as a result of tear gas cartridge discharge (Levine and Stahl, 1968). CN powder coalesces over time; therefore, the mechanical damage is greater with the use of old cartridges (Laibson and Oconor, 1970). In addition to large powder CN agglomerates, traumatic effects from the propellant charge, wadding, or foreign pieces from the cartridge should also be suspected when evaluating eye damage from CN.

Although RCAs produce short-lived effects, rabbits exposed to 10% CN solution caused iritis and conjunctivitis for more than 7 days and caused corneal opacity (Grant, 1986) lasting longer than 2 months (Gaskins et al., 1972). CS at the same concentration produced moderate conjunctivitis without iritis or corneal opacity, and eyes returned to normal within 1 week. Another difference between the two agents is that CN produces a more severe reaction than CS when applied to the eye in powder form or as a spray at close range (McNamara et al., 1968).

In addition to opacification, corneal effects from particulate CN exposure may include possible penetration of the corneal stroma, melanosis, severe scarring and ulceration, and deficits in the corneal reflex (Blain, 2003; MacLeod, 1969; Scott, 1995). Penetration of the corneal stroma may lead to stromal edema and later vascularization, resulting in further ocular complications. These may include pseudopterygium, infective keratitis, symblepharon, trophic keratopathy, cataracts, hyphema, iridocyclitis, posterior synechia, deformities of anterior chamber angle, secondary glaucoma, vitreous hemorrhage, and traumatic optic neuropathy (Gray and Murray, 1995; Hoffmann, 1967; Leopold and Lieberman, 1971). Furthermore, a 4% CN formulation produced permanent corneal injury but a 10% CS product did not (Gaskins et al., 1972). In animal studies, high concentrations of CN produced ocular necrosis (Grant, 1986).

12.6.1.3 Dibenz(b,f)-1:4-oxazepine

Higginbottom and Suschitzky (1962), who discovered CR, first noted the intense lacrimal response to this compound. A splash of CR (0.01%–0.1% range solution) causes immediate ophthalmodynia, lacrimation, and blepharospasm, similar to CS and CN (Sidell, 1997). These effects can last 15–30 min before subsiding. Blepharitis (edema of the eyelids), periorbital edema, and injected conjunctivae can last for up to 6 h. In rabbits and monkeys, CR (0.1% solution) causes mild transient erythema, chemosis, and keratitis in the eye. Moderate conjunctivitis has been demonstrated with higher CR concentrations (5% solution) applied directly to the rabbit eye (Rengstorff et al., 1975). Ballantyne et al. (1975) showed that increasing CR concentrations as a solution

caused dose-dependent corneal thickening but minor eye effects (mild conjunctivitis and lacrimation) as an aerosol. In animal studies, the effects of CR are very transient and produce far less toxicity to the eye than CN (Salem et al., 2006).

12.6.1.4 Capsaicin

Contact of the eyes with OC causes redness, swelling, pain, tingling, lacrimation, and blepharospasm (Yeung and Tang, 2015). In a retrospective study of 81 patients who presented to the emergency department after aerosol exposure from law enforcement use of OC, 56% of individuals developed ophthalmodynia, 44% developed conjunctivitis, 40% developed conjunctival erythema, 13% developed lacrimation, and 9% developed corneal abrasions (Watson et al., 1996). Kearney et al. (2014) systematically reviewed human exposures to OC recorded into the electronic database of the California Poison Control system during 2002−11. Of the 3671 victims, 1913 (52.1%) reported an ocular route of exposure. Of these, 161 (8.4%) suffered from more severe ocular symptoms that required medical attention, such as persistent pain (more than an hour beyond the completion of a sufficient eye irrigation), reduction of vision, sensation of foreign body, photophobia, discharge or exudate, or periorbital swelling. These symptoms are suggestive of a possible corneal abrasion, iritis, or ocular infection, and persisted from a minimum of 3 h to 5 days. Another study involved exposure of 47 human volunteers to OC for evaluating effects on the cornea and conjunctivae (Zollman et al., 2000). All subjects reported significant eye pain, blurred vision, and lacrimation 10 min after exposure to OC pepper spray, but symptoms improved by 1 h later. Corneal abrasions were not apparent, but 21% of subjects showed evidence of punctate epithelial erosions and reduced corneal sensitivity. Corneal abnormalities were absent 1 week after exposure.

Long-lasting or permanent ocular injuries after OC exposure are rare. Gerber et al. (2011) reported conjunctival proliferation in a young child after OC spray injury which was refractory to steroid therapy. A complete excision of the proliferative tissue was performed 6 weeks after the injury with no recurrence during 2 months of follow-up. Rasier et al. (2015) observed a decrease in tear production in OC victims associated with impaired corneal reflex lacrimation. Additionally, Epstein and Majmudar (2001) reported a case with persisting corneal stromal opacity resulting in irregular astigmatism.

In mice, a single subcutaneous injection of 12.5, 25, or 50 mg/kg capsaicin causes corneal changes characterized by neuronal axon degeneration in the corneal epithelium (Fujita et al., 1984). In rats and rabbits, capsaicin instilled in the eyes (at concentrations up to 100 μg/mL) induces acute irritation, marked disorganization of the corneal epithelia and stroma, and increases opacity, while it decreases corneal membrane permeability, reduces tear secretions and nerve conduction, and increases the expression of inflammatory cytokines (Krishnatreyya et al., 2018).

12.6.2 Nasal/pharyngeal toxicity

RCAs produce oral and nasal symptoms immediately after exposure. Inhalation exposure to CS and CN causes rhinorrhea, sneezing, and burning pain within seconds (Beswick, 1983); a similar burning sensation with increased salivation occurs after oral contact with aerosolized powder or solution. The salivation, pharyngitis, and glossalgia occur within minutes after exposure (Beswick, 1983; Thorburn, 1982). A CR solution (0.01%−0.1% range) splashed in the mouth causes salivation and burning of the tongue and palate for several minutes. Splashes of the solution can cause nasal irritation and rhinorrhea (Sidell, 1997). Fumes from burned *Capsicum* plants or capsaicin-containing pepper sprays are highly irritating to the nasal mucosa and cause immediate rhinorrhea (Geppetti et al., 1988).

12.6.3 Cardiovascular toxicity

RCAs have apparent effects on the cardiovascular system. The response of vessels depends on their localization. For instance, in skin, TRPA1 agonists induce a biphasic reaction associated with vasoconstriction through TRPA1-dependent superoxide production stimulating α_{2C}-adrenoceptors and Rho-kinase-mediated MLC phosphorylation, followed by vasodilation via sensory nerve-derived neuropeptides and neuronal nitric oxide (Aubdool et al., 2014; Pan et al., 2018). Vasodilation has been observed in brain and mesenteric arteries by endothelium-dependent mechanisms (Jin et al., 2019; Pires and Earley, 2018).

Inhalatory exposure to CS in vivo is, however, associated with tachycardia and mild hypertension (Beswick, 1983). Bypassing the pain receptors of the nose and upper airway by endotracheal administration of CS leads to a decrease in blood pressure, effects also seen after intravenous injection. This suggests the initial pressor effect (together with irregular respiration) is possibly a generalized response to noxious stimuli, whereas the bypass causes vasodilation through pulmonary nerve-derived neuropeptides and vagal reflexes. Similar results were found in CR models. Splash contamination of the face or whole-body drenching with dilute CR solution (0.0010% and 0.0025%) causes an immediate increase in blood pressure and bradycardia (Ballantyne et al., 1976). Intravenous administration of CR in cats causes transient but dose-dependent tachycardia. These pressor effects are

postulated to be secondary to CR effects on sympathetic tone to the cardiovascular system or the result of stress and discomfort from the irritation (Ballantyne, 1977; Ballantyne et al., 1977).

TRPA1 agonists have been also shown to have a direct effect on the heart. *TRPA1* activation contributes to Ca^{2+} overload and hypercontraction, worsens myocardial infarction in an ischemia/reperfusion model (Conklin et al., 2019), and increases myocardial dyssynchrony (Thompson et al., 2019). Although Brimblecombe et al. (1972) demonstrated no significant effects of CS on isolated perfused rabbit heart, another report linked exposure of high CS concentrations to the development of congestive heart failure (Hu et al., 1989). Furthermore, underlying cardiac disease has been shown to exacerbate toxicity from CS (Worthington and Nee, 1999).

Capsaicins act on the cardiovascular system largely as agonists of TRPV1. Capsaicin enhances adrenal medullary adrenaline secretion, transiently elevating heart rate and blood pressure in humans (Hachiya et al., 2007). When administered intravenously in rats, a triphasic pressure response is produced, including immediate hypotension, intermediate recovery, and delayed hypotension. Bradycardia occurs at immediate and intermediate phases through stimulation of vagal C-fibers. Vagotomy abolishes immediate hypotension and potentiates the intermediate recovery as hypertensive response (Dutta et al., 2013; Teófilo et al., 2019). A similar triphasic response was found after intravenous injection of nonivamide or nonivamide succinate (Yeh and Chen, 1991). TRPV1 activation is also associated with vasoconstriction of coronary vessels (Szolcsanyi et al., 2001). This is possibly mediated by endothelin release from sensory nerve terminals (Ohanyan et al., 2011). Such a mechanism might explain myocardial infarction (Cil et al., 2012) and two deaths reported in victims with preexisting heart arrhythmia and coronary artery disease following OC exposure (Toprak et al., 2015).

12.6.4 Respiratory toxicity

RCAs are disseminated as an aerosol powder or solution. Therefore, inhalation is a common route of absorption. Inhalation of RCAs causes burning and irritation of the airways, leading to cough, chest tightness, dyspnea (Beswick, 1983; Blain, 2003; Hu et al., 1989), shortness of breath (Euripidou et al., 2004), bronchospasm, and bronchorrhea (Folb and Talmud, 1989).

12.6.4.1 Ortho-chlorobenzylidene malononitrile

According to Dimitroglou et al. (2015), respiratory clinical effects have been reported in 40% of cases after contact with CS. The latency varies from immediate/a few minutes to 2 weeks. Although the symptoms are usually mild and self-limiting, CS has been associated with serious pulmonary complications, including reactive airways dysfunction syndrome, hypersensitivity with pneumonitis and bronchoconstriction, laryngeal obstruction, or laryngospasm.

Laryngospasm can occur immediately or may be delayed for 1−2 days after CS exposure.

Reactive airways are associated with high-level exposure to CS (Blain, 2003). Pulmonary effects typically resolve by 12 weeks after exposure. Roth and Franzblau (1996), however, demonstrated that paroxysmal cough, shortness of breath, and chest tightness, the characteristics of reactive airway disease, may last up to 2 years and can be associated with a need for daily medication.

Pulmonary edema may occur up to 24 h after exposure (Stein and Kirwan, 1964). Delayed-onset bronchopneumonia might occur from prolonged exposure to some RCAs in enclosed spaces (Beswick, 1983). Krapf and Thalmann (1981) reported a 43-year-old man who developed pulmonary edema complicated by pneumonia, heart failure, and hepatocellular damage after contact with CS. Furthermore, in two cases, overexposure to a mix of CS and CN and a mix of CS and OC was the cause of death due to acute necrotizing laryngotracheobronchitis and pulmonary injury, respectively (Toprak et al., 2015).

There is no evidence that CS causes permanent lung damage after one or several exposures to field concentrations (Blain, 2003). Inhalation of an irritant might be expected to exacerbate underlying pulmonary disease such as asthma, emphysema, or bronchitis. Histories of asthma and chronic obstructive pulmonary disease may exacerbate effects from CS (Worthington and Nee, 1999). CS may exacerbate chronic bronchitis or precipitate an attack in individuals with known asthma (Anonymous, 1971). A higher risk of respiratory illnesses was also observed in recruits exposed to CS (Hout et al., 2014).

In animal studies, exposure to aerosol CS (unreported concentration) in male Wistar rats for 20 min can cause decreased minute ventilation and induce histological lesions of the trachea (cytoplasmic vacuoles in epithelial cells) and lung (emphysema) (Debarre et al., 1999).

12.6.4.2 Chloroacetophenone

CN may present symptoms similar to CS. The deaths resulting from prolonged exposure to CN in enclosed spaces were reported to result from pulmonary injury and/or asphyxia due to acute pulmonary edema or necrotizing laryngotracheobronchitis (Blain, 2003; Kim et al., 2016).

In animal models, the cause of death from CN inhalation is also the result of toxicity in the pulmonary system. Postmortem examination from acute toxicity lethality

studies in animals exposed to CN aerosols reveal pulmonary congestion, edema, emphysema, tracheitis, bronchitis, and bronchopneumonia in dogs, and pulmonary congestion, edema, and bronchopneumonia in mice, rats, and guinea pigs (Olajos and Salem, 2001). Sublethal CN aerosol exposure (62.6 mg/m^3, 0.1 LC50) for 60 min causes cellular degeneration in the bronchiole epithelium and alveolar septa thickening attributable to infiltration of mononucleocytes (Kumar et al., 1995).

12.6.4.3 Dibenz(b,f)-1:4-oxazepine

CR does not produce any significant respiratory toxicity (Sidell, 1997). It causes tachypnea and labored breathing in multiple animal species. In humans, aerosol exposure to CR causes respiratory irritation, choking, and dyspnea. One human study involving aerosol exposure to CR (0.25 mg/m^3) in volunteers for 60 min noted decreased expiratory flow rate minutes after exposure. CR was thought to stimulate irritant receptors in the conducting portion of the pulmonary system, causing bronchoconstriction (Ashton et al., 1978). Additionally, CR increased blood volume in the lungs by driving sympathetic tone. Two animal studies evaluated the effect of CR aerosol exposure on the physical and ultrastructural changes in rat lungs (Colgrave et al., 1983; Pattle et al., 1974). Even high CR aerosol doses did not produce significant pulmonary damage. Gross examination of the lungs was normal in both studies. Microscopic examination showed mild congestion, lobar hyperinflation characteristic of emphysema, and hemorrhage. Further pulmonary damage was evident on electron microscopy. CR-exposed lungs showed capillary damage of the endothelium and a swollen epithelial layer.

12.6.4.4 Capsaicin

Minor and self-limiting symptoms, such as cough and transient irritation, were usually observed following OC exposure. Severe adverse effects were observed only in 2.0%–10.7% of cases (Haar et al., 2017; Kearney et al., 2014) and included shortness of breath, chest tightness, and wheezing (Kearney et al., 2014).

In children, capsaicin spray was demonstrated to cause severe bronchospasm and pulmonary edema (Billmire et al., 1996). In the Billmire study, a 4-week-old infant was exposed to 5% pepper spray after discharge from a self-defense device. The infant suffered respiratory failure and hypoxemia requiring immediate extracorporeal membrane oxygenation. Inhaled capsaicin also causes an immediate increase in airway resistance (Fuller, 1991). This bronchoconstriction is dose-dependent (Fuller et al., 1985) and more pronounced in patients with chronic idiopathic cough or asthma (Johansson et al., 2019). While deaths are rare, Toprak et al. (2015) reported several cases related to OC exposure and respiratory failure. The causes of death were associated with asphyxiation due to bronchospasms, acute bronchial asthma, or acute laryngeal edema.

12.6.5 Neurologic toxicity

RCAs are irritants to the peripheral nervous system (COT/COM/COC, 1999), inducing discomfort, burning pain, and associated reflexes. Their neurologic toxicity can range from paresthesias of the lips to burning pain of the eyes (ophthalmodynia), tongue (glossalgia), nose (rhinodynia), throat (pharyngodynia), and skin (dermatalgia). Because RCAs affect the senses, the feeling can become disorienting after exposure, which may explain why some experience temporary loss of balance and orientation after exposure (Thorburn, 1982).

According to Anderson et al. (1996), headache appears to be a common neurologic sign among symptomatic CS victims. Agitation and panic may develop in those not previously exposed to CS and CN (Beswick, 1983; Stein and Kirwan, 1964). Syncope has also been reported (Athanaselis et al., 1990; Thorburn, 1982), but this is likely attributed to panic. When CN was released into 44 prisoner cells, eight inmates experienced malaise and lethargy; among those hospitalized, one experienced syncope and a severe systemic illness (Thorburn, 1982).

A clinical case report of hand injuries caused by accidental discharges from tear gas pens (Adams et al., 1966) revealed specific neuronal toxicological findings. In each case, CN penetrated into the skin to cause a wound. Neurological examination indicated hyperesthesia of select digits in all cases. Biopsies of digital neurons performed for pathology showed thickened epineurium and tendon sheaths. Some of the patients reported paresthesias months after exposure. The study suggests a possible link between direct chemical injury and nerve damage. The same investigators exposed the sciatic nerves of rabbits to the agent by discharge of a CN pen or by dusting the exposed nerve with 0.2 g CN powder. These animal studies suggested that CN can cause inflammation and necrosis in skeletal muscle, loss of axon cylinders, and replacement of neural elements with granulation tissue and fibroblasts (Adams et al., 1966). Animals exposed to CR exhibit fasciculations, tremors, convulsions, and ataxia; intraperitoneal administration of CR can also cause muscle weakness (Salem et al., 2006). These symptoms can be linked with TRPA1 receptors or their function (Nirenberg et al., 2018). In addition, Schwann cells express TRPA1 receptors. Schwann cell TRPA1 mediates neuroinflammation that sustains macrophage-dependent neuropathic pain in mice (De Logu et al., 2017). However, the exact role of TRPA1 in peripheral neuronal damage after RCA exposure remains unknown.

Activation of TRPV1 leads to transitory excitation followed by a prolonged refractory period, indicative of an apparent nonconducting and desensitized state of the receptor. Capsaicin renders the eyes and skin of humans and animals insensitive to various types of painful chemical stimuli (Bernstein et al., 1981). In humans, OC exposure eventually causes loss of the corneal blink reflex (Olajos and Salem, 2001). Furthermore, capsaicin when applied at high doses is an ablative agent for pain-sensing neurons. The mechanism is possibly related to the influx of Ca^{2+} and Na^{+} leading to cell swelling, mitochondrial Ca^{2+} loading, and production of reactive oxygen species (Pecze et al., 2016). Administration of capsaicin in neonatal rats causes destruction of the dorsal root ganglion neurons (Jancsó et al., 1977).

Concerns have been raised about the psychiatric effects of RCAs. Unuvar et al. (2017) explored psychiatric morbidity in a group of individuals seeking medical care for injuries after the 2013 Gezi Park protests in Turkey. The police reported that they mostly used OC and CS as RCAs. Psychiatric evaluations were conducted in 117 cases. Of these, 83 (71%) met the diagnostic criteria for acute stress disorder, posttraumatic stress disorder, or major depressive disorder.

12.6.6 Gastrointestinal toxicity

In a systemic review covering 90 cases, gastrointestinal effects were reported in 13% of cases after contact with CS (Dimitroglou et al., 2015). Salivation, nausea, vomiting, anorexia, abdominal pain, diarrhea, hematemesis, mouth ulcers, and alterations in taste have been reported in clinical case reports of exposure to CS (Anderson et al., 1996; Athanaselis et al., 1990; Solomon et al., 2003) and CN (Blain, 2003; Thorburn, 1982). The involvement of retching and emesis tends to occur if the individual is sensitive, the concentration is sufficiently high, the exposure is prolonged, the range is close, or the event occurs in a confined space. Vomiting was reported in 25% of patients with severe reactions to CN in a confined area (Thorburn, 1982). Emesis did not resolve until the following week in one patient. Inhalation of RCAs often leads to parageusias or altered taste of the tongue. In particular, a metallic or burning sensation is often reported (Folb and Talmud, 1989).

Ingestion of CS can also produce episodes of nausea, vomiting, crampy abdominal pain, and diarrhea (Blain, 2003; Solomon et al., 2003). Seven patients in the Solomon study drank juice contaminated with CS pellets and primarily developed gastrointestinal symptoms. Two of the seven patients reported emesis and diarrhea; all patients reported abdominal pain, epigastric discomfort, and burning gastroesophageal reflux. Symptoms resolved 24 h later. Surprisingly, they did not develop parageusia or burning of the tongue after CS ingestion, which is often the case after inhalational CS exposure. Another study designed for patients to taste an admixture of sugar and CS (5−10 pellets, 500 mg each, dissolved in 10 L of water) indicated that patients experienced a 30 s delay in onset of altered taste (Kemp and Willder, 1972); this was most likely because of a masking effect from the sugar. In animal studies, rabbits and rats develop gastroenteritis on CN or CS exposure by ingestion (Gaskins et al., 1972).

Gastrointestinal symptoms have been documented also following contact with OC. According to the electronic database of the California Poison Control system during 2002−11, ingestion was the primary route of exposure in 4.2% of cases. Severe symptoms that required medical attention were extremely rare (0.05%) (Kearney et al., 2014). The symptoms usually include mouth irritation, nausea, and vomiting (Ballantyne, 2006). Nausea has also been reported in individuals exposed to pepperball tactical powder containing capsaicin (Hay et al., 2006). Capsaicin causes effects on gastric mucosa, including mild erythema, edema, epithelial cell damage, and gastric hemorrhage (Desai et al., 1977).

12.6.7 Dermatological toxicity

RCAs are primary irritants of the integumentary system. Skin can be sprayed directly. However, hours after dissemination, CS, CN, or CR can pose a toxic danger because they are persistent in the environment. During the riots of the late 1960s, CS was frequently used to control crowds. Inadvertently, firefighters in those metropolitan areas sometimes were exposed as they entered buildings where CS had been disseminated. The force of water from fire hoses and movement within the buildings reaerosolized enough agent to cause erythema and edema around the eyes and other areas of exposed skin (Rengstorff and Mershon, 1969a). In 2003, a number of staff working in a retail store in Scotland became ill after the delivery of furniture exposed to CS, which was used to detect unauthorized stowaways aboard a vehicle (Hankin and Ramsay, 2007).

12.6.7.1 Ortho-chlorobenzylidene malononitrile

According to Dimitroglou et al. (2015), dermatitis is described in 61% of cases following contact with CS. The latency varies from immediate/a few minutes to 2 weeks depending on the symptom. Low concentrations cause erythema, pruritis, subcutaneous edema, paresthesias, and/or burning sensations in exposed areas of the skin within minutes. Burning sensation and erythema are often the first signs of contact dermatitis, subsiding approximately 1 h after exposure. These agents follow a time course of

skin damage similar to that of mustard agent. Further, if the skin is wet or abraded, then the toxic effects on the skin are more prominent (Holland and White, 1972; Sidell, 1997; Thorburn, 1982). Exposure to higher doses leads to worsening erythema, edema, vesication with bullae (observed hours later), and fever. Typically, edema and vesiculation (bullae dermatitis) occur 24 h after CS exposure (Sidell, 1997). Ongoing skin contact can cause wound overgranulation, hypertrophic scarring, or burns requiring surgical debridement and grafting (Agrawal et al., 2009).

The extent of toxic effects also depends on the thickness of the stratum corneum and time of exposure. Furthermore, contact with water up to 48 h after exposure can exacerbate the painful symptoms (Blain, 2003; Pinkus, 1978). High humidity, diaphoretic subjects, and warm temperatures can all exacerbate the contact dermatitis from RCAs (Hellreich et al., 1969). Areas of occlusive dress over the skin may also result in worse reactions. Common sites of bullae are areas under the cuff of a shirt or glove and just under the collar. One study examined the effect of high CS concentrations (300 mg/m^3) tested on the arms of volunteer study patients for exposure times ranging between 15 and 60 min (Hellreich et al., 1967). All participants experienced burning pain approximately 5 min after exposure onset. A Ct range of 4440−9480 mg min/m^3 caused immediate patchy erythema, which subsided after 30 min. A Ct range of 14,040−17,700 mg min/m^3 led to greater dermal toxicity and required several hours to subside. Bullous dermatitis occurred in 50% of subjects as a delayed reaction. These bullous lesions resolved in 2 weeks, but an inflammatory hyperpigmentation of the skin remained 6 weeks after exposure. Differences in individual sensitivities are attributable to skin pigmentation, complexion, and susceptibility to sunburns (Hellreich et al., 1969).

Dermal exposure to CS may lead to allergic contact dermatitis (Watson and Rycroft, 2005), a delayed hypersensitivity reaction that develops from a previous exposure to RCAs. Initial exposure to CS may not cause significant toxic signs or symptoms. Exposure to small amounts of the same agent years later, however, it may produce a severe allergic erythematous, patchy rash with edema, bullae, purpura, and necrosis. Sensitization is likely to occur after dermal exposure to high concentrations of RCAs (Holland and White, 1972). Hypersensitivity reactions can persist for up to 4 weeks. This phenomenon has been demonstrated so far by CN (Frazier, 1976; Ingram, 1942) and CS (Ro and Lee, 1991), but not CR.

12.6.7.2 Chloroacetophenone

CN is a more potent irritant than CS. In a human study involving dermal application, CN (0.5 mg) powder caused irritation and erythema when applied on the skin for 60 min (Holland and White, 1972). It took 20 mg CS to cause similar effects for the same duration of exposure. CN is also a more potent sensitizer (Chung and Giles, 1972).

12.6.7.3 Dibenz(b,f)-1:4-oxazepine

Dermal exposure to CR causes a burning sensation and erythema several minutes later. The burning pain goes away after 15−30 min, but the erythema lasts up to 2 h (Holland, 1974). CR does not induce inflammatory cell migration to the site of injury, bullous dermatitis, or contact sensitization (Ballantyne et al., 1977). Repeated application of CR to the skin (applied 5 days/week for 12 weeks) has little effect (Marrs et al., 1982). Similarly to the eye and lungs, CR does not demonstrate significant toxicity to the skin.

12.6.7.4 Capsaicin

A dermal route of exposure was observed in 59.5% of cases. Severe symptoms, such as rash and blisters, are present in 2.8% of exposed individuals (Kearney et al., 2014). Symptoms usually involve immediate and severe erythema and edema in the skin (Herman et al., 1998). Similarly, pepperball pellets fired at individuals will cause erythema, pain, and edema at the site of impact. The initial point of contact may become infected, scar, or heal with hyperpigmentation (Hay et al., 2006). Although capsaicinoids may have a vesicant effect, depending on the length of exposure, in most cases it produces only a burning sensation and mild erythema (Herman et al., 1998; Watson et al., 1996). Skin blistering and rash may occur after chronic or prolonged capsaicin exposures. Capsaicin can cause allergic contact dermatitis (Lambrecht and Goossens, 2015).

12.6.8 Other toxicity

One report noted renal tubular nephritis in a worker killed after an explosion inside a plant manufacturing CS agent (Cookson and Nottingham, 1969). Hepatocellular injury has been linked to serious CS inhalation (Krapf and Thalmann, 1981). To date, animal studies have not documented any relationship between RCA exposure and teratogenicity (Folb and Talmud, 1989; Upshall, 1973). CS did not demonstrate mutagenic potential with the Ames assay (Rietveld et al., 1983) and lacks mutagenicity in several test systems (Wild et al., 1983). Ames assay did not reveal any genetic toxicity of CN (NTP, 2018). CR did not have carcinogenic effects in mice or hamsters (Blain, 2003). In the case of capsaicin, both positive and negative effects have been found in classical genetic toxicology assays. Genotoxicity seems to be absent in studies

conducted with high-purity capsaicin, even with metabolic activation. Therefore, it is possible that the genotoxic potential observed in some of the studies was associated with other compounds or mutagenic impurities in the test compounds (Bley et al., 2012; Tsuchiya et al., 2011).

12.6.9 Lethality

Human deaths have been reported from RCA exposure. Estimates of the human LCt50 are presented in Table 12.2. The large safety ratio for CR is clearly evident as compared with the other agents, including OC and PAVA (Satpute et al., 2018). According to the study by Toprak et al. (2015), which analyzed 10 cases of lethal exposure to RCAs, death occurs between 18 and 22 min and 4 days following the initial contact. Death is usually the result of excessive concentrations used, confined spaces, and prolonged exposures. Not surprisingly, several cases involved prison inmates or a subject who barricaded himself in his room after struggling with the police and was exposed to CN in this room for approximately 30 min with limited ventilation (Thorburn, 1982; Toprak et al., 2015). Preexisting cardiovascular and/or pulmonary problems can be factors contributing to death. Drug use may also increase RCA toxicity. This was demonstrated by the combination of cocaine and capsaicin in mice (Mendelson et al., 2010).

12.6.10 Traumatic injuries

Although rare, mechanical trauma can occur when RCAs are deployed. Traumatic effects usually arise from direct targeting of individuals, both with the projectile canister as well as spray to the face (Haar et al., 2017). Severe maxillofacial injuries were observed (Çorbacıoğlu et al., 2016). Alhillo et al. (2018) reported a case of a tear gas-induced direct traumatic injury to the neurocranium. The energy density of the gas jet and the high temperatures of the exploding gas volume cause extensive soft tissue damage and burns, which in this case resulted into the patient's death 1 h after the admission. The largest series of traumatic injuries was reported from India on 18 patients with vascular injury caused by tear gas shells (Wani et al., 2011). Of these, six cases (33%) were associated with nerve injuries, four (22%) with skeletal fractures, and three (17%) resulted in amputations.

RCAs may also spark mass panic and stampedes that contribute to significant morbidity and mortality, particularly in enclosed spaces without safe avenues (Haar et al., 2017). This includes a case of at least 17 deaths in a club in Venezuela in 2018 due to a tear gas canister, causing panic among the hundreds of visitors (Casey, 2018).

12.7 Risk assessment

The ideal process in RCA risk assessment is to characterize the effectiveness and risk from exposures to situations in which RCAs may be used (NAS/NRC, 1994; Patterson et al., 2004; TERA, 2001). To do that, one must identify all pertinent effects of the RCA in question, develop a dose–response assessment, consider an exposure assessment, and finally characterize the risk. When used as intended, RCAs are thought to be safe and of sufficiently low toxicity. However, they are not without additional unwanted effects, especially in circumstances in which high concentrations are used or exposure is prolonged. The previous sections have provided sufficient discussion regarding the potential toxicity to humans as a result of exposure to RCAs, including case reports.

12.7.1 Identification of intended and unintended effects

By providing a minimal force alternative for controlling and managing individuals, RCAs are a desired public health and safety tool for military, domestic law enforcement, and civilian use. As with any chemical intended to benefit the public, it is important first to identify the compounds, their potential adverse impact (unintended effects), and their beneficial impact (intended effects). There are a number of chemicals designed and used as RCAs. In general, they are compounds with low vapor pressures and dispersed as fine particles or in solution from a variety of devices. These dispersal methods can include the gamut from aerial spray (Fig. 12.6) to large spray tanks (see Figs. 12.2 and 12.4) and small hand-held devices for self-protection. The modern RCAs used today include CN, CS, CR, OC, and PAVA. Their major adverse effects are summarized in Table 12.2. The intended effect for all RCAs is a change in behavioral response of the target. A better measure of this intended effect would be the actual physiological effects produced by RCAs on the eyes, skin, and respiratory tract (Patterson et al., 2004). These are the target organs designed for irritation by RCAs (see Fig. 12.11 for review).

12.7.2 Dose response

Dose–response assessment involves evaluating the dose required to produce a particular effect of interest. Ideally, quantitative data on specific doses and their corresponding responses are desired. In reality, threshold data for a particular target organ or effect in a target organ are often available as a substitute. The ophthalmic threshold levels and toxicity estimate for human responses to CN, CS, and CR are shown in Table 12.2. If empirical dose–response

data are available, then a dose–response evaluation for a given RCA might include plotting the percent of individuals responding as a function of dose for each toxicological sign or symptom and target organ of interest. Dose–response curves can then be used in modeling studies to estimate the probabilities of intended and unintended effects for a particular risk assessment scenario (Patterson et al., 2004).

12.7.3 Exposure assessment

The crux of exposure assessment is creating a scenario for human exposure to a given RCA and identifying the exposure factors. This would involve describing the intended targets, environmental conditions (windy, rainy, hot weather, etc.), crowd size and characteristics, delivery device (tear gas canisters or grenades, powder or aerosol), hazards associated with the delivery system such as blunt trauma, the nature of the agent selected (physicochemical properties, solvents, concentration/dose), and duration of exposure. An exposure assessment might include estimation of the amount of systemic exposure through RCA inhalation, absorption through the skin from dermal contact, or intestinal uptake after ingestion. Availability of quality data for each of the aforementioned exposure factors will estimate exposure with high confidence and a minimal uncertainty level. Unavailability of data is a major limitation if models are used to estimate exposure.

12.7.4 Characterization of the risk and risk management

Estimating or developing probabilities of toxic effects within a population is at the heart of risk characterization. It integrates dose–response and exposure assessments. It is designed to provide the probability of occurrence for effects induced by a given RCA given a particular exposure scenario. For example, a decision-maker will use risk characterization to estimate the probability of a group of effects occurring as a result of clearing a confined space with CS. The probability can be derived as a function of the number of tear gas grenades used. Unfortunately, there is a dearth of specific federal risk assessment and risk management guidance or mandates on RCAs. Therefore, the potential for risk management or mitigation of concerns is not optimized for the health and benefit of the public good (Hauschild et al., 2004). Standardization of the process for assessing risk of toxic chemicals (Burke, 1993) and computer modeling with empirical can be a powerful predictor for risk assessment of any toxic chemical.

12.8 Treatment

Exposure to RCAs leads to a generalized stress reaction, causing leukocytosis (Thorburn, 1982), hypokalemia, hyponatremia, hypochloremia, elevated total protein, increased globulin, and high bicarbonate levels (Beswick et al., 1972). Treatment for RCA toxicity is not often required because the course of intoxication is self-limiting for the most part. Clinical signs and symptoms from RCA exposure subside in less than an hour. Initial care involves removing the victim from a potentially crowded area of dispersal immediately to minimize exposure time. It is important to note that these victims may require additional assistance during evacuation because of their reduced vision and disorientation. In circumstances in which the concentration of the agent is substantially elevated or the area of release is confined, increased complications and risks of morbidity may arise in the eyes, skin, airways, and lungs.

12.8.1 Eyes

If the eyes are involved to any degree, then a protective mechanism to close the eyelids will be initiated as a result of conjunctivitis, iritis, or keratitis. Photophobia, blepharospasm, and apraxia of eyelid opening prevent the clinician from evaluating the damage. However, a local anesthetic applied to the eye will help with eye pain and allow for further evaluation of the eye by slit lamp. Contact lenses should be immediately removed and the eyes flushed of any dusting or agglomerated solid particles (see Fig. 12.12). Eyes should be irrigated with copious volumes of water or saline for at least 15 min to adequately flush the irritant. The irrigation liquid must be cold as otherwise symptoms can worsen (Svinos, 2011). Diphoterine has been used for eye and skin decontamination after CS exposure (Viala et al., 2005). Boric acid wash is contraindicated (Kim et al., 2016). If symptoms or signs of toxicity persist, consultation with an ophthalmologist is critical because there is a possibility of embedded particles that need removing. Elderly patients should be monitored for evidence of possible acute glaucoma (Yih, 1995).

12.8.2 Skin

Early signs of skin toxicity at the time of clinical presentation will often be contact or allergic dermatitis because blisters form hours later. Removal of clothing should be the first step in decontamination. Placement of contaminated clothes in sealed plastic bags by first responders will prevent secondary contamination as a result of reaerosolized agent (Horton et al., 2005). Early studies of CS indicated that mixing CS with sodium hypochlorite

(or household bleach) produced a greater reaction than CS alone in patch testing (Punte et al., 1963). Despite its usefulness as a decontaminant for many chemical agents, hypochlorite should never be used to decontaminate RCAs on skin. Use of water for decontamination of skin may result in an initial worsening of the burning sensation (described previously). A solution of 6% sodium bicarbonate, 3% sodium carbonate, and 1% benzalkonium chloride has been shown to provide immediate relief from CS dermatitis as the alkaline solution hydrolyzes the agent (Sidell, 1997; Weigernd, 1969). Consultation with a burn unit should be considered when large areas of skin are involved or when children are affected. Medical treatment for dermatitis may include topical steroids such as triamcinolone acetonide, oral antihistamines for pruritis, and topical antibiotics such as silver sulfadiazine (Hellreich et al., 1967; Sidell, 1997). Systemic antibiotics can be administered for secondary infection. Oozing lesions from bullae dermatitis should be treated with wet dressings and changed daily. Deroofing closed vesicles is controversial (Carvajal and Stewart, 1987). Tetanus prophylaxis should be considered.

12.8.3 Respiratory

Removing an exposed patient from the source of intoxication to fresh air will provide immediate improvement. Patients should be evaluated for hypoxia with pulse oximetry and arterial blood gases. Pulmonary function tests may be helpful in patients with prolonged pulmonary symptoms and followed-up until symptoms resolve. Chest radiography might be useful if the concentration was sufficiently high, exposure was prolonged, or dispersal occurred in a confined space. Pulmonary edema may be delayed for 12–24 h after exposure, suggesting a need for follow-up radiographs (Solomon et al., 2003; Stein and Kirwan, 1964). Laryngospasm is a serious complication that may require tracheal intubation to secure a patent airway. Bronchospasm may be treated with inhaled beta-2 agonists, steroids (methylprednisolone), and aminophylline (Ballantyne and Swanston, 1978; Folb and Talmud, 1989). Arterial blood gas and pulse oximetry should be continued if patients are symptomatic hours after exposure.

12.9 Concluding remarks and future directions

The goal of RCAs is to irritate or produce temporary incapacitation. Law enforcement agencies and military personnel use RCAs for quelling protestors, controlling crowds, subduing combatants, clearing buildings, training in chemical warfare, and area denial. Individuals use hand-held devices for self-protection against an assailant. RCAs are dispersed as aerosols or sprays, causing irritation of mucous membranes of the eyes, respiratory tract, and skin. Symptoms and signs of toxicity typically subside by 30–60 min.

Several lines of evidence suggest that RCAs are safe if used as they were originally intended. Even though RCAs are considered safe, nonlethal, temporary incapacitating agents, they are not without risk. Some of the adverse clinical effects from RCA exposure reported in the literature have involved indiscriminate use (excessive concentrations), prolonged exposure, and dissemination of compounds in a confined space. In summary, these nonlethal agents can pose a serious health hazard in their intended targets. Some RCAs have such a poor safety profile that they were abandoned long ago (DM and CA). CN and CS have a large body of literature from which to compare and contrast their safety, toxicity, and potency. As the data clearly suggest, CS is a safer compound compared with CN. The latest newcomers to the RCA scene are the inflammatory capsaicinoids. OC and PAVA are highly effective irritants that cause similar symptoms as CN and CS. Capsaicinoids gained considerable attention in the 1990s from police departments and the public at large for safe and effective chemical incapacitation of individuals. Although OC and PAVA produce a similar constellation of toxic signs and symptoms, little is known about PAVA. More research will be required to determine whether it is safe for humans.

Another gap is opening for possible future use of TRPA1 and TRPV1 antagonists. Although TRPA1 and TRPV1 antagonists are not generally available, several have been undergoing clinical trials. They are expected to be optimal for attenuating pain and other neuroinflammatory-related conditions. Such compounds may however significantly affect protective reflexes as well as pain-related behavior, resulting in excessive exposure to RCAs. Research starting with dose–response assessment in animal models testing RCAs together with TRPA1 or TRPV1 antagonists at clinically relevant concentrations up to epidemiological studies correlating the use of antagonists with the occurrence and severity of adverse effects will be necessary to help decision-makers on future utilization of RCAs.

Chapter 13

Phosgene oxime

Neera Tewari-Singh

Department of Pharmacology & Toxicology, Michigan State University, East Lansing, MI, United States

13.1 Introduction

Amongst the several chemical warfare agents manufactured or developed, vesicating agents comprise of chemicals like mustard agents sulfur mustard [SM; bis(2-chloroethyl) sulfide, HD]; nitrogen mustards [HN1 (bis(2-chloroethyl) ethylamine), HN2 (2,2′-dichloro-*N*-methyldiethylamine), and HN3 (tris(2-chloroethyl)amine hydrochloride)]; and arsenical vesicant lewisite [L; LEW; dichloro(2-chlorovinyl) arsine] that cause blistering in addition to acute and debilitating injuries to several organs (Young and Bast, 2009). Alkylating mustard vesicating agent SM has been most commonly used as a chemical agent of warfare and terrorism that causes painful skin blisters and injury largely to the skin, eyes, and respiratory system, and also systemic toxicity (Balali-Mood and Hefazi, 2005; Ghabili et al., 2010, 2011; Layegh et al., 2015). Phosgene oxime (dichloroformoxime; Cl_2CNOH), grouped with vesicating agents, is a halogenated oxime, urticant, nettle, or corrosive agent and does not cause blisters (Augerson, 2000; McManus and Huebner, 2005; Bartelt-Hunt et al., 2006; Patocka and Kamil, 2011). The military designation of phosgene oxime is "CX." Upon exposure CX causes intolerable pain, intense itching, and a rash similar to hives, leading to violent effects with severe tissue damage upon exposure (Augerson, 2000; Patocka and Kamil, 2011; Tewari-Singh, 2018). Although use of CX in warfare has not been reported, CX was first produced in Germany in 1929 and is reported to have been developed by both Germany and Russia and stockpiled during World War II as a potent chemical weapon. CX penetrates clothing and rubber much more quickly than other chemical agents; therefore, could be used alone or with other chemical warfare agents to cause startlingly rapid incapacitation, injuries, and death (Augerson, 2000; Patocka and Kamil, 2011). The intense pain from CX can cause removal of protective masks and clothing and its corrosive effects might render human skin more vulnerable to penetration by other chemical agents such as nerve agents. The extreme irritation and instant eye damage and future lung injury are also of high military significance.

There are suggestions of Iraqi use of an agent whose effects resembled CX against Iran, but there is no confirmation of this use. More recently, in a surprise report [March 20th 2019 (News9.com)], an FBI investigation found chemical warfare agent inside a Lawton home in Oklahoma, USA; testing uncovered that it was CX (https://www.news9.com/story/40170458/fbi-investigation-finds-chemical-warfare-agent-inside-lawton-home). Its easy synthesis makes it a dangerous chemical with both military and terrorist potential. CX penetrates clothes and rubber much more rapidly than other chemical agents and causes quick onset of severe and prolonged effects, including skin lesions that are comparable to those caused by a strong acid (Augerson, 2000; Patocka and Kamil, 2011; Tewari-Singh et al., 2017). CX is the most potent and dangerous chemical threat agent categorized with the vesicants; however, it is the least studied categorized vesicating agent and its mechanism of action is not fully understood, with no specific antidote available (Augerson, 2000).

13.2 Properties and chemistry

CX (Cl2C═N−OH, CAS RN 1794-86-1; Table 13.1) is a halogenated oxime and a colorless, crystalline solid at temperatures below 95°F with a strong, disagreeable odor and violently irritating vapor (Patocka and Kamil, 2011; Ubels et al., 1982). As a munitions ranking compound, CX is in liquid form, with a yellowish-brown appearance. Prismatic crystals of CX are hygroscopic and have a melting point of 39°C−40°C, and a boiling point of 128°C at 76 mm of Hg. It has a high vapor pressure (11.2 mmHg at 25°C) and could easily vaporize at ambient temperature (c20max = 21 g/m^3). CX can possess high mobility in soil

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00013-1

TABLE 13.1 Phosgene oxime.

Synonyms	Dichloroformoxime; CX
CAS No.	1794-86-1
Chemical formula	$CHCl_2NO$
Chemical structure	
based on an estimated adsorption coefficient K_{oc} of 68. It can partially exist as an anion in the environment as it is a weak acid with an estimated p*K*a of 6.5. It is soluble in water and organic solvents (alcohol, ether, and benzene) and hydrolyzes very quickly, predominantly in the presence of an alkali to form hydrogen chloride and hydrolamines. Its hydrolysis at an unspecified half-life and temperature is reported to be 83 days. It decomposes in contact with most metals as it is also corrosive to most metals. CX possesses a very unpleasant and irritating odor and is also very unstable, reactive, and volatile (1800 mg/m^3 at 20°C). CX is heavier than air and thus settles in low-lying areas but does not last in the environment for long. CX can be synthesized by the reduction of chloropicrin with tin in the presence of hydrochloric acid (Patocka and Kamil, 2011). The physical and chemical properties of CX are summarized in Table 13.2. It can be mixed with other chemical threat agents, such as SM, LEW, and nerve agents, and rapid skin damage from its exposure makes the target more susceptible to the second agent exposure. CX is grouped together with vesicating agents, however, it is an urticant or nettle agent and not a pure vesicant as it does not lead to blister/vesicle formation (Tewari-Singh et al., 2018). The nature of injuries caused by CX resembles those caused by urticants or acids, therefore it is often referred to as a nettle or corrosive agent (Patocka and Kamil, 2011).

TABLE 13.2 Physicochemical properties of phosgene oxime.

Property	Phosgene oxime
Physical state	Colorless, crystalline solid or yellowish-brown liquid (munitions-grade); solid form can sublime
Molecular weight	113.93 Da
Boiling point	128°C (760 mmHg)
Melting point	35°C–40°C
Solubility	Readily soluble in water (70% solubility); very soluble in organic solvents
Vapor density (compared to air)	<3.9
Vapor pressure	11.2 mmHg at 25°C (solid) and 13 mmHg at 40°C (liquid)
Volatility	1800 mg/m^3 (20°C)
Decomposition temperature	<128°C
Odor	Disagreeable, prickling odor

13.3 Exposure and toxicity

Toxicity upon exposure to chemical warfare agents like vesicants varies extensively depending on the dose, route, and form of its exposure. CX occupational exposure could be infrequent as there are no industrial uses of this compound similar to other vesicating agents like SM and L, it has only been reported as a chemical warfare agent. Exposure to vesicating agents leads to ocular, skin, and pulmonary damage even at low doses, while higher dose exposures cause multiorgan toxicity (Augerson, 2000). CX exposure in liquid or vapor form can cause more severe damage to the skin, eyes, and lung tissues than other vesicating agents due to its fast penetration (it can even penetrate rubber gloves and clothing) but has not been well studied. This leads to instant pain, tissue destruction, skin damage, severe systemic toxicity, and rapid mortality (Augerson, 2000).

It is reported that within seconds of exposure to low doses of CX (0.2 mg min/m^3), skin and pulmonary membrane irritation begins, and unbearable pain and irritation can start minutes after exposure to a dose of 3 mg min/m^3. Lethal systemic dose of CX estimation [LCt50 (concentration-time product capable of killing 50% of exposure areas)] is 1500–2000 mg min/m^3 (Ubels et al., 1982; Costagliola et al., 2013). People could be exposed to CX mainly via cutaneous, ocular, or pulmonary routes with local tissue destruction. If liquid CX contaminates water or food, people can be exposed by drinking water or eating contaminated food (Patocka and Kamil, 2011).

The rapid cutaneous injury instigated by CX makes the skin vulnerable to damage from other chemical agents. The LD50 for CX cutaneous exposure is estimated as 25 mg/kg. At higher concentrations or increased skin exposure time, CX causes more damage and triggers instant pain followed by tissue necrosis, systemic effects, and mortality (Augerson, 2000). After instant dermal absorption, CX exposure results in immediate itching, pain, skin blanching, erythema, edema, and hives

formation (Tewari-Singh et al., 2018). These lesions can be extremely painful and immediate, resembling stinging nettle with a blanched (white) exposed skin area surrounded by an erythematous ring (Patocka and Kamil, 2011; Tewari-Singh et al., 2017). Within minutes to an hour, the exposed area is edematous, which resolves within a day with dark pigmentation and severe necrosis. With time, more severe desquamation with necrosis of the skin could be observed, followed by eschar formation and polymorphonuclear infiltrates with intense inflammation, with healing taking weeks to months (Augerson, 2000; Tewari-Singh et al., 2017). Severe CX cutaneous exposure could result in pulmonary edema, other systemic effects, and mortality; however, long-term effects are unidentified (Augerson, 2000; Patocka and Kamil, 2011; Tewari-Singh et al., 2017).

Immediate eye and respiratory irritation upon CX vapor exposure causes cough, throat pain, increased lachrymation, and impaired vision (Augerson, 2000). Eyes are reported as the most sensitive organ to vesicating agent exposure (Gordon et al., 2009; Kadar et al., 2009, 2013a,b; Ghasemi et al., 2013; McNutt et al., 2012; Goswami et al., 2016a,b; Tewari-Singh et al., 2016). Ocular CX exposure results in instant and severe pain, irritation, edema, lacrimation, conjunctivitis, and blepharospasm. Severe or long-term CX exposure can result in keratitis, iritis, corneal perforation, and blindness (Patocka and Kamil, 2011). In contract to SM, there are no documented reports on the long-term ocular effects of CX. Upon inhalation, CX can be rapidly absorbed, triggering instant and incapacitating irritation, pain, runny nose, hoarseness, as well as local tissue obliteration of the upper airways at low exposure doses. At higher CX exposure doses, serious complications such as pulmonary edema followed by tachypnea, dyspnea, and cyanosis can transpire (Ubels et al., 1982; Augerson, 2000; Patocka and Kamil, 2011). Exposure to CX aerosol can cause necrotizing bronchiolitis and pulmonary edema with pulmonary vein thrombosis (Augerson, 2000). Like ocular complications, long-term respiratory effects of CX are unidentified, although it is believed to result in pulmonary fibrosis (Augerson, 2000).

In addition to toxic effects to the eyes, respiratory, and skin systems, CX exposure can also cause severe and life-threatening injury to internal organs as reported from our recent study (Tewari-Singh et al., 2017). CX cutaneous exposure resulted in dilatation of the peripheral vessels (including capillaries and sinusoids) and the pooling of red blood cells (RBCs) in the vessels of the lung, liver, spleen, kidneys, and heart tissues (Tewari-Singh et al., 2017). This severe vascular dilation and perhaps leakage could result in a marked loss of blood from the vessels into the adjacent tissue and could lead to low blood pressure, relative hypoxia, and shock, leading to mortality. This could be similar to the "lewisite shock" effect, where death may result from fluid loss, hypovolemia secondary to capillary leakagefrom high-dose exposure of LEW (Snider et al., 1990; Watson and Griffin, 1992).

13.4 Mechanism of action

Among vesicants, molecular mechanisms of SM (Dacre and Goldman, 1996; Kehe et al., 2008; Shakarjian et al., 2006, 2010; Mouret et al., 2015) and LEW (Goldman and Dacre, 1989; Augerson, 2000; Kehe et al., 2009; Nguon et al., 2014; Li et al., 2016; Srivastava et al., 2016) toxicity have been extensively studied. Unlike vesicating agents like SM and LEW, studies and reports on the acute toxicity, long-term effects, and related mechanisms from CX exposure are unidentified (Augerson, 2000).

It is possible that CX possesses alkylating and nucleophilic properties like vesicants or its effects are due to its breakdown products like chlorine, oxime, or carbonyl groups. Its toxicity could be direct, involving corrosive injury, cell death, and tissue destruction, or indirect (involving activation of alveolar macrophages, recruitment of neutrophils, and release of hydrogen peroxide) including an inflammatory response which could lead to delayed tissue injury and pulmonary edema (Augerson, 2000; Tewari-Singh et al., 2017). To study the pathophysiology of acute CX cutaneous exposure, we have recently conducted comprehensive research in SKH-1 hairless mice. Immediate increases in skin injury parameters, including skin bi-fold thickness, erythema and edema, and necrosis was observed. These studies indicate that the toxicity response and skin urticaria from CX resembles the anaphylactic reaction and urticaria from allergic reactions, involving an inflammatory response mainly due to mast cell activation. Data from our published (Tewari-Singh et al., 2017) and completed studies (data not published) in SKH-1 hairless mice show that CX cutaneous exposure causes mast cell degranulation and release of mediators including histamine and tryptase, proinflammatory cytokines, and an inflammatory response in the skin tissue that is associated with edema, erythema, necrosis, urticaria, and blanching. CX cutaneous exposure in mice also caused vasculature dilation and blood congestion in multiple organs, resulting in systemic toxicity, decreases in breath and heart rate, temperature drop, and mortality. These symptoms are similar to anaphylaxis (potentially lethal multisystem allergic reaction with acute respiratory and cardiovascular compromise leading to unconsciousness, shock, and mortality), which is a result of sudden systemic release of mediators from mast cells. There are reports that neutrophil infiltration could also play a key

role in skin inflammation related to mustard vesicating agents (Wormser et al., 2005; Shakarjian et al., 2010; Jain et al., 2014).

In the skin tissue, DNA damage, and p53 phosphorylation and accumulation have also been shown to play a significant role in vesicating agent-induced cell death and injury (Kehe and Szinicz, 2005; Paromov et al., 2007; Goswami et al., 2016a,b). Similar to mustard vesicating agents, published reports from our studies indicate that p53 phosphorylation and its accumulation in skin tissue could be important consequences of CX-induced skin injury. Cutaneous CX exposure also resulted in TNF-α and COX-2 level increases in the skin tissue, paralleling reports of exposure of the skin tissue with other vesicating agents (Shakarjian et al., 2010; Tewari-Singh et al., 2009, 2017). Cutaneous exposure to mustard vesicating agents at higher doses results in damage to multiple organ systems, but mortality is rare (Dacre and Goldman, 1996; Kehe et al., 2008; Patocka and Kamil, 2011; Goswami et al., 2015). However, our studies indicate that CX is absorbed instantaneously, leading to more severe systemic toxicity and mortality compared to other vesicating agents.

These recent studies suggest that further examination to dissect the mechanism of action of CX from its exposure are warranted, mainly to investigate if mast cell activation and associated release of mediators are the major events following CX cutaneous exposure. Such studies are being carried out in our laboratory to identify the signal transduction pathways and novel targets for therapeutic intervention to mitigate CX-induced morbidity and mortality.

13.5 Protection, decontamination, and treatment

If there is an exposure to CX, moving immediately upward and toward an area where fresh air is available is an important protection since CX is heavier than air and settles down (Patocka and Kamil, 2011). Pressure-demand, self-contained breathing apparatus (SCBA) could be helpful in situations of CX exposure. Although CX can attack butyl rubber gloves and boots, these are protective against field concentrations of CX. Since CX is absorbed very rapidly, skin and eye decontamination are needed immediately; hence, the timing of decontamination is very critical. CX reacts with tissues very rapidly and causes extreme pain and itching—if this occurs then decontamination will have no effect. All alkaline agents can be used for chemical inactivation. Chlorinated agents cannot be used for CX decontamination and water can only be used to flush the chemical from eyes. Clothing exposed to CX should be immediately removed and sealed in a bag to avoid any further exposure and contamination. Immediate and lifesaving care might be required within minutes following CX exposure at an emergency station. Long-term care, hospitalization, and lifesaving surgery can be required, and delay in this care can adversely affect the injury and survival outcomes.

There is no effective antidote available against CX-induced toxicity and any treatment is mostly helpful to reduce indications, prevent infections, and help healing. Systemic analgesics are a better option compared with topical anesthetics because use of the latter may increase the severity of corneal damage (Ubels et al., 1982). Dilution with water or milk could be helpful in oral exposures. For eye injury, washing with a large amount of water could be supportive, while for necrotic skin lesions, surgical intervention may be essential. Recovery depends on the extent of injury and could take several months (Patocka and Kamil, 2011). Reports indicate that mast cell activation and histamine release could be involved in CX-induced inflammation, toxicity, and urticaria (Hennino et al., 2006; Jain, 2014; Tewari-Singh et al., 2017). Employment of therapies that can ameliorate anaphylactic symptoms and counteract mast cell activation-related release of inflammatory mediators like histamine alone or in combination is a pioneering strategy for investigation to ameliorate CX-induced morbidity and mortality from its cutaneous exposure. Additionally, second-generation antihistamine with mast cell-stabilizing properties, analgesics, and antibiotics could be given to reduce pain, prevent infections, and promote healing.

13.6 Concluding remarks and future directions

CX is a manufactured urticant or nettle agent, and is a highly reactive and corrosive chemical warfare agent. Although it has never been used in warfare, its potent nature, fast penetration ability, easy synthesis, and toxic consequences make it a potential military and/or terrorist weapon. It could be produced easily and weaponized with other chemical warfare agents to increase their deleterious effects. Compared to other vesicants, CX is absorbed very rapidly through clothing and causes instantaneous and severe damaging effects to the skin, eyes, and mucus membranes with instant pain. Even though it is considered the most potent and damaging vesicant that can be used for rapid incapacitation and death, very little is known regarding the toxic effects and mechanism of action of CX following its exposure, and no antidote is available. To overcome these limitations, comprehensive studies to investigate the pathophysiology of the toxic effects of CX are needed to develop effective targeted therapies.

Acknowledgment

Support from Countermeasures Against Chemical Threats (CounterACT) Program, Office of the Director National Institutes of Health (NIH OD), and the National Institute of Neurological Disorders and Stroke (NINDS) [Grant Number R21 AR073544] to Neera Tewari-Singh is acknowledged.

Chapter 14

Psychotomimetic agent BZ (3-quinuclidinyl benzilate)

Josef Fusek[1,2], Alzbeta Dlabkova[1] and Jan Misik[1,3]

[1]Department of Toxicology and Military Pharmacy, Faculty of Military Health Sciences, University of Defense, Hradec Kralove, Czech Republic, [2]Faculty of Health Studies, University of Pardubice, Pardubice, Czech Republic, [3]Biomedical Research Centre, University Hospital Hradec Kralove, Hradec Kralove, Czech Republic

14.1 Introduction

Experiences with the use of chemical warfare agents (CWAs) during World War I and under the pressure of general public opinion, have led to the search for novel chemicals with decreased lethal effects for military use (Ketchum et al., 1973). This research was focused on contemporary incapacitants influencing behavior with no severe/irreversible effects on important vital functions. An incapacitant is a chemical agent which causes a disabling condition that persists for hours to days after exposure to the agent. D-Lysergic acid diethylamide (LSD-25) was the first candidate for such an incapacitating agent. LSD-25 causes excessive neuronal activity by facilitating neurotransmission. However, its physical-chemical properties and unpredictable postexposure behavior led to the exclusion of LSD-25 from military research.

Other incapacitating agents included the esters of glycolic acid, that is, atropine-like anticholinergic compounds. The psychotomimetic effect of some natural anticholinergic substances has been known since ancient times. The first mention of deadly nightshade (*Atropa belladonna*) and its effect comes from a Greek philosopher and naturalist, Theophrastus (331−287 BCE), known as the "father of botany." From ancient times to the Middle Ages, atropine and other natural alkaloids were commonly used for religious ceremonies, Sabbaths, or as a tool of poisoners. The beginnings of medical use for these substances date back to the 17th century. In the 1950s, various anticholinergic drugs were investigated for potential military and industrial uses, including agent BZ. BZ (also known as *3-quinuclidinyl benzilate*, *QB*, *QNB*, *BZ agent*, *Buzz agent*, *Ro 2-3308*, or *EA 2277*) is a prototype of the CNS depressants; a prototype of CNS stimulants are LSD-25, cannabinol, or amphetamines.

Among the many tested compounds, anticholinergic drugs were chosen as promising for further research. The anticholinergics are generally "glycolates" (substituted glycolic and tropic acid esters) of which the representative and best-known member is atropine. Major symptoms of low-level atropinization include xerostomia ("dry mouth"), mydriasis, and tachycardia. Under high doses of atropine, central excitation becomes more prominent, leading to restlessness, irritability, disorientation, hallucinations, or delirium. Excessive doses caused depression, coma, and medullary paralysis.

A number of anticholinergic compounds influencing higher nervous functions have been tested (Table 14.1).

This group of compounds appears to have both peripheral and central properties. The psychotomimetic effects of atropine have been known since antiquity (the use of *Atropa belladona* extracts to induce hallucinations during Sabbaths and other rituals). The central effects of cholinergic compounds increase in the following order: atropine, scopolamine, benactyzine, ditrane and, finally, BZ and other esters of glycolic acid (Albanus, 1970). BZ was originally investigated as an antispasmodic drug in the therapy of gastrointestinal diseases. Nevertheless, even low excesses in dosing were likely to cause severe side effects including confusion and hallucinations. Therefore, BZ was withdrawn from commercial studies and referred to the US military forces as a possible candidate as an incapacitating agent (Sidell et al., 1997). Nowadays, BZ is used in research into cholinergic neurons in the peripheral nervous system (PNS) and CNS, nonneuromuscular cells and tissues for identification of muscarinic receptors

via several laboratory techniques, mainly radioligand binding assays (Monica et al., 2008; Yamada et al., 2008; Soukup et al., 2011). BZ has also been implicated in several experimental epilepsy models (Schneider and de Lores Arnaiz, 2013), animal models in Parkinson's disease (Knol et al., 2014), animal behavioral studies (Misik et al., 2014), neurodegenerative disorders, such as Alzheimer's disease (AD), and other types of dementia (Wyper et al., 1993; Pakrasi et al., 2007; Schliebs and Arendt, 2011). In the 1960s, many similar compounds including BZ were studied in the framework of the military through industrial liaison programs (Pearson, 2006); following the criteria of politico-military goals and requirements, the general characteristics of an optimal incapacitating agent were:

- Low effective doses (acting in μg/kg or less);
- Rapid onset (minutes);
- Defined duration (optimally minutes to hours)
- Reversibility with no permanent effect;
- Stability at storage and delivery;
- Significant and predictable effect;
- Capability of rapid dissemination in defined conditions;
- High safety ratio.

14.2 Background

BZ is a white crystalline substance with a bitter taste that is soluble in aqueous and organic solvents. It is stable at field conditions for at least 1 or 2 days with no loss of its incapacitating activity. BZ is effective by all routes of administration and is metabolized primarily in the liver and excreted by the kidneys. After exposure to an effective dose (ED), mild peripheral effects occur within 1 h and central effects occur after about 4 h. The central effects peak at 8–10 h and last 24–48 h. The physicochemical properties are summarized in Table 14.2.

TABLE 14.2 Physicochemical properties of 3-quinuclidinyl benzilate (BZ, QNB).

Appearance	White crystals	References

14.3 Toxicokinetics and mechanism of action

BZ is absorbed by all usual routes of administration (oral, parenteral, and inhalation). When administered by inhalation, the absorption into the transport system (bloodstream) is more pronounced in comparison with oral administration. Experimental studies were performed with parenteral administration and, in this case, i.v. administration is without losses because of direct involvement of BZ in the transport system. The compound binds to the plasma proteins (preferably albumin) and is transported to the target point of the toxic effect—the CNS and PNS. At these localizations, BZ interferes with cholinergic nerve transmission at muscarinic sites, both in the peripheral autonomic nervous system and in the brain and spinal cord. Due to the wide distribution of muscarinic receptors, effects are observed upon almost every phase of neural regulation. BZ readily crosses the blood–brain barrier (BBB) and is distributed to all areas of the brain and spinal cord where it interacts with cholinergic receptors as a competitor of the physiologically active neurotransmitter ACh. The effect is manifested as a relative lack of acetylcholine. At the periphery, BZ binds to acetylcholine muscarinic receptors (e.g., of smooth muscles), similarly to atropine, with a strong antagonistic effect on receptors (Fusek et al., 1971; Table 14.3).

TABLE 14.3 Pharmacological activity of compounds tested on isolated rat jejunum.

Compound	i.a.	$pD_2 \pm P_{95}$	$pA_2 \pm P_{95}$
Acetylcholine	$\alpha = 1$	6.79 ± 0.06	
Muscarine	$\alpha = 1$	6.59 ± 0.05	
Atropine	$ß = 0$		8.92 ± 0.05
Benactyzine	$ß = 0$		7.64 ± 0.07
Scopolamine	$ß = 0$		8.83 ± 0.06
Ditrane	$ß = 0$		8.36 ± 0.07
BZ	$ß = 0$		8.55 ± 0.09

α, Intrinsic activity of agonist; $ß$, intrinsic activity of antagonist; *i.a.*, intrinsic activity; P_{95}, 95% confidence limits; pA_2, negative decadic logarithm of antagonist ED_{50} (−log ED_{50} antagonist); pD_2, negative decadic logarithm of agonist ED_{50} (−log ED_{50} agonist).

At the ACh, BZ binds to all subtypes of muscarinic receptors (M1–M5), each showing different functions in the brain (Lefkowitz, 2004). The particularly long duration of the central action of BZ may be related to its higher affinity for nervous tissue, especially the strong adsorption by mitochondria. This feature of BZ leads to a reduction in oxygen consumption by nerve cells, which is stimulated in various ways (Jovic and Zupanc, 1973).

14.4 Toxicity

The acute toxicity, expressed as LD_{50}, for various species and routes of administration is shown in Table 14.4.

In general, the acute toxicity of anticholinergic drugs is relatively low and the dose causing incapacitation is substantially lower. Therefore the ratio between the lethal and incapacitant doses is in the range of a logarithmic scale.

The effective doses (EDs) of some psychotomimetic drugs for humans are shown in Table 14.5.

BZ at a single dose of less than 1 mg produces delirium lasting several days. The safety margin (ratio of lethal to incapacitating dose) for man is estimated to be at least 30. The median effective dose (ED_{50}) of BZ under field conditions is approximately 60 mg/min.m^3 for a man of 75 kg body weight with a volume of respiration of

15 L/min. Rodents seem to be generally more resistant to the effects of BZ. Doses between 2.0 and 10.0 mg/kg administered intramuscularly induced only mild to moderate signs of anticholinergic stimulation (e.g., hyperactivity, piloerection, mild tremor) which diminished spontaneously within approximately 1 h (Misik et al., 2014).

14.5 Symptoms

BZ is effective via intravenous, intramuscular, respiratory, or oral routes of administration. The effect of BZ in a case of percutaneous administration, when mixed with suitable solvent, is limited. The limited data available indicate that the higher doses caused stronger effects and prolonged duration. In 1960–69, field tests of BZ were conducted by the US military. Sidell's (1982) description of the effects induced by BZ (4.5–17.1 μg/kg) is as follows.

At low doses, the effects include a dry mouth, decreased gastric motility, inhibition of sweating, an increase in heart rate, mydriasis and loss of accommodation, mild sedation, and mental slowing.

These effects intensify under higher doses. There are marked disturbances of cognitive and locomotor functions at all levels of CNS, including alteration of motor coordination and a decline in attentiveness and control of thought and learning process. Confusion, restlessness, impairment in perception, interpretation, and memory disturbances are observed. The first symptoms occur dependent on the route of administration; judgment and deficient insight are all features of this syndrome. True hallucinations are present. Under excessive doses, the subject may become stuporous or even comatose for several hours.

After a single intramuscular injection (BZ doses of 5.0–6.4 μg/kg) the following symptoms were observed:

- 10 min: lightheadedness and giggling;
- 30 min: xerostomia, blurred vision, nausea, chilly sensations, and twitching;
- 1 h: flushed skin, lack of coordination, fatigue, unsteadiness, sleepiness, and quivering legs;
- 2 h: many of the above symptoms, plus poor concentration, restlessness or sleepiness, hallucinations, slurred speech, and muscle fasciculation;
- 3 h: the above symptoms, plus tremors;
- 4 h: the above symptoms, plus difficulty in handling the subject and an increased pulse rate up to 130;
- 8 h: the above symptoms, plus delirium and hallucinations;
- 24 h: persistent delirium, hallucinations, restlessness, unsteadiness, and increased pulse rate in some (but not all) subjects;
- 48 h: persistent impairment of cognitive functions.

Mydriasis and disturbed accommodation remain unchanged depending on the dose at 2 or 3 days. The mean time of incapacitation is about 70 h. In real-life situations, wide variations in absorbed dose would occur, and thus the intensity and duration of symptoms will also vary over a large time scale.

14.6 Risk assessment

BZ was stockpiled by the US military forces in 1980. In 1992, the US delegation at the Conference on Disarmament in Geneva declared that all stocks of BZ had been destroyed. However, it cannot be excluded that BZ has been stored by some other armed forces (no official data available). The military use of BZ was limited to special operations and, at present, BZ agent can be considered as a potential agent for special military operations. Nowadays, the threat presented by a group of incapacitants (other than anticholinergic hallucinogens) known as "nonlethal chemicals" with extremely strong effect, is real (e.g., fentanyl derivatives involved in the Moscow theater incident, 2002). The potential misuse of similar compounds by terrorist groups cannot be excluded, as well as use against groups of people or aimed groups of people, for example, military staff (Pearson, 2006).

14.7 Treatment

The treatment of BZ intoxication is in principle based on reversion of the mechanism of action (simply described as a lack of neuromediator ACh). Generally, for an increase in the ACh level, inhibitors of cholinesterases are the drugs of choice. However, use of the majority of these compounds is limited due to small ratio between the therapeutic and toxic doses. Reversible inhibitors are preferred, although some experiments with highly toxic nerve agents (VX and sarin) as an antidote against BZ have been performed on healthy volunteers (Sidell et al., 1973). Peripherally acting anticholinesterase drugs that do not cross the BBB (e.g., pyridostigmine, neostigmine, and pilocarpine) are ineffective against the central effects of BZ.

Physostigmine was the first antidote against BZ. Its antidotal effect against *A. belladona* extract has been known for more than 150 years. It is known that physostigmine acts as a potent antidote against scopolamine intoxication and is able to mitigate all symptoms on electrophysiological, psychiatric, and biochemical levels. Physostigmine was considered as a potential antidote against anticholinergic incapacitants including esters of glycolic acid. Administration of physostigmine (2–3 mg i.m.) is required to alleviate symptoms of BZ intoxication. Repeated injections at intervals of approximately 15 min to 1 h may be required to build appropriate levels. Once a

desirable effect is achieved, it should be maintained by slow intravenous injection or infusion. Doses of 2−4 mg every 1−2 h may be required. Oral dosing (2−5 mg every 1−2 h) should replace i.v. therapy as soon as possible.

Nevertheless, the therapeutic index of physostigmine is rather narrow, showing side effects and short time duration of the therapeutic effect. Therefore attempts have been made to obtain new inhibitors with lowered toxicity in comparison with physostigmine. Acridine derivatives were of great interest (Albert, 1966). From these compounds, 1,2,3,4-tetrahydro-9-aminoacridine (Fusek et al., 1974), tacrine, was found to be effective not only against anticholinergics but also against morphine and curare overdosage. Tacrine is an inhibitor of cholinesterases comparable with neostigmine or physostigmine and also showing antihistaminic activity. Its effect is prolonged in comparison with physostigmine. Historical studies investigating antidotes against anticholinergic hallucinogens recognized tacrine as the most promising antidote at that time (Gershon and Angrist, 1973). The antidotal effect of tacrine against ditrane intoxication including improvement of the EEG misbalances was approved by Itil and Fink (1966) in 74 patients. Atropine, scopolamine, and ditrane intoxications were successfully treated using physostigmine and tacrine but also sarin (Ketchum et al., 1973). However, the side effects of tacrine, including hepatotoxicity, were the reason for its limited use and finally, it was abandoned (Marx, 1987).

7-Methoxy derivative of tacrine (7-MEOTA) has been synthesized and tested (Fusek et al., 1986). 7-MEOTA inhibited in vitro preferably butyrylcholinesterase (BuChE) ($I_{50} = 3.5.10^{-7}$ M) rather than acetylcholinesterase (AChE) ($I_{50} = 3.5.10^{-6}$ M). The inhibition is of a competitive−noncompetitive reversible type. The characteristics of AChE inhibition indicate that 7-MEOTA binds on the active surface of AChE in the gamma-anionic site, like galantamine or coumarin. Inhibition of blood AChE by *O*-ethyl-*S*-(2-dimethylaminoethyl) methylphosphonothioate (0.042 mg/kg = 1 × LD_{50}, i.m.) after premedication with 7-MEOTA (100 mg/kg, i.m.) was substantially lower than in intoxicated animals pretreated with saline, which underlines its possible use for preventing intoxication by organophosphorus anticholinesterase agents. 7-MEOTA enhanced the contraction response of the guinea pig atria (ED_{50} positive inotropic effect = 1.7×10^{-6} M), reduced the frequency of contractions (by binding the compound to the effectors of the cholinergic system of the heart tissue), increased the contraction response of the isolated rat diaphragm, and antagonized the effect of D-tubocurarine. The dose of 3×10^{-6} M of 7-MEOTA entirely suppressed the effect of a dose of 2×10^{-6} M D-tubocurarine. 7-MEOTA elicited a contraction response (1×10^{-7} M) and intensified the response of the isolated rat jejunum to the applied concentration of cholinomimetics. The long-term increase of intestinal peristaltic function after low concentrations of 7-MEOTA (1×10^{-7} M) testifies to the inhibitory effect of the compound on tissue cholinesterases (Fusek et al., 1979). On the other hand, the surface cutaneous electrogastrography did not prove a significant impact of 7-MEOTA on dominant frequency of gastric slow waves in pigs. In this study 7-MEOTA caused only a short-term late increase in the power ratio (ratio of the areas of amplitudes after and before study drug administration) at 60 min after administration. Blood cholinesterase activity did not correlate with any EGG parameter (Bureš et al., 2015). Depending on the dose, 7-MEOTA effectively antagonized symptoms of intoxication elicited by anticholinergics in dogs. A dose of 5 mg/kg of 7-MEOTA shortened the time needed for a fall in the score of intensity of symptoms elicited by BZ (0.05 mg/kg) from 210 min in untreated intoxication to 54 min, respectively (Fusek et al., 1979).

Besides the direct influence on effectors of the cholinergic system, the effect of 7-MEOTA might be mediated via the induction of cholinesterase inhibition in the CNS and PNS. Additional beneficial properties of 7-MEOTA in comparison with physostigmine suggest the possible therapeutic use of this compound in cases where hitherto physostigmine was used before. In contrast to physostigmine, there is no need for repeated doses to maintain the therapeutic effect of 7-MEOTA at low dosage and, moreover, minimal side effects appear.

This medicament has not only use as an antidote against BZ intoxication but it can be used in general as a drug for the treatment of cholinergic disturbances such as AD. 7-MEOTA is a potent, centrally active cholinesterase inhibitor. In isolated rat jejunum, 7-MEOTA increased muscle contractility and in isolated guinea pig ventricular myocytes this compound was found to prolong transmembrane action potential and decrease amplitude of the plateau. In isolated rat diaphragm, 7-MEOTA increased muscle contractility after electric stimulation of the phrenic nerve.

7-MEOTA was found to antagonize the convulsive action of pentamethylenetetrazole and significantly decreased the number of surviving animals following administration of this drug. Results from behavioral studies indicated that 7-MEOTA antagonized anticholinergic syndrome evoked by scopolamine, ditrane, and BZ. Nevertheless, some contemporary anticholinergic drugs used for therapy of neurodegenerative disorders including rivastigmine or donepezil and some novel experimental compounds derived from 7-MEOTA showed increased effectiveness against 7-MEOTA in laboratory rats (Misik et al., 2015).

The antidotal effect of 7-MEOTA on the anticholinergic syndrome was potentiated by nootropics, diazepam, and especially opioid peptides (Fusek, 1977).

TABLE 14.6 Lethal doses of tacrine, 7-methoxytacrine, physostigmine, and 6-chlorotacrine in laboratory animals.

Compound	Animal	Route of administration	LD_{50} (mg/kg)
Tacrine	Mouse	i.m.	28.9 (24.2–35.8)
	Rat	i.m.	33.8 (28.8–40.6)
	Rat	p.o.	103.7 (84.6–135.8)
	Rat	i.p.	20.2 (16.4–24.8)
	Rat	i.v.	12.0 (10.7–13.6)
	Rabbit	i.n.	13.3 (8.0–18.8)
	Dog	i.m.	12.6 (10.1–14.7)
7-Methoxytacrine	Mouse	i.m.	125 (110–143)
	Rat	i.m.	258 (224–313)
	Rat	p.o.	793 (662–950)
	Rat	i.p.	73.3 (61–90)
	Rat	i.v.	22.2 (19.9–25.2)
	Rabbit	i.m.	75.3 (60–89)
	Dog	i.m.	18.9 (15.2–22.1)
Physostigmine	Mouse	i.m.	0.86 (0.7–1.0)
	Rat	i.m.	2.2 (1.9–2.4)
	Dog	i.m.	0.83 (0.68–0.95)
6-Chlorotacrine	Rat	i.p.	9.0 (6.8–12.3)

7-MEOTA also antagonized the side effects of tricyclic antidepressants and protected AChE against inhibition by some organophosphate anticholinesterase compounds.

As is shown in Table 14.6, the acute toxicity of 7-MEOTA was rather low; LD_{50} (i.m.) was 125 mg/kg for mice and 258 mg/kg for rat. With p.o. administration to rat LD_{50} was 793 mg/kg. Analogous values for tacrine at the same order were: 29, 34, and 104 mg/kg (Fusek, 1977). 7-MEOTA was found to be markedly less toxic than tacrine also for dogs and rabbits. Subacute toxicity study of 7-MEOTA (3-months administration) demonstrated that the compound was well tolerated at doses of 25 mg/kg (i.m.) and 50 mg/kg (p.o.) in rats and at a dose of 2.5 mg/kg (i.m. and i.v.) in Beagle dogs. No pathological changes were observed in biochemical, hematological, and morphological investigations.

Some recent studies investigated the antidotal effect of several novel analogs of tacrine, donepezil, and 7-MEOTA (Misik et al., 2015, 2016, 2018). One of numerous derivatives is 6-chlorotacrine hydrochloride (6-Cl-THA; 6-chloro-9-amino-1,2,3,4-tetrahydroacridine hydrochloride, Table 14.1) containing a chlorine atom in the C6 position, which strongly increases inhibitory potential compared to the parent compound. Accordingly, a significantly increased inhibitory effect against the parent compound was observed in vitro and some other advantages, such as enhanced blood–brain barrier penetration and increased selectivity toward AChE were proposed. Thus 6-Cl-THA was utilized in the development of novel dual binding site inhibitors or multitarget-directed ligands (Camps et al., 2009; Di Pietro et al., 2014; Eckroat et al., 2013; Nepovimova et al., 2014; Liao et al., 2015; Nepovimova et al., 2015). In vivo evaluation of 6-Cl-THA revealed a procognitive effect in several behavioral tasks. Rats administered with 1.8 mg/kg of 6-Cl-THA showed improved spatial navigation in a water maze, even resembling the performance of untreated animals (Misik et al., 2018). Unfortunately, chlorine increased toxicity of 6-Cl-THA in relation to the parent compound and the LD_{50} of 6-Cl-THA in rats is three times lower compared with parent compound tacrine and eight times lower compared with 7-MEOTA. Thus, increased toxicity of 6-Cl-THA is the main limiting factor. Other modification of the molecule or hybridization leading to decreased toxicity and increased biological efficacy might be the solution.

14.8 Analytical methods

BZ determination in biological samples and other complex matrices is possible using HPLC analysis with UV detection or LC-MS/MS technique. The sensitive and rapid LC-MS/MS method for agent BZ determination in plasma and tissue homogenates was developed by Herman et al. (2019) for the purpose of investigating its fate in the organism. Sample preparation was based on solid-phased extraction on C-18 cartridges and the chromatographic separation was performed on a modified C-18 stationary phase with alkaline (pH 11) mobile phase which reflects the alkaline character of the target compound. Mass spectrometry was accomplished on a linear ion trap instrument, coupled with a heated electrospray ionization probe operated in the positive ion mode. The assay was linear in the concentration range 0.5−1000 ng/mL ($r^2 = 0.9947$) with the limit of detection (LOD) 0.15 ng/mL, and the lower limit of quantification (LLOQ) 0.5 ng/mL. Described parameters were found to be sufficient to measure levels of BZ in rat plasma and tissue samples. The maximum concentration of BZ in plasma and brain tissue was measured 3 and 5 min after intramuscular administration, respectively (Herman et al., 2019). The gass chromatography represents another approach to the BZ determination in biomatrices. A method of the BZ and its metabolites assessment in urine based on gass chromatography coupled with mass spectrometry was published for example by Byrd et al., 1992.

At present, the BZ compound is frequently used as a radiolabeled ligand of muscarinic receptors in order to measure anticholinergic activity (Schreiber et al., 2018) using a radioreceptor assay developed by Tune and Coyle (1980) or binding capacity of muscarinic receptors using the time course of radioactivity concentration assay (Inoue et al., 2018).

The fluorometric method for 7-MEOTA determination in biological material was developed and blood-concentration profiles of 7-MEOTA in rats and healthy volunteers were estimated (Filip et al., 1991).

Maximal concentrations of 7-MEOTA in human blood were observed approximately 0.5−1 h after i.m. and 4 h after p.o. application of drug. The half-life was 5 h, and the effective level was maintained for 12 h. Similar results in rats with radiolabeled (H^3) 7-MEOTA were obtained (Patocka et al., 1996).

In healthy volunteers, 7-MEOTA was well tolerated in q single dose of 2 mg/kg (p.o.) or 1 mg/kg (i.m.) following daily administration (7 days). The compound did not influence the cognitive functions of healthy persons. The blood-concentration profiles of volunteers corresponded well with those in rats. Clinical testing of this drug was performed on patients with tardive dyskinesias which occurred after long-term administration of neuroleptics with good therapeutic efficacy (Zapletalek et al., 1989).

Based on the results obtained, tablets of 7-MEOTA (100 mg) and injections (50 mg in 2 mL) were introduced into the Czech armed forces as an antidote against psychotomimetic agents. Modern analytical instrumentation also enables determination of 7-MEOTA in biological samples. Soukup et al. (2013) developed an HPLC method based on reverse phase separation and fluorescent detection (excitation and emission wavelength 240 and 360 nm). The LOD and LLOQ in plasma samples were 2.10 and 6.25 ng/mL, respectively.

14.9 Agent BZ in behavioral research

Proper functioning of the central cholinergic system is crucial for cognition. A shortage of cholinergic transmission in target areas of the brain (prefrontal cortex, hippocampus, striatum, or amygdala) is connected with behavioral alterations including impairments of learning and memory. Thus, some compounds with anticholinergic activity, such as scopolamine, atropine, trihexyphenidyl, biperiden, or pirenzepine have been investigated for their behavioral and neurochemical effects (Bymaster et al., 1993; De-Mello and Carobrez, 2002; von Linstow Roloff et al., 2007; Klinkenberg and Blokland, 2010; Doguc et al., 2012) aimed at finding an appropriate experimental model of neurodegenerative disorders in laboratory animals.

As a standard drug, mainly scopolamine was used. Nevertheless, agent BZ has been several times investigated and proved to be a potent compound able to simulate cognitive impairment in experimental animals, similar to those observed in patients with Alzheimer's disease.

The effect of BZ seems to be very similar to the effect of scopolamine with the difference of prolonged action on behalf of BZ. The amnesic effect of 2.0 mg/kg of BZ in Wistar rats was observed up to 24−48 h postadministration (Misik et al., 2014). In contrast, the effect of scopolamine is usually shorter, up to approximately 8 h (Fig. 14.1).

The effect of agent BZ is specifically modified across the stages of learning and memory processes, including acquisition, consolidation, and retrieval. However, the influence on acquisition is extensive, and minimal affection of retrieval and consolidation was observed (Misik et al., 2014; Fig. 14.2). Experimental animals administered with BZ before training (acquisition stage) were less effective in behavioral tasks, whereas a minor effect was observed when the agent was administered to trained animals exposed to a retrieval behavioral task (Fig. 14.2). This finding corresponds to the hypothesis that the cholinergic system is mainly essential for acquisition, and the

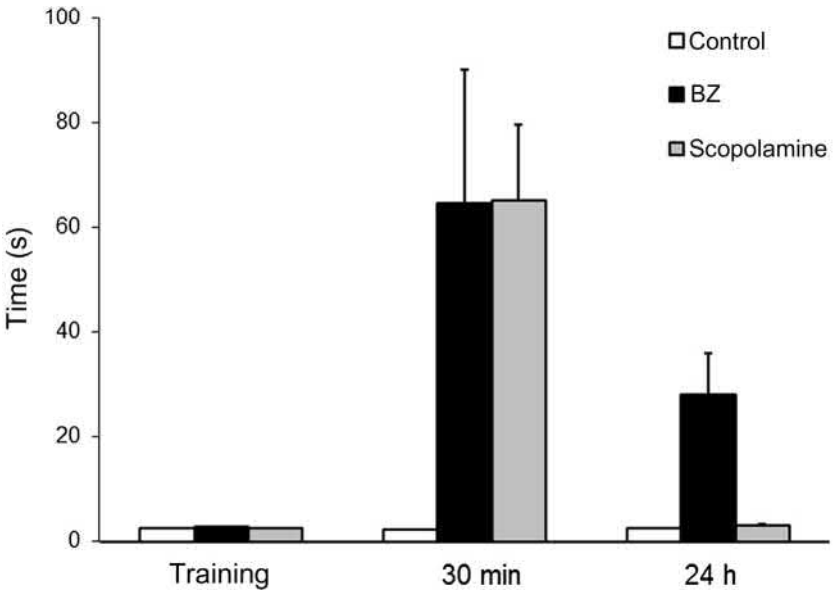

FIGURE 14.1 The prolongation of passage times in male Wistar rats performing the multiple T-maze test 30 min and 24 h postadministration of agent BZ (2.0 mg/kg) and scopolamine (0.3 mg/kg). The multiple T-maze task is focused on spatial navigation.

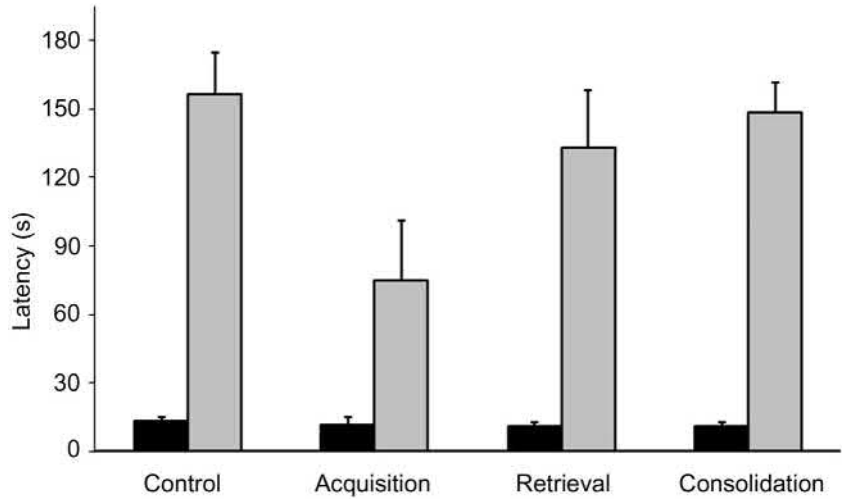

FIGURE 14.2 Effect of agent BZ on acquisition, retrieval, and consolidation in male Wistar rats performing passive avoidance task. There is training (*black columns*) and test (*gray columns*) entrance latency of control versus BZ-treated rats (2.0 mg/kg). Agent BZ was administered according to three different protocols aimed to affect the specific stage of learning and memory process. The passive avoidance task is based on fear conditioning.

blockade of M receptors during the acquisition stage impairs memory formation (Deiana et al., 2011).

In general, BZ may serve as an effective, long-acting alternative to the commonly used scopolamine in animal models of cognitive deficits, whereby new drugs (mainly cholinesterase inhibitors) could be tested.

14.10 Concluding remarks and future directions

BZ was recognized as an incapacitant agent for military use. It was stockpiled and stored as a CWA by the US military, but all stocks were destroyed in 1992. Nevertheless, the use of this agent is not completely excluded. Its mechanism of action is based on the interaction with cholinergic receptors. The symptomatology is characterized by peripheral action (vegetative symptoms) and the number of central symptoms affecting cognition and behavior. The effective antidotal therapy is of vital interest and it is based on the main principle of cholinesterase inhibition in the CNS, possibly using commonly available physostigmine or 7-MEOTA, eventually donepezil and rivastigmine, according to current animal data. Finally, the use of BZ in research into the cholinergic nervous system cannot be omitted.

15.1 Introduction

Fluoroorganic compounds attracted the attention of researchers more than 70 years ago when among a large class of biologically inert chemicals a group of very toxic compounds was revealed, having the general formula CH_2FCOOR and the common name "fluoroacetate" (FA). The toxicological effects of FA do not become apparent immediately, even after exposure to lethal doses, but only after a latent period of half an hour to several hours for animals and humans. The level of FA in some plants can reach up to 5 g/kg dry weight (Hall, 1972) and it can cause death of livestock and domestic animals, sometimes with appreciable economic damage (McCosker, 1989; Minnaar et al., 2000a; Lee et al., 2012). FA can be found in fog and raindrops in some industrial regions (Rompp et al., 2001). The best known representative of FA is its sodium salt (SFA, compound 1080). This substance is used in several countries for controlling populations of some vertebrates, and sometimes causes the death of pasture animals (Giannitti et al., 2013). There are also series of fluorocompounds whose metabolism is connected with the formation of FA, these are antineoplastic drugs (5-fluorouracil and isomers of fluoronitrosourea); *N*-(2-fluoroethyl) derivatives of the narcotic analgesics normeperidin and normethazocin; pesticides, 1,3-difluoro-propanol and fluoroacetamide (FAA, compound 1081); and 1-(di) halo-2-fluoroethans and fluoroethanol (Reifenrath et al., 1980; Tisdale and Brennan, 1985; Feldwick et al., 1998). The urgency of the problems associated with FA toxicity and the need for an effective therapy for acute intoxication has greatly increased in connection with a new threat—international terrorism (Holstege et al., 2007). The physicochemical features of FA, the lack of taste and odor, delayed manifestation of toxicity, and the similarity of clinical signs of intoxication to some natural indispositions are these characteristics that necessitate comprehensive studies of the mechanisms of action of FA and the search for effective therapeutic means for treatment of acute intoxication.

15.2 Background

FA was initially synthesized in 1896 and decades after that was found in *Dichapetalum*, *Gastrolobium*, *Oxylobium*, *Acacia, Palicourea, Mascagnia, Tanaecium*, and *Amorimia* plants growing in Australia, South and Central Africa, and South America (Oerlichs and McEwan, 1961; de Oliveira, 1963; McEwan, 1964; Aplin, 1971; Vickery et al., 1973; Camboim et al., 2012a; Lee et al., 2012; Esters et al., 2013). Chemically pure FA is a very stable compound, and the energy of dissociation of the fluoro−carbon bond in the molecule is regarded as one of the highest among the natural compounds (Ichiyama et al., 2004). However, FA is broken down in biological preparations from plants (Minnaar et al., 2000a). In soils, the major degradation pathway for SFA is through microbial degradation to the hydroxyl metabolite, hydroxyacetic acid, and microbial mineralization to CO_2; temperature, rather than soil type or moisture content, is the dominant factor affecting the rate of degradation (Northcott et al., 2014). Seven bacteria from soil and plant samples able to degrade SFA were identified by 16S rRNA gene sequencing as *Paenibacillus* sp. (ECPB01), *Burkholderia* sp. (ECPB02), *Cupriavidus* sp. (ECPB03), *Staphylococcus* sp. (ECPB04), *Ancylobacter* sp. (ECPB05), *Ralstonia* sp. (ECPB06), and *Stenotrophomonas* sp. (ECPB07) (Camboim et al., 2012a). Also, two SFA-degrading bacteria from

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00015-5

caprine rumen, *Pigmentiphaga kullae* (ECPB08) and *Ancylobacter dichloromethanicus* (ECPB09) (Camboim et al., 2012b), and one from bovine rumen belonging to the phylum Synergistetes (Davis et al., 2012) have been identified, the last functioning in anaerobic conditions.

After inhalation or ingestion, FA is easily absorbed by tissues and its high toxicity is independent of its route of entry into organisms (Chenoweth, 1949). The mechanism of toxic action of FA is widely known as "lethal synthesis" (Peters, 1952; Peters and Wakelin, 1953), the essence of which is conversion of nontoxic FA to toxic fluorocitrate (FC) within the cells of an organism. The main causes of death are considered to be imbalance of intracellular ions, osmotic imbalance, and a deficit of ATP as a consequence of aconitase blockade (Buffa et al., 1973). The latent period, from the moment of poisoning with FA to the manifestation of clinical signs, is 0.5−3 h (in warm-blooded animals). This period reflects penetration of FA into blood and cells and conversion of FA to FC, with the consequent uncoupling of intracellular metabolism. Death usually occurs within 24−48 h, but can be later. At autopsy there are no specific signs of intoxication (Peters et al., 1981). For those warm-blooded animals least adapted to FA the lethal dose is less than 2 mg/kg (Atzert, 1971). However, there is a considerable species-specific difference in clinical signs of intoxication and differences in sensitivity to the poison (Chenoweth, 1949). The mean lethal dose varies within the range from 0.05 mg/kg for dogs to 150 mg/kg for possums. The most common criterion of tolerance, or vice versa sensitivity, of animals to FA is intensity of metabolism. Thus, in the lizard *Tiliqua rugosa* the level of metabolism of FA is 10-fold lower in comparison with that of the rat *Rattus norvegicus*, and the lethal dose for the lizard is 100-fold higher than that of the rat (Twigg et al., 1986). A low intensity of metabolism means a low conversion of FA to FC, which makes possible more effective excretion and detoxification. In the absence of specific clinical, physiological, and morphological signs of intoxication, determination of FA in tissues together with citrate and fluoride ions can be a diagnostic confirmation of FA intoxication (Schultz et al., 1982; Koryagina et al., 2006).

15.3 Toxicokinetics

15.3.1 Detoxification

The main pathway of detoxification of FA is its defluorination via a glutathione-dependent mechanism involving nucleophilic attack on the β-carbon atom and formation of fluoride and *S*-(carboxymethyl)glutathion, with subsequent cleavage of the latter into amino acids and an *S*-(carboxymethyl) conjugate complex excreted in the urine (Mead et al., 1979; Tecle and Casida, 1989). The highest defluorinating activity was found in the liver, followed by the kidneys, lungs, heart, and testicles in descending order. No defluorinating activity was found in the brain. The activity of enzymes responsible for defluorination depends on the glutathione (GHS) concentration with a maximum above 5 mmol/L, the apparent Km being 7 mmol/L at saturating concentrations of GHS (Soiefer and Kostyniak, 1983). Defluorination is mainly carried out by anionic proteins having glutathione transferase activity, though the anionic fraction contains nearly 10% of proteins without this activity but also capable of defluorination of FA. Moreover, cationic enzymes were shown to be responsible for about 20% of cytosolic defluorination of FA (Wang et al., 1986). The GHS-dependent enzyme defluorinating FA is not identical to GHS-dependent S-transferases; it is an FA-specific defluorinase with an acidic isoelectric point (pH = 6.4) and a molecular weight of 41 kDa (27 kDa for the main subunit) (Soiefer and Kostyniak, 1984). The activity and specificity of defluorinase isoenzymes vary markedly and are subjects of research presently (Tu et al., 2006; Nakayama et al., 2012).

15.3.2 Analytical procedure

The analysis of biological samples for FA is rather problematic because of the high polarity of the fluorine−carbon bond in the molecule. Liquid chromatography (LC) has been applied for analysis of FA in different media (Allender, 1990), and analysis of FA in plants and gastric contents by HPLC with UV detection has also been described (Minnaar et al., 2000b). Being a nonvolatile substance, FA was commonly analyzed by gas chromatography (GC), as a methyl derivative (Stevens et al., 1976), ethyl or *n*-propyl derivatives (Peterson, 1975), and as pentafluorobenzyl esters (Vartiainen and Kauranen, 1984). Derivatization with 2,4-dichloroaniline in the presence of *N*,*N*-dicyclohexylcarbodiimide was used for GC analysis of SFA in water (Ozawa and Tsukioka, 1987) and blood serum (Demarchi et al., 2001). A modified procedure by Eason et al. (1994) achieved low detection limits for FA at the level of 0.01 μg/g in plasma and urine, and 0.002 μg/g in tissue and feces of sheep and goats. However, this procedure is labor- and time-consuming, and the GC-electron capture detection procedure applied is considered to be unreliable at this level of sensitivity.

The main problem for GC analysis of FA in biological samples is co-elution of the matrix components. This can be overcome by sampling of the analyte from an equilibrium vapor phase. Static head-space analysis of SFA as ethyl fluoroacetate, with a linear range for SFA in water of 5−200 μg/mL and a detection limit of 0.5 μg/mL has been reported (Mori et al, 1996). Solid-phase microextraction (SPME) from an equilibrium vapor phase has

all the advantages of head-space analysis, whilst being a much more sensitive technique. We reported on a novel procedure for determination of FA in water and biological samples, involving ethylation of FA with ethanol in the presence of sulfuric acid, SPME of the ethyl fluoroacetate formed with subsequent analysis by GC-MS (Koryagina et al., 2006). To overcome the problem of the presence of the components co-eluting with FA derivatives we made use of GC-MS in the SIM (selective ion monitoring) mode. To avoid partial overlapping of the internal standard's peak with the sample matrices' components, quantification was performed with the use of two internal standards—carbon tetrachloride and toluene. The calibration plots for the determination of SFA in biological samples was linear in the SFA concentration range 0.01−5.0 μg/mL for both internal standards, and a linear relationship in blood plasma was observed in the range of 0.01−5.0 μg/mL ($r = 0.95$). With toluene as internal standard, the linear regression equation was $Y = 0.014\ X$ [Y was the ratio S(EthylFA)/S(toluene); X was the concentration of SFA, μg/mL]. The RSD (relative standard deviation) for fluoroacetate quantification at 0.1 μg/mL was 12% ($n = 5$). With carbon tetrachloride as an internal standard, a linear relationship in plasma was observed in the range of 0.01−5.0 μg/mL ($r = 0.98$). The linear regression equation was $Y = 0.1656\ X$ [Y was the ratio S(EthylFA)/S(CCl4); X was the concentration of FA, μg/mL]. The RSD for FA quantification at 0.1 μg/mL was 6% ($n = 5$), and the detection limit was 0.005 μg/mL ($S/N = 3$). The calibration characteristics of rat organ homogenates were identical to those of plasma. A decade has passed since our publication, but it seems that no sensible progress in analytical methodology has been achieved, taking into regard the levels of detection and quantification of FA in biological tissues (Liu et al., 2018).

15.3.3 Distribution in tissues and elimination

The data on toxicokinetics of FA are rather contradictory, apparently depending on analytical procedures and the dose of the poison; also, there is evidence for animal species specificity. The first data on toxicokinetics of FA demonstrated its rather uniform distribution between organs, with some predominance in the heart, brain, and kidneys (Gal et al., 1961). The half-life was calculated to be not less than 2 days, and this could cause secondary toxicity arising from ingestion of meat from poisoned animals (Aulerich et al., 1987). The half-life of FA was shown to be 10.8 h for sheep and 5.4 h for goats, that were administered 0.1 mg/kg; maximal concentration of FA 2.5 h after the poisoning was revealed in blood plasma (0.098 μg/mL), followed by kidneys (0.057 μg/g), skeletal muscles (0.042 μg/g), and liver (0.021 μg/g). Only traces of FA were found in all the tissues examined 96 h after

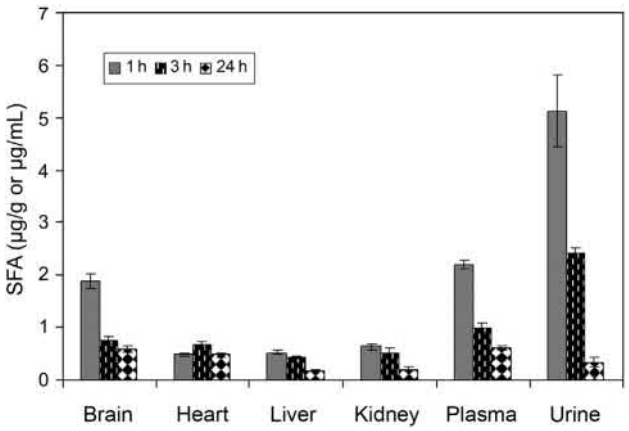

FIGURE 15.1 Data on the determination of FA (recounted as SFA) in rat organ homogenates and body fluids, at times following poisoning with SFA at a peroral dose of 2 mg/kg ($1/2LD_{50}$). Standard deviations (shown) were based on four to six replicate analyses.

the poisoning (Eason et al., 1994). At 1 and 12 h after introduction of SFA (0.25 mg/kg) to rats a similar ratio of FA was found in rat plasma (0.26 and 0.076 μg/mL, correspondingly) (Eason and Turck, 2002), the half-life period being 2.9 h. On the other hand, for rabbits under subacute intoxication with FA the half-life was found to be 1.1 h, and the level of FA in rabbit muscles, kidneys, and liver was much higher than in blood plasma (Gooneratne et al., 1995).

In our experimental work, the use of the above-mentioned SPME method in combination with GC-MS produced the following results (Fig. 15.1): maximal concentrations were found in rats 1 h after the poisoning, 2.2 μg/mL in blood plasma and 1.89 μg/g in brain; there was 3−4-fold less FA in rat kidneys, liver, and heart (from 0.64 to 0.50 μg/g). After a further 2 h the distribution between the tissues was more equal, resulting from a prominent decrease of FA in plasma and brain and a small decrease or even elevation of FA in other organs. A further decrease of FA was found in all tissues, except for heart, 24 h after the poisoning. After 72 h, no FA was detected in plasma; we did not measure FA in rat organs at this time point. The half-life was calculated to be 3.6 h.

15.4 Mechanism of action

15.4.1 Molecular mechanism of aconitase inhibition

The mechanism of the inhibitory effect of FA on aconitase [citrate (isocitrate) hydrolyase, EC 4.2.1.3] is one of the most interesting in biochemistry. Upon entering an organism, nontoxic FA undergoes a series of metabolic conversions the result of which is synthesis of highly toxic fluorocitrate (FC); this process is termed

"lethal synthesis" (Peters, 1952). FC is formed by the enzymatic condensation of fluoroacetyl-CoA with oxaloacetate, catalyzed by citrate (*si*)-synthase (EC 4.1.3.7) (Eanes and Kun, 1974). FC was initially considered to be a competitive aconitase inhibitor, but in the early 1990s it was suggested that FC acts as a "suicide substrate," because it has a high affinity for aconitase at any concentration of the competitive citrate (Clarke, 1991). Aconitase effects conversion of citrate to isocitrate through an intermediate, *cis*-aconitate, which binds with aconitase in two different ways, swung 180 degrees to the $C^{\alpha}-C^{\beta}$ bond (Gawron and Mahajan, 1966). Aconitase includes a [4Fe-4S] cluster and the catalytic conversion involves substrate coordination to a specific iron atom in this cluster, Fe_a (Lauble et al., 1992). The single inhibitory isomer was shown to be (−)-*erythro*-2-flurocitrate (2*R*, 3*R*) (Carrell et al., 1970), from which aconitase removes fluoride ion with a stoichiometry of $1F^-$ per enzyme molecule (Tecle and Casida, 1989). The defluorination results in the generation of an actual aconitase inhibitor, 4-hydroxy-*trans*-aconitate (HTA), which binds very tightly—though not covalently—with aconitase (Lauble et al., 1996). The natural aconitase substrate isocitrate should be at a 10^6-fold excess in order to slowly displace HTA from its complex with aconitase. The HTA−aconitase complex involves four hydrogen bonds, which hold together HTA, a water molecule, Asp165, and His167 (Lauble et al., 1994, 1996). In contrast, isocitrate has only one such bond.

15.4.2 Physiological and biochemical effects of fluoroacetate

15.4.2.1 Effects of fluoroacetate and fluorocitrate on mitochondria and other intracellular organelles

Functional disturbances of mitochondria (MCh) precede the appearance of structural anomalies (Buffa and Pasquali-Ronchetti, 1977) and consist of their decreased capacity to oxidize the substrates introduced. Within the mitochondrial matrix, FA induces changes which develop in several minutes, resulting in its swelling and loss of electronic density. These changes are explained by the accumulation of citrate, rise of osmotic pressure, and decrease of energy production; change in the level of ATP is not caused by uncoupling of respiration and phosphorylation (Corsi and Granata, 1967). Mitochondrial volume changes are accompanied with their conformational reorganizations: these are displacement of granules and disintegration of cristae, and extension and rupture of their membranes. Axonal cylinders stretch in 3−4 h after small doses of the poison and in 1−2 h after lethal doses. The cylinders are filled with MCh (most of which is swollen and degenerated), multilamellar lysosome-like bodies,

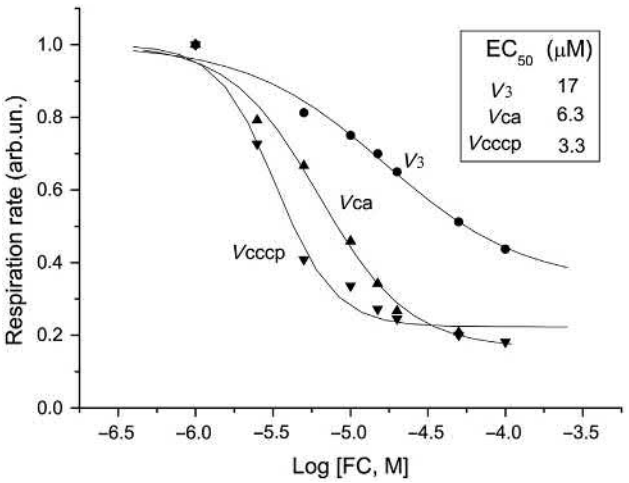

FIGURE 15.2 Effects of FC on respiration of rat liver MCh. Dependence of respiration rate activated by ADP (V_3), calcium transport (V_{Ca}), and protonophore CCCP (*V*cccp) upon concentration of FC. Substrates: pyruvate *plus* malate.

vesicles, and neurofibrils. In the Golgi complex, a condensation of cisternae takes place (McDowell, 1972). Concurrently a disruption of endoplasmic reticulum, swelling of nucleus, and reduction of aggregated chromatin can be seen.

Having studied the in vitro effects of FC on rat liver MCh, we revealed that maximal inhibition of respiration was registered when MCh were uncoupled (Fig. 15.2). The level of alkalinization of the medium at addition of ADP was much lower in the presence of FC, thus evidencing an inhibition of ATP synthesis. The amplitude of alkalinization was also decreased, which could be caused by incomplete ATP synthesis, an additional transmembrane redistribution of protons, and/or change to the binding constant of ADP. FC induced a leak of Ca^{2+} from MCh, which was consistent with the observed inhibition of oxygen consumption in respiratory state 1. Addition of the substrates caused re-entry of Ca^{2+} into MCh. In the presence of FC, the MCh only partially took up the Ca^{2+} ions added to the medium, followed by their spontaneous efflux through an electroneutral $2H^+/Ca^{2+}$ exchanger with $K_{1/2} = 10$ μmol/L (Teplova et al., 1992).

The effects observed under exposure of MCh to SFA developed at much higher concentrations (from 4 mmol/L), as compared to FC, and greatly depended on respiratory substrates. With pyruvate as substrate, the time period of oxidative phosphorylation (OP) and the level of NADH oxidation increased linearly at increasing SFA concentration in the medium (Zinchenko et al., 2007). However, with utilization of succinate and especially glutamate, SFA had no effect on OP in concentrations as high as 8 mmol/L (Fig. 15.3A) and even 16 mmol/L (not shown here). Moreover, the effect of SFA with pyruvate

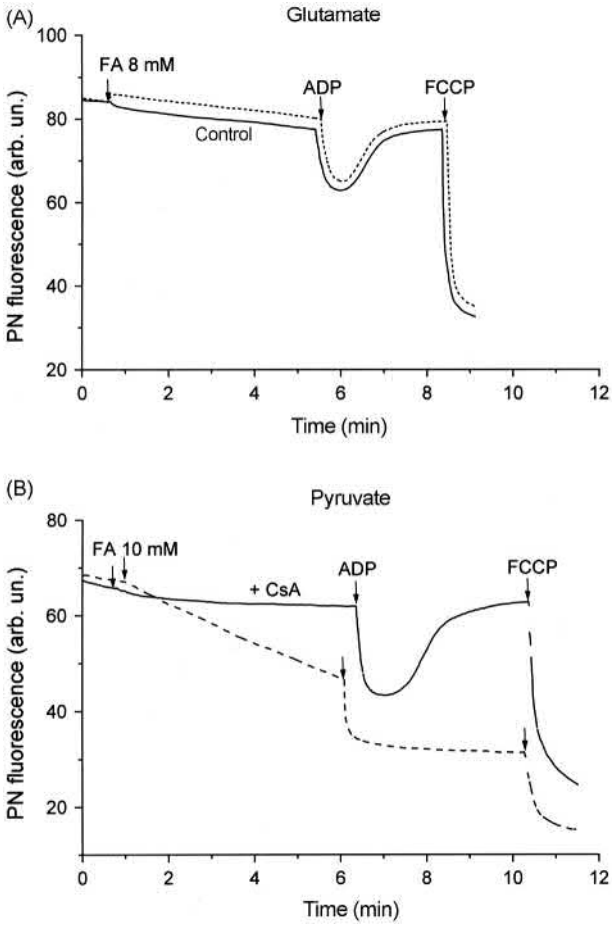

FIGURE 15.3 Effects of FA on redox state of pyridine nucleotides (PN) of rat liver MCh. (A) Glutamate as respiratory substrate. (B) Prevention of PN oxidation and/or leakage by cyclosporin A (CsA) when pyruvate was used as respiratory substrate. Additions: (A) SFA 8 mmol/L (*dots*) or sodium acetate 8 mmol/L (control line), ADP 120 μmol/L, FCCP 1 μmol/L; (B) SFA 10 mmol/L (*dots*) or SFA 10 mmol/L *plus* CsA 1 μmol/L (*line*).

as respiratory substrate can be prevented by incubation of MCh with cyclosporine A, a known inhibitor of the mitochondrial transition pore (Fig. 15.3B). This means that under exposure to FA, development of mitoptosis and apoptosis is possible, but opening of the pore is reversible in nature and preventing oxidation or leak of NADH from MCh can return them back to their normal functional state.

15.4.2.2 Effects of fluoroacetate on isolated cells

The effects of FA on the physiological and biochemical status of cells and tissues are highly dependent upon their level of oxidative metabolism. Thus, FA does not inhibit phagocytosis because of the low level of TCA cycle activity within macrophages (Cifarelli et al., 1979). We investigated a series of cell types—transformed lines and those obtained from animals—under exposure to FA or FC. The level of NAD(P)H in Ehrlich ascite tumor (EAT) cells slowly decreased and the level of Ca^{2+} increased when the cells were incubated with SFA (Zinchenko et al., 2007). SFA obviously induced depletion of intracellular calcium stores and/or activation of influx of extracellular Ca^{2+} ions through the store-operated calcium (SOC) channels. Discovery of other calcium channels, such as TRPV5 and TRPV6 (Hoenderop et al., 2003; van de Graaf et al., 2006), which remain inactivated when cytosolic $[Ca^{2+}]_i$ is increased and become activated when $[Ca^{2+}]_i$ is decreased, stimulated an investigation of the level of calcium ions in endoplasmic reticulum (ER) with chlortetracycline (CTC). FC does not affect the velocity of calcium efflux from ER, so the signal transmission from P2Y receptor via G-protein is not inhibited in EAT cells exposed to FC (Zinchenko et al., 2007). However, FC induced growth in both amplitude of Ca^{2+} leakage and velocity of its influx into ER. A rather long period (8−10 min) of Ca^{2+} influx into ER was observed, which indicated efflux of intracellular Ca^{2+} from cells by plasma membrane Ca-ATPase immediately after mobilization and leaving ER. This greatly reduces $[Ca^{2+}]_i$ for transport back to ER. It was demonstrated earlier (Zinchenko et al., 2001) that the velocity of return transport of Ca^{2+} into ER depends upon the activity of plasma membrane SOC channels. Therefore, we suggest that FA (or FC) somehow impede the entry of calcium ions into cells through SOC channels. This may happen due to chelating of calcium ions by increased extracellular citrate anions leaving the cells through anion channels.

The toxic effects of FC on endothelial cells have been shown to be similar to its effects on other energy-dependent tissues: a reduction of ATP level and oxygen consumption, but an accumulation of lactate and a considerable decrease in protein synthesis (Rist et al., 1996). We have demonstrated with rat aorta endothelial cells in culture a gradual decrease in the mitochondrial membrane potential and elevation of $[Ca^{2+}]_i$ under exposure to SFA, similar to that observed with EAT cells (not shown here). Conversely, in cardiomyocytes SFA induced a slow enhancement of the mitochondrial membrane potential together with a rise of basal $[Ca^{2+}]_i$; propagation of calcium waves along the surface of sarcoplasmic reticulum, or visible elevation and velocity of spreading of the preexisting waves, was also observed (Zinchenko et al., 2007). Probably the increased level of $[Ca^{2+}]_i$ is the reason for its transport into MCh with a subsequent inhibition of the proton ATPase and rise of membrane potential. Mechanistically this phenomenon could be explained by the existence of a Ca^{2+}-dependent protein inhibiting H^+-ATPase (Hubbard and McHugh, 1996).

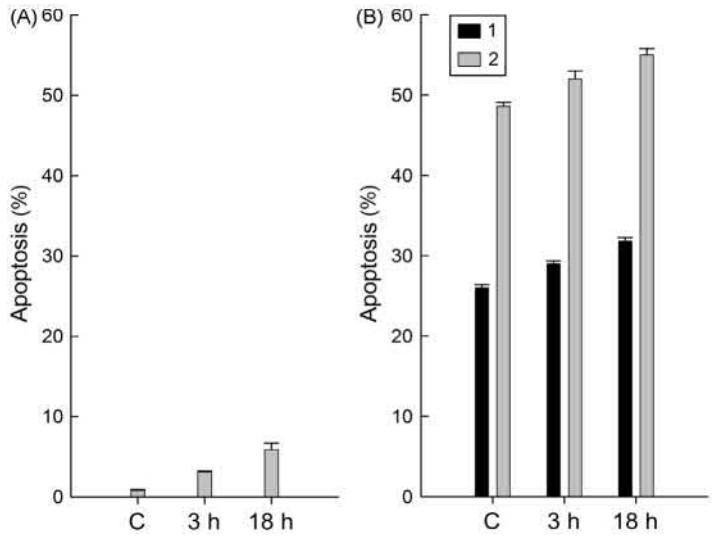

FIGURE 15.4 Effect of SFA on development of apoptosis of rat thymocytes 3 and 18 h after administration of SFA at $1/2LD_{50}$. Registration of apoptosis with Hoechst-33258. (A) Apoptosis in freshly isolated thymocytes; (B) apoptosis in thymocytes cultivating for 20 h after isolation in the absence (1, *black*) and presence (2, *gray*) of dexamethasone. C, control.

We have also studied kinetic parameters of platelet aggregation in experiments with rats in vitro and ex vivo (Mindukshev et al., 2006). Aggregation of platelets was induced with ADP over the concentration range 10−100 nmol/L. The median effective concentrations (EC_{50}) of ADP for the cells exposed to SFA at 10 and 5 mmol/L were calculated to be 25 and 35 nmol/L, correspondingly, and these platelets can be characterized as hypersensitive to ADP. Studying the kinetic parameters of platelet aggregation under intoxication of rats with SFA, we encountered a problem of spontaneous aggregation of the platelet-rich plasma, which is in agreement with the data on primary transition of the platelets to the hypersensitive state. However, the cells that avoided aggregation demonstrated an extremely high level of desensitization. In some experiments, ADP could not induce platelet aggregation at very high (nonphysiological) concentrations near 10 μmol/L. Thrombocytopenia found in cats after the poisoning is in agreement with our observations (Collicchio-Zuanaze et al., 2010).

Under intoxication with SFA a significantly reduced thymus, as well as a prominent quantity reduction of freshly obtained thymocytes and elevation of apoptosis were revealed (Fig. 15.4A). SFA also caused an acceleration of apoptosis of intact and dexamethazone-treated human lymphocytes in vitro (Fig. 15.4B), although spontaneous apoptosis of human neutrophils was inhibited (not shown here). Moreover, SFA either inhibited (high doses) or had little effect on reactive oxygen species (ROS) production by peritoneal macrophages of mice in our experiments in vitro (not shown here). In this regard it should be noted that dexamethasone, in contrast to its effect on lymphocytes, also inhibits apoptosis of neutrophils induced by ROS (Ruiz et al., 2002). One can suggest that the inhibitory effect of FA on neutrophil apoptosis is realized through ROS, whereas the enhanced apoptosis and depression of the cells responsible for adaptive immunity is a nonspecific reaction under SFA intoxication, reflecting a general decline and redistribution of energy resources of the organism. To this end, leucopenia was found in cats after the poisoning (Collicchio-Zuanaze et al., 2010).

15.4.2.3 Biochemical parameters under intoxication with fluoroacetate

Among the biochemical effects caused by FA are: accumulation of citrate and disturbance of its transport from MCh; elevation of lactate and disturbances in carbohydrate metabolism; decrease or increase in free fatty acids (FFA) concentration; elevation of adenosine and ammonia; imbalance of bivalent cations and acid−base equilibrium; hypokalemia; changes in GABA balance in brain; hypo- or hyperphosphatemia; and rise of various enzymes in blood plasma, including creatine kinase enzyme and creatine kinase cardiac isoenzyme (Buffa and Peters, 1950; Engel et al., 1954; Maytnert and Kaji, 1962; Stewart et al., 1970; Buffa et al., 1973; Liang, 1977; Taitelman et al., 1983a; Bosakowski and Levin, 1986; Szerb and Redondo, 1993; Tsuji et al., 2009; Collicchio-Zuanaze et al., 2010). We have specified changes in triglycerides and FFA after acute intoxication with SFA (Table 15.1). As expected, the total level of triglycerides and FFA changed in opposite directions within 3 h after poisoning, with the former reduced and the latter elevated up to 75%. Reduced level of triglycerides persisted over 24 h, whereas the total concentration of FFA dropped below the normal level, though not significantly. GC-MS analysis of 36 fatty acids after extractive alkylation revealed reliable changes in concentration for seven of them, in agreement with total FFA changes.

*$P < .05$, **$P < .01$.

Among such a variety of biochemical changes, citrate seems to be the only parameter whose qualitative (but not quantitative) trends are not a matter of controversy. In rat hearts under acute intoxication with FA, the concentration of citrate can exceed control values by 8−15-fold (Bosakowski and Levin, 1986). Elevation of citrate concentration is in direct proportion to the respiratory activity of a tissue: metabolically active tissues—such as heart, kidneys and spleen—maximally accumulate citrate. However, in liver, which is also characterized by high respiratory level and metabolic activity, a small accumulation of citrate has been observed (Cole et al., 1955; Twigg et al., 1986). In our experiments with rats poisoned with SFA at a dose $1/2LD_{50}$, the concentrations of citrate in blood plasma and organs increased within an hour (Fig. 15.5). The most prominent elevation of citrate was revealed 6 h after the poisoning in the heart (fivefold), kidneys (threefold), and brain (2.5-fold). There was a doubling of the level of citrate in blood plasma after an hour, though it was the only biochemical parameter of plasma that remained elevated for 3 days.

Transfer of citrate through the inner membrane of MCh is provided by a tricarboxylate transporter (molecular weight 32.5 kDa), which also catalyzes transport of *treo*-D_s-isocitrate, *cis*-aconitate, and other tricarboxylates (Kaplan et al., 1990). This is electroneutral exchange for either another tricarboxylate or dicarboxylate (e.g., malate or succinate), or for phosphoenolpyruvate. Formation of glutathione-citryl thioester is irreversibly inhibited by (−) erythrofluorocitrate ($IC_{50} = 25$ pmol FC/mg protein), which makes a stable adduct with the synthase (Kun et al., 1977). However, the block of citrate transport is not absolute and universal for all organs and tissues. There are data on citrate transfer from MCh to cytosol with its subsequent utilization by cytoplasmic aconitase (c-aconitase), which is virtually unaffected under FA intoxication, and then by cytoplasmic NADP-dependent isocitrate dehydrogenase (cICDH) (Max and Purvis, 1965). Around 32% of citrate produced in MCh can be transported to cytosol (Buffa et al., 1972). These processes should be regarded as adaptive and positive, they lead to reduced oxygen consumption because the NADPH generated does not require further oxidation in the respiratory chain and can be utilized in other metabolic pathways.

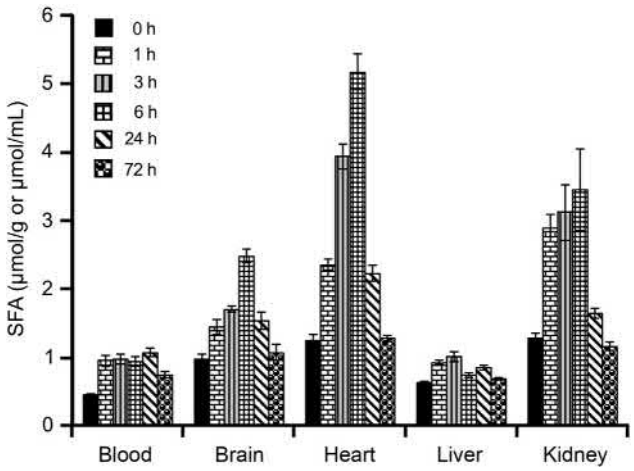

FIGURE 15.5 Concentration of citrate in blood and organs of rats under intoxication with SFA at $1/2LD_{50}$.

Among the negative consequences of citrate accumulation is a change of electrolyte composition and acid−base imbalance in the organism. Moreover, elevation of the citrate level in cells leads to a disturbance of glucose metabolism due to inhibition of the key glycolytic enzyme phosphofructokinase (Bowman, 1964; Peters, 1972). Hyperglycemia during intoxication with FA can be very prominent, in spite of inactivation of gluconeogenesis (Godoy et al., 1968; Bobyleva-Guarriero et al., 1983). Nevertheless, we could not find significant changes in rat blood glucose throughout the periods of intoxication with FAA or SFA at a dose $1/2LD_{50}$; at the same time,

there was a significant increase of glucose level in the liver, heart, and brain (not shown here). This may signify a utilization of glucose by other tissues, and first of all by skeletal muscles, as a result of which the local increase of glucose in organs is not reflected by the level of glucose in blood. Thus, glucose cannot serve as a reliable criterion of intoxication.

Some researchers considered the elevated glucose level to be a result of decreased insulin secretion by pancreatic β-cells due to their damage by FA (Cole et al., 1955; Karam and Grodsky, 1962). Along with hyperglycemia, there was hyperketonemia, observed characteristically for the diabetic state, caused by inhibition of TCA cycle and depletion of oxaloacetate (Buffa et al., 1973; Taitelman et al., 1983a). Also consistent with diabetes is inhibition of hormone-induced lipolysis in adipose tissue (Taylor et al., 1977). Moreover, FA increased glucose conversion to fatty acids, and such a coincidence of antilipolytic and lipogenetic effects of FA provides a basis for suggesting a relation in effects of FA and insulin. However, injection of insulin does not alleviate FA intoxication in general and "FA diabetes" in particular (Reichelt, 1979). During FA intoxication, the initial hyperglycemia can even be reversed into hypoglycemia (Boquist et al., 1988), therefore this effect of FA was considered to be an insulin-like phenomenon (Zieve et al., 1983). The principal distinction, however, should be depletion of glycogen stores in different tissues under intoxication with FA (Godoy et al., 1968; Boquist et al., 1988). After poisoning with FA, glycogen levels in animal tissues may decrease by 75% in 1 h and by 90% in 2 h (Buffa et al., 1973; Zhou et al., 1984). According to our data, during SFA intoxication ($1/2LD_{50}$) glycogen levels are maximally decreased after 6 h in both liver (by 55%) and brain (by 40%), and the dynamics of the glycogen levels were similar in these organs. Such a decrease could result from the indirect action of adrenaline or sympathetic regulation (Buffa et al., 1973). In addition, inhibition of de novo glycogen synthesis has been reported (Zhou et al., 1984).

Nevertheless, disturbances in hormonal regulation during FA intoxication can also take place: reduction of calcium concentration in blood plasma could be caused by a poor reabsorption of calcium ions in kidneys due to a decrease in the parathormone level; an excess of Ca^{2+} excretion up to 0.173 mg/min (the control rate being 0.06 mg/mL) has been registered (Perez and Frindt, 1977). A decrease in the calcium level could be the cause of so-called "hypocalcemic tetanus" (Roy et al., 1980), manifesting itself as typical convulsions, disturbances of blood clotting, and hypotension leading to vascular attacks. The level of decrease of calcium correlates with extension of the $Q-T$ interval on ECG, which is a consequence of the broad spectrum of cardiac arrhythmia (Buffa and Peters, 1950; Arena, 1970).

The ATP level is usually reduced, and ADP and AMP levels can be elevated in the first hours of the FA intoxication, with a subsequent decrease (Bowman, 1964; Stewart et al., 1970). There are other reports of a constant level of ATP in some organs and tissues. For example, FA did not affect ATP and GTP, as well as cyclic nucleotides levels in hepatocytes in vitro (Dohi and Murad, 1981). When dogs were intoxicated with sublethal doses of FA, there were no decreases in oxygen consumption and ATP level observed, which was explained by utilization of glutamate and aspartate which can enter the TCA cycle distally of aconitase (Liang, 1977). The inversion of reactions at glutamate dehydrogenase (GDH) is a simple and effective compensative mechanism during blockade of the TCA cycle in kidney cells: instead of glutamine synthesis, glutamate is deaminated to form 2-oxoglutarate to support the flow of reducing equivalents in the TCA cycle and ATP synthesis, while the ammonia produced neutralizes local tissue acidosis (Yu et al., 1976). Such utilization of glutamate may account for the significant reduction of glutamate level in rat organs, beginning from the first hour after intoxication with FA. The data obtained according to the GC-method of Matsumura et al. (1996) have also shown decreases in glutamate, aspartate, and some other amino acids in rat brain (Fig. 15.6), as well as a decrease in glutamate and nearly complete absence of glutamine in the blood plasma of rats and rabbits (not shown here), 3 h after poisoning with SFA. The levels of amino acids in blood plasma of animals indicate the extent of protein breakdown in muscles, on one hand, and the level of their utilization by other organs and tissues, on the other hand. Under intoxication with FA, glutamate and its precursor glutamine are probably the main

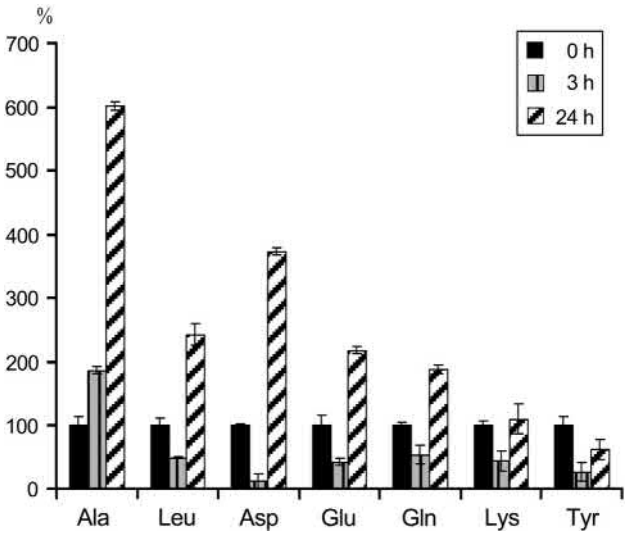

FIGURE 15.6 Changes to some amino acids in rat brain 3 and 24 h after administration of SFA at $1/2LD_{50}$.

nutrients. Elevation of amino acid levels in blood plasma of rats within 3 h after poisoning signifies an elevation of protein breakdown. Furthermore, this indicates that other amino acids—because of their transport, catabolism, etc.—are not nutrients of primary importance under energetic deficit conditions.

Elevation of the lactate level in the blood of animals poisoned with FA has been reported (Engel et al., 1954; Taitelman et al., 1983a). In agreement with these data, we observed a prominent rise in lactate levels in blood just after convulsions (not shown here). In rat heart and brain, lactate levels decreased under intoxication with SFA or FAA, irrespective of convulsions. During SFA intoxication the decrease in lactate level (and increase in glucose level) in rat heart takes place earlier and to a greater extent than for FAA intoxication: 38% decrease in 3 h for lactate, as compared with 25% in 6 h in the case of FAA; 100% increase in 3 h for glucose, as compared with 67% in 6 h in the case of FAA. Also, the maximal increase in citrate was registered at 24 h after poisoning with FAA, but at 6 h after poisoning with SFA. These and other biochemical data are consistent with clinical pictures of intoxication with equipotential doses of SFA and FAA: intoxication with SFA is generally more violent and takes a shorter period of time.

15.4.2.4 Effects of fluoroacetate on the cells of the nervous system: interaction of glia and neurons

Acetate is metabolized in astrocytes near 18-fold faster than in cortical synaptosomes, though activity of acetyl-CoA synthase in synaptosomes is almost double that in astrocytes (5.0 and 2.9 nmol/min mg/protein, respectively). The principal difference in the acetate metabolism rates is explained by differences in the kinetics of its transport, which is mediated by a monocarboxylate carrier (Hosoi et al., 2004); acetate uptake by astrocytes, unlike synaptosomes, rapidly increases and follows saturation kinetics ($V_{max} = 498$ nmol/min/mg protein, $K_M =$ 9.3 mmol/L) (Waniewski and Martin, 1998). Having penetrated into astrocytes at one site, FA can diffuse into other cells through gap junctions (Ransom, 1995). Citrate accumulating in astrocytes is readily released from cells and effectively penetrates other astrocytes (Westergaard et al., 1994). The TCA cycle in nerve tissues is blocked by FA but not completely, only by 35%−55% (Patel and Koenig, 1968). This leads to decreased consumption of glucose and increased consumption of glutamine (if the latter is available); no reduction of ATP was observed (Hassel et al., 1994). The natural metabolic pathway is switched over to utilization of glutamine, glutamate, and 2-oxoglutarate in the TCA cycle. GDH of astroglia plays a large role in this switching over, promoting the ATP-independent utilization of glutamate (Plaitakis and Zaganas, 2001). The absence of an aspartate/glutamate mitochondrial exchanger (the key component of the malate/aspartate cycle) in astrocytes also plays a part in support of this (Xu et al., 2007). There is little GDH in neurons as compared to astrocytes, with activity of GDH depending not only upon proximity to glutamatergic fibers and terminals, but also upon the activity of neighboring neurons regardless of their functional specialization; a deficiency in GDH activity in astroglia may be a cause of cytotoxic effects of glutamate and aspartate (Aoki et al., 1987).

The uptake of glutamate by astrocytes is an electrogenic process in which one molecule of glutamate is cotransported with three sodium ions (or $2Na^+$ and $1H^+$), being exchanged for $1K^+$ and $1OH^-$ or $1HCO_3^-$ (Bouvier et al., 1992). To re-establish the ionic balance, Na^+/K^+-ATPase would work with ATP provided by phosphoglycerate kinase bound to plasma membrane. This stimulates glycolysis and lactate production in astrocytes. Lactate is released from astrocytes and then is taken by neurons to be further oxidized. Pyruvate, which is also produced in astrocytes can be utilized in the TCA cycle to form 2-oxoglutarate or transaminated to form alanine; the latter can also enter neurons (Tsacopoulos and Magistretti, 1996; Tsacopoulos, 2002). However, the rate of alanine metabolism through alanine transaminase (ALT) in synaptosomes is much less than its rate of uptake. Moreover, neuronal ALT and AST work mainly to synthesize alanine and aspartate (Erecinska and Silver, 1990). Hence, we observed a stable elevation of alanine level—in contrast to that of other amino acids—in brains of rats poisoned with SFA (Fig. 15.6). The role of alanine as a source of glutamate is increased during the restoration period after ischemia/hypoxia, when the alanine concentration is elevated and the glutamate concentration is reduced (Erecińska et al., 1994).

Inhibition of glutamate uptake by astroglial cells can be one of the causes of convulsions observed under intoxication with FA (Szerb and Issekutz, 1987). The toxic effect is governed mainly by citrate, which is thought to chelate calcium ions (Fonnum et al., 1997). Intrathecal injection of FC in mice caused convulsions in about 15 s, and about 37 min by intracerebroventricular injection (Hornfeldt and Larson, 1990). Moreover, intrathecal injection of sodium citrate caused the same effect. This means that the main target of FC and citrate, and the area for generation of convulsions, should be the spinal cord. Convulsions could also be generated by other compounds having the common property of chelating calcium ions; these are EDTA, EGTA, glutamate, and lactate (Hornfeldt and Larson, 1990). Thus, along with elevation of citrate level, activation of anaerobic oxidation of glucose in neurons followed by accumulation of

lactate in cerebrospinal fluid, could also lead to coma and convulsions (Stewart et al., 1970). Chelation of zinc and other divalent cations by citrate enhances the signaling activity of NMDA receptors (Westergaard et al., 1995). In addition, disturbances of GABA metabolism were revealed as a result of the TCA cycle blockade: after injection of FA, there was initially an elevated level of GABA registered in different regions of the brain, followed by its reduction concurring with the beginning of clonic-tonic convulsions (Maytnert and Kaji, 1962; Stewart et al., 1970).

The convulsive state is aggravated by an increasing concentration of ammonia ions (Raable, 1981), an excess of which can lead to redistribution of K^+ and Cl^- ions, disturbances of neuronal depolarization and hyperpolarization, and impairment of postsynaptic inhibition. The neuron dysfunctions observed result in encephalopathy, ataxia, convulsions, and coma (Iles and Jack, 1980; Raable and Lin, 1983; Xiong and Stringer, 1999). Normally, ammonia specifically promotes GSH synthesis and export from astrocytes and increases its extracellular degradation, which may improve the availability of precursors for GSH synthesis in neurons and their resistance to ammonia toxicity; FA abrogates this defense mechanism (Hilgier et al., 2010). Lymphocyte-mediated neuroprotection is also mediated by astrocytes and there is no wonder it is inhibited by FA (Shrestha et al., 2014). Moreover, FA impairs enhancement of synaptic transmission and facilitation of long-term memory caused by nicotine, the effect being mediated by the gliotransmitter D-serine, an endogenous co-agonist of NMDA receptors (López-Hidalgo et al., 2012). On the other hand, FC affecting astroglia cause a drop in membrane potential and depolarization, and decrease of $[K^+]_i$ (Largo et al., 1997); this should lead to compensatory transport of bicarbonate ions into astrocytes and acidification of the extracellular medium. Together with the natural carbonate acidification of the medium close to chemoreceptors of the retrotrapezoid nucleus, this activates the diaphragmal nerve and increases the expired minute ventilation (Erlichman et al., 1998; Holleran et al., 2001): maximum ventilation is attained at 4% CO_2 against 8%−10% in control hypercapnic trials. Control of extracellular pH in nervous tissue is coupled with functioning of the Na^+/HCO_3^- cotransporter, existing in plasma membrane of astrocytes but lacking in that of neurons (Deitmer, 1992; Romero and Boron, 1999). This transport has an electrogenic character, because two or even three bicarbonate ions are transferred per one sodium ion. Again, however, a continuous supply of glutamine to the glutamatergic nerve terminals is the necessary condition of respiratory rhythm generation; blockade of the TCA cycle in astroglial cells with FA can impair the respiratory activity (Hulsmann et al., 2000).

15.4.3 Physiology of blood vessels under intoxication with fluoroacetate

FA does not affect circulation in resting organs, but a significant increase of blood flow can be seen in working respiratory muscles (Johnson and Reid, 1988). Conversely, a reduction of blood was registered in the hepatic artery, and contractive activity of isolated portal veins was suppressed after introduction of FA into the medium (Liang, 1977). These data, along with data on the effects of FA on endothelial cells in vitro, suggested that the endothelium of blood vessels could be one of the primary targets for FA. If so, the endothelium-dependent relaxation of blood vessels would be affected. To test the hypothesis, we administered SFA to rats subcutaneously at a dose of 2−3 mg/kg (LD_{50}−LD_{84}), and investigated endothelium-dependent relaxation of rat aorta 3 and 24 h after the poisoning. Norepinephrine in saturating concentrations induced a rapid constriction of the aorta followed by a smooth transition to plateau; in contrast, vasoconstricting hormones angiotensin II, vasopressin, and 5-hydroxytryptamine induced a bell-shaped vasoconstricting response of aorta. To assess the functional state of endothelium, carbocholine was introduced at 10^{-5} mol/L. Acting on muscarinic receptors of endothelial cells, it induced the generation of nitric oxide and release of endothelium-derived hyperpolarizing factor (McCulloch et al., 1997). All the agonists applied had similar effects on contraction of aortas obtained from control and poisoned animals (not shown here). The experiment clearly demonstrated that FA has no influence upon the contractile properties of isolated rat aorta at 3 and at 24 h after poisoning. This endothelial function is not affected, at least not directly, under intoxication with FA.

15.4.4 Body temperature of rats and rabbits under intoxication with fluoroacetate

One of the main pathophysiological features of intoxication with FA is a decrease in the body core temperature of endotherms, which indicates a disturbance of heat production and/or regulation (Brockmann et al., 1955; Misustova et al., 1980; Taitelman et al., 1983b). It is interesting to note that the effects of FC are comparable with those of selective inhibitors of p38 MAP-kinases (activation of which precedes production of pyrogens) and antagonists of cytokines TNF, IL-1, and IL-6 (Milligan et al., 2001, 2003). In our experiments, following administration of lethal doses of SFA to male rats, a marked decrease in rectal temperature was registered beginning from 1 h after the poisoning and gaining minimal levels in 6 or 24 h depending on the dose. Then a gradual increase in temperature took place in surviving rats, returning to normal in 2−7 days. For example, under

intoxication with SFA at a dose LD_{50}, a minimal rectal temperature of the surviving male rats (31.5°C as compared to 38.5°C in control animals) was registered in 6 h, and 7 days after the poisoning the temperature was 1°C below the control level. Under intoxication with FAA at equipotential doses, a minimal rectal temperature of the surviving male rats (32.6°C as compared to 38.9°C in control animals) was registered in 2 days, and even 7 days after the poisoning the temperature was 3°C below the control level. However, we observed much less change in rectal temperature in rabbits after s.c. administration of SFA at a dose LD_{50}: maximal decrease was only 1°C (38°C as compared to 39.1°C) in 6 h. According to our observations, a decrease in the temperature below 38°C in 3 h serves as a reliable sign forecasting the lethal outcome of the poisoned rabbits.

15.4.5 Electrophysiological studies of fluoroacetate intoxication

Clinical analysis of ECG of rats poisoned with SFA or FAA (Kuznetsov et al., 2007) revealed a similar dynamic of the temporal parameters of ECG, with slowing down and delay of the repolarization processes being the most important (Table 15.2). A drop in amplitudes of the atrial and ventricular ECG complexes can be observed within an hour after poisoning, followed by a decrease in the systolic index in 24 h, thus indicating an impairment of the contractile capacity of myocardium. Registration of ECGs of rats which died within 2 days of intoxication with SFA revealed a sharp drop in the heart rate (down to 120−180 per min) 24 h after the poisoning, together with complete absence of the P wave, which reflects atrial depolarization (Fig. 15.7A). Simultaneous reduction of both the amplitude and duration of the T wave can be seen. An upward shift of the ST segment, though not accompanied by growth of the T wave amplitude, was registered in 70% of rats (Fig. 15.7B). The cumulative evidence of the shape and amplitude changes of the ECG waves indicates the development of acute myocardial ischemia, though this was transient and maximally expressed 24 h after the poisoning. Reduction of the S wave amplitude could be caused by disturbances of excitation processes in basal ventricular regions and in some areas of the right ventricle. Taking into account an increase in the duration and shape distortions of the ventricular complex, one cannot exclude an incomplete right bundle-branch block. A significant extension of the T wave during the course of examination is indicative of deceleration of the fast repolarization of myocardium, though the process of slow repolarization (the QT interval in ECG, corresponding to the systole of ventricles) is accelerated within 3−24 h after the poisoning.

Respiratory rhythm was gradually increased in rats under intoxication with SFA, and there were additional respiratory components in 50% of animals 24 h after administration of the poison (Fig. 15.8) which may indicate disturbances of innervation of respiratory muscles. Spectral analysis of the respiratory curve demonstrated that there was an enhanced synchronization of the respiratory rhythm observed within 3 h after the poisoning. Simultaneously, the amplitude of respiration increased followed by a gradual decrease to the third day. Over the same period, a certain reduction in the lability of respiratory rhythm was noted, accompanied by the appearance of two distinct peaks corresponding with frequencies of 90 and 120 cycles of respiration per minute. By the seventh day, the respiratory spectrogram was similar to the initial one, though the frequency of respiration was not completely restored. Comparison of spectrograms of respiration and ECG demonstrates disturbances of control mechanisms underlying generation of the second-order waves (respiratory arrhythmia visible at the spectrogram as a peak in the high-frequency region 0.8−2.5 Hz). One day after administration of SFA, there was a marked frequency maximum at the respiratory spectrum, in contrast to that of the ECG spectrogram.

Analysis of the heart rate variability (HRV) demonstrates that 1 h after poisoning an enhancement of parasympathetic influence took place, and this was accompanied by insignificant and paradoxical enhancement of heart and respiratory rates (Table 15.3). Then, against a background of enhancement of humoral (metabolic) and sympathetic influences and simultaneous decline of parasympathetic influence, a stable decrease in heart and respiratory rates took place, indicating a prominent divergence between vagosympathetic balance and resulting physiological parameters. Previously it was shown in experiments with dogs that systemic, pulmonary, and coronary hemodynamic parameters during the first hours after introduction of FA were not mediated by the autonomic nervous system and adrenergic neuromediators (Liang, 1977). This is in partial agreement with our results obtained with rats, though this cannot be extrapolated to all the periods of intoxication and all animal species.

15.5 Toxicity and risk assessment

A characteristic feature of the clinical picture of intoxication with FA is a latent period of 0.5−6 h (Egekeze and Oehme, 1979). The duration of the latent period depends on animal species' metabolism and dose administered (Chenoweth, 1949; Goncharov et al., 2006). A broad variability of clinical manifestations of FA effects in different animal species is one of its characteristic features. There is a correlation between food specificity and the toxic

effect of FA; the cardiovascular system is mainly affected in herbivores, while the CNS is mainly affected in carnivores. Accordingly, four groups were recognized in terms of clinical signs of intoxication (Chenoweth and Gilman, 1946). The first comprised herbivores (rabbits, goats, sheep, cattle, and horses), in which FA induced ventricular fibrillation without notable CNS disorders (Marais, 1944; Chenoweth, 1949; Egekeze and Oehme, 1979). The second group comprised dogs and guinea pigs, in which the CNS was primarily affected. In dogs, a species highly sensitive to FA, symptoms of secondary intoxication appear after a latent period of 1–10 h (Chenoweth and Gilman, 1946; Egyed and Shupe, 1971). For animals of the third group the clinical pattern of intoxication is

similar to that of the second group of animals, but slightly less pronounced. This group comprised rats and hamsters relatively tolerant to FA. After a latent period lasting 1−2 h, tremor and elevated excitability were common symptoms. Death usually occurred within 4−6 h as a result of respiratory depression, after exposure to high FA doses (Chenoweth and Gilman, 1946; Pattison, 1959). The surviving animals demonstrated depression, weakness, ataxia, and strongly pronounced bradycardia down to 30 heartbeats per minute. At sublethal doses of FA, full recovery can occur in 72 h after poisoning (Chenoweth and Gilman, 1946; Pattison, 1959). A mixed response to FA exposure was described in animals of the fourth group—cats, pigs, and rhesus monkeys; it included disturbances of both the CNS and the cardiovascular system. On acute poisoning, adynamia, salivation, vomiting, frequent defecation, pupil dilatation, nystagmus, accelerated respiration, enhanced excitability, tremor, and clonic-tonic convulsions were observed in these animals (Chenoweth, Gilman, 1946; Gammie, 1980). In cats, lesions were observed characteristic of degenerative and ischemic processes in the heart, kidneys, liver, brain, and lungs (Collicchio-Zuanaze et al., 2010).

Nevertheless, the classification outlined above was criticized (Sherley, 2004). The division of animals into cardiac and neurological symptomatic groups is considered to be unnatural as it ignores common neurological signs manifested in all the groups: among these are tremor, ataxia, hypersensitivity, myotonic convulsions, weakness, and partial paralysis. The cardiac response in a pure form was not a common event and was described just for a limited number of animals, though CNS involvement is obviously widespread.

As for humans, exposure to stock solution during formulation and dermal or respiratory exposure during application of baits, as well as accidental or intentional acute intoxications, are the main human health concerns. Formulators and pest control workers are the largest occupational risk group (Norris, 2001; Beasley et al., 2009). Early monitoring indicated exposures were highest in relation to cereal bait manufacturing and aerial carrot baiting procedures (Beasley et al., 2009).

The clinical picture of acute intoxication of humans is similar to that of rhesus monkeys, and among the symptoms are nausea, vomiting, abdominal pains, salivation, irrational fear, weakness, tachypnea, cyanosis, and sometimes sweating and increased temperature (Brockmann et al., 1955; Pattison, 1959; Arena, 1970; Taitelman et al., 1983b). Psychomotor agitation and sometimes a loss of spatiotemporal feeling can occur. In addition, tremor, nystagmus, involuntary defecation and urination, muscle spasms, hypertonus of the extremities, and even alalia, have been reported (Gajdusek and Lutheer, 1950; Robinson et al., 2002). The most characteristic signs of intoxication involve generalized recurrent convulsions alternating with deep depression. Sudden loss of consciousness and coma may occur. These symptoms were associated with metabolic acidosis and hypotension (Pattison, 1959; Chi et al., 1996, 1999), as well as cardiac rhythm disturbances, such as tachycardia, bradycardia, asystolia, and sustained ventricular fibrillations (Gajdusek and Lutheer, 1950; Reigart et al., 1975; Trabes et al., 1983). Death usually occurs in 3 h to 5 days from heart block, arrhythmia, or respiratory failure (Reigart et al., 1975). Important diagnostic symptoms registered with ECG are arrhythmia, the QT and ST intervals, and the T wave (Pattison, 1959; Taitelman et al., 1983b; Chi et al., 1996). The kidneys are among the most sensitive organs: acute renal failure associated with uremia and increased level of creatinine in serum can be observed under acute FA poisoning (Chung, 1984; Chi et al., 1996). Pathomorphological abnormalities of humans poisoned with FA are also nonspecific and similar to those of animals. In the case of lethal outcome, petechial hemorrhages and excess blood filling of internal organs (Hayes, 1982), edema of lungs and brain, and sometimes mediastinal emphysema and acute inflammatory reaction with coagulating necrosis in the esophagus were registered in humans (Brockmann et al., 1955). The morphological basis of cardiotoxic effects is acute myocardial dystrophy, a characteristic of which is diffuse lesions of cardiac muscle (Pattison, 1959; Taitelman et al., 1983b). Acute renal failure develops due to the influence of FA on subcellular structures of the kidneys. Metabolic acidosis aggravates the clinical course of renal failure. Diffuse degeneration of renal tubules was observed (Hayes, 1982). For cases that lack clinical and morphological specificity, biochemical data and primarily citrate and fluoride levels can be used for diagnostic purposes (Pattison, 1959; Schultz et al., 1982). Thus, under acute intoxication with FAA, citrate (108 μg/g in heart and 23.9 μg/g in kidneys) and fluoride (6.3 mg/g dry weight of heart and kidneys) were found in a human corpse; the dose of FAA was estimated to be near 23 mg/kg (Hayes, 1975). In addition, the indubitable diagnostic confirmation of the intoxication should be based on determination of the poison in tissues. Under acute SFA poisoning with lethal outcome, FA was found in urine (368 μg/mL), liver (58 μg/g), and brain (76 μg/g) (Harrison et al., 1952).

Among the aftereffects that develop after acute intoxication with FA or its derivatives are various neurological disturbances: impaired muscular tonus and reflex activity, transient spasmodic and meningeal syndromes, cerebellar dysfunction, such as ataxic gait, dysarthria, and intention tremor (Pridmore, 1978; Trabes et al., 1983; Kim and Jeon, 2009). Long after an acute poisoning (from 1.5 to 9 years) tendencies for epileptoid seizures, ataxia, extremity muscular hypertension, spastic tetraplegia, blindness

of cortical origin, diffuse brain atrophy, and psychic disorders were observed. A case of chronic intoxication with FA of a farm worker has been described (Parkin et al., 1977); the clinical signs were renal insufficiency and less pronounced injuries of other organs.

15.6 Treatment

Decades of studies on the toxicology of FA have led scientists to the conclusion that the treatment of intoxications can be successful only if timely general and symptomatic therapy is applied, but not specific antidotes (Dorman, 1990; Norris, 2001). Much experimental work over an extensive period has been undertaken in an effort to find effective donors of acetate groups, because of their property to inhibit conversion of FA to FC. Ethanol, monoacetin (glycerol monoacetate), acetamide, and cortisone acetate were tested for their potency to serve as antidotes (Hutchens et al., 1949; Chenoweth, 1949; Cole et al., 1955; Giller, 1956; Egyed, 1971; Egyed and Shlosberg, 1977). A therapeutic effect was revealed for simultaneous introduction of ethanol and acetate (Hutchens et al., 1949; Tourtelotte and Coon, 1949). Negative effects of monoacetin and acetamide were enhancement of hyperglycemia and metabolic acidosis, damage to capillaries and hemolysis of red blood cells, and an increase in the citrate concentration in different organs (Engel et al., 1954; Egyed and Shlosberg, 1973). The administration of cortisone acetate inhibited FC synthesis and prevented the development of ketosis, though there was increased hyperglycemia (Cole et al., 1955).

Several antidotes were tested for their capacity to activate transport of the TCA cycle intermediates through mitochondrial membranes. For this purpose, fluoromalate was proposed, though positive results were negligible (Peters, 1972). Malate was also tested, but proved to be effective only in in vitro experiments (Buffa et al., 1972). Also in vitro, glutathione and a series of SH-containing compounds (cysteamine and *N*-acetylcysteine) were tested (Mead et al., 1985). However, they were incapable of replacing glutathione in enzymatic defluorination of FA and have not found practical application. TCA cycle intermediates (succinate, malate, citrate, and glutamate) were tested, but did not exhibit a protective effect (Hutchens et al., 1949). A positive result was observed in experiments with mice, which were administered calcium gluconate and succinate (Omara and Sisodia, 1990). This therapy was barely more effective than ethanol. Some 16 years later another research group tested the therapy with cats, which are known to be much more sensitive to FA. Again, differences in survival between treated and nontreated animals were not significant ($P > .05$) (Collicchio-Zuanaze et al., 2006). Administration of calcium chloride to cats under acute intoxication with FA made it possible to postpone their deaths by up to 166 min; combination of calcium chloride with monoacetin gave a similar effect (Taitelman et al., 1983a). Nevertheless, calcium chloride caused a reduction in the QT interval and favored survival of humans in cases of their intoxication with FAA (Taitelman et al., 1983b).

Our strategy for the development of therapeutic means of treating acute FA intoxication was based on a deep analysis of the biochemical literature, together with our own experimental data. Thus, high sensitivity of aconitase to inhibition by superoxide anion and nitric oxide (Gardner et al., 1994; Andersson et al., 1998; Castro et al., 1998) means that ROS and NO could be competitive antagonists of FC to avert its effect on aconitase. Also, as considered earlier, during FA intoxication glutamate could be utilized in the TCA cycle through GDH or transaminases (Yu et al., 1976; Liang, 1977; Hassel et al., 1994). Moreover, the effects of FC could be prevented by prior introduction of isocitrate (bypass of inhibited aconitase) and fructose-1,6-bisphosphate (energy substrate for neurons) (Lian and Stringer, 2004).

We have demonstrated that FA can adversely affect mitochondrial functions only if pyruvate was available as a respiratory substrate, and that changes to the redox state of pyridine nucleotides (PN) or their leakage from MCh could be critical factors that impair mitochondrial respiration and lead to cell death (Zinchenko et al., 2007). Opening of the mitochondrial pore is a reversible phenomenon: prevention of oxidation and/or leakage of NAD(P)H from MCh can restore the normal functional state of MCh. For example, when succinate or glutamate was used as the respiratory substrate, mitochondrial functions were not affected by FA (Fig. 15.3A).

As for other alternative substrates, we suggest that the accumulating intracellular citrate could be one of them. As discussed earlier, blockade of citrate transport from MCh under FA intoxication is not an obligatory event, and citrate can enter cytosol to be further utilized by cICDH (Max and Purvis, 1965; Buffa et al., 1972). The cICDH activity is almost equally distributed between cytosol and MCh of astroglia and microglia, whereas cICDH accounts for about 75% of activity in neurons and oligodendrocytes (Minich et al., 2003). We have not found data on the ratio of mitochondrial and cytoplasmic aconitases in the cells of the nervous system, but it is interesting to note that a similar ratio of m- and cICDH exists in hepatocytes (Rakhmanova and Popova, 2006), and that c-aconitase accounts for 65% of the aconitase in these cells (Konstantinova and Russanov, 1996). In rat heart a similar ratio of m- and c-aconitases has been revealed: 35% and 65%, correspondingly (Medvedeva et al., 2002). Based on these data, one may suggest that an effective pathway for citrate utilization and NADPH synthesis exists in these (and other) cells in the case of

inhibition of m-aconitase. This alternative pathway could play a positive physiological role because NADPH might be used for anabolic reactions and heat generation, glutathione reduction and NO synthesis, and for regulation of blood vessel tone by means of ROS generation (Winkler et al., 1986; Bobyleva et al., 1993; Lee and Yu, 2002; Gupte and Wolin, 2006). As was pointed out earlier, studies focused on the pentose cycle as the main source of NADPH need to be re-evaluated taking into consideration the metabolic activity and substrate specificity of a tissue (Winkler et al., 1986). cICDH along with malic enzyme and transhydrogenase participates in NADPH regeneration to further reduce glutathione in brain mitochondria (Vogel et al., 1999), but cICDH can provide a sevenfold greater generation of NADPH as compared to malic enzyme (Winkler et al., 1986). The level of cytoplasmic NADPH can influence potassium channels and calcium balance (Wolin et al., 2005; Gupte and Wolin, 2006). In our in vitro studies, FA induced a slow elevation of $[Ca^{2+}]_i$ in different cells (Zinchenko et al., 2007). This could indicate an activation of the SOC channels; the process is not affected by FA and does need ATP to be implemented, at least in glial cells (Lian and Stringer, 2004). We suppose this mechanism to be common for many types of cells, and this could explain a primary hypersensitivity of platelets exposed to FA (Mindukshev et al., 2006). In cardiomyocytes, elevated $[Ca^{2+}]_i$ can stimulate their functional activity observed in our experiments in vitro and also supported in vivo by a primary increase in the systolic index (Table 15.1). As for modulating effects of Ca^{2+} on bioenergetics of MCh, it is pertinent to recall "classic" activation of the TCA cycle dehydrogenases followed by increase of mitochondrial potential and NADH generation: 2-oxoglutarate dehydrogenase (OGDH) and mICDH can be activated by calcium ions through allosteric mechanisms and pyruvate dehydrogenase is activated due to dephosphorylation by the Ca^{2+}-dependent phosphatase (McCormack et al., 1990; Hansford, 1994). The exact role of these dehydrogenases in the bioenergetic status of MCh affected by FA needs to be clarified, though one can suppose that OGDH could derive a special benefit from such an activation if it is provided with exogenic or endogenic 2-oxoglutarate.

According to the above discussion, we have defined several directions for biochemical correction under acute intoxication with FA and suggested suitable preparations for therapeutic complexes: (1) competitive inhibition of FA and CoA interaction; (2) competitive inhibition of FC and aconitase interaction; (3) replenishment of the TCA cycle distally of aconitase; and (4) utilization of accumulating citrate. In previous publications we presented the first data on the effectiveness of therapeutic complexes named METIS (Goncharov et al., 2006, 2009). These consisted of ethanol, methylene blue (MB), sodium glutamate (SG), and glycerol trinitrate (GT). Indices of therapeutic efficiency (ratio $LD_{50}^{treated}/LD_{50}^{nontreated}$) for different METIS complexes applied in different regimens are presented in Table 15.4. In addition to these data, a spectrum of physiological and biochemical data was also obtained. Animals treated with METIS complex had little changes to body weight, temperature, and oxygen consumption. The dynamics of citrate in brain, kidneys, and blood was also improved, and kinetic parameters of platelet aggregation were corrected. Comparative analysis of the FA level

TABLE 15.4 Assessment of the therapeutic effectiveness of METIS preparations under acute intoxication of rats with SFA.

Therapy	Treatment regimen after the poisoning with SFA	Index of therapeutic efficiency
		Ratio LD_{50} treated/LD_{50} nontreated
Ethanol ($n = 42$)	10 and 120 min	1.6
METIS-1 ($n = 48$)	10 and 120 min	2.5
METIS-2 ($n = 92$)	10, 60 and 120 min (ethanol and GT); 60 and 120 min (MB)	3.3
METIS-4 ($n = 39$)	10, 60 and 120 min, 24 h and 48 h (ethanol, GT, and SG); 10 and 120 min, 24 h and 48 h (MB)	4.3
Ethanol ($n = 43$)	30 and 120 min	2.6
METIS-3 ($n = 45$)	30 and 120 min	3.2

n, Number of animals used in the experiment to calculate the index.
Experimental conditions and METIS components. SFA was dissolved in distilled water and administered intragastrically at 0.2 mL per 100 g of rat body weight, after 7–8 h fasting. METIS-1 is a combination of two compounds: aqueous solution of MB administered subcutaneously (s.c.) at a dose of 5 mg/kg, and aqueous solution of SG administered intraperitoneally (i.p.) at a dose of 250 mg/kg. METIS-2 is a combination of three compounds: MB (5 mg/kg, s.c.), ethanol and GT administered i.p. (corresponding doses for pure ethanol and GT were 1 g/kg and 10 mg/kg). METIS-4 is a combination of four compounds: MB (5 mg/kg, s.c.), and aqueous solution of ethanol (1 g/kg), GT (10 mg/kg), and SG (100 mg/kg) administered i.p. METIS-3 is a combination of three compounds: MB (5 mg/kg, s.c.), ethanol, and SG administered i.p. (corresponding doses for pure ethanol and SG were 1 g/kg and 200 mg/kg).

in tissue homogenates, blood plasma, and urea of rats revealed that the METIS complexes reduced the level of FA in the brain almost twofold, thus indicating inhibition of FA utilization first of all in the cells of the nervous system.

15.7 Concluding remarks and future directions

The extreme toxicity of FA is determined by its similarity to acetate, which has a central role in cell metabolism. FA enzymatically condenses with CoA-SH to produce fluoroacetyl-CoA, which replaces acetyl-CoA entering the TCA cycle and produces FC. The latter reacts with aconitase and blocks the TCA cycle. Energy production is reduced, as well as the concentration of metabolites generated distally to aconitase. 2-Oxoglutarate is the most important of these, being a precursor of glutamate, which is a neuromediator in the CNS and participates in neutralizing ammonia either directly through glutamine synthase or indirectly through the urea cycle. Accumulation of citrate is one of the causes of metabolic acidosis. Chelating of Ca^{2+} is apparently one of the central events in the pathogenesis of intoxication.

The first papers on FA toxicology were published in the 1940s. The long history of investigations was fruitful, with several important discoveries: biochemical mechanism of "lethal synthesis"; structure of aconitase; functional relations of glia and neurons; and switching of metabolic pathways. However, the main problem of toxicology (for any poison) was not solved—development of an effective therapy. Analysis of the scientific literature has demonstrated that reciprocal relations of signaling and metabolic pathways under intoxication with FA are unclear. Inhibition of m-aconitase causes blockade of the TCA cycle, reduction of pyridine nucleotides, accumulation of citrate, disturbances of intracellular signaling, deenergization, and cell death. However, the dynamics and significance of these events are different depending on the type of cells and tissues, which is why it is very difficult to predict the primary reaction of different cells and more so the whole organism.

Biochemical pathways underlie the basis of physiological rhythms; they should have a certain space−time structure and presuppose coordinated interactions of different cells. Thus, one of the causes of disturbances of normal respiration under FA intoxication could be disturbances in rhythmic activity of respiratory neurons; but suppression of these neurons is a consequence of an inhibiting effect of FA on astrocytes, not neurons (Hulsmann et al., 2000). We described the development of cardiac and respiratory tachyarrhythmias reflecting reproduction of decasecond rhythms characteristic of immature or abnormal excitatory structures (Kuznetsov et al., 2007). Previously it was suggested that such endogenic rhythmic activity could be determined by the level of pentose cycle activity (Kuznetsov, 2002). This cycle plays an important role in neurons, protecting them from oxidative or traumatic stress (Ben-Yoseph et al., 1994; García-Nogales et al., 2003; Bartnik et al., 2005). However, it should be noted that although the activity of NADPH-generating enzymes of the pentose cycle in astrocytes (glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase) is two- to threefold higher than in brain as a whole, the activity of cICDH is also very high in these cells (Rust et al., 1991). This metabolic pathway is interesting primarily because under FA intoxication citrate is accumulated, and the pathway may be regarded as a form of biochemical adaptation that facilitates utilization of the central metabolite. It was suggested that spatial and temporal division of m- and c-aconitases do not only provide regulation of iron balance in cells, but also provide regulation of balance between catabolic and anabolic processes (Tong and Rouault, 2007).

Providing the cells have utilized citrate entering the cytosol, another problem should be utilization of generating NADPH. One of the possible and very important mechanisms of PN oxidation is heat generation through shiver and nonshivering thermogenesis. A rise in the activity of NADPH-generating enzymes and pathways, including c-aconitase and cICDH, is accompanied by enhanced thermogenesis (Bobyleva et al., 1993). It was shown that NADPH could be used together with or even instead of NADH as a reducing cofactor for cytoplasmic glycerophosphate dehydrogenase (Bobyleva et al., 1993; Fahien et al., 1999). However, if the role of this pathway for transferring electrons from cytoplasma to MCh in skeletal muscles is rather clear, then the level of activity and functional state of glycerophosphate shuttle in brain cells are contradictive. For example, its activity in brain is explained by the need for glycerol-3-phosphate as a substrate for phospholipid synthesis in oligodendroglia (Adler and Klucznik, 1982; Nguyen et al., 2003). In neurons and astrocytes, the activity of glycerophosphate dehydrogenases is much lower than in oligodendrocytes (Rust et al., 1991; Nguyen et al., 2003). There are data, however, that indicate an important role of this shuttle in astrocytes, taking into consideration: (1) the absence of malate−aspartate shuttle in these cells (Waagepetersen et al., 2001; McKenna et al., 2006), and (2) the elevated level of mRNA of cICDH in astrocytes after convulsions, under exposure to morphine, indometacin, and some other preparations (Link et al., 2000).

It is noted that FA can prevent the development of tolerance to morphine (Song and Zhao, 2001). Another positive aspect of FA in nontoxic concentrations is its radioprotective power due to its capacity to reduce body

temperature and oxygen consumption (Misustova et al., 1980). Moreover, we have estimated that SFA significantly inhibits growth of Ehrlich tumor carcinoma. In experiments with autochthonous induced by benzo[a]pyrene subcutaneous tumors, SFA was not active in the monotherapy regimen, though it exhibited enhancement of the antitumor effect of cyclophosphamide, significantly increasing the number of mice with stabilized or decreased tumor volume as well as the duration of this effect (Anikin et al., 2013). These findings provide a basis for additional studies of the mechanism of the antitumor effect of SFA. Thus, we suggest that future progress in toxicological (and pharmacological) studies of FA will depend on comprehensive consideration of these and more recent data, together with re-evaluation of old and forgotten data.

Chapter 16

Strychnine

Jiri Patocka

Department of Radiology and Toxicology, Faculty of Health and Social Studies, University of South Bohemia Ceske Budejovice, Hradec Kralove, Czech Republic

16.1 Introduction

Strychnine is a poisonous indole-type alkaloid found in the genus *Strychnos*. Its basic compound forms colorless or white rhombic crystals. These have a bitter taste and melt at approximately 290°C. Strychnine was the first alkaloid to be identified in plants of the genus *Strychnos*, Family Loganiaceae. *Strychnos*, created by Linnaeus in 1753, is a genus of trees and climbing shrubs of the gentian order. The genus contains 196 various species and is distributed throughout the warm regions of Asia (58 species), America (64 species), and Africa (75 species). Plants of the genus *Strychnos* have opposite leaves and bear cymes of white or yellowish flowers that have a four-lobed or five-lobed calyx, a four-part or five-part corolla, five stamens, a solitary pistil, and they bear fruit in the form of a berry. The seeds and bark of many plants in this genus contain the powerful poison strychnine. Strychnine is obtained commercially from the seeds of the Saint Ignatius bean (*Strychnos ignatii*) and from the nux-vomica tree (*Strychnos nux-vomica*) (Volfova and Patocka, 2003). *S. nux-vomica*, also known as poison nut, semen strychnos, and quaker buttons, is a deciduous tree native to India and southeast Asia. It is a medium-sized tree that grows in open habitats. The seeds contain approximately 1.5% strychnine and the dried blossoms contain 1.0% (Harry, 1968). However, the tree's bark also contains other poisonous compounds (Guo et al., 2018). Strychnine was first discovered in the Saint Ignatius bean by French chemists Joseph-Bienaime Caenoiu and Pierre-Joseph Pelletier in 1818. In some *Strychnos* plants the 9,10-dimethoxy derivative of strychnine brucine, is also present (Li et al., 2006). Strychnine, along with its close relative brucine, has been found in a number of trees growing in the tropical regions of the world, especially in India and the Far East. Brucine is not as poisonous as strychnine (Teske et al., 2011).

16.2 Background

16.2.1 Chemistry and physicochemical properties

Strychnine has the molecular formula $C_{21}H_{22}N_2O_2$, and its structural formula is shown in Fig. 16.1 [CAS No: 57-24-9 (base), 60-41-3 (sulfate)]. It occurs as white crystals or powder that is odorless, with a melting point of 286°C, boiling point of 270°C at 5 mmHg, density of 1.36 g/cm^3, vapor density of 11.0 (air = 1), and vapor pressure 0 torr at 20°C (Mackison et al., 1981). Strychnine is a stable compound and incompatible only with strong oxidizing agents.

Water solubility of strychnine is negligible, only 160 mg/L at 25°C and pH of the saturated solution is 9.5. Octanol/water partition coefficient ($\log K_{ow}$) is 1.93 (Hansch et al., 1995). Strychnine is very slightly soluble in ether, slightly soluble in benzene, ethanol (6.7 g/cm^3), and acetone, and soluble in chloroform and pyridine (Ng and Poe, 1956; Budavari, 1996).

16.2.2 History

The toxic and medicinal effects of strychnine have been well-known since the times of ancient China and India. The inhabitants of these countries had ancestral knowledge of the species *nux vomica* and Saint Ignatius bean. The species *S. nux vomica* is a tree of native Indonesia that attains a height of 12 m. The tree has a crooked, short, thick trunk and the wood is close-grained and very durable. The fruit has an orange color and is approximately the size of a large apple with a hard rind and contains five seeds that are covered with a soft wool-like substance. The ripe seed looks like flattened disks and is very hard. These seeds are the chief commercial source of strychnine and were first imported and marketed to

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00016-7

FIGURE 16.1 Chemical structure of strychnine.

Europe as a poison to kill rodents and small predators. *S. ignatii* is a woody climbing shrub of the Philippines. The fruit of the plant contains as many as 25 seeds embedded in the pulp. The seeds contain more strychnine than other commercial alkaloid plants. The properties of *nux-vomica* and Saint Ignatius seeds are substantially those of the alkaloid strychnine (Haller, 1973; Buckingham, 2007).

Strychnine was discovered and identified as the main toxic principle of *Strychnos* in 1818, although *nux vomica*, the unpurified plant extract in which it is the active component, had been known and used for both medicinal and criminal purposes for some time. Historic records indicate that the strychnine alkaloid has been used to kill dogs, cats, and birds in Europe as far back as 1640. The structure of strychnine was first determined in 1946 by Sir Robert Robinson and in 1954 this alkaloid was synthesized in the laboratory by Robert W. Woodward (Woodward et al., 1954). This is one of the most famous syntheses in the history of organic chemistry. Both chemists won the Nobel prize, Robinson in 1947 and Woodward in 1965.

16.2.3 Therapeutic uses

Strychnine does have some history of use for therapeutic purposes, although in most cases this was entirely misguided and dangerous. It has a very bitter taste and so stimulates salivary and gastric secretion. This increases appetite and was used to counteract the loss of appetite associated with illness, giving the impression that strychnine had restorative properties. In fact, any constitutional improvement resulting from the increased appetite would probably be outweighed by the harmful effects of strychnine, and the underlying illness would be more or less unaffected. This is the same mechanism that gives tonic water its apparent "tonic activity," although in that case the bitter agent is quinine, which is much less dangerous (McGarry and McGarry, 1999).

Strychnine has an undeserved reputation as a useful therapeutic agent. There is no current justification for its presence in any medication. However, preliminary experimental reports suggest that judicious treatment with strychnine may modify the neurological deterioration in some infants with nonketonic hyperglycinemia, a rare metabolic disorder characterized by abnormally high concentrations of glycine in the brain and cerebrospinal fluid (MacDermot et al., 1980; Warburton et al., 1980). Strychnine was used as a tonic stimulant at one time for atonic constipation and as a stomachic and bitter. It produces no selective gastrointestinal effects and has no place in the therapy of any gastrointestinal disorder. At present strychnine has no demonstrated therapeutic value in human medicine, despite a long history of unwarranted popularity. It was first used in medicine in 1540, but it did not gain wide usage until 200 years later (Gilman et al., 1985; Hur et al., 2019).

Although strychnine was previously used extensively in animals, it no longer has a rational place in the therapeutic resources of the veterinarian. Its only interest is from a veterinary toxicology standpoint because animals are sometimes poisoned inadvertently or intentionally (Booth and McDonald 1982; Motas-Guzmán et al., 2003; Berny et al., 2010; Cowan and Blakley, 2015, 2016; Gupta, 2018).

16.3 Pharmacokinetics and toxicokinetics

16.3.1 Absorption, distribution, metabolism, and excretion

Strychnine is rapidly absorbed from the gastrointestinal tract, mucous membranes, and parenteral sites of injection (Thienes and Haley, 1972) as well as from the oral cavity (LaDu et al., 1971). A nonfatal case of strychnine poisoning through dermal exposure has been described (Greene and Meatherall, 2001). Strychnine is transported by plasma and erythrocytes, but protein binding is slight and distribution to the tissues occurs rapidly. Within a few minutes of ingestion strychnine can be detected in the urine and excretion via that route accounts for approximately 15% of a sublethal (4 mg) dose over 6 h. Little difference was noted between oral and intramuscular administration of strychnine in a 4 mg dose. Blood levels in human poisoning were less than 0.5 μg/mL from 1 to 48 h after ingestion of a sublethal dose (700 mg), 2.7 μg/mL in a patient who survived the acute episode, and 40 μg/mL in a patient who died after massive ingestion (Haddad and Winchester, 1983). In persons killed by strychnine, the highest concentrations are found in the blood, liver, and kidney (Hayes and Laws, 1991). The half-life of absorption is approximately 15 min and the half-life of metabolism is approximately 10 h. The apparent volume of distribution in one patient was 13 L/kg (Ellenhorn et al., 1997).

Strychnine is rapidly metabolized by the liver microsomal enzyme system and requires NADPH and O_2. Five metabolites formed in vitro by rabbit liver were isolated and identified as 2-hydroxystrychnine, 11,12-dehydrostrychnine, strychnine-21,22-epoxide, 21,22-dihydroxy-22-hydrostrychnine, and strychnine-*N*-oxide, which was the major metabolite and accounted for approximately 15% of the metabolized strychnine. All other metabolites accounted for less than 1% (Mishima et al., 1985). Similar metabolites were identified in rat urine where the major metabolite was strychnine-21,22-epoxide (Oguri et al., 1989). The metabolic fate of strychnine in humans is not known.

Strychnine competes with the inhibitory neurotransmitter glycine, producing an excitatory state characterized clinically by hyperreflexia, severe muscle spasms, and convulsions. However, the toxicokinetics after overdose have not been well-described. In most severe cases of strychnine poisoning, the patient dies before reaching hospital (Shadnia et al., 2004; Prat et al., 2015).

Palatnick et al. (1997) described the case of a 34-year-old man who presented to the emergency department 20 min after ingesting 125 mL of 2% strychnine sulfate (2.25 g). He was alert and oriented and experiencing muscle spasms. His condition deteriorated, prompting sedation, muscle paralysis, and tracheal intubation. He was administered activated charcoal 100 g via nasogastric tube. He was admitted to intensive care, where he was managed with diazepam, pentobarbital, and pancuronium. Despite mild rhabdomyolysis, he recovered and was extubated on day 3. Although receiving prophylactic heparin therapy, a massive fatal pulmonary embolus ensued. Eighteen blood specimens for strychnine analysis were obtained from 20 min to 51 h after ingestion. Serum concentrations were determined with gas chromatography-mass spectroscopy. Disappearance followed a first-order process with a $t_{0.5}$ of 16 h. These results confirm the findings of a previous case report of 19 strychnine levels obtained between 4 and 19 h that described first-order kinetics with a $t_{0.5}$ of 10−16 h.

In a case report by Wood et al. (2002), a 42-year-old man ingested an unknown quantity of strychnine powder. Eight serum samples were taken over the first 5 days and analyzed subsequently for strychnine concentrations. The initial concentration at 1.5 h after ingestion was 4.73 mg/L, falling to 0.38 mg/L at 74 h postingestion. Serum concentrations followed a monoexponential elimination curve with a calculated elimination half-life of 12 h. The initial serum concentration of 4.73 mg/L is the highest reported concentration in a patient who has survived.

16.4 Clinical symptomatology

Symptomatology of human intoxication begins 15−30 min after ingestion of strychnine, usually without any warning, and the subject may experience violent convulsions. Convulsions lead to severe lactic acidosis that secondarily results in visceral (lung, heart, kidney, liver, and brain) collapse and death (Gordon and Richards, 1979). Prodromal symptoms are described such as apprehension, restlessness, heightened acuity of hearing, vision, and feeling, hyperreflexia, abrupt movement, and muscular stiffness of the face and legs. Generalized convulsions last from 30 s to 2 min. At 10−20 min after exposure, the body's muscles begin to spasm, starting with the head and neck. At first convulsions are clonic, but a tetanic phase quickly follows. The body typically arches in hyperextension, the legs are adducted and extended, arms are flexed over the chest and fists are tightly clenched. The jaw is rigidly clamped, the face is fixed in a grin, and the eyes protrude in a fixed stare (Philippe et al., 2004; Lages et al., 2013).

The convulsions progress, increasing in intensity and frequency until the backbone arches continually. Death comes from asphyxiation caused by paralysis of the neural pathways that control breathing or by exhaustion from the convulsions. The subject usually dies within 2−3 h after exposure. At the point of death, the body "freezes" immediately, even in the middle of a convulsion, resulting in instantaneous rigor mortis.

Initial symptoms of strychnine poisoning are tightness and twitching of the muscles, agitation, and hyperreflexia. Stiffness of the body, lockjaw, frothing of the mouth, and cessation of respiration occur. Tetanus-like episodes occur every 10−15 min. During these episodes, the eyeballs protrude and the pupils enlarge. Severe cyanosis, which disappears after the episode subsides, also occurs. The episodes (each lasting approximately 3−4 min) appear to be spontaneous, while other times they are the result of external stimuli, for example, noises, slight movements, or flashes of light. The patient never loses consciousness. When the poisoning is left untreated, each episode lasts longer than the previous and the interval between them grows shorter. Up to 10 episodes occur before death or recovery. This could happen from 10 min to 3 h and is a result of asphyxiation or inner tissue paralysis.

16.5 Mechanism of action

Strychnine acts as a blocker or antagonist at the inhibitory or strychnine-sensitive glycine receptor, a ligand-gated chloride channel in the spinal cord and the brain (Song et al., 2006). The glycine receptor (GlyR) is the receptor for the amino acid neurotransmitter glycine (Rajendra et al., 1997). It is one of the most widely distributed

inhibitory receptors in the central nervous system. Glycine receptors are found in most brain areas, including the hippocampus, amygdala, ventral tegmental area, and periaqueductal gray (Choi et al., 2013). The strychnine-sensitive glycine receptor is a member of a family of ligand-gated ion channels (Alexander et al., 2015). This ionotropic receptor can be activated by a range of simple amino acids, except glycine, β-alanine, and taurine, and can be selectively blocked by the high-affinity competitive antagonist strychnine. The receptor is arranged as five subunits surrounding a central core, with each subunit composed of four α-helical transmembrane segments. There are presently four known isoforms of the α-subunit (α_{1-4}) of GlyR that are essential to bind ligands and a single β-subunit (Huang et al., 2015). The adult form of the glycine receptor is the heteromeric $\alpha_1\beta$ receptor, which is believed to have a stoichiometry of three α_1 subunits and two β subunits or four α_1 subunits and one β subunit (Kuhse et al., 1993, 1995). The strychnine-binding subunit of the glycine receptor shows certain homology with nicotinic acetylcholine receptors (Grenningloh et al., 1987). The glycine receptor is highly enriched in microdomains of the postsynaptic neuronal surface apposed to glycinergic afferent endings. There is substantial evidence suggesting that the selective clustering of the glycine receptor at these sites is mediated by the cytoplasmic protein gephyrin (Meier et al., 2000). Gephyrin is a multimeric scaffold protein which interacts with cytoskeletal elements and stabilizes GlyRs and individual subtypes of gamma-aminobutyric acid A receptors at inhibitory postsynaptic sites (Maas et al., 2006).

16.6 Toxicity

Strychnine has been placed in toxicity category I, indicating a high degree of acute toxicity, for oral and ocular effects. Inhalation toxicity is also presumed to be high. Acute toxicity of strychnine to birds is very high. Mammalian studies indicate that strychnine is very highly toxic to small mammals on both an acute oral basis and a dietary basis. The extent of poisoning caused by strychnine depends on the amount and route of strychnine exposure; in humans, it depends on the person's condition of health. The signs of toxicity, including death, occur within 1 h.

16.6.1 Animal toxicity

Reported toxic doses of strychnine administered by different routes in some animals and humans are summarized in Table 16.1.

Strychnine toxicity in rats depends on sex. It is more toxic to females than to males when administered subcutaneously or intraperitoneally, and differences are attributable to the higher rate of metabolism by male rat liver microsomes (Parke, 1968). Dogs and cats are more susceptible among the domestic animals, pigs are believed to be as susceptible as dogs, and horses are able to tolerate relatively larger amounts of strychnine (Humphreys, 1988). Birds affected by strychnine poisoning exhibit feathers fluffed or held tightly against the body, ataxia, wing droop, salivation, tremors, muscle tenseness, and convulsions. Death occurs as a result of respiratory arrest.

The clinical signs of strychnine poisoning relate to its effects on the central nervous system. After oral ingestion of strychnine, symptoms of poisoning usually appear within 15−60 min. The first clinical signs of poisoning include nervousness, restlessness, twitching of the muscles, and stiffness of the neck. As the poisoning progresses, muscular twitching becomes more pronounced and convulsions suddenly appear in all the skeletal muscles. The limbs are extended and the neck is curved to opisthotonus. The pupils are widely dilated. As death approaches, the convulsions follow one another with increased rapidity, severity, and duration. Death results from asphyxia because of prolonged paralysis of the respiratory muscles (Humphreys, 1988; Gupta, 2018).

16.6.2 Human toxicity

People exposed to low or moderate doses of strychnine by any route will have the following signs or symptoms: agitation; apprehension or fear; ability to be easily startled; restlessness; painful muscle spasms possibly leading to fever and to kidney and liver failure; uncontrollable arching of the neck and back; rigid arms and legs; jaw tightness; muscle pain and soreness; difficulty breathing; dark urine; and initial consciousness and awareness of symptoms. The reported medium lethal doses of strychnine in humans ranges from 5 to 120 mg/kg.

Cases of human poisoning have been reported. A 46-year-old man presented 2 h after ingestion of approximately 250 mg strychnine with severe, violent, generalized convulsions triggered by external stimuli. During the convulsion-free periods, there were no abnormal signs in the physical examination (Scheffold et al., 2004). A 28-year-old man was admitted 2 h after ingestion of 1−1.5 g of strychnine. He was severely agitated and in mild respiratory distress; blood pressure was 90/60 mmHg, pulse was 110 per minute, and peripheral pulses were weak. He had generalized hyperactive reflexes and had several generalized tonic-clonic convulsions in the emergency department. Treatment consisted of gastric lavage with water, oral administration of activated charcoal and sorbitol solution, continuous intravenous administration of midazolam, followed by sodium thiopental, furosemide, sodium bicarbonate, and hemodialysis for acute renal failure. His clinical course included respiratory distress,

agitation, generalized tonic-clonic convulsions, hyperactivity, oliguria, and acute tubular necrosis before recovery in 23 days. This patient ingested what would normally be a fatal amount of strychnine. He had signs and symptoms of severe toxicity and recovered, suggesting that with aggressive supportive care patients may have favorable outcomes (Shadnia et al., 2004). In another case report described by Wood et al. (2002), a 42-year-old man presented soon after ingestion of an unknown but warranted lethal quantity of strychnine powder. After respiratory arrest with intensive supportive management requiring admission to an intensive care unit, he survived.

People exposed to high doses of strychnine may have respiratory failure, possibly leading to death or brain death, within the first 15–30 min of exposure. No postmortem lesions are observed with the exception of small pinpoint hemorrhages in the lungs resulting from death attributable to asphyxia. Rigor mortis occurs soon after death and persists for days.

Toxicity of strychnine in humans, expressed as LD_{Lo} (lethal dose low), is approximately 30 mg/kg. Strychnine is less toxic in humans than in most animals. If the person survives the toxic effects of strychnine poisoning, long-term health effects are unlikely. However, long-term effects may result from damage caused by the poisoning, for example, brain damage from low oxygen or kidney failure. People severely affected by strychnine poisoning are not likely to survive.

At the present time, fatal strychnine poisoning is uncommon. It is no longer used as a therapeutic drug and its availability to the public is controlled by legislations in various jurisdictions. Nevertheless, it is still in use as a rodenticide, a herbal remedy, and an adulterant in street drugs (Cole et al., 2011; Singhapricha and Pomerleau, 2017). Illicit drugs very often contain substances that are a serious risk to health. Strychnine may be one such substance (Prat et al., 2015). Homicide by strychnine is extremely rare (Lynch, 1948; Bogan et al., 1966; Jaulmes and Hamelle, 1968). Autopsy findings are subtle, so strychnine poisoning could easily be overlooked and a homicide might go undetected. It is important in deaths in which there are no gross autopsy findings, sudden death in particular, that routine toxicology be performed because strychnine is likely to be detected (Kodikara, 2012). Exceptionally, strychnine has been used as a poison to commit suicide (Kordrostami et al., 2017). In the Western world, strychnine poisoning is much less common.

16.6.3 Diagnosis

A tentative diagnosis can be made based on clinical signs and history. However, a positive diagnosis can only be made by identifying strychnine in the stomach contents, viscera, or blood. The drug can be identified by chemical tests and microscopic identification of typical strychnine crystals. Sensitive analytical methods have already been developed to identify and quantify strychnine in various biological materials (Egloff et al., 1982; Wang et al., 2004; Neely et al., 2018).

16.7 Risk assessment

16.7.1 Human health hazard

The human health assessment for strychnine is based on acute toxicity. Strychnine has been placed in Toxicity Category I, indicating the greatest degree of acute toxicity, for oral and ocular effects. It has been reported that the probable lethal oral dose is 1.5−2 mg/kg (Gosselin et al., 1984). Inhalation toxicity is also presumed to be high. An oral dose of 1.5−2 mg/kg is equivalent to 70−93 mg/m^3 for 30 min for a 70-kg human.

Strychnine was first registered as a pesticide in the United States in 1947; however, this natural toxin had been used in many counties to control vertebrate animals for many years before that time. Currently, strychnine is registered for use only below ground as a bait application to control pocket gophers. The end-use products are formulated as grain-based bait or pastes. Baiting can be performed manually or with the use of application equipment.

The European Union (EU) withdrawal of strychnine marked its end as a method of mole control. The EU directive 91/414/EEC is midway through an ambitious program to review all pesticides used within Member States. This requires manufacturers to provide health and safety data to support the continued registration of their products. Strychnine was to be reviewed in the fourth part of this program, but manufacturers have failed to provide such data. Despite last-ditch appeals by users, since September 1, 2006, strychnine has no longer been legal to use.

However, strychnine in the form of a homeopathic preparation is still used and in exceptional cases may also cause poisoning. Gicquel et al. (2012) presented the case of a bulimic woman who was admitted to the emergency unit for painful muscle spasms and hypertonic crisis with respiratory blocking, after application of homeopathic nux vomica mother tincture, which contains indole alkaloids including strychnine. Toxicological screening revealed the presence of strychnine in the blood sample. This was corroborated by the patient, who explained that she had swallowed a whole bottle of nux vomica mother tincture as an emetic during a bulimic episode. This corresponded to 212 mg strychnine ingested. The therapeutic patient management consisted of symptomatic medication by diazepam and paracetamol and monitoring of biological parameters and vital functions including respiratory functions. Determination of strychnine concentrations in blood samples contributed to the control of poisoning. A blood concentration of 3 mg/L was first evaluated at admission of the patient, followed by a progressive decrease to 0.5 mg/L on the second day and a favorable clinical outcome for the patient.

16.7.2 Safety data

Strychnine oral reference dose (RfD) of 0.0003 mg/kg/day or 0.02 mg/day for a 70-kg person is derived from the Seidl and Zbinden (1982) short-term to subchronic study by applying an uncertainty factor of 10,000. This factor accounts for extrapolation from a less-than-chronic to a chronic exposure study, extrapolation from animals to humans, and differences in sensitivity among the human population. An additional factor of 10 is used because a LOAEL/FEL (2.5 mg/kg/day) was utilized in the estimation of the RfD instead of a NOAEL. The immediate dangerous to life and health dose for strychnine by NIOSH REL is 0.15 mg/m^3, and the current OSHA PEL is 0.15 mg/m^3.

The work of Seidl and Zbinden (1982) is the only oral short-term or subchronic study reported in which rats received daily doses of 0−10 mg/kg of strychnine by gavage for 28 days. Data recorded for the surviving animals included blood cell counts, electrocardiograms, eye

examinations, urine chemistry, weight gain, tissue histology, organ weights, behavioral tests, and food and water consumption. Mortality was observed in 5 of 12 male rats receiving 10 mg/kg and in 1 of 12 in each of the 5 mg and 2.5 mg/kg groups. All deaths occurred 0.5−6 h after oral doses.

An additional study (Gitzelmann et al., 1978) reported that a 6-month-old human patient received strychnine doses of 0.3−1.1 mg/kg/day over an 18-month period without any adverse effects. However, the patient may have had a higher strychnine tolerance as a result of nonketotic hyperglycinemia. Risk phrases of strychnine: R27/R28 R50/R53.

16.8 Treatment

There is no specific antidote for strychnine, but recovery from strychnine exposure is possible with early hospital treatment. Treatment consists of removing the drug from the body (decontamination) and getting supportive medical care in a hospital setting. Supportive care includes intravenous fluids, medications for convulsions and spasms, and cooling measures for high temperature.

Treatment of strychnine poisoning involves an oral application of an activated charcoal infusion that serves to absorb any poison within the digestive tract that has not yet been absorbed into the blood. Unabsorbed strychnine can be removed from the stomach by gastric lavage of tannic acid (strong tea) or potassium permanganate solutions used as chemical antidotes. Seizures are controlled and anticonvulsants such as phenobarbital or diazepam are administered to control convulsions, along with muscle relaxants such as dantrolene to combat muscle rigidity. Diazepam is the anticonvulsant of choice but is not effective in all cases, so a combination with midazolam, fentanyl, and pancuronium is recommended for controlling convulsions (Scheffold et al., 2004). To avoid a fatal outcome of strychnine poisoning demands aggressive management with early intubation, control of muscle tremors, and prevention of rhabdomyolysis and renal failure. If the patient survives past 24 h, then recovery is probable.

Small doses of strychnine were once used in medications as a stimulant, a laxative, and as a treatment for other stomach ailments. Strychnine has stimulant effects at low doses, but because of its high toxicity and tendency to cause convulsions, the use of strychnine in medicine was eventually abandoned once safer alternatives became available.

16.9 Concluding remarks and future directions

Strychnine is a highly poisonous natural substance that is used in some countries for the control of wild animals. Today, strychnine is used primarily as a pesticide, particularly to kill rats. Its use is restricted by law. Because strychnine is highly toxic and can be rapidly absorbed through the mucous membranes of the mouth, stomach, and small intestines, theoretically it could be used as a military toxin or terrorist agent. There are three main ways that strychnine can enter the body: inhalation, ingestion, and broken skin.

Goal-directed misuse of strychnine against humans is unlikely. Its misuse against domestic animals is realistic and more likely.

Uncommonly, strychnine is found mixed with "street" drugs such as LSD, heroin, and cocaine. It is very probable that seizures observed occasionally after cocaine application may be caused by admixed strychnine (Haddad and Winchester, 1983; Wijesekera et al., 1988). After analysis of heroin samples seized in the Florence area between 1975 and the first half of 1981, no dangerous substances were found in the samples and strychnine, if present, was found in very low concentrations (Mari et al., 1982).

Chapter 17

Superwarfarins

Michael J. Murphy
University of Minnesota, St. Croix Trail N, Stillwater, MN, United States

17.1 Introduction

Chemical warfare agents may be manufactured from a wide range of commercially manufactured household industrial products, such as bleach, antifreeze, fertilizers containing anhydrous ammonia, pesticides, or anticoagulant rodenticides, particularly superwarfarins (Feinstein et al., 2016), Superwarfarins are a group of commercially available, long-acting, anticoagulant rodenticides that are structurally similar to warfarin but are many times more potent. Many of them have the capacity to cause severe bleeding problems that may last for 2−8 months in humans. Superwarfarins may be used to harm or terrorize people through the ingestion of contaminated food, water, or drugs.

This group of long-acting anticoagulants may be used as chemical warfare agents because of their high potency and duration of action. The capability of terrorists to use these commercially available poisons depends upon the availability of large amounts of high-concentration product (whether obtained legally or illegally), the target population and its vulnerability, and the method of effective delivery and dissemination. Although these anticoagulants may be absorbed through the skin and lungs, the main route of exposure is ingesting food, water, or adulterated drugs containing the product (Jones et al., 1984; Katona and Wason, 1989; Swigar et al., 1990; Wallace et al., 1990; Exner et al., 1992; Rauch et al., 1994; Gallo, 1998; Corke, 1997; Ross et al., 2019; Tole et al., 2019; Navon et al., 2019; Alipour et al., 2019; Arepally and Ortel, 2019; Boyack and Opsha, 2019; Kelkar et al., 2018; Riley et al., 2019; Panigrahi et al., 2018; Hussain et al., 2018; Moritz et al., 2018). Superwarfarin poisoning may result in a large number of casualties if these substances are ingested (Palmer et al., 1999; Baker et al., 2002; EPA, 2005; POISINDEX, 2007; HSDB, 2008).

Superwarfarin rodenticides are used to kill urban and agricultural pests. They are now less available to the general public (EPA, 2019) but are readily available to pest controllers and are easy to obtain and conceal, so they may pose a risk of being used as chemical warfare agents. These rodenticides are available as meal bait packs, pellets, minipellets, blocks, miniblocks, wax blocks, liquid bait formulations, tracking powder, concentrate, and perhaps other formulations (POISINDEX, 2007).

17.2 Background

Anticoagulants were discovered in the early 20th century after livestock had eaten moldy sweet clover contaminated with bis-hydroxycoumarin and died of hemorrhagic disease. Newer long-acting warfarin derivatives such as brodifacoum, bromadiolone, diphacinone, and chlorophacinone can produce profound and prolonged anticoagulation and bleeding after a latency period that generally lasts 24−72 h (FDA, 1985; Smolinske et al., 1989; Routh et al., 1991; Exner et al., 1992) (Table 17.1).

In the 1940s, a small British pharmaceutical company suggested that dicoumarol might have rodenticidal properties. Trials carried out by Armour and Barnett (1950) confirmed the idea and started the era of anticoagulant rodenticides. Warfarin was the first anticoagulant rodenticide; it was introduced into the market shortly after World War II and became widely used in many countries. Other anticoagulant compounds with potency similar to that of warfarin were also synthesized. These early anticoagulant rodenticides have often been called *first-generation anticoagulant rodenticides.* These compounds generally have moderate toxicity, with acute LD_{50} values ranging from 10 to 50 mg/kg body weight (Table 17.2).

The first-generation compounds often needed continuous bait exposure for rodent control. Many rodent species developed a resistance to warfarin (Jackson et al., 1975),

Name	Molecular formula	Commercial names
Brodifacoum CAS: 56073-10-0	C_{31}-H_{23}-Br-O_3	D-Con Mouse-Prufe I & II, Havoc, Klerat, Ratak Plus, Talon G, Void Finale, Folgorat, Matikus, Mouser, Rodend, Volak, Volid
Difenacoum CAS: 56073-07-5	C_{31}-H_{24}-O_3	Compo, Diphenacoum, Frunax DS, Matrak, Neosorexa, Rastop, Ratak, Ratrick, Silo
Bromadiolone CAS: 28772-56-7	C_{30}-H_{23}-Br-O_4	Apobas, Bromard, Bromone, Bromatrol, Bromorat, Contrac, Deadline, Hurex, Lanirat, Maki, Morfaron, Musal, Maki, Ramortal, Ratimon, Rodine-c, Slaymore, Super-caid, Toidon
Diphacinone CAS: 82-66-6	C_{23}-H_{16}-O_3	Diphacine, Ditrac, Gold Crest, Kill-Ko, P.C.Q., Promar, Ramik, Rat Killer, Rodent Cake, and Tomcat
Chlorophacinone CAS: 3691-35-8	C_{23}-H_{15}-Cl-O_3	Caid, Liphadione, Microsul, Ramucide, Ratomet, Raviac, Rozol, Topidox
Difethialone[a] CAS: 104653-34-1	C_{31}-H_{23}-Br-O_2-S	None to report
Pindone[a] CAS: 83-26-1	C_{14}-H_{14}-O_3	Pestanal, Pindone, Pival, Pivalyn, Pivalyl Valone, Tri-ban
Coumatetralyl[a] CAS: 5836-29-3	C_{19}-H_{16}-O_3	Racumin
Coumafuryl[a] CAS: 117-52-2	C_{17}-H_{14}-O_5	Fumarin, Tomarin
Valone CAS: 83-28-3	C_{14}-H_{14}-O_3	None to report
Flocoumafen[a] CAS: 90035-08-8	C_{33}-H_{25}-F_3-O_4	None to report

Available forms include: meal bait packs, pellets, minipellets, blocks, miniblocks, wax blocks, liquid bait formulations, and tracking powder.
[a]*No longer produced or used in the United States.*

TABLE 17.2 The oral LD_{50} values (mg/kg body weight) of some anticoagulant rodenticides.

Animals	Bromadiolone	Brodifacoum	Difenacoum
Rat (acute)	0.65	0.27	1.8
Rat (chronic)	(0.06–0.14) × 5	(0.05–0.08)	0.15 × 5
Mouse	0.99	0.4	0.8
Rabbit	1.0	0.2	2.0
Pig	3.0	10.0	80.0
Dog	10.0	3.5	50.0
Cat	25.0	25.0	100.0
Chicken	5.0	10.0–20.0	50.0
Guinea pig	2.8	–	–
Opossum	–	0.17	–
Sheep	–	10.0	100.0

presumably due to continued exposure and widespread use. Consequently, new chemical structures were synthesized and used as anticoagulant rodenticides. These newer compounds are generally more toxic than warfarin, with acute LD_{50}s of 0.2–3.9 mg/kg body weight. For example, a bait concentration of only 50 ppm of brodifacoum is adequate to control the population in a single feeding for most rodents and noncommensal species (Matolesy et al., 1988).

These newer compounds were called *second-generation anticoagulant rodenticides* and are often now referred to as *superwarfarins* in the contemporary medical literature (Routh et al., 1991; Exner et al., 1992; Rauch et al., 1994; Hui et al., 1996; Sharma and Bentley, 2005; Dolin et al., 2006).

During the past 30 years, there have been hundreds of articles published in medical literature relating to the clinical assessment, laboratory testing, and treatment of human and nonhuman patients exposed to superwarfarins. A great number of these articles are about children under 6 years old who accidentally ingested small amounts of these products and, in most cases, did not experience adverse effects (Brands et al., 1995; Ingels et al., 2002; AAP, 2003; Osterhoudt and Henretig, 2003). A few cases describe coagulopathies, and some fatalities, in patients who intentionally ingested large amounts of the substance (Wallace et al., 1990; Casner, 1998; Walker and Beach, 2002; AAPCC, 2006). Most of the health hazard is associated with ingestion of superwarfarins (Bruno et al., 2000; POISINDEX, 2007). Many publications concern nonhuman animals (Newton et al., 1990; Stone et al., 1999). Virtually all animal exposures are due to accidental direct or indirect ingestion. The great majority of domestic animal exposures are in dogs. Many of these cases require referral to a veterinarian for clinical evaluation and often treatment (DuVall et al., 1989; Hornfeldt and Phearman, 1996; McConnico et al., 1997; Robben et al., 1997; Borst and Counotte, 2002). Occasionally gastric decontamination will be indicated; coagulopathies frequently respond to vitamin K_1 therapy.

Warfarin and dicoumarol found application as both oral anticoagulants and as rodenticides. Sweet clover requires the action of molds to form dicoumarol; giant fennel does not. Giant fennel (*Ferula communis*) grows in Mediterranean countries. It has a naturally occurring anticoagulant effect. An association between the plant and anticoagulation was first reported in the 1950s (Costa, 1950a,b; Carta, 1951). It was further investigated in Italy (Corticelli and Deiana, 1957; Corticelli et al., 1957; Mazzetti and Cappelletti, 1957; Cannava, 1958), and then in Israel (Shlosberg and Egyed, 1983). The anticoagulant activity of the plant in Morocco has also been reviewed (Lamnaouer, 1999).

Warfarin and its congeners are still used as therapeutic agents. Oral anticoagulants available therapeutically in Europe include warfarin, phenprocoumaron, and nicoumalone—also called acenocoumarol (Shetty et al., 1993). Oral anticoagulants are used therapeutically to reduce thromboembolic events. Warfarin examples include a reduction in catheter-related thrombosis (Magagnoli et al., 2006); early venous thrombosis after operations (Pan et al., 2005), including hip surgery; atrial fibrillation (Reiffel, 2000); and myocardial infarction (Asperger and Jursic, 1970). A number of adverse events have been recognized, most of which are related to drug interactions (Dayton and Perel, 1971).

An association between vitamin K_1 and coagulopathies was made in the mid-1930s (Dam, 1935; Fieser et al., 1939). Soon thereafter, Karl Paul Link reported the discovery of dicoumarol in moldy hay (Last, 2002). Naturally occurring coumarin in sweet-clover hay is converted by fungi to dicoumarol. Dicoumarol was found to be the causative agent of the disease, so the elements needed for the disease were coumarin-containing plant material plus mold growth. Subsequently, a range of molecules were synthesized, and one of these, warfarin, became the most popular (Duxbury and Poller, 2001). Warfarin takes its name in part from the Wisconsin Alumni Research Foundation and the rest from coumarin.

17.2.1 AAPCC data on superwarfarins

Every year, tens of thousands of accidental ingestions of long-acting anticoagulant rodenticides (LAARs) are reported worldwide in medical literature. These include the annual report from the American Association of Poison Control Centers (AAPCC). Table 17.3 summarizes exposures, reasons, and deaths associated with LAARs reported by the AAPCC in recent years. All fatalities were in adults who committed intentional suicide.

17.3 Classification of superwarfarins

Anticoagulant rodenticides are also categorized by chemical structure. The chemical structure of the currently marketed products fits in one of two chemical classes: 4-hydroxycoumarins and indanediones.

17.3.1 4-Hydroxycoumarins

This group of compounds has a 4-hydroxycoumarin ring with different side-chain substituents at the 3-position. Commonly used superwarfarin anticoagulant rodenticides in this group are bromadiolone, brodifacoum, coumatetralyl, coumafuryl, and difenacoum. Brodifacoum, difenacoum, and bromadiolone are three of the most commonly used rodenticides around the world. These rodenticides share most of their physical and chemical characteristics, as well as their mechanism of toxicity, and the medical management is the same for all superwarfarins. Generally brodifacoum has longer elimination kinetics.

TABLE 17.3 Number of exposures to long-acting anticoagulant rodenticides and deaths reported by the American Association of Poison Control Centers—National Poison Center Annual Reports 2012–2017.

Year	No. of exposures to long-acting anticoagulant rodenticides	Reason: unintentional	Reason: intentional	Reason: other	Deaths
2012[a]	9299	8887	310	70	1
2013[a]	8510	8101	292	77	1
2014[b]	8372	7960	301	76	3
2015[c]	7125	6796	222	72	1
2016[d]	5453	5198	164	53	0
2017[e]	4810	4612	106	55	1

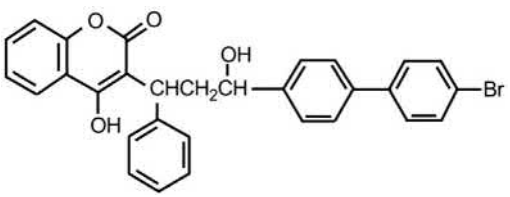
17.3.1.1 Bromadiolone

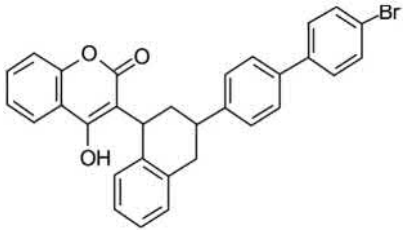
Chemical formula: $C_{30}H_{23}BrO_4$



Bromadiolone [3-(3-(4′-bromobiphenyl-4-yl)-3-hydroxy-1-phenyl propyl)-4-hydroxycoumarin] was synthesized and marketed by the French company Lipha SA during the mid-1970s. It is used widely for control of commensal and field rodents in many countries. Technical-grade bromadiolone is 97% pure. It is a yellowish powder and stable up to 200°C (Chalermchaikit et al., 1993). It is very soluble in dimethylformamide (730 g/L), but less soluble in ethyl acetate (25 g/L) and ethanol (8.2 g/L), and sparingly soluble in water (0.019 g/L). Bromadiolone is considered more palatable to rodents than most other anticoagulants. Its concentration in baits is usually 50 ppm (Chalermchaikit et al., 1993). Although bromadiolone is considered a second-generation anticoagulant rodenticide, resistance has been reported in *Rattus norvegicus* and *Mus musculus* in the United Kingdom and Denmark (Rowe et al., 1981; Lund, 1984; IPCS, 1995d).

17.3.1.2 Brodifacoum

Chemical formula: $C_{31}H_{23}BrO_3$



Brodifacoum [3-(3-(4′-bromobiphenyl-4-yl)-1,2,3,4-tetrahydro naphth-1-yl)-4-hydroxycoumarin] is one of the more potent second-generation anticoagulant rodenticides. It was first introduced in 1977 by Sorex Ltd. of London, and then developed by the Imperial Chemicals Incorporated (ICI) Plant Protection Division (Chalermchaikit et al., 1993).

Pure brodifacoum is an off-white to fawn-colored powder with a solubility of 6–20 g/L in acetone, 3 g/L in chloroform, 0.6–6 g/L in benzene, and less than 10 mg/L water. It is very stable in the environment with no loss after 30 days of exposure to direct sunlight (Chalermchaikit et al., 1993).

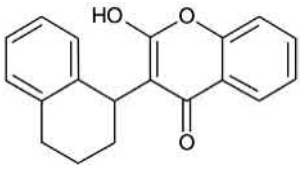
Brodifacoum has been marketed in several countries for the control of a wide range of rodent pest species. It is available as a 0.005% pellet for rat and mouse control, a smaller 0.001% pellet for field rodent control, and as 29 g wax blocks for sewer rat control. It is the only anticoagulant rodenticide found to produce 100% mortality in most

rodent species after only a 24 h dose (Chalermchaikit et al., 1993). Brodifacoum was effective against warfarin-resistant rats and mice in 1984, but resistance has been reported (Lund, 1984).

Species variation in susceptibility exists. Dogs are susceptible and are commonly exposed to potentially toxic quantities of brodifacoum (Chalermchaikit et al., 1993).

17.3.1.3 Coumatetralyl

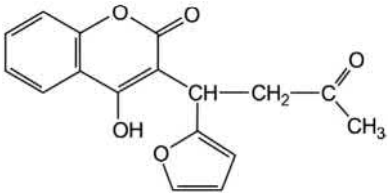
Chemical formula: $C_{19}H_{16}O_3$



Coumatetralyl [3-(alpha-tetralyl)-4-hydroxycoumarin] was introduced by Bayer AG with the trademark name of Racumin. It has been used for commensal rodent control in many countries. It is formulated as a dry bait (0.0375%), a liquid bait of its sodium salt, and a 0.75% tracking dust (Chalermchaikit et al., 1993). Pure coumatetralyl is a colorless powder that is stable at temperatures below 150°C. Its solubility is 20–50 g/L in propan-2-ol, 50–100 g/L in methylene dichloride, and 4 mg/L in water. The acute and chronic LD_{50}s of *R. norvegicus* are 16.5 and 0.3 mg/kg for five consecutive doses, respectively. Chickens are somewhat resistant to coumatetralyl, with a chronic LD_{50} of 50 mg/kg for eight consecutive doses. Signs did not appear in fish until the concentration of coumatetralyl reached 1000 mg/L in water (Chalermchaikit et al., 1993). Despite its low toxicity, it is reported to be more effective than warfarin against *R. norvegicus*, apparently due to a higher palatability. Coumatetralyl was introduced after the detection of warfarin-resistant rat populations and showed considerable success for a number of years, but resistance has been reported in the United Kingdom and Denmark (Rowe and Redfern, 1968; Lund, 1984).

17.3.1.4 Coumafuryl

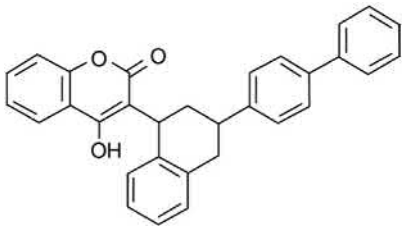
Chemical formula: $C_{17}H_{14}O_5$



Coumafuryl [3-(alpha-acetonylfurfuryl)-4-hydroxycoumarin] is a German anticoagulant, introduced in 1952, used at 0.025%–0.05% in baits. Its toxicity is considered equal to warfarin for *R. norvegicus*, but slightly less efficient against *M. musculus*. The chronic LD_{50} in *R. norvegicus* is 1.4 mg/kg for five repeated doses. Cats and dogs seem to be almost as susceptible as rats, with dogs being killed by 2 mg/kg for five repeated doses and cats by 10 mg/kg for four repeated doses (Chalermchaikit et al., 1993).

17.3.1.5 Difenacoum

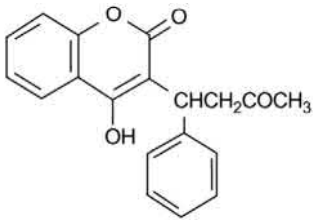
Chemical formula: $C_{31}H_{24}O_3$



Difenacoum [3-(3-*p*-diphenyl-1,2,3,4-hydronaphth-1-yl)-4-hydroxycoumarin] was synthesized in the United Kingdom and marketed in 1975 by Sorex Ltd. under the trademark Neosorexa, and by ICI Plant Protection Division under the trademark Ratak as a 0.005% pelleted bait, and as a wax block. Pure difenacoum is an off-white powder with a solubility of greater than 50 g/L in acetone, 600 mg/L in benzene, and less than 10 mg/L in water. It is more toxic than warfarin but less palatable (IPCS, 1995c). Difenacoum is still effective against many populations of warfarin-resistant rats (Desideri et al., 1979), but resistance has been reported in the United Kingdom (Greaves et al., 1982).

17.3.1.6 Warfarin

Chemical formula: $C_{19}H_{16}O_4$



Warfarin [3-(a-acetonylbenzyl)-4-hydroxycoumarin] was the first anticoagulant rodenticide. It was introduced shortly after World War II by the Wisconsin Alumni Research Foundation. Warfarin is still used widely, especially for the control of *R. norvegicus* in areas where resistance has not yet developed. In its racemic form, warfarin is colorless and crystalline, insoluble in water but readily soluble in acetone,

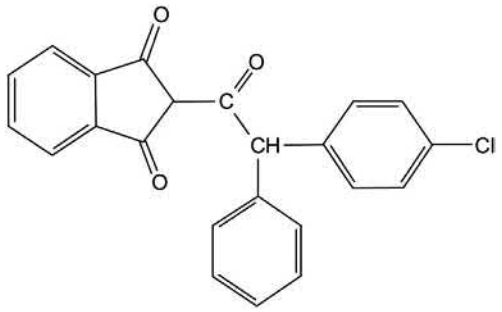
dioxane, and moderately soluble in alcohols. Warfarin is formulated as dry bait (0.005%−0.05%), liquid bait, based on the sodium salt, and a tracking dust (0.5%−1.0%). It is generally applied as the S-isomer, which is 10 times more potent than the R-isomer. The acute and chronic LD_{50}s for *R. norvegicus* are around 10−12 and 0.75 mg/kg for five repeated doses, respectively (Colvin and Wang, 1974). Warfarin is sometimes combined with an antibacterial agent, sulfaquinoxaline, to reduce the bacterial production of vitamin K in the rat intestine, but the effectiveness of this combination is not well established. Warfarin is considered one of the safest anticoagulants, as far as nontarget animals are concerned. Serious resistance problems have been reported in Europe. It has recently been evaluated against sewer rats in London (Channon et al., 2000).

17.3.2 Indanediones

This group of compounds has a 1,3-indanedione structure with different side-chain substituents at the 2-position. The most common superwarfarins in this group are chlorophacinone and diphacinone.

17.3.2.1 Chlorophacinone

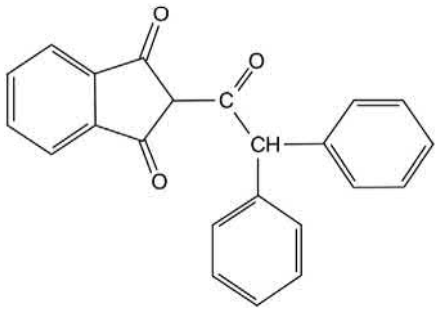
Molecular formula: $C_{23}H_{15}ClO_3$



Chlorophacinone [2-(alpha-4-chlorophenyl-a-phenylacetyl)-1,3-indandione] was introduced in the mid-1960s by Lipha SA at concentrations of 0.05% in baits and 0.2% in tracking dust. Pure chlorophacinone is a yellow crystalline solid that is very soluble in acetone, ethanol, and ethyl acetate, but is only somewhat soluble in water. It is quite stable and resistant to weathering. Chlorophacinone does not induce bait-shyness and is compatible with cereals, fruits, roots, and other potential bait substances. Its acute LD_{50} in *R. norvegicus* is about 20.5 mg/kg, which is less toxic than warfarin, but it has a stronger initial effect on rats and mice. For control of house mice populations, a prolonged feeding period is needed. Chlorophacinone may not be effective against warfarin-resistant rodents (Chalermchaikit et al., 1993).

17.3.2.2 Diphacinone

Molecular formula: $C_{23}H_{16}O_3$



Diphacinone (2-diphenylacetyl-1,3-indandione) is an old anticoagulant rodenticide introduced by Vesicol Chemical Corp. and the Upjohn Co. It has been produced and used primarily in the United States as a 0.005% dry or liquid bait. Pure diphacinone is a yellow powder that is very soluble in chloroform (204 g/kg), toluene (73 g/kg), xylene (50 g/kg), and acetone (29 g/kg), but only somewhat soluble in water (0.30 g/L). It will decompose in water due to sunlight. The acute LD_{50}s in *R. norvegicus* are 22.7 mg/kg in females and 43.3 mg/kg in males. It is more toxic than warfarin to rats, mice, and dogs, but its palatability is somewhat lower. Diphacinone may not be effective against some warfarin-resistant rodents (Chalermchaikit et al., 1993). The anticoagulant rodenticides are marketed to have efficacy against a number of target pest species.

17.4 Toxicokinetics

17.4.1 Absorption, metabolism, and excretion in laboratory animals and humans

Superwarfarins are generally well absorbed from the gastrointestinal tract. Almost 90% is absorbed, with peak plasma concentrations often occurring within 12 h of ingestion. Binding to plasma proteins may prolong distribution and half-life. Toxicity after dermal or respiratory exposure is reported, but rare (Boermans et al., 1991; Berry et al., 2000; Spiller et al., 2003).

The metabolism and elimination of the *trans*-isomer is more rapid than that of the *cis*-isomer. Elimination from the liver is biphasic, with an initial rapid phase of 3 days and a slower phase with a half-life of 120−130 days. The liver is the major organ for detection of the unchanged parent compound. The major route of elimination in different species after oral administration is via the feces. The urine is a very minor route of elimination (Watt et al., 2005).

17.5 Mechanism of action

The mechanism of action of all anticoagulant rodenticides is similar to that of warfarin, specifically inhibition of vitamin K_1 epoxide reductase (Park et al., 1979; Leck and Park, 1981; Breckenridge et al., 1985). In the coagulation cascade, clotting factors II, VII, IX, and X must bind calcium ions to be active in clot formation. The Ca^{2+}-binding ability requires converting glutamyl residues on these clotting factors to carboxyl glutamyl residues by the process of carboxylation. This carboxylation uses vitamin K_1 hydroquinone as a cofactor. This vitamin K-dependent carboxylase reaction converts vitamin K_1 hydroquinone to its epoxide form, vitamin K_1 2,3-epoxide. Normally vitamin K_1 2,3-epoxide is reduced to the original vitamin K_1 (phylloquinone) by epoxide reductase, thus being "recycled." The anticoagulant rodenticides interfere with vitamin K_1 epoxide reductase, resulting in the depletion of vitamin K_1 and subsequently impairing the synthesis of normal clotting factors II, VII, IX, and X (Craciun et al., 1997, 1998). Clinical coagulopathy soon follows the depletion of active clotting factors in circulation. In the dog, these clotting factors have plasma half-lives of 41, 6.2, 13.9, and 16.5 h, respectively. The coagulation system may function reasonably well until about 3–5 days after ingestion (depending on the compound and dose), when the natural decay of clotting factors occurs. The interrelationship of vitamin K, prothrombin, and gamma-carboxyglutamic acid is reviewed in Stenflo (1978). The interaction of warfarin and vitamin K is reviewed in Suttie (1990).

17.6 Toxicity

17.6.1 Clinical effects: signs and symptoms

Clinical signs and symptoms of acute intoxication by superwarfarins range from a mild tendency to bleed (in less severe poisoning cases) to severe coagulopathy. Mild bleeding tendencies often show themselves clinically as nose or gum bleeding, hemoptysis, ecchymosis, bloody or melenotic stools, hematuria, abdominal or flank pain, enhanced bruising, and ventral hematomas (in animals). Severe bleeding leads to shock and death. Internal and external bleeding are the most frequent clinical signs, followed by tachycardia and hypotension, then failure of multiple organs due to substantial blood loss. The onset of clinical signs is normally not evident until a few days after absorption (Baker et al., 2002; Tsutaoka et al., 2003).

17.6.1.1 Animal toxicology

Clinical signs are usually delayed until 24–36 h after ingestion. The most common signs include, dyspnea, weakness, lethargy, anorexia, hematuria, or melena. Other signs, such as pale mucous membranes, bleeding from the nose and gums, and generalized bruising, also may be noticeable. Internal bleeding also causes generalized pain; lameness from bleeding into a joint; bleeding into the thorax or abdomen, brain, or pericardium; or sudden death (Braithwaite, 1982; Berny et al., 1995; Munday and Thompson, 2003).

17.6.1.2 Pediatric exposures

The great majority of human exposures are children under the age of 6 due to accidental/unintentional ingestion. Children usually do not require any medical intervention or routine follow-up laboratory studies and can be adequately managed by poison control centers with home observation and parent education (Mullins et al., 2000; Ingels et al., 2002; Kanabar and Volans, 2002; Shepherd et al., 2002). Children with accidental ingestions of a pellet may often be managed without gastric decontamination or prophylactic vitamin K. Laboratory testing for coagulopathy should be reserved for cases involving clinically evident bleeding abnormalities (Ingels et al., 2002).

A small number of reported cases of children have presented with mild to moderate hematological effects, requiring minimal intervention (Smolinske et al., 1989; Watts et al., 1990; Babcock et al., 1993; Travis et al., 1993; Golej et al., 2001; Osterhoudt and Henretig, 2003).

On the other hand, intentional suicidal ingestion of large amounts of product conveys a greater risk of severe toxicity and increased mortality, normally requiring referral to a healthcare facility for examination and treatment (Ingels et al., 2002).

17.6.1.3 Adult exposures

The great majority of adult exposures to rodenticides are due to deliberate acute or chronic ingestion. Bleeding disorders may persist for 6 weeks to many months. Serious poisoning has been reported in adults with massive overdoses. These long-acting anticoagulants have produced rapid and persistent bleeding due to hypoprothrombinemia (Chong et al., 1986; Hoffman et al., 1988; Katona and Wason, 1989; Wallace et al., 1990; Routh et al., 1991; Barnett et al., 1992; Exner et al., 1992; Mack, 1994; Morgan et al., 1996; McCarthy et al., 1997; Gallo, 1998; Berry et al., 2000). A risk of spontaneous abortion and transplacental distribution has been reported. (Lipton and Klass, 1984; Zurawski and Kelly, 1997; Nelson et al., 2006; Mehlhaff et al., 2013; Yan et al., 2013; Rutović et al., 2013).

The severity of the intoxication depends on the amount of rodenticide ingested, preexisting comorbidity, and coingestion of other toxic substances (Seidelmann et al., 1995;

Palmer et al., 1999; Stanziale et al., 1997; Tecimer and Yam, 1997; Walker and Beach, 2002). Fatalities are usually due to intentional suicidal ingestion of large amounts. Bleeding disorders and organ failure have been described in adults due to deliberate acute and chronic surreptitious ingestion. See Table 17.3 for a summary of exposures, reasons, and deaths reported by the AAPCC in recent years

17.6.1.4 Household pets and farm animal exposures

Household pets and farm animals may be accidentally exposed to rodenticides. The possible effects on nontarget organisms can be considered in two types: direct poisoning and secondary poisoning. Secondary poisoning is generally considered to occur after an animal has consumed anticoagulant rodenticide-poisoned target species, such as rodents. The most common type of exposure is direct poisoning by eating a cereal-based bait containing the rodenticide. The most commonly affected household pets are dogs, followed by cats, hamsters, rabbits, and pet birds (Redfern and Gill, 1980; Park and Leck, 1982; Boermans et al., 1991; Woody et al., 1992; Hornfeldt and Phearman, 1996; Peterson and Streeter 1996; McConnico et al., 1997; Robben et al., 1997, 1998; Munday and Thompson, 2003; Radi and Thompson, 2004).

Cats may be more resistant to the toxic effects of brodifacoum and difenacoum than dogs. Cases of abortion and hemorrhage in sheep and goats after misuse of brodifacoum have been reported (Jones, 1996; Watt et al., 2005). Recent case reports suspect anticoagulant rodenticide toxicosis in pregnant women (Mehlhaff et al., 2013; Yan et al., 2013) and a whelping dog (Fitzgerald et al., 2018).

17.6.1.5 Nontarget wildlife exposures

Nontarget wildlife also may be exposed to rodenticides. The possible effects on nontarget organisms can also be considered in two types: direct poisoning and secondary poisoning. The potential for secondary poisoning is more likely in carnivorous wildlife (Mathur and Prakash, 1980; Mahmoud and Redfern, 1981; Greaves et al., 1982; DuVall et al., 1989; Newton et al., 1990; James et al., 1998; Borst and Counotte, 2002; Eason et al., 2002). The most commonly affected species are birds such as great horned owls, barn owls, eastern screech owls, golden eagles, red-tailed hawks, Cooper's hawks, and crows. Bird species varied in their susceptibility. Other wild animals also may be exposed, such as polecats, wildcats, and foxes. Brodifacoum was highly toxic for fish when tested as a technical material.

17.6.1.6 Laboratory/monitoring and general recommendations

Superwarfarins lower the active blood concentrations of the vitamin K-dependent clotting factors II, VII, IX, and X; this results in prolongation of prothrombin time (PT) and partial thromboplastin time (PTT). PT and PTT should be repeated at least twice daily until normal PT and PTT levels are established. Also, the blood clotting time and the bleeding time should be measured. Blood is often demonstrable in the excreta. Secondary hypochromic or microcytic anemia may be marked (Goldfrank et al., 2002; Nelson et al., 2006). A PT 24−48 h after exposure in asymptomatic children with accidental ingestions of large or unknown amounts should be obtained. In adults with deliberate ingestions and children with clinical evidence of bleeding, an initial PT and PTT should be obtained and then repeated at 24 and 48 h after ingestion (Manoguerra and Cobaugh, 2005).

Evaluation of a point-of-care anticoagulant rodenticide test for dogs has been reported (Istvan et al., 2014).

17.6.1.7 Analytical methods

A number of analytical methods have been reported for detecting anticoagulant rodenticides in various matrices. Early fluorimetric methods were used to detect warfarin in serum (Vesell and Shivley, 1974; Fasco et al., 1977; Hanna et al., 1978; Lee et al., 1981) and GLC for warfarin (Mildha et al., 1974).

Warfarin-specific methods were generally inadequate for subsequent anticoagulant rodenticides, so a number of other methods were developed. These methods include thin-layer chromatography (TLC), high-pressure liquid chromatography (HPLC), mass spectroscopy (MS), and antibody-mediated tests. Coumarin anticoagulant rodenticides were initially detected using TLC (Lau-Cam and Chu-Fong, 1972; Mallet et al., 1973). A high-performance TLC method with an estimated detection limit of 200 ppb and 87% recovery from liver was reported (Berny et al., 1995).

Early HPLC methods focused on an individual chemical. For example, methods to detect chlorophacinone in formulations (Vigh et al., 1981), brodifacoum in serum (Murphy et al., 1989), brodifacoum (Ray et al., 1989), bromadiolone (Subbiah et al., 2005), chlorophacionone (Hunter, 1985), difethiolone (Goldade et al., 1998), and difenacoum (Mundy and Machin, 1977) in tissue have been reported.

Subsequently, methods were developed to look for all anticoagulant rodenticides in the same sample at the same time. An initial method succeeded in extracting and detecting eight anticoagulant rodenticides in serum and liver using fluorescence and ultraviolet (UV) detection.

Samples were extracted with acetonitrile then cleaned up on solid-phase columns. Four hydroxycoumarins were detected by fluorescence with excitation at 318 nm and emission at 390 nm. The indandiones were detected at 285 nm. An extraction recovery of 75% from serum and 69% from liver was reported. Hydroxycoumarins may be detected down to about 1 ng/mL of serum and 1 ng/g of liver, and indandiones down to 10 ng/mL of serum and 10 ng/g of liver (Felice and Murphy, 1989; Felice et al., 1991; Chalermchaikit et al., 1993). Another HPLC method for detecting brodifacoum in serum and liver using difenacoum as the internal standard has been reported (O'Bryan and Constable, 1991). There is also a method for the simultaneous detection of five superwarfarin rodenticides in human serum (Kuijpers et al., 1995). Other serum methods have been reported; for example, detection limits of 3–12 ng/mL for fluorescence and 20–75 ng/mL for UV detection (Mura et al., 1992; Kuijpers et al., 1995; McCarthy et al., 1997; Feng et al., 1999).

Tissue methods include a solid-phase cartridge extraction from liver, with recoveries ranging from 52% for difenacoum to 78% for warfarin. The limit of detection is 10 ppb for warfarin and difenacoum and 110 ppb for chlorophacinone (Addison, 1982; Jones, 1996; Fauconnet et al., 1997).

HPLC methods have also been published to distinguish *cis*- and *trans*-isomers of difenacoum with detection limits of 5 ng/mL (Kelly et al., 1993). An early, interesting approach was to use a postcolumn pH shift to enhance fluorescence detection (Hunter, 1985). Several earlier HPLC methods have also been reported (AOAC, 1976a,b; Hunter, 1983): diphacinone (Bullard et al., 1975, 1976), fluorescence for bromadiolone (Deepa and Mishra, 2005), brodifacoum (Fu et al., 2006), brodifacoum in tissues (Hoogenboom and Rammell, 1983), difenacoum (Hadler and Shadbolt, 1975), determination of Rozol in parafinized formulations (Kawano and Chang, 1980), and bromadiolone in tissues (Nahas, 1986).

A recent method uses diode-array detection (Yang et al., 2001). Contemporary confirmatory methods use MS, for example, liquid chromatography-electrospray ionization-mass spectroscopy (LC-EIS-MS) has been reported for the analysis of 10 anticoagulant rodenticides with a quantity limit of about 5 μg/L (Grobosch et al., 2006). Other recent methods use LC-MS-MS for unknown drugs, including warfarin (Marquet et al., 2003), and LC-ESI-MS and HPLC UV to detect anticoagulant rodenticides as low as 20 ng on a column (Mesmer and Flurer, 2000). Recently reported methods tend to use liquid chromatography with one or more MS units (Robinson and Sisco, 2018; Qiao et al., 2018; Smith et al., 2017; López-García et al., 2017; Saito-Shida et al., 2016; Maršálek et al., 2015; Jagerdeo et al., 2015; Bidny et al., 2015).

A prior immunoassay was used to detect diphacinone and chlorophacionone (Mount et al., 1988). Enantiomers of warfarin, coumachlor, and coumafuryl can be separated chromatographically (Armstrong et al., 1993).

Serum concentration of dogs with anticoagulant rodenticide poisoning ranged from less than 10 to 851 ng/L for brodifacoum, difethialone, and difenacoum (Robben et al., 1998).

Animal samples are routinely analyzed in veterinary diagnostic laboratories. For example, the Texas Veterinary Medical Diagnostic Laboratory, in College Station, TX (http://tvmdl.tamu.edu/), performs such analyses. A list of other laboratories performing anticoagulant rodenticide analyses on animal samples can be obtained from the American Association of Veterinary Laboratory Diagnosticians (www.aavld.org). Human samples are generally analyzed at either the National Medical Services Laboratory in Willow Grove, PA, or the Medtox Scientific Laboratories in St Paul, MN.

17.7 General treatment recommendations

17.7.1 Referral to healthcare facilities

In the case of a suspected terrorist act, misuse, intentional criminal, or any deliberate intentional suicidal ingestion, or when the amount ingested is either large or indeterminate, the patient should be referred to a healthcare facility for clinical and laboratory assessment, as well as treatment if necessary (Manoguerra and Cobaugh, 2005; POISINDEX, 2007). Therapeutic approaches to anticoagulant rodenticide toxicoses have been reviewed (Schulman and Furie, 2015).

A recent review of dogs with coagulopathies reports that 60.9% tested positive for anticoagulant rodenticides, 31.3% had neoplasia, 14.6% immune-mediated disease, and 10.4% gastrointestinal bleeding. Dogs with anticoagulant rodenticide intoxication had the best prognosis, with a survival rate of 98.7% (Waddell et al., 2013).

17.7.2 Home observation criteria

Accidental ingestion of a small amount (less than a few pellets) can normally be adequately managed at home by either poison control centers or a healthcare professional with home observation and parent education. Usually, these types of exposures do not require any medical intervention or routine follow-up laboratory studies. Gastric decontamination has no effect on the clinical outcome after "taste" (one-fifth of a spoonful) amounts are ingested by children (Mullins et al., 2000; Kanabar and Volans, 2002; Shepherd et al., 2002).

If the amount ingested by a child is a "moderate amount" (defined as more than a handful, or a mouthful),

or is questionably high, then the parent should contact a physician or call a local poison control center for instructions on how to induce emesis (Tenenbein et al., 1987; AAP, 2003).

The amount ingested by nonhuman animals is rarely known. When the amount ingested is unknown, or cannot be estimated, then a local poison control center or veterinarian should be contacted for instructions on how to induce emesis and to obtain a 24- to 48-h blood test (PT) to determine the need for treatment with vitamin K_1 (Murphy et al., 1989; Munday and Thompson, 2003).

17.7.3 Treatment at healthcare facilities

A PT should be obtained 48 h after exposure in asymptomatic children with accidental ingestion of a suspected large amount of rodenticide (Babcock et al., 1993; Berry et al., 2000). Adults with intentional ingestion and children with clinical evidence of bleeding should obtain an initial PT and PTT, repeated at 24 and 48 h after ingestion (Goldfrank et al., 2002). If any significant prolongation or evidence of bleeding is observed, PT should be repeated every 6–12 h. Determination of factors II, VII, IX, and X may be abnormal in patients with a normal PT and PTT, which may provide evidence of earlier significant ingestion (Pavlu et al., 2005; Spahr et al., 2007). Hemoglobin and hematocrit should be monitored in patients with clinical evidence of bleeding or significant coagulopathy. Determination of the ABO blood type may be necessary in cases of toxic ingestions and bleeding. Patients may require red blood cell transfusions or the administration of fresh frozen plasma (Bruno et al., 2000; Laposata et al., 2007; Olmos and Lopez, 2007).

17.7.3.1 Emesis

Currently, there is controversy regarding the use of syrup of ipecac. The American Academy of Pediatrics reversed its policy position about its use in poisoning emergencies in children (AAP, 2003). Simultaneously, the AAPCC indicates that syrup of ipecac has a place in therapy, and "concluded that individual practitioners and poison control centers are best able to determine the particular patient population, geographic and other variables that might influence the decision to recommend having ipecac on hand" (Manoguerra and Cobaugh, 2005). For dosing of ipecac, see Table 17.4. The first action for a caregiver of a child who may have ingested one of these rodenticides is to consult with their local poison control center (AAP, 2003) (Table 17.5).

Emesis is contraindicated in patients with a prolonged PT or a bleeding disorder due to the risk of bleeding following ipecac-induced increased intracranial pressure (POISINDEX, 2007). Taste amounts (a few pellets or a bite of one block of bait) do not require emesis. If the amount is more than two mouthfuls or one block of bait, or if an unknown amount is ingested, then emesis is most effective if initiated within 30 min to 1 h from the time of ingestion. The decision to induce emesis or not is often controversial; so must be carefully considered. It could be most appropriate in prehospital settings and is not recommended once the patient is in the emergency room (Chyka and Seger, 1997; Krenzelok et al., 1997).

Contraindications: Patients with a bleeding disorder, particularly those under treatment with anticoagulants or with histories of chronic, long-acting anticoagulant ingestion, are at risk from gastrointestinal and central nervous system (CNS) bleeding from ipecac-induced emesis. The administration of activated charcoal is preferred when large amounts have been ingested or chronic ingestion has occurred. Also, it is contraindicated if there is a risk for choking or aspiration, CNS excitation or depression, coma, seizures, or signs of oral, pharyngeal, or esophageal irritation (Golej et al., 2001; Goldfrank et al., 2002).

Before or after ipecac is administered, patients should be encouraged to drink water. Adults are given approximately 8 oz (240 mL), and children 4–8 oz (120–240 mL) (Goldfrank et al., 2002; POISINDEX, 2007).

TABLE 17.4 Dosing of ipecac.

Adult[a]	15–30 mL
Adolescent[a]	15–30 mL
Child 1–12 years old	15 mL
Child 6–12 months	Dose: 5–10 mL (position child in left lateral decubitus position to reduce risk of aspiration)
Child under 6 months of age	*Not* recommended for prehospital use

[a]*Katona and Wason (1989).*

TABLE 17.5 Dosing of activated charcoal (Chyka and Seger, 1997).

Charcoal dose recommended to dilute 240 mL of water per 30 g charcoal (FDA, 1985)	
Adults and adolescents	50–100 g
Children aged 1–12 years	25–50 g
Infants up to 1 year old	1 g/kg of body weight

17.7.3.2 Activated charcoal

For patients with a potentially toxic ingestion who are awake and able to protect their airway, activated charcoal diluted in water may be administered before going to the hospital. It is more effective when administered within 1 h after ingestion. It is recommended to dilute the mixture with 240 mL of water per 30 g charcoal (Chyka and Seger, 1997).

In patients who are at risk of onset of seizures or depression, activated charcoal should be administered by medical or paramedical personnel capable of airway management to prevent aspiration in the event of spontaneous emesis (POISINDEX, 2007).

Use of a cathartic is not routinely recommended, as there is no evidence that cathartics reduce drug absorption, and cathartics can cause adverse effects such as nausea, vomiting, abdominal cramps, electrolyte imbalances, and occasionally hypotension (Chyka and Seger, 1997; Golej et al., 2001). Use of cholestyramine has been reported to increase survival in a rabbit brodifacoum model (Lindeblad et al., 2018).

17.7.3.3 Gastric lavage

Gastric lavage is recommended within 1−2 h after ingestion; but not afterwards, as it may induce bleeding in patients with significant coagulopathy (Brands et al., 1995).

17.7.3.4 Laboratory monitoring

PT and PTT values should be obtained 24 and 48 h postingestion in asymptomatic children with accidental ingestion of a "large amount." Adults with intentional ingestions and children with clinical confirmation of bleeding should obtain initial PT and PTT readings, repeated at 24 and 48 h postingestion, followed by blood type verification (Barnett et al., 1992; Ellenhorn et al., 1997; Robben et al., 1998). If significant prolongation or evidence of bleeding is observed, PT should be repeated every 6−12 h. Determination of factors II, VII, IX, and X may be abnormal in patients with a normal PT and PTT, which may provide support of earlier ingestion. Serial hemoglobin and hematocrit values in patients should be followed with clinical evidence of bleeding or significant coagulopathy (Babcock et al., 1993; Robben et al., 1998). Hematocrit should be monitored every 4 h until the patient is stable (Brands et al., 1995).

Hematest should be performed in stools and vomit for occult blood, and PT and PTT monitored routinely. PT and PTT readings obtained within 48 h postingestion may not be predictive of subsequent coagulopathy (Greeff et al., 1987). A 24 and 48 h PT and PTT, therefore, are recommended every 6−12 h to assess the efficacy of therapy. If prolongation is observed, then PT or international normalized ratio measurements should be repeated (Hoffman et al., 1988; Smolinske et al., 1989).

Antidote: Vitamin K_1 (Phytonadione: AquaMephyton, Mephyton) is the specific antidote and should be administered to any patient with a prolonged PT (Braithwaite, 1982; Bruno et al., 2000; Tsutaoka et al., 2003). Blood and fresh or frozen plasma are recommended if the anticoagulation is severe.

Administration of vitamin K_1 orally is recommended if anticoagulation is excessive. In anemic patients, the hematocrit should be monitored about every 4 h until it is stable. Stools and vomit may also be tested using Hematest (Hornfeldt and Phearman, 1996).

Oral vitamin K_1 may be administered in small doses after the patient has been stabilized. Recommended doses are 15−25 mg p.o. in adults, 5−10 mg in children (Greeff et al., 1987), and 2.5−5 mg/kg body weight in animals. A large daily maintenance dose of vitamin K_1 may be required for prolonged therapy in severe overdoses, particularly in patients in whom vitamin K_1 absorption is variable (Lipton and Klass, 1984; Hoffman et al., 1988; Ross et al., 1992; Murphy, 2012).

Intravenous phytonadione may be instituted in severe cases where rapid correction is needed. *Note*: Anaphylaxis is reported to occur during i.v. injection of vitamin K1, particularly if rapidly injected. The adult dose is a minimum of 10 mg diluted in saline or glucose, injected intravenously (i.v.) at a rate not exceeding 5% of the total dose per minute. Doses should be repeated at intervals of 6−8 h. Initial i.v. doses of 25, 100, 150, 160, and 400 mg have been required in patients actively bleeding (Hoffman et al., 1988; Vogel et al., 1988).

Coagulation factors: Recently, prothrombin complex concentrates (Doyle et al., 2018; Wang et al., 2016) and plasma exchange (Deng and Qiu, 2016) have been reported for anticoagulant rodenticide toxicoses. Autologous blood transfusions in dogs with thoracic or abdominal hemorrhage have been used in dogs in emergency situations (Higgs et al., 2015).

17.8 Concluding remarks and future directions

A large number of industrial and household chemicals, including the superwarfarins, have the potential to be used as chemical warfare or terrorist agents. However, the Federal Insecticide, Fungicide, and Rodenticide Act classifies these rodenticides in the "low-toxicity group." Nevertheless, they may be used to harm and terrorize people through the ingestion of contaminated food, water, or adulterated drugs. Superwarfarins are available to consumers as meal bait packs, pellets, minipellets, blocks, miniblocks, wax blocks, liquid bait formulations, and tracking

powder in diluted to concentrated formulations. The ingestion of small amounts may not cause any bleeding problems. Ingestion of greater amounts or repeated exposure provides increased risk of severe bleeding in 36–48 h. The coagulopathy may last several weeks to months despite vitamin K_1 treatment.

What should be done at this time? Be wary if people from a community that attended the same event, meal, party, or restaurant show similar signs of bleeding disorders. Ingestion of superwarfarins may go unnoticed when they are mixed with food, and signs or symptoms are delayed 36–48 h. Consequently, the victims may not associate the ingestion with the coagulopathy.

Identification of superwarfarins is easy nowadays. Analytical methods for the detection of these products in serum and tissues are readily available. Routine laboratory tests for coagulopathy may help support the need for such analytical chemistry testing. It may be useful to create stockpiles of vitamin K_1, particularly in places where large stocks of superwarfarin rodenticides are used.

Although viral infections manifest with different signs and symptoms, it is possible that members from a community who are victims of superwarfarins may begin to panic, thinking that they were victims of a virus such as Ebola, but the signs and symptoms of superwarfarin ingestion differ from viral infection. Superwarfarin intoxication may have no signs or symptoms other than the appearance of bleeding in the stools, urine, mucous membranes, or the thoracic or abdominal cavities. The Ebola virus causes sudden hemorrhagic fever, weakness, muscle pain, headache, and sore throat, followed by vomiting, diarrhea, rash, limited kidney and liver functions, and both internal and external bleeding. Various hemorrhagic disease of animals also occur; an example of current interest is African swine fever. Anticoagulant rodenticide ingestion should be considered in the differential diagnosis in these cases.

Consequently, good differential diagnostic and laboratory work-up algorithms are needed for both humans and animals. Teams of subject matter experts for both humans and animals may be useful in this regard. Community education programs, for example, fact sheets may be developed to inform residents about superwarfarin rodenticides and other household commercial chemicals that could be used as chemical warfare or terror agents. Identifying those at risk, as well as deciding when they should be informed, may be a useful part of this education campaign. Such a program may also improve security in industrial plants and limit access from outsiders to all industrial and storage facilities where flammable or highly toxic chemicals are stored.

Finally, surveillance of food sources, particularly those derived from livestock, should be assessed.

Chapter 18

PCBs, dioxins, and furans: human exposure and health effects

Bommanna G. Loganathan[1] and Shigeki Masunaga[2]

[1]*Department of Chemistry and Watershed Studies Institute, Murray State University, Murray, KY, United States,* [2]*Yokohama National University, Yokohama, Japan*

18.1 Introduction

Polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), polybrominated biphenyls (PBBs), polybrominated dibenzo-*p*-dioxins (PBDDs), and polybrominated dibenzofurans (PBDFs) are members of the group of halogenated aromatic hydrocarbons (HAHs). This group of chemicals has been identified by national and international agencies as priority environmental pollutants posing significant effects on aquatic and terrestrial animals, including humans (Loganathan and Kannan, 1994; Jacobson, 1994; Van den Berg et al., 1998; Kodavanti et al., 2008; International Programme on Chemical Safety (IPCS), 1998). PCBs were produced in large quantities (millions of pounds) for a variety of industrial uses during the 1940s to the late 1970s, especially by developed nations. PBBs were produced as flame retardant mainly before the 1970s. Whereas PCDDs and PBDDs (dioxins), PCDFs and PBDFs (furans) were never produced commercially. These compounds are formed in small quantities as byproducts of combustion and various industrial as well as natural processes (Gabos et al., 2001). Due to their persistent, bioaccumulative, and toxic properties, these residues are found in every component of the global ecosystem (Lipnick et al., 2001; Kodavanti et al., 2008). Some PCBs (coplanar PCBs), dioxins, and furans are three structurally and toxicologically related families of compounds that are classified as the most toxic manmade chemical substances to a variety of animal species, including humans (Tucker et al., 1983; Loganathan et al., 1995; ATSDR, 1998). Production of PCBs was banned during the 1970s, however, already-produced PCBs are still causing environmental and health problems (Loganathan et al., 2008; Sajwan et al., 2008; Loganathan, 2016). Fortunately, these compounds were never used as chemical warfare agents, weapons of mass destruction, or agents of threat or terror by contamination of air, water, food/feed, etc. However, inadvertent poisonings of these chemicals have caused significant environmental and health problems (Yusho Support Center, 2007; Loganathan, 2012; Kodavanti and Loganathan, 2012). In this chapter, the historical background, chemical characteristics, analysis, pathways of human exposure to these compounds, and toxic effects associated with exposures are presented.

18.2 Historical background

PCBs were first synthesized in the early 1880s (Schmidt and Schultz, 1881) and commercial production began in 1929. Biphenyls were reacted with Cl_2 in the presence of ferric chloride catalyst, and some of the hydrogen atoms were replaced by chlorine atoms. PCBs were produced as complex mixtures potentially containing 209 congeners formed by chlorinating biphenyl with from 1 to 10 chlorines (Fig. 18.1). The amount of chlorination of biphenyls corresponded to the duration of the chlorination process. For example, Aroclor 1221, 1242, 1248, 1254, 1260, and 1268 are commercial preparations that were formerly produced by the Monsanto Chemical Company in the United States (St. Louis, MO) that contain 21%, 42%, 48%, 54%, 60%, and 68% chlorine by weight, respectively, as indicated by the last two digits in the numerical designation (Giesy and Kannan, 1998). The PCB mixture formulations were different depending on the country of origin, and were produced in Germany (Clofen), France (Phenoclor and Pyralene), Japan (Kanechlor), Italy (Fenclor), Russia (Sovol), and Czechoslovakia (Delor).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00018-0

Compound	Molecular Wt.	Chemical structure
PCBs	188–498	PBBs	232–943	PCDDs	218–460	PCDFs	202–444	PBDDs	263–816	PBDFs	247–800	
FIGURE 18.1 Generalized structures of PCBs, dioxins, and furans.

PCB mixtures were produced for a variety of uses such as fluids in electrical transformers, capacitors, heat transfer fluids, hydraulic fluids, lubricating and cutting oils, and as additives in plastics, paints, pigments, copying paper, printing inks, adhesives, and sealants (Loganathan et al., 1989; Safe, 1990; Grimm et al., 2017; Dhakal et al., 2018). PBBs were once synthesized widely as flame retardants for plastics. In 1973, several thousand pounds of PBB-based flame retardant, FireMaster BP-6, were accidentally mixed with livestock feed in Michigan, USA, and caused damage to chickens, cattle, and pigs (Carter, 1976). PBBs are now controlled under the RoHS directive in EU and hexabromobiphenyl, one of their homologue, is listed in the Stockholm Convention on Persistent Organic Pollutants. Dioxins and furans are not produced deliberately, but are produced unintentionally as byproducts of the combustion of organic matter in the presence of chlorine. Dioxins and furans consist of 135 possible chlorinated (or brominated) dibenzofuran and 75 chlorinated (or brominated) dibenzo-*p*-dioxins with from one to eight chlorine (bromine) substituents (Fig. 18.2). PCDDs/DFs are found as byproducts during the manufacture of some industrial chemicals such as PCBs, polychlorinated naphthalenes, chlorinated phenols, chlorinated

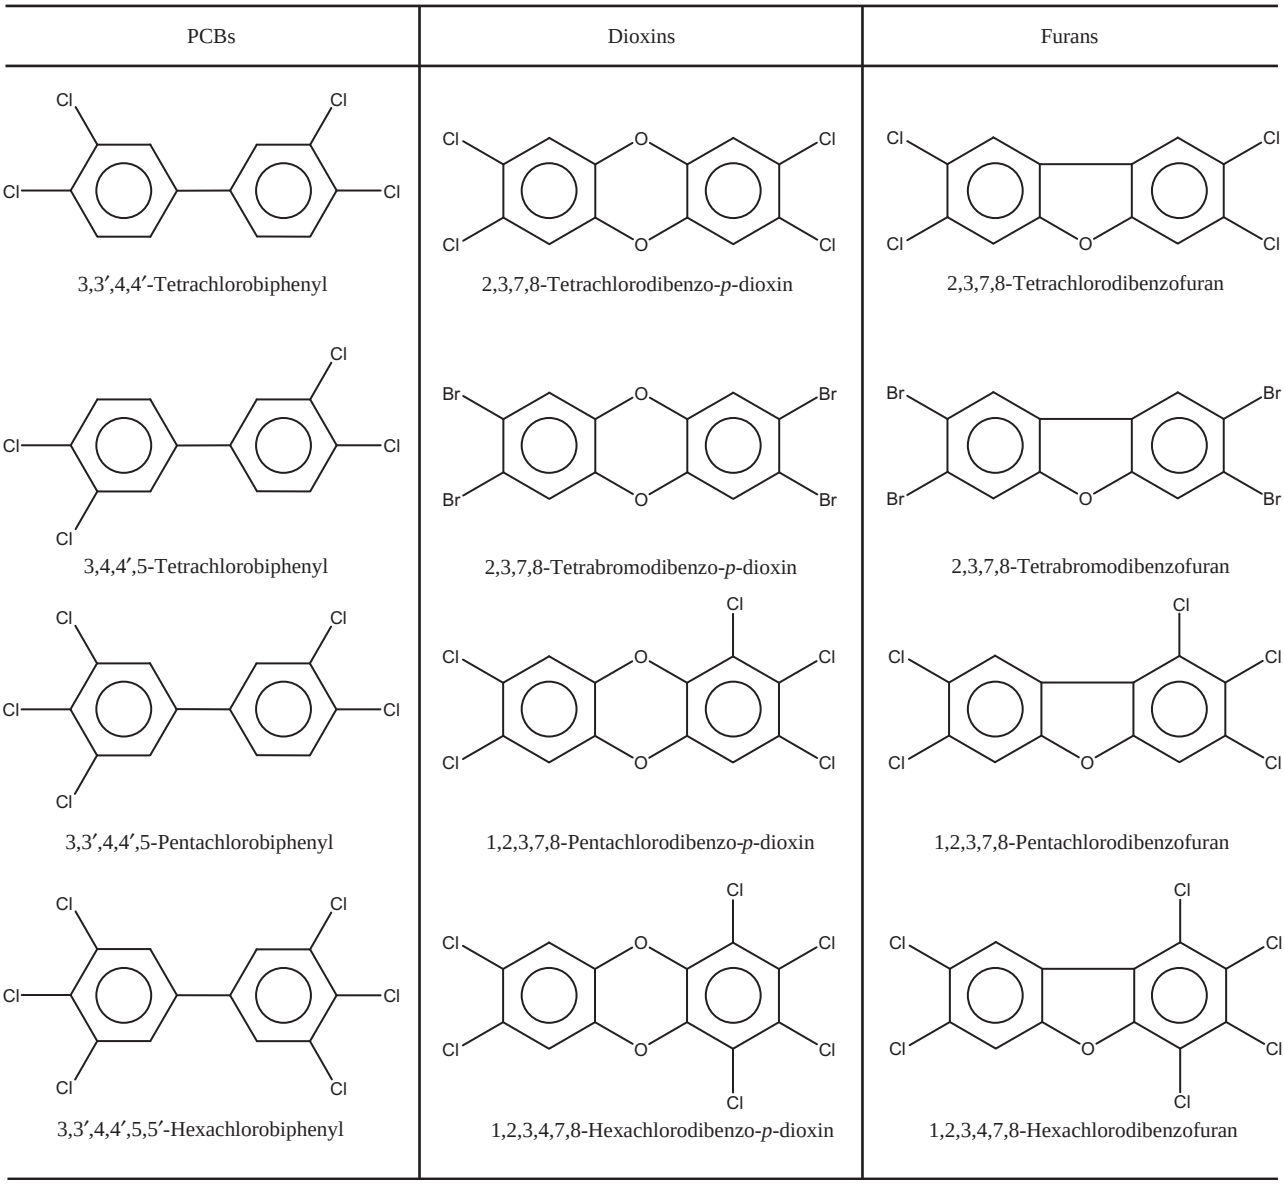

FIGURE 18.2 Structures of highly toxic PCBs, dioxins, and furans.

phenoxyacids, polychlorinated diphenyl ethers, polyvinyl chlorides, and chlorinated phenoxy-2-phenols (Hutzinger et al., 1985; Hryhorczuk et al., 1986; ATSDR, 2001; Masunaga et al., 2001a). Similarly, PBDDs/DFs are found as byproducts in brominated organic chemicals such as brominated flame retardants [polybrominated diphenyl ethers (PBDEs), decabromobiphenyl, 1,2-bis(tribromophenoxy)ethane, tetrabromobisphenol A (TBBPA), etc.] (International Programme on Chemical Safety, 1998). These compounds are also formed during incineration of industrial and municipal waste, forest fires, fireplaces, and combustion engines (Loganathan et al., 1997; Feil and Larsen, 2001; Villa et al., 2016). Because of anthropogenic as well as natural processes, PCBs, dioxins, and furans are widely dispersed in the global environment and their presence has been reported in air, water, soil, sediment, and aquatic and terrestrial organisms including human tissues (Loganathan and Kannan, 1994; Giesy and Kannan, 1998; Masunaga et al., 2001b; Ogura et al., 2001).

18.3 Human exposure to PCBs, PCDDs, and PCDFs

Direct human exposure to PCBs/PCDFs has occurred due to inadvertent poisoning due to consumption of PCB-contaminated food such as Yusho and Yucheng poisoning

(oil disease) in Japan and Taiwan in 1968 and 1979, respectively. Yusho Support Center (2007) states that "39 years have passed since the outbreak of YUSHO, the PCB/dioxin tragedy – the most unprecedented incident in the history of mankind whereby people ingested toxic chemicals unknowingly, directly through food." The outbreak of a strange disease "Yusho" (Kanemi Oil Poisoning) occurred in the western part of Japan in 1968. The major symptoms and signs of the disease consisted of acne-like eruptions, pigmentation of the skin, nails, and conjunctivas, increased discharge from eyes, and numbness in the limbs (Yao et al., 2002; Yusho Support Center, 2007). The epidemic was identified later (1969) to be an unprecedented mass food poisoning caused by the ingestion of commercial brand rice oil that had been contaminated by PCBs and their related compounds. The number of people who reported having ingested the rice oil was about 14,000, and 1867 persons were designated as Yusho victims. A similar outbreak of "oil disease" occurred in Taiwan in 1979. Toxicological studies revealed that PCDF congeners, including 2,3,4,7,8-pentachlorodibenzofuran (which were byproducts of PCBs and also formed by heat during the use of PCBs as a heat exchange oil), played an important role in the pathogenesis of the disease. Research conducted on Yusho victims revealed harmful effects of the exposure continued for two generations (Yusho Support Center, 2007). A recent study revealed the concentration of 2,3,4,7,8-PeCDF, the most toxic compound in Yusho patients, was significantly correlated with the presence of comedones or acneiform eruption, oral pigmentation, numbness in the hands and legs, and arthralgia (Mitoma et al., 2015).

Direct human exposure to dioxin occurred in southern Vietnam. It was estimated that southern Vietnam has been contaminated by 160–600 kg of dioxin as a result of 80 million liters of defoliant herbicides (Agent Orange, a 50:50 mixture of 2,4,5-T and 2,4-D) being sprayed by the US military over a large area of forests and crops of southern Vietnam from 1962 to 1971 (Westing, 1984; Schecter et al., 2006; Le Hong Thorn et al., 2007). The defoliant was contaminated with a very toxic form of dioxin (TCDD) known to have caused adverse effects on human health. Dioxin may cause harmful effects on the whole body and can affect separately the functioning of systems such as nervous system, immune responses, carcinogenicity, hepatotoxicity, and metabolic and enzyme toxicity (Le Hong Thorn et al., 2007). Recently, Pham and his research group compared the toxic effects of dioxins in mother–newborn pairs from the Bien Hoa airbase, the most contaminated area with dioxin (due to Agent Orange) and Ha Dong district of Ha Noi city, an unexposed area in Vietnam. After studying 288 mother–newborn pairs recruited in 2012 and 2015, who were highly exposed to dioxin, and 120 pairs recruited in 2014 from the unexposed area, the authors found that decreased expressive and composite language scores in boys and motor scores in girls were found in children exposed to TCDD $>=5.5$ pg/g lipid in maternal breast milk (Pham et al., 2019). However, the National Academies of Sciences, Engineering, and Medicine asserted in their 2016 update on Vietnam veterans that the epidemiologic evidence is sufficient to conclude that there are positive associations between exposure to herbicide and health outcomes, such as soft-tissue sarcoma (including heart), non-Hodgkin lymphoma, chronic lymphocytic leukemia (including hairy cell leukemia and other chromic B-cell leukemias), Hodgkin lymphoma, and chloracne (National Academies of Sciences, Engineering, and Medicine, 2016).

FIGURE 18.3 Dioxin poisoning. Ukrainian former Prime Minister and presidential candidate Viktor Yushchenko, with his face disfigured by illness due to dioxin poisoning. *Photo: http://news.bbc.co.uk/2/hi/europe/4105035.stm (accessed 18.07.19.).*

Another example of direct human poisoning of dioxin was food poisoning of Mr. Viktor Yushchenko (Fig. 18.3), Ukrainian presidential candidate, in 2004. The dioxin poisoning caused a mysterious illness that resulted in his face becoming pockmarked and ashen (BBC News, December 17, 2004: http://news.bbc.co.uk/2/hi/europe/4105035.stm). Manahan (1992) classified dioxin (2,3,7,8-TCDD) as super toxic in comparison with other know toxic substances (Table 18.1).

18.4 Physicochemical properties and global distribution

The unusual industrial versatility of PCBs was directly related to physical and chemical properties which include

TABLE 18.1 Toxicity level of various chemical compounds.

Toxicity level	Compounds	LD_{50} estimated from laboratory animals[a] (mg/kg)
Slightly toxic	Ethyl alcohol	10,000
	Sodium chloride	5000
Moderately toxic	Malathion (organophosphorus pesticide)	1000
	Chlordane (termite exterminator)	500
Very toxic	Heptachlor (pesticide)	100
Extremely toxic	Parathion (pesticide)	10
	Dioxin (2,3,7,8-TCDD)	5 (Hamster)
	Tetraethyl pyrophosphate (pesticide, raticide)	1
Super toxic	Tetrodotoxin (toxin of blowfish)	0.1
	Dioxin (2,3,7,8-TCDD)	0.0006 (Guinea pig)
	Botulin (toxin of botulinum)	0.00001

[a]*LD_{50} are rough values estimated from oral-dose experiments on laboratory animals (usually rats). Unit: mg/kg body weight.*

resistance to acids and bases, compatibility with organic materials, resistance to oxidation and reduction, excellent insulating properties, nonflammability, and thermal stability (Hutzinger et al., 1985). The physical and chemical stability of PCBs are vital to industrial applications and the same properties have been responsible for global environment contamination. In addition, multimedia releases and volatility lead to long-range environmental transport, both via water and the atmosphere, resulting in widespread environmental contamination of humans and wildlife at sites distant from their use (Lipnick and Muir, 2001; Loganathan et al., 2008). In PCBs, dioxins, and furans, the properties vary widely and depend on the number and position of chlorine (or bromine) atoms attached to the molecule. In general, vapor pressure, water solubility, and biodegradability decrease with an increasing number of chlorine atoms. Lipophilicity adsorption capacity shows a reverse trend (Loganathan and Kannan, 1994). Because of these unique properties, PCBs, dioxins, and furans have been detected in air and water (rivers, lake ecosystems) (Pearson et al., 1997; Loganathan et al., 1998a,b, 2001). Apart from this, these compounds were recorded in fish, birds, and marine mammals of several other ecosystems, such as the Atlantic, Baltic, and Pacific oceans and Swedish environments (Kawano et al., 1988; Loganathan et al., 1999). They have been identified in processed fish and other food products (Kannan et al., 1997; Patandin et al., 1999). Further, the residues of these contaminants were found in human adipose tissue, blood, and milk, and also in numerous other matrices (Loganathan et al., 1993, 1998a,b, 1999; Petreas et al., 2001; Czaja et al., 2001).

The comparison of PCDD/DFs and PBDD/DFs in terms of toxic equivalents (TEQs) calculated based on WHO-TEF (World Health Organization's toxic equivalent factors) in pooled human milk samples from 17 countries showed that PBDD/DF levels are significantly lower than the PCDD/DF (mean PBDD/DF:PCDD/DF-TEQ ratio was 0.13 and its range was 0.06 − 0.25), indicating that exposure to PCDDs/DFs is much greater than PBDD/DFs and more important to human health (Kotz et al., 2005). This was supported by a study on human adipose tissue and plasma, in which TEQs for PBDD/DFs (0.2−0.8 pg TEQ/g lipid) were 1% − 15% those of PCDD/DFs-TEQs (Jogsten et al., 2010) and the contribution of PCDD/DFs, dioxin-like PCBs, and PBDDs/DFs to total TEQ in human blood were 47%, 31%, and 21%, respectively, on a median basis (Fromme et al., 2016). In some environmental media, however, the contribution of PBDD/DFs to TEQs cannot be neglected. The median TEQ contributions of PBDFs, PCDDs, PCDFs, non-*ortho* Co-PCBs, PCNs, and mono-ortho Co-PCBs determined by GC-HRMS in indoor dusts to the TEQ evaluated by in vitro bioassay (CALUX-TEQs) (range 38−1400, median 160 pg TEQ/g) were 17%, 14%, 8.8%, 0.98%, 0.10%, and 0.019%, respectively (Suzuki et al., 2010). Analyses of 12 PBDD/DF congeners by GC-HRMS in composited, archived biosolids collected from 94 wastewater treatment plants in the United States revealed that the TEQ of PBDD/DFs was 162 (range: 15 − 672) ng TEQ/kg and at 75% (range: 12% − 96%) of the total TEQ (Venkatesan and Halden, 2014).

Because of the large production and indiscriminate use of PCBs in industry, these contaminants extended

their boundaries of distribution over the global environment and this was evidenced by their detection even in pristine environmental media and biota such as the Arctic and Antarctic atmosphere, hydrosphere, and biosphere (Muir et al., 1988; Corsolini et al., 2002; Kumar et al., 2002). The discovery of widespread environmental occurrence, the increased general environmental concern, and the apparent link to carcinogenesis and other health disorders prompted a public outcry which resulted in the prohibition of PCBs as well as chlorinated pesticides in several developed nations during the early 1970s. The following section deals with the chemical analysis of PCBs, dioxins, and furans in environmental and biological samples.

18.5 Analytical methods

PCBs and PCDDs/DFs consist of a total of 419 individual congeners and PBDDs/DFs have 210 congeners. In addition, dioxins and furans with mixed chlorine and bromine substitution can occur. These congeners have quite a variety of toxicity and some of these congeners, especially planar dioxins, furans, and dioxin-like PCBs (non-*ortho* chlorine substituted coplanar PCBs) are extremely toxic, even at very low concentrations (Table 18.1). Therefore, determination of some toxic congeners to a very low concentration (parts per trillion) has become important.

Congener-specific determination was required for those congeners that have toxic equivalency factors (TEFs), namely 2,3,7,8-chlrine substituted dioxins and dioxin-like PCBs (Table 18.2). Thus, these compounds are analyzed using a high-resolution gas chromatograph high-resolution mass spectrometer (HRGC-HRMS). A schematic flow chart of the representative analysis procedure for environmental and biological samples is shown in Fig. 18.3 based on standard analytical methods, such as US EPA methods 1613, 1668, 1668a, and JIS K0312 (US EPA, 1994, 1997, 1999; JISC, 2008).

Biological samples are either freeze-dried or dewatered (homogenized) with anhydrous sodium sulfate salt and spiked with internal standards (cleanup spike) and then extracted using a Soxhlet apparatus. Obtained extracts are concentrated and their solvents are changed to an appropriate solvent such as hexane. They then go through a series of cleanup procedures to remove lipid and other interfering chemicals. Then eluates are concentrated again and spiked with internal standards. The prepared samples are injected into HRGC-HRMS and monitored by multiple ion monitoring mode.

Concentrations are calculated by the isotope dilution method. Stable isotope-labeled target compounds are used as internal standards and spiked into samples. Calibration with internal standards and determination by isotope dilution are necessary to obtain reliable data under very low concentrations and after repeated pretreatment and cleanup procedures.

Solid samples, such as soil and sediment, are air-dried and extracted by a Soxhlet/Dean-Stark apparatus. Aqueous samples are separated into solids and filtrates by filters. Solids are Soxhlet extracted similarly to biological samples and filtrates are liquid–liquid extracted. Then, these extracts are cleaned up and injected into HRGC-HRMS, similarly to biological samples.

In cases when congener-specific information is not necessary, other simpler methods can be used. EPA methods 608 and 8082a use GC/EDC to determine the concentration of PCBs in terms of Aroclor (Federal Register,

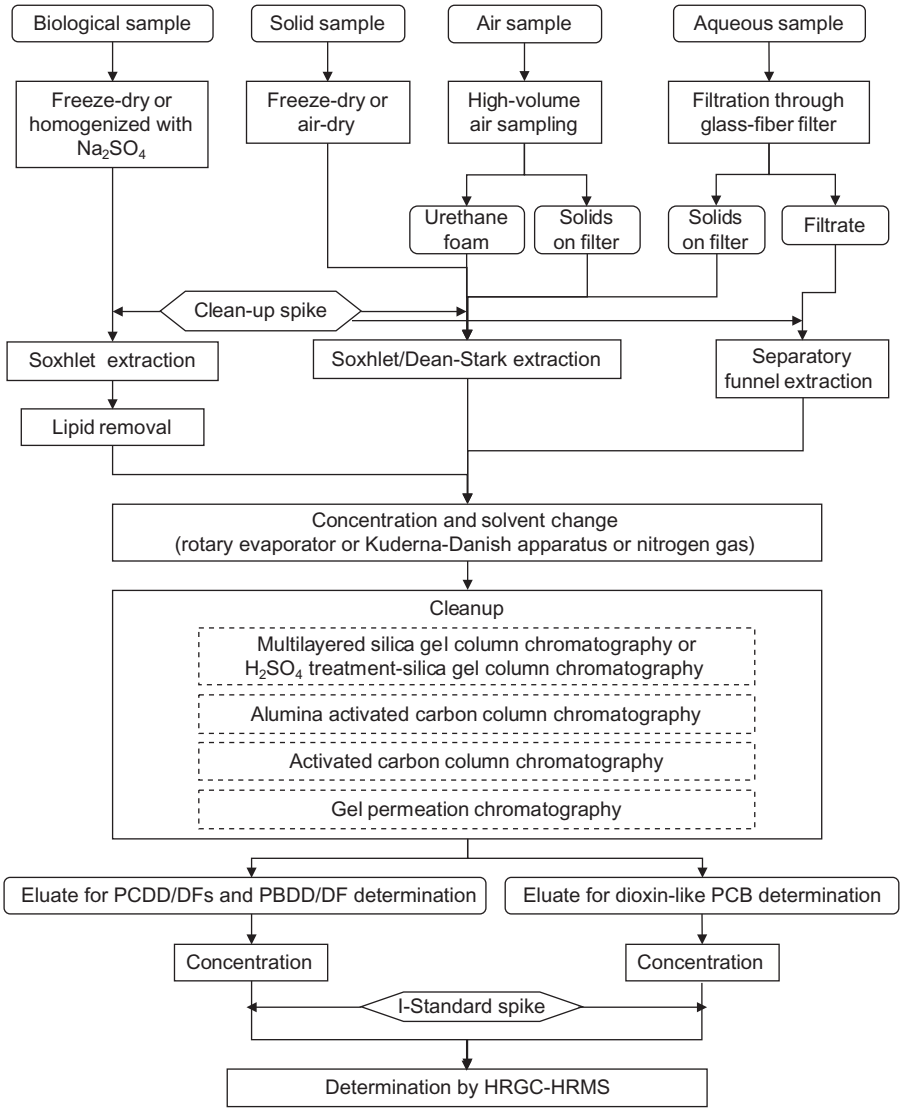

FIGURE 18.4 Analytical procedure of dioxins, furans, and dioxin-like PCBs.

1984; US EPA, 2007). EPA method 680 (US EPA, 1985) uses GC/MS (low-resolution mass spectrometer) to determine the homolog concentration of PCBs (Fig. 18.4).

18.6 Mechanism of action and toxicity

The toxicities of PCBs, PCDDs/DFs, and PBDDs/DFs are complicated by the presence of a large number of congeners, each with its own toxicity. Commercial PCB mixtures elicit a broad spectrum of toxic responses that are dependent on several factors, including chlorine content, purity, dose, species, age and sex, and duration of exposure. Immunotoxicity, carcinogenicity, and developmental toxicity as well as biochemical effects of commercial PCB mixtures have been studied extensively in various laboratory animals, fish, and wildlife (Giesy and Kannan, 1998). Several studies have confirmed the common receptor-mediated mechanism of action of toxic halogenated aromatics and has resulted in the development of a structure−activity relationship for this class of chemicals (Safe, 1990). The most toxic halogenated aromatic is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), which is assigned the maximum toxicity factor of 1, the relative toxicities of individual halogenated aromatics have been determined relative to TCDD (i.e., toxic equivalents). The 17 congeners of PCDD/DFs and the 12 congeners of dioxin-like PCBs are assigned TEFs lower than TCDD (Table 18.2). In June 1997, the World Health Organization established the levels of toxicity factors (WHO-TEFs) to be applied to evaluating the risks for humans and animals (Van den Berg et al., 2006). The

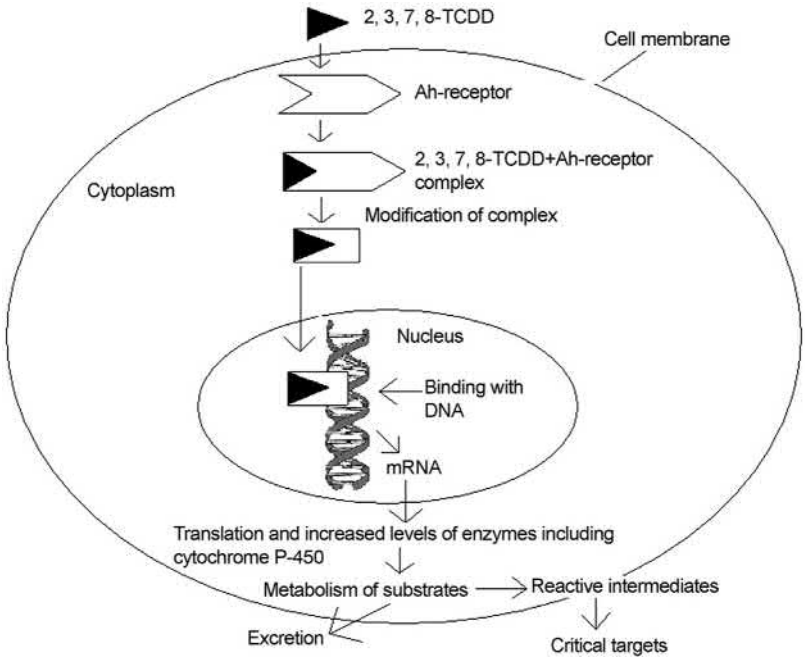

FIGURE 18.5 Possible mechanism of toxic action of dioxins and dioxin-like PCBs.

WHO consultation set the tolerable daily intake (TDI) between 1 and 4 pg TEQ/kg body weight, emphasizing that the aim was to lower the TDI level to under 1 pg TEQ/kg body weight (Guerzoni and Raccanelli, 2004). The most toxic PCB congeners are those that have chlorine substitution in most of the non-*ortho* positions, such as 3, 4, and 5 in each ring. These coplanar PCB congeners (Fig. 18.2) are structurally similar to highly toxic 2,3,7,8-TCDD and exhibit similar toxic responses (Ah-receptor-mediated toxicity) (Fig. 18.5). There are no WHO-TEFs for 2,3,7,8-substituted PBDDs/DFs and dioxin-like PBBs, yet. However, use of the same TEF values for structurally corresponding brominated and chlorinated congeners for human risk assessment was recommended by a joint WHO and United Nations Environment Programme (UNEP) expert consultation in 2011 (Van den Berg at al., 2013). 2,3,7,8-TCDD and structurally related halogenated aromatic compounds induce a variety of microsomal enzymes primarily in the liver. 2,3,7,8-TCDD evokes dose-related induction of cytochrome-P-450-associated AHH (aryl hydrocarbon hydroxylase) activity. The most widely studied of these responses are induction of AHH and EROD (markers of CYP1A activity) in mammalian cell cultures and in laboratory rodents (Goldstein and Safe, 1989).

Ah-receptor-mediated toxicity resulted in a wide range of biological responses, including alterations in metabolic pathways, body weight loss, thymic atrophy, impaired immune responses, hepatotoxicity, chloracne and related skin lesions, developmental and reproductive effects, and neoplasia.

18.7 Concluding remarks and future directions

PCBs, dioxins, and furans are persistent organic pollutants (POPs) which have negative effects on the environment and health of humans including skin toxicity, immunotoxicity, neurotoxicity, negative effects on reproduction, teratogenicity, endocrine disruption, and a predisposition to cancer. A major pathway of exposure to these chemicals is through consumption of food contaminated by PCBs dioxins and furans. The Committee of Experts on Food of the European Commission proposed a dose called the "tolerable weekly intake" given by a total of dioxins and PCBs of 14 pg TEQ/kg of body weight, which is an average of 2 pg TEQ/day/kg of body weight (Guerzoni and Raccanelli, 2004). By reducing the environmental contamination, we can diminish the food chain accumulation and ultimately we can reduce the intake levels of PCBs and dioxins and their toxic health effects.

19.1 Introduction

Airborne polycyclic aromatic hydrocarbons (PAHs) arise from incomplete combustion of carbon-based fuels. They are common in the environment, arising from multiple sources including industrial emissions from coal-fired power plants, motor vehicle emissions (especially diesel exhaust), tobacco smoke, and dietary sources such as charbroiled foods (Banks et al., 2019). Exposure to PAHs is rapidly being recognized as a global problem, particularly in major urban centers in the United States and developing nations such as China, where urban environmental protections tend to be weaker and where biomass is used as a source of indoor fuel (Zhang and Tao, 2009). In these situations, these contaminants accumulate to toxic levels in the body within a short period of time and enter the environment rapidly (ATSDR, 1995; WHO, 2010). Chronic exposure to even low concentrations of PAHs causes long-lasting damage, such as cancer, infertility, and neurotoxicity to humans and wildlife (Banks et al., 2019).

The goal of this chapter is to encourage research activity into both novel intervention strategies and therapeutic approaches to mitigate the neurotoxicity associated with in utero exposure to PAHs as combustion-derived agents of urban industrialization and warfare (acts of arson, which includes setting of oil well fires, terrorism, burning of ammunition dumps, etc.; Lederman et al., 2004; Fent et al., 2014; Masiol et al., 2016; Joyeta, 2018). The focus of this chapter is to highlight current epidemiological data pertaining to the known neurobehavioral outcomes from PAH exposures, as well as supporting data in animals. An attempt is made to suggest potential operative pathways contributing to PAH exposure-induced neurodevelopmental deficits.

A critical review of the post-September 11, 2001, literature has resulted in a specific focus on studies that have revealed critical neural signaling/activity pathways and the identification of primary targets of PAH toxicity, as well as toxicity modifiers. It is hoped that this chapter will stimulate multidisciplinary efforts to look at the conduct of temporal and spatial integrative analyses of developmental processes affected by exposure to PAHs.

19.2 Background

19.2.1 Epidemiological evidence for the negative effects of PAHs on pregnant women

A number of cohort studies have been undertaken to assess pregnancy outcomes and early life impacts

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00019-2

associated with the September 11, 2001, attack and other airborne PAH exposures. To study the acute exposure of pregnant women either working in the World Trade Center (WTC) or residing in the communities of lower Manhattan on September 11, 2001, a Mount Sinai Hospital cohort was assembled (Berkowitz et al., 2003). Of the 187 recruited pregnant women, 12 (about 6%) were inside the WTC towers at the time of attack, and an additional 121 (65%) were within eight blocks (Wolff et al., 2005). A comparison group ($n = 2367$) consisted of all private patients not known to have been near the WTC who delivered at Mount Sinai Hospital during the same time period.

Another cohort of 300 women who lived, worked, or delivered their infants in lower Manhattan in the weeks and months after September 11 were recruited to examine chronic exposure after the attacks (Lederman et al., 2004). These women were followed by the Columbia Center for Children's Environmental Health. The New York City Department of Health and Mental Hygiene and the Agency for Toxic Substances and Disease Registry (ATSDR) established the World Trade Center Health Registry, a voluntary registry to prospectively monitor physical and mental health in the aftermath of the attacks among those with a high probability of direct exposure, including pregnant women (Lipkind et al., 2010).

In recognition of the impact of environmental toxicants encountered in utero and the disparities in adverse birth outcomes among inner-city, minority populations, the Columbia Center for Children's Environmental Health established a prospective cohort to follow pregnant women and their children longitudinally (Perera et al., 2003). Nonsmoking Dominican and African-American women residing in three NYC neighborhoods were monitored for exposure to environmental tobacco smoke (ETS), airborne PAHs, and pesticides. A parallel prospective cohort was assembled in Krakow, Poland, with the same eligibility criteria, study design, and air-monitoring methods (Jedrychowski et al., 2009). In Tongliang, China, the effects from PAH exposure secondary to coal combustion were studied prior to and after the shutdown of a coal-fired power plant (Perera et al., 2005a; Tang et al., 2006).

19.2.2 Conclusion from prospective epidemiology cohort studies

Table 19.1 outlines the main findings from follow-up studies of the cohorts described earlier in this chapter. Analysis of the 187 exposed women in the Mount Sinai WTC cohort revealed nearly a twofold increase in the odds of intrauterine growth retardation in their babies [IUGR; adjusted odds ratio (AOR) 1.90; 95% CI, 1.05−3.46] (Berkowitz et al., 2003). Biologically plausible causes of IUGR in these babies include exposures to fine particulate matter (PM) and PAHs. Previous studies have found associations between particulate air pollution and IUGR (Dejmek et al., 1999; Bobak et al., 2001). Other investigations have linked air pollution to preterm births (Ritz et al., 2000). Additionally, high levels of PAH-DNA adducts in umbilical cord leukocytes are associated with reduced birth size (Perera et al., 1998).

Among the cohort of 300 nonsmoking women who were pregnant on September 11, 2001, and lived within a 2-mile radius of the WTC during the following month, a number of decrements were found in their babies compared to the babies of other pregnant women studied. Infants born to exposed women showed a decrease of 122 g in birth weight and 0.74 cm in birth length after adjusting for gestational duration, sociodemographic, and biomedical risk factors (Lederman et al., 2004). Infants born to women who were in their first trimester at the time of the attacks had significantly shorter gestation (−3.6 days) and smaller head circumference (−0.48 cm) compared to infants born to mothers exposed during their second or third trimester. The 446 births recorded in the World Trade Center Registry also showed a variation in mean gestational age by trimester on September 11, in addition to differences in birth weight (Lipkind et al., 2010). Analysis of births from previous years, however, revealed that the effect of trimester observed may have been due to a seasonal effect unrelated to exposure. It is important to note that the odds of low birth weight and preterm delivery were higher in registry-linked births to mothers that probably had posttraumatic stress disorder (PTSD; Lipkind et al., 2010).

19.2.3 Effects of maternal stress

In addition to PAH exposure during pregnancy, maternal stress associated with a terrorist attack or disaster has been shown to affect birth outcomes and later neurocognitive development. Among the 187 women in the Mount Sinai cohort who were pregnant and living or working within close proximity to the WTC on September 11, 52 women completed at least one psychological assessment prior to the delivery of their child. In this analysis, Engel et al. (2005) found that posttraumatic stress symptomatology (PTSS) was associated with decrements in infant head circumference at birth. These decrements could later influence neurocognitive development, although follow-up on this cohort has not yet been reported.

Analysis of live singleton births to women enrolled in the World Trade Center Health Registry between September 11, 2001, and October 31, 2002, also found an apparent effect of maternal stress. When comparing women enrolled in the registry (who were exposed) to

TABLE 19.1 Summary of findings from studies examining cognitive and developmental outcomes resulting from in utero exposure to PAHs.

Cohort and authors	Age	Development measure	Findings
Tongliang, coal-fired power plant pre- and post-shutdown (Perera et al., 2008)	2 years of age	GDS	Significant association between elevated cord blood adducts and decreased motor development quotient and average development quotient in 2002 cohort (pre-shutdown), but not 2005 (post-shutdown)
Tongliang, coal-fired power plant pre- and post-shutdown (Tang et al., 2013)	Summary of birth–2 years	GDS	Children born after the power plant shutdown had greater head circumference ($P = .001$), reduced levels of cord blood adducts ($P < .001$), and were exposed to lower levels of ambient PAHs compared to the cohort born prior to shutdown ($P = .01$)
Tongliang, coal-fired power plant pre- and post-shutdown (Tang et al., 2014)	Summary of birth–2 years	GDS	An inverse association was found between BDNF and PAH-DNA adducts in cord blood. Developmental quotient scores were positively associated with BDNF levels
A subset of the CCCEH cohort pregnant on 9/11 or became pregnant in following month ($n = 300$) (Perera et al., 2007)	3 years	BSID-II	A significant interaction between cord blood DNA adducts and in utero exposure to ETS on MDI score ($P = .02$), but cord blood adducts or ETS alone were not significant predictors of cognitive development
The 182 of the WTC cohort versus Mt. Sinai births (Mt. Sinai Pregnancy Outcome Study) (Berkowitz et al., 2003)	Birth outcomes		No differences in mean gestational age, mean birth weight, frequency of preterm birth
			Twofold increase in IUGR among WTC exposed women
			No association found between probable PTSD and RR of preterm birth, LBW, or IUGR
The 52 of the 182 of the WTC cohort versus Mt. Sinai births (Mt. Sinai Pregnancy Outcome Study) (Engel et al., 2005)	Birth outcomes		PTSS and depression were associated with longer gestational duration
			PTSS was associated with decrements in head circumference
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2003)	Birth outcomes		Among African Americans, high PAH exposure was associated with lower birth weight ($P = .003$) and smaller head circumference ($P = .01$)
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2006)	3 years	BSID-II	Prenatal exposure to PAHs significantly associated with lower MDI at age 3, but not at 1 or 2 years. Prenatal PAH exposure was also unrelated to PDI
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2009)	5 years	WPPSI-R	High PAH levels, above the median of 2.26 ng/m^3, were associated with full-scale IQ (4.31 lower, $P = .009$) and verbal IQ (4.67 lower, $P = .002$) reductions compared to less exposed children
Dominican and African American (Washington Heights, Central Harlem, and South Bronx) (Perera et al., 2012)	6–7 years	CBCL	High PAH exposure, defined as greater than the median exposure from personal air monitoring, or detectable and higher maternal and cord adducts, was associated with symptoms of anxious/depressed and attention problems ($P \leq .05$)
Krakow, Poland cohort (2001–2006 enrollment) (Edwards et al., 2010)	5 years	RCPM	Children with higher than the median (17.96 ng/m^3) prenatal exposure to airborne PAHs had decreased RCPM scores at age 5. These reduced scores correspond to an estimated average decrease of 3.8 IQ points

BSID-II, Bayley-II Scales of Child Development; *CBCL*, Child Behavior Checklist; *ETS*, Environmental Tobacco Smoke; *GDS*, Gesell Development Schedules; *MDI*, Mental Development Index; *PDI*, Physical Development Index; *RCPM*, Raven Colored Progressive Matrices; *WPPSI-R*, Wechsler Preschool and Primary Scale of Intelligence-Revised. Included are studies related to the events of September, 11, 2001, as well as international studies of PAH exposures.

those not in the registry and who lived in a NYC census tract more than 5 miles from the WTC site, adjusted analyses found no differences in birth weight, gestational age of delivery, the odds of low birth weight, or the odds of preterm delivery. However, when comparing women with a high PTSD score to those with a lower score, increased odds of preterm delivery (AOR 2.48, 95% CI 1.05−5.84) and low birth weight (AOR 2.49, 95% CI 1.02−6.08) were detected (Lipkind et al., 2010).

In analysis of birth certificate data obtained from the Office of Vital Statistics in New York State and NYC, excluding lower Manhattan, Eskenazi et al. (2007) found an increased chance of very low birth weight (<1500 g) around the start of 2002 (i.e., among infants that would have been in their first or second trimester of gestation at the time of the September 11 attacks). This same finding was noted in births 33−36 weeks after the disaster (i.e., those conceived around or shortly after September 11). The authors suggest that these effects could be the result of the increased stress associated with a terrorist attack (Eskenazi et al., 2007). A study of maternal stress resulting from the 1998 ice storm in Quebec, Canada, found that more severe prenatal maternal stress was associated with decrements in Bayley Scales of Infant Development (BSID)−Mental Development Index (MDI) scores and parent-reported language abilities at 2 years of age (Laplante et al., 2004).

An interaction between exposure to PAHs and maternal stress has been suggested. Among children who experienced high prenatal exposure to PAH, maternal demoralization during pregnancy has a greater negative effect on children's neurobehavioral development. In the longitudinal study of 248 children from the Krakow cohort, maternal demoralization had an effect on syndromes of depression (anxious and withdrawn), rule-breaking and aggressive behaviors, and composite internalizing and externalizing scores at age 9 (Perera et al., 2003). These effects were seen only in those with high prenatal exposure. Both prenatal PAH exposure (Tang et al., 2014) and prenatal stress (Neeley et al., 2011) have been found to decrease hippocampal mature brain-derived neurotrophic factor (mBDNF) expression and signaling cascades for long-term potentiation (LTP), providing a potential mechanism for the observed interaction.

19.2.4 PAH-DNA adducts

PAH-DNA adducts provide a reflection of individual variation in exposure and toxicokinetics and have been associated with risk of cancer and reproductive and developmental effects (Tang et al., 2006; Perera et al., 2007). In the cohorts followed by researchers from the Columbia Center for Children's Environmental Health, mean DNA adduct concentrations in both maternal and fetal cord blood, as well as the proportion of samples with detectable adducts, increased across the populations studied in a manner consistent with the trend in estimated ambient exposure to PAHs ($P < .001$, northern Manhattan < WTC < Krakow < Tongliang). Data from these four populations indicate that the developing fetus may have a 10-fold greater susceptibility to DNA damage than mothers (Perera et al., 2005a).

Higher adduct levels have been associated with a number of adverse birth and neurocognitive developmental outcomes. In a cohort of 150 mother−infant dyads in Tongliang County, China, that received exposure from a seasonally operated, coal-fired power plant, those with higher than median PAH-DNA cord blood adducts weighed less than their low-exposure counterparts at 18, 24, and 30 months of age (Tang et al., 2006). Exposure for a longer duration was associated with shorter length at birth and height at 18, 24, and 30 months. In children who were in utero during power plant operation, there was a 91% increase in the odds of being developmentally delayed in the motor area for each 0.1-unit increase in cord blood adducts (0.1 adducts/10^8 nucleotides). The mean cord adduct levels in this cohort were 0.32 adducts/10^8 nucleotides (Perera et al., 2008). After the shutdown of the power plant, the head circumference of the children was greater than that of those born prior to the shutdown (33.766 vs 34.130 cm; $P < .05$), and consistent with the reduced levels of ambient PAHs and reduced levels of cord blood adducts (Tang et al., 2013).

In comparisons of these pre- and post-shutdown cohorts, it was also found that the mean level of mBDNF was significantly higher in the 2005 post-shutdown cohort (1266.56 vs 752.87 pg/mL; $P < .05$) (Tang et al., 2014). The brain-derived neurotrophic factor (BDNF) levels were inversely correlated with PAH-DNA adducts in cord blood in both cohorts ($P < .01$) and positively associated with average, motor area, and social area development quotients. Based on their analyses, Tang et al. (2014) deemed BDNF to be a potential mediator between PAH-DNA adducts measured in cord blood and later cognitive outcomes. This is consistent with findings that prenatal exposure to ETS, of which PAHs are a component, was linked to downregulation of BDNF through increased methylation of the BDNF exon (Toledo-Rodriguez et al., 2010).

Among women in the WTC cohort who were also exposed to ETS during pregnancy, increased PAH-DNA adducts were associated with reduced birth weight (276 g; 8% for a doubling of adducts) and head circumference (1.3 cm; 3% for a doubling of adducts) (Perera et al., 2005b). At age 3, children born to these mothers had an average reduction in MDI of 6% for a doubling of adducts (Perera et al., 2007). Lower MDI at age 3 was also found in the cohort of African-American and Dominican mothers and children (Perera et al., 2006).

Assessment of gene and environment interactions has found that both maternal and newborn haplotypes of CYP1A1 and CYP1B1 appear to be important effect modifiers of MDI at 12, 24, and 36 months of age (Wang et al., 2008, 2010). Subsequent analysis has identified a potential relationship between maternal haplotypes of XRCC1 and GSTM3, in addition to a maternal haplotype of CYP1B1, maternal PAH exposure, and newborn cord blood adducts in African Americans (Iyer et al., 2014). This study also found interactions with maternal PAH exposure and newborn cord blood adducts with newborn CYP1A2 and XRCC1 in African Americans, maternal XRCC1 among Dominican women, and newborn NQO1 in Dominican infants (Iyer et al., 2014).

19.2.5 Refinement of our susceptibility-exposure paradigm to assess the effects of in utero exposure to PAH aerosols on neurodevelopmental processes

The determination of the embryonic "critical period of development" for the brain structures involved in learning and memory processes in mice is based on the original work by Rodier (1976). This study identified the embryonic time frames for peak neurogenesis and neuroepithelial proliferation for cerebral cortex, hippocampus, septum, amygdala, corpus striatum, thalamus, hypothalamus, cerebellum, and olfactory bulb as the period from embryonic day E14 through E17. Rodier documented almost 40 years ago that the specific time of the central nervous system (CNS) insult is an important factor in subsequent effects on both anatomy and behavior. Therefore, this early work established what we refer to as the embryonic "critical period of development." The report suggested that the behavioral effects of toxicants such as benzo(a)pyrene (B(a)P) are similar in both rats and mice. This study was one of the first to demonstrate that mice could be used successfully as subjects in a variety of behavioral evaluation experiments.

Novel object discrimination testing has been used for over two decades because it is perfectly suited to test the effects of pharmacological and genetic interventions on learning and memory processes (Dere et al., 2007). When comparisons are made among experimental model systems of learning and memory, the object discrimination test is more closely related with the conditions under which human recognition memory is measured. This is primarily due to a shortened training period coupled with the fact that novel object discrimination does not induce high levels of arousal and stress in animals (Ennaceur and Delacour, 1988). The component of memory likely affected by PAH is the medial prefrontal cortex (mPFC) and is referred to as *relative recency memory* (Fuster, 2001). In support of this argument concerning relative recency memory, it is known that lesions to the mPFC impair relative recency discrimination in humans, nonhuman primates, and rodents across a wide range of stimulus modalities (Fuster, 2001). This is true despite the fact that, in some instances, recognition of novel and familiar stimuli is preserved.

Conversely, studies have reported that after bilateral mPFC lesions, an impairment or deficit is observed with respect to the ability to differentiate between previously presented and recently presented familiar objects (Mitchell and Laiacona, 1998). Results from our laboratory testing in utero of B(a)P aerosol-exposed $Cpr^{lox/lox}$ offspring in object discrimination paradigms were consistent with results from the aforementioned bilateral mPFC lesion studies. They support the suggestion that the mPFC is involved (at least in part) in making judgments regarding the sequence and order of object presentations. Additionally, the involvement of cortical glutamate receptors in performance of the novel object discrimination task in rodents is well established, as deficits and impairments have been reported following the application of AMPA (CNQX) or NMDA (AP-5) antagonists. By characterizing the effects of in utero exposure to PAH on $Cpr^{lox/lox}$ and brain-*Cpr*-null offspring, we further validate novel object discrimination phenotying as a measure of prefrontal and limbic circuit integrity by demonstrating that this behavior is negatively affected subsequent to in utero B(a)P exposure.

19.2.6 Refinement of our susceptibility-exposure paradigm to assess the effects of in utero exposure to PAH aerosols on behavioral phenotypes

Cytochrome-P_{450} is an important modifier of mental development at an early age. Recently, significant interactions were reported among a maternal haplotype in the cytochrome P_{450}1B1 (CYP1B1) gene (ACCGGC), PAH exposure, and reductions in the MDI in a cohort of children (Wang et al., 2010). These studies have important implications for our society; they are valuable from a translational standpoint because they can inform the design of molecular neurotoxicology studies using experimental model systems.

Recently, Xia et al. (2011) evaluated the effects of subchronic exposure to B(a)P (intraperitoneal injections of 6.25 mg/kg B(a)P/day for 14 weeks) versus diluent on both neurotransmitter receptor gene expression and performance in a Morris water maze. Microarray results revealed that 1016 genes were differentially expressed in B(a)P-treated specimens versus diluent controls. The Database for Annotation, Visualization, and Integrated

Discovery was used to analyze those genes differentially expressed in the gene ontology and Kyoto Encyclopedia of Genes and Genomes pathways. Their analysis showed that the most significantly affected category was behavior, and the fourth-highest was learning and memory. They ranked 22 genes involved in learning and memory and 25 genes associated with neuroactive ligand–receptor interactions. Both lists included upregulation of the ionotropic glutamate receptor *N*-methyl D-aspartate 2A (GRIN2A). A conclusion was that "neuroactive ligand–receptor interactions" were among the most negatively affected by B(a)P exposure at ($P < 7.7\ E-6$). In the Morris water maze test, B(a)P-treated rats had spatial learning deficits and had a decreased number of platform crossings and time spent in the target area, suggesting that B(a)P caused a deleterious effect on long-term memory. Several other studies have also suggested that neurotransmitter and neurotransmitter receptor gene expression play important roles in modulating neurobehavioral effects, especially within the context of learning and memory.

These results confirmed the notion that the PAH component can have a direct negative impact on the developmental expression of (1) key glutamatergic regulators of NMDA-mediated processes (receptor tyrosine kinase-MET) and (2) behavioral deficit phenotypes.

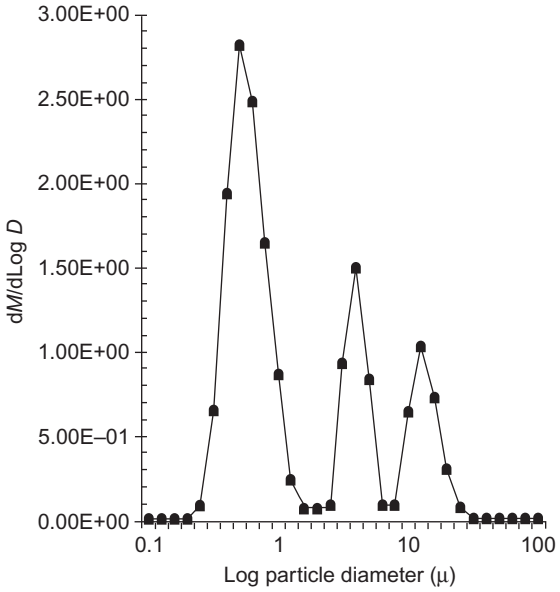

FIGURE 19.1 Differential particle-size distribution representative of B(a)P:carbon black aerosol delivered to timed pregnant $Cpr^{lox/lox}$ and brain-*Cpr*-null dams (100 μg/m^3).
During a typical exposure, aerosol was collected on substrates every 30 min during a 4 h exposure period from E14 to E17. Subsequent to the exposure period each day, substrate post-weights were uploaded into a custom impactor data reduction program to generate average particle-size distributions as previously described (Wu et al., 2003).

19.3 PAH experimental model systems

19.3.1 Toxicological observations from modeling B(a)P aerosols

In our experimental model system, $Cpr^{lox/lox}$ and brain-*Cpr*-null timed-pregnant dams were exposed to a B(a)P aerosol on E14–E17 exhibiting a trimodal distribution with a 93% cumulative mass less than 5.85 μm, 91% cumulative mass less than 10 μm, 57.6% cumulative mass less than 2.5 μm, and 43% less than 1 μm (Fig. 19.1 and Table 19.2). The characterization of the aerosol atmospheres generated in these studies was comparable to those generated previously for rat studies (Hood et al., 2000). The B(a)P aerosol used in our earlier rat studies comprised a mass median aerodynamic diameter with a geometric standard deviation of 0.9 ± 0.09 μm, compared to 1.0 ± 0.07 in the present *Cpr* mouse experiments. Analysis of live birth indices revealed no significant differences in the number of mouse pups born per litter between control $Cpr^{lox/lox}$ dams and B(a)P-exposed $Cpr^{lox/lox}$ dams. The analysis of the live birth index for control $Cpr^{lox/lox}$ dams was 6.12 ± 0.42, compared to 5.9 ± 0.9 for B(a)P-exposed $Cpr^{lox/lox}$ dams, and 5.7 ± 0.31, compared to 5.99 ± 0.41 for the control and B(a)P-exposed brain-*Cpr*-null dams, respectively. Statistical analysis ($P = .241$) indicated no significant difference in this index between these groups. This finding is consistent with our previous reports using rat and mouse models (Hood et al., 2000, 2006; Wormley et al., 2004a,b; Brown et al., 2007; Sheng et al., 2010). During the prenatal exposure period, as well as the subsequent preweaning period, there were no identifiable B(a)P-related effects on conventional reproductive indices of toxicity, and there were no convulsions, tremors, or abnormal movements noted in any of the control or B(a)P-exposed *Cpr* litters.

19.3.2 In situ generation of "oxidative metabolites" in neocortical tissue from in utero exposure to B(a)P aerosol

The quantitation of B(a)P metabolites from $Cpr^{lox/lox}$ and brain-*Cpr*-null offspring is shown in Fig. 19.2A and B. In neocortical tissue from in utero B(a)P aerosol-exposed $Cpr^{lox/lox}$ offspring, we found 4.5-, 7.8-, 9-, and 10-diols, 3.6- and 6.12-diones, and 3-OH and 9-OH B(a)P metabolites, indicating the presence of an active phase 1 biotransformation pathway (Fig. 19.2A). In contrast, in brain-*Cpr*-null offspring, all metabolites were essentially below the level of detection (note the change in the *y*-axis values in Fig. 19.2B). The important point in Fig. 19.2A is the identification of the developmental period over which there is formation and/or accumulation of the reactive 3-OH and 9-OH metabolites. These metabolites can

TC_p and T_{premix} were generally high enough for top side of orifice plate $> T_{sat}$, rows 1–3 of each group of four rows. For each group, values greater than the second row are given in the fourth row for the purposes of evaluating overheating of the humidified B(a)P stream. Bold values in row 2 indicate the experimental conditions under which the studies were conducted. Assume $T_{Wright} = 70°F$; $m = 0.565$; $b = 37.432$ (for details, see Li et al., 2012).

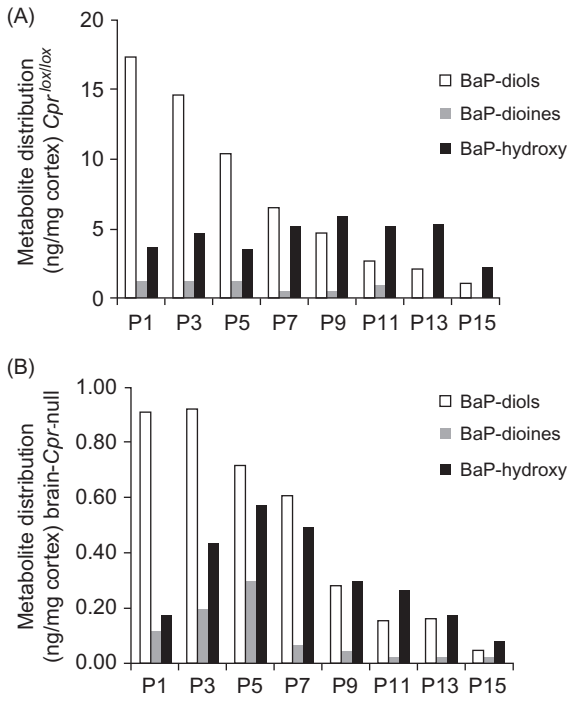

FIGURE 19.2 Metabolite distribution of cortical B(a)P metabolites during the critical postnatal period when synapses are forming for the first time in B(a)P-exposed *Cpr* offspring.
Timed-pregnant $Cpr^{lox/lox}$ or brain-*Cpr*-null dams received either carbon black only or 100 μg/m^3 B(a)P via nose-only inhalation on E14–E17 for 4 h/day. Offspring were sacrificed on P1, 3, 5, 7, 9, 11, 13, and P15. Shown are the distribution of metabolites detected in B(a)P-exposed (A) *Cprlox/lox* offspring or (B) brain-*Cpr*-null offspring.

further oxidize to form B(a)P quinones that can undergo redox cycling and generate reactive oxygen species (Li et al., 2012). F_2-isoprostane measures assessed the in vivo prefrontal cortex (PFC) oxidative milieu occurring primarily in neuronal membranes. Fig. 19.3 shows the quantitation of F_2-isoprostanes derived from neocortical homogenates from control and B(a)P-exposed $Cpr^{lox/lox}$ offspring (Fig. 19.3A), and control and B(a)P-exposed brain-*Cpr*-null offspring (Fig. 19.3B). (Note: There are no control *brain-Cpr-null* mouse isoprostane data for P3 to P15 due to the lack of available tissue.) The data document a sustained high neocortical tissue burden of F_2-isoprostanes in B(a)P-exposed $Cpr^{lox/lox}$, including the period from P7–P14, the extent of which was not observed in null mice (Fig. 19.3B).

19.3.3 Temporal modulation of NMDA-mediated developmental processes as a result of in utero exposure to B(a)P aerosol

Evidence supporting the hypothesis that an early insult to an NMDA-mediated signaling system leads to phenotypical changes that manifest later in life as elevated glutamate concentrations in mPFC is provided in Fig. 19.4A. Fig. 19.4A shows a time course plot indicating basal levels of glutamate in C57BL background controls, $Cpr^{lox/lox}$, B(a)P-exposed $Cpr^{lox/lox}$, and B(a)P-exposed brain-*Cpr*-null offspring obtained by microdialysis. Studies were carried out in a control group of mice performing the same task and B(a)P aerosol-exposed *Cpr* offspring over a 120-min sampling period. Quantitation of the results in Fig. 19.4 shows a statistically significant increase in the basal concentration of glutamate in the mPFC of B(a)P-exposed $Cpr^{lox/lox}$ offspring compared to WT C57BL, WT $Cpr^{lox/lox}$, or B(a)P aerosol-exposed brain-*Cpr*-null offspring. The basal glutamate concentrations obtained in our Cpr mouse model are in agreement with recent reports in the literature for dorsal hippocampus in a 129/SvEv mice KATII KO model (*45*) and for the PFC in a Wistar rat ethanol model (Chefer et al., 2011). These findings are consistent with the idea that increases in glutamate concentration promote altered inward currents via the NMDA receptor.

As a means of assessing the impact of in utero exposure to B(a)P aerosol on developmental NMDA-mediated processes, we evaluated developmental expression profiles for NMDA receptor subunits compared to those of Sp4 and Sp1 proteins with and without in utero B(a)P exposure. Inspection of the expression profile (P1–P15) in control $Cpr^{lox/lox}$ offspring (Fig. 19.5A, left panel) revealed that Sp4 expression is constitutively low on P1, reaches peak expression levels on P7, and subsides to constitutive levels by P15, which is consistent with earlier reports (Li and Pleasure, 2005). Conversely, the Sp4 developmental expression profile in B(a)P-exposed $Cpr^{lox/lox}$ offspring (Fig. 19.5B, right panel) indicates that as early as P1, Sp4 reaches near maximal levels and, by P3, it reaches peak expression levels and remains at maximal levels through P7. The interpretation of this finding is that the leftward shift in peak Sp4 expression is in response to in utero B(a)P aerosol exposure occurring during the E14–E17 period. The consequence of this exposure is the mistiming of peak Sp4 expression in B(a)P-exposed $Cpr^{lox/lox}$ offspring, which could significantly affect downstream signaling processes, perhaps in a way similar to those reported for Sp4 null mice (Zhou et al., 2007).

Having demonstrated that B(a)P exposure shifts the Sp4 expression profile to the left and given that NR2A is a Sp4 target gene, it is not surprising that B(a)P exposure also modulated the temporal expression of NR2A. The Sp4 nontarget NR2B developmental expression profile, on the other hand, for control $Cpr^{lox/lox}$ offspring (Fig. 19.5A, left panel) revealed that expression was low from P1–P3 and gradually increased until peak NR2B levels were present on P15. The NR2B developmental expression profile in B(a)P-exposed $Cpr^{lox/lox}$ offspring (Fig. 19.5B, right panel) is strikingly similar to that of

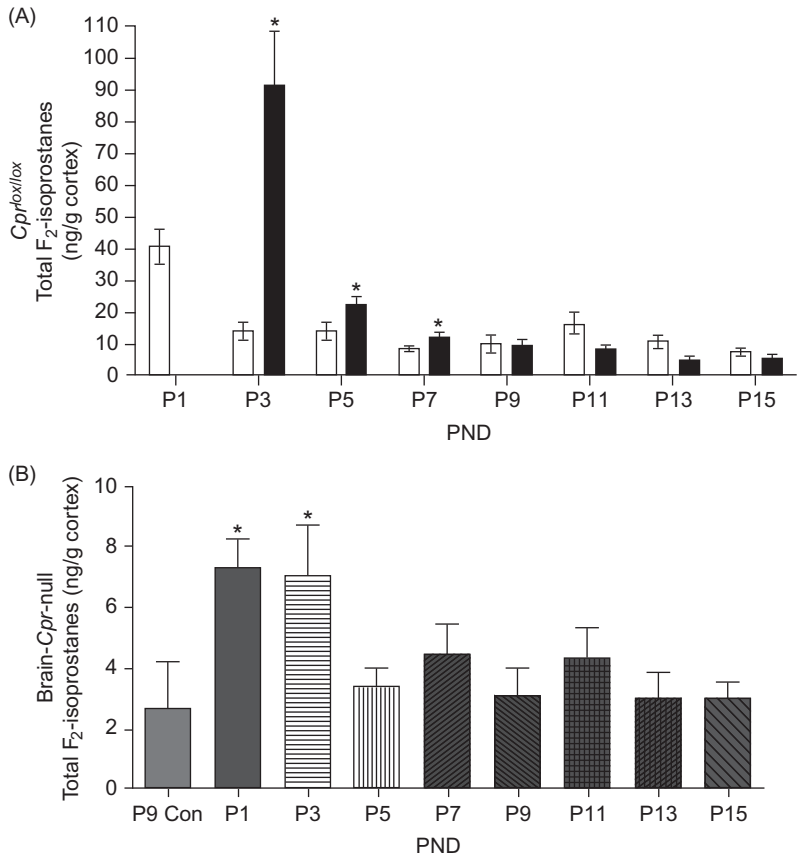

FIGURE 19.3 In utero exposure to B(a)P aerosol (100 μg/m^3) produces an approximate 10× higher concentration of F_2-isoprostanes on P3 in B(a)P-exposed $Cpr^{lox/lox}$ offspring as compared to B(a)P-exposed brain-*Cpr*-null offspring. (A) F_2-isoprostanes levels derived from control (white bars) and B(a)P-exposed $Cpr^{lox/lox}$ (black bars) offspring neocortex. (B) F_2-isoprostane levels derived from control PND9 (white bar) and B(a)P-exposed (black bars) brain-*Cpr*-null offspring neocortex. Due to the limited number of control offspring, only PND9 was used for time points in favor of reserving pups for behavioral determinations in later life. *$P = < .05$ versus control.

controls. What is apparent is the significant change in the NMDA subunit ratio of NR2B:NR2A on P7 in control $Cpr^{lox/lox}$ offspring (NR2B:NR2A = 1/0.4, as seen in Fig. 19.5A, lower-left panel) as compared to B(a)P-exposed $Cpr^{lox/lox}$ offspring (NR2B:NR2A = 1/0.78, seen in Fig. 19.5B, lower-right panel). Reminiscent of Sp4 expression, the NR2A developmental expression profile in B(a)P-exposed $Cpr^{lox/lox}$ offspring (right panel) is constitutively "on," beginning from P1−P5, and by P13, it reaches maximal expression levels compared to P15 in B(a)P-exposed offspring.

The developmental expression profiles for brain-*Cpr*-null offspring are shown in Fig. 19.6. Inspection of the expression profiles from these *null* mice (P1−P15) in control brain-*Cpr*-null offspring (Fig. 19.6A, left panel) revealed that Sp4 expression is constitutively low on P1 and reaches peak expression levels on P13. Conversely, the Sp4 developmental expression profile for B(a)P-exposed brain-*Cpr*-null offspring (Fig. 19.6B, right panel) indicates that as early as P1, Sp4 expression is evident, reaches maximal levels by P3, and then drops to constitutive expression levels by P7. What is apparent from the brain-*Cpr*-null offspring data is that the NMDA subunit ratio of NR2B:NR2A on early postnatal days (P1, P3, P5, and P7) in B(a)P-exposed brain-*Cpr*-null offspring (NR2B:NR2A = 1/0.5, seen in Fig. 19.6B, lower-right panel) is approximately the same as for P7 in control $Cpr^{lox/lox}$ offspring (NR2B:NR2A = 1/0.5, as seen in Fig. 19.6A, lower-left panel). Based on the results of a recent NR2A subunit knockout study in mice (Brigman et al., 2008), it would be reasonable to predict that in our null model, the absence of modulation in NMDA subunit ratios would mean that these mice would not exhibit a behavioral deficit phenotype. Such a finding would support our hypothesis that a significant deficit in behavioral learning results from the loss of proper temporal functioning of the NR2A subunit.

19.3.4 Rescue of spatial discrimination deficit phenotypes in brain-*Cpr*-null offspring subsequent to in utero exposure to B(a)P aerosol

Novel object discrimination testing was used to measure B(a)P-induced behavioral effects as described in our recent report (Sheng et al., 2010). Data in Fig. 19.7 show that control $Cpr^{lox/lox}$ offspring mice were better able to discriminate between novel and familiar objects (8.1 ± 0.31), as compared to B(a)P-exposed $Cpr^{lox/lox}$ offspring (2.0 ± 0.17). An analysis of variance revealed significant

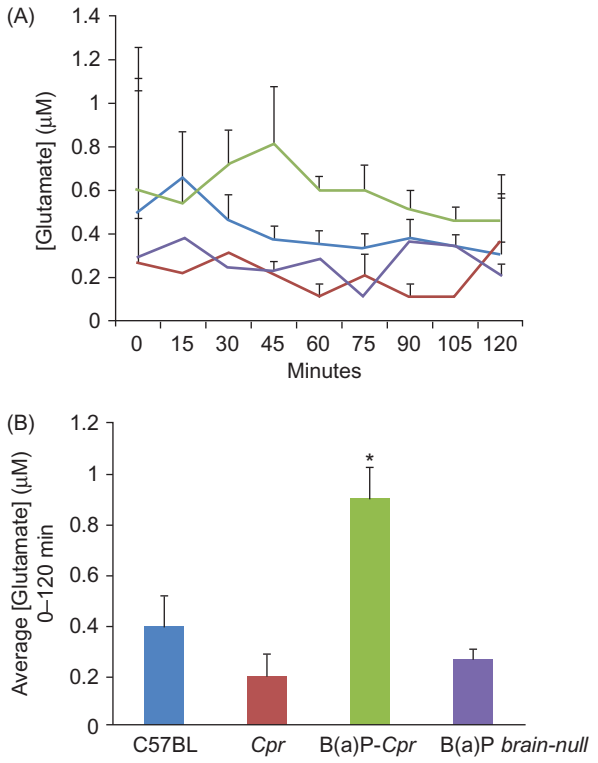

FIGURE 19.4 In utero exposure to B(a)P aerosol (100 μg/m^3) results in a robust increase in prefrontal cortical glutamate concentrations as assessed in awake behaving *Cpr*$^{lox/lox}$ offspring but not in brain-*Cpr*-null offspring (PND100). (A) Glutamate concentrations assessed from medial PFC as a function of time. (B) Quantitation of average glutamate concentrations over this time period (μM) assessed in control C57BL, control *Cpr*$^{lox/lox}$ offspring versus B(a)P-exposed *Cprlox/lox* and brain-*Cpr*-null offspring. See text for details (C57BL, blue; *Cpr*, red; and B(a)P-*Cpr*, green; B(a)P brain-*Cpr*-null, purple). *$P = < .05$ versus *Cpr*.

differences between the control *Cpr*$^{lox/lox}$ offspring (observational, small zone, and large zone) with regard to entries into the novel zone compared to the B(a)P-exposed *Cpr*$^{lox/lox}$ offspring. The exposed group exhibited a diminished ability to discriminate novel from familiar objects as indicated by a significantly reduced time as compared to controls ($P < .05$ for the 100 μg/m^3 group). Post hoc analysis using the Bonferroni's test revealed the significance at $P < .01$. Testing of control brain-*Cpr*-null offspring versus B(a)P-exposed brain-*Cpr*-null offspring in the 100 μg/m^3 group revealed no significant differences in object discrimination at 9.1 ± 1.4 versus 9.0 ± 0.8. Given that brain-*Cpr*-null offspring are incapable of producing significant levels of B(a)P metabolites via CYP1B1, these data strongly implicate a sustained-oxidative neocortical tissue metabolite burden during the critical period from P0 to P5 that contributes to the discrimination deficit phenotype observed in B(a)P aerosol-exposed *Cpr*$^{lox/lox}$ offspring.

Fig. 19.8 shows coronal sections of adult neocortical sections from *Cpr*$^{lox/lox}$ offspring that were analyzed for cytoarchitecture by immunohistochemical staining for NeuN. Neocortical neurons were counted in *Cpr*$^{lox/lox}$ offspring that had not been exposed to B(a)P in utero (A, low magnification; B, higher magnification) and compared to *Cpr*$^{lox/lox}$ offspring that were exposed to the B(a)P in utero (C, low magnification; D, higher magnification). Fig. 19.8E shows the plot resulting from stereological analysis of neocortical neurons subsequent to application of a two-tailed *t*-test. As can be seen, no significant differences were seen in the density of neocortical neurons as a result of in utero exposure to B(a)P aerosol.

Negative modulation of cortical inward currents in neurons derived from B(a)P-exposed *Cpr*$^{lox/lox}$ offspring. Finally, electrophysiology experiments were performed on ex vivo primary cortical neurons as a means of ascertaining potential B(a)P exposure-induced effects on cortical currents. On the seventh day in culture, ex vivo primary cortical neurons derived from control and B(a)P-exposed *Cpr*$^{lox/lox}$ offspring were voltage-clamped using the whole-cell configuration and held at −60 mV, in an Mg^{2+}-free external solution. The current−voltage (I−V) relationship of cortical neurons derived from control and B(a)P-exposed (100 μg/m^3) *Cpr*$^{lox/lox}$ offspring was nearly linear between −100 and −20 mV (Fig. 19.9A). Fig. 19.9B shows a representative current trace obtained from carbon black control and cortical neurons derived from 100 μg/m^3 B(a)P aerosol-exposed offspring at −80 mV using the same experimental configuration as in Fig. 19.8A. Although there were no apparent differences between the current recorded results in control and B(a)P-exposed cortical neurons at positive membrane potentials, there was a statistically significant, voltage-dependent decrease in the inward currents recorded at negative membrane potentials, as shown in Fig. 19.8C ($t = -2.92789$, $P < .0429$).

19.4 Implications

We have presented complementary biophysical, molecular, neurochemical, and neurobehavioral approaches examining how the PAH component of combustion processes negatively affects gestational and developmental processes in our experimental model systems. Our central findings are that in utero exposure to the PAH component of *c* (as B(a)P aerosol; Fig. 19.1) in the *Cpr* mouse results in a substantial neocortical oxidative tissue burden of B(a)P metabolites (Fig. 19.2) and F_2-isoprostanes (Fig. 19.3) during a period when synapses are developing for the first time. Such a sustained neocortical tissue burden might be expected to contribute to an increased cortical oxidative load. The presence of three distinct categories of metabolites (diols, diones, and hydroxy-derivatives) indicates an active phase 1 biotransformation pathway in our control *Cpr* mouse model. Present in B(a)

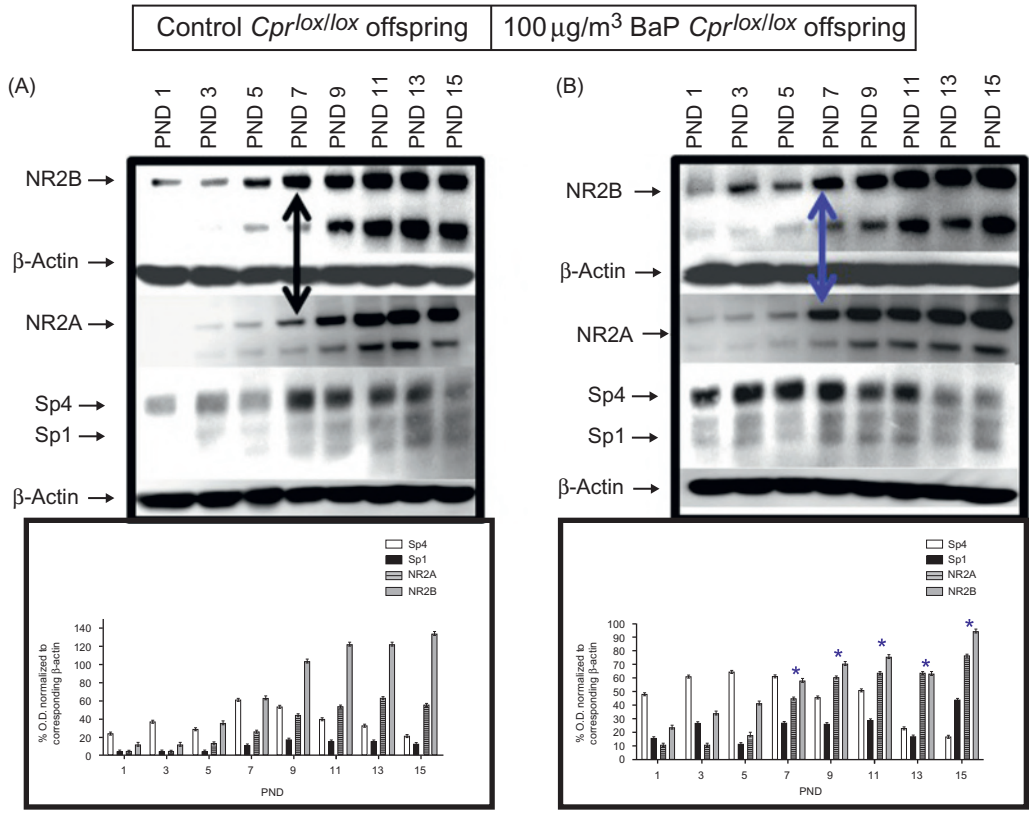

FIGURE 19.5 In utero B(a)P aerosol exposure (100 μg/m^3) induces a leftward shift in the peak temporal developmental expression of Sp4 and alters NMDA subunit ratios in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring (B, right panel) as compared to control *Cpr*$^{lox/lox}$ offspring (A, left panel). Representative results from a typical experiment. The panels show developmental expression profiles from PND1 to PND15 for NR2B-Sp4 nontarget gene, NR2A-Sp4 target gene, and Sp4-Sp1 proteins following SDS-PAGE of neocortical tissue from offspring gauged relative to internal β-actin controls. Lower panels represent quantitation of left and right upper panels. Post hoc analysis with the Bonferroni test with significance shown at $P < .05$.

P-exposed *Cpr*$^{lox/lox}$ offspring were the 4.5-, 7.8-, 9-, and 10-diols, the 3.6- and 6.12-diones and the 3-OH and 9-OH B(a)P metabolites. The important point in interpretation of these data is the identification of the developmental period over which there is formation and accumulation of 3-OH and 9-OH metabolites. These metabolites further oxidize to form B(a)P quinines that could undergo redox cycling and generate reactive oxygen species (Li et al., 2012). While the data from the brain-*Cpr*-null support the suggestion that accumulation of hydroxy-metabolites and their conversion into reactive intermediates in the *Cpr*$^{lox/lox}$ mouse likely contribute to the observed neurotoxicity, the levels may be below the threshold required to cause gross alterations in neuropathology (Fig. 19.8). Additional experiments will be needed to gain a better mechanistic understanding on why there were no observable pathologies in the neocortical cytoarchitecture in B(a)P-exposed animals. While speculative, one possibility may be that the plastic state of these young brains allows for certain compensations—for example, these mice may have an improved mitochondrial capacity. Such an effect has already been noted in response to severe hyperglycemia and hyperinsulinemia. Also, no studies are available on the effect of B(a)P on the NRF2 transcription factor, a master switch that regulates an antioxidant pathway. We may find that the susceptibility-exposure paradigm inherent to the present study causes upregulation of several or all antioxidant genes in response to Nrf2. Thus, despite dysregulation of glutamate homeostasis and ROS production, gross morphological alterations may be absent. Furthermore, it should be considered that the lack of change in total cell numbers would not take into consideration a more subtle change in cellular migration patterns and synaptogenesis in *Cpr*$^{lox/lox}$ offspring exposed in utero to a beno(a)pyrene aerosol.

The present study demonstrates that in utero exposure to a B(a)P aerosol in a *Cpr* experimental model system results in a temporal modification of upstream Sp4 transcription factor protein expression (Fig. 19.5) during a time when synapses are forming for the first time. It is likely that this response has negative effects downstream as follows: (1) Sp4 target gene−subunit ratio protein expression (NR2A, Fig. 19.5); (2) homeostatic glutamate

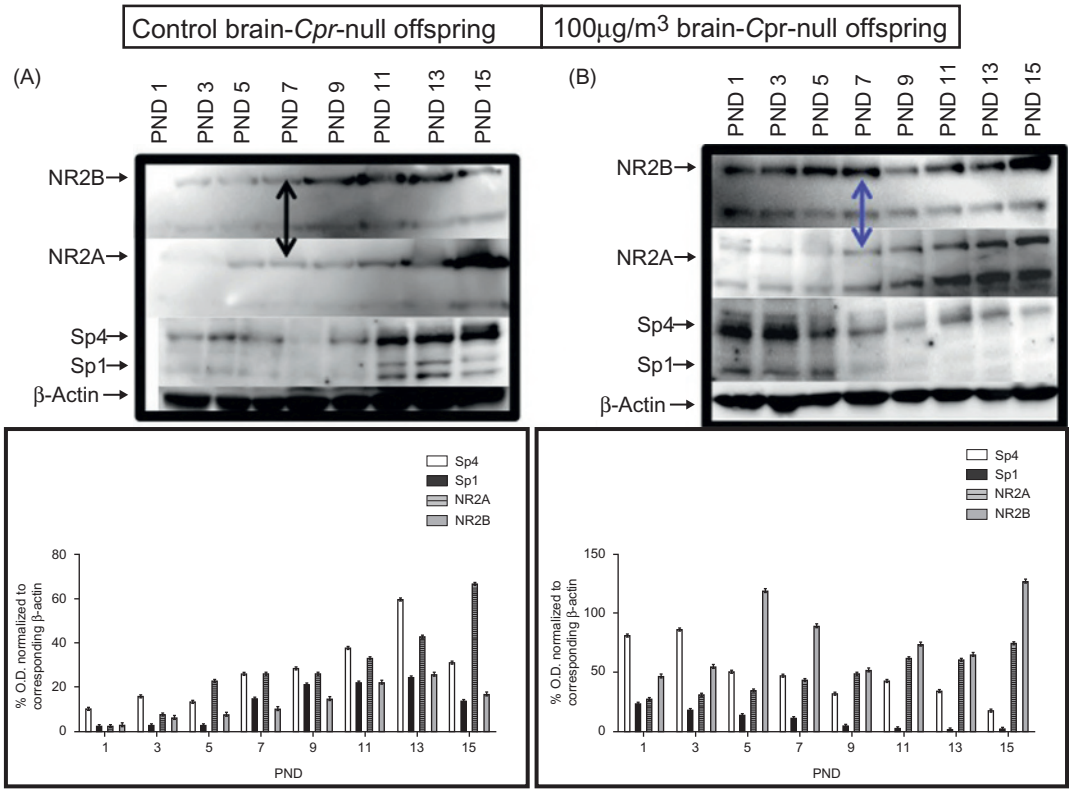

FIGURE 19.6 In utero B(a)P aerosol exposure (100 μg/m^3) upregulates developmental expression of Sp4 in brain-*Cpr*-null offspring (right panel) with accompanying dysregulation of NMDA subunit ratios as compared to control *Cpr*$^{lox/lox}$ offspring (left panel).
Representative results from a typical experiment. The panels show developmental expression profiles from PND1 to PND15 for NR2B-Sp4 nontarget gene, NR2A-Sp4 target gene, and Sp4-Sp1 proteins following SDS-PAGE of neocortical tissue from offspring gauged relative to internal β-actin controls. Lower panels represent quantitation of left and right upper panels. Post hoc analysis with the Bonferroni test with significance shown at $P < .05$.

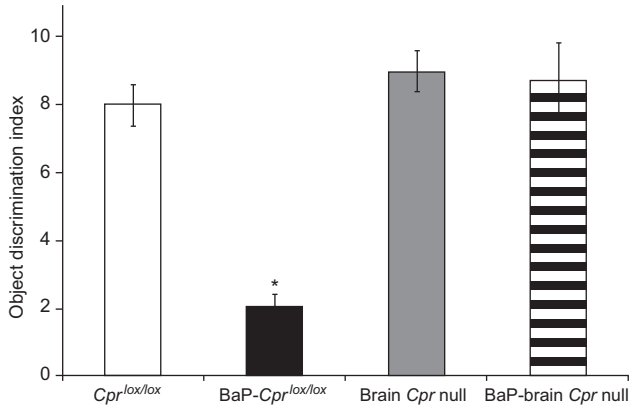

FIGURE 19.7 In utero B(a)P aerosol exposure induces a significant deficit in object discrimination in B(a)P-exposed *Cpr*$^{lox/lox}$ offspring as compared to control *Cpr*$^{lox/lox}$, WT brain-*Cpr*-null, or B(a)P-exposed brain-*Cpr*-null offspring.
Object discrimination index for control *Cpr*$^{lox/lox}$ offspring mice was 8.1 ± 0.31 and 2.0 ± 0.17 for B(a)P-exposed *Cpr*$^{lox/lox}$ offspring. An analysis of variance revealed a significant difference ($P < .05$ for the 100 μg/m^3 group). Testing of control brain-*Cpr*-null offspring revealed an index of 9.1 ± 1.4 versus 9.0 ± 0.8 for the B(a)P-exposed brain-*Cpr*-null offspring. Post hoc analysis with the Bonferroni test failed to reveal a statistically significance difference at $P < .05$.

neurotransmitter concentrations (Fig. 19.4); (3) novel object discrimination phenotype (Fig. 19.6); and (4) the magnitude of inward currents in cortical neurons (Fig. 19.9). The latter finding presents the potential for pharmacological augmentation of NR2A-mediated currents at cortical synapses as a means of modulating evoked activity in a structure-specific manner. The basal glutamate concentrations obtained in our *Cpr* experimental model system are identical to recent reports in the literature for dorsal hippocampus in a 129/SvEv mice KATII KO model and for the PFC in a Wistar rat ethanol model. These findings are consistent with the concept that increases in glutamate concentration promote alteration of inward currents via NMDA receptor expression. Whether these elevated concentrations of glutamate result from modulation in the activities of vesicular, glial, or astrocyte transporters (VGluT, GLT, or GLAST) remains to be seen.

That the mPFC integrity is, in part, important for the expression of object discrimination memory is supported by several studies where hippocampal lesions per se were found not to impair object discrimination (i.e., the ability to recognize a familiar object and discriminate it from a

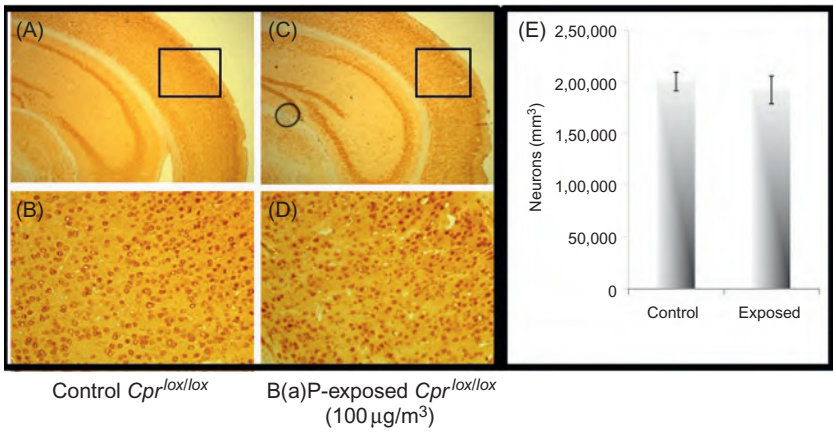

FIGURE 19.8 Post-behavior characterization of neocortical cytoarchitecture.
Coronal sections of adult neocortical sections from *Cpr*$^{lox/lox}$ offspring were analyzed for cytoarchitecture by immunohistochemical staining for NeuN. Neocortical neurons were counted in *Cpr*$^{lox/lox}$ offspring that had not been exposed to B(a)P in utero (A, low magnification; B, higher magnification) and compared to *Cpr*$^{lox/lox}$ offspring that were exposed to the B(a)P in utero (C, 4×—low magnification; D, 20×—high magnification). (E) It shows the plot resulting from stereological analysis of neocortical neurons subsequent to application of a two-tailed *t*-test. As can be seen, no significant differences in the density of neocortical neurons is observed as a result of in utero exposure to B(a)P aerosol.

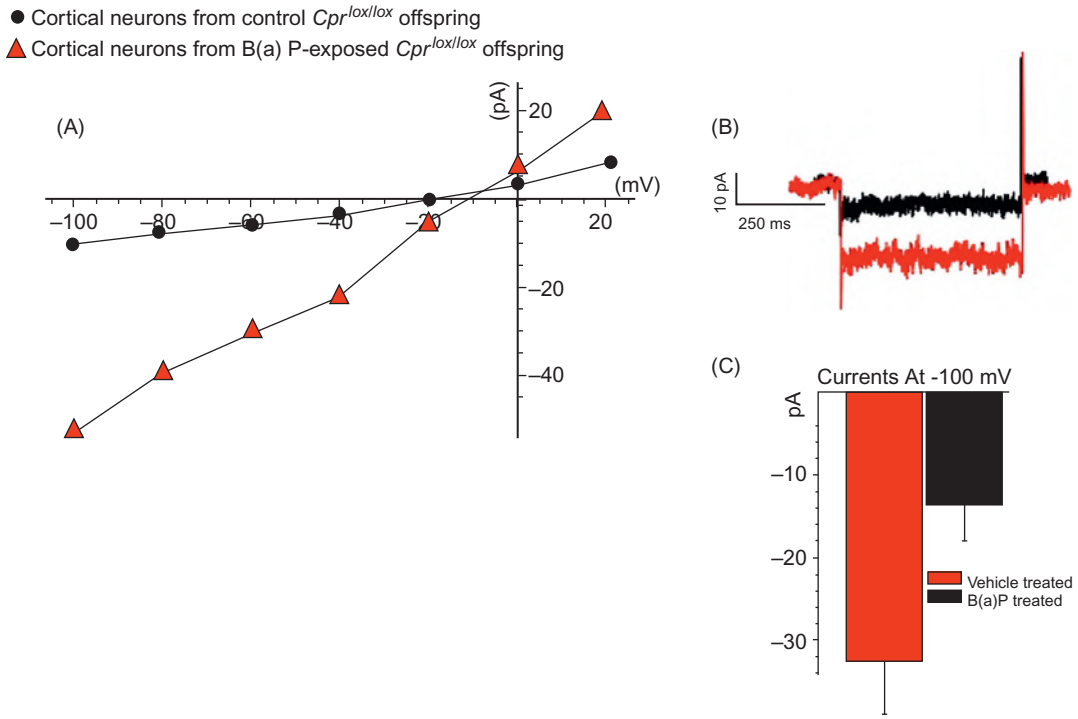

FIGURE 19.9 B(a)P aerosol exposure (100 μg/m^3) induces a voltage-dependent decrease in the inward currents of cortical neurons derived from B(a)P-exposed *Cpr*$^{lox/lox}$ offspring.
Cortical neurons were voltage clamped using whole-cell configuration in an Mg^{2+}-free external solution. Current–voltage relations were generated using a voltage step (1 s) protocol ranging from −80 to 20 mV separated by 20 mV from a holding potential of −60 mV. The experimenter was blind to the type of treatment. (A) Representative *I*–*V* currents for cortical neurons derived from carbon black and 100 μg/m^3 B(a)P aerosol-exposed *Cpr*$^{lox/lox}$ offspring. There is a voltage-dependent decrease in the magnitude of inward currents at negative membrane potentials in the cortical neurons derived from 100 μg/m^3 B(a)P-exposed *Cpr*$^{lox/lox}$ offspring. (B) Representative current traces obtained from carbon black control and cortical neurons derived from 100 μg/m^3 B(a)P aerosol-exposed offspring at −80 mV using the same experimental configuration as in (A). (C) Bar graph shows pA inward current recorded at −100 mV in control and B(a)P-exposed cortical neurons ($t = -2.92789$, $P < .0429$, $n = 3–5$).

novel object). These studies would suggest that the hippocampus is not totally required for the type of discrimination utilized in the present study. We agree that there are examples in the literature demonstrating that hippocampal lesions can impair object discrimination when the memory for the sample object includes spatial information. This is to say that when an object is presented in a complex environment with many visual and tactile cues, it appears less salient to the animal and therefore can be encoded by the hippocampus as part of this "complex" environment. Conversely, when an object is placed in an impoverished environment, it might appear highly salient and therefore can be encoded by the perirhinal cortex (for example), separate from the environment. The data from these studies may facilitate a discussion regarding the currently accepted hypotheses as to why rodents with hippocampal lesions may or may not be impaired in the object discrimination paradigm under complex but not impoverished environment conditions.

Other pharmacological studies have investigated the role of the parahippocampal glutamate receptor within the context of performance on the object discrimination task, and those results support our findings. The parahippocampal region is located dorsal to the hippocampal formation, and the evidence argues against a role of hippocampal NMDA receptors in object discrimination. In one study, intraseptal infusions of a low (0.4 mg) dose of the NMDA receptor antagonist AP-5 (d, l-2-amino-5-phosphono-pentanoic acid) improved object discrimination at a delay of 24 h, but not 45 min in rats when the dose was given either prior to or after the sample, or prior to the test trial. Another study reported that a subcutaneous (s.c.) injection of kynurenic or 5,7-dichlorokynurenic acid (antagonists at the glycine site of the NMDA receptor) given before the sample trial in doses of 0.6 or 30 mg/kg also improved one-trial object recognition in rats at a 1 h delay. These studies argue against a crucial role for the hippocampal NMDA receptor, thereby diminishing the necessity of performing in vivo microdialysis to delineate a role for glutamate in hippocampal formations within the context of performance of the object discrimination task.

It has been previously demonstrated that subacute exposure to B(a)P (0−200 mg/kg) (one intraperitoneal injection per day for 10 days) in adult mice modulated gene expression of NMDA-NR1 subunits in brain regions highly involved in cognitive function (Grova et al., 2007). Subacute exposure to B(a)P seemed to differentially affect NMDA-R1 expression in different parts of the brain. Cerebral regions, including the temporal cortex, showed no change in expression regardless of the B(a)P dose administered. In the hippocampus, exposure to B(a)P led to a 17-fold increase in a dose-dependent manner. In the frontal cortex, mRNA expression decreased 4−35 times with increasing doses of B(a)P. The results from these subacute studies in adult mice at relatively high doses in comparison to the present study suggest a link between in utero exposure to B(a)P aerosol, expression of functional obligatory NMDA-R1 mRNA, and impairments in short-term and spatial memory.

We know that postnatal brain development requires experience-dependent input that can induce the release of glutamate and thereby promote critical aspects of synaptic maturation. It is during this process of postnatal synaptogenesis that the effects of in utero B(a)P exposure on neural activity are most likely to alter the expression of genes, each with its unique temporal expression profile. In neurons of the neonatal brain, NR2A mRNA progressively increases during development and is dependent upon synaptic activity (Cull-Candy et al., 2001). In sensory pathways, Philpot et al. (2001) showed that the developmental shift from NR2B to NR2A can be postponed by sensory deprivation (Philpot et al., 2001). Studies such as these have predicted whether an alteration in the biophysical or molecular properties of NMDA receptors (NMDARs) from insertion of NR2A, loss of the NR2B, or both, places upper-limit constraints on the length of the critical period with respect to neural activity and experience-dependent fine-tuning of certain circuits.

A study by Zhou et al. (2007) reported on postnatal development of the hippocampus in the complete absence of the Sp4 gene. Notable observations were that the dentate granule cell precursors appeared to divide less during postnatal development in Sp4 *null* mice. Dentate granule cells from Sp4 *null* mice displayed less dendritic growth and arborization than those from wild-type mice placed into primary neuronal cultures. Additionally, Sp4 *null* mutant adult mice displayed both decreased neuronal cell density in the dentate granule layer and presented with a smaller dentate gyrus. The dentate gyrus is the primary gateway for hippocampal trisynaptic circuits to process the information received from the entorhinal cortex. The overall conclusion from this Sp4 *null* report is that abnormalities in circuitry exist in the *null* mouse characterized by a reduced hippocampal volume, representing a significant risk factor for some neurobehavioral deficit disorders. Collectively, results from genome-wide analyses predict an overlap of Sp protein transcription factor family members with the AhR network, and the Grin family of ionotropic glutamate receptor subunits (e.g., NR2A). Earlier studies have reported that knockdown of the transcription factor Sp4 in mice leads to increased numbers of highly branched dendrites during the maturation of cortical neurons in primary neuronal cultures (Ramos et al., 2007). The results from this report suggest that the Sp4 transcription factor likely controls dendritic patterning during development by limiting branch formation and by promoting activity-dependent pruning during a time when synapses are forming for the first time.

The signaling events that regulate deactivation kinetics for the establishment of fast synapses are preceded by changes in the subunit composition of the NMDA receptor at the synapse. This occurs during the postnatal critical switch period and is represented by the preweaning, postnatal period from P1 to P14. Results from a study by Brigman et al. (2008) illustrate the principle that NMDA receptor subunit proteins mediate certain forms of synaptic plasticity and learning. A touch-screen system was used to assess spatial discrimination learning in an NR2A subunit protein knockout (KO) mouse (Brigman et al., 2008). The study found that NR2A KO mice exhibited a significantly retarded discrimination learning pattern, supporting the currently accepted hypothesis that relative increases in the NR2A subunit protein during development ultimately serve to stabilize memories by constraining excessive synaptic plasticity.

Alternatively, NR2B-containing NMDARs appear to be the dominant form found during development, and their activity can initiate anatomical and functional plasticity, including LTP (Feldman and Knudsen, 1998). Paradoxically, NR2B does not contain GC-box elements within the 5′ promoter region, suggesting a potential mechanism for regulation of NR2A by the Sp4 transcription factor during the time when synapses are developing (Fig. 19.10). The rationale for the Sp4 transcription factor and its target genes as viable targets for B(a)P exposure-induced modulation during critical periods of development is based on the identification of canonical xenobiotic responsive element consensus sequences and GC-box elements within the 5′ promoter region (Fig. 19.11A). This is thought to render this gene and its target genes susceptible to modulation by B(a)P during critical phases of development. Fig. 19.11B shows the 5′ promoter region of the GRIN2B (NR2B) gene, which contains a single Sp4-binding site (GC box) and no xenobiotic response element (XRE) sequence in its 5′ promoter. The NR2B gene, however, does have seven XRE sequences in its 5′ UTR (Fig. 19.11B). Due to the absence of canonical XRE sequences and multiple GC-box elements in the 5′ promoter region, NR2B would not be classified as an Sp4 target gene. Conversely, the GRIN2A gene (NR2A) contains two Sp4-binding sites (GC-boxes) and six XRE sequences in its 5′ promoter (three in a forward orientation and three in a reverse orientation) (Fig. 19.11C). There are two additional XRE sequences in the ORF of GRIN2A (one forward and one reverse), as is shown in Fig. 19.11C. The NR2A receptor subunit thus qualifies as a Sp4 target gene and has been reported as such (Liu et al., 2003).

Clearly, the novel object discrimination task is sensitive enough to detect deficits in response to object discrimination that are reflective of learning and memory impairments. PAH aerosol-induced negative modulation in the temporal developmental expression of Sp4 demonstrates a particular sensitivity to environmental exposure during a critical period of development. Studies in the immediate future will seek to elucidate the functional

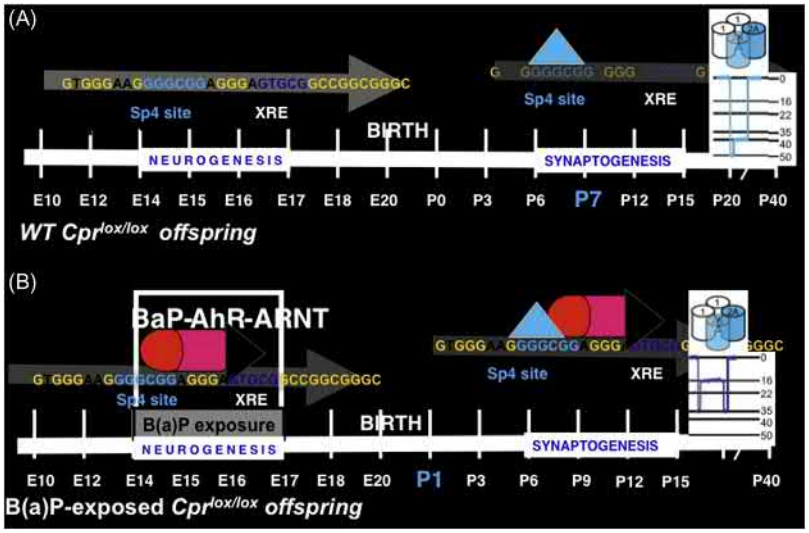

FIGURE 19.10 (A) Normal glutamate and NMDA-NR2A homeostasis. (B) Dysregulated (elevated) cortical glutamate and NMDA-NR2A homeostasis. (A) Normal temporal activation of Sp4 expression and of its target genes during embryonic development in timed-pregnant control $Cpr^{lox/lox}$ dams is depicted from E10 to E20 (birth). During the early postnatal period, the Sp4 target gene NR2A facilitates in establishing constitutive NMDA-NR2A-driven cortical currents. This occurs during the *critical period of synapse formation* (P7−P15) and contributes to a normal object recognition/discrimination phenotype in $Cpr^{lox/lox}$ offspring. (B) Premature activation of Sp4 expression and of its target gene, NR2A, occurs subsequent to in utero exposure of timed-pregnant $Cpr^{lox/lox}$ dams to B(a)P in aerosol. During the early postnatal period in exposed $Cpr^{lox/lox}$ offspring, dysregulated Sp4 and target gene expression results in upregulated NMDA-NR2A-driven cortical currents. This occurs during the *critical period of synapse formation* when NR2A-NR2B subunit ratios are altered (P7−P15), thus contributing to an impaired object recognition/discrimination phenotype in exposed $Cpr^{lox/lox}$ offspring.

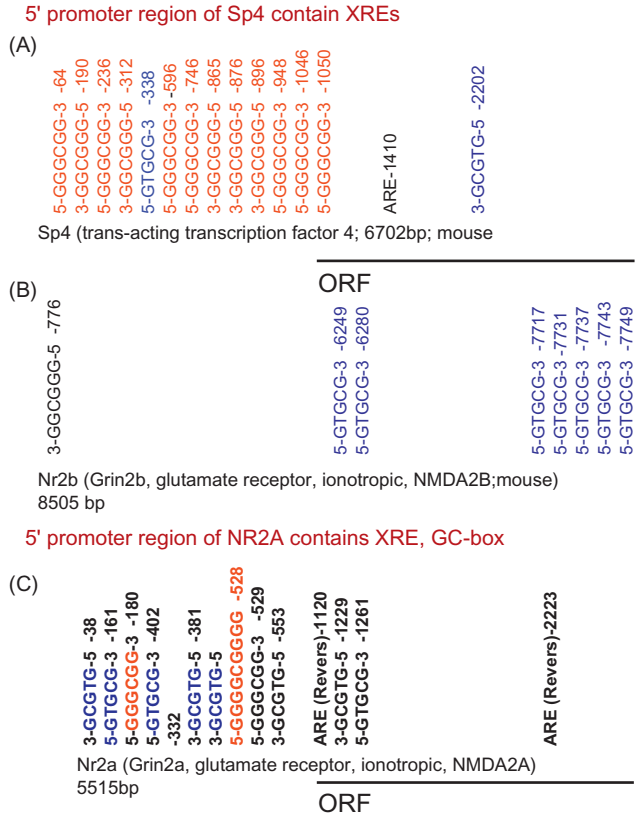

FIGURE 19.11 Promoter analyses for canonical XRE and GC-box consensus sequence requirements in Sp4 target gene versus nontarget genes.
(A) Core Sp4 promoter; (B) core GRIN2B (NR2B) promoter; (C) core GRIN2A (NR2A) promoter. *Blue*—XRE, xenobiotic response element; *Red*—GC box/Sp4-binding site; *Black*—ARE, antioxidant response element.

changes and mechanisms undergirding alterations in Sp4 target gene-driven neural activity (NMDA-NR2A-mediated) and plasticity using our *Cpr*-null model. Translating these new concepts into animal studies offers the promise of advancing our ability to establish the presently absent mechanistic connections between exposure-induced diseased phenotypes, due to disturbances in temporal expression patterns during critical windows of development. In order for significant advances in the field to come to fruition, molecular-level hypotheses of in utero air pollution exposure effects on later-life phenotypes must continue to be investigated by multidisciplinary teams.

19.5 Other model systems used for PAH-induced neurotoxicity and role of the microbiome

The aforementioned narrative details the sequelae of events subsequent to prenatal and postnatal exposures to PAHs through aerosol as the emphasis of this chapter is on neurotoxicity of agents released during chemical warfare and related operations that involve combustion during war settings. However, some rodent, nonrodent, and human cell line model systems have been used that studied the impact of PAH-induced neurotoxicities subsequent to noninhalation exposures. Some of those studies are briefly mentioned here as the research strategies used and the mechanisms identified will be of relevance to aerosol exposures as well.

Male Wistar rat pups, which received 2 μg B(a)P/kg bw on PND5 through intracisternal administration revealed neurobehavioral (spontaneous motor hyperactivity) changes, and alleviation of dopamine in striatum and neurodegenerative (histopathological changes in striatum) consequences in adult life (Das et al., 2016). The role of NMDAR in regulating inhaled B(a)P toxicity is mentioned elsewhere in this chapter. Additional evidence in support of NMDAR perturbation leading to neurotoxicity induced by orally administered B(a)P was furnished by Chepelev et al. (2016). Microarray profiles of adult male Muta™ mouse orally administered with 1, 35, or 70 μg B(a)P/kgbw showed increased expression of NMDAR subunits Grina and Grin2a. The B(a)P-induced transcriptional profiles of hippocampus from Muta mouse were similar to the neurotoxicity outcomes seen in B(a)P-exposed rats and mice.

Metabolomic studies also provided compelling evidence that postnatal subchronic oral B(a)P exposures (2 mg/kg/day for 7 weeks) contribute to neurobehavioral impairment in Sprague−Dawley rats (Li et al., 2018). Pathway analysis revealed that those affected were energy, methionine, cysteine, and glutathione metabolic pathways, which were correlated to cerebellum injury. Using the above-mentioned experimental regimen, in addition to metabolomics, epigenetic and transcriptomic studies were conducted by this research group (Wang et al., 2018) to determine the mechanistic basis of B(a)P neurotoxicity. Their studies revealed that exposure to B(a)P caused changes in the levels of DNA methylation and expression profiles of ncRNAs and mRNAs. Additionally, changes in metabolism-related enzymes that regulate the synthesis of glycine, phenylalanine, and leucine were observed in the hippocampus. Taken together, these results suggest that long-term exposure to B(a)P leads to depletion of energy pools (which are key to meeting the energy requirements of neurons) and disruption of neurotransmitter homeostasis, ultimately leading to cognitive dysfunction.

Aside from rodent models, developmental exposure to B(a)P has been shown to affect larval behavior and adult learning in zebrafish (Knecht et al., 2017a). Experiments carried out by this research group (Knecht et al., 2017b) also revealed the transgenerational impact of the above-mentioned deficits as manifested by alterations in morphological (increased body mass index in F2 generation),

physiological (decreased heart beat and mitochondrial function in F0 and F2 generation; increased oxygen consumption in F2 generation), and neurobehavioral parameters (social-anxiety-like behavior in F0 generation; hyperavoidance behavior in F2 generation).

Another study using cell systems lends support to the notion that early life exposures to PAHs may have health effects later in life. Slotkin et al. (2017) used in vitro models to demonstrate the effect of developmental PAH exposure on neurotoxicity. This group used two cell types, which shows differences in "decision node" or period of neurodifferentiation due to PAH exposure. The two cell models used were the Neural Stem Cell (NSC) model, which represents differentiation of stem cells into neuronal or glia cells and the PC12 model, which represents multiple processes that include neuronal cell growth, extension of neuritic projections, etc. The PAHs evaluated were either single compounds [B(a)P] or an environmentally derived PAH mixture [Elizabeth River Sediment Extract (ERSE); from a Superfund site]. Benzo(a)pyrene had a profound effect on the PC12 cells, impacting the transition from cell replication to cell growth. On the other hand, ERSE affected the NSC model resulting in increased cell replication and enhanced neurodifferentiation. These studies bring into light two important aspects: (1) the chemical behavior and the consequent toxicity differs among individual PAH compounds and; (2) the potential window of neurodevelopmental susceptibility is greater than thought previously.

Recently there has been a surge in literature on the role played by the microbiome in maintaining optimal health as well as the susceptibility to disease. How the microbiome affects the xenobiotic metabolism through the host hepatic biotransformation enzymes and impacts human health has not been well researched (Clarke et al., 2019). On one hand, the enzymes from microbes that reside in the host may generate neurotoxic metabolites of their own in the host's body, in addition to those arising from their own metabolism of xenobiotics. Gut microbes were known to stimulate neurons of the enteric system, which sends signals to the brain through the vagus nerve. As a consequence, the hypothalamus−pituitary−adrenal axis is affected, resulting in memory and cognition disorders (Galland, 2014). Dietary intervention through increased intake of nutrients/antioxidation, pro- and prebiotics is one strategy to offset the damage to the CNS caused by these microbes. Whether this strategy would work for all neurotoxicants and/or neurotoxicants that are highly lipophilic and sequestered in the CNS is not known. Additionally, to what extent this strategy would be effective for long-term developmental exposures to airborne xenobiotics is open for speculation. There is a lot of scope for omics studies to delineate the neurotoxicity of PAHs and other semivolatile xenobiotics and also characterizing the resident microbiome and its contribution to either ameliorating or exacerbating the toxicity of these compounds.

19.6 Concluding remarks and future directions

The research described in this chapter represents the contribution toward leading the development of a novel methodology to systematically discover and develop therapeutic glutamate receptor/aryl hydrocarbon receptor antagonists that will mitigate the neurotoxicity associated with in utero exposures to B(a)P aerosol. A fundamental premise of future research takes into account the need for simultaneous temporal measurements, and integrative physiological analysis of critical signaling processes, to better understand the mechanisms of PAH exposure-induced neurotoxicity. Future experiments should also define the signatures of PAH exposure-induced neurotoxicity and novel therapeutics/protectants in experimental model systems. Additionally, monitoring changes in the microbiome profile would help trace the "neurodevelopmental fingerprints" for single PAH compounds and mixtures in the presence or absence of specific microbial species.

Chapter 20

Thallium

Larry J. Thompson
Thompson Tox, Edwardsville, IL, United States

20.1 Introduction

Thallium (Tl) is a soft, bluish-white metal that occurs naturally in the Earth's crust. It was discovered by Sir William Crookes in 1861 while making spectroscopic determinations of tellurium in residue material from a sulfuric acid plant. The name comes from the Greek word "thallos," which means a green shoot or twig, a reference to the green spectral emission lines originally used to identify the element. It is a heavy metal (density 11.83 g/cm^3, atomic number 81) whose mainly use is in the electronics industry (e.g., infrared detectors, semiconductor materials) with smaller quantities used in glass manufacturing and pharmaceutical industries, including the radioactive isotope Tl-201. Thallium can be released into the environment by cement manufacture, the burning of certain coal deposits, and the production of nonferrous metals (Kazantzis, 2000; Peter and Viraraghavan, 2005). Normally, Tl is found in the environment in low concentrations, commonly as the Tl (+1) or Tl (+3) oxidation state. The MCL (maximum contaminant level) for Tl in drinking water is 0.002 mg/L (US EPA, 2009a), the level at which no adverse human health effects are anticipated. Commercial Tl is usually obtained during the refining process for iron, cadmium, lead, or zinc (USGS, 2019). Thallium is a highly toxic element and salts of Tl are colorless, odorless, and tasteless. Thallium has no known biological function and has been the least studied of the toxic metals including lead, mercury, and cadmium. Thallium salts were introduced as pesticides in Germany in 1920. The sulfate salt is most commonly used and has been widely used as a rodenticide and ant killer. Tl has been associated with intentional and accidental poisonings since that time, although problems decreased greatly after its use was banned in many parts of the world (Saddique and Peterson, 1983).

20.2 Background

Thallium has two important oxidation states, Tl (+1) and Tl (+3). The trivalent form more closely resembles aluminum and the monovalent form more resembles alkali metals such as potassium. The toxic nature of the monovalent Tl is due to its similarity to potassium in ionic radius and electrical charge (US EPA, 2009b). Thallium sulfate use as a pesticide was restricted in 1965 in the United States and the World Health Organization (WHO) recommended in 1973 against its use as a rodenticide due to its toxicity (WHO, 1973). From 1912 to 1930, thallium compounds were used extensively for medicinal purposes, for example, in the treatment of ringworm (because of the depilatory effects), dysentery, and tuberculosis. The narrow margin between toxicity and therapeutic benefit, however, eventually eliminated the practical use of these compounds. Due to its highly toxic nature, delayed symptoms, and lack of taste or odor, Tl salts have been used in suicide attempts and in the intentional poisoning of individuals or small groups of people. Although the reported symptoms of Tl poisoning are diverse, the classic syndrome involves gastroenteritis, polyneuropathy, and alopecia. Fictional accounts of Tl as the agent of an intentional poisoning include Agatha Christie's book, *The Pale Horse*. More recent accounts or suspicions of Tl use include medical case reports as well as lay press reports. Chronic Tl exposure has been reported in industrial settings and exposure limits have been established (Peter and Viraraghavan, 2005). However, there are currently insufficient epidemiological data concerning the chronic effects of Tl on humans, as well as a lack of data concerning the mutagenic effects and the effect of Tl on genetic material (Rodríguez-Mercado and Altamirano-Lozano, 2013). The radioactive isotope Tl-201 is a gamma emitter and is used in cardiac imaging, similar to technetium-99, with a

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00020-9

half-life of approximately 3 days. Although Tl-201 is the most common isotope in use, Tl-204 decays by beta particle emission and has a half-life of 3.8 years.

20.3 Toxicokinetics

Thallium is rapidly absorbed from the gastrointestinal tract and is well absorbed through the skin. There is little information concerning absorption from the respiratory tract. Once absorbed, Tl is rapidly distributed throughout the body to all organs, with the highest concentrations occurring in the kidney following an acute exposure. Both monovalent and trivalent Tl appear to distribute in similar manners, and it is not known if metabolic processes can change the valence state. Thallium can pass through the placental barrier as well as the blood–brain barrier (Sullivan, 1992).

Elimination of Tl is mainly through the gastrointestinal tract but elimination also occurs through the kidneys, saliva, hair, skin, sweat, and breast milk. Relative amounts excreted by each route vary by species. Thallium is likely excreted through intestinal and gastric secretions associated with potassium loss or excretion. Likewise, reabsorption of Tl also occurs, mainly from the colon. The estimated biological half-life of Tl is 10 days but values up to 1 month have been reported (WHO, 1996).

20.4 Mechanism of action

Although the exact mechanism of action of Tl is unknown, its similarity to potassium has been shown to play a significant role. Thallium has an atomic radius similar to potassium and has shown a 10-fold affinity over potassium in Na^+/K^+-ATPase, resulting in lower activity of the enzyme. Tl inhibits the influx and efflux of potassium in mitochondria, without affecting the movement of sodium. In addition to disturbing mitochondrial function, Tl has been shown to increase the levels of hydrogen peroxide and also to increase lipid peroxidation and oxidative stress (Hanzel and Verstraeten, 2005). The metabolism of glutathione can be disrupted by Tl, increasing the susceptibility to reactive oxygen species (Cvjetko et al., 2010). Thallium can also inactivate sulfhydryl groups, including those affecting the permeability of the outer mitochondrial membrane. Thallium can act as a Lewis acid, having an affinity for organosulfur compounds, which may account for its action to cause hair loss. The binding of cysteine by Tl may inhibit keratinization of hair by preventing the cross-linking of proteins (Mulkey and Oehme, 1993).

20.5 Toxicity

The available human literature on Tl is mainly case reports from the results of acute poisonings, accidental ingestions, or suicide attempts. Although the acute classic syndrome of Tl poisoning involves gastroenteritis, polyneuropathy, and alopecia, not all these effects are observed in every case. The onset and sequence of symptoms will vary with the dose and duration of exposure. The lowest known toxic dose in a human is 0.31 g, which was reported to cause symptoms but did not cause death (Cavanagh et al., 1974). Oral doses of 6–40 mg/kg have been lethal within 10–12 days. Other oral human toxic doses are given as 10–15 mg/kg (WHO, 1996; Moore et al., 1993). Children have been poisoned with Tl at 4–8 mg/kg.

Several hours following an acute exposure, the initial symptoms may include gastroenteritis including nausea, vomiting, and diarrhea. With a relatively small dose, these symptoms may be relatively mild and diffuse, with little progression for 2–5 days. Gastrointestinal bleeding or constipation may then develop along with central and peripheral nervous system effects. These include paresthesia with reports of the feeling of "burning feet." Additional neurological symptoms can include lethargy, delirium, seizures, and coma (Tsai et al., 2006). An initial presentation simulating Guillain-Barré syndrome has been reported (Misra et al., 2003). Nonspecific kidney and liver damage can develop. In severe exposures, circulatory symptoms may include hypertension, tachycardia, and cardiac failure. Initial dermatological involvement may include anhydrosis (which can cause fever), and this can be followed some time later by diaphoresis. In the second week following exposure additional dermatologic symptoms appear, including increased darkening of the hair papillae followed in several days by a developing alopecia. By 3 weeks following exposure there may be almost complete alopecia. At this time in the syndrome there may be ataxia and tremors with a painful neuritis in the lower extremities that may be severe. Following a lethal dose, death commonly occurs within 10–12 days caused by renal or cardiac failure. Recovery from Tl poisoning can require several months and residual neurological problems may remain including weakness, memory impairment, and psychological disturbances (Pau, 2000; Tsai et al., 2006).

20.6 Risk assessment

Although reported as an agent of intentional poisoning for an individual or small group of people, the broad use of Tl as an agent in chemical warfare or terrorism has not

been reported (Salem et al., 2008). The most commonly available radioisotope of Tl-201 is a gamma emitter with a short half-life, making it a poor candidate for a radiological dispersion device (Burnham and Franco, 2005; Chin, 2007). Although the Tl-204 isotope is a beta emitter with a half-life of 3.8 years, its commercial use is limited. The chelating agent used for treatment of Tl exposure (Prussian blue) is also used in the treatment of radiocesium exposure, thus it is included in many antidote stockpiles (Ansari, 2004).

20.7 Treatment

Diagnosis of Tl poisoning is based upon exposure history if available, compatible clinical time course and symptoms, along with the finding of above-background levels of Tl in urine, serum, or other clinical specimens. The appropriate methodology for urine or blood Tl includes atomic absorption spectroscopy (flame or flameless) as well as other methodology such as ICP (inductively coupled plasma emission spectroscopy). Use of colorimetric analyses of these specimens can lead to false positives (CDC, 1987). Normal or background concentrations of Tl in urine are given as <0.5 μg/L up to a level of <10 μg/L, depending upon the laboratory reference, with concentrations elevating several hundred- to several thousand-fold following an acute exposure. Treatment should be initiated when 24-h urinary Tl excretion exceeds 0.5 mg. Additionally, a toxic level of Tl in the urine of >300 μg/L has been suggested (Sullivan, 1992). Blood Tl levels in exposure situations are less well characterized and values above 5 μg/L are considered to be evidence of excess Tl exposure (CDC, 1987). Prussian blue [ferric-hexacyanoferrate (II)] is the treatment of choice for Tl exposure in that it acts by binding Tl in the gastrointestinal tract, making it unavailable for reabsorption (Altagracia-Martínez et al., 2012). This will increase the fecal excretion of Tl and decrease the half-life. Prussian blue is also used in the treatment of radiocesium and acts by the same mechanism (Yang et al., 2008). The suggested dosage regimen is 3 g given orally three times a day for adults and adolescents. Children between the ages of 2 and 12 years can be given 1 g orally three times a day. The clinician should insure proper gut functioning because constipation is a common finding in Tl intoxication. Fluid diuresis and other symptomatic and supportive care should also be provided. Recently a workgroup composed of international experts assembled to review and provide recommendations on the use of extracorporeal treatment for poisonings. In the case of severe Tl poisoning, the workgroup strongly recommended extracorporeal removal for Tl, although it was acknowledged that limited evidence exists (Ghannoum et al., 2012).

20.8 Concluding remarks and future directions

Thallium remains a toxic metal of concern for both accidental and intentional exposure. Its historical use as an intentional poison against individuals or small groups is based on its delayed onset of symptoms and the nature of its salts being tasteless and odorless. Although the incidence of intoxication with Tl has been decreasing with its decreasing availability, clinicians should remain familiar with its clinical features, diagnostic considerations, and treatment regimens. History has shown Tl not to be an agent of choice for chemical warfare or terrorism, and the use of radiological Tl for these purposes is also unlikely. However, preparations for such an unlikely event are relatively straightforward with major considerations being the stockpiling of Prussian blue, also needed for radiocesium treatment, and the retention of analytical capabilities for Tl in biological and other samples.

Chapter 21

Arsenicals: toxicity, their use as chemical warfare agents, and possible remedial measures

Sakshi Srivastava and Swaran J.S. Flora

National Institute of Pharmaceutical Education and Research-Raebareli, Transit Campus, Lucknow, India

21.1 Introduction

Arsenic is a metalloid (semimetal) member of group V elements of the periodic table, having oxidation states of +3 (As III) and +5 (As V). Both species occur in organic as well as inorganic compounds. Arsenic combines chemically with most nonmetals to form a variety of both inorganic and organic compounds (Susan et al., 2019). Arsenic-based chemical agents have revealed long-term effects in humans that can be life threatening if left untreated. A number of organic arsenicals have been developed for use as chemical warfare (CW) agents (Radke et al., 2014). The use of chemical weapons in war guarantees overall efficiency because chemical agents do not depend on explosive force to achieve objectives, while infrastructure remains intact. Also, the production, storage, and transport (in a sealed container) require relatively low cost and low technology. The use of chemical agents, including arsenical agents, offers many unique advantages, which vastly differ from those of conventional weapons and are of human and ecotoxicologic relevance (Polat et al., 2018). The story of arsine and lewisite encapsulates the key elements of the history of chemical weapons and their continuing influence. Although information about arsenic and its inorganic and organic derivatives is well documented, there is very little literature available on their role as CW agents. This chapter provides readers with updated information about the organic arsenicals as CW agents and also gives a comprehensive account of toxicity due to inorganic arsenicals. Unfortunately, chronic arsenic poisoning due to exposure to agricultural agents currently remains a significant cause of morbidity and mortality, particularly in the developing world. Inorganic salts of arsenic are the most toxic, in particular trivalent arsenic (III) such as arsenic trioxide, and pentavalent arsenic (V) which is approximately 60 times less toxic. Arsenic (III) has many toxic effects relating to enzyme inhibition, but in particular it inhibits pyruvate dehydrogenase, interfering with the Kreb's cycle, whereas arsenic (V) directly poisons ATP by displacing inorganic phosphate and other features may result from binding sulfhydryl groups of surface proteins and oxidative stress from glutathione depletion. The lethal oral dose in humans is variously reported as 120−200, 100−300, or 200−300 mg (Rosenberg et al., 2016).

21.2 Background

CW agents are incapacitating, damaging, toxic, and lethal compounds. It is known that CW agents have been used since 600 BCE. Even though these agents have been used many times intermittently, their use increased significantly in the course of World War I (WWI), when cyanide, phosgene, chlorine, sulfur mustard, etc., were weaponized in Polat et al. (2018).

Arsenic (As) occurs in a variety of different chemical forms, among them volatile (gaseous) species, usually referred to as arsine and methylarsines. Arsine, the most toxic form of arsenic, exhibits some characteristics that may make it useful as a CW agent. At concentrations above 0.5 ppm, a garlic-like odor may be noted, but arsine is toxic at much lower concentrations. Acute arsine poisoning due to inhalation of arsine gas (AsH_3) is rare but it has no known antidote. It is the most acutely toxic form of arsenic, causing rapid and severe hemolysis immediately on exposure. The mechanisms of hemolysis are not

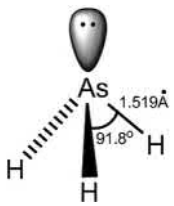
Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00021-0

completely understood. Arsine has a short half-life (27–96 h) and is converted to various arsenic derivatives. A number of other arsine-derived organo-arsenic compounds have been developed and used as CW agents, including lewisite (L), methyldichloroarsine (MD), diphenylchloroarsine (DA), and ethyldichloroarsine (ED). It is also well known as an insecticide in the form of lead arsenate, arsenic acid, etc. and in pharmacy, especially in the form of salvarsan and neosalvarsan. Arsenic derivatives are also of value from the point of view of CW agents. However, on calculating the amount of arsenide required to establish a lethal concentration of arsine, this suggest no possibility of using the material in the field. Organic arsenic derivatives are the most important compounds from a military point of view. The first substance used was diphenylchloroarsine, a white solid, which readily penetrated the canister and caused sneezing. This was used alone, and in solution in diphenylchloroarsine. Later methyl and ethyl dichloroarsines were introduced (Beckett, 2008).

The arsines family includes compounds with various toxicities; however, arsenic trihydride or arsine is the most toxic form. It is a powerful hemolytic gas but has never been used as a chemical weapon because it exerts nonimmediate and nonpersistent toxicity. However, cases of occupational exposure are still reported despite strict regulation. This agent, whose mechanism of action is still not well defined, is poorly recognized because of the rarity of intoxication. Fast detection means are available, however health professionals still need to learn to recognize arsine intoxication in order to provide early, specific treatment and to avoid damage to health (Plantamura et al., 2011).

Arsenicals are considered a threat, not so much from large nation states but from smaller, less developed nations and/or by terrorist organizations. The relative ease of production coupled with their effectiveness against an unprotected population make organic arsenicals a continued threat in the 21st century. This chapter describes the human health aspects of arsine, some of the important organic arsenicals including inorganic arsenic and the current status of development of suitable therapeutic measures.

21.3 Arsine



Arsine (AsH_3) (arsenic hydride, arsenic trihydride, hydrogen arsenide, and arsenous hydride) is a colorless, extremely flammable gas with a garlic-like odor. The relative molecular mass of arsine is 77.95. Its boiling point is −62°C and vapor pressure at 20°C is 1043 kPa. Arsine is a strong reducing agent, deposits arsenic on exposure to light and moisture, and is easily transformed into other oxidized arsenic forms [e.g., As (III) and As (V)]. Arsine gas is colorless, odorless, and 2.5 times denser than air (Table 21.1). Arsine is a class of organoarsenic compounds of the formula $AsH_{3-x}R_x$, where R = aryl or alkyl.

It is used in the production of organic chemicals and lead storage batteries. Arsine is metabolized to trivalent arsenic as well as pentavalent arsenic. Arsenic (III) is methylated to monomethylarsonate (MMA) and dimethylarsinate (DMA). Arsine metabolites are mainly excreted via urine (Sattar et al., 2016).

Arsine, the most toxic form of arsenic, is a potential CW agent. It is believed that arsine causes massive hemolysis of red blood cells by (1) formation of hydrogen peroxide and adducts with oxyhemoglobin, (2) interaction with the sodium–potassium pump, red blood cell swelling and bursting, and (3) finally, massive hemolysis generally leads to renal failure (Sattar et al., 2016). Inhaled arsine gas is distributed rapidly and causes massive red blood cell hemolysis that can potentially lead to cellular hypoxia. Exposure to other arsenic compounds to which arsine is metabolized can induce lung, bladder, kidney, and skin cancer in humans. Occupational sources where exposures to arsine at levels sufficient to cause acute arsine intoxication have occurred include copper smelting and refinery bronzing process, chemical company cleaning of clogged drains, transistor industry, burnishing of metals, etc. Many processes including electrolyte refining, galvanizing, soldering, etching, lead plating, metal smelting, and extraction

TABLE 21.1 The physical and chemical properties of arsine.

Properties of arsine	
Molecular formula	AsH_3
Molar mass	77.95 g/mol
Appearance	Colorless gas
Density	4.93 g/L, gas; 1.640 g/mL (−64°C)
Melting point	−117°C (157K)
Boiling point	−62.5°C (210K)
Solubility in water	0.07 g/100 mL (25°C)
Molecular weight	77.95

may expose workers to toxic concentrations of arsine (Chein et al., 2006).

21.3.1 Synthesis of arsine

Arsine is formed whenever nascent hydrogen is released in the presence of arsenic or by action of water on a metallic arsenide. The formation of arsine can be described with the help of the following reaction (Radke et al., 2014).

$$3\,H_2 + HAsO_2 \rightarrow AsH_3 + 2\,H_2O$$

AsH_3 is also prepared by the reaction of As^{3+} sources with H^- equivalents (Bellama and Macdiarm, 1968)

$$4\,AsCl_3 + 3\,NaBH_4 \rightarrow 4\,AsH_3 + 3\,NaCl + 3\,BCl_3$$

Alternatively, sources of As^{3-} react with protonic reagents to produce arsine:

$$Zn_3As_2 + 6\,H^+ \rightarrow 2\,AsH_3 + 3\,Zn^{2+}$$

21.3.2 Metabolism of arsine

21.3.2.1 In animals

The main route of arsine excretion is via urine after metabolism. Arsenic was excreted exponentially in intravenously arsenite-administered mice and, after 24 h, less than 10% of the dose remained. On the other hand, arsenic arising from inhalation exposure to 180 mg/m^3 arsine for 120 min was excreted more slowly and after 24 h about 45% of the arsenic remained in the exposed mice. The major metabolites determined in urine were As (III) and As (V), MMA and DMA.

21.3.2.2 In humans

Arsenic has been detected in the tissues, blood, and urine of workers in the petroleum industry poisoned with arsine. Arsenic was also found in the liver at a concentration of 11.8 mg/g, spleen at 7.9 mg/g, kidneys at 3.2 mg/g, brain at 0.6 mg/g, and in the urine at 0.6 mg/m in a fatal case of arsine poisoning (Apostoli et al., 1997). As (III) also gets oxidized to As (V) in urine of humans exposed to arsine 1–2 days following exposure. Trivalent arsenic is methylated to MMA and DMA (Flora, 2011).

21.3.3 Mechanism of toxicity

Arsine gas causes rapid destruction of red blood cells leading to hypoxia and renal failure on inhalation. It also causes massive hemolysis of red blood cells by (1) formation of hydrogen peroxide and adducts with oxyhemoglobin, (2) interaction with the sodium–potassium pump, red blood cell swelling and bursting, and (3) finally, massive hemolysis generally leads to renal failure. Oxyhemoglobin (oxyHb) has been recognized as a necessary component for overall mechanism of AsH_3-induced hemolysis, as conversion of oxyHb to carboxyHb prevents hemolysis in erythrocytes exposed to AsH_3 (Sattar et al., 2016; Flora, 2011).

Sulfhydryl groups of glutathione (GSH) prevent hemoglobin oxidation and are essential for the maintenance of intact erythrocyte structure and a 60% decrease in reduced GSH level in erythrocytes was noted post arsine exposure.

Arsine reacts with the sulfhydryl group of Na^+K^+-ATPase, causing impairment in the sodium–potassium pump which subsequently causes red cell swelling and hemolysis (Fig. 21.1) (Flora, 2011). Profound abnormalities in membrane ultrastructure and in red blood cell volume also have been recently reported, which were manifested by potassium leakage, sodium influx, and increases in hematocrit in arsine-exposed red cells (Susan et al., 2019).

21.3.4 Effects on humans

Toxicity of arsine to humans was first demonstrated in 1815 when a German chemist accidentally inhaled arsine vapor during an experiment.

21.3.4.1 Acute arsine poisoning

Persons exposed to arsine gas are often unaware because there are no symptoms at the time of exposure. The majority of cases of arsine exposure are clinically acute, however, lower levels of chronic exposure have been reported in the literature also (Casarett and Doull, 2001). Most patients report little or no discomfort at the time of exposure. Although a garlic-like odor may be noted with higher ambient arsine concentrations, serious toxicity may result

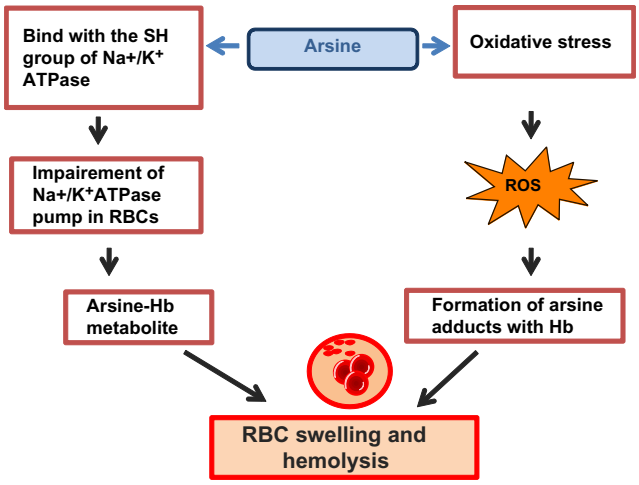


FIGURE 21.1 Hemolytic activity of arsine.

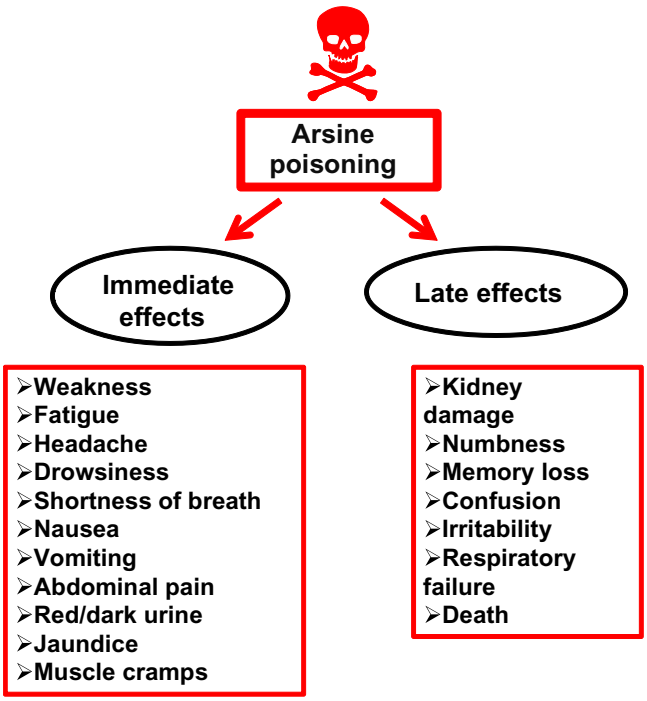

FIGURE 21.2 The signs and symptoms of arsine poisoning.

from clinically nondetectable exposures (Lenza, 2006; Song et al., 2006) (Fig. 21.2).

21.3.4.2 Immediate effects

Clinical manifestation of arsine intoxication appears within 24 h of exposure. Renal failure due to tubular destruction is an important consequence of arsine exposure. The urine is frequently discolored brown, red, or black, with hemoglobin in the urine thought to be the major cause. Urinalysis typically shows large amounts of protein and free hemoglobin with only a few red blood cells. The characteristic red/bronze tint of the skin is induced by hemolysis and may be caused by hemoglobin deposits. Hemolytic anemia is the most consistent clinical finding in humans. Massive hemoglobinuria may lead to anuria, which, if untreated, is often the cause of death.

21.3.4.3 Late effects

Late consequences of acute arsine poisoning include chronic renal damage, hematological changes, polyneuritis, and neuropsychological symptoms (e.g., irritation, confusion, memory losses, agitation, and disorientation). Peripheral neuropathy also has been reported within 6 months post-exposure (Sattar et al., 2016). An increase in total cell count and macrophages in bronchoalveolar lavage was observed in an arsine-exposed worker. Progressive improvement in diffusing capacity of lungs was observed only after 2 months of treatment.

21.3.4.4 Long-term exposure

Long-term exposure may cause symptoms similar to those observed in acutely poisoned individuals. The main differences include delay in onset and development of peripheral neuritis, development of gastrointestinal tract involvement, and the development of hemolysis and renal impairment (Sattar et al., 2016).

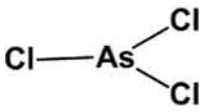
21.3.5 Diagnostic tests

Lab studies include complete blood count, methemoglobinemia, urinalysis, arsenic levels, electrocardiogram, and imaging studies.

Complications include hemolytic anemia, renal failure, hyperkalemia, and death.

Overwhelming exposures cause rapid death from massive hemolysis; most deaths occur from renal failure in patients who survive acute exposure.

21.4 Organic arsenicals



These arsenicals are a series of blister agents based around a chloroarsine ($AsCl_3$) molecule in which one of the chlorine atoms is replaced by an organic radical. These chloroarsines are effective cytochrome oxidase destroyers or blood agents. Arsenic seeks to replace calcium in the bones, thus causing bone marrow destruction as the endocrine system is concurrently attacked. Many organic radicals penetrate human skin, carrying their compounds with them (Cohen et al., 2006).

21.4.1 Mechanism of toxicity

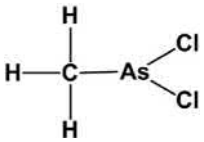
The exact mechanism for the toxic effects of organic arsenicals remains unknown. DNA alkylation and/or inhibition of glutathione-scavenging pathways are two postulated mechanisms (Nesnow et al., 2002). On contact with arsenicals a blistering reaction occurs on skin, eyes, or pulmonary tissues (Cohen et al., 2006). Animal data and limited human trials have suggested that organic arsenicals readily penetrate the skin. Within seconds of contact, the chemical fixes itself to the epidermis and dermis. The separation of dermis from epidermis together with capillary leakage causes fluid-filled vesicles (Naranmandura and Suzuki, 2008). Intravascular

hemolysis of erythrocytes with subsequent hemolytic anemia may result (Wu et al., 2003).

21.4.2 Symptoms

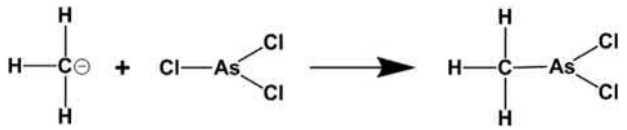
Vapor contact with the conjunctiva may be the victim's first symptom. Severe conjunctival irritation and blepharospasm may lead to loosening of corneal epithelial cells and swelling and edema of the cornea. Mucosal damage starts in the nose and descends down the respiratory mucosa in a dose-dependent fashion. Immediate pain, lacrimation, and irritation accompany the damage. DA vapor causes vomiting, which develops within 1−2 min after exposure to DA. The immediate onset of symptoms following exposure makes severe or systemic toxicity to organic arsenical unlikely. However, prolonged contact may lead to multi-organ involvement (Kinoshita et al., 2007).

21.5 Methyldichloroarsine



Germans referred to MD as methyldick, a toxic irritant, a vesicant, and a systemic poison. It causes pain, coughing, nasal discharge, frothing at the mouth, and irritation of the eyes, skin, nasal passages, and lungs. Inhalation of the vapor or dust produces a burning sensation along the entire respiratory tract and gasping for breath. Later, bloody expectorations are produced (Polat et al., 2018).

The structure of MD consists of a trichloroarsine ($AsCl_3$) molecule combined through catalyzation with a methyl (CH_3) group.



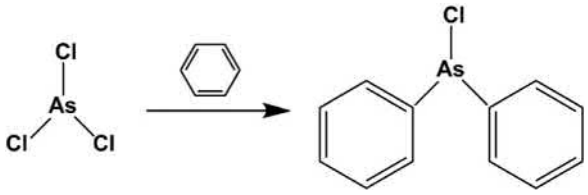
21.6 Dlphenylchloroarsine

DA is an irritating substance which was developed in 1918 for use in a smoke generator known as the M-device. DA has a very powerful irritant action on the mucous membranes of the eyes and nose, causes painful blistering of the skin, and is very dangerous for those working with it, since its vapor causes respiratory embarrassment, faintness, and long-lasting paralysis and anesthesia of the extremities (Kato et al., 2007).

As DA and related compounds cause intense effects on the nasal and upper respiratory passages, they are referred to as "sneeze gas" (sternutators).

21.6.1 Structure

DA is prepared from trichloroarsine ($AsCl_3$):

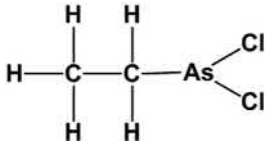


Two chlorine ions are replaced by benzene groups, forming a stable compound which may be safely stored under all field conditions.

21.6.2 Effects of dlphenylchloroarsine

The immediate effects of DA are those associated with tear-gas compounds: severe irritation to the eyes, nose, and throat. Severe headache and feelings of tightness of the chest and bowels occur within a minute of inhalation of this compound. The headache rapidly develops into a general nausea which results in vomiting within 3 min. In closed or confined spaces DA can produce fatalities through first causing unconsciousness and then asphyxiation (Ochi et al., 2004).

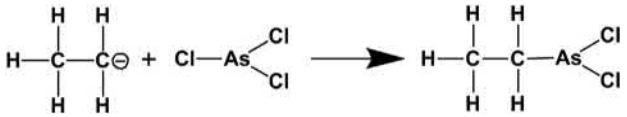
21.7 Ethyldichloroarsine



ED is fast acting compared to mustard or phosgene. ED is a colorless liquid that smells like rotting fruit and has multiple effects on the body. Within seconds of contact with the skin, the agent fixes itself to the epidermis and dermis, causing immediate pain. The agent penetrates deeper into the skin layers causing the destruction of subcutaneous tissue and fluid-filled blisters after prolonged exposure. Inhalation can cause pulmonary edema or "dry-land drowning." A lethal exposure, however, depends upon the period of exposure. A dose of 3000−5000 mg min/m^3 is generally lethal.

21.7.1 Structure

The structure of ED consists of a trichloroarsine ($AsCl_3$) molecule combined through catalyzation with an ethyl (C_2H_5) group.

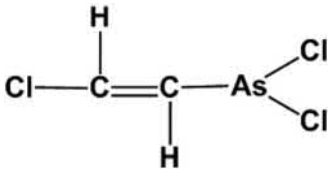


Production of ED is similar to that of MD, involving the ethylation of a chlorinated arsenite or arsenate salt, or in reductions of arsenious oxide, As_4O_6, a naturally occurring compound (Bartelt-Hunt et al., 2006).

21.7.2 Effects of ethyldichloroarsine

Chlorine bonds in ED result in its blistering, lachrymatory, and harsh respiratory effects. Dosages as low as 5 mg min/m^3 may cause severe discomfort to the eyes and throat. Sublethal dosages are detoxified by the body. ED's ethyl arsenic group may cause systemic damage to bone marrow and to the digestive and endocrine systems. Blisters may appear within 2–4 h following skin redness or rash. Like the mustards, ED actively attacks lung tissue and the damage is permanent to its survivors. ED causes permanent corneal damage.

21.8 Lewisite



Lewisite (chlorovinyldichloroarsine), a colorless, oily liquid at room temperature, has a faint "geranium-like" odor. It dissolves lowly in water and hydrolyzes rapidly to hydrochloric acid and lewisite oxide. Lewisite produces irritation and blistering of the skin and injury to the eyes and lungs after high exposure while, at lower levels, the effects resemble exposure to tear gas, with irritation of the skin, eyes, and respiratory tract. Chronic exposure may lead to development of chronic bronchitis and predispose to Bowen's squamous cell intraepithelial cancer of the skin (Sattar et al., 2016).

21.8.1 Background

Lewisite hydrolyzes in acidic medium forming hydrochloric acid (HCl) and chlorovinylarsenous oxide. Chlorovinylarsenous oxide is a compound which has a less potent blistering effect than lewisite. Trisodium arsenate, which is a toxic compound, may occur when lewisite is exposed to alkaline solutions. It is not used in industry. It is estimated that the LD_{50} (lethal dose, 50%) of lewisite is 30 mg/kg and the LC_{50} (lethal concentration, 50%) of lewisite is 100,000 mg min/mm^3 for dermatologic problems. Lewisite was discovered during WWI but has not been used in warfare because it hydrolyzes in water and the desired effect cannot be achieved in humid weather conditions. Lewisite is an agent which can penetrate ordinary clothes and rubber (Sattar et al., 2016).

21.8.2 Mechanism of action and toxicokinetics

Lewisite, a lipotropic agent, can be easily adsorbed via the skin and its systemic absorption may be lethal. Lewisite's major target organs are the skin, eyes, and airways. It causes a burning sensation, painful erythematous inflammation, and blisters on the skin. It leads to inhibition of pyruvate dehydrogenase by binding to the two thiol groups of lipoic acid. Pyruvate dehydrogenase is an enzyme which converts pyruvate to acetyl coenzyme A. Thus, lewisite causes a deterioration in oxidative phosphorylation. It also may lead to oxidative stress, DNA adducts, and apoptosis (Polat et al., 2018).

A no-observed-adverse-effect level (NOAEL) of 0.016 mg/kg/day in rabbits and 1.5 mg/kg/day in rats has been identified. Lewisite is capable of producing DNA damage; however, direct tests of its mutagenic potential have been inconclusive (Datta et al., 2007).

21.8.3 Clinical and pathological findings

Lewisite damages capillary walls; it causes hypovolemia and refractory hypotension. This phenomenon is called "lewisite shock" and causes death. Laboratory tests of the blood of persons exposed may show hemoconcentration; animal studies suggest elevated liver enzymes, including lactate dehydrogenase (Polat et al., 2018; Susan et al., 2019) (Fig. 21.3).

21.9 Inorganic arsenic

Arsenic is a metalloid belonging to group VA of the periodic table. It exists in three oxidation states: metalloid (0), trivalent (−3 or +3), and pentavalent (+5). The most common inorganic trivalent arsenic compounds are arsenic trioxide, sodium arsenite, and sodium trichloride. Pentavalent inorganic arsenic compounds are arsenic pentaoxide, arsenic acid, and arsenate, for example, lead arsenate and calcium arsenate. In general, the toxicity of arsenic compounds is in the following order: arsine > arsenites > arsenates > organic > elemental (Sattar et al., 2016).

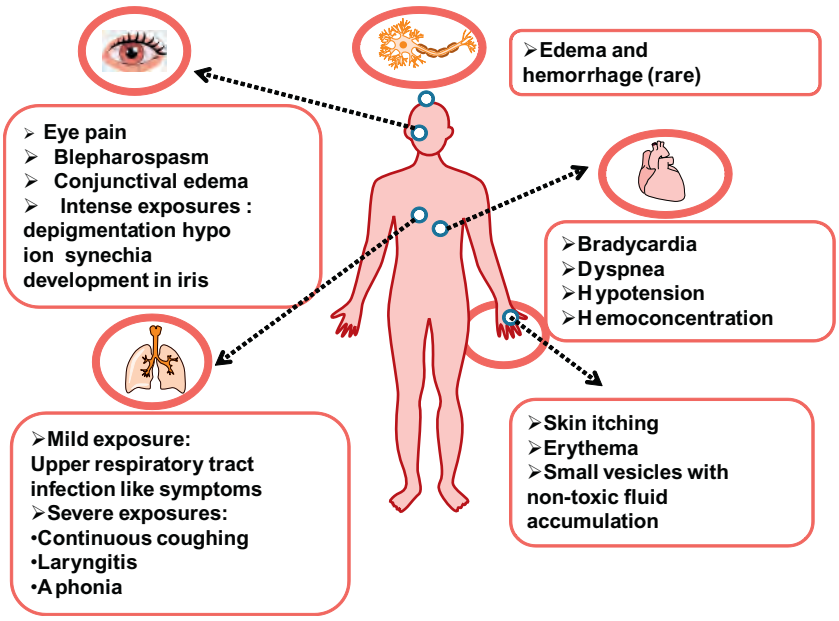


FIGURE 21.3 Lewisite toxicity in various organs.

21.9.1 Sources and uses

21.9.1.1 Uses

Arsenic is used as a bronzing and decolorizing agent in the manufacture of glass, and in the production of semiconductors (Tanaka, 2004), as a desiccant and defoliant in agriculture, and is a byproduct of the smelting of nonferrous metals, particularly gold and copper, from coal residues (Hall, 2002).

21.9.1.2 Exposure

Arsenic exposure occurs from inhalation, absorption through the skin, and primarily by ingestion of arsenic-contaminated drinking water. The exposure may come from natural sources, industrial processes (semiconductor manufacturing), commercial products, food, or medicines (Kosnett, 2013). Acute arsenic poisoning is limited to homicidal or suicidal attempts.

21.9.2 Toxicokinetics

Respiratory absorption of arsenic is a two-stage process, involving deposition of the particles on to airway and lung surfaces, followed by absorption of arsenic from deposited particulates. Trivalent and pentavalent inorganic arsenic have been reported to cross the placenta in laboratory animals and humans. The main form of arsenic bound to rat hemoglobin is dimethylarsinic acid (DMA), the primary metabolite of inorganic arsenic (Lu et al., 2004).

Exposure to either arsenite or arsenate leads to an initial accumulation in the liver, kidneys, and lungs. There have been many reports of arsine poisoning in workers. Findings indicate induction of acute kidney injury by arsine. The evidence suggests incidents of acute arsine poisoning are complicated by acute kidney injury (Lee et al., 2013). Clearance from these tissues is rapid, and long-term retention of arsenic is seen in hair, skin, squamous epithelium of the upper gastrointestinal tract, epididymis, thyroid, lens, and skeleton. Arsenic metabolism is characterized by two types of reaction: (1) reduction of the pentavalent arsenic to trivalent arsenic which is catalyzed by arsenate reductase (Radabaugh et al., 2002), and (2) oxidative methylation reactions in which trivalent forms of arsenic are sequentially methylated to form mono-, di-, and trimethylated products using *S*-adenosyl methionine as the methyl donor and GSH as an essential co-factor (Vahter, 2002). Pentavalent arsenic has been reported to be less toxic than inorganic trivalent arsenic. Metabolic methylation had historically been considered as a detoxification process, as shown in Fig. 21.4. Recently, it has been established that trimethylated arsenicals, particularly monomethylarsinous acid [MMA(III)] and dimethylarsinous acid [DMA(III)], which exist as intermediates in the metabolic methylation process of inorganic arsenic in humans (Fig. 21.4) (Mandal et al., 2001), are more active than the parent inorganic arsenic for enzymatic inhibition, cytotoxicity, and genotoxicity. The major route of excretion following exposure to inorganic arsenic is via the kidneys (Csanaky and Gregus, 2005).

21.9.3 Biochemical and toxic effects

21.9.3.1 Hematopoietic

Varieties of hematological abnormalities, basophilic stippling, increased bone marrow vascularity, and rouleau

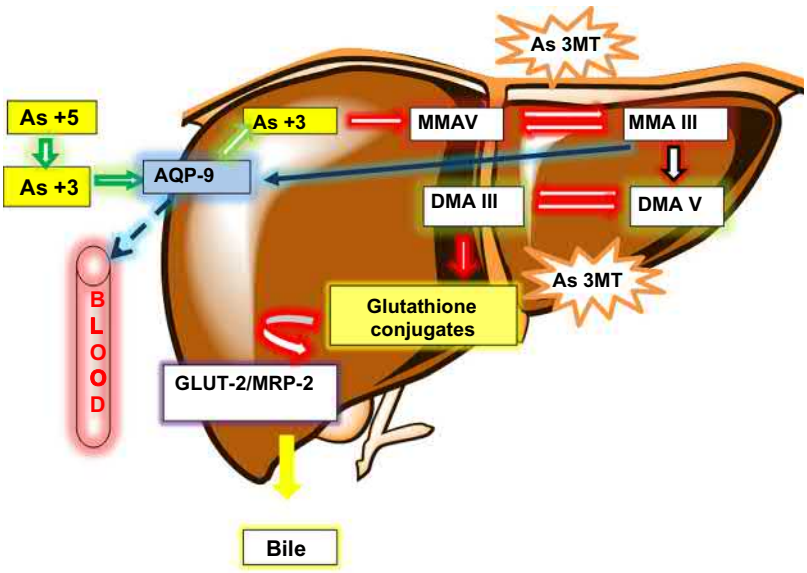

FIGURE 21.4 Detoxification process of arsenic in humans.

formation have been reported. These effects may be due to a direct hemolytic or cytotoxic effect on the blood cells and the suppression of erythropoiesis, and are mediated through depletion of intracellular GSH, resulting in the oxidation of hemoglobin. Subchronic exposure to arsenic affects the heme synthesis pathway (Flora et al., 2002) including inhibition of δ-aminolevulinic acid synthetase (ALA-S) and ferrochelatase activities, leading to increases in uroporphyrin (URO), coproporphyrin, and COPRO urinary excretion. Arsenic alters heme metabolism as shown by an inversion of the urinary COPRO/URO ratio. Profile of urinary porphyrins is recommended as early biomarkers for arsenic toxicity.

21.9.3.2 Skin (dermal)

Arsenic-induced dermal changes include hyperpigmentation, melanosis, hyperkeratosis, warts, and skin cancer (Rossman, 2003). Arsenic-exposed skin cancer occurs mostly in unexposed areas such as the trunk, palms, and soles. The most common skin cancers include Bowen disease, squamous cell carcinomas, basal cell carcinomas, and combined forms. Brittle nails, the surfaces of which are marked by transverse bands (leukonychia striata arsenicalis transverses), are characteristic bands of arsenic and are known as *Reynolds Aldrich-Mees lines*.

21.9.3.3 Hepatic

Arsenic is one of the first chemical agents to which liver disease was attributed in humans. Early symptoms in patients with arsenic-induced hepatic injury include bleeding esophageal varices, ascites, jaundice, or simply an enlarged tender liver. Changes in hepatic enzymes occur on arsenic exposure and these enzyme changes involved in the antioxidant defense system and membrane damage due to lipid per oxidation precede the pathomorphological lesions of arsenic-induced hepatic fibrosis in mice (Flora, 2011).

21.9.3.4 Gastrointestinal

Gastrointestinal symptoms are common during acute poisoning. Gastrointestinal effects due to chronic arsenic poisoning are called arsenicosis. High levels of exposure to arsenic dusts or fumes result in nausea, vomiting, and diarrhea. Patients complain of a metallic taste and garlic odor (Rosenberg et al., 2016). The toxic effects of arsenic on the gastrointestinal mucosal vasculature are vasodilatation, transduction of fluid into the bowel lumen, mucosal vesicle formation, and sloughing of tissue fragments. Rupture of vesicles may cause bleeding, profuse watery stools ("rice-water stools") and protein-losing enteropathy. The most likely mechanism of gastrointestinal toxicity is damage to the epithelial cells, with resulting irritation.

21.9.3.5 Respiratory

Respiratory disease is more common in patients with characteristic skin lesions due to chronic arsenic toxicity (Mazumder et al., 2000). Humans exposed to arsenic dust or fume inhalation often complaint of irritation of the mucous membranes, resulting in laryngitis, bronchitis, rhinitis, and trachea bronchitis, causing a stuffy nose, sore throat, dyspnea, chest pain, and chronic cough (ATSDR, 2000).

21.9.3.6 Cardiovascular

Chronic inhalation of arsenic trioxide may increase the risk of death in humans from cardiovascular disease.

Both acute and chronic arsenic exposure cause altered myocardial depolarization and cardiac arrhythmias that may lead to heart failure. Arsenic causes direct myocardial injury, cardiac arrhythmias, and cardiomyopathy. Two risk genotypes have been recently identified in humans: ApoE and Monocyte Chemotactic Protein-1 (MCP-1). When subjects were exposed to $>10\ \mu g/L$ the risk of carotid atherosclerosis was found to increase by greater than 10-fold (Flora, 2011). Excess intake of arsenic leads to a variety of vascular diseases such as blackfoot disease, Reynaud's phenomenon, cardio- and cerebrovascular diseases, and atherosclerosis (Sattar et al., 2016).

21.9.3.7 Reproductive and developmental

Arsenic readily crosses the placenta and may cause malformations, intrauterine death, and growth retardation. Spermatogenesis and/or sperm function may be impaired by organic arsenicals (Sarkar et al., 2003). Ahmad et al. (2001) observed pregnancy outcomes in women chronically exposed to arsenic through drinking water.

21.9.3.8 Neurological

Arsenic crosses the blood–brain barrier and may lead to alternations in whole rat brain biogenic amine levels in animals (Tseng, 2004). Usually, peripheral neuropathy, sensory neuropathy (Hafeman et al., 2005), and encephalopathy are the initial complaints associated with acute arsenic poisoning (Rodriguez et al., 2003). Other neurological symptoms arising due to arsenic are primarily those of a peripheral sensory neuritis, predominantly numbness, severe paresthesia of the distal portion of the extremities, diminished sense of touch, pain, heat, and cold, and symmetrically reduced muscle power.

21.9.3.9 Diabetes mellitus

Noninsulin-dependent (type II) diabetes is the prevalent form of diabetes mellitus found in populations chronically exposed to inorganic arsenic from the environment (Sattar et al., 2016; Flora, 2011). Type II diabetes is characterized by insulin resistance of internal organs and peripheral tissues that results in impaired glucose utilization, and consequently, in abnormally high blood glucose levels between and especially after meals. Insulin resistance and β-cell dysfunction can be induced by chronic arsenic exposure and these defects may be responsible for arsenic-induced diabetes mellitus.

21.9.4 Mechanisms of toxicity

Arsenic in its free form generates free radicals resulting in lipid peroxidation, depletion of antioxidant enzymes, and DNA damage, thereby establishing oxidative stress as the major mechanism of As-induced toxicity and carcinogenicity (Sattar et al., 2016; Flora, 2011). Arsenite inhibits pyruvate dehydrogenase (PDH) activity, perhaps by binding to the lipoic acid moiety. Inhibition of PDH leads to decreased production of ATP. Inhibition of PDH may also explain in part the depletion of carbohydrates observed in rats administered arsenite. Methylated trivalent arsenicals such as MMA^{III} are potent inhibitors of GSH reductase and thioredoxin reductase. The inhibition may be due to the interaction of trivalent arsenic with critical thiol groups in these molecules. The reduction of arsenate to arsenite occurs in vivo. Another potential mechanism is the replacement of phosphate with arsenate. Oxidative injury causing damage to DNA molecules and various cell components, such as polyunsaturated fatty acid residues of phospholipids, amino acids, peptides, and proteins has been reported as one of the foremost consequences of arsenic exposure as they are susceptible targets of metal-induced ROS attack (Flora, 2011).

21.9.4.1 Oxidative stress

Oxidative stress has now been established as one of the major mechanisms involved in arsenic-induced carcinogenesis. A number of recent reports have provided direct evidence of inorganic arsenic-induced free radical formation or production of oxidative stress (Flora, 2011). Reactive oxygen species (ROS) that damage DNA in vitro are generated from iron released from ferritin. The results suggest that some clastogenic effects of arsenic are mediated via free radicals and could increase the production of ROS, activation of transcription factors (e.g., AP-1, *c-fos*, and NF-κB) and oversecretion of proinflammatory and growth-promoting cytokines, resulting in increased cell proliferation and finally carcinogenesis (Sattar et al., 2016). Increased ornithine decarboxylase activity is often interpreted as a biomarker for cell proliferation. Arsenite appears to have an effect on the cell cycle, which may alter cell proliferation. Amplification of the gene, which codes for the enzyme dihydrofolate reductase, is enhanced by arsenic.

21.9.5 Diagnosis

21.9.5.1 Clinical features

Clinical features like skin lesions and neuropathy are crude and imprecise indicators of the severity of poisoning. White striae in the fingernails are also a useful clue to the diagnosis of arsenic toxicity, these white striae are also known as "Mee's line." Other symptoms include anemia, leucopenia or pancytopenia, gangrene of the feet (blackfoot disease), hyperpigmentation, hypopigmentation, and hyperkeratosis. Keratosis and pigmentation are the characteristic skin lesions associated with arsenic

toxicity. They are typically exhibited by diffuse thickening of the palms and soles, alone or in combination with nodules, and the presence of raindrops in the form of numerous rounded hyperpigmented macules in the body (Mendez et al., 2016; Hunt, 2014). In severe cases, cracks and fissures may be seen in the soles (Ahsan et al., 2009). Leucomelanosis is another common skin lesion, consisting of hypopigmented macules with a spotty white appearance. They are preferable samples to detect and quantify exposure to arsenic, as absorbed arsenic accumulates in both hair and nails, and elevated levels are noted within a few weeks of acute poisoning. The arsenic content of the fingernails and toenails has also been used as a bio-indicator of past arsenic exposure, and fingernail arsenic has been reported to be significantly correlated with hair arsenic content. The segmental growth of the hair shaft also provides valuable information about the duration and type of arsenic poisoning.

Blood arsenic levels are highly variable. Blood arsenic, normally less than 1 μg/dL may be elevated on acute intoxication. This is probably the most important diagnostic test for detecting arsenic exposure. Arsenic metabolites (inorganic arsenic + MMA + DMA) in urine have also been used as biomarkers of recent arsenic exposure. Arsenic is cleared from blood within a few hours after being absorbed. A study showed that acute arsenic poisoning can also be confirmed by speciation analysis of arsenic compounds in the plasma and urine by HPLC-ICP-MS. Multiple blood purification methods can also be used as a combined treatment for acute arsine poisoning (Wu et al., 2010).

Clouded urine is frequently seen in the most severely arsenic-intoxicated patients as absorbed arsenic if primarily excreted through the urine. Increased urinary protein content and aberrant excretion of trace elements also signify enhanced renal dysfunction. Though estimation of urinary arsenic is a consistent biomarker of exposure, it possesses some drawbacks which include accurate sample collection time, the volume of urine to be voided, etc.

21.9.5.2 Other biomarkers

Laboratory tests should include complete blood count, liver and renal functional tests, and blood, nail, and urine arsenic levels. Table 21.2 illustrates various biomarkers for effective diagnosis of arsenic intoxication. Other

TABLE 21.2 Routes of exposure and relevant biomarkers for various arsenic compounds.

#	Compounds of arsenic	Route of exposure	Symptoms/biomarkers	References
Arsine				
		Inhalation	Vertical white lines on nails, discolored brown, red, or black urine, free hemoglobin in urine, red/bronze tint in skin	Pinto et al. (1976), James and Wood (2006)
Organic arsenicals				
1.	Methyldichloroarsine	Dermal exposure	Blistering in skin, "dry-land drowning"	Bennett and Dill (1994), Pitten et al. (1999)
2.	Dlphenylchloroarsine	Inhalation	Irritation in the mucous membranes of eyes and nose, painful blistering in skin	Ochi et al. (2004), Kato et al. (2007)
3.	Ethyldichloroarsine	Dermal, Inhalation	Fluid-filled blisters form in skin, pulmonary edema or "dry-land drowning"	Bartelt-Hunt et al. (2006), Henriksson et al. (1996)
4.	Lewisite	Dermal, Inhalation,	Irritation and blistering of the skin, immediate eye pain and blepharospasm	McManus and Huebner (2005)
Inorganic arsenic				
		Inhalation, dermal, Ingestion	Hyperpigmentation, melanosis, hyperkeratosis, warts, decrease in ferrochelatase, increase in hepatic 5-aminolevelinic acid synthetase activity, pulmonary edema, peripheral neuropathy, sensory neuropathy and encephalopathy, diabetes mellitus, clouded urine, sister chromatid exchange	Hafeman et al. (2005), Woods and Southern (1989), Rossman (2003), Mazumder et al. (2000), Hughes and Kitchin (2006), Ghosh et al. (2006)

biomarkers of arsenic exposure include nonerythrocyte porphyrin enzyme activities and urine transforming growth factor TNF-α, accompanied by induction of heme oxygenase, mitogen-activated protein kinases, the ubiquitin-dependent proteolytic pathway, and protein kinase C in various tissues. These tests are still being investigated in laboratories and their clinical usefulness remains to be proven (Flora, 2011).

Cytogenetic markers, such as chromosomal aberrations, contribute significantly toward detection of this carcinogen. People suffering from chronic arsenicosis have been shown to have increased chromosomal aberrations (Ghosh et al., 2006) and sister chromatic exchange. However, it is still not the most interesting biomarker to detect the early effects of arsenic and is difficult to use on a large scale in epidemiological studies given its cost and difficulty of implementation (Eslava, 2004). The presence of micronuclei (MN) in isolated bladder and buccal cells has been considered as possible target tissues from direct exposure to As from drinking water (Bonassi et al., 2007).

21.9.5.3 Treatment

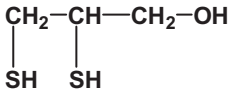
Highly specific treatment is required for poisoning with arsenicals, and there is no specific antidote for the treatment of arsine poisoning. Victims may be administered high-flow oxygen. One of the earlier strategies for the treatment of arsine poisoning involves stopping the ongoing hemolysis which may lead to renal dysfunction. Exchange transfusion is currently the treatment of choice. Chelation therapy generally is not recommended to reduce hemolysis, however chelating agents are shown to reduce arsenic in arsine-exposed subject. Since World War II, dimercapol has been the standard treatment for poisoning by arsenicals. DMPS (unithiol) and DMSA (succimer), dithiol water-soluble analogs of BAL, were mainly used for the chelation treatment of arsenic intoxication for more than half a century (Kosnett, 2013). However, treatment should be initiated as rapidly as possible because delay may result in a reduction of efficacy as the time interval between metal exposure and onset of chelation increases. DMPS and DMSA have a higher therapeutic index than BAL and do not redistribute arsenic or mercury to the brain. Although chelation may accelerate metal excretion, potential therapeutic efficacy in terms of decreased morbidity and mortality is largely not established in cases of chronic metal intoxication. We discuss below the efficacy of chelating agents for treating arsenicals, their drawbacks, and recent advancements in the area.

21.9.6 Chelating agents and chelation therapy

Chelators form a complex with the respective (toxic) ion and these complexes reveal a lower toxicity and are more easily eliminated from the body. This mechanism could be represented as: Metal − In vivo site + Chelating agent → In Vivo site + Metal-Chelating agent complex.

Chelation may thus be defined as the incorporation of a metal ion into a heterocyclic ring structure. Some of the chelating agents listed below have been reported to be useful in the treatment of arsenic.

21.9.6.1 2,3-Dimercaprol (dimercaprol; British antilewisite)



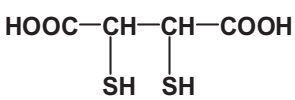
Dimercaprol or 2,3-dimercapto-1-propanaol, commonly referred to as BAL was originally developed to treat the effects of lewisite, namely systemic poisoning and local vesication. The empirical formula of BAL is $C_6H_8OS_2$ and its molecular weight is 124.21. It is an oily, clear, colorless liquid with a pungent, unpleasant smell typical of mercaptans and has a short half-life. The thiol groups present in BAL complex with arsenic and the resultant chelate is eliminated through the urine (Kosnett, 2013).

21.9.6.1.1 Drawbacks

BAL−arsenic complexes when oxidized result in the release of arsenic, which is detrimental to the system. In addition to rapid mobilization of arsenic from the body, it causes a significant increase in brain arsenic (Flora and Pachauri, 2010) and is also associated with nephrotoxicity, hypertension, tachycardia, and poor therapeutic index. Due to its oily nature, BAL requires deep intramuscular injection, which is extremely painful and causes an allergic reaction.

Two water-soluble analogs of dimercaprol have also been studied as lewisite antidotes. These are meso 2,3-dimercaptosuccinic acid (DMSA) and 2,3-dimercapto-1-propane sulfonic acid (DMPS). These two drugs circumvent two major disadvantages associated with treatment with BAL, that is, the need for intramuscular injection and limitation of dose by toxicity.

21.9.6.2 Meso 2,3-dimercaptosuccinic acid



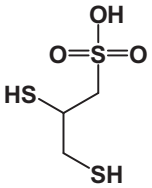
Another widely employed arsenic chelator is DMSA, which has low toxicity and does not redistribute arsenic to other organs. It chelates arsenic through two thiol groups. The empirical formula of DMSA is $C_4H_6O_4S_2$

and its molecular weight is 182.21. It is a weak acid and is soluble in water.

21.9.6.2.1 Drawbacks

Its use is limited by its inability to cross the cell membrane and hence it is not capable of chelating arsenic from intracellular compartments. Additional side effects such as gastrointestinal problems, placid neutropenia, elevated liver enzymes, and skin allergies have also been attributed to meso-DMSA administration (Susan et al., 2019).

21.9.6.3 Sodium 2,3-dimercaptopropane-1-sulfonate



DMPS, first introduced as "Únithiol" as a BAL analog, has the empirical formula $C_3H_7O_3S_3Na$ and molecular weight 210.3. It is a water-soluble derivative of BAL and has emerged as effective therapy against arsenic. It employs an organic anion transport pathway to permeate into the cell and form an insoluble complex with arsenic (Polat et al., 2018).

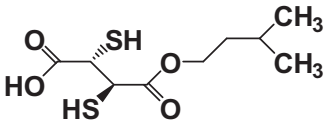
21.9.6.3.1 Drawbacks

Though no major adverse effects have been reported with the use of DMPS, mild effects such as headache, nausea, taste impairment, pruritis, and skin allergies have been reported. However, a dose-dependent decrease in copper content was found in the serum, liver, kidneys, and spleen (Susan et al., 2019). Oral administration of DMPS did not adversely affect late gestation, parturition, or lactation in mature mice or fetal and neonatal development.

21.9.6.4 Monoesters of meso 2,3-dimercaptosuccinic acid

Recently some mono- and diesters of DMSA, especially the higher analogs, have been developed and tested against experimental heavy metal poisoning to address the shortcomings of DMSA, particularly in depleting intracellular arsenic (Flora et al., 2007b,c; Flora, 2011). Derivatives of DMSA with better permeability across cell membranes have been developed and are currently in different phases of clinical and preclinical trials. These include monoisoamyl DMSA (MiDMSA), monocyclohexyl DMSA (MchDMSA), and monomethyl DMSA (MmDMSA) (Flora, 2011; Susan et al., 2019).

21.9.7 Monoisoamyl DMSA



MiADMSA is a lipophilic derivative that retains high affinity for arsenic as its parent compound. It chelates arsenic through the sulfhydryl groups and does not redistribute the same to other organs. Its lipophilic nature enables it to chelate both extracellular as well as intracellular arsenic. It has also been found to reverse arsenic-induced oxidative stress and neurotoxicity. Monoisoamyl DMSA (MiADMSA) is a new and one of the most effective of the vicinal class of metal-mobilizing agents (Flora, 2011). No reports are available for the therapeutic efficacy of MiADMSA against lewisite toxicity and other arsenicals. However, we reported the effect of MiADMSA on the reversal of gallium arsenide (GaAs)-induced changes in hepatic tissue (Flora et al., 2002). MiADMSA was found to be better than DMSA in mobilizing arsenic and in the turnover of the GaAs-sensitive biochemical variables. Plasma kinetics of MiADMSA (plasma-free drug and total drug) at 50 and 100 mg/kg p.o. was carried out. MiADMSA at a 50 mg/kg dose administered orally provided about 45% and 75% protection against oxidative stress and in lowering body arsenic burden. Also, pharmacokinetic analysis supported prolonged availability of the drug through oral administration. Collectively, these findings led to the conclusion that oral administration of MiADMSA was more effective than intraperitoneal administration and that the minimum effective dose with the least side effects was 50 mg/kg (Flora et al., 2012).

Arsenic-induced free radical generation in rat neuronal cells, leading to diminished mitochondrial potential and enzyme activities of all the complexes of the electron transport chain responded favorably to the treatment of MiADMSA (Dwivedi et al., 2011). MiADMSA significantly reversed the As-induced alterations in behavior and biochemical variables suggestive of oxidative injury. Arsenic-exposed rats showed significant differences in behavioral functions and water maze learning. Arsenic toxicity leads to various skin manifestations and arsenic accumulation in keratinized tissue. Pretreatment of HaCaT cells with MiADMSA elicited significant protection against arsenic-induced oxidative stress and apoptotic cell death in vitro. The findings are of clinical relevance and suggest MiADMSA to be a promising candidate in protecting skin against arsenic-induced toxic effects (Pachauri et al., 2013). Human embryonic stem cell-derived embryoid bodies were used to test the efficacy of MiADMSA against arsenic poisoning. It was concluded that the data generated using human ES cells are highly

comparable with the in vivo animal model. The efficacy of MiADMSA against arsenic is mainly attributed to the ability of formation of an adduct utilizing the sulfhydryl and carboxyl groups (Flora and Mehta, 2009).

The above results suggest that MiADMSA may be a future drug of choice owing to its lipophilic character and the absence of any metal redistribution. However, significant copper loss requires further studies (Mehta et al., 2006). Moderate toxicity after repeated administration of MiADMSA may be reversible after the withdrawal of the chelating agent.

21.9.7.1 Drawbacks

It is reported that the toxicity of DMSA, with an LD_{50} of 16 mmol/kg, is much lower than the toxicity of MiADMSA with an LD_{50} of 3 mmol/kg but lower than BAL (1.1 mmol/kg). However, mild side effects such as depletion of the essential metal ion pool including copper and zinc in the body and induction of mild anemia have been reported with MiDMSA and some biochemical alterations to the hepatic tissue in female as compared to male rats (Mehta et al., 2006).

21.9.7.2 Role of antioxidants

Oxidative stress can be partially implicated in arsenic toxicity and a therapeutic strategy to increase the antioxidant capacity of cells may fortify the long-term effective treatment of arsenic poisoning. This may be accomplished by either reducing the possibility of metal interacting with critical biomolecules and inducing oxidative damage, or by bolstering the cells' antioxidant defenses through endogenous supplementation of antioxidant molecules (Susan et al., 2019; Flora et al., 2013). Although many investigators have confirmed arsenic-induced oxidative stress, the usefulness of antioxidants along or in conjunction with chelation therapy has not been extensively investigated yet. N-acetylcysteine (NAC) is a thiol, a mucolytic agent, and a precursor of L-cysteine and reduced glutathione. NAC is a source of sulfhydryl-containing antioxidant that has been used to mitigate various oxidative stress conditions. Combined administration of NAC and succimer post arsenic exposure led to a significant recovery in biochemical variables indicative of oxidative stress and arsenic depletion from soft organs (Flora, 2011; Kannan and Flora, 2006). Various vitamins have been found to reduce the toxic manifestation of heavy metals (Flora, 2011; Flora et al., 2013). It was observed that vitamin E prevented the arsenite-induced killing of human fibroblasts. The protective mechanism of vitamin E could be attributed to its antioxidant property or its location in the cell membrane and its ability to stabilize membrane by interacting with an unsaturated fatty acid chain. The results suggested that vitamin C was better at providing clinical recoveries and vitamin E was equally efficient in decreasing the arsenic burden from tissues. An interesting study by Wei et al. (2005) reported the involvement of oxidative stress in DMA-induced bladder toxicity and proliferation in rat, and inhibitory effects of vitamin C on these alterations.

The influence of the coadministration of vitamin C or vitamin E was investigated upon the efficacy of two thiol chelators, DMSA or monoisoamyl DMSA, in combating chronic arsenic toxicity. Combined administration of vitamin C plus DMSA and vitamin E plus MiADMSA led to a more pronounced depletion of brain arsenic. Also, supplementation of vitamins led to a significant restoration of inhibited blood δ-aminolevulinic acid dehydratase (ALAD) activity and other oxidative stress parameters in liver, kidneys, and brain. These results suggested that coadministration of vitamin E or vitamin C may be useful in arsenic poisoning, although it has only a limited role in depleting arsenic burden. In another study, alpha-lipoic acid has been shown to have substantial antioxidant properties, when administered (70 mg/kg body weight) once daily for 60 days along with arsenic. The effect of alpha-lipoic acid on arsenic-induced oxidant production and lipid peroxidation level (LPO) in discrete brain regions of rats was also examined. The cortex, hippocampus, and striatum exhibited a greater increase of LPO levels than the cerebellum and hypothalamus. Also, simultaneous lipoic acid treatment along with arsenic proved to be sufficient in reducing oxidant production and the LPO level in all rat brain regions. In summary, the study demonstrated that arsenic-induced deficits in brain regions can be overcome through simultaneous treatment with lipoic acid (Shila et al., 2005). Garlic is another well-known folk remedy for a variety of ailments, however, very few studies are available suggesting its beneficial role against arsenic toxicity. In a study by Flora et al. (2009), the protective efficacy of aqueous garlic extract on parameters suggestive of hepatic injury, tissue oxidative stress, and mobilization of arsenic was investigated using two different doses. The results suggested that garlic extracts have a strong antioxidant property which could be beneficial in preventing arsenic-induced toxicity in cells. A study was conducted in rabbits to assess the oxidative injuries caused by arsenic toxicity and to evaluate the detoxifying effects of exogenous antioxidants, vitamins, zinc, selenium, or a plant polyphenol. The results indicated that arsenic induces toxicity in rabbits associated with an increase in lipid peroxidation and nitric oxide production in the body.

Administration of exogenous antioxidants such as polyphenols and recipe of vitamins, zinc, and selenium, however, was found to be useful for arsenic detoxification (Rabbani et al., 2003). Taurine (2-aminoethanesulfonic acid) has also been shown to exert a protective effect against arsenic-induced cytotoxicity in murine hepatocytes.

The cytoprotective activity of taurine against arsenic poisoning was found to be comparable to that of a known antioxidant, vitamin C. This further suggests that taurine protects mouse hepatocytes against arsenic-induced cytotoxicity (Sinha et al., 2007). Among various herbal extracts, *Moringa oleifera* (*M. oleifera*) seed powder also has been shown to restore arsenic-induced oxidative stress and reduce body arsenic burden. Hence it was concluded that concomitant administration of *M. oleifera* seed powder with arsenic could significantly protect against arsenic-induced toxic manifestations and thus could also be beneficial during chelation therapy with a thiol chelator (Susan et al., 2019). Concomitant oral supplementation of *Centella asiatica* (100, 200, or 300 mg/kg, orally once daily) during arsenic exposure (20 ppm in drinking water for 4 weeks) has also been shown to be an effective strategy against arsenic toxicity. More extensive studies are recommended for determining the effect of coadministration of *C. asiatica* during chelation therapy with a thiol chelator (Gupta and Flora, 2006).

Not only altered biochemical variables, but supplementation of antioxidants has also led to alleviation of arsenic-induced molecular alterations. Contamination of arsenic in drinking water is associated with several human diseases including cancer. In one study, a significant increase in the levels of protein oxidation, DNA strand breaks, and DNA−protein cross-links was observed in the blood, liver, and kidneys of rats exposed to arsenic (100 ppm in drinking water) for 30 days. However, upon coadministration of ascorbic acid and alpha-tocopherol to arsenic-exposed rats, a substantial reduction in the levels of arsenic-induced oxidative products of protein and DNA was seen. The results support the fact that free radical generation is one of the major mechanisms of arsenic-induced toxic manifestations and also suggest that ascorbic acid and alpha-tocopherol supplementation can improve the arsenic-induced molecular alterations (Kadirvel et al., 2007). Cardiac dysfunction has been shown to be associated with arsenic toxicity, which results in reduced cardiomyocyte viability, increased ROS production and intracellular calcium overload, and induced apoptotic cell death by mitochondrial dependent caspase-3 activation and poly-ADP ribose polymerase (PARP) cleavage. All these changes were found to be associated with increased IKK and NF-kappaB (p65) phosphorylation. Arsenic also markedly elevated the activity of p38 and JNK MAPKs. Taurine effectively suppressed these apoptotic actions, suggesting its protective role by attenuation of p38 and JNK MAPK signaling pathways. The results suggest that taurine effectively prevented arsenic-induced myocardial pathophysiology, attenuated NF-kappaB activation via IKK, p38, and JNK MAPK signaling pathways, and hence could be an effective therapy against As-induced cardiovascular burden (Flora, 2011; Susan et al., 2019).

21.10 Combination treatment

In an effort to improve the therapeutic index of the chelating agents, a combination of these agents has also been investigated. A combination of DMSA and MiDMSA was found to effectively abrogate the deleterious effects of arsenic exposure in guinea pigs. The combination was able to reverse oxidative stress-induced calcium influx in neurons either by deactivation of L-type calcium ion channels or scavenging calcium ions. Recently, MiDMSA was encapsulated in 50-nm polymeric nanoparticles and was found to be more efficient in mitigating the adverse effects of arsenic-induced toxicity in rodent models. Research has also revealed that zinc and selenium have the ability to increase the elimination of arsenic, thereby reducing the toxic manifestations of arsenic. Hence, concomitant administration of these ions with the chelating agents has also been attempted as a therapeutic stratagem (Susan et al., 2019).

As discussed above, metal chelators are given to increase the excretion of arsenic but, unfortunately, the uses of these chelators are comprised by a number of drawbacks. These drawbacks have opened the search for new treatments that have no side effects. A number of strategies have been discussed (Kalia and Flora, 2005). Among these strategies, combination therapy is a new and a better approach to treat cases of metal poisoning (Flora et al., 2007c; Mishra et al., 2008). In one study, we investigated whether coadministration of thiol chelators, like DMSA or sodium 2,3-dimercaptoprpane 1-sulfonate (DMPS), along with a newly developed thiol chelator, monoisoamyl DMSA, is more beneficial than monotherapy with these chelators, in counteracting chronic arsenic toxicity (Flora, 2011). It was concluded that concomitant administration of DMSA, a chelator known for its extracellular distribution with lipophilic chelators like MiADMSA, could play a significant and important role in abating a number of toxic effects of arsenic in animals compared to treatment with these chelators alone. We suggested that analogs with a long carbon chain (MiADMSA and MchDMSA) are better chelators than those with shorter carbon chains (MmDMSA) or DMSA. It is assumed that analogs of DMSA eliminate arsenic simultaneously from the cell and provide assistance in bringing GSH homeostasis toward normalcy. Further combinational therapy with DMSA and MiADMSA or MchDMSA proved more beneficial than combined treatment with MmDMSA and DMSA (Mishra et al., 2008).

Generation of ROS is one of the major mechanisms for arsenic-mediated oxidative stress; therefore, a study was conducted to explore the kinetic relationship of ROS with calcium and to dissect the calcium ion channels responsible for calcium imbalance after arsenic exposure. Another crucial aspect investigated was whether mono- or

combinational chelation therapy prevents arsenic-induced neuronal apoptosis in guinea pigs. The results indicated that arsenic caused a significant increase in ROS followed by NO and calcium influx, which was mainly dependent on L-type voltage-gated channels that disrupt mitochondrial membrane potential, and increase bax/bcl2 levels and caspase-3 activity leading to apoptosis. Another interesting and useful finding was that combinational therapy of DMSA and MiADMSA was most effective in reversing arsenic-induced alterations. The results provide strong evidence for the role of L-type calcium channels in regulating arsenic-induced calcium influx and that DMSA + MiADMSA combinational therapy may be a better and much more effective strategy than monotherapy in mitigating chronic arsenicosis (Pachauri et al., 2013).

As only few experimental evidences are available, there is a need for in-depth investigation in this area. It is thus proposed to investigate the effects of combination therapy, particularly in the case of chronic arsenic poisoning, where a strong chelating agent is administered along with another structurally different chelating agent (Kalia and Flora, 2005) to evaluate whether combination treatment is able to promote the elimination of arsenic and restore arsenic-induced biochemical and clinical alterations.

21.11 Concluding remarks and future directions

The use of arsenicals remains a potential threat as they are relatively easy to manufacture and may cause significant morbidity and mortality. Lewisite is one of the arsenicals that has not been studied in detail with very little information available on the detailed toxic effects of organic arsenicals, particularly carcinogenicity, mutagenicity, and teratogenicity. It is an organic arsenical war gas which is a vesicant that has been reported for its ability to bind with a thiol group leading to the possibility of its undesirable effects on a variety of enzymes. Thus there is a very strong possibility that exposure to lewisite might also lead to carcinogenic effects, however this hypothesis requires experimental and epidemiological evidence. It is not known whether lewisite is persistent. However, arsenic is an elemental poison and any residual hydrolysis, combustion, and decontamination product is likely to contain an arsenical compound. Some of the major thrust areas for future research directions include the possibility of a delayed or latent effect arising after organic arsenical (particularly lewisite) exposure. These effects, despite having been studied in detail recently after inorganic arsenic exposure, have very little information available after organic arsenical exposure. The development of antidotes is another area which requires immediate attention. Although one approved antidote, BAL, is available for lewisite, further investigations are required with other derivatives of BAL such as DMSA, DMPS, or monoesters of DMSA like MiADMSA. Chelators are generally not of any immediate benefit as far as toxicity of arsine and once hemolysis has begun. With some new chelating agents at experimental stages like MiADMSA, the effectiveness and safety results of these chelating agents against arsine poisoning is needed. The toxicodynamics of arsine is also an area which requires exploration as this information would be of immense help in developing suitable antidotes, particularly regarding hemolysis by removing or displacing arsine (Fig. 21.5).

Inorganic arsenic, particularly arsenic (III), is a well-documented potent carcinogen causing cancer of the bladder, lung, skin, and, possibly, liver and kidney. Because of failures in the attempts to study the carcinogenic effects of

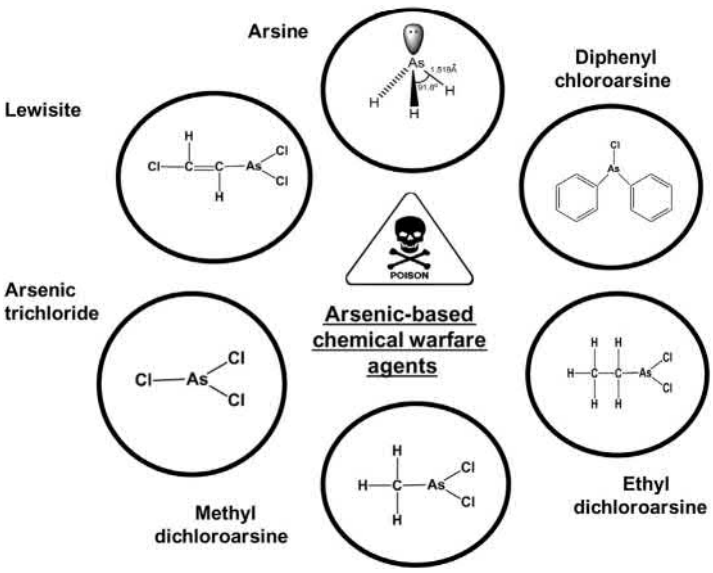


FIGURE 21.5 Arsenic-based chemical warfare agents.

arsenic in animal models, the mechanism of arsenic-induced carcinogenic effects remains unclear. The newly discovered potency of trivalent methylated arsenic metabolites opens up new opportunities for mechanistic studies. No treatment of proven benefit is currently available to treat chronic exposure. Treatment options advocated are vitamins, mineral supplements, and antioxidant therapy. The benefits of these treatment measures need to be evidence-based to receive endorsement and wider application. Further research work is also recommended in the areas of (1) the molecular mechanism of action of clinically important chelators, (2) intracellular and extracellular chelation in relation to the mobilization of aged arsenic deposits and the possible redistribution of arsenic to sensitive organs such as the brain, (3) the effect of metal chelators on biokinetics during continued exposure to arsenical, (4) combined chelation with lipophilic and hydrophilic chelators, (5) the use of antioxidants, micronutrients, or vitamins as complimentary agents or antagonists, (6) minimization of the mobilization of essential trace elements during long-term chelation, and (7) the fetotoxic and teratogenic effects of chelators.

Chapter 22

Chlorine

Sylvia Milanez
Oak Ridge National Laboratory, Oak Ridge, TN, United States

22.1 Introduction

Chlorine is a contact irritant in both humans and animals, and the respiratory tract is the primary initial target organ, with higher exposures affecting multiple internal organs. Very little chlorine gas exists in the environment due to its high reactivity and degradation by sunlight (Hov, 1985). Chlorine and sodium hydroxide are coproduced by the electrolysis of brines (the chlor-alkali process) using mercury, membrane, or diaphragm cells. The ion exchange membrane cell has become the predominant process, for economic and environmental reasons, and ~81% of global chlor-alkali capacity used membrane cell technology in 2017 (Burridge, 2005; CEH, 2018). Worldwide, there are over 500 chlor-alkali producers at over 650 sites, with an annual chlorine production capacity of 58 million tons (World Chlorine Council, 2012). Chlorine is one of the top 10 production volume chemicals in the United States, with over 10 million tons produced in 2010 and nearly that amount also produced in Europe in 2017 (U.S. Census Bureau, 2011; Euro Chlor, 2018).

Chlorine gas (Cl_2) has a pungent, suffocating odor and forms a greenish-yellow cloud near the ground when released in the environment due to its high vapor density (Rumble, 2018; O'Neil et al., 2013). The Cl_2 odor detection threshold varies considerably among humans. The mean value is approximately 0.2−0.4 ppm but values as low as 0.06 ppm have need detected, although odor perception tends to decrease over time (NIOSH, 1976; ATSDR, 2010). Chlorine gas is slightly water-soluble (~4.4 g/L; O'Neil et al., 2013), but it reacts quickly with water to form hydrochloric acid (HCl) and hypochlorous acid (HOCl). Selected chemical and physical properties of Cl_2 are listed in Table 22.1.

22.2 History of use and human exposure

Despite its potential hazards, chlorine continues to be produced, transported, and used in great quantities worldwide due to its great utility industrially and as a water disinfectant (Jones et al., 2010). The major uses of Cl_2 are in the manufacture of polyvinyl chloride and other plastics, chlorinated solvents, and pharmaceuticals; as a bleaching agent and biocide in pulp and paper production; and in water purification and waste treatment systems (Evans, 2005; CEH, 2018). Chlorine has been used as a water disinfectant in the United States since the early 1900s, dramatically cutting the death rate from typhoid fever (Toren and Blanc, 1997; Evans, 2005).

Use of chlorine gas as a chemical warfare agent began during World War I. The most notable release occurred near Ypres, Belgium, on April 22, 1915, when over 150 tons of chlorine gas were released in 5 min, killing an estimated 800 soldiers and incapacitating 2500−3000 others (Joy, 1997). Its use as a warfare agent declined after World War I because chlorine gas has significant warning properties (i.e., color and odor), allowing relatively easy avoidance to exposure. Its common use and availability, however, have made it easy to obtain in sufficient quantities to cause mass casualties in recent geopolitical conflicts. Chlorine gas has been used by terrorists in the Iraq war, with bombs being rigged to chlorine tanker trucks or cylinders intended for use in water treatment or for other industrial purposes (Wetz et al., 2007). More recently, chlorine gas has been used against both civilian and military targets in the war in Syria, where it was deployed in car or truck bombs or fired in rockets (Johnston, 2017; Devi, 2018; OPCW, 2014).

Accidental exposures to chlorine gas have occurred during its use as a water and surface disinfectant, and during its production and transport (primarily by rail). One of the deadliest accidents occurred on January 2005 in Graniteville, South Carolina, where nine people died and nearly 600 required medical attention when a chlorine tank ruptured from a train collision (Van Sickle et al., 2009; Jones et al., 2010; Mackie et al., 2014). Sites of recent documented human exposures included a

Water solubility	4.4 g/L at 25°C	O'Neil et al. (2013)

wastewater treatment plant (Bellenger and Frizzi, 2014); a metal recycling facility (Harvey et al., 2018); a factory handling chlorine (Kim et al., 2014); and public swimming pools (Vajner and Lung, 2013; Matos et al., 2017). Healthcare workers at Ebola treatment centers in Africa who were exposed to excessive chlorine gas from its use as a disinfectant developed respiratory, eye, and skin disease (Carpenter et al., 2016; Mehtar et al., 2016). A review of the literature from 2007 to 2017 by Tuong et al. (2019) described hundreds of cases of accidental chlorine exposure.

Brzozowska (2016) conducted computer simulations of the impact of a chlorine tanker truck collision that released 10 tons of chlorine into the atmosphere on a bypass in the city of Bielsko-Biała, Poland. The simulations indicated that depending on the wind direction, there could be over 22,000 people injured and up to 5000 fatalities. Fatemi et al. (2017) assessed the impacts on surrounding residents of a simulated nighttime chemical release of 1 ton of chlorine over a 1-h period from a warehouse in Ray, Iran. The number of affected people by chlorine release in the spring, summer, autumn, and winter was estimated as 22,500, 25,000, 28,100, and 27,500, corresponding to chlorine dispersal distances of 8.3, 8.8, 7.6, and 6.4 km, respectively. To assist in validating models for decision response and risk mitigation, Sohn et al. (2019) conducted a series of experimental releases of pressurized chlorine gas to examine indoor−outdoor exchange, transport through a multiroom structure, and the first-order loss rate due to reaction or sorption.

22.3 Absorption, distribution, metabolism, and excretion

The vast majority of inhaled chlorine (>90%) is absorbed via the respiratory tract in humans and animals (Nodelman and Ultman, 1999a,b; Morris et al., 2005; Abdel-Rahman et al., 1983). Human studies showed that >95% of an inhaled bolus of 0.5−3 ppm chlorine was absorbed in the upper airway and <5% in the lower airway, regardless of the mode of breathing or respiratory flow rate (Nodelman and Ultman, 1999a,b). Absorbed chlorine is not subject to metabolic biotransformation, and it joins the endogenous pool of chloride ions distributed largely in the extracellular pool throughout the body. Using an in vivo neutron activation analysis system, Mohseni et al. (2016) determined that the short-term kinetic behavior of chlorine (^{36}Cl) in the human hand followed an exponential function corresponding to the rapidly exchangeable pool, with a mean redistribution half-life of 24.2 ± 8.5 min. Rats that were orally administered H^{36}Cl in distilled water excreted the majority of ^{36}Cl in the urine (36.43%) and feces (14.80%) over a 96-h postexposure period (Abdel-Rahman et al., 1983).

22.4 Mechanistic studies

In both humans and animals, the respiratory tract is the primary initial target organ for inhaled chlorine, which exists predominantly as HOCl and the hypochlorite ion (OCl^-) in the fluid lining the respiratory tract surface (O'Neil et al., 2013; ATSDR, 2010; Squadrito et al., 2010). It is believed that chlorine toxicity is due to its oxidant properties, and is mediated largely by the hypochlorite ion (Morris et al., 2005; ATSDR, 2010). An alternative model has proposed that Cl_2 itself can react with biomolecules in the epithelial lining fluid in the respiratory tract, and may be able to penetrate the lung surface (Squadrito et al., 2010). This hypothesis was based on a kinetic analysis that found that the reaction rate of chlorine with water was several orders of magnitude lower than its reaction rate with low-molecular-weight antioxidants and N-terminal functions of peptides and proteins in lung epithelial fluid (Squadrito et al., 2010).

Inhaled chlorine reacts with the epithelial lining of the airways and lungs. Depending on the chlorine exposure concentration and duration, respiratory toxicity can be manifested as sensory irritation, increased airway resistance, and respiratory tract lesions (Withers and Lees, 1985; Bitron and Aharonson, 1978). In rats and mice, chlorine sensory irritation decreases the respiratory rate by stimulating the trigeminal nerve endings in the respiratory mucosa (Alarie, 1981). A mouse model for the mechanism by which chlorine exposure causes reactive airways dysfunction syndrome (RADS) was developed by Jonasson et al. (2013a). Numerous rodent studies showed that acute chlorine exposure can cause lung fibrosis, leading to long-term impairment of lung function (Yildirim et al., 2004; Musah et al., 2012, 2019; O'Koren et al., 2013; Mo et al., 2013; Jonasson et al., 2013b; Wigenstam et al., 2016).

In addition to causing epithelial injury, the presence of HCl and HOCl in the airways causes an inflammatory response. The recruited neutrophils and macrophages increase the local concentration of nitric oxide (NO) and H_2O_2, which can react with HOCl and HCl to produce hydroxyl radicals and reactive intermediates able to nitrate, chlorinate, and dimerize aromatic amino acids (Olin et al., 1999; Evans, 2005; Jones et al., 2010). Chemically induced neutrophil depletion, but not eosinophil or macrophage depletion, abolished airway hyperresponsiveness (AHR) in large airways and prevented increases in antioxidant gene expression and NRF2 nuclear translocation in mice (McGovern et al., 2015). Ano et al. (2017) showed that Nrf2-dependent phase II enzymes (NQO-1 and GPX2) are involved in the resolution of airway inflammation and AHR after acute exposure to Cl_2 (5 min at 100 ppm). Glutathione deficiency exacerbated the acute inflammation but not AHR. Upregulation of UPR signaling (protein kinase RNA-like endoplasmic reticulum kinase, inositol-requiring enzyme 1a, activating transcription factor 6a) and expression of hepcidin was seen in the lungs and skin of mice within 6 h of exposure (Li et al., 2013). Chlorine-exposed mice had lung hyaluronan damage, manifested as an increase in low-molecular-weight fragments (L-HA, $<$300 kDa) in bronchoalveolar lavage (BAL) fluid, which was proposed to cause oxidative lung injury leading to AHR (Lazrak et al., 2015). Acute chlorine exposure caused impaired lung surfactant function, neutrophilia, altered BAL phospholipid content, and increased pulmonary elastance in mice (Massa et al., 2014). Coagulation abnormalities were proposed to play a role in chlorine-induced lung damage, as treatment with heparin reversed increases in protein levels and inflammatory cells in the BAL of mice (Zarogiannis et al., 2014).

The heart was identified as a target organ following chlorine exposure in humans and animals, and in ex vivo myocyte cultures (Carlisle et al., 2016). A follow-up study of people living in the area affected by the Graniteville, South Carolina, chlorine spill found an increase in hypertension-related hospital discharge rates (Howell et al., 2019). Acute exposure studies with rats (400−600 ppm for 27−30 min) showed cardiotoxic effects including increased lactate in the coronary sinus, decreased systolic and diastolic blood pressure, left ventricular systolic and diastolic dysfunction, and biventricular failure (Zaky et al., 2015); decreased cardiac output (Okponyia et al., 2018); and bradycardia accompanied by increased blood hemoglobin, red blood cells, hematocrit, and fibrin (Luo et al., 2014). Primary cardiomyocyte cultures showed decreased total ATP content and loss of sarcoendoplasmic reticulum calcium ATPase (SERCA) activity due to chlorination of tyrosine residues and oxidation of cysteine-674 (Ahmad et al., 2015). Cell death and inhibition of SERCA were decreased by added thiocyanate, genetic SERCA2 overexpression, and pretreatment with SERCA activators ranolazine and istaroxime.

Biomarkers of Cl_2 inhalation exposure were identified in studies with rats and mice. These included 8-isoprostane in airways and blood (Elfsmark et al., 2018), chlorinated lipids 2-chloropalmitaldehyde, 2-chlorostearaldehyde, 2-chloropalmitic acid, and 2-chlorostearic acid in the lungs and plasma (Ford et al., 2016); and phosphatidylglycerol chlorohydrins in BAL (Hemstrom et al., 2016). The ratio of nitric oxide (eNO) to carbon dioxide (eCO_2) levels in exhaled breath was diagnostic of the degree and time-course of pulmonary injury in rats exposed to chlorine gas (Luo et al., 2014). Other biomarkers included hemoconcentration (increased hemoglobin, red blood cells, and hematocrit) and increased BAL protein levels.

In vitro mechanistic studies with bacteria and mammalian cells have led to various theories for the chlorine mechanism of action, including direct interaction of chlorine or hypochlorite with enzymes, other proteins, and nucleotide bases, and disruption or degradation of cell membrane structure and function (U.S. EPA, 1994). Chlorine was proposed to cause systemic endothelial dysfunction by inhibiting endothelial nitric oxide synthase (eNOS)-dependent signaling, based on its inhibition of eNOS-dependent vasodilation in isolated rat aortas (Honavar et al., 2011). Pulmonary arteries (PA) isolated from chlorine-exposed rats had increased superoxide formation and inhibition of NO-dependent vasodilation, whereas chlorine-treated rats had decreased PA pressure that was reversed by the iNOS inhibitor 1400W (Honavar et al., 2014a). This suggests that disruption of NO signaling that maintains PA tone plays a role in postexposure toxicity. Upregulation of autophagy mitigated mitochondrial damage in NCI-H441 cells exposed to chlorine gas, and was negated by pretreatment with the autophagy inhibitor methyladenine (Jurkuvenaite et al., 2015).

22.5 Toxicity

The predominant and most sensitive target of chlorine is the respiratory tract, although it can also damage the skin, eyes, and internal organs at sufficiently high exposures (Evans, 2005). Toxicity resulting from single or multiple exposures to chlorine gas has been evaluated in humans and laboratory animals, which showed many similarities in their responses.

22.5.1 Human studies

The human effects of chlorine inhalation have been described in single-exposure case reports and controlled studies with volunteers, in repeated-exposure studies with volunteers, and in occupational chronic exposure studies (Table 22.2). In a summary of various anecdotal case reports, Winder (2001) noted that exposures of up to 3 ppm caused mild irritation; 5−15 ppm caused moderate irritation; >15 ppm caused severe irritation with pulmonary involvement; and death occurred from exposure to ≥430 ppm after 30 min or less. A selective review of publications from 1966 through 2016 found that the most common clinical features in civilians exposed to chlorine gas were cough (29%), dyspnea (22%), sore throat (16%), eye irritation (12%), and excessive sputum (7%) (Govier and Coulson, 2018). Full recovery occurred in most cases, and deaths were rare (<1%). Chlorine injury of the distal airways, which are repaired less efficiently, can lead to persistent respiratory symptoms and lung-function decrements (Hoyle and Svedsen, 2016).

Controlled human studies generally found that exposure to 0.5−2 ppm Cl_2 for a period of a few minutes to 8 h caused slight to moderate irritation of the eyes, nose,

TABLE 22.2 Human chlorine inhalation studies.

Exposure time	Concentration (ppm)	Effects	References
Single-exposure human studies			
15 min	0.5	At 0 and 15 min postexposure, NAR was ↑ in rhinitics but not normal subjects; rhinitics had greater nasal irritation and congestion; no effect on pulmonary peak flow, rhinorrhea, or headache in either group	Shusterman et al. (1998)
15 min	1.0	At 0 and 15 min postexposure, NAR was ↑ in rhinitics but not normal subjects; effect ↑ with age; very slight nasal irritation and odor perception	Shusterman et al. (2003a)
15 min	1.0	At 0 and 15 min postexposure, NAR ↑ in rhinitics but not normal subjects; no effect on nasal lavage fluid levels of mast cell tryptase, or plasma neuropeptides, albumin, urea, lysozyme, or 7F10-mucin	Shusterman et al. (2003b, 2004)
15 min	1.01 ± 0.034	No subject smelled the chlorine or had respiratory symptoms, and there was no effect on the FEV1 or airway responsiveness. Exposure was with a newly developed closed-circuit apparatus	Ojanguren et al. (2018)

(*Continued*)

TABLE 22.2 (Continued)

Exposure time	Concentration (ppm)	Effects	References
1 h	0.4	No pulmonary function changes in those with AHR or asthma	D'Alessandro et al. (1996)
1 h	1.0	Modest changes in pulmonary function measurements, greater in hyperreactive subjects (± asthma), of which 2/7 had "respiratory symptoms"	
15 min–2 h (left room every 15 min)	0.5, 1.0	Barely perceptible irritation of eyes, nose, and/or throat	Joosting and Verberk (1974)
	2.0	Distinctly perceptible irritation of eyes, nose, and throat; some coughing	
	4.0	Nuisance level irritation of eyes, nose, and throat; some coughing	
4 h + exercise 15 min/h	0.5	Moderate or mild itching or burning of throat and nose; severity generally ↑ with exposure time	Anglen (1981)
	1.0	Moderate or mild irritation of throat, eyes, and nose; runny nose; severity ↑ over time; few had pharynx injection, ↑ mucous secretion, and inspiratory rales	
	2.0	Moderate or mild irritation of throat, eyes, and nose; runny nose; severity ↑ over time; few had pharynx injection or palpebral fissures, ↑ mucous secretion, inspiratory rales, altered pulmonary function	
8 h + exercise 15 min/h; had 30 or 60 min break after 4 h	0.5	Moderate or mild itching or burning of throat and nose; severity generally ↑ with exposure time	Anglen (1981)
	1.0	Moderate or mild itching or burning of throat, eyes, and nose; runny nose; urge to cough; severity ↑ with exposure time; few had pharynx injection or palpebral fissures, ↑ mucous secretion, and inspiratory rales after 4 and 8 h; after 8 h had slight changes in pulmonary function	
8 h + exercise 15 min/h	0.5	Slight changes in pulmonary function measurements after 4 and 8 h; changes were greater in an atopic subject	Rotman et al. (1983)
	1	Itchy eyes, runny nose, mild burning in throat, and slight changes in pulmonary function after 4 and 8 h; changes were sufficient in an atopic subject to terminate exposure after 4 h due to dyspnea and wheezing	
Multiple-exposure human studies			
6 h/d for 3 d	0.1, 0.3, and 0.5	At unspecified concentration(s) had eye, nose, and throat irritation, wheeze, nasal congestion and mucous production; pulmonary function normal	Schins et al. (2000)
10.9 ± 2.8 yr	0.146 ± 0.287	Male workers had fatigue, anxiety, dizziness, and white blood cell count; ↓ hematocrit. No effect on chest X-ray or pulmonary function	Patil et al. (1970)
>10 yr	0.298 ± 0.181	Workers had ↓CO lung diffusing capacity but no effects on pulmonary function measurements or ↑ in pulmonary emphysema	Capodaglio et al. (1970)

(*Continued*)

TABLE 22.2 (Continued)

Exposure time	Concentration (ppm)	Effects	References
13.9 ± 9.3 yr	< 0.05 (mean)	Male workers had no ↑ in respiratory symptoms or abnormalities in pulmonary function or chest radiographs. Possible coexposure to low levels of H_2S, methyl mercaptan, SO_2, and particulates	Chan-Yeung et al. (1980)
8.9 ± 8.6 yr	0.18 (mean)	Male workers had ↑ frequency of wheeze, chest tightness, chest illness, and decrements in pulmonary function. No ↑ in cough, phlegm, or dyspnea. Possible coexposure to low levels of SO_2, CH_3SH, and particulates	Enarson et al. (1984)
<10–25 yr	1.7 ± 0.12	Workers had sore or dry throat, shortness of breath, chest tightness or pain, headache, wheezing, chronic rhinitis and tonsillitis, olfactory deficiency, chest X-ray abnormalities, and impaired pulmonary function	Shi (1990)
6.76 ± 6.86 yr	0.27 ± 0.05	Exposed workers had increased prevalence of cough, phlegm, productive cough, and wheezing, and lower mean values of FEV1, FEV1/FVC ratio, and PEF than unexposed subjects	Neghab et al. (2016)

↑, increase(d); ↓, decrease(d); *AHR*, airway hyperresponsiveness; *d*, day(s); *FEV1*, forced expiratory volume during the first second of the test; *FVC*, forced vital capacity; *h*, hour(s); *NAR*, nasal airway resistance; *PEF*, peak expiratory flow; *yr*, year(s).

and throat, and small decrements in pulmonary function [such as the forced expiratory volume in 1 s (FEV_1) and airway resistance (R_{aw})] (Anglen, 1981; Rotman et al., 1983; D'Alessandro et al., 1996; Shusterman et al., 1998; Schins et al., 2000). The severity of irritation increased with exposure duration and concentration, and effects were greater in subjects with preexisting respiratory conditions (such as asthma and AHR) and in smokers. Ojanguren et al. (2018), however, found that subjects exposed to 1 ppm for 15 min did not detect its presence. A number of cases of RADS have been reported, and all were seen in individuals with preexisting respiratory conditions and current or former smokers (Evans, 2005). Withers and Lees (1985) applied probit analysis to human and animal lethality data to estimate that chlorine concentrations of 250 and 100 ppm were lethal to 50% of a regular and vulnerable population (LC_{50}), respectively, that was exposed for 30 min with an inhalation rate of 12 L/min. Based on chlorine inhalation lethality data for eight species (mouse, rat, guinea pig, rabbit, cat, dog, sheep, and goat), Sommerville et al. (2009) estimated 2-min exposure lethality values (LCT_{50}) of 13,500 and 9500 mg min/m^3 for the military and general population, respectively.

Few repeat-exposure human studies have been conducted with chlorine gas. In controlled studies, subjects exposed to 0.1, 0.3, or 0.5 ppm for 6 h/day for 3 days had no pulmonary function decrements, but did report eye and respiratory tract irritation (Schins et al., 2000). Workers exposed chronically to <0.1 ppm experienced no chlorine-related toxicity; exposure to ~0.2–0.3 ppm had little or no effect on pulmonary function but did result in fatigue, anxiety, wheezing, and chest tightness; and exposure to 1.7 ppm was associated with numerous respiratory symptoms (including sore throat, shortness of breath, chest tightness, wheezing, and rhinitis), chest X-ray abnormalities, and pulmonary function decrements (Patil et al., 1970; Capodaglio et al., 1970; Chan-Yeung et al., 1980; Enarson et al., 1984; Shi, 1990). The severity of effects increased with the number of working years and was greater in smokers. A recent retrospective cohort study found that occupational exposure to 0.27 ppm chlorine gas was associated with an increase in respiratory symptoms and statistically significant decrements in pulmonary function (Neghab et al., 2016).

22.5.2 Laboratory animal studies

The majority of the chlorine exposure animal studies were conducted using rats and mice, although studies were also conducted using monkeys, dogs, rabbits, guinea pigs, cats, sheep, and goats. Studies with rabbits, rats, guinea pigs, and mice are summarized in Table 22.3 (single exposure) and Table 22.4 (repeat exposure).

TABLE 22.3 Animal single-exposure chlorine inhalation studies.

Exposure time	Concentration (ppm)	Effect	References
Rabbits			
30 min	50	Temporary ↓ in lung compliance	Barrow and Smith (1975)
	100–250	Lung edema, hemorrhage, emphysema, inflammation, impaired function	
	500–1000	LC_{100}	
45 min	600	IM injection of nitrite (1 or 10 mg/kg) at 30 min after Cl_2 exposure caused up to 50% less protein and neutrophil accumulation in the airways and no mortality (~35% mortality over 18 h in controls)	Honavar et al. (2017)
Guinea pigs			
15–30 min	200	Severe lesions of upper respiratory tract mucous membranes, emphysema, inflammation, and exudate in bronchioles	Faure et al. (1970)
Rats			
2, 10 min	1500	Lung edema with bronchial epithelial sloughing and airway wall leukocyte infiltration; some epithelial regeneration after 72 h	Demnati et al. (1995)
10 min	579–2248	LC_{50} = 1931, 690, 448 ppm for 10, 30, 60 min; majority died in 1 wk; were restless, had eye and nasal irritation, dyspnea, and lesions in nose, larynx, trachea, and lung; some lesions were reversible	Zwart and Woutersen (1988)
30 min	547–645		
60 min	322–595		
15 min	200	After 24 h had AHR and ↑ neutrophils, eosinophils, cytokines IL-1β and IL-18 in BAL; edema in lung and heart; dexamethasone ↓ neutrophils but not AHR. After 14–90 d had signs of lung fibrosis (↑ pulmonary macrophages, TGF-β expression in BAL, airway collagen deposition)	Wigenstam et al. (2016)
15 min	200	The biomarker for oxidative stress 8-isoprostane was found in exhaled breath concentrate from airways at 24 h postexposure	Elfsmark et al. (2018)
15 min	1330	Lung eosinophilic accumulation, edema, and bleeding, which became interstitial fibrosis and thickening of alveolar septa after 45 d	Yildirim et al. (2004)
27–30 min	500–600	Respiratory failure, ↓ cardiac output, ataxia and hypotonia, seizures, death. Oxygen treatment ↑ survival to 6 h but also ↑ severity of acute respiratory failure, acidosis, and hypercapnia, and did not improve neuromuscular, cardiac, or respiratory effects	Okponyia et al. (2018)

(*Continued*)

TABLE 22.3 (Continued)

Exposure time	Concentration (ppm)	Effect	References
30 min	184, 400	Labored breathing, expiratory grunting; 1 h postexposure had ↓ arterial oxygen pressure and ↑ CO_2 levels, and respiratory acidosis. Had lung necrosis and epithelial sloughing, neutrophil accumulation, and mild alveolitis; BAL fluid had ↑ albumin, IgG, IgM, and phospholipid levels (400 ppm), and ↓ levels of ascorbate and reduced glutathione	Leustik et al. (2008)
30 min	400	Chlorinated lipids ↑ in the lungs and the plasma (2-chloropalmitic acid, 2-chlorostearic acid, free and esterified) (only parameters evaluated)	Ford et al. (2016)
30 min	400	Isolated pulmonary arteries (PA) had ↑ superoxide formation and inhibition of NO-dependent vasodilation. PA pressures in anesthetized rats were ↓ but restored by iNOS inhibitor 1400 W	Honavar et al. (2014a)
30 min	400	Transient hypoxemia, severe epithelial pathology in airways; increased BAL protein, neutrophils, epithelia; lung edema; effects lessened by sodium nitrite given IP at 2–6 h postexposure	Yadav et al. (2011)
30 min	413	Bradycardia and ↓ respiratory rate; ↑ exhaled (eNO/eCO_2) ratios, which were best toxicity predictors; ↑ hemoglobin, red blood cells, hematocrit, and fibrin in blood within 1 d postexposure	Luo et al. (2014)
30 min	500	Reduction in heart rate and oxygen saturation; increased chloramine and chlorotyrosine in blood plasma. Primary cardiomyocites had decreased total ATP content and loss of sarcoendoplasmic reticulum calcium ATPase activity	Ahmad et al. (2015)
30 min	500–600	At 500 ppm had ↑ lactate in the coronary sinus; after 20 h had ↓ systolic and diastolic blood pressure and left ventricular systolic and diastolic dysfunction, even with oxygen treatment. At 600 ppm had biventricular failure 2 h postexposure and death	Zaky et al. (2015)
60 min	213, 268, 338, 427	LC_{50} = 293 (260–329) ppm; had eye and nose irritation, and after 60 min had lacrimation, rhinorrhea, and gasping; survivors had lower weight gain. Liver tissue mottling was the most common finding at necropsy	MacEwen and Vernot (1972)
60 min	6, 30, 60	Nasal lesions (necrosis, inflammation, hyperplasia, degeneration), severity increasing with concentration and greatest in more anterior regions	Peay et al. (2010)

(*Continued*)

TABLE 22.3 (Continued)

Exposure time	Concentration (ppm)	Effect	References
6 h	0.1, 1.0, 5.0, 10	Nasal epithelial inflammation and hyperplasia, olfactory necrosis and degeneration; severity increased with concentration and was greatest in anterior regions; lesions seen at ≥1.0 ppm persisted at least 5 d	Peay et al. (2010), Jarabek et al. (2010)
6 h	9.1 ± 1.02	Nasal cavity lesions (epithelial degeneration, ulceration, and necrosis); most severe in olfactory mucosa	Jiang et al. (1983)
16 h	63	All survived 5 mo postexposure; had gross changes in brain, lungs, heart, stomach, intestines, liver, kidneys, and lung adhesions	Weedon et al. (1940)
	250, 1000	Lacrimation, dyspnea; all died by 16 h at 250 ppm and 1.7 h at 1000 ppm; had lesions in brain, lungs, heart, liver, stomach, intestine, and kidneys	
24 h	0.25, 1.25, 2.5	Nasal necrosis/degeneration followed by inflammation and hyperplasia; severity increased with concentration and greatest in anterior regions	Peay et al. (2010)
Mice			
5 min	100	Had ↑ airway resistance (methacholine challenge), ↑ BAL neutrophils, macrophages, and protein; ↑ 4-hydroxynonenal in whole lung tissue; attenuated by AEOL-10150 (metalloporphyrin antioxidant)	McGovern et al. (2011)
5 min	100	Cl-induced neutrophilia; ↑ expression of NRF2 mRNA, superoxide dismutase-1, and heme-oxygenase 1. Neutrophil depletion abolished AHR in large airways, ↑ in antioxidant gene expression, and NRF2 nuclear translocation, but not ↑ L-17 in BAL. Depletion of eosinophils and macrophages did not prevent AHR	McGovern et al. (2015)
5 min	100	AHR, increased cells, and glutathione in BAL, dimethylurea given IP 1 h before/after exposure decreased BAL protein and glutathione levels and prevented lung lipid peroxidation	McGovern et al. (2010)
	200, 400	As at 100 ppm but more severe; had microscopic pathological changes in airway epithelium (BAL fluid and effect of dimethylurea not evaluated)	
5 min	100, 200, 400, 800	Dose-related increases in airway responsiveness, airway epithelial loss, alveolar damage and inflammation, leukocytes and nitrate in BAL fluid, nitric oxide synthase expression, and oxidation of lung proteins	Martin et al. (2003)

(*Continued*)

TABLE 22.3 (Continued)

Exposure time	Concentration (ppm)	Effect	References
7.5 min	800	After 6 h: mortality was 8/8; 6/41; 0/40, 0/40; had increased lung weights (pulmonary edema), BAL protein and IgM levels, neutrophil infiltration, and airway epithelial denudation—more severe for the shorter exposures. After 24 h: only lung weight returned to sham control levels	Hoyle et al. (2010)
15 min	400		
30 min	200		
60 min	100		
10 min	0.7–38.4	RD_{50} = 9.3 ppm; respiratory rate ↓ was dose-related and was attained at each concentration within 5–7 min	Barrow et al. (1977)
10 min	1.0–760	RD_{50} = 25 ppm; appearance of animals was not addressed	Barrow and Steinhagen (1982)
10 min	~2.5–1000	RD_{50} = 10.9 ppm; animal appearance was not addressed	Chang and Barrow (1984)
10 min	579–1654	LC_{50} = 1034 and 517 ppm for 10 and 30 min, respectively. Animals had signs of restlessness, eye and nasal irritation, dyspnea, and ↑ lung weight	Zwart and Woutersen (1988)
30 min	458–645		
15 min	0.8, 2.0, 3.1, 3.8	RD_{50} = 2.3 ppm; dose-related ↓ in respiratory rate (30%–80% of baseline) and ↑ in airway resistance (64%–186%) and length of the expiratory pause (20–522 ms)	Morris et al. (2005)
15 min	25, 50, 100, 200	Concentration-related inflammatory response within 24 h postexposure with ↑ expression of IL-1β, IL-6, and CXCL1/KC in BAL fluid, ↑ in lung permeability, neutrophilic inflammation, fibrinogen, PAI-1, and cytokine 8-isoprostane, biomarker for oxidative stress	Elfsmark et al. (2018)
15 min	50, 200	After 6–12 h had lung edema, central and peripheral AHR, inflammation with macrophages and neutrophils. Inflammatory cells were found for ≥7 d and AHR for ≥28 d	Jonasson et al. (2013a)
15 min	200	Anorexia, lethargy, hypothermia; acute lung edema, collagen deposition (fibrosis), and inflammation; dexamethasone (IP) reduced severity if given within 1–6 h after exposure	Jonasson et al. (2013b)
15 min	200, 400	Potential Cl-specific markers in BAL (by mass spectroscopy) were chlorohydrins of unsaturated pulmonary surfactant phospholipids; the phosphatidylglycerol chlorohydrins were considered the best biomarkers	Hemstrom et al. (2016)
15 min	300	Postexposure treatment with dexamethasone and *N*-acetyl cysteine, together but not separately, protected against Cl_2-induced AHR and reduced neutrophils in BAL 24 h postexposure. AHR was unaffected by Triptolide, Reparixin, and Rolipram, but Triptolide ↓ inflammation	Wigenstam et al. (2015)

(*Continued*)

TABLE 22.3 (Continued)

Exposure time	Concentration (ppm)	Effect	References
30 min	55–179	The 30-min LC_{50} = 127 (106–152) ppm; ↑ lung weight; tracheal, bronchiolar, and alveolar lesions; regenerative changes seen after 9–10 d	Schlagbauer and Henschler (1967)
3 h	10, 22	Pathology as 30-min exposure; 8/10 died at 10 ppm and 10/10 at 22 ppm	
6 h	10	Similar pathology as after 30-min exposures, 9/10 died	
30 min	187	Preexisting respiratory syncytial virus infection ↑ chlorine-induced lung inflammation, AHR, oxygen desaturation, neutrophil infiltration, and MCP-1, MIP1, IL-10, IFN-, RANTES, and hyaluronan in BAL; type 2 cytokines were unaffected	Song et al. (2015)
30 min	200, 350	Bronchiolitis obliterans (BO) occurred in trachea and large airways within 10 d of exposure to 350 but not 200 ppm in areas where basal progenitor cells were eliminated. BO development included inflammatory cell infiltration by d 2 after exposure, fibroblast infiltration and collagen deposition by d 5, ingrowth of blood vessels by d 7, and lethal airway obstruction by d 9–12	O'Koren et al. (2013)
30 min	400	Hyaluronan low-molecular-weight fragments (L-HA, <300 kDa) and inter-alpha-trypsin-inhibitor (IαI) ↑ in BAL. Airway resistance (methacholine challenge) ↑ 24 h postexposure. AHR ↓ by intratracheal high-MW hyaluronan (H-HA) or antibody against IαI	Lazrak et al. (2015)
30 min	400	Lung deciliation, epithelial sloughing, alveolar inflammation, ↑ airway resistance, ↑ protein and inflammatory cells in BAL; arformoterol (β_2-agonist) given nasally starting 10 min postexposure reduced airway resistance, and improved alveolar clearance	Song et al. (2010, 2011)
30 min	400	In lungs and skin at 1 and/or 6 h postexposure had ↑ IL-6 and TNF-α, ↑ UPR signaling (↑ protein kinase RNA-like endoplasmic reticulum kinase, inositol-requiring enzyme 1a, activating transcription factor 6a), and ↑ expression of hepcidin	Li et al. (2013)
30 min	400	Chlorinated lipids ↑ in the lungs and the plasma (2-chloropalmitic and 2-chlorostearic aldehyde; 2-chloropalmitic and 2-chlorostearic acid, free and esterified) (only parameters evaluated)	Ford et al. (2016)
30 min	400	Had ↑ clotting time, clot formation time, D-dimers, and thrombin–antithrombin complexes in BAL. Treatment with aerosolized heparin ↓ protein levels and inflammatory cells in the BAL at 6 h postexposure	Zarogiannis et al. (2014)
45 min	600		

(*Continued*)

TABLE 22.3 (Continued)

Exposure time	Concentration (ppm)	Effect	References
45 min	600	IM injection of nitrite (10 mg/kg) at 30 or 60 min after Cl_2 exposure improved 24-h survival (20%–50%), with ↓ airway neutrophil accumulation. Females were more sensitive to toxicity and less responsive to nitrite therapy than males	Honavar et al. (2014b)
45 min	600	Most (14/18) died within 72 h of exposure; had labored breathing, lung inflammation, epithelial sloughing; lipid peroxidation; had less mortality (4/18) and toxicity if given ascorbate and deferoxamine (both IM and inhalation) starting 1 h postexposure	Zarogiannis et al. (2011)
60 min	60–160	Neutrophilia, ↑ expression of ARG1, CCL2, RETLNA, IL-1b, and PTGS2 genes, ecog-α, and mannose receptor in BAL fluid, and of activation markers in alveolar macrophages and pulmonary epithelium. Pulmonary elastance was elevated at 48 h	Massa et al. (2014)
60 min	122–193	LC_{50} = 137 (119–159) ppm; had eye and nose irritation, and gasping; survivors had weight loss; liver tissue mottling was seen at necropsy	MacEwen and Vernot (1972)
60 min	228–270	Lung edema and ↑ protein and IgM in BAL; AHR and impaired pulmonary function; rolipram given postexposure (IP or intranasally) inhibited pulmonary edema and airway hyperreactivity	Chang et al. (2012)
60 min	240	IM injection of microencapsulated formulations of rolipram, triptolide, and budesonide ameliorated chlorine-induced acute lung injury (pulmonary edema, AHR, ↑ neutrophils in lung tissue)	Hoyle and Svedsen (2016)
60 min	240	Sloughing of Clara and ciliated cells from tracheal epithelium at d 2; after 2–4 d had cell proliferation in K5- and K14-expressing basal cells; at d 7–10 fibrosis was seen primarily in distal trachea	Musah et al. (2012)
60 min	240	Upregulation of genes related to macrophage function. IM injection with budesonide for 7 d starting 1 h postexposure prevented influx of M2 macrophages, airway fibrosis, and AHR, but large airways had poorly repaired epithelium; same findings at 14 d postexposure	Musah et al. (2019)
60 min	240	Airway epithelial damage and hyperreactivity, neutrophil inflammation, lung edema and dysfunction; mometasone and budesonide (IP, given 1 h postexposure) decreased lung neutrophil levels and lung edema	Chen et al. (2013)

(*Continued*)

TABLE 22.3 (Continued)

Exposure time	Concentration (ppm)	Effect	References
60 min	240	FVB/NJ mice and A/J mice had fibroproliferative lesions in large airways 4 d postexposure, which by d 7 was repaired in A/J mice but fibrosis in FVB/NJ mice, latter had less keratin 5 in basal cells of large airways	Mo et al. (2013)
60 min	240	A/J mice had bronchial epithelium sloughing 1 d postexposure, repaired by d 7 with abnormal cell distribution. Developed (nonbacterial) pneumonitis with ↑ neutrophils and macrophages; had ↑ in chemokines, granulocyte colony-stimulating factor, and VEGF and protein in BAL	Mo et al. (2015)
60 min	1.7–8.8	RD_{50} = 3.5 ppm; appearance of animals was not addressed	Gagnaire et al. (1994)
120 min	2.2–6.6	Respiratory rate ↓ 31%–65% after 60 min, and ~38%–72% after 120 min	
67 min	179–263	Several mice died within 24 h after exposure; had edema, airway epithelial sloughing, and ↑ protein and neutrophils in BAL	Tian et al. (2008)
6 h	9.1 ± 1.02	Marked nasal cavity epithelial degeneration, ulceration, and necrosis, most severe in olfactory mucosa of anterior dorsal meatus	Jiang et al. (1983)
16 h	63	All survived; showed less distress than at higher concentrations	Weedon et al. (1940)
	250, 1000	Lacrimation, dyspnea, convulsions; all died after 8.4 h (250 ppm) and 50 min (1000 ppm); had lesions in lungs and numerous internal organs	
24 h	45	Mean survival time was 7.6–38 h for 40 strains; had lung hemorrhage, alveolar wall thickening, ↑ BAL protein and altered metabolite content	Leikauf et al. (2010, 2012)

↑, increase(d); ↓, decrease(d); *AHR*, airway hyperresponsiveness; *BAL*, bronchoalveolar lavage (fluid); *BW*, body weight(s); *d*, day(s); *IM*, intramuscular; *IP*, intraperitoneal; LC_{50}, the concentration that results in 50% mortality; *mo*, month(s); *min*, minutes; *OE*, olfactory epithelium (nasal); RD_{50}, concentration causing a 50% decrease in the respiration rate; *wk*, week(s); *yr*, year(s).

Single-exposure durations ranged from 2 min to 24 h, and repeat-exposure durations were 3 days to 2 years (1–8 h/day). Older single-exposure studies often evaluated toxicity for a period of days to weeks after exposure to chlorine concentrations extending into the lethal range. Some older studies quantified sensory irritation in rats and mice during a short-term exposure (10–60 min), by determining the concentration that caused a 50% decrease in the inhalation rate (i.e., the RD_{50}). Many recent studies treated animals with near-lethal chlorine concentrations for a short duration (<1 h), followed by sacrifice within hours or a few days. The latter studies were designed to explore aspects of the mechanism of chlorine toxicity, including its progression over time and postexposure tissue repair, as well as the ability of various classes of compounds to mitigate chlorine toxicity (see this Sections 22.4, 22.6, and 22.7).

The respiratory tract was consistently the primary and most sensitive target of toxicity, and similar effects were seen following single and repeated inhalation exposures. The upper respiratory tract was predominantly affected at lower chlorine concentrations, with symptoms such as sensory irritation and nasal lesions. Sensory irritation was manifested as a decreased respiration rate, sneezing,

TABLE 22.4 Animal repeat-exposure chlorine inhalation studies.

Exposure scenario	Concentration (ppm)	Effect	References
Monkeys			
6 h/d, 5 d/wk × 12 mo	0.10 ± 0.03, 0.50 ± 0.10, 2.3 ± 0.4	Eye tearing and reddening during exposure to 2.3 ppm seen after ~6 wk; after 1 yr had conjunctival irritation but no gross eye lesions. Had trace or mild nasal epithelial hyperplasia, loss of cilia and goblet cells (dose-related), with tracheal involvement at 2.3 ppm	Klonne et al. (1987)
Rats			
6 h/d × 3 d 6 h/d × 5 d	9.1 ± 1.02 (TWA)	BW ↓; marked nasal epithelial degeneration, cell exfoliation, ulceration, and necrosis; neutrophil infiltration of epithelium and squamous metaplasia after 5 d; milder lesions in pharynx, trachea, and lungs	Jiang et al. (1983)
6 h/d × 5 d	0.1, 0.5, 1.0 2.5	Nasal inflammation and hyperplasia in squamous and respiratory epithelium (concentration-dependent) but not OE; extended to the nasopharyngeal duct at 2.5 ppm	George et al. (2010), Jarabek et al. (2010)
With 7-d recovery	1.0, 2.5	Hyperplasia (concentration-dependent) in squamous and respiratory epithelium of anterior nasal sections	
6 h/d, 5 d/wk × 2 wk	12	Looked unkempt, wheezed, had swelling around eyes and nares, ↓ BW, and reversible ↑ in lung sulfhydryl level after 3–6 d	Dodd et al. (1980)
6 h/d, 5 d/wk × 6 wk	1	Signs of irritation, mild nasal, tracheal, bronchial, alveolar inflammation	Barrow et al. (1979)
	3	As at 1 ppm; also, lacrimation, conjunctivitis, nasal discharge, liver lesions	
	9	As at 3 ppm; also, gasping, lung rales, emaciation; 3/20 died by 30th exposure; lesions in lungs, liver, kidney, stomach, spleen, and thymus	
6 h/d × 104 wk; 5 d/wk (M) or 3 d/wk (F)	0.4, 1.0, 2.5	BW ↓ in all M and at 1.0 and 2.5 ppm in F after >3 mo; closed eyes at 2.5 ppm in F. All had nasal lesions, most severe in anterior and generally concentration-related (inflammation; OE degeneration; squamous metaplasia; goblet cell epithelial hypertrophy and hyperplasia)	Wolf et al. (1995)
Mice			
8 h/d × 3 d	2.5	BW was 93.2% of initial weight	Schlagbauer and Henschler (1967)
	5	BW was 87.5% of initial weight; lesions in tracheal epithelium and mucosa, bronchioles, and alveoli	
6 h/d × 3 d 6 h/d × 5 d	9.1 ± 1.02	BW ↓; marked nasal lesions (epithelial degeneration, ulceration, necrosis); neutrophil infiltration of epithelium and squamous metaplasia after 5 d; milder lesions in pharynx, larynx, trachea, lungs	Jiang et al. (1983)
6 h/d × 5 d	9.7	Nasal, tracheal, and lung lesions, with anterior to posterior severity gradient (exfoliation, necrosis, inflammation, squamous metaplasia, hyperplasia, bronchiolitis)	Buckley et al. (1984)
6 h/d, 5 d/wk × 104 wk	0.4, 1.0, 2.5	BW ↓ for M at 1.0 and 2.5 ppm and F at 2.5 ppm after >3 mo. All had nasal lesions, most severe in anterior and generally concentration-dependent (septal fenestration; proteinaceous accumulation; epithelial hyperplasia; squamous metaplasia; OE atrophy)	Wolf et al. (1995)

↑, increase(d); ↓, decrease(d); *BW*, body weight(s); *d*, day(s); *F*, female(s); *M*, male(s); *mo*, month(s); *OE*, olfactory epithelium (nasal); *wk*, week(s).

flared nostrils, reddened eyes, lacrimation, salivation, and foamy nasal secretions. Nasal symptoms included inflammation, epithelial necrosis, deciliation, hyperplasia, and metaplasia. At higher chlorine concentrations, the lower respiratory tract was also affected, and manifested as dyspnea, emphysema, bronchopneumonia, pulmonary edema, hemorrhage, and increased protein content and IgM in the bronchoalveolar (BAL) fluid. In many cases, the irritation and pulmonary toxicity were reversible, but at sufficiently high doses, lung toxicity led to permanent changes and/or death. Exposure to near-lethal concentrations caused lesions in organs outside the respiratory tract, including the spleen, thymus, brain, lungs, heart, stomach, intestines, liver, and kidneys. In the single-exposure studies, toxicity was generally influenced more by exposure concentration than exposure duration; this relationship was less clear in the repeat-exposure studies, which were complicated by intermittent periods of nontreatment (e.g., 5 days/week), allowing partial recovery of the chlorine-induced lesions.

No animal studies have linked chlorine exposure with developmental or reproductive toxicity or cancer. Genotoxicity studies with chlorine gas yielded negative results, but mixed results were obtained with the chlorine hydrolysis product hypochlorite (U.S. EPA, 1999; ATSDR, 2010).

22.6 Risk assessment

There are several factors to consider in defining the risk of chlorine inhalation on a diverse human population and in defining levels that are safe for short- and long-term exposures. For example, how do age, gender, and preexisting respiratory conditions such as asthma and AHR affect susceptibility to chlorine toxicity? How do chlorine exposure concentration and duration contribute to chlorine toxicity?

A review of human chlorine inhalation studies led White and Martin (2010) to conclude that there was no basis for considering young subjects more susceptible than adults to chlorine toxicity. Although it was speculated that children might be more susceptible than adults to chlorine toxicity based on reports of illness following several accidental chlorine releases, the actual air chlorine levels and exposure durations of the subjects were unknown (ATSDR, 2010).

Among healthy nonasthmatic adults aged 18−69 years who were exposed to 1.0 ppm chlorine for 15 min, nasal airway resistance, congestion, and irritation increased with age and preexisting allergic rhinitis, independent of gender (Shusterman et al., 2003a,b, 2004). Adults with nonspecific AHR or asthma, or those who smoke, were more susceptible to chlorine respiratory symptoms and pulmonary dysfunction and recovered more slowly after chlorine exposure (Rotman et al., 1983; D'Alessandro et al., 1996; ATSDR, 2010). Studies with mice showed that preexisting respiratory syncytial virus infection increased chlorine-induced lung inflammation and AHR (Song et al., 2015).

The degree to which endpoints such as respiratory tract irritation and mortality are influenced by chlorine exposure concentration or duration have been evaluated using studies that varied both parameters. The concentration−time relationship for many irritants and systemically acting vapors and gases can be described by the equation $C^n \times t = k$ (ten Berge et al., 1986), which is equivalent to Haber's rule ($C \times t = k$) when $n = 1$. A value of $n = 1.9$ was determined for chlorine gas nuisance irritation by ten Berge and Vis van Heemst (1986) using the Anglen (1981) human data. This value of n indicates that exposure concentration is a greater determinant of toxicity than duration. A similar conclusion was drawn by Shusterman et al. (2004) in their analysis of chlorine sensory irritation in a number of controlled human studies. Haber's rule did not adequately capture the type, incidence, and severity of nasal lesions in female rats exposed once to 0.1−10 ppm chlorine for 1−24 h, such that the product of the test concentration and duration ($C \times t$) was constant (Peay et al., 2010). Mice exposed to 100−800 ppm chlorine at a constant $C \times t$ of 100 ppm/h had much greater mortality and lung injury at 800 ppm (0.125 h exposure) than at 100 ppm (1 h exposure) (Hoyle et al., 2010).

Currently, US occupational exposure to chlorine is limited to a ceiling value of 0.5 ppm by NIOSH (REL) and 1 ppm by OSHA (PEL) (NIOSH, 2018). The ACGIH recently lowered its 8-h TLV-TWA from 0.5 to 0.1 ppm (ATSDR, 2010; Kurowski, 2018). These standards reflect human data showing that inhalation of 0.5−1 ppm chlorine, whether once or repeatedly, causes mild upper respiratory tract irritation, which is more severe in individuals with preexisting conditions such as asthma, rhinitis, and AHR (Anglen, 1981; D'Alessandro et al., 1996; Joosting and Verberk, 1974; Rotman et al., 1983; Shusterman et al., 1998, 2003a,b, 2004). The human studies also served as the basis for guidelines to prevent adverse but nondisabling effects from a single 10-min to 24-h inhalation exposure. The acute exposure guideline levels (AEGLs) limit chlorine air concentration to 0.5 ppm for 10−480-min exposures (Talmage, 2004). The provisional advisory levels (PALs) limit chlorine levels to 0.096 ppm for a 24-h exposure (Milanez et al., 2014). Additional AEGL and PAL values were developed for chlorine that are associated with serious irreversible effects or lethality (Talmage, 2004; Milanez et al., 2014). Development of sensitive methods to detect and quantify chlorine adducts 3-chlorotyrosine and 3,5-dichlorotyrosine in human blood (Crow et al., 2016) provides another tool for accurate

exposure assessment to use in chlorine human health and risk assessments.

22.7 Treatment

A chlorine-specific antidote has not been developed, although studies are underway to find treatments that are more specific and effective. Current medical treatment for chlorine inhalation is largely nonspecific and designed to alleviate the patient's symptoms (Jones et al, 2010; Govier and Coulson, 2018). The most commonly prescribed medications for people hospitalized following chlorine gas release in the 2005 train accident in Graniteville, South Carolina, were inhaled β-agonists, ipratropium bromide (an anticholinergic), and inhaled and oral corticosteroids (Van Sickle et al., 2009). Routine treatment after Cl_2 exposure includes humidified oxygen, inhaled beta-adrenergic agents if there is evidence of airway obstruction, and copious water irrigation of eyes if ocular irritation is present (White and Martin, 2010). Questions have been raised regarding the safety of oxygen treatment, as rat studies suggested that although it increased short-term survival, it exacerbated respiratory failure (Okponyia et al., 2018). Respiratory peak flow is measured in patients with mild or greater symptoms, and patients with moderate or severe effects should have a chest X-ray (IPCS, 2008). All symptomatic patients should be observed for 8−24 h for delayed pulmonary edema, which can be treated with positive airway pressure or endotracheal intubation and mechanical ventilation in extreme cases (Traub, 2006; IPCS, 2008). The majority of individuals exposed to mild to moderate chlorine levels see resolution of their symptoms in 3−5 days and recover normal pulmonary function within several months, although injury of the distal airways can lead to persistent respiratory symptoms and lung-function decrements (Jones et al., 2010; Hoyle and Svedsen, 2016; Govier and Coulson, 2018).

Various compounds have been tested in animals in the quest to develop an effective chlorine-specific treatment based on its mechanism of action (Tables 22.3 and 22.4). Sodium bicarbonate can theoretically neutralize the HCl and HOCl formed in the respiratory tract from Cl_2 hydrolysis, although its efficacy is questionable (Jones et al, 2010). Nebulized sodium bicarbonate increased the severity of pulmonary injury in rats at 30 min postexposure but had no effect 45 days after a 5-min exposure to 155 ppm chlorine (Al et al., 2010). Mice given a single intramuscular (i.m.) injection of nitrite (10 mg/kg) at 30 or 60 min after Cl_2 exposure had improved 24-h survival (from ∼20% to 50%), with decreased neutrophil accumulation in the airways (Honavar et al., 2014b). Similarly, rabbits given i.m. nitrite (1 or 10 mg/kg) at 30 min after Cl_2 exposure had up to 50% less protein and neutrophil accumulation in the airways and no mortality (∼35% mortality over 18 h in controls) (Honavar et al., 2017). The authors propose i.m. nitrite treatment for postexposure use in human mass-casualty scenarios. Yadav et al. (2011) showed that rats given intraperitoneal (i.p.) injections of sodium nitrite 10 min to 6 h after chlorine gas exposure had significantly less lung airway and epithelial injury than untreated rats.

Other evaluated compounds include corticosteroids such as mometasone, budesonide, and dexamethasone (Chen et al., 2013; Jonasson et al., 2013b; Hoyle and Svedsen, 2016; Musah et al., 2019), which are used to reduce the inflammatory response and lung scarring; the antioxidants dimethylthiourea, ascorbic acid, *N*-acetyl-L-cysteine, deferoxamine, and AEOL-10150 (Leustik et al., 2008; McGovern et al., 2010, 2011; Zarogiannis et al., 2011; Wigenstam et al., 2015, 2016; Zhang et al., 2018); the type 4 phosphodiesterase inhibitor rolipram (Chang et al., 2012; Hoyle and Svedsen, 2016), the β2-agonist arformoterol (Song et al., 2011); and the plant antiinflammatory product triptolide (Hoyle and Svedsen, 2016). Mice given i.p. doses of dexamethasone and *N*-acetyl cysteine, together but not separately, 1 h after chlorine exposure, were protected against Cl_2-induced AHR and neutrophilia (Wigenstam et al., 2015). Inhibitors of the vanilloid-type transient receptor potential channel TRPV4 decreased vascular leakage and improved blood oxygenation after chlorine gas exposure in mice, but their use in treating chlorine toxicity is limited by their concomitant inhibition of the immune response to pathogen-provoked injury (Morty and Kuebler, 2014). A recent review of animal models developed for treatment of acute chlorine injury included R-107, which is a nitric oxide donor, peroxynitrite modulator, and superoxide scavenger, in an ovine i.m. treatment model (Summerhill et al., 2017).

22.8 Concluding remarks and future directions

Chlorine is widely used in manufacturing and as a disinfectant and bleach, despite its toxicity and potential for nefarious use. Chlorine is a contact irritant and its toxicity is believed to be due to its oxidant properties and to be mediated by the hypochlorite ion, although the precise mechanism is unknown. The chlorine exposure concentrations and durations, and dose-response, associated with various degrees of toxicity have been evaluated in humans and laboratory animals. Upon chlorine inhalation, the respiratory tract is the predominant and most sensitive target organ in all species. The irritation and pulmonary toxicity resulting from exposure to low chlorine concentrations are in many cases reversible, but exposures to sufficiently high concentrations can led to permanent

lung lesions and to injury of other internal organs, and can be lethal. Treatment for chlorine inhalation is largely supportive and nonspecific, although a plethora of studies have attempted to elucidate chlorine's mechanism of action and find treatments to mitigate its toxic effects. To assist in providing guidance for decision response and risk mitigation after accidental chlorine release, computer simulations have been developed to predict the spread of chlorine gas, indoor−outdoor air exchange, and the potential number of people injured within a given radius. Many questions remain unanswered regarding the mechanism of chlorine toxicity and the optimal treatment for a population following an unexpected chlorine release.

Chapter 23

Phosgene

Cheryl B. Bast[1] and Dana F. Glass-Mattie[2]
[1]Keller and Heckman LLP, Washington, DC, United States, [2]Oak Ridge National Laboratory, Oak Ridge, TN, United States

23.1 Introduction

Phosgene is a colorless gas at ambient temperature and pressure. Its odor has been described as similar to newly mown hay (Leonardos et al., 1968). This mild odor and the weak acute irritant properties, however, provide little warning of its presence (Lipsett et al., 1994).

Phosgene is manufactured from a reaction of carbon monoxide and chlorine gas in the presence of activated charcoal. Phosgene is used in the manufacture of isocyanates, polycarbonates, pesticides, dyes, and pharmaceuticals. Manufacture of phosgene in the United States is almost entirely captive in that more than 99% is used in the manufacture of other chemicals within a plant boundary (US EPA, 2003). The odor threshold is between 0.5 and 1.5 ppm (NIOSH, 1976); unfortunately, the odor threshold is inadequate to protect against toxic inhalant exposure because damage to the deep respiratory tract can take place at lower concentrations (Sidell et al., 1997). Phosgene has an odor safety classification rating of "E," which indicates that fewer than 10% of attentive persons can detect the threshold limit value (Amoore and Hautala, 1983).

Inhalation is the most important route of exposure for phosgene. Because of its mild upper respiratory, eye, and skin irritancy, and a mildly pleasant odor, an exposed victim may not actively seek an avenue of escape before lower respiratory damage has occurred (Currie et al., 1987a,b; Lipsett et al., 1994). Small amounts of phosgene can be irritating to the eyes (lacrimation) and throat (coughing) as phosgene undergoes hydrolysis to create hydrochloric acid, which acts as an irritant. Far more dangerous, however, is the pulmonary edema that can develop after a latent period of 1−24 h after exposure. Exercise can increase the extent of pulmonary edema (Marrs et al., 1996). If severe clinical signs are not present after 48 h, then the chances of full recovery are excellent. Physical and chemical properties of phosgene are summarized in Table 23.1.

23.2 Background

Phosgene was first made in 1812 and was used as a chemical warfare agent in WWI. Because of its higher density compared with air, phosgene gas can accumulate in low-lying areas; thus, concentrated pockets within war trenches caused significant exposure during WWI. German troops in WWI used phosgene gas as a chemical warfare agent against British troops. Possibly up to 85% of deaths in WWI were due to chemical exposure (Ministry of Defense, 1987). Sandall (1922) examined 83 British soldiers 3 years after phosgene exposure. Shortness of breath on exertion (70%), cough with expectoration (54%), tight feeling in the chest (25%), sporadic giddiness (14%), and nausea (12%) were the most frequently reported symptoms. No physical lung abnormalities were noted in 53% of the men.

The concept of a "death product" was introduced by Haber to explain the relationship between the extent of exposure to phosgene and death (Haber, 1924). According to "Haber's law," the biological effect of phosgene is directly proportional to the exposure expressed as the product of the atmospheric concentration (C) and the time of exposure (T) or $CT = k$, where k can be death, pulmonary edema, or other biological effects of phosgene exposure (US EPA, 1986). Haber's law has subsequently been shown by other investigators to be valid for both nonlethal and lethal effects within certain limits. There appears to be little species variability with regard to lethality between rats, mice, and guinea pigs, and the $CT = k$ relationship appears to be generally valid (although at very high or very low concentrations or exposure times so short that the animal can hold its breath, the $CT = k$ relationship may not be relevant).

23.3 Toxicokinetics

After inhalation exposure, a small portion of phosgene hydrolyzes to hydrochloric acid (HCl) and carbon dioxide

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00023-4

TABLE 23.1 Physical and chemical data.

Parameter	Data	References
Synonyms	Carbonyl chloride, carbon oxychloride, carbonic dichloride, chloroformyl chloride	US EPA (1986) and Lipsett et al. (1994)
Chemical formula	$COCL_2$	Lipsett et al. (1994)
Molecular weight	98.92	Lipsett et al. (1994)
CAS registry No.	75-44-5	Lipsett et al. (1994)
Physical state	Colorless gas at room temperature	Budavari et al. (1989)
Odor threshold	0.5−1.5 ppm	NIOSH (1976)
Odor description	Pleasant, like newly mown hay	Dunlap (2001)
Vapor pressure	1215 mmHg at 20°C	Budavari et al. (1989)
Vapor density	3.5 (air = 1)	NIOSH (2010)
Specific gravity	1.92 (water = 1)	CRC Handbook (2013)
Melting/boiling/flash point	−118°C/8.2°C/nonflammable	NIOSH (2010)
Water solubility	Slightly soluble in water, decomposes rapidly ($t_{½}$ = 0.26 s)	US EPA (2003); NIOSH (2010)
Reactivity	Reacts with alcohols, alkalis, ammonia, and copper	NIOSH (2010)
Conversion factors in air	1 ppm = 4.1 mg/m^3 1 mg/m^3 = 0.25 ppm	NIOSH (2010)

(CO_2) in the mucous coating of the upper respiratory tract (Diller, 1985), but in the moist atmosphere of the terminal spaces of the lungs more extensive hydrolysis is thought to occur (Beard, 1982). Although phosgene is only slightly soluble in water, once in solution it rapidly hydrolyzes to HCl and CO_2. However, phosgene reacts even faster with other functional groups such as amino, hydroxyl, and sulfhydryl groups (Diller, 1985; Jaskot et al., 1991). Because of the affinity for lung tissue and the hydrolysis and acylation that take place in the pulmonary system, very little, if any, phosgene is dispersed to other locations in the body.

23.4 Mechanism of action

The toxicity of phosgene is attributable to both hydrolysis and acylation, with the latter being most important. Diller (1985) accumulated data and described the human clinical signs associated with phosgene exposure. Phosgene inhaled at concentrations of more than 1 ppm triggers a transient vagal reflex and causes shallow, rapid respiration with a decrease in respiratory volume and capacity, a decrease in arterial oxygen partial pressure, and bradycardia. The intensity varies greatly between individuals. Phosgene at more than 3 ppm becomes moderately irritating to the eyes and upper airways (cough) as some of the phosgene undergoes hydrolysis, producing HCl.

The acylation reaction of phosgene with nucleophiles, such as amino, hydroxyl, and sulfhydryl groups, also occurs rapidly, causing lipid and protein denaturation, irreversible membrane changes, and disruption of enzymatic function. These acylation effects observed at exposures more than 30 ppm/min produce pulmonary edema as the blood−air barrier becomes more permeable to blood plasma after a clinical latent period (1−24 h). This is called the clinical edema phase, which is characterized by increasing inefficiency of gas exchange as more defects in the blood−air barrier occur, allowing more accumulation of a protein-rich fluid. Clinical signs in this phase are labored breathing and a frothy expectorant. Progression usually results in death from paralysis of the respiratory center due to anoxemia with secondary cessation of heart function. If anoxemia is controlled, then circulatory shock may still occur. At very high concentrations (>200 ppm), phosgene may cause death within a few minutes from "acute cor pulmonale" (acute overdistension of the right heart), often before pulmonary edema can develop.

Phosgene depletes lung glutathione, whereas glutathione reductase and superoxide dismutase increase as a result of the lung's response to injury. On exposure to phosgene, cellular glycolysis, oxygen uptake, intracellular ATP, and cyclic AMP are decreased and associated with increased permeability of pulmonary vessels, leading to

pulmonary edema. Phosgene exposure also causes increased lipid peroxidation and leukotriene synthesis, with no change in cyclooxygenase metabolism (Borak and Diller, 2001).

In rats, the first event observed following high but sublethal acute exposure to phosgene was the stimulation of alveolar nociceptive vagal receptors; the nociceptive reflexes, with changes in cardiopulmonary function, resembled typical patterns of alveolar irritation (Luo et al., 2014). The degree and time-course of pulmonary injury were reflected best by exhaled nitric oxide/exhaled CO_2 ratios, hemoconcentration, and protein in bronchoalveolar lavage (BAL) fluid. Significant changes in cardiopulmonary function, ventilation:perfusion imbalances, and progressive pulmonary edema and phospholipoproteinosis were noted. Phosgene-induced acute lung injury showed evidence of persistent periods of apnea, bradycardia, and shifts of vascular fluid from peripheral to pulmonary circulation. Carbon dioxide in expired gas was suggestive of increased ventilation dead space and appeared to be predictive of developing lung edema. Treatment with the iNOS inhibitor aminoguanidine aerosol by inhalation decreased the severity of phosgene-induced ALI when applied at low dose-rates. Symptomatic treatment protocols were inferior to mechanistic treatment methods (Li and Pauluhn, 2017).

23.5 Toxicity

23.5.1 Human

23.5.1.1 Noncancer

Reports of human phosgene poisoning present a relatively consistent set of clinical effects and sequelae (Delephine, 1922; Hegler, 1928; Galdston et al., 1947a,b; Herzog and Pletscher, 1955; Everett and Overholt, 1968; Henschler, 1971; Stavrakis, 1971; Diller et al., 1979; Bradley and Unger, 1982; Misra et al., 1985; Regan, 1985; Wells, 1985; Cordasco et al., 1986; Kaerkes, 1992; Hardison et al., 2014). After acute phosgene exposure, brief (20 min) ocular and throat irritation, cough, nausea and vomiting, and dizziness are experienced, followed by a period (24 h) of apparent well-being. After this clinical latent phase, cough accompanied by expectoration, a sensation of pain or tightness of the chest, shortness of breath, and a choking sensation are experienced. Clinical findings may include hemoconcentration, leukocytosis, rales, and pulmonary edema. After recovery, rapid and shallow breathing, shortness of breath on exertion, and a sense of decreased physical fitness may persist for months. Pulmonary emphysema may occur with repeated exposure to phosgene.

Diller and Zante (1982) identified ocular irritation, throat irritation, and cough as acute irritating effects of phosgene. In a follow-up analysis, Borak and Diller (2001) also performed an extensive literature review concerning human phosgene exposure and concluded the following: the smell has no warning property; immediate irritation is not prognostic; and pulmonary edema can appear several hours after exposure and the length of clinical latency can be used as a prognostic indicator (i.e., the shorter the time to effects, the worse the prognosis). The data also show that although concentration is the primary driver for the onset and severity of symptoms, duration of exposure also plays a role. Information synthesized from these reviews is presented in Table 23.2.

23.5.1.2 Cancer

Epidemiology studies have shown no increase in cancer in workers exposed to phosgene compared with controls. Polednak (1980) and Polednak and Hollis (1985) examined a cohort of chemical workers exposed to chronic low levels of phosgene as well as daily exposures of more than 1 ppm. Approximately 35 years after exposure to phosgene, no increase in overall mortality or mortality from cancer or respiratory disease was noted.

23.5.2 Animal

23.5.2.1 Noncancer

Animal studies with phosgene show a steep concentration−response curve for pulmonary edema and mortality. Acute animal studies also indicate little species variability because rats, mice, sheep, pigs, and dogs exposed had development of similar clinical signs (dyspnea, labored breathing, and pulmonary edema after a latent period) and histopathological lesions in the lungs. Although there are no chronic animal data, subchronic studies indicate little accumulation of phosgene or increased severity of lesions with continuous exposure. BAL fluid analysis may be used to assess pulmonary edema/lung injury after acute inhalation exposure to phosgene (Pauluhn et al., 2007). Maximum protein concentrations in BAL fluid typically occur within 1 day after exposure, followed by a latency period up to 15 h. For acute exposures, the *CT* relationship is constant over a wide range of concentrations. However, after noncontinuous and repeated exposure, increased tolerance to subsequent exposures is observed. Although limited, the longer term data indicate that effects do not increase in severity over time but do increase with increased concentration, suggesting that chronic toxicity is dependent on an acute pulmonary threshold dose.

A comparison of BAL fluid constituents from acute inhalation studies in rats and dogs suggests that dogs are three to four times less sensitive to phosgene than rats (Pauluhn et al., 2007). Li and Pauluhn (2019) determined

TABLE 23.2 Summary of major signs and symptoms of phosgene inhalation exposure in humans.

Exposure			Acute effect	Time to onset of pulmonary edema (h)	Time to death
Concentration (ppm)	Duration	$C \times T$ product (ppm min)			
3	"Acute"	–	Throat irritation	–	–
4	"Acute"	–	Ocular irritation	–	–
4.8	"Acute"	–	Cough	–	–
1	20 min	20	–	–	–
5	5 min	25	–	–	–
1	150 min	150	–	10	–
50	5 min	250	–	5	–

Source: Data from Diller, W.F., Zante, R., 1982. Dosis-wirkungs-beziehungen bei phosgen-einwirkung auf mensch und tier. Zbl. Arbeitsmed. 32, 360–368 and Borak, J., Diller, W.F., 2001. Phosgene exposure: mechanisms of injury and treatment strategies. J. Occup. Environ. Med. 43, 110–119.

that increased lung weight in rats and dogs with phosgene-induced acute lung injury corresponded well with excess extravascular lung water in humans. Thus, this endpoint was considered the biomarker of choice for scaling lung edema from experimental animals to humans. The predictive value of data from dogs was better than that of rats, suggesting that canine data should be given preference over rodent data when scaling to the human. In rats, increased BAL protein may lead to overestimation of the phosgene edema potency due to secreted protein into airways. Thus, caution is advised when using BAL protein in isolation as a surrogate endpoint of pulmonary edema.

A summary of selected lethal and nonlethal animal toxicity studies is presented in Tables 23.3 and 23.4, respectively.

23.5.2.2 Animal cancer

A study by Selgrade et al. (1989) showed that exposure to very low levels of phosgene enhances the susceptibility of mice to lung tumor formation. Female C57BL/6 mice were exposed for 4 h to 0.01 ($N = 13$), 0.025 ($N = 28$), or 0.05 ppm phosgene ($N = 35$) and injected intravenously with syngeneic B16 melanoma cells the next day. Controls were injected with tumor cells and exposed to air. The lungs were removed 2–3 weeks after tumor cell injection and the tumors were counted. Compared with controls, there was a statistically significant ($P < .05$) increase in the number of B16 melanoma tumors in the lungs of mice treated with 0.025 or 0.05 ppm phosgene. Exposure to 0.025 ppm was considered the lowest observed effect level. Extending the exposure time from 4 to 8 h did not alter the susceptibility to B16 tumors at 0.01 ppm.

23.6 Risk assessment

Many inhalation regulatory and guideline levels have been derived for phosgene. These values are summarized in Table 23.5, and the definitions and basis for the values are described in the footnotes to Table 23.5.

23.7 Treatment

Treatments that have been proposed to prevent pulmonary edema in exposed persons include sedation, steroids, ibuprofen, *N*-acetylcysteine, B2-adrenergic agonists, aminophylline/theophylline, leukotriene agonists, and positive pressure airway ventilation. However, there is no known antidote for phosgene poisoning, and although animal studies suggest that these treatments may be effective, no clinical data are available to verify efficacy in humans (Borak and Diller, 2001; Grainge and Rice, 2010; ACC, 2013). Asymptomatic individuals exposed to phosgene should be observed and evaluated to determine if symptoms develop. Vital signs and lung auscultation should be

evaluated every 30 min and serial chest X-rays should be performed starting 2 h after exposure. If no clinical signs occur and no signs of pulmonary abnormalities are detected on the X-ray after 8 h, then patients may be discharged. If no X-ray is available, then patients should be observed for 24 h after exposure. If signs develop, then patients should be treated. Therapy for the cardiogenic pulmonary edema may include positive airway pressure and monitoring (endotracheal intubation and mechanical ventilation with high oxygen concentrations), steroids, theophylline, diuretics, and antibiotics (in patients who develop bacterial pulmonary infections) (Borak and Diller, 2001).

As discussed in Section 23.4, Li and Pauluhn (2017) show that mechanistic treatment protocols are superior to symptomatic treatment protocols with regard to acute lung injury in rats.

23.8 Concluding remarks and future directions

Phosgene is a colorless gas at ambient temperature and pressure, and inhalation is the most important route of exposure for phosgene. The odor of phosgene has been described as similar to newly mown hay. Because of its mild upper respiratory, eye, and skin irritancy, and mildly pleasant odor, an exposed victim may not actively seek escape before lower respiratory damage has occurred (Currie et al., 1987a,b; Lipsett et al., 1994). Pulmonary edema is the cause of death after a clinical latent period of 24 h (Franch and Hatch, 1986). Phosgene exhibits a steep concentration–response curve and little species variability with regard to lethality. Data (Pauluhn, 2006a,b,c; Pauluhn et al., 2007) suggest that with regard to physiology of the respiratory tract and acinar structure of the

[a]*AEGL (acute exposure guideline levels) (NRC, 2002) represent threshold exposure limits for the general public and are applicable to emergency exposure periods ranging from 10 min to 8 h. Three levels (AEGL-1, AEGL-2, and AEGL-3) are developed for each of five exposure periods (10 and 30 min, 1, 4, and 8 h) and are distinguished by varying degrees of severity of toxic effects. The three AEGLs tiers are defined as follows. AEGL-1 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience notable discomfort, irritation, or certain asymptomatic, nonsensory effects. However, the effects are not disabling and are transient and reversible upon cessation of exposure. The AEGL-1 is not recommended for phosgene because the odor threshold is at the concentration approaching AEGL-2 values, and odor cannot be used as a warning. AEGL-2 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience irreversible or other serious, long-lasting adverse health effects or an impaired ability to escape. The AEGL-2 for phosgene is based on chemical pneumonia in rats (Gross et al., 1965). AEGL-3 is the airborne concentration of a substance above which it is predicted that the general population, including susceptible individuals, could experience life-threatening health effects or death. The AEGL-3 is based on concentrations causing no death in rats or mice (Zwart et al., 1990).*

[b]ERPG *[*Emergency Response Planning Guidelines, American Industrial Hygiene Association *(AIHA, 2016)]. The ERPG-1 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing other than mild, transient adverse health effects or without perceiving a clearly defined objectionable odor. The ERPG-1 for phosgene is not derived. The ERPG-2 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing irreversible or other serious health effects or symptoms that could impair an individual's ability to take protection action. The ERPG-3 is the maximum airborne concentration below which it is believed nearly all individuals could be exposed for up to 1 h without experiencing or developing life-threatening health effects.*

[c]EEGL *[*Emergency Exposure Guidance Levels, National Research Council *(NRC, 1985)]. The EEGL is the concentration of contaminants that can cause discomfort or other evidence of irritation or intoxication in or around the workplace, but avoids death, other severe acute effects, and long-term or chronic injury. The EEGL for phosgene is based on the "most relevant animal exposure studies (Rinehart and Hatch, 1964; Gross et al., 1965)" and studies suggesting that animals do not tolerate phosgene at 0.2 ppm administered 5 h/day for 5 days (Cameron and Foss, 1941; Cameron et al., 1942).*

[d]IDLH *[*Immediately Dangerous to Life and Health, National Institute of Occupational Safety and Health*(NIOSH, 2010)] represents the maximum concentration from which one could escape within 30 min without any escape-impairing symptoms, or any irreversible health effects. The IDLH for phosgene is based on acute inhalation toxicity data in humans (Diller, 1978).*

[e]*NIOSH REL-STEL (Recommended Exposure Limits—Short Term Exposure Limit) (NIOSH, 2010) is defined as analogous to the ACGIH TLV-TWA.*

[f]OSHA PEL-TWA (Occupational Health and Safety Administration, Permissible Exposure Limits—Time Weighted Average) *(NIOSH, 2010) is defined as analogous to the ACGIH-TLV-TWA, but is for exposures of no more than 10 h/day, 40 h/week.*

[g]ACGIH TLV-TWA (American Conference of Governmental Industrial Hygienists, Threshold Limit Value—Time Weighted Average) *(ACGIH, 2013) is the time-weighted average concentration for a normal 8 h workday and a 40 h workweek, to which nearly all workers may be repeatedly exposed, day after day, without adverse effect. The ACGIH TLV-TWA was derived from the marked potential for pulmonary irritation after exposure to phosgene at concentrations greater than 0.1 ppm; this conclusion was based on two studies. Gross et al. (1965) found that phosgene at 0.5 ppm for 2 h caused some pathologic changes in the lungs of rats and Cameron et al. (1942) found that 0.2 ppm, 5 days/week for 5 consecutive days caused pulmonary edema in 41% of animals exposed (goats, cats, rabbits, guinea pigs, rats, and mice).*

[h]MAK [Maximale Argeitsplatzkonzentration (Maximum Workplace Concentration)*]* *Deutsche Forschungsgemeinschaft (German Research Association) 2017 is defined as analogous to the ACGIH-TLV-TWA.*

[i]MAC [Maximaal Aanvaaarde Concentratie (Maximal Accepted Concentration)]. *SDU Uitgevers (under the auspices of the Ministry of Social Affairs and Employment), The Hague, The Netherlands 2012 is defined as analogous to the ACGIH-TLV-TWA.*

[j]US EPA (US Environmental Protection Agency Reference Concentration) *(US EPA, 2005). The RfC is an estimate of a continuous inhalation exposure concentration to people (including sensitive subgroups) that is likely to be without risk of deleterious effects during a lifetime. The RfC was developed by using incidence of the lung histopathological findings from Kodavanti and Costa (1997) in a bench-mark dose analysis.*

[k]PAL (provisional advisory levels) *(Glass et al., 2008). Provisional advisory levels represent exposure limits for the general public applicable to emergency situations. Three levels (PAL 1, PAL 2, and PAL 3), distinguished by the degree of severity of toxic effects, are developed for up to 24-h, 30-day, 90-day, and 2-year durations of potential drinking water and inhalation exposures. The PALs have not been promulgated nor have they been formally issued as regulatory guidance. They are intended to be used at the discretion of risk managers in emergency situations when site-specific risk assessments are not available.* PAL 1 *represents the assumed continuous exposure concentration of a chemical in air or drinking water above which changes from baseline of specific biomarkers or physiological responses could have adverse health effects in the general population. Concentrations at or below PAL 1 are not expected to be associated with adverse health effects. Increasingly greater concentrations above the PAL 1 value could cause progressively harmful effects in the general population, including all ages and sensitive subpopulations.* PAL 2 *represents the assumed continuous exposure concentration of a chemical in air or drinking water above which serious, irreversible, or escape-impairing effects could result. Increasingly greater concentrations above the PAL 2 value could cause progressively harmful effects in the general population, including all ages and sensitive subpopulations.* PAL 3 *represents the assumed continuous exposure concentration of a chemical in air or drinking water above which lethality in the general population, including all ages and sensitive subpopulations, could occur.*

lung, dogs are more similar to humans than rodents. Mechanistic studies (Li and Pauluhn, 2019) also suggest that dog models are more predictive of human phosgene toxicity than are rodent models. Thus, it may be most appropriate to base future phosgene risk assessments on data extrapolation from dogs to humans when dog data are available. Recent studies appear to focus on acquiring an additional in-depth understanding of the mechanism of action of phosgene through the use of animal models (Chen et al., 2009; Wang et al., 2013; Luo et al., 2014; Li and Pauluhn, 2017).

Chapter 24

Carbon monoxide: can't see, can't smell, body looks red but they are dead

Rhian B. Cope
Australian Pesticides and Veterinary Medicines Authority, Canberra, Australia

24.1 Introduction

Carbon monoxide (CO) is a ubiquitous partial organic combustion product and a common cause of intentional, unintentional, and fire-related death. It is the predominant organic-derived combustion product at temperatures greater than 800°C. The breathable air concentration of CO can vary from 0.1 ppm in a clean atmosphere to 5000 ppm in the proximity of domestic wood fire chimneys (Fawcett et al., 1992). CO is a significant component of cigarette smoke (Hartridge, 1920; Hoffmann et al., 2001). Intercontinental transport of CO occurs due to its atmospheric lifetime of 1–2 months (Akimoto, 2003). Because of its ability to react with myoglobin to form red-colored carboxymyoglobin, CO has also been used to increase the visual appeal and marketability of meat products.

At toxic concentrations CO is a cause of "anemic hypoxia" in that it binds to hemoglobin with such high affinity that it prevents oxygen from binding, thus reducing the oxygen-carrying capacity of the blood. Using strict chemical weapon definitions, it is not a classical "blood agent" (i.e., it is not in the same weapon mode of action class as the cyanides, arsines, and phosgene) in that it does not prevent the exchange of oxygen and carbon dioxide between the blood and the body's cells/disrupt oxidative energy production. However, CO is often incorrectly included within the "blood agent" chemical weapon class primarily because one of its effects is to give venous blood a "cherry red" color similar to the effect of the cyanides. Notably, the causes of the venous blood color change between the cyanides and CO are different.

Although not formally listed in the Chemical Schedules of the 2005 Convention on the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and On Their Destruction, CO does have a number of potentially militarily useful features, namely (OPCW, 2005):

- It is odorless and initially non-nociceptive.
- It is initially incapacitating, produces unconsciousness, and is ultimately fatal, especially when present at high concentrations in poorly ventilated, confined spaces.
- It is heavier than air and thus tends to concentrate in low-lying spaces. Thus, it tends to displace breathable air in low-lying and/or enclosed spaces.
- It decreases the effectiveness of nonair/nonoxygen-supplied respirators and other nonair-supplied personal protective equipment since it reduces the safety of breathable air that passes through the filters of these devices.
- In enclosed environments high concentrations can be sustained over long periods of time, thus potentially exhausting and neutralizing the filters/scrubbers in personal protective equipment such as respirators.
- At high concentrations it can cause incapacitation and death relatively quickly and reputedly relatively painlessly; these properties have resulted in its use as a mass euthanasia agent for livestock (particularly poultry).
- Large quantities of the gas can be simply and easily produced, easily transported, easily and safely stored, and deployed with readily available, simple, and minimal personal protective equipment.
- Large numbers of simple improvised CO-producing devices can be rapidly produced and constructed from ubiquitous materials, for example, charcoal burners, fires, internal combustion engine exhausts, etc.

Due to these militarily attractive characteristics it has been used commonly and "informally" to both defend and

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00024-6

clear bunkers, tunnel systems, and other poorly ventilated enclosed fortifications, particularly in conflicts featuring irregular/asynchronous warfare. CO will likely continue to be used "informally" in specialized military and policing situations (National Academies of Sciences, Engineering, and Medicine, 2015).

Because combustion is an inevitable consequence of warfare CO will always be present, at least to some degree, under battlefield conditions (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008; National Research Council, 2002; Institute of Medicine, 2010, 2014). In a number of modern military circumstances, combined exposure to CO and cyanide may occur. While it is likely that CO has actively or accidentally been used in warfare for centuries, the modern descriptions of its detection at concentrations of medical importance in the battlefield environment first came from reports from the western European front during World War I (Anon, 1941; Miller, 1926). Systematic programs of ethnic cleansing (Einsatzgruppen operations in Eastern Europe and Russia and the initial Holocaust-related gassing operations at Chelmno followed by the subsequent expanded gassing operations at Belzec, Sobibor, and Treblinka) and elimination of the lesser abled (the child euthanasia program and the gassing phase of the subsequent T4 action) by CO-mediated mass killing were conducted by the Nazis during World War II (Kogon et al., 1993).

The main source of CO during these operations was diesel engine exhausts generated by mobile "gas vans" or diesel engine exhausts generated at stationary gas chambers.

A modern documented example of the deliberate military defensive use of CO was by the Viet Cong who used it to inflict casualties on the "tunnel ferrets" of the Royal Australian Engineers of the Australian Army during the Vietnam War (Rotman, 2006). Acute CO poisoning also may account for at least some of the casualties associated with the use of napalm.

More recently concerns have been raised about exposures occurring within weaponized armored vehicle system crews who are exposed to the gaseous byproducts of weapons propellants, within submarine environments and within military aircraft (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008).

Nonmilitary-related, unintentional CO poisoning remains extremely common. The US Centers for Disease Control and Prevention (US CDC) has reported that over the course of the 1999–2012 period, unintentional, nonfire-related, CO poisoning caused an average of about 440 deaths per year in the United States (Jiaquan, 2014; Sircar et al., 2015). Overall this form of CO poisoning was the second most common cause of nonmedicinal poisoning deaths in the United States over this period. Death rates were about threefold higher in males compared with females and were highest amongst the elderly. Outbreaks of unintentional CO poisoning due to inappropriate (i.e., indoor, enclosed, and/or inadequately ventilated spaces) use of combustion heating devices are classically associated with periods of sudden cold weather or storms, especially when combined with energy supply and/or heating failures and/or inadequate housing and/or socioeconomic disadvantage. Such outbreaks are especially common in socioeconomically disadvantaged populations during winter storms.

Reports of mysterious illnesses, strange visions, and inexplicable deaths of entire households are most likely due to malfunctioning chimneys or other malfunctioning combustion heating devices, resulting in CO poisoning. Nonlethal, but relatively high, CO concentrations are serious threats to pregnant women and their fetuses, and individuals with preexisting cardiac diseases.

CO is also an endogenously generated gas and has an important role in normal physiology. It is also pharmacologically active. Since the central theme of this chapter is on the use of CO as a weapon, the physiological actions of CO are only cursorily discussed when appropriate to the theme of the chapter.

24.2 Historical background

The toxicity of CO was recorded by Aristotle (384–322 BCE) in the third century BCE; by the first century BCE charcoal fumes were used for suicide and executions without any knowledge of the exact nature of the killer (Lewin, 1920; Shephard, 1983). Byzantine emperor Julian the Apostate and his successor, Jovian, were poisoned in CE 363 and 364, respectively, because coal was used to heat their braziers (Lascaratos and Marketos, 1998). In 1700, Bernardino Ramazzini (1633–1714), a physician and professor at the University of Modena, recognized that fumes from burning coal by confectioners caused headache and dyspnea, and that miners encountered "noxious vapors" from burning coals that, if not vented out, could "kill a man on the instant" (Shephard, 1983; Pankow and Penny, 2000). Purified CO was first prepared by the French chemist de Lassone in 1716 who thought it was hydrogen because it burned with a blue flame. Cruikshank eventually demonstrated that the gas that burned with the blue flame was an oxide of carbon (CO) that could be converted into carbon dioxide of carbon by exploding it with oxygen.

The French physiologist Bernard described the toxicity of experimental CO in dogs in 1846. On necropsy he noted that the blood was crimson in color in all the heart chambers as well as in the veins (Bernard, 1865). Bernard, correctly, assumed that the crimson color was

due to excess of oxygen in the blood. Subsequently Haldane identified carboxyhemoglobin (COHb) and determined its chemical nature (Haldane, 1895). Haldane's first law, which remains valid, states: "When a solution containing hemoglobin is saturated with a gas mixture containing O_2 and CO the relative proportions of the hemoglobin which enters into combination with the two gases are proportional to the relative partial pressures of the two gases, allowing for the fact that the affinity of CO for hemoglobin is about three times greater than that of O_2."

Haldane subsequently discovered that CO poisoning could be treated using oxygen, which still remains the most effective antidote for CO poisoning (Haldane, 1895; Haldane and Priestley, 1935; Sluijter, 1967; Tibbles and Edelsberg, 1996). Haldane (1895) also noted that the time of onset of CO poisoning was related to allometric scaling (the time to the onset of poisoning being shorter in smaller animals that have a higher surface area to volume ratio and thus a higher respiratory minute volume per unit body mass). Based on this principle, Haldane was the first to recommend the use of mice for the detection of CO in mines. Canaries, because of their higher respiratory efficiency than mammals in combination with allometric effects, were used from 1921 to 1987 when chemical detection methods replaced their use.

24.3 Epidemiological considerations

Morbidity and mortality from CO poisoning vary from country to country because of the different standards of surveillance, differing extent of urbanization, housing conditions, source of energy, and so on. The major source of CO in the modern developed world is the burning of fossil fuels, particularly petroleum distillates and gases. Because of their higher fossil fuel combustion levels per unit land area, megacities with a population of more than 10 million have an approximately 100-fold higher level of atmospheric CO in breathable air (typically up to 10 ppm) than smaller cities and rural areas (typically 100 ppb). The breathable air levels of CO in these cities can, at times, exceed safe levels.

In most countries, CO remains a common and important cause of unintentional deaths in peacetime. However, in the United States there have been some important and recent changes in its epidemiology (Chiew and Buckley, 2014). In part these changes appear to be due to the diagnostic criteria used and the use of presumptive treatments under circumstances where CO poisoning might be a factor. In the United States the current situation is that there are large numbers of patients diagnosed with CO poisoning; however, there are relatively few deaths ($<5\%$) (Chiew and Buckley, 2014). It has been claimed that the phenomenon of high case rates combined with low death rates is mostly due to: (1) malfunctioning or emergency improvised domestic heating (compared with fires or suicide in other locations); and (2) CO poisoning is often presumptively diagnosed and treated with supplemental oxygen at the site of assumed exposure (typically situations where smoke inhalation may have occurred) even in the absence of elevated blood COHb (Chiew and Buckley, 2014). In the United States it is rare for hospitalized patients with proven CO poisoning to have blood COHb over 50% (Chiew and Buckley, 2014). This may imply that individuals with more severe forms of poisoning are, more often than not, simply found dead.

The situation outside the United States remains quite different. In many countries severe and/or fatal CO poisoning (intentional or otherwise) remains common. In Australia and several other Asian countries deaths due to suicidal CO poisoning remain very common, with deaths often outnumbering the number of patients admitted for treatment (Chiew and Buckley, 2014). Many of these deaths are associated with the use of internal combustion engine exhaust or charcoal burners. It has been claimed that CO-associated suicide epidemics have occurred in some countries following media claims that such deaths are painless and free from violence (Chiew and Buckley, 2014). Of note are findings from the United States and Europe that the installation of catalytic converters into motor vehicles has reduced the completion of suicide rate and CO poisoning rates associated with vehicle exhausts. The cessation of use of coal gas for domestic heating and cooking gas supply also had a similar effect in the United Kingdom (Surtees and Duffy, 1989).

24.4 Physicochemical properties of carbon monoxide

CO is a colorless, odorless, tasteless, noncorrosive, stable, nonradical, diatomic, atmospheric molecule. CO has low water solubility and negligible quantities dissolve in blood at normally encountered pressure (Shephard, 1983). CO has a shorter interatomic distance ($\sim$1.13 Å) than would be anticipated for a single bond. It has high heat formation from the constituent atoms (bond strength 2.07 MJ/mol) and the electric charge is distributed rather uniformly between the carbon and oxygen atoms. Pauling (1960) postulated that under normal circumstances CO existed as a hybrid containing approximately equal proportions of three distinct chemical structures. The general physicochemical properties of CO are presented in Table 24.1.

24.5 Sources of carbon monoxide

There are two main sources of CO—exogenous and endogenous. Although atmospheric CO is the principal

TABLE 24.1 Physicochemical properties of carbon monoxide.

Property	Description
Chemical structure	:C≡O:
Molecular weight	28.01
Critical point	−140°C at 3495 kPa
Melting point	−199°C
Boiling point	−191.5°C
Fundamental vibration transition	2143.3 cm^{-1} (4.67 μm)
Density at 25°C, 101.3 kPa	1.145 g/L
Specific gravity relative to air	0.967
Solubility in water at 0°C	35.4 mL/L
Solubility in water at 25°C	21.4 mL/L
Explosive limit in air	12.5%–74.2%

cause of CO toxicity, endogenous produced CO can, under certain conditions, become pathological (Marks et al., 1991; Maines, 1997; Nezhat et al., 1996; Wu and Wang, 2005).

24.5.1 External sources of carbon monoxide

CO is always a product of incomplete combustion of organic materials, including fossil fuels. It is commonly encountered in the operation of vehicles, heating, coal power generation, and biomass burning (Godish, 2003). Leaking motor vehicle exhausts, operation of motor vehicles in enclosed spaces and driving vehicles with the tailgate open, and wakeboarding behind boats are important sources of exposure.

Natural geographical events such as volcanic eruptions, emission of natural gases, degradation of materials of biological origin, and forest fires all contribute to atmospheric CO. Approximately 40% of global CO comes from these natural sources. Anthropogenic activities such as fossil fuel consumption, garbage disposal, tobacco smoke, and charcoal fires contribute to the remaining 60% of global CO production (Jain, 1990; Vreman et al., 2000). Because human activity and density differ from place to place, atmospheric CO levels also vary greatly from place to place. In the United States CO emissions, and air levels, underwent a rapid decline from 1970 to 2010 and have continued to slowly decline since that time. Apart from various other changes, the developing world has been characterized by increasing migration of rural populations to slums and shanty towns on the outskirts of cities. This phenomenon has been associated with an increase in CO levels in city atmospheres which can, on occasion, exceed safe levels in breathable air.

24.5.2 Endogenous sources of carbon monoxide

The major source of endogenous CO in a healthy individual is from the degradation of heme by heme oxygenases (HO-1 is inducible and HO-2 is constitutive). Heme oxygenases degrade heme into CO and biliverdin, with the latter being rapidly converted into bilirubin (Coburn et al., 1963, 1967; Coburn, 1979; Mores and Sethi, 2002). This process is the rate-limiting step in the endogenous production of CO and accounts for about 86% of endogenous CO production. Notably, the older an individual erythrocyte, the greater is its heme catabolism and CO output. In neonates, red blood cells have a shorter lifespan, producing two- to three-times more endogenous CO than adult erythrocytes (Fallstrom, 1968). Fetal hemoglobin also has a higher affinity for CO binding. The rate of endogenous CO production and excretion also parallels the rate of bilirubin production. Thus, blood COHb levels can be used as an indirect measure of heme degradation and bilirubin production. A measurement of end-tidal CO in breath corrected for inhaled CO is also used as a measure of assessing infants at risk for severe hyperbilirubinemia because CO and bilirubin are produced in equimolar amounts (Bartoletti et al., 1979). The remainder of endogenous CO production derives from other hemoproteins such as myoglobin and many other iron-containing enzymes (Coburn, 1970; Vreman et al., 2000). Various medical procedures can also generate CO and increase blood COHb (Baum et al., 1995; Fang et al., 1995; Moon et al., 1992; Nezhat et al., 1996; Vreman et al., 2000; Wu et al., 1998).

24.6 Methods for carbon monoxide measurement

Appropriate techniques exist for the quantitation of CO in gaseous samples and tissue samples. In either case, caution needs to be exercised to ensure that CO concentration is not altered by interaction with the sample vessel during storage and transport. For example, Vacutainer tubes were found to greatly alter CO levels when used for storage of blood samples (Vreman et al., 1984). With the recognition of the hazardous nature of CO and its almost universal presence, several sophisticated methods for quantifying CO have been developed (IPCS, 1979; Vreman et al., 2000). Both gas chromatography and spectrophotometry are considered appropriate, although the former is favored (Coburn et al., 1964; Collison et al., 1968; Vreman et al., 1984, 1998; Constantino et al., 1986). The development and ready

availability of many forms of real-time personal and space CO monitors and alarms (including devices for household use) is a relatively recent and welcome development. These devices have no doubt prevented many cases of CO poisoning and have saved many lives.

24.7 Measurement of blood carbon monoxide

Blood CO is still mostly determined by measuring blood COHb levels because of the very high (200–240 times that of oxygen) affinity for CO for hemoglobin (Piantadosi, 1999). Notably COHb levels from venous blood samples appear to correlate with those in arterial blood samples. Fetal blood COHb levels are typically about 30% higher than maternal blood levels, because fetal hemoglobin has a higher affinity for CO than adult hemoglobin.

COHb in blood is quite stable and its concentration does not change over a long period (up to 6 months) provided the sample is stored in the dark and under sterile conditions. Blood levels of COHb are not normally expected to exceed 5% at ambient levels of CO. Several techniques for measuring COHb exist (IPCS, 1979). The more sensitive techniques require the release of CO from hemoglobin into a gas phase followed by direct detection by infrared absorption, difference in thermal conductivity between CO and the carrier gas, amount of ionization after conversion of CO to methane, or the release of mercury vapor resulting from interaction of CO with mercuric oxide. The conventional method of expressing CO in blood samples is as percent COHb, which is calculated using the following formula:

$$\%\ \text{COHb} = \frac{\text{Blood CO concentration mL/100mL of blood}}{(\text{Hb g/100mL of blood} \times 1.389)} \times 100$$

The factor of 1.389 is the combining capacity of CO for hemoglobin in mL of CO/g of hemoglobin. Most modern clinical pathology laboratories use dedicated blood co-oximeters (a form of dedicated spectrophotometer), which simultaneously measure total hemoglobin and fractional (%) values for COHb, oxyhemoglobin, deoxyhemoglobin, and methemoglobin, thus negating the need for manual calculations. Critically, determination of peripheral blood oxygen saturation with typical simple two-wavelength pulse oximeters will not take into account the presence of COHb in the blood and will potentially give spuriously high indications of tissue oxygenation.

24.8 Ambient air carbon monoxide

Because CO concentrations in ambient air and at workplaces are usually quite low, reliable methods for sample collection and transport, and also highly sensitive methods for measurement, are needed (Smith and Nelson, 1973; IPCS, 1979). The sampling method recommended by WHO (IPCS, 1979) comprises a sample introduction system consisting of a sampling probe, an intake manifold, tubing, and air remover. Known gas concentrations are periodically collected to verify the method. According to IPCS (1979), the analyzer system consists of an analyzer as well as sample preconditioning components fitted with a moisture-control system such as the nondispersive infrared (NDIR) analyzer. The infrared absorption near 4.6 μm, characteristic of CO, is used to measure its concentration. The most sensitive analyzers can detect CO concentrations as low as 0.05 mg/m^3 (0.044 ppm). The NDIR analyzer designed by Luft (1962) is considered appropriate because it is little affected by flow rate, requires no wet chemicals, has a short response time, and is sensitive over wide concentration ranges.

Other analyzers include gas chromatography, which is a sensitive, automated, and semicontinuous technique in which CO is separated from water, CO_2, and hydrocarbons (other than methane) by a stripper column and CO is passed through a catalytic reduction tube where it is converted to methane. The converted CO is passed through a flame ionization detector; its sensitivity range is 0.026–43.7 ppm (IPCS, 1979). Other methods such as small personal exposure monitors can measure CO concentrations on a continuous basis and store data on internal digital memories (Ott et al., 1986).

24.9 Home detectors

Residential CO detectors are designed like smoke detectors and provide protection from excessive CO concentrations inside homes by sounding alarms. They are based on an interactive-type sensor, such as tin oxide or artificial Hb that relies on an interaction between CO, and the sensitive element to generate an alarm. The alternate current-powered home detectors have a metallic sensor that reacts with CO. The battery-powered ones have a chemically treated gel that darkens on exposure to CO. They are all designed to sound an alarm within 90 min at CO concentrations of 100 ppm, within 35 min at 200 ppm, or within 15 min at 400 ppm (IPCS, 1979). Inhalation CO concentration of 400 ppm can relatively increase COHb to 10%, with toxicity occurring at levels higher than 10%.

24.10 Carbon monoxide in expired breath

Measurement of CO in the expired breath is based on the assumption that CO in alveolar air is in equilibrium with the partial pressure of CO in blood, which, in turn, is in equilibrium with CO bound to hemoglobin that is COHb (Douglas et al., 1912).

24.11 Toxicokinetics and toxicodynamics

24.11.1 Absorption, distribution, and elimination of carbon monoxide

Although the biological effects of CO differ depending on whether it is inhaled or endogenously produced, the ultimate fate of CO is the same regardless of its source. Exogenous CO reaches the body solely by pulmonary absorption. Once inhaled, CO combines reversibly with hemoglobin and, to a smaller extent, with myoglobin and other iron-containing macromolecules. When reacting with ferrous iron, carbon atoms of CO form a sigma bond, also involving a D-orbital electron from the third shell of Fe^{2+} (Shephard, 1983). In the body, Fe^{2+} also has four nitrogen linkages that contribute a substantial electron density. The effective valency is less than Fe^{2+}, enabling a more readily reversible reaction with both oxygen and CO. The solubility of CO in water is approximately 20% less than that of O_2 and for practical toxicological purposes absorbed CO is effectively absent from the plasma.

Because of the very high CO-binding capacity of hemoglobin within the blood, any CO diffusing into the blood becomes rapidly bound and thus does not contribute to the blood partial pressure of CO. This results in the maintenance of a large partial pressure gradient across the pulmonary capillary bed irrespective of pulmonary blood flow (i.e., right cardiac output) and alveolar ventilation rate (thus it is neither perfusion nor ventilation limited). The limiting factor for absorption of inhaled CO is its ability to diffuse across alveolar membranes. Thus, the inhaled absorption of CO is regarded as being "diffusion limited," a physiological property that is almost unique to CO. Because inhaled CO's partial pressure in the pulmonary capillary blood remains negligible across the entire alveolar membrane it is especially useful for measuring the diffusing capacity of the lung.

Because most of the CO in the body is bound to hemoglobin, the relative affinities of CO and oxygen for hemoglobin are of critical significance in terms of both its toxicity and excretion. This relationship was first described by Haldane (1922; Haldane's first law):

$$\frac{\text{COHb}}{\text{HbO}_2} = M \times \frac{p_{\text{CO}}}{p_{\text{O}_2}}$$

M is the relative affinity of hemoglobin for CO compared with oxygen (between 208 and 245 at 37°C). The Haldane relationship between CO, oxygen, and hemoglobin explains both the high toxic potential of CO and the advantages of hyperbaric oxygen treatment of CO poisoning (Pace et al., 1950; Peterson and Stewart, 1970; Jay and McKindley, 1997). The blood level of COHb as a percent of total hemoglobin is directly related to the exposure duration at any concentration of CO (Fig. 24.1; derived from the Coburn, Forster, and Kane equation). Table 24.2 shows the equilibrium percentage saturation of hemoglobin with CO at various alveolar pressures of CO, calculated using Haldane's first law (IPCS, 1979). Based on human experimental data there are several empirical models for predicting blood COHb levels as a function of ambient CO concentration and exposure time (IPCS, 1979). Under most circumstances the best all-around model for blood COHb prediction under military circumstances is the Coburn, Forster, and Kane equation (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008; IPCS, 1979):

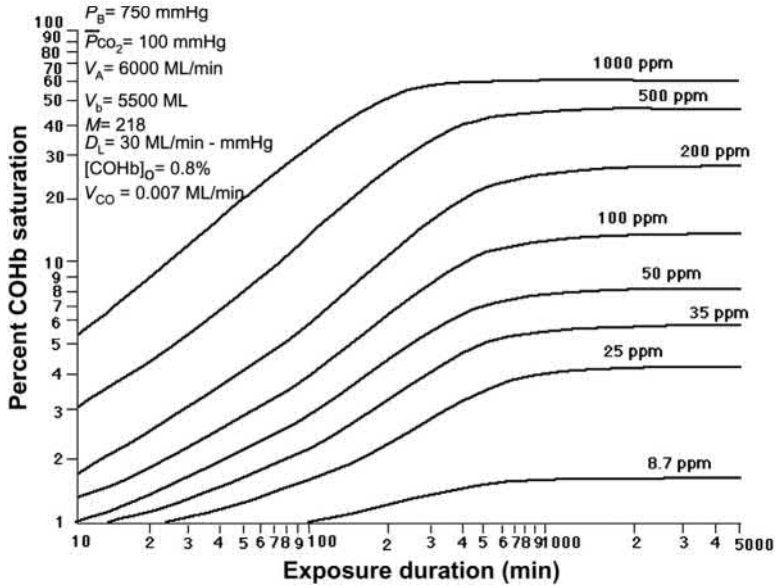

FIGURE 24.1 COHb for different exposure concentration−time combinations as predicted by the Coburn, Forster, and Kane equation. *From Chapter 2, Carbon Monoxide. National Research Council. 2010. Acute Exposure Guideline Levels for Selected Airborne Chemicals, vol. 8. The National Academies Press, Washington, DC. doi: 10.17226/12770.*

[a]*The alveolar oxygen pressure is assumed to be 13 kPA (98 Torr).*

$$\frac{(A \times \mathrm{HbCO}_t - (\mathrm{BV}_{\mathrm{CO}} + \mathrm{PI}_{\mathrm{CO}}))}{(A \times \mathrm{HbCO}_0 - (\mathrm{BV}_{\mathrm{CO}} + \mathrm{PI}_{\mathrm{CO}}))} = e^{-tAV_bB}$$

where:

$A = P_{c,O2}/M$ [HbO_2] where:
$P_{c,O2}$ is the average partial pressure of O_2 in lung capillaries (approximately 110 mmHg at sea level)
M is the ratio of the affinity of blood for CO to that for O_2 (approximately 218)
HbO_2 is the mL of O_2/mL blood, or $= 0.22 - [\mathrm{HbCO}]_t$
$[\mathrm{HbCO}]_t$, is mL of CO/mL blood at time t, or $= [\mathrm{COHb\%}]_t \times 0.0022$
$B = 1/DL_{CO} + PL\ V_A$ where:
DL_{CO} is diffusivity of the lung for CO (mL/min/mmHg), or $= 35VO_2.\ e^{0.33}$
V_A is alveolar ventilation rate (mL/min), or $= 0.933\ V_E - 132f$ and V_E is the ventilation volume (mL/min) and f is the ventilation frequency
PL is barometric pressure minus the vapor pressure of water (i.e., 49) at body temperature (mmHg)
V_{CO} is the rate of endogenous CO production (mL/min); approximately 0.007 mL/min
PI_{CO} is the is the average partial pressure of O_2 in lung capillaries (at sea level 110 mmHg)
$[\mathrm{HbCO}]_0$ is the mL of CO/mL blood at the beginning of the exposure (approximately 0.8% COHb, or 0.0176 mL CO/mL blood for a nonsmoker)
e is the base of natural logarithms (2.7182)
t is the exposure time (minutes)
V_b is the blood volume (mL) (typically assumed to be 74 mL/kg body weight)

Table 24.3 shows the predicted blood HbCO for males with various levels of activity and various breathable air CO concentrations based on the Coburn, Forster, and Kane equation (IPCS, 1979).

H, Heavy physical work; *L*, light physical work; *S*, sedentary subjects.

Table 24.4 shows the exposure conditions that would prevent COHb levels exceeding 5% in nonsmoking occupational groups performing light and heavy physical work (IPCS, 1979).

Under normal physiological conditions there is almost always a certain amount of COHb even when breathing CO-free air because the breakdown of Hb results in endogenous production of CO. This can result in 0.5%–0.8% COHb in normal blood (Lawther, 1975). At any CO concentration in the air COHb will attain an equilibrium and if CO in the air is lower than that required for a given COHb % at equilibrium, then CO will leave COHb and be exhaled until a new equilibrium is established (Fig. 24.1). This has practical implications. For example, a smoker with a relatively high COHb at equilibrium may exhale CO. Also, if the basal COHb is high, then an equilibrium at a high CO concentration in the air will be achieved more quickly than it would be at an initial low COHb.

In practical toxicological terms, CO is eliminated from the body by exhalation. The rate of excretion is primarily dependent on the amounts of CO and oxygen present, the magnitude of ventilation, and the quality of the alveolar diffusion barrier (IPCS, 1979). As a general rule the alveolar diffusion barrier thickens with age, potentially resulting in slower rates of excretion. There are mixed data on

TABLE 24.4 Exposure conditions that would prevent blood COHb levels exceeding 5% in nonsmoking occupational groups performing light and heavy physical work.

Concentration		Exposure time not to be exceeded		Concentrations that would produce 5% HbCO		Safety factor	
ppm	mg/m^3	Light work	Heavy work	Light work	Heavy work	Light work	Heavy work

whether or not biological sex affects excretion rates. The CO blood elimination curve is consistent with a two-compartment elimination model with an initial sharp decline in blood levels over the first 20 min following the cessation of exposure. This "distribution phase" is associated mostly with redistribution to splenic blood, myoglobin, and cytochrome enzymes. This is followed by a slower "elimination phase," which reflects the release of CO from hemoglobin and myoglobin, pulmonary diffusion, ventilation, as well as the fact that pCO generally decreases over time. The whole-body elimination phase kinetics is nonfirst order, that is, the elimination half-life is inversely proportional to blood COHb and is also affected by inhaled oxygen concentration. Under commonly encountered conditions the whole-body elimination half-life ranges from 2 to 6.5 h. This means that high blood COHb levels can occur even at relatively low levels of CO in the inspired air. Considerable interindividual variation in CO elimination is encountered. Previous sustained CO exposure may slow elimination (IPCS, 1979). The elimination half-life of CO in a healthy adult can be reduced by at least a factor of fourfold by the use of supplemental oxygen (Roughton and Root, 1945; Pace et al., 1950; Bartlett, 1968).

As is predictable from the Haldane equation, elimination is much slower under conditions of lower atmospheric oxygen partial pressure. This has been confirmed by studies of human subjects at high altitude (IPCS, 1979). Conversely, increasing the content and/or partial pressure of oxygen in inspired air results in an increased rate of excretion. This is the basis of the currently most reliable antidote for CO poisoning, that is, oxygen at normal or hyperbaric pressures. At high blood COHb levels (40%–70%) a 1-h exposure to a hyperbaric oxygen-enriched environment [oxygen level equivalent to 2.5 atmospheres, partial pressure of oxygen equal to 253 kPa (1900 Torr) or an alveolar oxygen pressure of 239 kPa (1801 Torr)] resulted in a reduction of blood COHb level to about 10%–15% of the initial level (IPCS, 1979). Based on animal data and under conditions of high blood COHb levels (60%–74%), 50% of the absorbed CO was excreted in 19 min when 5% carbon dioxide and 95% oxygen at normal pressures were breathed, compared with a time of 28 min for 100% oxygen, and 41 min for ambient air.

24.12 Mechanism of toxicity

24.12.1 Classical mode of action

The classical toxicological mode of action of CO is tissue hypoxia (Chiew and Buckley, 2014) due to several key events: (1) the preferential binding of CO to hemoglobin due to its >200-fold higher affinity for this molecule than oxygen; (2) the uptake of CO by Hb is very rapid, however the release of CO from COHb complex is slow, resulting in relatively slow excretion via exhalation; (3) as the concentration of COHb increases, the formation of oxyhemoglobin at any concentration of oxygen in the inhaled air decreases; (4) COHb cannot carry oxygen, reducing the oxygen-carrying capacity of the blood; and (5) COHb increases the affinity of the remaining hemoglobin oxygen-binding sites, shifting the oxygen–hemoglobin dissociation curve to the left. The sum total of these effects triggers homeostatic increased cardiac output and increased respiratory rate in order to maintain brain oxygenation and carbon dioxide excretion. Unfortunately, this homeostatic response has the overall effect of increasing CO uptake, exacerbating the pathophysiological situation.

Once a critical level of COHb is reached (which is individually variable) the homeostatic responses are

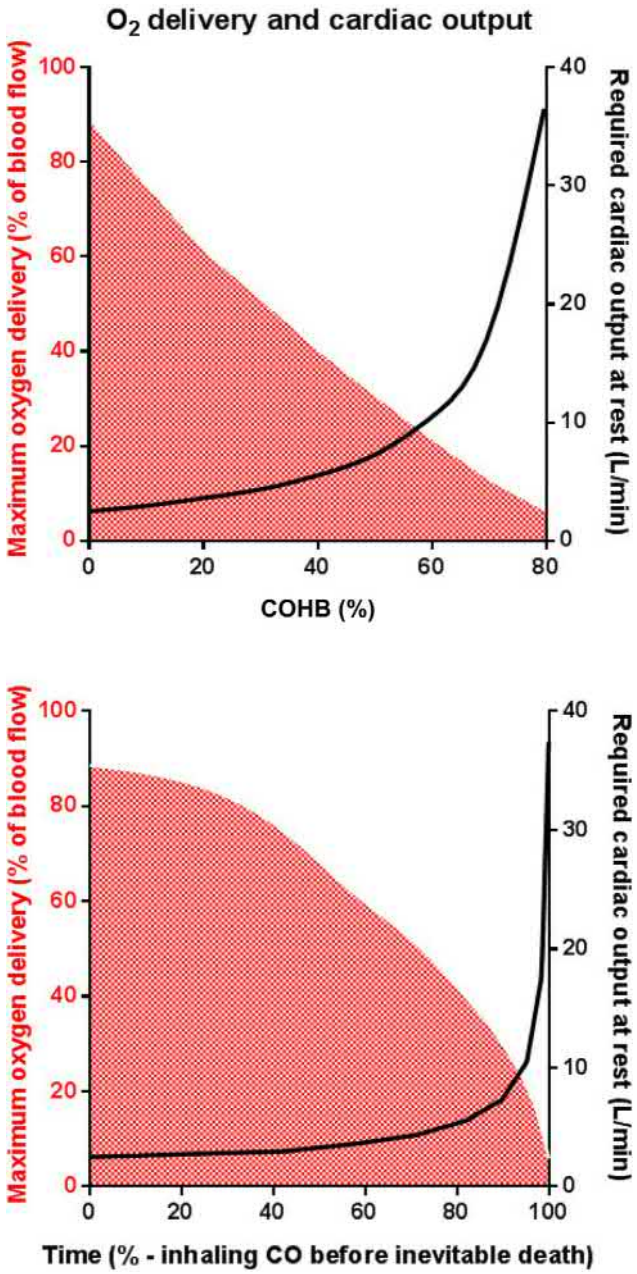

FIGURE 24.2 Carboxyhemoglobin (COHb) versus oxygen delivery capacity of the blood and increased cardiac output required to deliver the same amount of oxygen. (A) This is shown with a linear progression in COHb. (B) In the more likely scenario, there is continuous exposure to COHb and the rate of uptake of COHb is roughly proportional to cardiac output, resulting in a very rapid deterioration to life-threatening poisoning, after a relatively long mild poisoning stage. CO, carbon monoxide; O_2, oxygen. *Reproduced from Chiew, A., Buckley, N., 2014. Carbon monoxide poisoning in the 21st century. Crit. Care 18:221–229.*

unable to compensate for the decreased blood oxygen-carrying capacity and tissue oxygen availability, cardiac hypoxia results in decreased cardiac output exacerbating tissue hypoxia and then death ensues. These relationships are shown in Fig. 24.2 (Chiew and Buckley, 2014). Notably some of the early nonspecific, clinical signs and symptoms of CO poisoning (headache, nausea, and tachycardia) that occur at blood COHb of less than about 40% are more related to the compensatory homeostatic response rather than overt tissue hypoxia.

The biomarkers of the serious toxicity that occurs following the blood COHb level reaching the pathophysiological "tipping point," are sustained unconsciousness and evidence of brain hypoxia (Glasgow coma score of less than 9, seizures), increased blood cardiac injury biomarkers (cardiac troponin I level greater than or equal to 0.7 ng/mL, or creatine kinase-MB level greater than or equal to 5.0 ng/mL, and/or diagnostic electrocardiogram changes), increased serum S100B protein (greater than 0.165 μg/L), systolic blood pressure <90 mmHg, elevated creatine phosphokinase concentration, and leukocytosis (Pepe et al., 2011; Park et al., 2012; Henry et al., 2006). These findings are correlated with poor clinical outcomes.

24.12.2 Electrocardiographic/heart rhythm effects

Both intermittent and continuous CO exposure are arrhythmogenic in animals (Raub and Benignus, 2002). These effects have been presumed to be due to cardiac ischemia and/or sensitization of the myocardium. Indirect effects associated with changes in platelet aggregability have also been proposed. Exercise exacerbated the effects in some studies.

24.12.3 Cardiac hemodynamic effects

Although there are contradictory data in animal studies there is a general consensus that CO in sufficiently high doses can deleteriously affect many cardiac hemodynamic variables (Raub and Benignus, 2002). Homeostatic increases in coronary blood flow in response to increasing blood COHb levels have been demonstrated. Limited data suggest that once blood COHb levels of 6%–7% are achieved there is no further increase in coronary blood flow. This suggests that even small increases in blood COHb may be problematic in cardiac-disabled individuals. Relative underperfusion of the myocardial subendocardial layer (particularly of the left ventricle) and lowered local PO_2 have been demonstrated in animal models at blood COHb levels of 41%.

24.12.4 Cardiomegaly

Subchronic repeated daily exposure to moderate levels of CO has been repeatedly demonstrated to cause reversible whole heart cardiomegaly in animal models (Raub and Benignus, 2002). The cardiomegaly was accompanied by changes in cardiac lactate dehydrogenase isoenzyme composition that were similar to those reported in other

conditions that cause cardiac hypertrophy. In rats, the exposure threshold for the effect is about 200 ppm of CO in air, equating to about 12% blood COHb.

24.12.5 Other cardiac effects

The interaction of CO with myoglobin can also explain some of its toxic effects. This effect impairs oxygen supply to cardiac muscle mitochondria, resulting in an effect similar to myocardial ischemia. Patients with underlying cardiac conditions are therefore at high risk for cardiac arrhythmias after exposure to CO (DeBias et al., 1976; Henz and Maeder, 2005; Olson, 1984; Sangalli and Bidanset, 1990) as well as chest pain and death. The interaction of CO with skeletal muscle myoglobin can also cause muscle weakness (Herman, 1998; Wolf, 1994; Richardson et al., 2002).

24.12.6 Effects on cerebral blood flow

CO exposure triggers the stereotypical homeostatic response of the cerebral vasculature to hypoxia, namely increasing cerebral blood flow in order to maintain cerebral oxygen delivery and/or by increasing oxygen extraction in order to maintain cerebral oxygen utilization (Raub and Benignus, 2002). Notably, global cerebrovascular resistance decreases more with CO exposure than simple hypoxia and there are brain regional differences in tissue injury associated with severe CO poisoning. Brain regions that appear to be particularly sensitive are those with normally high blood flow and oxygenation requirements, such as the caudate nucleus and midbrain. The blood supply to the neurohypophysis, because of its unique physiological regulation in relation to hypoxia, does not change even with relatively severe CO poisoning.

24.13 Effects on brain metabolism

CO binds to many heme-containing proteins such as myoglobin, guanylyl cyclase, and cytochrome oxidase (Chance et al., 1970; Hill, 1994; Omaye, 2002; Kao and Nanagas, 2006). This results in an inhibition of cellular metabolism that remains even after COHb levels decline to within the normal range (Olson, 1984; Brown and Piantadosi, 1992; Piantadosi et al., 1995). However, the affinity of CO for cytochrome oxidase is very low and this interaction typically requires very high (lethal) CO concentrations (Prockop and Chichkova, 2007).

24.14 Redox and reoxygenation/reperfusion injuries in the brain

Even at sublethal concentrations, binding of CO to cytochrome may lead to the generation of superoxides (Zhang and Piantadosi, 1992; Hardy and Thom, 1994) and interference with cellular respiration. Inflammatory changes in acute CO poisoning also include neutrophil activation following interactions with platelets resulting in degranulation and perivascular oxidative stress. Additionally, CO promotes neutrophil adhesion to the microvasculature, resulting in the activation of xanthine oxidase and generation of oxidative radicals. Nitric oxide (NO) is also claimed to be an important mediator of CO-poisoning-induced oxidative effects (Kao and Nanagas, 2006). The overall end result of these effects is brain lipid peroxidation, one of the likely causes of CO poisoning-associated delayed neurological sequelae (along with changes in cerebral blood flow; Thom, 1990, 1993; Hardy and Thom, 1994; Thom et al., 1994, 1997, 2001; Ischiropoulos et al., 1996; Gilmer et al., 2002; Zhang and Piantadosi, 1992). Unfortunately, many of the studies that support these claimed modes of action lack positive controls, thus it is unclear if the observed effects are CO-specific or just oxidative effects associated with stereotypical tissue reperfusion injury.

24.15 The catecholamine crisis hypothesis

The basis for this hypothesis is that CO and sympathomimetics, such as cocaine and the amphetamines, produce similar characteristic basal ganglia injuries. According dopamine excess in the presence of hypoxia may result in neuronal excitotoxicity in the brain dopaminergic and/or serotonergic regions. This may explain the initial (acute) phase of CO-associated neurotoxicity. The hypothesis further posits that dopamine and/or serotonin excess can sustain for several weeks in the synapses in deep white matter, enhancing the oxidative metabolism of dopamine-generating reactive species and triggering abnormal inflammatory responses. As a result, serotonergic axonal injury and secondary myelin damage may lead to the delayed leukoencephalopathy or CO-associated DNS, in which leukoencephalopathy can be found in the white matter. A similar hypothesis has been proposed for 3,4-methylenedioxy-methamphetamine (MDMA) leukoencephalopathy.

24.16 Other possible mechanisms of central nervous system toxicity

Other potentially important events in CO-induced central nervous system damage include: (1) CO activation of guanylyl cyclase which triggers cerebrovascular vasodilation and cerebrovascular hypotension (Verma et al., 1993; Snyder and Ferris, 2000; Wu and Wang, 2005); (2) immune-mediated effects secondary to oxidative

damage to myelin basic protein (Ernst and Zibrak, 1998; Prockop and Chichkova, 2007; Thom et al., 2004); (3) glutamate-induced neuronal excitotoxicity (Ishimaru et al., 1992; Penny and Chen, 1996; Piantadosi et al., 1997); (4) atherogenesis (Lightfoot, 1972; Thom et al., 1999); and (5) apoptosis (Piantadosi et al., 1997).

24.17 Toxicity of carbon monoxide

24.17.1 Factors affecting susceptibility to poisoning

Important factors affecting individual susceptibility to CO poisoning are generally those that either produce higher initial COHb levels or affect the capacity of an individual to compensate for the decreased blood oxygen-carrying capacity. Common factors that fit into these categories include:

- Tobacco smoking due to increased initial blood COHb and effects on the cardiovascular and respiratory systems;
- Concurrent heart disease;
- Anemia;
- Concurrent exposure to agents that bind to hemoglobin and produce hemolysis and/or anemia, for example, dinitrotoluenes, nitroanilides, arsine, PAPP, other blood agent chemical weapons;
- Concurrent exposure to agents that produce methemoglobinemia, for example, nitrites;
- Respiratory diseases including asthma and chronic obstructive pulmonary disease;
- Lung damage due to inhalation of superheated gasses/air during following fire exposure;
- Concurrent physical exertion;
- Concurrent exposure to an oxygen-deprived environment;
- Concurrent exposure to high levels of both oxidative and/or acidic and/or particulate air pollution;
- Concurrent cyanide poisoning: some degree of concurrent cyanide poisoning is reputed to be common following some types of smoke inhalation. Concurrent cyanide exposure may also be relatively common in the battlefield environment;
- Concurrent exposure to hydrogen sulfide. A potentially common occurrence in enclosed environments containing decaying organic material, during coal mining, during petroleum and petroleum gas extraction, etc.;
- Concurrent exposure to agents that reduce central respiratory drive, for example, alcohol, barbiturates, promazine drugs, opioids, etc.;
- Concurrent exposure to agents affecting the cardiovascular system, for example, beta-blockers, calcium-channel blockers, nitrates, etc.;
- Concurrent hypothermia;
- Fetal stage of development due to the higher CO-binding affinity of fetal hemoglobin;
- Infants due to the presence of fetal hemoglobin;
- Pregnancy, particularly late-stage pregnancy, due to increased basal cardiovascular and respiratory system demand (and other factors);
- High altitude;
- Any factor that shifts the hemoglobin−oxygen dissociation curve to the left [decreased body temperature, decreased 2,3-diphosphoglycerate, decreased blood (H^+)];
- Concurrent exposure to noise exacerbates acute CO poisoning-associated hearing loss.

Other factors often relate to allometric parameters (e.g., higher respiratory minute volumes per unit body mass). These include:

- Fetal stage of development due to allometric factors;
- Infants due to allometric factors;
- Smaller body size in animals due to allometric factors, for example, mice are likely to die more quickly than humans due to their higher respiratory minute volume per unit of body mass;
- Respiratory efficiency, for example, the respiratory efficiency of birds on a per unit body weight basis is higher than that of mammals;
- Reduced capacity to escape, for example, alcohol consumption or use of other debilitating psychotropics, physically trapped, etc.

24.17.2 Combined exposures to carbon monoxide, cyanides, and other toxicological gases in battlefield and military circumstances

Modern weapons emissions are known to include CO, hydrogen cyanide, and other gases (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008). Furthermore, in naval operations combined exposures to CO, cyanides, gaseous ammonia, chlorine, vaporized hydrogen chloride, hydrogen sulfide, nitrogen dioxide, and sulfur dioxide may occur (National Research Council, 2002). The United States Army has, based on weight of evidence, concluded that (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008):

> *the adverse effects of CO and HCN at lethal and incapacitating concentrations inhaled over periods of about 30 minutes or less are additive. However, for exposures occurring at lower and varying concentrations over periods of several weeks to perhaps several years, it is not known whether*

military personnel, while also in the presence of other combustion gases, may experience similar additive effects. No relevant chronic or low-level exposure studies were found in the literature.

The recommendations of the United States Army are that (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008):

- The toxic effects of CO and HCN are probably additive, and, therefore, the effects from combined exposures to these chemicals should be assessed as a mixture and not individually.
- Until further findings suggest otherwise, the use of the HQ approach proposed by the Army is reasonable in establishing exposure limits for personnel simultaneously exposed to CO and HCN.
- The use of the CFK equation [Coburn, Forster, and Kane equation] for the prediction of COHb levels related to air concentrations of CO is appropriate (The United States Army uses the Coburn, Forster, and Kane (CFK) equation to estimate the percentage of COHb in the blood of military personnel in armored vehicles based on measurements of CO in the air inside of vehicles; however, it was recommended in 2008 that the Army utilize real-time instantaneous and running average gas monitoring (multiagent monitoring) equipment rather than total reliance on the CFK equation.).
- The CFK equation has not been adequately evaluated in environments with dynamically changing air concentrations, such as in a weaponized armored vehicle.
- The use of an air concentration for HCN in the HQ equation, as opposed to a blood concentration, is reasonable.

The United States Army has also identified a number of important data gaps regarding CO exposures within the modern battlefield/military contexts (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008):

further neurologic studies on sensory and motor performance at lower concentrations of HCN and CO because most studies on the combined toxicity of CO and HCN have been carried out at high concentrations and have focused on lethality and/or incapacitation; this makes it difficult to use those data to extrapolate to low levels of exposures and to assess more-subtle effects of interest to the Army. Finally, the committee recommended that the Army consider concurrent exposures to other chemicals (for example, other combustion products and diesel exhaust), which may have additional effects on the armored-vehicle crew.

24.17.3 Acute toxicity

Importantly, seemingly acute CO poisoning can result from both sudden exposure to high levels of the gas or the cumulative formation of COHb following more prolonged, slower, and more insidious exposures. Clinical signs associated with the acute CO poisoning toxidrome range from nociceptive effects (headache, weakness, upset stomach, vomiting, chest pain, and confusion) to dizziness to death. CO poisoning symptoms have been described as being "flu-like" and the clinical signs in some people can mimic those of alcohol intoxication, that is, some individuals can appear and behave like they are drunk due to ethanol consumption.

Symptoms of CO poisoning begin at approximately 20% COHb and death usually ensues between 50% and 80% COHb (Ryter and Otterbein, 2004). The classical relationship between blood COHb and toxic signs and symptoms is presented in Table 24.5. More detailed studies have also been performed on crew members of the MIR space station (National Research Council, 2008) (Fig. 24.3). The correlation between blood COHb level and clinical manifestations can be unreliable in many patients because of premeasurement delay, initiation of oxygen therapy before blood sampling, and/or concomitant cyanide or other types of poisoning.

Of critical note is that most modern pulse oximetry devices will not detect CO poisoning and are likely to

TABLE 24.5 Relationship of carboxyhemoglobin (COHb) to toxicity in humans following exposure to carbon monoxide.

COHb %	Signs and symptoms
<10	No effects in healthy individuals[a]
10–20	Mild headache, exertional dyspnea, cutaneous vasodilation
20–30	Throbbing headaches, nausea
30–40	Severe headaches, dizziness, visual disturbance, fatigue
40–50	Tachypnea, tachycardia, collapse, syncope
50–60	Coma, convulsions, Cheyne–Stokes respiration
60–70	Cardiorespiratory depression, possible death
>70	Respiratory failure and death

[a]*Symptoms may appear in subjects with cardiovascular disease. Concentration of COHb depends upon the duration of exposure to any concentration of CO in the air and is therefore not included in the table. Exposure to approximately 200 ppm for 2 h results in 10% COHb; ~12,000 ppm CO would produce lethal concentrations of COHb within two or three breaths.*

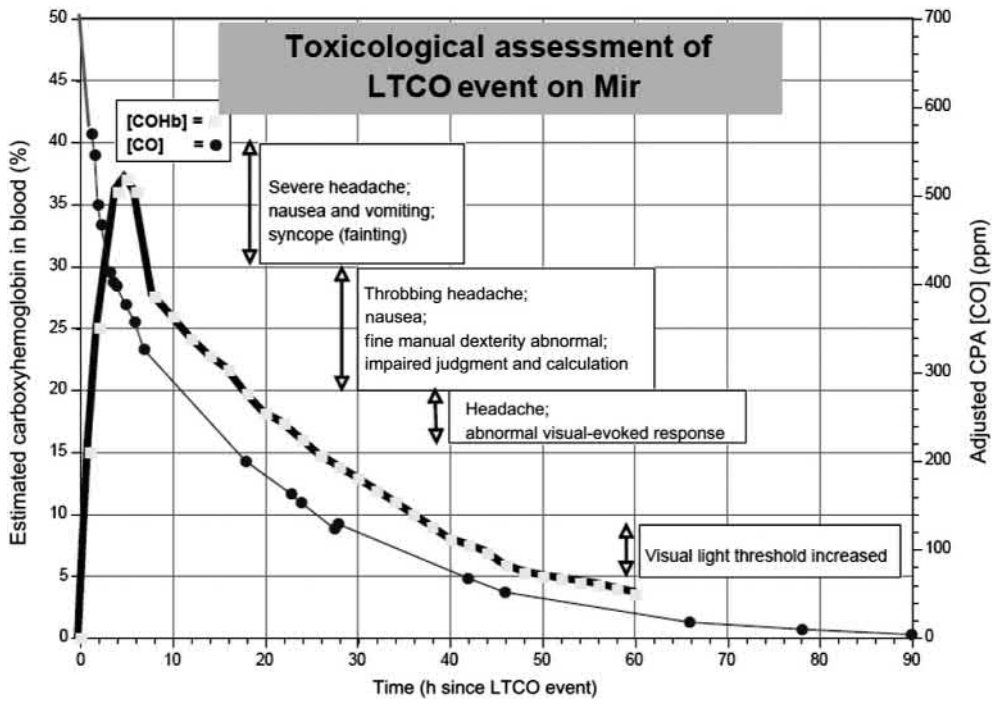

FIGURE 24.3 CO and COHb concentrations and toxic health effects observed on a space station (National Research Council, 2008).

give spurious indications of the level of peripheral blood oxygen saturation. When CO poisoning is suspected, a pulse CO-oximeter or breath CO monitoring should be used. Breath CO monitoring is advantageous in that there is a strong correlation between COHb levels and breath CO concentration.

24.17.4 Delayed (interval) manifestations of acute toxicity

Delayed neurological and neuropsychiatric effects in survivors of serious acute CO toxicity are extremely common and occur within 2−40 days post-exposure at a rate of between 2% and 40% of patients (Mannaioni et al., 2006; Raub and Benignus, 2002; Yoshii et al., 1998; Okeda et al., 1981; Hsiao et al., 2004; Parkinson et al., 2002). Early (acute phase) and late occurring (subacute phase) brain injuries have been noted. In many cases the observed injuries resemble those associated with ischemic-hypoxic central nervous system injuries due to other causes. The most common injuries are symmetrical bilateral basal ganglia abnormalities with the early-phase injuries most commonly being found in the basal ganglia and corpus callosum, and often more clearly, in bilateral globus pallidus. Later occurring injuries tend to be symmetrical deep brain leukoencephalopathies and diffuse inflammations in semicentrum ovale or periventricular brain regions. The neuroclinical manifestations of CO poisoning include memory loss, movement disorders/chorea, Parkinsonian-like syndromes, communication disturbances, depressed mood, dementia, and psychosis.

Visual disturbances after recovery from a period of CO-induced unconsciousness have also been reported (Kelly and Sophocleus, 1978). Moderate to severe CO poisoning can shorten lifespan because of myocardial injury (Henry et al., 2006).

Concurrent CO plus noise exposure has been found to cause hearing loss in humans (Sato, 1966; Morris, 1969; Goto et al., 1972; Makishima et al., 1977) and in animal models (Douglas et al., 1912; Fechter et al., 1988; Liu and Fechter, 1995).

24.18 Typical anatomic pathology findings

The classical gross anatomic pathology findings are cherry red liver mortis with bilateral hemorrhages and/or necrosis in the globus pallidus if the person has survived long enough. Important differential diagnoses for cherry red lividity include thallium poisoning, cyanide poisoning, and hypothermia. The cherry red discoloration is often relatively long-lived compared with cases of cyanide poisoning due to the somewhat slower postmortem reversion of COHb to hemoglobin compared with the postmortem deoxygenation of oxyhemoglobin. The possible presence of cherry red lividity is best evaluated against a white background.

Important microscopic findings, apart from general indications of tissue hypoxia, include foci of ischemic or hemorrhagic necrosis in globus pallidus and perivascular foci of demyelination in deep white matter with sparing of arcuate fibers. At the histopathology level important differentials include methanol poisoning manifesting as necrosis of the putamen and other causes of hypoxia.

24.19 Treatment of carbon monoxide overdose

24.19.1 Oxygen

The fundamental basis of using supplemental oxygen at normal or hyperbaric pressures has been described in detail above and was first elaborated by Haldane (Haldane, 1895, 1922; Haldane and Priestley, 1935). Supplemental oxygen remains the mainstay of treatment of CO poisoning. Hyperbaric oxygen is generally indicated in cases displaying loss of consciousness, ischemic cardiac changes, neurological deficits, significant metabolic acidosis, and COHb greater than 25%. However hyperbaric oxygen therapy remains somewhat controversial due to limited practical evidence of efficacy despite its seemingly valid theoretical justification (likely due to other detrimental modes of action apart from simple tissue hypoxia).

24.19.2 Targeted temperature management

Targeted mild therapeutically induced hypothermia has been used for the treatment of post-cardiac arrest or hypoxic–ischemic brain injury. The experimental underpinnings of the technique are based on the hypothermic inhibition of neurotransmitter (glutamate, dopamine, catecholamines) production, release and reuptake and thus the possible reduction of excitotoxicity and free radical generation (Arrich et al., 2016). Limited retrospective case series data ($n = 227$; Oh et al., 2016) regarding the use of the induced hypothermia in combination with hypobaric oxygen for treatment of patients with severe acute CO poisoning (defined as: history of CO exposure and any of Glasgow coma scale score <9 after acute CO exposure, blood COHb level $>25\%$, and S100B protein level $>0.165\ \mu g/L$) appears to show some beneficial effects. However, a control group was not included in the study.

24.19.3 Sympatholytics and sedation

The theoretical underpinnings for the use of sympatholytics (dexmedetomidine, remifentanil) and sedatives lie in the catecholamine crisis theory of CO poisoning-delayed neurological injury (Oh and Choi, 2015). The objective of sedation and/or sympatholytics is to suppress CNS sympathetic neurological activity. This approach can, at least in theory, be used concurrently with therapeutic hypothermia. There is currently little practical evidence of therapeutic benefit outside of these theoretical underpinnings.

24.19.4 Allopurinol and *N*-acetylcysteine

The basis for this approach is the evidence that some of the toxic effects of CO poisoning are produced by release of reactive oxygen metabolites and xanthine oxidase plays a major role in these processes (Kekec et al., 2010; Sokal and Kralkowska, 1985; Thom, 1992; Zhang and Piantadosi, 1992). Xanthine oxidase is a nicotinamide adenine dinucleotide (NAD)-dependent dehydrogenase, which is converted to oxidase under ischemic conditions utilizing molecular oxygen in place of NAD and, in the process, generates superoxide radicals and hydrogen peroxide. Allopurinol is a xanthine oxidase inhibitor and *N*-acetylcysteine is a sulfhydryl donor. Limited evidenced of efficacy of these agents against neuronal injury caused by CO has been documented (Kekec et al., 2010; Howard et al., 1987; Thom, 1992). However, substantive clinical trial evidence of efficacy is lacking.

24.19.5 Insulin

Hyperglycemia, which follows stroke or myocardial infarction, worsens the resulting neurological insult. Acute CO poisoning is also characterized by hyperglycemia, which has been found to worsen brain dysfunction in rats (Penny, 1990). Similar observations have also been made in CO-poisoned patients (Pulsinelli et al., 1980). Moreover, neurological complications of CO poisoning in diabetic patients seem worse than in healthy individuals. There is evidence that insulin treatment is effective in reducing neuronal damage caused by stroke or cardiac arrest, and limited evidence of efficacy is available for the treatment of CO poisoning in humans (White and Penny, 1994). Again, substantive evidence of benefit in clinical cases is lacking.

24.20 Acceptable exposure levels within the military context

The United States Army has established a maximum acceptable blood COHb limit of 5% for aviation crews and 10% for all other army personnel (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008). The Army also uses the current US American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) ceiling of 4.7 parts per million (ppm) for inhalable cyanide exposure. Because of the at least

additive effects of CO and cyanide the Army has developed a hazard quotient approach for short-term (less than 30 min) exposures (Committee on Combined Exposures to Hydrogen Cyanide and Carbon Monoxide in Army Operations, 2008):

$$\text{Hazard quotient} = \frac{\text{COHb\%}}{10\%} + \frac{15 - \text{minaverage HCN(ppm)}}{4.7\text{ppm}}$$

Hazard quotient of ≥ 1.0 indicated unacceptable over exposure.

The United States Navy has adopted an approach of assuming that the total irritancy effects of ammonia, chlorine, hydrogen chloride, hydrogen sulfide, nitrogen dioxide, and sulfur dioxide mixtures are additive but not synergistic and uses a cumulative exposure index approach in setting submarine escape action levels (SEALs) (National Research Council, 2002). However, the Navy has called for further research regarding the combined effects of gases that produce various forms of hypoxia, that is, the interactions between hydrogen cyanide, CO, and hydrogen sulfide (National Research Council, 2002). Combined exposures may also occur with acrolein, formaldehyde, hydrazine, methanol, monoethanolamine, and oxygen (National Research Council, 2007). The United States Navy Health Research Center's Toxicology Detachment has proposed two exposure levels, called submarine escape action level (SEAL) 1 and SEAL 2, for CO of 125 and 150 ppm, respectively (National Research Council, 2002, 2007). Importantly SEAL 1 is defined as the maximum concentration of a gas in a disabled submarine below which healthy submariners can be exposed for up to 10 days without experiencing irreversible health effects. The value is based upon a blood COHb level of less than or equal to 15%. SEAL 2 is defined as the maximum concentration of a gas in a disabled submarine below which healthy submariners can be exposed for up to 24 h without experiencing irreversible health effects. Exposures at SEAL 1 and SEAL 2 might produce moderate, reversible health effects but they will not impair the functions of the respiratory system and central nervous system to the extent of impairing the ability of crew members in a disabled submarine to escape or be rescued or perform specific tasks, such as shutting off a valve and using a fire extinguisher. The United States Navy has also set emergency exposure guideline levels (EEGLs) of 180 ppm for 1 h and 45 ppm for 24 h of exposure (National Research Council, 2007). Additionally, a continuous exposure guideline level (CEGL) of 9 ppm has been set for a 90-day exposure duration (National Research Council, 2007).

The United States National Aeronautics and Space Administration has established spacecraft maximum allowable concentrations (SMACs) for CO based upon studies of the performance of crew members of the MIR space station (National Research Council, 2008):

- 1-h SMAC = 425 ppm based on a ≤15% blood COHb level;
- 24-h SMAC = 100 ppm based on a ≤15% blood COHb level;
- 7-day SMAC = 55 ppm based on a ≤15% blood COHb level;
- 30- and 180-day SMAC = 15 ppm based on a ≤2% blood COHb level.

24.21 Defensive measures

Given that inhalation of CO is the major route of exposure of concern under virtually all military circumstances, defensive measures against exposure are potentially relatively simple. Appropriate nonair-supplied respirators and appropriate filters and/or gas scrubbing systems are cheap and readily available. Such systems provide adequate short-term protection from exposures provided that the associated atmosphere is not oxygen-depleted. Air-supplied systems will always be required in oxygen-deprived circumstances, such as those that might be encountered with compartment fires and in low-lying bunker systems, etc. The main limitations of all of these defensive systems are well known and have been recognized since the time of World War I and include: (1) the additional encumbrance of ground troops which limits their mobility and capacity to maneuver at speed; and (2) these defensive systems have a limited period of effective operation, that is, if the affected troops can be contained in such a manner that their gas protection systems become exhausted they then become especially vulnerable to further gas attack.

24.22 Concluding remarks and future directions

Being an inevitable consequence of the combustion of organic materials, battlefield CO exposures, whether deliberately applied or incidental, are likely an ancient phenomenon of warfare dating back to the very beginnings of recorded human history and beyond. Given that combustion is an integral part of the operation of modern military vehicles and weapons systems, incidental CO exposure will continue to be part of the battlefield experience for the foreseeable future. Given the simplicity, ease, and low cost of its production and other factors, the deliberate use of CO as a weapon in particular military circumstances will likely continue. While there is now a very substantial medical and toxicological understanding of the consequences of simple CO exposures there remain

important gaps in the understanding of the implications and role of CO in the effects of complex gas mixtures that are likely to occur in association with modern battlefields and modern weapons systems.

Chapter 25

Acute cyanide toxicity and its treatment: the body is dead and may be red but does not stay red for long

Rhian B. Cope

Australian Pesticides and Veterinary Medicines Authority, Canberra, Australia

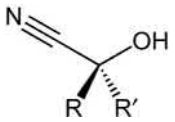
25.1 Introduction: basic terminology and a brief and tragic history of the use and misuse of cyanide

This chapter attempts to provide a basic introduction to the military and paramilitary use of acute cyanide toxicity as a weapon technology. The chapter does not attempt to cover other types of cyanide poisoning phenomena in depth nor does it discuss the various chronic toxicological syndromes associated with cyanide exposure.

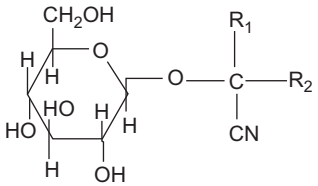
The chemical compounds referred to as cyanides all contain the $-C{\equiv}N$ cyano functional group consisting of a carbon atom triple-bonded to a nitrogen atom. In their inorganic forms cyanides typically exist in the forms of the CN^- anion in solution or its solid salts (commonly sodium cyanide or potassium cyanide). Acidification of cyanide salts results in the formation of the highly volatile liquid hydrocyanic acid (synonyms: hydrogen cyanide, prussic acid), which has the chemical formula HCN and the military designation "AC." Cyanogen chloride ($N{\equiv}C-Cl$) has the military designation "CK."

In military terms, cyanides were historically called "blood agents" (now redundant) since at their time of introduction onto the battlefields of World War I the other members of the suite of available chemical weapons acted at sites of first contact (i.e., the respiratory tract, mucous membranes, eyes, and skin), whereas cyanide produced "systemic effects" that required distribution to the tissues "by blood." In more modern toxicological parlance cyanides are histotoxic hypoxia agents since they inhibit the ability of cells to use oxygen from the bloodstream despite initially normal delivery of oxygen to the cells and tissues via the bloodstream.

Organic compounds that contain an $R-C{\equiv}N$ functional group are typically referred to as nitriles or contain the prefix "cyano." If there are multiple $R-C{\equiv}N$ functional groups in an organic compound it is typically referred to as a cyanocarbon. Cyanohydrins are a type of naturally occurring nitrile that can release hydrogen cyanide. The cyanohydrin functional group consists of a cyano and a hydroxyl group is attached to the same carbon molecule, that is:



Many plants, including some species that are important human and animal food sources, produce cyanogenic glycosides in response to adverse growth conditions and/or for the purposes of chemical defense. These phytotoxins consist of a sugar molecule bonded to a cyanohydrin via its hydroxy functional group (i.e., via a glycosidic bond); for example:



Due to hydrolysis, hydrogen cyanide is released from these molecules following crushing of the plant (e.g., during mastication), digestion, or during food processing.

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00025-8

The first reported isolation of hydrocyanic acid from Prussian blue [ferric hexacyanoferrate (II)] was by the Swedish chemist C.W. Scheele in 1782, and he was also reported to be its first victim when, in 1786, he accidentally broke a vial of the chemical in the laboratory and died from cyanide vapor poisoning (Ballantyne and Marrs, 1987). However, cyanide and its derivatives have been used as political and military tools since at least the days of ancient Rome (Sykes et al., 1981). Famously, the Roman emperor Nero used cherry laurel water, containing cyanide derived from cyanogenic glycosides during the distillation process, as a political assassination tool. Napoleon III proposed the lacing of soldiers' bayonets with cyanides during the 1870–71 Franco-Prussian War.

During World War I the French army used, largely unsuccessfully, about 4000 metric tons of cyanide in various types of weaponry. The lack of military effectiveness of these weapons has been attributed to several factors: (1) the small size of the munitions could not deliver sufficient amounts of cyanide to cause widescale biological effects under battlefield conditions; (2) hydrogen cyanide's high volatility meant that the agent would quickly evaporate and disperse rather than being persistent on the battlefield; (3) as a killing or maiming agent it had few militarily useful effects below the lethal concentration × time exposure level (i.e., its military useful effects were judged to be essentially "all or nothing"); and (4) German soldiers were adequately equipped to protect themselves from HCN exposure. Mixing HCN with other agents ("Vincennite" consisting of 50% HCN, 30% arsenic trichloride, 15% stannic chloride, and 5% chloroform) did not improve the military effectiveness of cyanide under World War I battlefield conditions.

In 1916, the French experimented with cyanogen chloride. Cyanogen chloride was considered to have the more desirable military properties of being heavier and less volatile than HCN. The effect of cyanogen chloride was similar to HCN. An additional perceived advantage of cyanogen chloride over HCN was that it caused marked lacrimation, rhinorrhea, and increased bronchial secretions in a manner similar to phosgene. Cyanogen bromide (C≡N − Br) was also briefly used in World War I.

The Soviet Union considered the use of cyanide-based weapons possibly as early as the 1920s. Grigory Mairanovsky, the head of the People's Commissariat for Internal Affairs (NKVD) Laboratory 1 from 1938 to 1946 is alleged to have conducted human prisoner experiments on cyanide. By the 1960s declassified US National Intelligence Estimates indicated that the Soviet military had the capacity to produce and maintain militarily effective concentrations of hydrogen cyanide for 10–15 min over a militarily useful area (National Intelligence Estimate Number, 1969).

The story of the development of Zyklon B in pre-Nazi Germany, and its subsequent deliberate, politically motivated misuse by the Nazi government, is of particular note in the history of pesticide toxicology; especially since these agents were developed with the best of intentions at a time of significant need (Robinson, 1971; Baskin and La Cleur, 1998). During World Wars I and II and the interwar period, one of the most feared epidemic public health diseases in the preantibiotic era was typhus, which is caused by *Rickettsia prowazekii*. Typhus is spread by the human body louse *Pediculus humanus*. Another militarily important disease of World War I that was spread by the human body louse is trench fever caused by *Bartonella quintana*. Yet another important, potentially high mortality disease in the preantibiotic era that is spread by the human body louse is relapsing fever caused by *Borrelia recurrentis*. The human body louse, and the diseases transmitted by it, were ubiquitous under the battlefield conditions of World War I; and then subsequently amongst the crowded, impoverished populations of Europe (particularly in Germany) during the interwar period. Thus the control of the human body louse became a major public health and military priority during World War I, the interwar period, and World War II.

During World War I, the interwar period, and World War II fumigation using volatile hydrogen cyanide had become recognized as one of the most effective and reliable ways to control human body louse-borne diseases (and other important food pests) in both military and civilian circumstances. However, the shelf-life of purified liquid hydrogen cyanide is quite short and mishandling of the agent was extremely dangerous. Accordingly, better solutions were actively sought.

During the 1920s scientists working at the Fritz Haber Institute in Germany determined that cyanide could be more safely handled if it was adsorbed into inert, porous materials. Its shelf-life could also be improved if it was coformulated with a chemical stabilizer. These discoveries, the desire to control potentially dangerous louse-borne epidemic diseases, and the desire to reduce pest-associated food loss during a time of widespread relative food insecurity, led to the German production of the now infamous Zyklon B pesticide family (Zyklon in German translates to "cyclone" in English; the letter B stood for *Blausäure*—prussic acid—and was used to distinguish the product from the Zyklon A pesticide product range which used methyl cyanoformate as the active ingredient).

Zyklon B formulations consisted of hydrogen cyanide (about 40% by mass) adsorbed into one of several different absorbents (calcium sulfate or diatomaceous earth were common; use of cyanide absorbents was a legal requirement in Germany at the time), one of several

different cautionary eye irritants (the inclusion of which, notably, was not a legal requirement in Germany at the time), and one of several different stabilizers. Cautionary eye irritants were used since it was well understood by this time that a portion of the population were functionally anosmic to the classic bitter almond smell of cyanide vapor. In a further attempt to ensure safe use, 200 g of the Zyklon B formulation was packed in metal cans that could only be opened with a special tool (Fig. 25.1). Based on the number of different patents for the Zyklon B formulation family (held by Deutsche Gesellschaft für Schädlingsbekämpfung mbH aka Degesch; whose first director, somewhat ironically given that several members of his family were subsequently eliminated using Zyklon B during the holocaust, was Fritz Haber) there was no chemically simple approach to the need for chemical stabilization.

For its time, Zyklon B fumigation proved highly effective and beneficial in reducing human body louse-borne disease, for controlling various vertebrate and invertebrate pests, and for minimizing pest-associated food loss. In many cases (including at Holocaust sites) legitimate Degesch-designed tunnel/chamber delousing facilities were used. The correct civilian use of Zyklon B in the manner that was originally intended was reputedly, for the era, relatively safe and likely saved many human lives.

FIGURE 25.1 Canisters of Zyklon B found in the Dachau concentration camp. *United States Holocaust Memorial Museum; Provenance William and Dorothy McLaughlin. Source Record ID: Collections: 2005.442.*

By 1936 Degesch, was part owned by Degussa AG (which, ironically, also produced the plasticizer and anti-graffiti coating used in the 2005 Berlin Holocaust Memorial), and IG Farben. These companies produced the Zyklon B without eye irritant (perfectly legal in Germany at the time) that was subsequently sold to the German army and the Schutzstaffel via the companies of Tesch & Stabenow GmbH (Testa) and Heerdt-Linger (Heli).

Dissatisfied with the use of carbon monoxide and shooting as methods of quick and efficient systematic mass murder, Rudolf Hoess, the Schutzstaffel commandant of the Auschwitz extermination camp from 1940 to 1943, and his deputy Karl Fritzsch began experimenting with the use of Zyklon B on humans. At the time Zyklon B fumigation was legitimately being used within the German prisoner of war and forced labor camps for human body louse and other pest control. Based on Hoess's experiments that involved the gassing of 600 Soviet prisoners of war and 250 sick prisoners judged to be incapable of forced labor, Zyklon B was judged to be the quickest and most efficient mass murder method available. The pesticide formulation, which had been developed with the best of intentions, subsequently became the chosen method of mass murder at Auschwitz (and across the other Nazi killing centers and concentration camps), and was eventually adopted across the entire Nazi "final solution" operations.

Following his capture, Rudolf Hoess claimed that he introduced Zyklon B because he considered it to be more humane than killing by shooting, brutalization, and starvation. In his memoirs he claimed Zyklon B gassings were reassuring to him because his victims supposedly suffered less than if they had been shot. However, subsequent historical investigations demonstrated that the use of Zyklon B was more based on practical expedience rather than any pretensions of "humanitarianism." It is of note that some Zyklon B formulations produced a blue stain on areas of contact. These stains remain visible on the walls of the gas chambers in the Nazi killing centers (Fig. 25.2).

Japanese military forces also actively used chemical weapons during World War II. It has been claimed that cyanide-based munitions were used in some of the approximately 2000 chemical attacks instigated by Japanese military forces in China during the 1931–45 period (Yan 2014). The degree of military effectiveness of these weapons is unknown. The Japanese army chiefs of staff also allegedly ordered the killing of over 400 prisoners and staff using food laced with potassium cyanide as part of a cover up of activities by the Pingfan BC/Unit 731 warfare facility in China during August 1945 (Harris, 2002).

FIGURE 25.2 Interior view of a gas chamber at the Majdanek concentration/extermination camp in Poland (post-liberation) showing blue staining on the walls due to the use of Zyklon B. *Panstwowe Muzeum na Majdanku. Copyright: Public Domain.*

The use of cyanide-based weapons may have reoccurred during the 1980–88 Iran-Iraq War. One of the perhaps better known incidents occurred during the Iranian offensive against the Kurdish city of Halabja. While a mixed chemical weapon attack involving mustard gas, a nerve agent (possibly tabun or sarin or VX or a combination of these agents) and cyanide was reported at the time, it has subsequently been claimed that most of the fatalities were caused by cyanogen chloride (Baskin and Rockwood, 2002; Segal, 1986; USDIA, 1988). Iranian physicians have claimed that some of the victims of the attack were successfully treated using inhalation of amyl nitrite and injection of thiosulfate; however, definitive diagnoses of acute cyanide poisoning were never established. Subsequent investigators have noted that people affected by the attack appeared to have been killed by surprise while going about their normal daily activities and have noted that the predominant skin discoloration seen amongst the dead was blue (cyanosis) and not red (however, while considered "classical," red skin discoloration is not always, in practice, a regularly observed clinical sign of acute cyanide poisoning). On this basis there have been alternative claims that most of the deaths during the attack were due to a nerve agent (likely tabun) and that hydrogen cyanide poisonings were secondary to the hydrolytic or thermal decomposition of this agent. Other reputed cyanide-based chemical weapon attacks during this conflict include those on the Iran-Iraq border towns of Sardasht, Marivan, Sarpol-e Zahab, Gilan-e-gharb, and Oshnavieh.

Cyanide sources have also been used as part of religion-associated chemical terrorism and/or mass murder-suicide. The archetypical example of cyanide use with religion-associated mass murder-suicide were the events at the Peoples Temple Agricultural Project ("Jonestown") in Guyana in 1978. Doctors associated with the sect reputedly tested the efficacy of cyanide as a killing agent on pigs based on their claim that the metabolism of this species closely resembles that of humans.

Another example of religious/cult-associated attacks that may have utilized cyanide is the Aum Shinrikyo attacks in Tokyo in 1995 (Sidell, 1996). Cyanide gas precursor compounds were found in several subway restrooms following these attacks. Allegedly, cyanide was also added to the explosives used in the first attack on the World Trade Center in New York (Brennan et al., 1999). Al-Qaeda and other organizations with claimed affiliation with the Osama bin Laden terrorist franchise also allegedly experimented with the use of hydrogen cyanide (Pita, 2015).

The use of cyanides as a tool of political and military assassination is also well known. Famously, cyanide-laced food and drink failed to kill Grigori Rasputin during an assassination attempt in 1916. In 1954, the Soviet KGB agent Nikolai Khoklov was ordered to assassinate the Russian anti-communist exile Georgiy Okolovic in Frankfurt, Germany, using an electrically operated, suppressed cyanide gun disguised as a cigarette packet. Khoklov did not go through with the assassination, subsequently defected to the United States, and provided details of the plot during a broadcasted interview. The murders of two Ukrainians, Rebet (1957) and Bandera (1959), were committed by a Soviet agent in Munich using a gas pistol containing cyanide (Anders, 1963).

The American Mafia hitman and serial killer Richard Kuklinski reputedly favored the use of cyanide by injection, in food, as an inhaled aerosol spray, or by skin contact as an assassination tool. In his view it killed quickly, was not messy, could in some cases be mistaken for an acute cardiopulmonary death and, at that time, was reputedly hard to detect during routine toxicology testing.

The toxicology of acute cyanide poisoning and its treatment have been extensively discussed by many authors (Ballantyne and Marrs, 1987; Baskin et al., 1997; Borowitz et al., 1992; Gonzales and Sabatini, 1989; Marrs et al., 1996; Salkowski and Penney, 1994; Vennesland et al., 1981; Way, 1984). However, the key modes of action of acute cyanide poisoning have only been fully elucidated relatively recently (Borowitz et al., 2001; Gunasekar et al., 1996; Sun et al., 1997).

25.2 Sources of exposure

The use of cyanide for "purely" military purposes has been, overall, relatively limited and fortunately largely ineffective for the reasons described above. However, as a tool of assassination and mass killing, it has proven to be highly effective. Most human acute poisoning cases

involve civilians and most nonhomicidal cases are due to fires or industrial accidents. Human–cyanide interactions remain very common because of its widespread industrial use. Worldwide industrial consumption of cyanide is estimated to be 1.5 million tons per year, with occupational exposure accounting for many cases of acute cyanide poisoning (Cummings, 2004; Logue et al., 2010; Coentrão and Moura, 2011). Acute cyanide poisoning may occur from a broad range of exposure sources (summarized in Table 25.1).

25.3 Toxic levels of cyanide

It is not easy to determine the lethal dose of cyanide in humans. Haber's law is a reasonable predictor of mortality associated with acute cyanide poisoning, that is, the dosimetry follows the concentration multiplied by time function. The maximum permissible concentration for HCN in humans is 11 mg/m^3 (Ballantyne, 1974). Taken orally, the fatal dose of HCN to adults is estimated to be 50–100 mg; for KCN it is estimated to be 150–250 mg (DuBois and Geiling, 1959). On a mass per unit body weight basis the fatal dose of HCN is estimated to be in the 0.7–3.5 mg/kg range (Hallstrom and Moller, 1945). However, victims ingesting as much as 3.0 g of KCN have been saved with immediate treatment (Van Heijst et al., 1987). Table 25.2 shows that inhalation of HCN at a concentration of 300 mg/m^3 (approximately 270 ppm) will be immediately fatal, whereas at 20–40 mg/m^3 mild symptoms will appear after several hours of exposure (Rumack and Newball, 1983). Victims with a blood cyanide level of 2.5–3.0 μg/mL frequently succumb to respiratory cessation within 20–30 min of exposure but some may survive up to 3 h (Ballantyne, 1974; Van Heijst et al., 1987). Oral ingestion of cyanide may also produce rapid onset of symptoms, typically because the doses encountered far exceed the minimal lethal dose. Studies of experimental animals have shown that absorption of cyanide decreases with alkaline stomach pH due to the relatively high pKa of HCN. However, based on simple Hendersen–Hasselbalch calculations a quite high gastric pH would be required to significantly reduce absorption.

TABLE 25.1 Various possible sources of cyanide poisoning.

Fire smoke	Smoke generated after combustion of silk, polyurethanes, polyacrylonitriles, nylon, melamine resins, plastics, etc., in accidents including industrial, residential, car, aircraft, ship fires
Industrial exposure	Plastics production, dyeing, printing and photography, fumigation of pesticides/rodenticides, synthetic rubber production, fertilizer production, metal polish, tanning in leather industry, electroplating, metallurgy, paper and textile manufacture
Drugs	Sodium nitroprusside, laetrile, succinonitrile
Dietary	Cassava, lima beans, linseed, bamboo sprout, macadamia nuts, hydrangea, Rosaceae family (plum, peach, pear, apple, bitter almond, cherry), *Sorghum* species (Johnson grass, sorghum, Sudan grass, arrow grass), *Linum* species (flax, yellow pine flax)
Others	Cigarette smoking, phencyclidine synthesis, ingestion of nail polish remover, suicide, homicide, terrorist attack, chemical warfare, capital punishment

TABLE 25.2 Toxicity of hydrogen cyanide by inhalation.

Concentration		Effects
mg/m^3	ppm	
20–40	18–36	Slight symptoms after several hours
50–60	45–54	Endurable for 20–60 min without effect
120–150	110–135	Very dangerous (fatal) after 30–60 min
150	135	Lethal after 30 min
200	181	Lethal after 10 min
300	270	Immediately lethal

Normally most cyanide is absorbed within 2−3 h of ingestion (Ryan and Viccellio, 1998). However, substances such as nitrile compounds and cyanogenic glycosides like amygdalin from plants require enough time for conversion to cyanide before they can produce symptoms of toxicity (Ryan and Viccellio, 1998).

Laetrile (often called by its misnomer "vitamin B17") is a claimed complementary/alternative "pseudo-medicine" for cancer treatment. It is synthesized from the cyanogenic glycoside amygdalin, which is most commonly encountered in the seeds of stone fruits from *Prunus* sp. One gram of laetrile contains the equivalent of 60 mg of cyanide, and each laetrile tablet may contain up to 100 mg of laetrile. A 12- to 18-tablet laetrile overdose is sufficient to produce severe metabolic acidosis and convulsions in humans (Ellenhorn et al., 1997).

The lethal toxicity of HCN and its alkali salts by different routes for different species of animals and sexes has been discussed elsewhere (Ballantyne and Lindstrom, 1984; Ballantyne and Marrs, 1987). A study performed using rabbits revealed the following order of decreasing toxicity of KCN administered by different routes: intravenous > intramuscular > intraperitoneal > oral > instillation into conjunctival sac > percutaneous (Ballantyne and Lindstrom, 1984). The comparative oral LD_{50} values of KCN for different species of animals are given in Table 25.3. Rabbits are generally regarded as being more susceptible than rats and mice.

25.4 Detection and estimation of cyanide

Determination of cyanide or its metabolites in biological fluids is necessary for forensic, clinical, military, research, and veterinary purposes. The choice of analytical methods depends on a variety of factors including sensitivity, specificity, rapidity, convenience, facilities, and expertise. The selection of biological sample, time of sampling, time to analyze, storage conditions, and interfering substances are other factors that influence the choice of analytical methods (Troup et al., 1987; Jackson et al., 2014). There are several convenient and sensitive methods for measuring cyanide in biological fluids, but many of them have limitations. Some of these methods are summarized here.

TABLE 25.3 Acute lethal toxicity of KCN by oral route for different species of animals.

Species	Sex	LD_{50} (mg/kg)
Mouse	Male	8.50
	Male	12.5
Rat	Male	10.0
	Female	7.49
	Female	14.1
Rabbit	Female	5.82

One of the most common procedures includes diffusion and trapping of cyanide in the alkaline media before colorimetric analysis in pyridine−pyrazolone mixture (Epstein, 1947). This method was subsequently modified for microdiffusion analysis of cyanide (Feldstein and Klendshoj, 1954). This procedure is widely used during the treatment of cyanide intoxication and thiosulfate is known to interfere in the colorimetric estimation, which was subsequently resolved (Morgan et al., 1979). A rapid (approximately 20 min), specific, and sensitive spectrophotometric method for whole blood cyanide assay has also been developed (LaForge et al., 1994). All these procedures are based on the König reaction, which starts with the production of cyanogen chloride. A spectrofluorometric determination of cyanide and thiocyanate based on a modified König reaction in a flow-injection system was also reported with detection limits of 30 nM for both anions (Tanaka et al., 1992). Spectrophotofluorometry is also a convenient, sensitive method provided that previous microdiffusion has been performed to isolate and concentrate the cyanide. The fluorometric methods using pyridoxal are more sensitive and require fewer and more stable reagents than the colorimetric method (Takanashi and Tamura, 1970). However, sodium thiosulfate is known to interfere with the chemical conversion of the fluorophore and it is possible to circumvent the interference by using acetate buffer (pH 5.2) as the acidifying agent. Another fluorescent method with an advantage over pyridoxal uses para-benzoquinone, and this method is not known to have any extraneous interference (Guilbault, 1976).

The potentiometric determination of cyanide using ion-selective electrodes has become yet another very popular technique because it is a convenient, rapid, and sensitive method of analysis (Frant et al., 1972). Microdiffusion of biological samples containing cyanide is recommended before potentiometric determination. The use of a cyanide ion-selective electrode in combination with the Conway microdiffusion method for the measurement of cyanide concentrations in human red blood cells (RBCs) and plasma was reported with remarkable recovery of cyanide (Yagi et al., 1990). Ion chromatographic determination of sulfide and cyanide in real matrices using pulsed amperometric detection on a silver electrode was reported by Giuriati et al. (2004). Ion chromatography with pulsed amperometric detection has also been used to determine cyanide in urine and saliva samples (Jaszczak et al., 2017).

The measurement of HCN directly by gas chromatography has also been reported, but this method lacks sensitivity with most detectors (Valentour et al., 1974). Gas chromatographic techniques are not widely used for measuring cyanide because other methods are more convenient. A simple and sensitive method was devised for determining cyanide and its major metabolite, thiocyanate, in blood using an extractive alkylating agent (pentafluorobenzyl bromide). The detection limits of cyanide and thiocyanate were 0.01 and 0.003 μmol/mL, respectively (Kage et al., 1996). Rapid quantitation of cyanide in whole blood by automated headspace gas chromatography was performed on clinical samples from fire victims. This method could detect a wide concentration of blood cyanide (30−6000 μg/L) in approximately 17 min (Calafat and Stanfill, 2002).

A direct and sensitive isotope dilution−mass spectrometry determination of blood cyanide by headspace gas chromatography was developed with a detection limit of 0.3 μmol/L (Dumas et al., 2005). This method was also compared with other techniques in a round-robin exercise. Cyanide can also be measured by indirect atomic absorption spectrometry where a metal−cyanide complex is formed and is then extracted in organic solvent to determine the metal content (Manahan and Kunkel, 1973). An original high-performance liquid chromatographic−mass spectrometric (HPLC-MS) procedure was developed for the determination of cyanide in whole blood. The limits of detection and quantitation were 5 and 15 ng/mL, respectively. Also, several other methods including HPLC, using post-column derivatization with *o*-phthalaldehyde (Sumiyoshi et al., 1995), capillary electrophoresis with fluorescence detection, polyphenol oxidase/clay biosensors, capillary electrophoresis microchip, ICT-based probes (Badugu et al., 2005), and microchemiluminiscence have been reported for different environmental or biological samples. However, their utility to detect cyanide in blood samples is yet to be ascertained. A technique to detect cyanide currently utilized by water treatment facilities was used to rapidly detect concentrations of cyanide in the clinically important range. The CYANTESMO test strips accurately and rapidly detect cyanide of more than 1 μg/mL. A paper test for cyanide (CYANTOSNO) in whole blood is now commercially available in the United States (Ellenhorn et al., 1997).

25.5 Toxicokinetics of cyanide

25.5.1 Absorption

Oral absorption of cyanide is rapid, and toxic effects can occur within minutes. When salts of cyanide are ingested hydrochloric acid in the stomach causes the release of HCN. HCN is a weak acid with a p*K*a of 9.2 and is thus mostly in its more lipophilic, readily absorbable, unionized form within the acid environment of the stomach. HCN is also generally rapidly absorbed at other sites of exposure (respiratory tract, eyes) (Ballantyne, 1974; Borowitz et al., 2001; Ellenhorn et al., 1997; Ryan and Viccellio, 1998).

In rabbits, cyanide introduced into the conjunctival sacs was quickly absorbed in significant quantities to produce systemic toxicity (Ballantyne, 1983). Predictably, dermal absorption is somewhat slower. However, it is notable that at the typical skin pH range of 4−5.5, HCN's pKa implies that it is mostly in its more easily absorbed, relatively lipophilic, nonionized state. The large skin surface area also likely facilitates absorption. Nitriles are more readily absorbed through the skin, but the onset of toxicity is delayed due to the time required for them to be metabolized and cyanide released.

25.5.2 Distribution

After absorption, distribution is rapid (Sylvester et al., 1983) with an apparent volume of distribution of about 40% of total body weight. This implies distribution mostly to the extracellular fluid volume and a lack of apparent tissue sequestration. Consistent with this are the findings that after oral poisoning a significant amount of cyanide was traced in the brain, blood, kidney, stomach wall, liver, and urine (Ansell and Lewis, 1970). Cyanide is rapidly transported in the body by blood and approximately 60% is bound to plasma proteins with a RBC: plasma ratio of 100:1 (Ellenhorn et al., 1997; Ryan and Viccellio, 1998). Following acute exposure the plasma elimination half-life of cyanide is estimated to be 14.1 min (Egekeze and Oehme, 1979).

25.5.3 Elimination

Cyanide is rapidly detoxified in mammals. To determine the effect of species on cyanide metabolism, toxicokinetics of cyanide was studied in rats, pigs, and goats after oral dosing of KCN (Sousa et al., 2003). The study showed that metabolism of cyanide and its main metabolite, thiocyanate, is species-linked, with goats being the most sensitive to the toxic effects of cyanide. The detoxification rates following intravenous dosing of humans, dogs, guinea pigs, and rabbits are 0.017, 0.020, 0.04, and 0.008 mg/kg body weight per minute, respectively (Hinwich and Saunders, 1948; NIOSH, 1975). The major pathway of cyanide detoxification (approximately 80%) is through enzymatic transulfuration to thiocyanate (SCN^-), which is subsequently excreted in urine (Lang, 1933). This reaction is catalyzed by rhodanese (thiosulfate cyanide sulfur transferase; EC.2.8.1.1). Rhodanese uses a precursor like thiosulfate as a source of sulfane sulfur

(divalent ionized sulfur bound to another sulfur atom). The endogenous supply of this substance is very limited. Thus detoxification of large doses of cyanide depends on an exogenous supply of thiosulfate (Westley et al., 1983). However, cyanide detoxification by this pathway is often debated because rhodanese is located principally in the mitochondria and penetration of the cell wall and mitochondrial membrane by thiosulfates is very slow (Bhat et al., 1983). It is presumed that the sulfane sulfur binds first to the serum albumin to yield a sulfane sulfur albumin complex that eventually reacts with cyanide to form thiocyanate (Westley et al., 1983; Way, 1984). In normal metabolism of cyanide, the serum albumin−sulfane complex may be the primary detoxification mechanism (Sylvester et al., 1983).

Unlike many other chemical warfare agents, cyanide is present in blood, urine, and expired breath (Lundquist et al., 1988). Cyanide and its metabolites are eliminated from the body by several mechanisms. After 3 h, approximately 90% of injected cyanide has been shown to be eliminated in the dog model (Sylvester et al., 1983). A small amount of administered cyanide is excreted in the urine and via the lungs after being incorporated into cyanocobalamin (vitamin B_{12}), oxidated to formate and carbon dioxide, and incorporated with cystine (Ballantyne and Marrs, 1987). Other minor pathways of detoxification include enzymes like mercaptopyruvate sulfur transferase, thiosulfate reductase, and cystathionase γ-lyase or disulfide cystine, and 2-iminothiazolidine-4-carboxylic acid (2-ICA) or its tautomer, 2-aminothiazolidine-4-carboxylic acid (2-ACA) (Baskin et al., 2004; Wood and Cooley, 1956). Cyanide reacts with cystine to produce β-thiocyanoalanine, which spontaneously undergoes ring closure to form 2-ICA and 2-ACA, depending on the pH in the cells (Borowitz et al., 2001).

25.6 Mechanism of action

The toxic effect of cyanide is attributed predominantly to the production of cellular anoxia after inhibition of the metal-containing enzymes. The critical interaction appears to be the inhibition of the terminal respiratory chain enzyme, cytochrome oxidase a_3 (containing iron), within the mitochondria. The enzyme is essential for the production of adenosine triphosphate (ATP). As a result, aerobic oxidative metabolism and phosphorylation are impaired, leading to cellular hypoxia. The pyruvate that is produced can no longer be used and is now reduced to lactate. The shunt from aerobic to anaerobic metabolism leads to profound lactic acidosis (Solomonson et al., 1981). Cyanide toxicity may not be ascribed solely to a single biochemical lesion but rather to a complex phenomenon. Cyanide reacts with several metalloenzymes, carbonyl groups of different enzymes, coenzymes, and substrates, resulting in

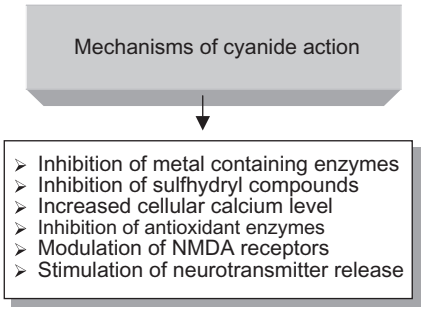


FIGURE 25.3 Mechanisms for the toxic manifestations of cyanide exposure.

inhibition of normal activity. Cyanide also interacts with sulfhydryl compounds like cystine, mercaptopyruvate, reduced glutathione, and oxidized glutathione to form different complexes (Borowitz et al., 1992; Way, 1984). Cyanide also strongly interacts with iron in protein molecules, inhibiting enzymes including carbonic anhydrase and succinic dehydrogenase (Ballantyne and Marrs, 1987). Formation of cyanhemoglobin by interaction of cyanide with ferric iron abolishes the ability of hemoglobin to carry oxygen (Way, 1984). The classical mechanism of cyanide toxicity is summarized in Fig. 25.3.

Cyanide is regarded as a selective neurotoxin and its toxicity has frequently been associated with elevated levels of cellular calcium (Johnson et al., 1986), inhibition of antioxidant defense enzymes in the brain (Ardelt et al., 1989), and generation of reactive oxygen species (ROS), leading to lipid peroxidation (Ardelt et al., 1994; Kanthasamy et al., 1997). Whether or not these effects are fully "de novo" effects of cyanide or are, at least in part, downstream secondary effects due to the failure of cellular energy generation in a high energy demand tissue is not fully elucidated.

Cyanide increases intracellular calcium through activation of voltage-sensitive calcium channels (Johnson et al., 1987), direct redox modulation and "excitotoxin-like" enhancement of *N*-methyl-d-aspartate (NMDA) receptor function (Patel et al., 1992; Sun et al., 1997), and mobilization of intracellular calcium stores (Yang et al., 1997). It was proposed that elevated cytosolic calcium activates proteases, which in turn convert xanthine dehydrogenase to xanthine oxidase. In the presence of oxygen, xanthine oxidase can catalyze the formation of superoxide radicals that initiate lipid peroxidation (Fig. 25.4) (Cheung et al., 1985). Overall, it appears that oxidative stress plays a crucial role in cyanide-induced neurotoxicity (Ardelt et al., 1989; Kanthasamy et al., 1994).

Modulation of NMDA receptor has been widely implicated in cyanide-induced neurotoxicity. Nitric oxide and ROS generation after NMDA receptor activation was found to mediate cyanide-induced neurotoxicity (Gunasekar et al., 1996). Several other studies also

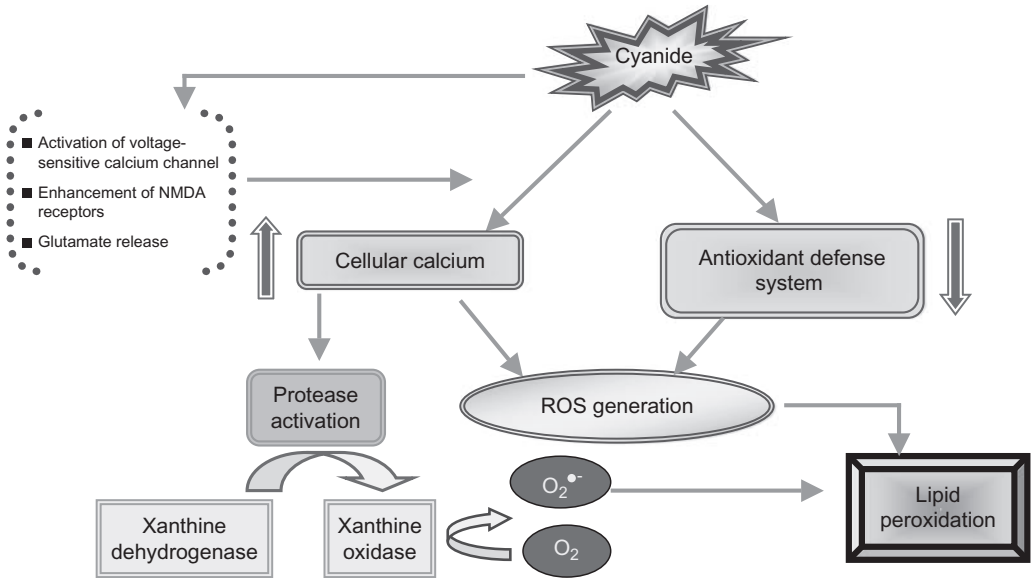

FIGURE 25.4 Pathway of cyanide-induced oxidative stress. O_2, Oxygen; $O_2^{\bullet-}$, superoxide anion; *ROS*, reactive oxygen species.

showed activation of NMDA receptors during cyanide toxicity (Patel et al., 1992; Sun et al., 1997). Cyanide can also stimulate release of glutamate from intracellular stores, resulting in elevation of cytosolic Ca^{2+} through NMDA receptor activation. There is also evidence that cyanide may interact directly with the NMDA receptor to enhance NMDA receptor-mediated Ca^{2+} influx (Patel et al, 1994; Sun et al., 1995). It was further shown that cyanide selectively interacted with NMDA subunits, possibly by formation of thiocyanate adduct with a cysteine residue located in the NR1 receptor subtype (Arden et al., 1998).

Cyanide is also known to interact with cystine to produce 2-ICA and 2-ACA, and the former is responsible for memory loss, convulsions, and loss of consciousness (Bitner et al., 1991). Cyanide can also produce dopaminergic toxicity characterized by loss of dopaminergic neurons in the basal ganglia that is accompanied by impaired motor function (Kanthasamy et al., 1994). It has been suggested that the convulsive effects of cyanide are due to changes in the levels of dopamine (Cassel, 1995). Cyanide is also known to stimulate neurotransmitter release in both the central and peripheral nervous systems (Kanthasamy et al., 1991). Modulation of protein kinase C, calmodulin, and nitric oxide (NO)-dependent cyclic guanosine monophosphate-dependent enzymes and ATP depletion may also contribute to the induction of convulsions. Other biochemical processes that may mediate or at least influence cyanide toxicity include severe lactic acidosis, mitochondrial ADP ribosylation, and hyperammonemia (Borowitz et al., 1992).

Another important aspect of acute cyanide toxicity is its cardiotoxic manifestations (Baskin, 1991; Borowitz et al., 1992). The acute, pro-arrhythmogenic cardiac effects of cyanide likely explain way its effects can, in some cases, mimic an acute "heart attack-like" or an acute cardiopulmonary failure-like clinical presentation, that is, sudden collapse with cardiopulmonary failure and a few premonitory clinical signs. Apart from redox effects with mechanisms similar to those described above perhaps one of the key effects of acute cyanide poisoning on the heart is disruption of calcium homeostasis and excitation–contraction coupling in cardiac excitable cells (Cheung et al., 1985). Its effects on the physiological functions of calcium in these cells are complex and include multiple different excitation–contraction abnormalities, depolarization of resting membrane potential, reduced action potential amplitude, prolonged action potential duration, depolarization of mitochondrial membrane potential, and suppression of depolarization-activated K^+ currents.

25.7 Diagnosis and clinical features of cyanide poisoning

The signs and symptoms of acute cyanide poisoning are often nonspecific and vary in both time and intensity depending on the scale of exposure (Ballantyne, 1974, 1987; Ellenhorn et al., 1997; Hall et al., 1987; Nicholson and Gupta, 2012; Way, 1984). The signs and symptoms of acute cyanide poisoning reflect cellular hypoxia and can be fairly nonspecific. The onset of the toxidrome depends on the dose, route, and duration of exposure. In general, clinical signs and symptoms correlate with the whole blood cyanide level (Table 25.4). However, the

TABLE 25.4 Whole blood cyanide levels and clinical signs and symptoms.

Whole blood cyanide		Signs and symptoms
μg/mL	μmol/L	
0–0.5	8–20	No symptoms
0.5–1.0	20–38	Tachycardia, flushing, headache, hyperpnea, dizziness
1.0–2.5	48–95	CNS depression including giddiness, tachypnea, nausea, vomiting feeling, suffocation, confusion
2.5–3.0	95–114	Respiratory depression, convulsion, coma, cyanosis, apnea, circulatory collapse, fixed dilated pupils
≥3.0	114	Death

overall severity of poisoning does not correlate particularly well with serum cyanide concentration.

Early clinical manifestations due to effects on the CNS include anxiety, headache, giddiness, dizziness, confusion, and mydriasis. Cardiovascular effects can be somewhat variable but all derive from cyanide-induced hypoxia and depression of the cardiovascular system. Bright (cherry red) retinal veins due to elevated venous PO_2 have been suggested as a possibly clinical useful early clinical observation. Other early cardiovascular effects may include palpitations, diaphoresis, dizziness, flushing, tachycardia, and hyperventilation. Initially, increased cardiac output and blood pressure may occur due to catecholamine release. However, eventually vasodilatation, hypotension, reduced cardiac ionotropic effects, and shunting of blood to the brain and heart will ensue. At an overall level cyanide exposure triggers sinoatrial node depression, negative cardiac ionotropic effects, and a pro-arrythmogenic state. This leads to unstable hemodynamic states, atrioventricular blocks, ventricular arrhythmias, bradycardia, heart block, cardiac arrest, and death.

Later clinical manifestations of acute cyanide poisoning also include loss of consciousness, seizures, paralysis, coma, and hypoventilation/apnea. Classically, skin and mucous membrane color has been described as being "cherry red" due to the presence of increased venous PO_2 despite the presence of tissue hypoxia. However this classical description is not reliable since skin and mucous membrane color can appear normal to somewhat ashen. Perhaps the most critical feature is a *lack of cyanosis or disproportionately mild cyanosis for a given level of cardiovascular/respiratory failure* due to high venous PO_2.

Based on a review of 21 cases of acute cyanide poisoning associated with suicidal ideation the three leading manifestations of the toxidrome were sudden loss of consciousness (about 71% percent of cases), severe metabolic acidosis (about 66% of cases), acute cardiopulmonary failure (about 43% of cases), and anoxic encephalopathy (about 29% of cases; Yen et al., 1995). In this case series, diabetes insipidus-like syndromes were considered to be an ominous clinical development in patients with cyanide-associated encephalopathy.

Laboratory tests suggestive of cyanide intoxication include arterial blood gases (metabolic acidosis with normal PO_2), serum electrolytes (elevated anion gap), central venous percent O_2 saturation (elevated), calculated arterial percent O_2 saturation (normal), and measured arterial percent O_2 saturation (decreased). Serum lactate levels greater than 8 mmol/L are associated with acute cyanide poisoning.

Quantitative determination of cyanide in whole blood, urine, gastric contents and tissues, and plasma thiocyanate levels are also important (Ballantyne, 1983). Serum concentrations of cyanide greater than 0.5 mg/L are typically associated with acute cyanide poisoning. Unfortunately, these tests take several hours and the results may not be available to the clinician during the acute phase of poison management. The Prussian blue reaction can be used as a quick bedside test that can qualitatively detect cyanide in gastric aspirate; however it is prone to false-positive results (Hall et al., 1987; Lee-Jones et al., 1970).

There are no reliable pathognomonic anatomic pathology lesions that can be used to definitively diagnose acute cyanide toxicity. If present, cherry red skin/mucous membrane discoloration tends to fade relatively quickly after death (unlike with carbon monoxide poisoning where the discoloration is more persistent due to the presence of carboxyhemoglobin), especially if venous blood is exposed to normal air. This is because the potentially high venous PO_2 levels typically dissipate fairly quickly after death.

Animal experiments indicate that anatomic pathology lesions are often in the central nervous system (CNS), particularly within white matter (Ballantyne, 1974). However, these findings are usually a general manifestation of anoxic encephalopathy and are not necessarily pathognomonic of acute cyanide poisoning.

25.8 Treatment of cyanide poisoning

The onset of toxicity after cyanide poisoning is very fast. The prognosis of the victim depends on termination of further exposure, supportive care, and institution of immediate and aggressive specific treatment. Early diagnosis and clinical information would enhance the chances of recovery. Critically, first responders and treatment teams are potentially at risk of cyanide poisoning when attempting to recover and treat patients. Degassing of cyanide vapors from poisoned patients as well as environmental sources are important forms of exposure under such circumstances. The use of appropriate personal protective equipment is strongly recommended.

The first principle of therapy is termination of further exposure, which can be facilitated by the following: (1) remove the victim from the contaminated atmosphere; (2) apply a protective mask to the patient as soon as possible to prevent further inhalation; (3) remove any liquid on skin or clothing as soon as possible; and (4) remove all contaminated clothing, rinse skin with soap and copious amounts of water or water alone if there is liquid on the skin (Baskin et al., 1997). Despite poor binding to activated charcoal, animal data suggest that a single oral dose of the material at a rate of 1 g/kg body weight with a maximal dose of 50 g may decrease mortality. Single dose activated charcoal treatment is unlikely to be of much benefit if dosing is delayed for 2−3 h.

25.8.1 Antidotal therapy

Antidotal therapy should be commenced as soon as possible. Hydroxocobalamin is the antidote of choice because it is regarded as being effective and does not further compromise cellular hypoxia and acidosis. The standard dose is 5 grams given intravenously (i.v. over 15 min; be aware that this antidote turns urine dark red: this is not due to myoglobinuria).

Various cyanide antidotes have been proposed over a period of many years (Table 25.5). Cyanide antidotes have been classified into three main groups based on their mechanism of action: methemoglobin inducers, sulfur donors, and cobalt compounds. The definitive treatment of cyanide poisoning differs in various countries because of different medical practices and guidelines. The safety and efficacy of all the antidotes are still being debated. However, it is important to note that hydroxycobalamin has now largely replaced the older antidotal protocols.

25.8.2 Methemoglobin inducers

The basic aim of rapid detoxification of cyanide is prevention or reversal of inhibition of cytochrome oxidase by cyanide. This is usually facilitated by providing a large pool of ferric iron in the form of methemoglobin to complex cyanide. Cyanide preferentially competes with the

TABLE 25.5 Supportive therapy and specific antidotal therapy for acute cyanide poisoning.

	Agents	Drug category and action
Supportive therapy	100% oxygen or hyperbaric oxygen	Oxygen: Potentiates the efficacy of nitrite−thiosulfate therapy
	Sodium bicarbonate	Alkalizing agent: Corrects lactic acidosis
	Diazepam	Anticonvulsant: Depresses CNS activities
	Epinephrine	Sympathomimetic: Improves coronary and cerebral blood flow, corrects anaphylactoid reactions
Specific antidotal therapy	Amyl nitrite	Methemoglobin inducers: Converts hemoglobin to methemoglobin, which binds with cyanide to form cyanmethemoglobin. In the presence of sodium thiosulfate cyanide is excreted as thiocyanate
	Sodium nitrite	
	4-Dimethylaminophenol	
	Sodium thiosulfate	Sulfur donors: Facilitates enzymatic conversion of cyanide to thiocyanate
	Dicobalt edentate	Cobalt compounds: Forms stable metal complexes with cyanide
	Hydroxocobalamin	

Fe^{3+} of methemoglobin as compared with that of cytochrome oxidase and eventually binds with the former to form cyanmethemoglobin. Thereby, the activity of inhibited cytochrome oxidase is restored (Baskin et al., 1992). The various methemoglobin inducers used as cyanide antidotes are discussed below.

25.8.3 Amyl nitrite

Although inhalation of amyl nitrite as a first aid measure for cyanide poisoning has been known for many years, its efficacy as a methemoglobin inducer is often disputed because of its inability to generate methemoglobin more than 6% (Jandorf and Bodansky, 1946). Approximately 15% of methemoglobin is required to challenge one LD_{50} of cyanide (Van Heijst et al., 1987). The protective effect of amyl nitrite is attributed to its vasodilatory effect, which can reverse the early cyanide-induced vasoconstriction (Van Heijst et al., 1990). Artificial ventilation with amyl nitrite broken into Ambu bags has been reported as a life-saving therapy in cyanide-poisoned dogs before induction of significant levels of methemoglobinemia (Vick and Froehlich, 1985).

25.8.4 Sodium nitrite

Sodium nitrite is the most prevalent drug for cyanide poisoning. It takes approximately 12 min to generate approximately 40% of methemoglobin after intravenous administration of the recommended dose (Van Heijst et al., 1987). Despite this delay in inducing a significant level of methemoglobinemia, reasonable protection offered by sodium nitrite can be attributed to its vasodilatory effects (Van Heijst et al., 1990). A major drawback with sodium nitrite is that it causes serious cardiovascular embarrassment, particularly in children (Berlin, 1970). Because methemoglobinemia impairs oxygen transport, sodium nitrite cannot be recommended for fire victims when concomitant exposure of HCN and carbon monoxide usually occurs. Because carbon monoxide also reduces the oxygen-carrying capacity of blood, administration of sodium nitrite would further aggravate the underlying hypoxic condition. Sodium nitrite is also contraindicated for individuals with glucose-6-phosphate dehydrogenase-deficient red cells because of the possibility of serious hemolytic reactions (Way, 1984). Excessive levels of methemoglobin are known to be reverted by intravenous administration of 30 mL of 1% methylene blue solution (Van Heijst et al., 1987). In the United States, the Lilly Cyanide Antidote Kit (manufactured by Eli Lilly and Company, Indianapolis, IN) includes 10 mL ampoules of 3% sodium nitrite solution and 50 mL of 25% sodium thiosulfate solution. The kit also contains amyl nitrite encased in glass "pearls," which are meant to be broken so the drug could be inhaled. In India, a similar kit is manufactured by Troikaa Pharmaceuticals Ltd (Thiol).

25.8.5 4-Dimethylaminophenol

The relatively slow rate of methemoglobin formation by sodium nitrite prompted the development of rapid methemoglobin formers like aminophenols. 4-Dimethylaminophenol (DMAP) is the treatment of choice for cyanide poisoning in Germany. Administered intravenously, a dose of 3.25 mg/kg DMAP was reported to produce methemoglobin levels of 30% within 10 min and 15% methemoglobinemia was attained within 1 min without any immediate effect on the cardiovascular system (Kiese and Weger, 1969). However, there are differences in individual susceptibility to DMAP that may result in undesirable levels of methemoglobin even after normal therapeutic doses (Van Dijk et al., 1987). Intramuscular injection of DMAP results in local abscess and fever. Its clinical utility remains limited because of its other toxicological implications like nephrotoxicity.

25.8.6 Sulfur donors

After the initial therapy of methemoglobin inducers, cyanide has to be converted to thiocyanate, which is eliminated in urine. This enzymatic detoxification of cyanide is facilitated by a sulfur donor like sodium thiosulfate. The mechanism of this reaction was discussed previously under the elimination of cyanide. High tissue oxygen markedly potentiates the effects of this reaction. In cases in which methemoglobin formation is not desirable, sodium thiosulfate together with oxygen alone is sufficient. The utility of thiosulfate alone is limited because of its short biological half-life and its small volume of distribution (Sylvester et al., 1983). Also, thiosulfate is contraindicated in patients with renal insufficiency because the thiocyanate formed may cause toxicity (Van Heijst et al., 1990).

25.8.7 Cobalt compounds

The cobalt ion, which forms a stable metal complex with cyanide, is an effective therapeutic agent against cyanide poisoning (Evans, 1964; Hillman et al., 1974; Linnell et al., 1987). Various cobalt-containing compounds known to antagonize cyanide poisoning are discussed below.

25.8.8 Dicobalt edetate (Kelocyanor)

Dicobalt edetate chelates cyanide as cobalticyanide. This drug is known to antagonize cyanide more quickly than the nitrites, but its clear superiority has not been established. Intravenous administration of 300 mg of dicobalt edetate in glucose solution is the current treatment of choice in France and the United Kingdom. Serious side effects like vomiting, urticaria, anaphylactoid shock, hypotension, and ventricular arrythmias have been reported in patients receiving Kelocyanor (Van Heijst et al., 1990).

25.8.9 Hydroxocobalamin (Cyanokit)

With the exchange of the hydroxy group of hydroxocobalamin (vitamin B_{12a}) for cyanide, nontoxic cyanocobalamin (vitamin B_{12}) is formed (Hall and Rumack, 1987). An injectable solution of hydroxocobalamin (5 g in water) has been used in France and Germany. In France, a 4 g hydroxocobalamin solution in 80 mL of sodium thiosulfate has also been used (Van Heijst et al., 1990). EMD Pharmaceutical Company has produced a lyophilized packaging of 2.5 g of hydroxocobalamin that can be readily reconstituted in a 100-mL sodium chloride solution. This product is pending FDA approval. It has been in use in Europe since 1996 as the Cyanokit. Hydroxocobalamin is also used in other countries, including Sweden, Denmark, Spain, Japan, and Hong Kong. Sodium thiosulfate or hydroxocobalamin has also been recommended for empiric treatment of cyanide poisoning (Hall et al., 2007). There are several disadvantages in the clinical use of this drug. It has a relatively short half-life because it decomposes in light, and the dose required to counter cyanide poisoning is quite large. Also, recorded side effects include anaphylactoid reactions and acne (Van Heijst et al., 1990). However, in a case study, clinical laboratory data did not show any evidence of toxicity (Borron et al., 2007).

25.8.10 Supportive therapy

The details of supportive therapy are presented in Table 25.5. The single most important form of supportive treatment is 100% oxygen. This includes mechanical airway support, artificial ventilation with 100% oxygen. If amyl nitrite is being used as an antidotal treatment it can be included in the breaking circuit (e.g., an Ambu bag containing the contents of two 0.6-mL ampoules of amyl nitrite) in association with cardiac monitoring (Van Heijst et al., 1987). Anecdotal evidence suggests that hyperbaric oxygen augments the protective efficacy of nitrite–thiosulfate therapy (Goodhart, 1994).

Lactic acidosis resulting from anaerobic metabolism and convulsions should be treated with intravenous administration of sodium bicarbonate and diazepam, respectively (Baskin et al., 1997; Van Heijst et al., 1990).

25.9 Concluding remarks and future directions

Currently, cyanide is considered not to be an important chemical weapon agent. It has been used, with moderate success, as an assassination agent. However, the threat of its possible use in local terrorism cannot be overlooked. Cyanide toxicity is mainly ascribed to its ability to inhibit cytochrome oxidase, an end-chain enzyme of cellular respiration. Numerous new mechanisms of action of cyanide unfold the complex toxic phenomena occurring at cellular and molecular levels. Many of these mechanisms have been the target for pharmacological interventions. Hydroxocobalamin has become the cyanide antidote of choice in recent times.

Chapter 26

Methyl isocyanate: the Bhopal gas

Ramesh C. Gupta[1] and Daya R. Varma[2]
[1]Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, KY, United States, [2]Montreal, Canada

26.1 Introduction

Methyl isocyanate (MIC), the smallest, most reactive, and most toxic member of the isocyanate family, was generally unheard of until December 2−3, 1984, when nearly 40 metric tons of this deadly chemical leaked out of the Union Carbide India Limited (UCIL) pesticide plant at Bhopal within a period of 45−60 min. Bhopal became a "city of death," in the words of *India Today* (December 30, 1984). The journal *Nature* (Opinion, 1984) wrote: "... the anguish vividly carried round the world by the television cameras seems not to have matured into the anger, even hysteria, there would have been had the accident occurred on the edge of a European city—or in Connecticut [the site of Union Carbide's US headquarters]."

Prior to the Bhopal disaster, there had been only one scientific report on MIC toxicity (Kimmerle and Eben, 1964); this led *Lancet* (Editorial, 1984) to comment: "In a year's time we will have learnt a lot more about MIC—at an appalling price." The Bhopal disaster evoked immense interest amongst journalists, scientists, the corporate world, lawyers, social activists, and the Indian government (Chemical & Engineering News, 1985; Varma and Saxena, 1986). This chapter describes the physicochemical characteristics of MIC and its toxicity, and how the Bhopal disaster took place and how such disasters can be prevented in developing countries like India, which lacks rigorous safety protocols for hazardous chemicals.

The population of Bhopal in 1984 was 800,000. The Union Carbide plant was within 1 kilometer of the Bhopal railway station and not far from the city's two large hospitals; densely populated slums lay across the road just a few hundred meters from the factory. The toxicity of a chemical, barely tested in animal models, was now suddenly being observed as it acted on 200,000 people, as well as on animals and plants living in Bhopal. There is no precise information on how many people died in the immediate aftermath of the disaster; usually a figure of 2500 is quoted, but our estimate based on projecting deaths in a sample survey (Varma, 1987) is that about 8000 people died. Most of the deaths happened between 24 and 48 h after the discharge of MIC, which would not have been the case if the culprit had actually been hydrogen cyanide (HCN), as was thought initially (HCN acts within minutes). A British medical student on her elective at a Bhopal hospital wrote: "The dead and dying arrived by the truckload, others came by rickshaw or were carried by relatives. For some, the effort of the journey itself proved too much, and they died soon after arrival" (Sutcliffe, 1985).

Soon after the Bhopal accident, the government of India promised to conduct a comprehensive study on the acute and long-term effects of exposure to MIC. The Indian Council of Medical Research (ICMR) released approximately $2 million for research; a cohort of 80,021 gas-exposed people and 15,931 controls were registered, but only 16,860 exposed subjects and 5741 controls could be contacted in 2010 (Sharma, 2013). Researchers were not recruited to study all aspects of toxicity. No definite criteria were set to make a quantitative assessment of the exposure to MIC; the best estimate has remained the distance from the Union Carbide factory (Dhara et al., 2002). A number of laboratories in the United States and United Kingdom initiated research on MIC, but their interest faded quickly.

26.2 The making of a disaster

For days after the disaster, no one was sure how the accident had happened. A detailed account of how MIC escaped from Tank E-610 of UCIL was ultimately provided by Stewart Diamond in *The New York Times* on January 28, and this report also was corroborated by others (Varadarajan et al., 1985; Varma and Saxena, 1986). Although it is highly unlikely that an accident

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00026-X

would occur exactly in the way it happened in Bhopal, the accidental escape of hazardous chemicals is not uncommon. The US Environmental Protection Agency (EPA) had recorded 28 instances of minor leaks of MIC from the Union Carbide plant in Institute, West Virginia, between 1980 and 1984, and a leak of aldicarb oxime from the same plant on August 11, 1985, sent 200 people to hospitals.

According to Diamond's article, water entered the pipes on the floor of the factory during routine cleaning, which took place without placing safety slips at the joints. It would seem that the floor of a chemical factory was cleaned with no more precautions than are taken when cleaning the platform of an Indian railway station. The water reached Tank E-610. The exothermic reaction between the water and MIC increased the temperature of the tank, converting liquid MIC into gas. The increase in pressure forced open the vent valve, allowing most of the MIC to escape as gas. Various safety measures to neutralize MIC, such as caustic soda scrubbers, were either inadequate or completely nonfunctional. Even if safety measures had been in perfect working order, they were not designed to handle such a large leak. MIC gas, being almost twice as heavy as air, settled on the ground, and affected all living beings in the area. Undoubtedly, the lack of rigorous safety procedures in the maintenance was the cause of the accident.

Fortunately, MIC stored in the other two tanks (E-611 and E-619) was not affected. The Indian Council of Scientific and Industrial Research (CSIR) decided that the safest way to dispose of the remainder of the MIC was to convert it into carbaryl, the pesticide for which the factory had been set up to produce. This exercise was termed "Operation Faith," and it was extensively covered by Indian and international media. Operation Faith ended safely on December 22, 1984, without any further mishap. Nonetheless, the disaster frightened the people of Bhopal so much that despite all assurances by the Indian government, almost half of the population left the town; some never returned to Bhopal.

The Bhopal disaster clearly indicates that the accident would not have occurred if all necessary precautions had been taken in the maintenance and operations of UCIL. Union Carbide had sent a team of American experts in May 1982, and they pointed out many lapses in the operation of the plant. However, the company failed to act on their suggestions. In addition, after making a number of visits to the plant, local journalist Rajkumar Keswani warned of the impending disaster 4 months before the accident.

MIC was used in the United States, Germany, and Japan, but it was stored in Bhopal in much greater quantities than in any of these other places. The question of whether the operation of hazardous industries (like the chemical industry) can be both safe and profitable is debatable. What is not debatable, however, is that safety must remain the top priority. Following a cyclohexane explosion in Flixborough in 1974, an Advisory Committee on Major Hazards was set up in the United Kingdom, and the European Economic Council Directive of 1982 was triggered by the Sevesco accident of 1976 in Italy. However, the Bhopal disaster of 1984, which was far worse than the Flixborough and Sevesco accidents (in fact, it was the worst in history), has not led to additional regulations outlining corporate and state responsibilities, despite the strong case for global monitoring of potentially toxic materials (Sriramachari and Chandra, 1997).

26.3 Chemistry and toxicokinetics of isocyanates

As stated previously, MIC is a member of the isocyanate family of chemicals. The high chemical reactivity of isocyanates is central to their commercial use, but it is also a key element of their toxicity. No clinical use of isocyanates has so far been demonstrated.

26.3.1 Chemistry of isocyanates

Organic isocyanates were first synthesized in 1849. Isocyanates (Table 26.1) are highly reactive heterocumulene

TABLE 26.1 Commonly used isocyanates.

Isocyanates	MW	LC_{50} (ppm)[a]	Ceiling (ppm)[b]
Methyl isocyanate (MIC)	57	5.1	0.02
Hexamethylene diisocyanate (HDI)	168	55.9	0.02
Toluene diisocyanate (TDI)	174	49.0	0.02
Isophorone diisocyanate (IPDI)	222	28.5	0.02
Diphenylmethane diisocyanate (MDI)	250	36.0	0.02
Dicyclohexylmethane diisocyanate (SMDI)	262	–	0.01
1,5 Naphthalene diisocyanate (NDI)	210	–	0.02

[a] *LC_{50} (lethal concentration killing 50% of experimental animals) values are after 4 h exposure.*
[b] *To convert ppm to mg/m^3, divide it by (24.4/MW); see, review by Varma and Saxena (1986).*

chemicals. The general structure of isocyanates is R—N=C=O, which is distinct from that of cyanate (N=C—O—H). The reactivity of organic isocyanates is due to the strain in the cumulative double bonds (—N=C=O) of isocyanates (Varadarajan et al., 1985).

Most of the commercially used isocyanates are diisocyanates, and R is an aromatic ring. MIC is an exception; its structure is $H_3C—N=C=O$. The physicochemical properties of MIC differ from those of other isocyanates (Lowe, 1970). Because of the high chemical reactivity of MIC with alcohols, it serves as an intermediate in the production of carbaryl, a pesticide. Diisocyanates are primarily used for the manufacture of polyurethanes.

26.3.1.1 Synthesis of methyl isocyanate

MIC ($CH_3N=C=O$) can be synthesized using different reactions. The commercial synthesis of MIC by Union Carbide, Bayer, and Dupont is described next.

At Union Carbide Corporation, Bhopal, India:

$$CH_3NH_2(\text{monomethyl amine}) + COCl_2(\text{phosgene}) \rightarrow CH_3N=C=O + 2HCl$$

At Bayer, Germany:

$$CH_3NH\tilde{a} - CO - NHCH_3(\text{dimethyl urea}) + (C_6H_5O)_2CO(\text{diphenyl carbamate}) \rightarrow CH_3N=C=O + \text{by products}$$

At Dupont, the United States:

$$CH_3 - NH - CHO(\text{methyl formamide}) + O_2CH_3N=C=O + H_2O$$

MIC was produced and stored in Bhopal, whereas CO and phosgene, which also are required for the production of carbaryl, were not stored; rather, they were produced and utilized immediately. In the United States and Germany, MIC is produced as needed; it is not stored.

The various steps in the production of carbamate pesticide at Bhopal were as follows (Varadarajan et al., 1985):

1. Petroleum coke (2C) was reacted with oxygen to produce 2CO.
2. CO and chlorine were reacted to produce phosgene ($COCl_2$).
3. Phosgene and methylamine (CH_3NH_2) were reacted to form methylcarbamoyl chloride ($CH_3NHCOCI$) plus HCl.
4. Methylcarbamoyl was then pyrolyzed to yield MIC ($CH_3N=C=O$) and HCl.
5. Finally, MIC was reacted with a slight excess of α-naphthol in the presence of a catalyst in carbon tetrachloride solvent to produce the desired pesticide carbaryl.

In the system used in Bhopal, the stored liquid MIC was transferred through pipes to charged pots weighing 1 metric ton and under 16 psi of pressure of nitrogen. These charged pots were connected to two reactors, where MIC and α-naphthol reacted to produce carbaryl. The charging of α-naphthol was done by dissolving it in carbon tetrachloride at approximately 50°C in the presence of a trimethylamine catalyst. The reaction between MIC and α-naphthol is exothermic. The temperature was maintained at 70°C for efficient production of carbaryl.

$$CH_3N=C=O + a - \text{naphthol} \rightarrow 1 - \text{naphthyl} - N - \text{methyl carbamate (carbaryl)}$$

The alternative method to make carbaryl involves reacting α-naphthol with phosgene to generate α-naphthol chloroformate. Then, α-naphthol chloroformate reacts with methylamine to produce carbaryl.

26.3.1.2 Physicochemical reactions with methyl isocyanate

MIC can interact with a large number of molecules, as well as with itself. Indeed, 21 products were identified (Varadarajan et al., 1985) and almost 10 unidentified chemicals (Sriramachari, 2004) were detected leaking from Tank E-610. An MIC trimer, as well as other metabolites of MIC such as dimethyl isocyanurate and 2,4-dione of MIC, were identified in autopsies of Bhopal victims. Reaction of MIC with water is important because it will occur whenever MIC comes into contact with the body or the environment, as happened in Bhopal. It is important to note that while excess water can neutralize MIC, only small quantities of water are enough to generate heat during the reaction, which leads to the vaporization of MIC, and this is what happened in Bhopal. Some important interactions of MIC are enumerated next.

1. Polymerization (self-addition of many MIC molecules);
2. Trimerization: 3 ($CH_3N=C=O$) → trimethyl isocyanurate;
3. Dimerization is common with aromatic isocyanates, but is rare with aliphatic isocyanates like MIC;
4. Additive reactions with molecules containing reactive hydrogen species, which migrate to the nitrogen of MIC;
5. General reaction of MIC with molecules containing hydroxylic groups:

$$CH_3N=C=O + ROH \rightarrow CH_3NHCOOR \text{ (urethane)}$$

6. Reactions with water:

$$CH_3NCO + H_2O \rightarrow CH_3NH_2(MMA) + CO_2$$

$$2(CH_3NCO) + H_2O \text{ (excess)} \rightarrow CH_3NHCONHCH_3(DMU)_+ CO_2$$

$$3(CH_3NCO) \text{ in excess} + H_2O \rightarrow CH_3NHCON\,(CH_3)\,CONHCH_3(TMB) + CO_2$$

$$4(CH_3NCO) + H_2O \rightarrow DMI + (CH_3)2NH\ (DMA) + CO_2$$

7. Reaction with DMA:

$$CH_3NCO + DMA \rightarrow (CH_3)2N - CO - NH - CH_3(TMU)$$

8. Reaction with alcohols and phenols (used by UCIL to produce carbaryl pesticide):

$$CH_3NCO + \alpha - naphthol \rightarrow$$
$$1 - naphthyl - N - methyl\ carbamate\ (carbaryl)$$

9. Reaction with primary and secondary amines:

$$CH_3NCO + R - NH_2 \rightarrow CH_3 - NH - CO - NH - R$$

10. Reaction with nitrates and nitrites:
    The reaction of MIC with nitrates and nitrites, which are normally present in water, can yield carcinogenic nitrosamines;
11. Decomposition into HCN at temperatures in the range of 427°C–548°C at 55–300 torr (Blake and Ijadi-Maghsoodi, 1982);
12. Reaction with HCN at normal temperatures, leading to the formation of other cyanides (Slotta and Tschesche, 1927).
13. Reactions with body constituents.

In general, interactions between isocyanates and endogenous molecules are reversible (Tse and Pesce, 1978). MIC has been shown to cause a greater interaction with macromolecules than aryl isocyanates (Brown et al., 1987). Reversible conjugation of isocyanates with glutathione (Slatter et al., 1991), which occurs both spontaneously and enzymatically, may have been the mechanism of distributing MIC molecules to different parts of the body and the reason behind its diffuse toxicity profile (Baillie and Slatter, 1991; Pearson et al., 1991). MIC can act as a hapten, which leads to the generation of antibodies in both animals and humans (Karol et al., 1987). MIC can carbamylate macromolecules (Segal et al., 1989). MIC has been shown to be an effective antisickling agent in vitro; it combines with α-amino groups of hemoglobin and thus increases its oxygen-binding affinity (Lee, 1976).

26.3.1.3 Quantification of methyl isocyanate

Measurement of MIC in the workplace requires the collection of samples with special tubes and then reacting it with an amino-based reagent such as 1-(2-methoxyphenyl) piperazine (2MP) or other similar substances (von Zweigbergk et al., 2002). Sampling under controlled experimental conditions can be done using gas-tight syringes. Several techniques have been used for the quantitative analysis of MIC. Methods used by Ferguson et al. (1986) and by ourselves (Varma et al., 1987) used a Perkin-Elmer Model 3920 gas chromatograph equipped with a nitrogen-phosphorus detector. The absolute retention time for MIC under these conditions was approximately 1 min and sensitivity of the method was 0.8 ng MIC.

26.4 Mechanism of death following exposure to methyl isocyanate

The immediate effect of exposure to MIC in Bhopal was lacrimation, choking sensations, and difficulty in breathing, followed in many cases by death. An important element of the fatalities in Bhopal was a lag period of several hours between the exposure to MIC and death (Paintal, 1986; Varma and Saxena, 1986). Most deaths occurred more than 24 h after the exposure. Delayed death was also observed in experimental animals exposed to MIC (Alarie et al., 1987; Bucher et al., 1987; Varma et al., 1988). It would thus appear that the lethal effects of MIC were caused by pulmonary complications. It was also found that a single exposure to MIC can produce long-lasting pulmonary complications (Ferguson and Alarie, 1991; Kamat et al., 1992; ICMR, 2004).

The pattern of death in experimental animals (i.e., rats, mice, and guinea pigs) following exposure to MIC was biphasic and similar to that observed in Bhopal. Even excessive concentrations (3506 ppm for 15 min) of MIC were not lethal to rats in a 10 min period. Exposure to MIC caused a significant decrease in body weight within 24–48 h (Varma et al., 1988), suggesting substantial loss of body fluid. In the only controlled experiments on humans, Kimmerle and Eben (1964) noted that subjects could not tolerate 21 ppm MIC even for a few seconds.

26.5 The cyanide controversy

In the chaos that prevailed in Bhopal following the disaster, a number of journalists, social activists, and even some scientists contended that the culprit was HCN, not MIC. HCN poisoning leads to cherry-red venous blood (which showed up in the autopsies of the victims) because oxygen is not being used by the tissues. Sodium thiosulfate is a known antidote for HCN, and because there were reports that the victims benefited from this type of treatment, that further supported the theory of HCN involvement. Also, MIC can be converted into HCN at high temperatures and pressure (Sriramachari, 2004). However, this was not borne out by the sum total of evidence that emerged. The physicochemical properties and toxicity profiles of MIC and HCN are shown in Table 26.2.

Cyanide is an instant killer at a certain dose level. However, deaths by pulmonary edema after a lag period (Paintal, 1986) and other toxicities observed in Bhopal victims (Varma, 1987) are not known to be caused by

TABLE 26.2 Properties of MIC and HCN.

Property	MIC	HCN
Molecular weight	57	27
Appearance	Liquid	Liquid/gas
Boiling point (°C)	39.1	25.7
Vapor density (air = 1)	1.97	0.95
Threshold limit value (ppm)	0.02	10.0
Lethal level 1 h exposure (ppm)	3.0	100
Concentration immediately fatal (ppm)	Undetermined	>270
Antidote	None	Sodium thiosulfate
Long-term effects	Many	None identified

cyanide. Some cyanide is present in most individuals, and more so if exposed to smoke and fire. Any beneficial effect of sodium thiosulfate could be explained by environmental exposure to cyanide, especially because a majority of the victims were slum dwellers who may have been using fires to keep their homes warm, and many were chronic smokers. Cherry-red blood could have resulted from the formation of carboxyhemoglobin from exposure to atmospheric carbon monoxide.

Under controlled experimental conditions, sodium thiosulfate did not reduce the toxicity of MIC (Alarie et al., 1987; Bucher et al., 1987; Varma et al., 1988). Finally, HCN is a fast killer at concentrations > 100 ppm (Goldstein et al., 1968), and the concentrations of MIC that were achieved in Bhopal would not have killed anyone if the gas had been HCN. Moreover, HCN could not descend to the ground because, unlike MIC, it is lighter than air. Moreover, there is definite evidence of long-term effects in survivors of the Bhopal disaster (Bucher, 1987; Dhara and Dhara, 2002; Dhara et al., 2002; Sriramachari, 2004), whereas a single dose of cyanide is not known to produce such effects (Goldstein et al., 1968). Sodium thiosulfate is well known to be an effective antidote against cyanide poisoning, and it should be administered almost immediately for that purpose, rather than several days or even months later (Chen and Rose, 1956; Goldstein et al., 1968).

26.6 Toxicity of isocyanates

Commonly used isocyanates include toluene diisocyanate (TDI), methylenediphenyl diisocyanate (MDI), naphthalene diisocyanate (NDI), and hexamethylene diisocyanate (HDI). All isocyanates are toxic (Rye, 1973) to varying degrees; TDI seems to be the most toxic.

The National Institute of Occupational Safety and Health in the United States projected as early as 1978 that approximately 50,000−100,000 workers would be exposed to these chemicals within 2 years (NIOSH, 1978). The routine method of exposure of workers to isocyanates is by inhalation, and their toxicity is greater following inhalation than following oral ingestion; isocyanates that produce both pulmonary and sensory irritation are more toxic than those that cause only sensory irritation (Weyel et al., 1982).

26.7 Toxicity of methyl isocyanate

Experimental research on the toxicity of MIC vapor on rats, mice, rabbits, and guinea pigs, as well as on human volunteers, was first reported in 1964 (Kimmerle and Eben, 1964). For the next 20 years, though, no follow-up studies were done. It is to the credit of Kimmerle and Eben (1964) that their stringent observations were confirmed by all the studies that followed the Bhopal disaster of 1984. It is tragic that the toxicity of poisons is tested on humans during wars, more often than not by the most developed countries. It is equally unfortunate that one finds out about human toxicity of chemicals during industrial accidents or as a consequence of environmental neglect. In this sense, Bhopal offered the most expansive opportunity to observe and investigate the toxicity of MIC on such a large scale on humans, as well as livestock and vegetation. Surprisingly, however, most of the obvious questions raised in the aftermath of the Bhopal disaster have not been answered.

Although human toxicity to MIC has only been observed following inhalation, animal experiments reveal that it is also toxic following injection; this contradicts the prediction by the visiting American team soon after the disaster that MIC is so reactive that it would be

destroyed upon contact with the body. Metabolites of MIC are also toxic (Varma and Guest, 1993).

For the sake of simplicity, data on the toxicity of MIC on humans and animals are presented separately in the rest of this chapter. It is worth mentioning, however, that almost all the data derived from animal studies seem to confirm what has been observed in humans in Bhopal.

26.7.1 Toxicity of methyl isocyanate in animal models

26.7.1.1 Mortality

Barely 4 h after the disaster on December 3, 1984, the streets of Bhopal were littered with dead animals—790 buffalo, 18 bullocks, 84 calves, 270 cows, 483 goats, 90 dogs, and 23 horses (Varma and Saxena, 1986). According to autopsy reports, the dead animals showed swollen livers and lymph nodes, bloated digestive tracts, engorged blood vessels, edema, necrosis in lungs with blood clots, and congested hearts and kidneys (Varma and Saxena, 1986). House flies survived, however, but it is not known why.

Kimmerle and Eben (1964) estimated an LC_{50} value of 5 ppm in rats following a 4 h exposure, and 21 ppm following a 2 h exposure. Unlike with cyanide, death followed several hours after MIC exposure and continued for up to 18 days. In later studies, it was found that 10 min exposure to as much as 3506 ppm was not immediately lethal (Dodd et al., 1986), although guinea pigs died during exposure to high concentrations (i.e., greater than 500 ppm). In general, deaths following exposure to MIC occur 1−2 days later, and a second phase of mortality follows after a week or more (Alarie et al., 1987; Bucher et al., 1987; Varma et al., 1988). Guinea pigs are more sensitive to MIC toxicity than rats (Dodd et al., 1986).

26.7.1.2 Pulmonary toxicity

Kimmerle and Eben (1964) reported that MIC caused lacrimation, mucosal irritation, and pulmonary edema in rats, mice, rabbits, and guinea pigs. Other studies also found that MIC causes both sensory and pulmonary irritation; if death did not ensue, the recovery from these pulmonary effects was very slow to occur (Ferguson et al., 1986; Alarie et al., 1987). Exposure to MIC caused concentration-dependent degenerative changes in bronchiolar and alveolar epithelium in rats and guinea pigs, resulting in the plugging of major airways and atelectasis (Nemery et al., 1985; Fowler et al., 1987), increase in lung weight (Bucher et al., 1987; Stevens et al., 1987), pulmonary (Bucher et al., 1987), and olfactory epithelial necrosis, airway obstruction, and compromised cardiopulmonary function (Tepper et al., 1987) in surviving animals.

In a retrospective study of 4782 Bhopal gas victims and 1190 control subjects, De (2012) found a much higher risk of developing obstructive pulmonary complications in younger subjects (age 10−29 years) exposed to MIC than older ones (age 30−60 years).

26.7.1.3 Ocular toxicity

As was the case in humans, lacrimation has also been found to be one of the earliest effects of MIC vapor in experimental animals (Bucher et al., 1987; Varma et al., 1988). However, exposure of rats to 3, 10, or 30 ppm MIC for 2 h (which approximates the situation in Bhopal) was not found to cause any damage to the cornea, although copious lacrimation was observed up to 3 months. Similar findings have been reported in mice (Boorman et al., 1987). On the other hand, exposure of lens explants to MIC in vitro has been shown to cause opacity (Harding and Rixon, 1985). It is very likely that profuse lacrimation acted as a protective mechanism, by chemically inactivating MIC.

26.7.1.4 Reproductive toxicity

Exposure of mice on day 8 of gestation (gestation period 19 days) to 2, 6, 9, and 15 ppm MIC for 3 h or 1−3 ppm for 6 h on days 14−17 of gestation caused concentration-dependent fetal loss and maternal mortality (Varma, 1987; Varma et al., 1987); lengths of different fetal bones were significantly reduced in mice following exposure to 9 and 15 ppm MIC (Varma, 1987). MIC also caused maternal and fetal toxicity in rats; pregnancy loss accompanied a sudden decrease in progesterone, although it could not be determined which of the two events occurred first (Varma et al., 1990). Given the extensive nature of MIC toxicity, it is difficult (if not impossible) to determine if MIC-induced reproductive toxicity is a direct effect on the conceptus or a consequence of general toxicity; however, several observations indicate the possibility of a direct effect.

Radio-labeled MIC rapidly reaches the fetus (Ferguson et al., 1988). Intraperitoneal injection of MIC also caused reproductive toxicity of a similar magnitude as with inhalation (Varma et al., 1990). Moreover, MIC metabolite methylamines also produced reproductive toxicity without other obvious effects on pregnant mice. Of the three amines tested, monomethylamine, dimethylamine, and trimethylamine, the last was most toxic in vivo, as well as in mouse embryos in culture (Varma and Guest, 1993). Interestingly, administration of trimethylamine during mouse pregnancy resulted in stunting of male but not female progeny (Guest and Varma, 1993), similar to the effect reported years later in Bhopal

victims (Ranjan et al., 2003). Another metabolite of MIC, *S*-(*N*-methylcarbamoyl) glutathione (GSH) and MIC metabolite trimethylamine exerted marked toxicity on cultured mouse embryos, as well as yolk sac and limb bud (Guest et al., 1992).

26.7.1.5 Immunotoxicity, genotoxicity, and carcinogenic effects

MIC has been found to generate specific antibodies in guinea pigs following both inhalation and subcutaneous injections (Karol et al., 1987). MIC was found to be genotoxic in rats (Dutta et al., 1988) and caused dose-dependent increases in sister chromatid exchange, as well as chromosomal aberrations in hamster ovary cells in addition to cell cycle delay in mice (Shelby et al., 1987). MIC has also been reported to be mutagenic in mammalian and bacterial cell cultures (Caspary and Myhr, 1986; Meshram and Rao, 1988); MIC has been estimated to have a 76.6% probability of being a genotoxic carcinogen, but only in tests with low specificity (Ennever and Rosenkranz, 1987). Mishra et al. (2009) examined the carcinogenic potential of MIC using cultured human lung fibroblasts and found that MIC induced an inflammatory response, resulting in extensive DNA damage and genomic instability.

26.7.1.6 Other toxic effects

MIC caused dose-dependent necrosis of rat brain cells in culture (Anderson et al., 1990); these findings show that MIC can exert its effects even in liquid media. Exposure of mice to 1−3 ppm MIC was found to inhibit erythroid precursors, pluripotent stem cells, and granulocyte-macrophage progenitor; recovery from this inhibitory effect was found within 3 weeks after 1 ppm but not after 3 ppm (Hong et al., 1987). At higher concentrations of 6−15 ppm, MIC inhibited cell cycling in bone marrow, alveolar cells, and T lymphocytes (Shelby et al., 1987); similar data were reported by others (Tice et al., 1987). MIC can inhibit bone marrow cell proliferation in mice (Meshram and Rao, 1988). Exposure of rats, mice, and guinea pigs to MIC vapor caused a dramatic body weight decrease in the first 2 days, which was followed by incomplete to complete recovery (Dodd et al., 1986; Bucher et al., 1987; Varma, 1987). The most likely cause of the rapid decrease in body weight is fluid loss, which may also explain the increase in hematocrit.

MIC also caused an increase in creatinine kinase, hemoglobin, hematocrit, reticulocytes, neutrophils, and blood PCO_2 in rats and guinea pigs (Dodd et al., 1986), as well as a decrease in blood pH and PO_2. MIC can cause hyperglycemia, lactic acidosis, and hypothermia in rats (Jeevaratnam and Vaidyanathan, 1992). Mishra et al. (1991) exposed rats to different concentrations of MIC vapor for 8 min and measured drug-metabolizing enzymes in lungs and found that aminopyrene demethylase and aniline hydroxylase activities were inhibited, but glutathione-*S*-transferase activity was increased.

26.7.2 Toxicity in humans

The human toxicity of MIC has been reviewed by several investigators (Mehta et al., 1990; Dhara and Dhara, 2002; Sriramachari, 2004). Toxicity in Bhopal consisted of minor eye ailments; throat irritation and cough; severe conjunctivitis, keratitis, acute bronchitis, and drowsiness; severe pulmonary edema; and convulsions followed by cardiorespiratory arrest (Kamat et al., 1985; Misra et al., 1987).

26.7.2.1 Acute toxicity

Nonlethal effects

Eye irritation, lacrimation, choking sensations, and difficulty in breathing were first reported by Kimmerle and Eben (1964), who exposed human volunteers to MIC vapor; the observations of these workers were confirmed by thousands of the victims of the Bhopal disaster. In addition, many of the victims lost consciousness, which some, but not all, regained (Varma and Saxena, 1986).

Fatal effects

Although the precise number of people who died after being exposed to MIC is still not known; our estimate, based on fatalities in 3270 households surveyed to determine effects on pregnancy (Varma, 1987), would suggest 6000−8000 deaths within 24−72 h after the gas leak in Bhopal. Deaths can be attributed to pulmonary edema. As mentioned earlier, deaths did not occur as quickly as is characteristic of cyanide poisoning; rather, it happened after a delay of several hours.

26.7.2.2 Subacute and chronic toxicity

Anecdotal reports suggest that the Bhopal disaster resulted in approximately 20,000 deaths over approximately 2 years. Since late deaths have been observed by several workers in animal models (various articles in EHP, 1987), it is reasonable to assume that there will be reports of late deaths in humans as well. It is very likely that severe lung damage accounted for most of these late deaths, although a contributory role of dehydration, internal hemorrhage, and other complications cannot be ruled out.

26.7.2.2.1 Pulmonary complications

Examination of 500 exposed people within 3 days of the Bhopal disaster (Sharma and Gaur, 1987) identified alveolar edema and destructive lesions in 8%. A retrospective study of 978 patients found mortality in 7.14%, breathlessness and cough in 95%, irritation and choking in the throat in 46%, and chest pain in 25% (Misra et al., 1987). Evidence of necrotizing lesions in respiratory tract, as well as radiological changes and compromise in lung function, has been documented (Gupta et al., 1988; Misra and Nag, 1988). Since the prevalence of compromise in lung function was higher in the population closer to the Union Carbide plant than in the population farther away, it is very likely that this occurred as a result of exposure to the toxic gases rather than preexisting bronchitis, tuberculosis, or emphysema. A follow-up of 113 exposed patients revealed worsening of pulmonary symptoms 2 years later, forced expiratory flow (FEF) between $FEF_{25\%}$ and $FEF_{75\%}$ of forced vital declined progressively over a 2-year period (Kamat et al., 1985, 1992; Patel et al., 1987), a 1- to 7-year period (Vijayan et al., 1989; Vijayan and Kuppurao, 1993; Vijayan and Sankaran, 1996), and a 10-year period (Acquilla et al., 1996; Dhara et al., 2002). Likewise, other researchers have found a direct relationship between pulmonary function compromise and inflammatory alveolitis and the severity of exposure (Vijayan et al., 1989). A causative relationship between the intensity of exposure to toxic gases and a decrease in $FEF_{25\%-75\%}$ is also suggested by another follow-up study of 454 adults conducted 10 years after the disaster (Cullinan et al., 1997).

Persistent airway hyperreactivity after a single exposure to chemical irritant has been termed *reactive airways dysfunction syndrome (RADS)* (Brooks et al., 1985). There is a strong likelihood of RADS among the victims of the gas exposure in Bhopal (Nemery, 1996); however, the question of whether the exposed Bhopal population suffers from RADS has not been carefully studied.

26.7.2.2.2 Ocular toxicity

There are reports that eye irritation and some level of lacrimation was a common experience of workers at the UCIL pesticide plant. Indeed, because of these frequent episodes of eye irritation, workers initially did not suspect that something unusual was happening in the early morning of December 3, 1984. It would seem that the eyes are most sensitive to MIC toxicity since eye irritation was experienced even by people who lived quite far from the plant and seem not to have experienced pulmonary and other symptoms (Varma and Saxena, 1986). Exposure to MIC produced ocular burning, watering, pain, and photophobia (Dwivedi et al., 1985), as well as conjunctivitis and corneal opacity (Maskati, 1986). Within the first 2 weeks of the disaster, Andersson et al. (1988) found no case of blindness in a community-based survey; surprisingly, the incidence of photophobia and interpalpebral erosion were highest in areas where the death rates were lowest.

Follow-up studies up to 2 years after the incident revealed persistent eye watering, itching, redness, photophobia, burning, Bitot's spots, and even corneal opacity (Khurrum and Ahmad, 1987; Andersson et al., 1988). It is noteworthy that in a gas-exposed cohort of 232 children admitted to the Pediatric and Eye Ward of the Hamidia Hospital, respiratory and cardiac complications were not accompanied by equally serious eye injuries (Dwivedi et al., 1985). It is very likely that poor living conditions, which favor infection (especially in children), further worsened ocular toxicity (Dhara and Dhara, 2002). On the other hand, it was feared at the time of the accident that a large number of survivors might be left with severe visual impairment; fortunately, this does not seem to be the case, which does indicate that profuse watering, a toxic effect of MIUC, also had the effect of minimizing ocular toxicity.

26.7.2.2.3 Reproductive toxicity

A follow-up study of 865 pregnant women living close to the UCIL pesticide plant at the time of the Bhopal disaster found that 379 (43.8%) did not give birth to live babies (Varma, 1987). Another follow-up of 2566 pregnant women from 18,978 households also found that 23.6% of the exposed women suffered miscarriages, as compared to 5.6% of 1218 control cohorts (Bhandari et al., 1990). Kanhere et al. (1987) found that exposure to toxic gases resulted in decreased placental and fetal weights. In addition, approximately 14% of the subjects experienced increased loss of pregnancy and infant deaths within 1 month, 2 years, and 5 years after birth, compared with 2.6%−3% within the pre-accident period (Varma et al., 1990). Other effects of exposure to MIC in women include leucorrhea, suppression of lactation, pelvic inflammatory disease, and irregular menstruation (Varma and Saxena, 1986). No effect on spermatogenesis was detected within 6 months after the Bhopal disaster (Daniel et al., 1987).

26.7.2.2.4 Genotoxicity

In a study involving 43 gas-exposed women and 40 gas-exposed men 3 years after the disaster, a significant increase in chromosomal aberrations was reported; these aberrations included breaks, gaps, and dicentric rings, which were more marked in females than in males (Ghosh et al., 1990). Chromosomal aberrations

(Goswami, 1986; Ghosh et al., 1990) and cell cycle abnormalities have been identified in Bhopal victims (Deo et al., 1987).

26.7.2.2.5 Carcinogenicity

The possibility of cancer in the Bhopal population exposed to MIC was raised by journalists. Usually, multiple contacts with a carcinogen are needed to produce cancer, but a single dose of a chemical can have the same effect (Calabrese and Blain, 1999). A cancer registry was initiated by the ICMR. However, no conclusive evidence of an increase in cancer in the exposed population has been documented. Senthikumar et al. (2011) have reported a total of 1261 cancer patients in the long-term Bhopal survivors, but they do not provide information about the size of the population examined; it is, therefore, difficult to infer whether exposure to MIC increased the number of cancer cases.

26.7.2.2.6 Immunotoxicity

Saxena et al. (1988) studied 31 exposed adults and found a significant increase in abnormal lymphocytes; however, they saw no compromise in humoral and cellular immunity in exposed populations in Bhopal. Anti-MIC antibodies were detected in blood samples from gas-exposed subjects, but the clinical implications of this discovery are not clear (Karol et al., 1987).

26.7.2.2.7 Neurotoxicity and psychological effects

Soon after the Bhopal disaster, there were displays of bizarre drawings by the surviving children, almost all of whom depicted gusts of flames going upward—starkly different from the usual pictures painted by children. Many of these drawings reflected their loss of parents or other family members or friends. While these drawings are unlikely to be specific to MIC, they probably reflected the children's response to unanticipated horror. Psychological trauma was experienced by adults, which shared many similarities with that experienced by soldiers returning from combat missions. One study categorized post-disaster psychological impact into four categories: (1) posttraumatic stress disorder characterized by anxiety, restlessness, and sleep disorder; (2) pathological grief reactions expressed as suicidal tendencies and helplessness at not being able to save family members; (3) emotional reaction to physical problems imposed upon them; and (4) exacerbation of preexisting problems (Murthy and Isaac, 1987). A survey of 164 gas-exposed children 105 days after the disaster found them apprehensive and jittery (Irani and Mahashur, 1986).

Dr. Varma and Dr. Mulay encountered a volunteer at Sambhavana Trust Clinic, which is located near the now-decommissioned pesticide plant. This young man, whose parents died during the disaster, was found to be perfectly normal on many occasions, but other workers at the clinic mentioned that, from time to time, he would become very depressed. One day in 2007, he committed suicide. There are reports of other such cases, although it is never possible to causally link such tragic events with exposure to MIC. Sethi et al. (1987) reported that a large number of survivors suffered from neurological problems, including neuroses, anxiety states, and accentuation of previous psychological problems. Bharucha and Bharucha (1987) also observed neurological and neuromuscular abnormalities in both adults and children and concluded that the incidence was lower than expected following a disaster of such magnitude as occurred in Bhopal; 24 of the 47 children examined by these authors experienced coma lasting for a maximum duration of 24 h. Neurological problems have also been reported by others (e.g., Kamat et al., 1985; Gupta et al., 1988; Misra and Kalita, 1997). Raphael and Middleton (1988) have suggested that 30%–59% of those exposed to a disaster may suffer from traumatic neuroses.

26.7.2.2.8 Other toxic effects

Soon after the disaster, Bhopal was flooded with people hoping for a cure, as well as vendors selling all kinds of medicines that they claimed would provide one. Some did not know what to expect in the days following the accident and hoped that pills would safeguard against existing ailments like loss of appetite, weakness, and breathlessness, and prevent complications.

After 35 years since the Bhopal incident, it is difficult to relate many of the symptoms, such as weakness, loss of appetite, anxiety attacks, and menstrual problems to MIC. However, many subjects continue to suffer from pulmonary dysfunctions and some compromise in visual function. As mentioned earlier, most of the victims of the disaster belonged to economically disadvantaged groups and lived in poor housing with nonexistent sanitary facilities. Therefore, they already probably suffered from many chronic diseases, including bronchitis, tuberculosis, and malaria. Even so, the Bhopal disaster certainly worsened their maladies.

26.8 Treatment

By their very nature, disasters involving chemicals pose serious problems because they concern a large number of people in a state of panic, all at the same time. Most places are not equipped to deal with such situations, especially if there is confusion about the nature of the chemical. If the chemical is a pulmonary irritant, as was the case with MIC, there is a good likelihood of suspecting cyanide poisoning, as happened in Bhopal. The other

reason for mass confusion is the erroneous belief that antidotes exist for every poison.

Laypeople are not expected to know that supportive therapy is the cornerstone of managing drug overdose or poisoning, rather than antidotes; a few exceptions include cyanide, narcotic analgesics, acetaminophen, methanol, organophosphates, digitalis, and carbon monoxide. It was legitimate for the media and people in Bhopal to demand an antidote. Therefore, conveying accurate information to the panicked population was vital. In the case of Bhopal, nondisclosure of the nature of the chemical for some period of time, inaccurate information on the cause (like the mistaken belief that it was cyanide), and lack of proper treatment proved as harmful as the poison itself. For example, if people had been warned not to run away, but instead encouraged to stay still and cover their faces with wet cloth, the benefits would have been significant. In the midst of all the confusion, the doctors in Bhopal worked out as rational a treatment as possible, which comprised of atropine, antibiotic eyedrops, and antispasmodics. Treatment of pulmonary edema requires hospitalization and positive pressure respiration; Bhopal neither had enough beds nor equipment to provide this.

Long-term treatment is also supportive and is unrelated to the initiating factors. For example, the treatment of pulmonary, ophthalmic, or neurological complications has nothing to do with whether these occur due to MIC or phosgene poisoning or due to some other cause. Cyanide, unless ingested on a regular basis from the environment or food, does not produce long-term disability if it fails to cause death.

A redeeming feature of the Bhopal tragedy was the overwhelming response of the Indian people. Hundreds flocked into Bhopal on the morning of December 3 from nearby villages, and some came from far away. In addition, doctors did a commendable job working for long hours without a break. In contrast, the medical team dispatched by Union Carbide arrived 10 days later and tried to assure the public that MIC would be destroyed rapidly and that no long-term effects were to be expected. The government of India could not summon a high-level medical team to deal with the disaster and failed miserably in following up as well. Voluntary groups and nongovernmental organizations shared a major burden of reassuring people and helping with both treatment and rehabilitation.

26.9 Toxic potential of methyl isocyanate beyond the Bhopal disaster

The Bhopal incident was the first case of mass exposure of humans, animals, and vegetation to MIC. Several factors influenced the toxicity of MIC, such as the living conditions of the victims. Under identical conditions in a developed country, the consequences most likely would have been different. At the same time, the exposure of the Bhopal population was to a specific concentration of MIC and for a specific duration.

The accidental release of MIC can happen wherever the chemical is stored. A minor leak occurred from the Union Carbide plant in West Virginia only a few months after the Bhopal disaster, and a school in the area had to be evacuated. Exposures to MIC at higher concentrations and for longer durations than in Bhopal can also occur, and these can be fatal to a substantially greater percentage of population regardless of where they happen. The fact that MIC is heavier than air makes it a potentially highly hazardous chemical, both in enclosed and open spaces.

If animal experiments were solely directed to answer questions relating to the Bhopal disaster, the use of excessively high concentrations of MIC (Dodd et al., 1986; Fowler et al., 1987) and repeated exposures would not have been very relevant. However, workers are likely to encounter repeated exposure to MIC; indeed, anecdotal reports suggest that the impending disaster was not suspected because workers were used to minor leaks (and consequently, eye irritation) in the Union Carbide plant.

No workers died inside the plant in Bhopal because MIC spewed outside the factory; however, an accident worse than Bhopal cannot be ruled out, especially if the space is enclosed.

The confusion caused by the lack of transparency about the identity of the poison by the concerned authorities at the Union Carbide headquarters and conflicting instructions only worsened the tragedy.

26.10 Benzyl chlorines and other chemicals at Bhopal

MIC and many other chemicals were stored in Bhopal. The disaster in 1984 led to the closure of the UCIL factory. While the remaining MIC was disposed of during Operation Faith, Union Carbide closed its Bhopal location, and several hundred metric tons of hazardous waste stored in open areas and sheds were not destroyed. The first study on this topic, by Dikshith et al. (1990), demonstrated the presence of 1-napathol in the soil and water in Bhopal. In all, 15 other studies were conducted between 1990 and 2010 by groups like Greenpeace International, Centre for Science and Environment (CSE), and National Environmental Engineering Research Institute (NEERI), to address the issues of whether the stored pesticides and chemicals on the factory grounds, solar evaporation ponds, and soil surrounding the factory contaminated the drinking water, and if so, which chemicals were present in levels that exceeded permissible levels. There is close agreement about the extent and type of contamination

among several studies. In studies by CSE (Johnson et al., 2009; CSE, 2013), the maximum concentration found in soil samples from specific locations like the storage, processing, and dump areas recorded contamination with carbaryl (51,003 ppm), aldicarb (7876 ppm), dichlorobenzene (2049 ppm), HCH isomers (99,700 ppm), and α-naphthol (9914 ppm), as well as heavy metals like mercury (128,000 ppm), lead (406 ppm), and chromium (1065 ppm). The NEERI report downplayed contamination of groundwater, stating that it most likely occurred due to runoff from the material dumped in the pesticide plant; but the CSE report (2013), along with several other studies, concluded that the groundwater was contaminated significantly with chemicals. All the reports acknowledged that there was very little information on the contaminants in the solar evaporation ponds where factory waste was discharged during the entire operation of the UCIL plant (CSE, 2013). Both the CSE and the NEERI reports documented the type and amount of chemicals dumped within the factory premises from 1969 to 1984. What is most surprising is that none of these reports were published in mainstream journals.

Why remediation of the site has not occurred is no secret. The cost of incineration of over 1 million metric tons of contaminated soil would be well over 10,000 million rupees, and no one—neither the Indian government nor Dow Chemical, which bought Union Carbide in 2001—was prepared to pay the bill. So, to date, very little has been done to get rid of the contaminated soil, let alone treat the contaminated water. In addition, the area surrounding the old UCIL plant has grown in population (now over 40,000 people), and these people have been drinking the chemical-laced water for 5–10 years, or even longer (up to 2 decades). There is a concern that these chemicals (some known to be teratogens) might increase the incidence of birth defects. Indeed, a systematic study by the authors is under way to document the effect on people of exposure to contaminated water, gas, or both, as compared to people who were not exposed to any toxic substances.

26.11 Concluding remarks and future directions

This chapter described the chemistry, pharmacology, and toxicology of MIC in the context of the more commonly used diisocyanates. Combatants and civilians have been subjected to lethal and debilitating chemical agents during war. However, no poisonous chemical other than MIC has the dubious distinction of killing nearly 8000 people within 72 h, and many more in the subsequent years and maiming civil society on a scale as large as what happened in Bhopal in peacetime. Unlike the September 11, 2001, terrorist attack in the United States, where the total number of casualties is accurately known, no one is certain of the exact death toll from the Bhopal incident, whether immediately afterward or in the subsequent months and years; unfortunately, the same can be said about most disasters in the developing parts of the world. While acute deaths were most likely caused by pulmonary edema, only a well-planned epidemiological study coordinated by official agencies could have determined the nature and magnitude of long-term effects. Unfortunately, such a study was not done, and many of the long-term effects cannot be identified retroactively. Carcinogenicity and genotoxicity require long-term follow-up of a large population. So far, the results have been disappointing.

MIC toxicity demonstrates that the full dimension of the pharmacology of a chemical cannot be predicted from its chemical structure, but it can be approximated by careful and painstaking research. Such an inquiry into MIC would be advisable.

Acknowledgments

This chapter is dedicated to the victims of the 1984 Bhopal disaster.

Chapter 27

Other toxic chemicals as potential chemical warfare agents

Jiri Bajgar[1], Jiri Kassa[2], Josef Fusek[2], Kamil Kuca[1] and Daniel Jun[2]

27.1 Introduction

For the development of new chemical weapons (CWs), a number of criteria are necessary: a research base including scientists and equipment, access to information, chemical and arms industries, and, of course, financial support. It is noteworthy that the development of CWs is possible not only for states, but also for terrorists. It is necessary to stress that the intention of this chapter is not to describe new CWs or chemical warfare agents (CWAs), but to comment on a number of trends in toxicology with the aim that these chemicals may be proposed for inclusion in the Chemical Weapons Convention (CWC) verification mechanisms. However, the text of the CWC is comprehensive and covers practically all chemicals that may be misused as CWs.

The objective of this chapter is to briefly describe a number of chemicals that could be used as toxic compounds or CWAs against humans.

27.2 General

27.2.1 Chemical weapons convention: article II, definitions and criteria

1. "CWs" means the following, together or separately:
   a. Toxic chemicals and their precursors, except where intended for purposes not prohibited under this Convention, as long as the types and quantities are consistent with such purposes.
   b. Munitions and devices, specifically designed to cause death or other harm through the toxic properties of those toxic chemicals specified in subparagraph (a), which would be released as a result of the employment of such munitions and devices.
   c. Any equipment specifically designed for use directly in connection with the employment of munitions and devices specified in subparagraph (b).
2. "Toxic chemical" means:

Any chemical which, through its chemical action on life processes, can cause death, temporary incapacitation or permanent harm to humans or animals. This includes all such chemicals, regardless of their origin or their method of production, and regardless of whether they are produced in facilities, in munitions, or elsewhere. Therefore, CWAs can be characterized as toxic chemicals. Initially, it is difficult to differentiate between the research aimed at protection against CWAs (defense) and development of new CWAs (offense). Both actions deal with the synthesis of chemicals, based on either information or ideas, or incidentally synthesized toxic compounds. A typical example is the synthesis of organophosphates (OPs) by G. Schrader, originally dedicated to the development of new pesticides. Another example of the development of a new CW would be the synthesis of OP compounds of the V series. After synthesis, the compound in question will be characterized chemically and biologically, and sometimes modified to increase its military properties (toxicity and physicochemical properties, such as stability and volatility). Then the compound can be studied in detail for its pharmacological and toxicological characteristics by using more convenient species and routes of administration. At this stage, it is practically impossible to decide if the research is offensive or defensive though some indications would lead to the opinion that the direction is offensive; for example, when attention is given to its efficacy following percutaneous or inhalation administration. Studied methods of

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00027-1

dispersion under field conditions are an indication of an offensive approach; testing for protective qualities under real conditions can be regarded as a defensive approach. However, further steps, like production of large quantities and weaponization, are clearly offensive. It is useful to compare the time from synthesis to production or use of certain CWs. After the synthesis of phosgene and diphosgene (1812 and 1887), their use in 1916 was observed; a similar situation was observed for mustard (1866–1917); for CS, this period was shortened (synthesis in 1928 and use in 1950); and VX was synthesized in the early 1960s and weaponized in 1968. The big question is: What is meant by large quantities? This can be addressed using the approach contained in the CWC. Quantities would also be compared with the contamination density prescribed for different CWAs. For instance, for yperite, it is 19 tons/km^2 for percutaneous administration and 4 tons/km^2; for *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX) (percutaneous) it is 2 tons/km^2; for sarin and 3-quinuclidinyl benzilate (BZ) (by inhalation), this value is about 0.5–0.6 tons/km^2 (Robinson, 1985). Of course, it does not apply to the synthesis or production of these substances for terroristic purposes.

Apart from this "classic" approach, it would be possible to "improve" the properties of known CWs (e.g., microencapsulation so that less stable or highly volatile substances can be used). Nanotechnology offers new possibilities, as described recently by Price and Petersen (2008). The other option is to improve penetration using known enhancers like dimethyl sulfoxide (DMSO). While the percutaneous toxicity (expressed as LD_{50} in rats) of one of the toxic OPs (namely, *O*-isopropyl *S*-2-diisopropylaminoethyl methyl phosphothiolate) is 59.1 μg/kg, when it is mixed with DMSO, this value decreases to 10.1 μg/kg (Bajgar, 1989).

Binary technologies are also acknowledged; however, the development of other methods of synthesis is not excluded (the more steps involved in synthesis, the more difficult it is to control the process). An alternative is to search for compounds either used or synthesized already. From the groups of highly toxic chemicals, these could be fluorophosphorylcholines (unstable) or toxic silatrans. In the group of medications, there are also highly toxic chemicals like cardiac glycosides (digoxin), sympathomimetics (noradrenalin), and myorelaxans (succinylcholine, curare derivatives). The other compounds to be included are insulin, cantharidin, aconitin, galantamine, pancuronium, pipecuronium, some derivatives of vitamin D (cholecalcipherol), some antibiotics, cytostatics, etc. It is necessary to point out that their use is limited (e.g., parenteral administration of insulin or delayed acute effect of cytostatics). A possible candidate would be centrally acting alpha 2-adrenergics with antihypertensive and sedative properties. All bioregulators are of great interest, especially in connection with the increased possibility of obtaining significantly sufficient quantities for military and terroristic purposes. All these examples are more or less hypothetical and require further testing. There exist some groups of compounds whose misuse is more probable and some of these chemicals are under suspicion (not proved) of being introduced into military arsenals. An illustrative but not exhaustive list of warfare agents is given next.

27.3 Specific agents

27.3.1 Carbamates

Compounds in the carbamate group have a broad spectrum of toxicities—from relatively slightly toxic (carbaryl) to highly toxic compounds comparable with nerve agents (T-1123) (Fig. 27.1). As described by Robinson (1971), carbamates including T-1123 had been studied by British and Canadians as CW agents since 1940. Other carbamates were described in detail by Badawi and Hassan (1995). They are well absorbed by the lungs, gastrointestinal tract, and the skin. The clinical representation of poisoning is similar to that for nerve agents, though perhaps with more expressed peripheral signs because of quaternary nitrogen in the molecule (T-1123); therefore, penetration through the blood–brain barrier is difficult

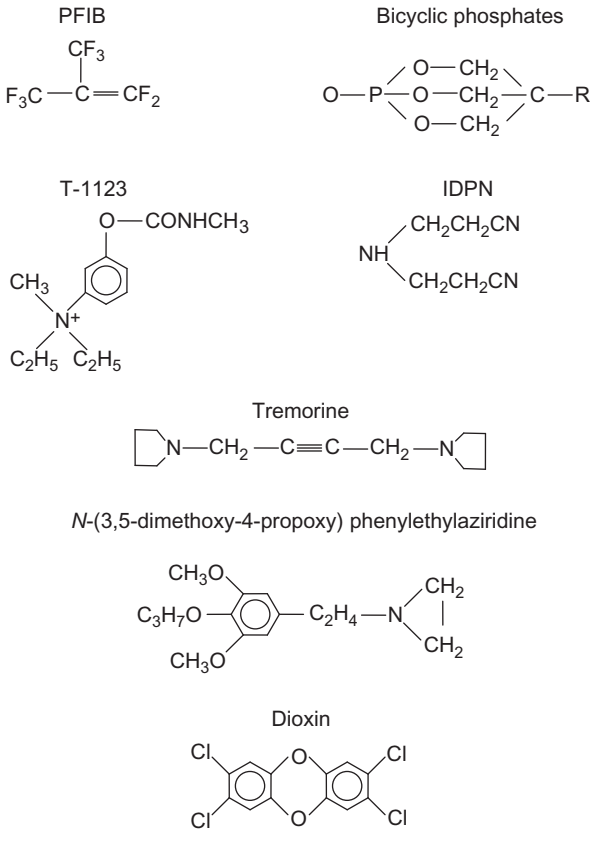

FIGURE 27.1 Chemical formulas of some toxic chemicals.

(Bajgar and Patocka, 1976; Fusek et al., 1996a). The basic mechanism of action is reversible inhibition of cholinesterases. However, the inhibition of carbamates is based on carbamylation of the active center of the acetylcholinesterase (AChE). Spontaneous decarbamylation is a relatively quick process (taking approximately 24 h) and carbamylated cholinesterases are resistant to the effect of reactivators. Therefore, the treatment is symptomatic, preferably using only atropine. These difficulties would be reasons for military use (Patočka, 1990).

27.3.2 Dioxin

Dioxin is one of the most toxic low-molecular-weight compounds (Fig. 27.1). Its oral LD_{50} for guinea pigs is 2−20 μg/kg; for monkeys, it is 2 μg/kg; for rats, it is 18−60 μg/kg; and for humans (subcutaneous administration), it is about 107 μg/kg (Bajgar, 2006; Patočka, 2004). Dioxin interferes with the metabolism of porphyrins (and the main symptom of poisoning is derived from an increase of porphyrins in the organism—i.e., porphyria cutanea tarda) by induction of delta aminolevulate synthetase. Dioxin also has carcinogenic, hepatotoxic, nephrotoxic, teratogenic, and embryotoxic effects and causes dermal changes (except porphyria cutanea tarda), including chloracne, followed by development of cachexia. There is no specific antidote, making treatment very difficult and symptomatic. Effects of dioxin following acute administration are relatively delayed. This is a limiting factor for its use as a CW. Dioxin in the organism is bound to lipids and concentration of dioxin in plasma fat in persons exposed to dioxin was 100−1000× higher than that of the normal population (Neuberger et al., 1999; Pelclová et al., 2011; Klement et al., 2013). It should be mentioned that dioxin is one of the polychlorinated biphenyls and dibezofurans that appears to be problematic for the environment (Sofronov et al., 2001; Bajgar, 2006). Dioxin was used to poison Ukraine's President Viktor A. Yushchenko (Sorg et al., 2009).

27.3.3 Bicyclic phosphates

Bicyclic phosphates have been used as flame retardants, antioxidants, stabilizers, and for spectroscopic studies. At present, however, they are being replaced by other compounds that are not as highly toxic. In a chemical structure (Fig. 27.1), when R is substituted by isopropyl, the toxicity is very close to that of sarin (LD_{50} = 0.18 mg/kg, i.m. in rats). Bicyclic phosphates act rapidly—within minutes following parenteral administration. Clinical symptoms include behavioral perturbation, muscle weakness, hyperactivity, muscle tremors, and convulsions leading to paralysis. Intoxication is slightly similar to poisoning with nerve agents, but with a different mechanism of action; that is, probably connected with gamma-aminobutyric acid receptors. Specific antidotal therapy does not exist, but a relatively good effect was observed following administration of benzodiazepines (Patočka, 2004; Bajgar, 2006).

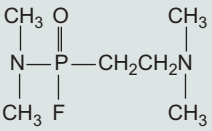
27.3.4 Perfluoroisobutene

Perfluoroisobutene (PFIB) is designated a chemical 2 by the CWC and therefore is contained in Schedule 2A. Its chemical structure is shown in Fig. 27.1. PFIB is produced by thermal decomposition of Teflon and has high inhalation toxicity characterized by pulmonary edema. PFIB has been characterized in more detail in an *ASA Newsletter* (Patočka and Bajgar, 1998). Therapy is symptomatic.

27.3.5 Organophosphates

There are other known OPs having relatively high toxicity, like amiton (Tetram), Armin, dimefox (Hanane, Terrasytam), paraoxon (E 600), and TEPP (Tetron). These compounds could be used for military and terrorist purposes; however, it would be uneconomic for the military to replace these substances. However, a new group of OP compounds has been described and characterized. This class of OPs can be described in general as 2-dialkylaminoalkyl-(dialkylamido)-fluorophosphates. In their chemical formulas, structural similarities with the group of so-called G-compounds (i.e., sarin, soman, and tabun) and V-compounds (i.e., VX and others) are found. These chemicals were designated as *GP* or *GV compounds* (Bajgar, 1992; Bajgar et al., 1992; Halámek et al., 1995; Fusek et al., 1996b). The toxicities of the most toxic derivatives are shown in Table 27.1. Intoxication with this

TABLE 27.1 LD_{50} values of GV in mice and rats following various routes of administration.

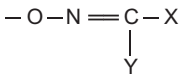


LD_{50} (μg/kg) with their 95% confidence limits

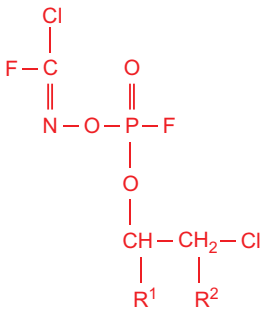
Route of administration	Mice	Rats
i.v.	27.6 (25.6−29.4)	11 (8.5−17.6)
i.m.	30.5 (28−55)	17 (15.5−23.6)
s.c.	32 (29−53)	21 (18−26)
p.o.	222 (194−255)	190 (881−272)
p.c.	Not tested	1366 (881−3138)

compound has practically the same syndromes as observed with nerve agents. Treatment with atropine and reactivators is difficult because of the absence of the ability to reactivate inhibited cholinesterases by common oximes (Kassa, 1995; Fusek et al., 1996b; Kassa et al., 2006; Kuca et al., 2006). The lack of reactivation is different from that observed for soman (i.e., aging and dealkylation) and it is probably caused by steric hindrance in the cavity of cholinesterase. The volatility of GV compounds is between VX and sarin and therefore these agents are effective when penetrating through uniforms. This is an example of an intermediate volatility agent.

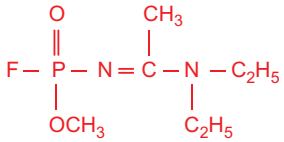
There are sources of information that suggest a new nerve agent known as Novichok or Novichok 5. In 1982, the Soviets began a secret CW development program that was code-named Foliant. The program had the apparent goal of developing new binary nerve agent weapons. Novichok has been described as a new toxic agent, and it is very difficult to treat poisoning by it (practically impossible; the toxicity was about 10 times greater than VX agents). Its exact chemical structure is unknown. The Novichok class of chemicals almost certainly belongs to the organophosphorus compounds containing the dihaloformamide group (Bajgar, 2006):



where X and Y are Cl, F, Br, or even a stable pseudohalogen like −CN. An example of Novichok (Kuca et al., 2013) could be as follows:



Another possibility could be compound A232:



There are other analogs of A232, including A230 and A234. Because these chemicals are relatively unstable, binary recepture was probably developed (Halamek and Kobliha, 2011). Novichok derivatives are close to the V agents family, and are effective at percutaneous administration. Different parts of the V agent molecules are responsible for toxicity and the rate of penetration into the organism (e.g., Bajgar et al., 2019).

27.3.6 Toxins

Toxins are prohibited by the Convention on the Prohibition of the Development, Production, and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on their Destruction (known for short as the Biological Weapons Convention), signed in London, Moscow, and Washington on April 10, 1972. Their isolation from natural sources is sometimes difficult, but some toxins are possible to synthesize using biotechnology. Their toxicity is very high (e.g., the inhalation LD_{50} of botulinum toxin and tetanotoxin is measured in tens of $mg/kg/m^3$). Some other known toxins are saxitoxin, tetrodotoxin, and batrachotoxin. They also are highly effective by other routes of administration. Effects are observed within 10−20 min, beginning with muscle weakness, insensitivity of tongue, fingers, and mouth, followed by muscle paralysis, including respiratory muscles. Specific therapy is unknown, therefore it is necessary to save basic life functions (using artificial ventilation, etc.). When death is not observed within the first 24 h after exposure, the prognosis is relatively good.

Other types of toxins are mycotoxins, mostly trichothecenes. Their production is straightforward by fermentation, and they are highly stable and therefore may be stored for a long time. They are effective by all routes of administration, including inhalation and percutaneous absorption. Their toxicity is not very high, and the effect is prolonged. Symptoms of intoxication vary greatly, including fever, hemorrhagic eruption, bleeding, necrotic angina, decrease of leukocytes, and sepsis. Some toxins are carcinogenic, teratogenic, mutagenic, and hepatotoxic, while some also have a neurotoxic effect. There is no specific therapy; treatment is focused only on relieving symptoms (Patočka, 2004). They caused an epidemic (alimentary toxic aleukia) in the former Soviet Union and were the subject of discussion for possible use in Asia (yellow rain).

In August 1981, based on limited physical evidence, the United States announced that trichothecene mycotoxins had been used—but the findings were less than convincing to the scientific community and the issue became extremely contentious. This controversy was never totally resolved, and no definitive evidence was found (Bajgar, 2006).

The question of neurotoxins and neurotoxicity mechanisms was extensively described by Segura-Aguilar and Kostrzewa (2006). Some of these are described next.

27.3.6.1 Aziridines

Aziridines are 2-(trisubstituted phenyl) ethyl aziridines that induce changes in behavior and motor-influencing neurotransmission. Their toxicity is not very high, and they play a role in modeling a number of diseases. Their effect is long-lasting, and mostly irreversible without specific antidotal treatment. Some aziridines, for example, *N*-(3,5-dimethoxy-4-propoxy) phenylethylaziridinium (Fig. 27.1), have convulsive properties. Convulsions are treatable with benzodiazepines (Herink, 1977, 1995).

27.3.6.2 Tremorine

A relatively simple compound (Fig. 27.1), tremorine is known to induce symptoms similar to Parkinson's disease in mice and monkeys. The onset of symptoms, such as salivation, miosis, lacrimation, muscle weakness, and bradycardia, was evident within 15−30 min after administration. Typical symptoms are muscle twitch or fine tremor of the head and extremities, decrease in body temperature, and analgesia. This stage usually lasts for a few hours. Therapy is symptomatic only and not very effective (Bajgar, 2006; Patočka, 2004).

27.3.6.3 Imino-β,β-dipropionitrile

Imino-β,β-dipropionitrile (IDPN) is one of the compounds (Fig. 27.1) isolated from *Lathyrus sativus*, also called *lathyrogenic substances.* The toxicity of IDPN (and also of aziridines and tremorine) expressed as LD_{50}, is not very high, falling in the range of tens of mg/kg. Following administration of lower doses of IDPN, a condition called *waltzing syndrome* is characterized by a circling movement in both directions, and sometimes movement of the head similar to chorea (and hyperkinetic syndrome). High doses of IDPN are known to produce conjunctivitis and edema of the eyelids. In severe cases, it causes hemorrhages in the retina with the possibility of blindness. Hyperkinetic syndrome is irreversible and does not react to therapy (Bajgar, 2006).

27.3.7 Bioregulators

A variety of agents have the potential to be used as weapons of bioterrorism. These weapons have been used in wars from the start of recorded history (Metcalfe, 2002). The development of technologies on a modern militarily significant scale was initiated in several countries during the period between the two world wars (Roffey et al., 2002). However, as a result of modern technology, the risks are greater now, and the outcomes more serious (Henderson, 1999). Today, agents include not only toxins, but also a new group of compounds and bioregulators. Bioregulators are naturally occurring organic compounds that regulate diverse cellular processes in all organisms. There are substances normally found in the body that regulate normal and critical biological processes, such as blood pressure, heart rate, breathing, muscle contraction, temperature, mood control, consciousness, sleep, emotions, and immune responses. Their characteristics include activity in extremely low doses and they frequently have rapid effects. Unlike traditional disease-causing biowarfare agents that take hours and days to act, bioregulators can act within minutes after administration. There is comprehensive knowledge available on these compounds because all these compounds work as regulators and modulators of all vital biochemical pathways, linked with physiological functions of living organisms. If bioregulators were exploited for the purpose of terrorism, they could potentially cause profound pathophysiological effects. The main group of bioregulators under discussion includes different biochemicals such as neurotransmitters, hormones, and proteolytic enzymes. The common property of all bioregulators is their ability to induce biological effects and a consequential rapid fall in their concentrations in tissues. The problem is their route of administration (Patočka and Merka, 2004; Patočka et al., 2013).

A brief description of some bioregulators from a military viewpoint is given next. These peptides have been chosen based on the criteria of bioregulators intended for terrorism and warfare agents (Bokan et al., 2002).

27.3.7.1 Angiotensins

Angiotensins regulate blood pressure and contribute to sustaining hypertension (Mazzolai et al., 1998). The principal effect of angiotensin is to stimulate the synthesis of aldosterone and elevate blood pressure via vasoconstriction of the smooth muscle in arterioles.

27.3.7.2 Bombesin

Bombesin is a tetradecapeptide isolated from the skin of the amphibian frog *Bombina bombina* (Anastasi et al., 1971). It has been proposed that bombesin-related peptides may be released from the gastrointestinal tract in response to ingested food, and that they bridge the gut and brain via neurocrine means to inhibit further food intake (Merali et al., 1999).

27.3.7.3 Bradykinin

Bradykinin is a vasoactive nonapeptide, which is the most important mediator generated by the kinin system, and it is involved in inflammation processes (Calixto et al., 2000). Kinins identified thus far include bradykinin and kallidin. They cause local increases in the permeability of small blood vessels. Bradykinin is a potent stimulator of pain receptors in the skin and has a powerful influence on stimulating smooth muscle contraction, inducing

hypotension, and increasing blood flow and permeability of capillaries (Cyr et al., 2001).

27.3.7.4 Endorphins

Endorphins are peptides that bind to the neuroreceptors in the brain to give relief from pain (Terenius, 1992). Beta-endorphin is the most active, and is about 20 times more potent than morphine.

27.3.7.5 Endothelins

Endothelins constitute a family of peptides (Hart and Hart, 1992). They are very potent endogenous vasoconstrictors and vasopressors and are secreted by various cells and tissues in the human body. Of the three isoforms, endothelin-1 (ET-1) is one of the most potent contractors of vascular smooth muscles (Miller et al., 1993). Endothelins have very similar structure and biological properties to sarafotoxins (Kloog and Sokolovsky, 1989), and the toxic peptides are obtained from the venom of mole vipers (Atractaspidae).

27.3.7.6 Enkephalins

Enkephalins are endogenous pentapeptides. Two enkephalins have been identified: Met-enkephalin and Leu-enkephalin. Both enkephalins are relatively weak analgesics, which activate all opioid receptors but appear to have the highest affinity for the delta-receptors. In the central nervous system, enkephalins have been found in many areas, but predominantly those associated with nociception (Przewlocki and Przewlocka, 2001).

27.3.7.7 Histamine-releasing factor

Histamine-releasing factor (HRF) is one of the many immune system protein molecules called *cytokines*, which trigger allergic reactions. Unlike other cytokines, HRF stimulates basophils to release histamine (MacDonald, 1996).

27.3.7.8 Neuropeptide Y

Neuropeptide Y (NPY) is the most abundant neuropeptide in the brain. Its concentration is many times higher than other neuropeptides. It is a member of a family of proteins that include pancreatic polypeptide, peptide YY, and seminalplasmin. In addition to its function of stimulating feeding behavior, several other physiologic roles have been assigned to NPY, including involvement in circadian rhythms, sexual function, anxiety responses, and vascular resistance (DiBona and Neuropeptide, 2002; Halford and Blundell, 2000).

27.3.7.9 Neurotensin

Neurotensin is an endogenous peptide neurotransmitter inducing a variety of effects, including analgesia, hypothermia, and increased locomotor activity. It is also involved in regulation of dopamine pathways. Neurotensin is found in endocrine cells of the small intestine, where it leads to secretion and smooth muscle contraction (Moore and Black, 1991).

27.3.7.10 Oxytocin

Oxytocin is a nine-amino-acid peptide that is synthesized in hypothalamic neurons and transported down through axons of the posterior pituitary for secretion into blood. Oxytocin has three major physiological effects: stimulation of milk ejection, stimulation of uterine smooth muscle contraction at birth, and establishment of maternal behavior.

27.3.7.11 Somatostatin

Somatostatin is a cyclic tetradecapeptide hormone, characterized as the major physiological inhibitor of growth hormone released from the pituitary, but inhibits the release of many other physiologically important compounds, including insulin, glucagon, gastrin, and secretin (Wolkowitz, 1994).

27.3.7.12 Substance P

Substance P is an 11-amino-acid polypeptide, and a physiologically significant (and the best-known) member of a family of three related peptides known as *neurokinins*. The specific receptor subtypes corresponding to these three neurokinins are known (Sandberg et al., 1982). These neurotransmitters appear to play a key role in the regulation of emotions, and antagonists of their receptors may be the novel psychotropic drugs of the future. Koch et al. (1999) demonstrated that substance P, in combination with thiorphan, administered as an aerosol, is highly potent and extremely toxic. Exposure to the substance at extremely low air concentrations may result in incapacitation of humans.

27.3.7.13 Vasopressin

Vasopressin, also called *antidiuretic hormone (ADH)*, is a cyclic nonapeptide hormone released from the posterior pituitary. Its primary function in the body is to regulate extracellular fluid volume by affecting renal handling of water. Specific actions include inhibition of diuresis, contraction of smooth muscles, stimulation of liver glycogenesis, and modulation of adrenocorticotropic hormone release from the pituitary gland. ADH belongs to the family of vasoactive peptides involved in normal and pathological cell growth and differentiation.

27.3.8 Thyroid-stimulating hormone

Thyrotropin [also known as *thyroliberin* and *thyroid-stimulating hormone (TSH)*] is a peptide released by the anterior pituitary gland that stimulates the thyroid gland to release thyroxine (Ladram et al., 1994). The release of TSH is triggered by the action of thyrotropin-releasing factor, a peptidic substance found in the hypothalamus of the brain and influencing the secretion of glandula thyroidea.

Not long ago, most bioregulators had been unavailable in the amounts needed for terroristic attacks or military operations. However, by the end of the 20th century and beginning of the 21st century, there had been intensive developments in biomedical sciences, biotechnology, and chemical engineering in the pharmaceutical industry, and because of the revolution in the science and technology of drug discovery, the control of bioregulators will be significantly complicated.

In the near future, genomic and proteomic methods will stimulate increasing use of computer modeling techniques to identify new biologically active compounds and then determine their mode of action. Currently, new compounds are being generated in large numbers by combinatorial methods and assayed for potential activity, and it seems likely that genomic and proteomic methods will make these compounds accessible in amounts necessary for terroristic use. This is a very disagreeable situation and a new problem for the control of chemical and biological weapons.

27.4 Nonlethal weapons

Nonlethal weapons can be of a chemical, physical, or pharmacological character (Hess et al., 2005). Such weapons are designed and primarily employed for the purpose of incapacitating personnel or material while minimizing fatalities, permanent injury to personnel, and undesired damage to property and the environment (Pearson, 2006). Weapons used for physically immobilizing personnel include lasers, microwave impulses, ultrasound, electric current, nets, solidifying foams, and sliding gels. For CWs, immobilizing gases and irritants and smelly bombs can be considered. For pharmacological immobilization, ketamine, benzodiazepines, and onset accelerators are the compounds of real interest. Basic requirements for the use of immobilizing drugs are necessary, such as minimal cardiovascular and respiratory side effects; easy administration, primarily by inhalation; rapid onset; high biological accessibility and well-controlled effects; and specific antagonists that can be used within a large therapeutic range. These drugs are used for animal immobilization, using narcotizing blowpipes, darts, or guns. This group is also called *calmatives*. The compounds considered include ketamine and phencyclidine, alpha-2-agonist, opioids (including etorphine, fentanyl, and carfentanyl) and muscle relaxants (Patočka and Cabal, 2001; Dejmek, 2004; Patočka and Fusek, 2004; Streda and Patočka, 2004; Hess et al., 2005; Halamek and Kobliha, 2011; Klement et al., 2013).

As for fentanyl derivatives, there are more effective drugs than fentanyl. These include carfentanil (probably used in Moscow in 2002 against terrorists), whose effectiveness is 500−3000 times greater than morphine, and remifentanil, which is 5500−11,000 times more effective (Halamek and Kobliha, 2011). Methods of determination of fentanyl derivatives have been described (Jelinkova et al., 2013).

27.4.1 Genetic and ethnic weapons

Another possible threat is modification of the effects of commonly used chemicals or biological agents. The first administration produces no toxic effect, but the second administration of the same or another compound causes damage. The present genetic material of a human population could be misused. Recent advances in biological research could eventually lead to the creation of new types of CWs targeting a specific group of human beings with common genetic characteristics, as is perhaps the case with certain ethnic groups. Biologically, there are more similarities than differences between human beings. However, differences do exist, and if the data on ethnic differences are known, the selective effect of different chemicals to the groups cannot be excluded. Glucose-6-phosphate dehydrogenase, the enzyme that catalyzes the dehydrogenation of glucose-6-phosphate to 6-phosphogluconate, has been genetically determined and found to be low or nonexistent in some groups (though it appears more frequently in Africans and Scandinavians). It is connected with the male chromosome, and in men where it appears, hyperbilirubinemia is observed. Following administration of some normal medications, like acetylsalicylic acid, sulfadimidine, chinine, and chloramphenicol, a hemolytic syndrome is induced. Individuals with other pathologic states (e.g., chronic methemoglobinemia) will be more sensitive to drugs that are able to increase the level of methemoglobin, including analgesics, antipyretics, and nitrates. Deficiency of alpha-1-antitrypsine can cause increased sensitivity to asphyxiation agents. Plasma cholinesterase activity is also genetically determined, and individuals with decreased cholinesterase activity are more sensitive to myorelaxants. It is very probable that these people will be more sensitive to nerve agents (Bajgar, 2006).

Comparison of some criteria for the use of new chemicals for military or terroristic purposes is shown in Table 27.2.

TABLE 27.2 Different criteria for the suitability of different chemicals to be a CW.

Criterion	Carbamates	New OP	Dioxin	Bicyclic phosphates	Toxins	Incapacitants
Occurrence of first symptoms	Minutes	Minutes	Hours–days	Minutes	Different	Minutes
Death observed within	Hours	Hours	Weeks–months	Hours	Hours–weeks	Not in incapacitant doses
Availability of antidotes	Symptomatic	Yes	No	Symptomatic	Symptomatic	Yes
Easy to synthesize	+	+	+	++	+++	++
Toxicity	High	High	Very high	High	Varied	Low
Stability	+	+	+++	+	Different	++
Cost	+	+	+	++	+++	+++

For military purposes, using new nerve agents is the most likely possibility; however, their use is generally prohibited by the CWC. For terroristic purposes, there is a wide range of toxic chemicals and their choice is very dependent on the capabilities of potential users and their aims—namely, to achieve immediate effects or the liquidation or incapacitation of people over longer periods.

In the end, let us consider (very hypothetically!) terroristic use of one of the most obvious drugs: insulin. It is known that some other routes (e.g., inhalation) of administration for medical purposes have been developed (Mastrandrea, 2010). Therefore, this does not rule out the development of effective administration by inhalation. If suitable stability and aerosolization is achieved, could we realistically conclude that this drug would *not* be misused by terrorists? The effects are quick and antidotes to protect potential users would not be a problem. Military use of this drug for states or groups that are not CWC members is not ruled out either.

27.5 Concluding remarks and future directions

This chapter explains that the misuse of knowledge of pharmacology and toxicology is possible and can be applied to all human activities. The task is to be well informed in cases where it is important to know the best protection and therapeutic means, and to control all activities connected with the synthesis and possible availability of CWs/CWAs to both nonqualified and qualified people.

28.1 Introduction

Biological toxins are produced by a vast number of different life forms ranging from the simplest to the most complex. Each toxin has a distinctive mode of action in conjunction with a characteristic molecular structure and biochemistry. A common feature to all toxins, is that minute quantities will exert a pronounced effect on their intended targets. Algal toxins constitute a very diverse group of compounds ranging from simple ammonia to complex polypeptides and polysaccharides. Dinoflagellates are a source of some potent, nonprotein toxins, such as saxitoxin and tetrodotoxin; one such toxin causes the deleterious effects during a red tide. A red tide is the common name for an estuarial algal bloom when the photosynthetic pigments of certain species of phytoplankton can alter the hue of water; colors vary from purple to almost pink, but normally they are red or green. The mycotoxins are secondary metabolites, which are nonprotein substances produced by molds and fungi. Many molds produce more than one toxin, and in several cases, combinations of mycotoxins synergize to enhance toxicity (Gao et al., 2016; Gupta et al., 2018a,b). Leaves, roots, or seeds from some plants can be poisonous. Examples include a number of toxins produced by animals, including the nonprotein batrachotoxin found in certain species of frogs (poison dart frog), Melyridae beetles, and birds (*Pitohui*, *Ifrita kowaldi*), and a wide variety of peptides and proteins from marine snails, scorpion venoms, and snake venoms. The protein toxins ricin, derived from castor beans, and abrin, from the jequirity pea, are other examples.

In the wake of recent terrorist-related incidents across the globe, biological agents have become well-known for the threat they pose to the US and allied militaries and the civilian populations they guard. The agents are attractive to both foreign states and terrorists because they are relatively inexpensive to produce and require minimal technical infrastructure.

Ricin is defined as a biological category B agent that has the potential to pose a severe threat to public health and safety. There are currently 41 agents and toxins, including ricin, listed in the Centers for Disease Control and Prevention (CDC) regulation found in Part 73 of Title 42, Code of Federal Regulations (Possession, Use, and Transfer of Select Agents and Toxins).

Both the ricin toxin and castor bean plant have a long history of human use. The earliest human records contain references to the castor bean plant, which was known and cultivated by the ancient Egyptians. Oil pressed from the beans was used as a lubricant, and the beans were sometimes ingested to treat constipation. Even today, castor oil is still commercially produced globally. Castor oil is presently used in bath oil products, detergents, lubricants, dying agents, and most recently in the production of biodiesel fuel.

The ricin toxin is easily produced from the castor bean mash, remaining after the beans are pressed to extract castor oil (Wannemacher et al., 1992). Peter Hermann Stillmark first isolated and named the toxin ricin in 1888. Initially, the ricin protein was not known for its toxicity, but rather for causing the agglutination of erythrocytes. Later, the field of immunology was founded based on Paul Ehrlich's research with ricin. By introducing small amounts of the toxin to mice, Ehrlich was able to induce immunity specifically to ricin. This seminal work proved that in response to a challenge, certain serum proteins (antibodies) are produced that afford the host protection.

During the era of the biological weapons offensive program in the United States, ricin, by virtue of its toxicity, availability, and ease of production, was one of the first agents to be weaponized (Cookson and Nottingham, 1969). Today, ricin is one of the few biological agents utilized with known success. The most prominent of these was the attack leading to the death of the Bulgarian exile, Georgi Markov. On September 7, 1978, Markov was jabbed in the leg with an umbrella while waiting at a bus

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00028-3

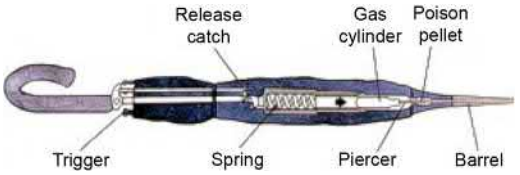

FIGURE 28.1 An artist's conception of the "umbrella gun." *From James, S.T., 2014. The Notorious Umbrella Assassination of Georgi Markov: Upon Further Investigation. <http://st-james.hubpages.com/hub/The-Notorious-Umbrella-Assassination-of-Georgi-Markov-Upon-Further-Investigation>.*

stop. A man holding the umbrella apologized to Markov before casually walking away from the scene (Crompton and Gall, 1980). Markov would later tell doctors that the man had spoken with a foreign accent. He recalled feeling a stinging pain from the site where he had been jabbed with the umbrella tip and noticed that a small, red, raised wound had formed at the site. That evening, he developed a high fever and was admitted to a hospital, where he died 3 days later. An autopsy revealed a 1.52-mm-wide metal pellet in the wound, speculated to be a watch bearing. Two 0.34-mm-diameter holes had been drilled at right angles to form a well inside the bearing. The pellet contained no trace of the poison that killed Markov, and investigators relied on standard differential diagnosis techniques and intel (military discipline that exploits a number of information collection and analysis approaches to provide guidance and direction to commanders in support of their decisions) to identify the causative agent. A host of toxins were considered, including tetanus, diphtheria, dioxin, and several nerve agents. Ricin seemed most likely because intelligence agents knew that it had been under research for decades in the Soviet Union. Working together, scientists and investigators surmised that an "umbrella gun" shot a ricin-laced pellet. The modified umbrella may have contained a cylinder of compressed air that propelled the pellet after pulling a trigger mounted in the umbrella's handle. An artist's conception of the "umbrella gun" is shown in Fig. 28.1.

Two years later, another assassination attempt with ricin occurred at a shopping mall parking lot in Tyson's Corner, Virginia, United States. Boris Korczak, a Soviet citizen who had been a CIA double agent, felt a slight sting, "something like a mosquito bite" he reported, while walking across the parking lot. He developed a fever of 106°F a few hours later, followed by a sharp decline in body temperature. Internal bleeding and an irregular heartbeat ensued. After his recovery, he extracted a tiny metal ball from his "mosquito bite" (Fig. 28.2) (Douglas and Livingston, 1987).

In another incident, ricin was discovered in a Las Vegas motel room. Roger Von Bergendorff awoke from a comatose condition on March 14, 2008, at which time he

FIGURE 28.2 Ricin-laced pellet extracted from Boris Korzak.

was questioned by police as to why he had such a large quantity of ricin. Subsequently, he was arrested on April 16, 2008, and charged with possession of a biological toxin and two weapons offenses. Several other related cases involving ricin on US soil occurred in November 2003. Ricin was found in the mailroom that served Senate Majority Leader Bill Frist's office. No injuries were reported. The White House mail-processing facility and a mail-sorting facility in Greenville, South Carolina, discovered ricin. The envelope discovered in Greenville was addressed to the US Department of Transportation and labeled "Caution Ricin Poison." The enclosed letter threatened to "turn DC into a ghost town." There are more than a dozen other events that have occurred in the past (CNS, 2008).

28.2 History of biological weapons

The known use of biological weapons dates back to the beginning of written records, with many examples of their use on the battlefield. In 190 BCE, Hannibal hurled venomous snakes onto enemy ships on Pergamus at Eurymedon. Scythian archers used arrows dipped in the blood of decomposing bodies in 400 BCE. Biological weapons have also seen use in more recent times on the North American continent. In 1763, during the Pontiacs Rebellion in New England, the British officer Colonel Henry Bouquet gave blankets infected with smallpox to Native Americans at Fort Pitt, Pennsylvania, an act that devastated the Native American population. In 1863, Confederate soldiers retreating through Mississippi left dead animals in wells and ponds to deny drinking water to Union troops. Another US Civil War use of biological weapons was executed by Dr. Luke Blackburn, who attempted to infect clothing with smallpox and yellow fever for sale to unsuspecting Union troops (Diamond, 1997).

Biological weapons research and development in the United States was very active during World War I, with the impetus provided by the American Anton Dilger. After joining the German Army in 1914, Dilger experienced a nervous breakdown and returned home to the United States, which was neutral at that point. At the request of the German Government, Dilger brought strains of anthrax and glanders with him for inoculating horses awaiting shipment to Europe (Erhard, 1999). After becoming aware of Germany's involvement with biological weapons, the US Government initiated its own biological weapons program, using ricin for retaliatory use in 1918 US Department of the Army, 1977; Carter, 2000). Two methods of dispersal were examined: the adherence of ricin to pellets contained in an artillery shell and the production of a ricin dust cloud. Due to limited amounts of purified ricin on hand, and its less efficient delivery via the respiratory tract, the latter approach was considered less promising. Although both approaches were laboratory-tested to some degree, neither was perfected for battlefield use before the end of the war.

During the early 1920s, the US military leadership determined that conducting further research into the use of biological weapons was not an efficient use of resources. Germany, France, Great Britain, Canada, and Japan, however, aggressively pursued the development of offensive biological weapons (Carter, 2000). The reported use of cholera, dysentery, typhoid, plague, and anthrax by the Japanese against the Chinese motivated the United States to reinitiate a biological offensive development program. The US Army's biological warfare program began at the Edgewood Arsenal (now the Edgewood Area of the Aberdeen Proving Ground, MD) and was later moved to Camp Detrick (now Fort Detrick, Frederick, MD). The first agents produced at Camp Detrick were botulinum toxin, anthrax, and brucella, but none was weaponized before the conclusion of World War II. After the war, research continued into the weaponization of biological agents until President Nixon's decision in 1969 to redirect the research toward a defensive posture, where the United States stands today.

Because biological warfare agents are typically etiological agents of naturally occurring disease, the majority of military defensive efforts are focused on vaccine development and diagnostic testing. Although research continued, the program was only a skeleton of the former offensive effort. Despite a 1979 anthrax outbreak in Sverdlovsk, Russia, which exposed Russia's ongoing biological weapons research, the United States did not place much weight on the possibility of its forces facing biological weapons. This position, however, changed after the invasion of Kuwait by Iraqi troops and the deployment of US troops to the Persian Gulf. Iraq had a large biological agent production facility and a history of using biological and chemical agents during military offensives (Warrick, 2006). To counter this, intensive research focused on measures for protection, detection, and destruction; these efforts are still ongoing today. In addition to state-sponsored entities, the revelation that terrorist organizations, such as the Aum Shinrikyo in Japan, were actively developing biological agents has brought attention to domestic defense against biological weapons. Defending against these agents requires not only an understanding of the agent but also an understanding of how an adversary might utilize it.

28.3 The weaponization of biological agents

Although many pathogens and toxins cause disease or toxicity, relatively few of the naturally occurring agents can be adapted for use as a biological weapon. Paramount is its ability to survive the mechanical rigors of large-scale aerosol dissemination. Other important characteristics include an agent's availability, ease of production and storage, its lethality, or its ability to incapacitate through morbidity (North Atlantic Treaty Organization, 1992). While some pursue agents of death, the philosophy of others is that the most attractive agents are those that incapacitate an adversary.

During the era of the US biological offensive program, agents such as *Staphylococcus aureus* enterotoxin B (SEB) and Venezuelan equine encephalitis were selected for their ability to incapacitate rather than kill. It was estimated that an afflicted soldier would require the care from a minimum of three personnel, whereas a dead soldier placed no burden on personnel. Providing care to sickened forces can quickly render entire military units mission-ineffective by overloading field-forward medical facilities intended to treat the wounded. In addition, these same agents could also be turned on civilians, concentrating the population at care centers, which in turn would facilitate attack and invasion by our forces. A final mark of an ideal agent is one that renders the adversary defenseless while the disseminating force is unaffected.

Terrorist organizations have historically lacked technical expertise; this often leaves insurmountable challenges for large-scale production and agent delivery. Thus, these organizations require an agent that can be easily disseminated in open air using common items such as crop dusters or liquid spray devices. Agents that can survive drying have high inhalational efficiency and can effectively cause infection or toxicity, which makes them ideal biological threat agents. The options for indoor dissemination or individual targets are much broader and essentially only limited to the creativity of the perpetrator. Use of the postal service, for instance, before the anthrax attacks on the United States, was believed to be impossible.

During decontamination efforts after the anthrax attack, it was also discovered that reaerosolization was a threat. The optimal agent particle size is dependent on the delivery mode. For aerosol dissemination, the smaller the particle size, the longer it will stay airborne and the more likely it can be reaerosolized after settling. Bacterial agents have a minimum size that is limited by their cellular dimensions; this is typically 1−5 μm. Alternatively, viral agents can be as small as 0.1 μm, and toxins are limited only by their molecular weight. It has been shown that particles of less than 10 μm can stay airborne for extended periods of time (Winters and Chenoweth, 2002). Particle size is inconsequential for attack via injection, ingestion, or transdermal transmission.

Agent stability after production is another important factor to consider when selecting an agent for weaponization. Environmental factors, including temperature, relative humidity, atmospheric pollution and sunlight, can all have an effect on agent viability. Feasible options for storage of agents are as liquid samples at room temperature, as liquid samples under refrigeration, as dry samples at room temperature, and as dry samples under refrigeration. The most desirable option is dry sample storage at room temperature, because this eliminates the need for refrigeration, allows for particle sizing before dissemination, and minimizes the environmental effects on dissemination.

By all means, toxins are probably the most suitable biological agents for use in any attack. In contrast to replicating agents, using toxins as biological agents requires that a lethal amount must be injected, ingested, or inhaled. Given this caveat, a sizeable amount of toxin must be available for dispersion in large-scale attacks, severely limiting the effective toxins to those that are the most lethal and easily produced. Ricin is one of only a few toxins that meet these requirements, along with botulinum toxin, SEB, and the trichothecene mycotoxins (Haschek and Beasley, 2009). Principally, because of its suitability as a biological warfare agent, the ricin toxin has been one of the biological weapons of choice for state-sponsored organizations (Kortepeter and Parker, 1999).

28.4 The family of ribosome-inactivating proteins

Ribosome-inactivating proteins (RIPs) are toxins that act intracellularly. They consist of two different subunits: a subunit A that is responsible for the enzymatic activity of the toxin and a subunit B that binds to a specific receptor on the host cell membrane, thus allowing the A subunit, the enzyme, to cross the cell membrane (Spooner, and Lord, 2011). The enzymatic component is not active until it is released from the native (A + B) toxin. Isolated A subunits are enzymatically active but lack binding and cell entry capability. Isolated B subunits may bind to target cells (and even block the binding of the native toxin), but they are nontoxic.

There are a variety of ways that toxin subunits may be synthesized and arranged: A + B indicates that the toxin is synthesized and secreted as two separate protein subunits that interact at the target cell surface; A-B or A-5B indicates that the A and B subunits are synthesized separately, but associated by noncovalent bonds during secretion and binding to their target; 5B indicates that the binding domain of the protein is composed of five identical subunits. A/B denotes a toxin synthesized as a single polypeptide, divided into A and B domains that may be separated by proteolytic cleavage (Todar, 2014).

Ricin is a ribosome-inactivating lectin isolated from the beans of *Ricinus*. Ricin and other plant lectins, for example, abrin and modeccin, consist of two peptide chains, A, the toxin, and B, a lectin, linked together by a disulfide bond. Lectins are a class of carbohydrate-binding proteins that interact specifically with glycoconjugates present in other organisms. Specific carbohydrate-binding activity distinguishes lectins from other plant proteins (Zhu-Salzman et al., 1998). This interaction is as specific as enzyme−substrate or antigen−antibody interactions.

Another characteristic property of lectins is that they agglutinate cells and precipitate polysaccharides and glycoproteins. That is because lectins are, as a rule, divalent or oligovalent, meaning, each lectin molecule has at least two carbohydrate-binding sites that allow cross-linking between cells (by combining with sugars on their surfaces) or between sugar-containing macromolecules. Lectins have accordingly been defined as sugar-binding proteins of nonimmune origin that agglutinate cells and precipitate polysaccharides or glycoproteins (Goldstein et al., 1980).

Lectins are present in numerous edible plants. For many years it has been known that they occur in major food sources for humans and animals such as soybeans, kidney beans, lima beans, mung beans, lentils, garden peas, and peanuts. One family is composed of proteins that contain one or more 30- to 43-amino-acid cysteine-rich chitin-binding domains. Another family, mainly legume lectins, binds carbohydrate substrates by way of interactions involving specific amino acid residues that are located spatially throughout the peptide. The exact role of lectins in plants is unclear, although they can serve as potent insecticides. Castor beans contain so much lectin that they are toxic to most organisms. The binding ability and specificity of the lectin is preserved when bound to the toxic A chain. It is the lectin that directs the toxin to its target within the cell. There are a number of toxins that are bound to lectins. These are all classified as type III toxins. This classification is based on the mode of

entry into the cell. There are two categories of type III toxins: those that are bound to a single lectin, referred to as an AB toxin, and those that are bound to four lectins, known as AB5 toxins. The most commonly known type III toxins are listed here.

AB toxins (usually plant toxins):

1. Ricin;
2. Abrin;
3. Mistletoe (viscumin);
4. Modeccin;
5. Diphtheria.

AB5 toxins (usually bacterial toxins):

1. *Campylobacter jejuni* enterotoxin (from *Campylobacter jejuni*);
2. Cholera toxin (*Vibrio cholerae*);
3. Heat-labile enterotoxins (LT and LT-II) (*Escherichia coli*);
4. Pertussis toxin (*Bordetella pertussis*);
5. Shiga toxin (*Shigella dysenteriae*);
6. Shiga-like toxin (or verotoxin) enterohemorrhagic varieties of *E. coli* including (O157:H7).

Cholera toxin, Shiga toxin, ricin, and abrin are protein toxins that damage mammalian cells by a mechanism that includes four essential events: receptor-mediated endocytosis; retrograde transport into the lumen of the endoplasmic reticulum (ER); passage through the ER membrane into the cytoplasm; and catalytic inactivation of a target substrate in the cytoplasm. The receptor-binding site of a protein toxin is usually within a subunit or domain that is distinct from the subunit or domain that bears the catalytic activity of the toxin. Both cholera toxin and Shiga toxin belong to the AB5 protein toxin family in which the A chain is the enzymatic subunit, and each of the five identical B chains binds cell surface receptors.

Some peptide and protein toxins have been classified into families containing a number of different toxins with the same biological activity. Within any one family, the toxins can differ in amino acid sequence and number, but their molecular architectures and active site conformations are conserved. One of the most intensely studied toxin families is that of the RIPs, which includes ricin. The term "ribosome-inactivating protein" was introduced to designate plant proteins that inactivate animal ribosomes. The toxins were later found in certain bacteria and fungi (Endo et al., 1988). These are cytotoxins that catalytically and specifically inactivate the large subunit of eukaryotic or prokaryotic ribosomes (Stirpe and Barbieri, 1986). Historically, RIPs have been classified into two types based on their quaternary structure.

The type I RIPs are the most numerous and are all synthesized as a single-chain enzyme of approximately 30 kDa. Type II RIPs are synthesized as larger precursors that accumulate in protein bodies and contain an approximately 30-kDa A-chain linked by a disulfide bond to a lectin B-chain of similar size (Stirpe and Barbieri, 1986). Plant RIPs, including all type I toxins and the A-chains of type II toxins, are RNA *N*-glycosidases capable of hydrolyzing the nitrogen−carbon glycosidic bond of a specific adenosine located in the sarcin/ricin domain of the largest ribosomal RNA (Barbieri et al., 2006). The B-chain is able to bind the D-galactose-terminated receptors on the membranes of animal cells and facilitates the internalization of the enzymatic A-chain. To date, more than 50 type I RIPs and approximately 15 type II RIPs have been identified (Stirpe and Barbieri, 1986). Although there is some variation at the N- and C-termini of their respective polypeptide chains, the active sites of the type I RIPs and the A-chains of type II RIPs are well-conserved, as are their three-dimensional conformations (Gasperi-Campani et al., 1985).

Originally, type I and type II RIPs were identified based on biological activities. Type II RIPs were discovered more than a century ago, when Stillmark isolated the toxic protein ricin from castor beans. As mentioned, the toxicity of ricin was initially attributed to its agglutination activity for red blood cells and not by ribosome inactivation. Type II RIPs attribute their carbohydrate-binding activity to their B-chain, which contains two or possibly three binding sites (Robertus, 1991). The multiple binding sites allow B-chains to aggregate with red blood cells and platelets.

Duggar and Armstrong observed that the so-called *Phytolacca Americana* antiviral protein (PAP) inhibited the transmission of tobacco mosaic virus in plants. In 1978, PAP was recognized as an inhibitor of protein synthesis. Not all type I RIPs, however, are believed to be antiviral proteins (Lam and Ng, 2001). Unlike their type II counterparts, type I RIPs exhibit low toxicity because they are not able to bind and cross the cell membrane efficiently. Type I RIPs, however, are cytotoxic to certain cells such as macrophages. The cells can absorb type I RIPs by pinocytosis and subsequently succumb to RIP activity. Recently, a type III RIP has been isolated from *Hordeum vulgare*, the common barley plant. The RIP consists of an amino-terminal domain resembling type I RIP and is linked to an unrelated carboxyl-terminal domain with unknown function (Bolognesi et al., 2002). The type III RIP accumulates in the barley kernel as an inactive precursor that, on germination, is processed into a two-chain RIP by removal of an internal peptide from the catalytic domain (Peumans et al., 2001).

RIPs have been identified in more than 50 different plant species and have also been found in fungi, bacteria, and at least one algal species. The highest quantity of RIPs has been isolated from the carnation family Caryophyllaceae, the elder family Sambucaceae, the

FIGURE 28.3 Photograph of a castor bean plant (A) and castor beans (B). *From Audi, J., Belson, M., Patel, M., 2005. Ricin poisoning: a comprehensive review. JAMA 294, 2342–2351.*

family of gourd-producing plants Cucurbitaceae, the Euphorbiaceae family of flowering plants, the pokeweed family Phytolaccaceae, and the family of flowering grasses Poaceae (Reinbothe et al., 1994). Presently, the role of RIPs in plant physiology is not entirely clear. Based on their variable activity toward heterologous and autologous plant ribosomes, several possible roles have been proposed: antiviral activity, antifungal activity, herbivore defense, a role in the arrest of cellular metabolism during periods of senescence, and, finally, a role as storage proteins (Bolognesi et al., 2002). Conclusive evidence has been obtained that RIPs not only deadenylate ribosomal RNA but are also capable of removing adenine residues from DNA and several other polynucleotide substrates. Thus, it has been proposed to rename RIPs as polynucleotide:adenosine:glycosidases (Shakirova and Bezrukova, 2007).

28.5 The ricin toxin structure and biosynthesis

Ricin is a toxin originating from *Ricinus communis*, the castor bean plant. A photograph of the plant is shown in Fig. 28.3A; a photograph of the beans it produces is presented in Fig. 28.3B. As for all type II RIPs, ricin is a protein consisting of two folded peptide chains, designated the A-chain and B-chains. The two are linked by a single disulfide bridge. Ricin has a molecular weight of approximately 64–65 kDa; ricin A-chain (RTA) is a 267-amino-acid globular protein domain containing eight α-helices and eight β-sheets (Wright and Robertus, 1987). The catalytically active site occurs as a long cleft on the A-chain surface. Within the active site, glutamic acid 177 is a key catalytic residue, and conversion to glutimate reduces activity 180-fold.

Ricin B-chain is a 262-amino-acid protein domain that conforms to a barbell-shaped architecture. The folded domain has a sugar-binding site at each end, allowing hydrogen bonding to galactose and *N*-acetyl galactosamine typically found on cell surfaces. The B-chain is not toxic and the A-chain alone is not toxic. In fact, many

FIGURE 28.4 Representation of the ricin protein derived from X-ray crystallographic data. The A-chain and B-chain are blue and orange, respectively. Random coil regions are strings, β-sheets are flat ribbons, and α-helices are coiled ribbons. *From GS, 2014. <Globalsecurity.org> <http://www.globalsecurity.org/wmd/intro/bio_ricin-pics.htm> (accessed 29.04.14.).*

edible plants such as barley synthesize A-chain. The B-chain has been expressed in monkey COS-M6 cells with no adverse effects (Weston et al., 1994). A representation of the ricin protein based on X-ray crystallographic data is presented in Fig. 28.4.

The biosynthesis of ricin and RCA occurs in the endosperm cells of maturing *R. communis* seeds for storage in subcellular vacuolar compartments referred to as protein bodies. This entire process is illustrated schematically in Fig. 28.5. Biosynthesis begins with the translation of a propolypeptide encompassing both the A-chain and B-chain as well as an amino-terminal signal sequence (Butterworth and Lord, 1983; Lord, 1985). The signal sequence directs the nascent chain to the ER lumen, where it is cleaved and removed from the rest of the long polypeptide chain. The resulting proricin is N-glycosylated in the lumen, and protein disulfide

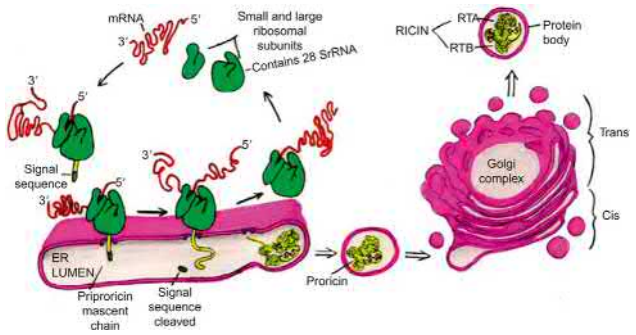

FIGURE 28.5 Biosynthesis of the ricin toxin. *From EHSO, 2014. Environment, Health and Safety Online. <http://www.ehso.com/ricin.php> (accessed 29.04.14.).*

isomerases catalyze disulfide bond formation as the proricin chain folds into two globular protein domains. Proricin undergoes further oligosaccharide modifications within the Golgi complex before it is transported within vesicles to the protein bodies (Hiraiwa et al., 1997). The toxins are stored in the protein bodies until their ultimate destruction by hydrolysis, typically only a few days after germination of the mature (Lord, 1985).

28.6 The cellular internalization of ricin

The entry of ricin into a living cell begins with the reversible binding of its B-chain to cell-surface glycolipids and glycoproteins bearing $\beta(1\rightarrow4)$-linked galactose residues (Moya et al., 1985). The toxin has two galactose-binding sites for cell surface binding, but ricin may also be bound to certain cells by an entirely different mechanism. Ricin, a glycoprotein, contains mannose-rich N-linked oligosaccharides in both of its constituent subunits. On the surface of cells in the reticuloendothelial system, mannose receptors are present that have been shown to bind these carbohydrates (Simmons et al., 1986). Further, the binding by these mannose receptors results in subsequent cell death (Simmons et al., 1986), and deglycosylation of the toxin abolishes both binding and intoxication by the mannose receptor pathway (Foxwell et al., 1987). It is estimated that 10^6-10^8 toxin molecules may bind to a single cell at one time. The toxin molecules are internalized into cells via endocytosis in coated pits and vesicles, or smooth pits and vesicles (Moya et al., 1985). Once in the cytosol, these vesicles fuse with endosomes that can return some of the toxin molecules to the cell surface by exocytosis or, as shown in Fig. 28.5, endosomes can fuse with lysosomes that will destroy the ricin molecules (Sandvig and Olsnes, 1979; Sandvig et al., 2004). Alternatively, the endosomes can carry ricin molecules to the Golgi complex and ER by retrograde transport (Sandvig et al., 2004) (Fig. 28.6). Ricin molecules reaching the trans Golgi network can penetrate its membrane and reach the cytosol

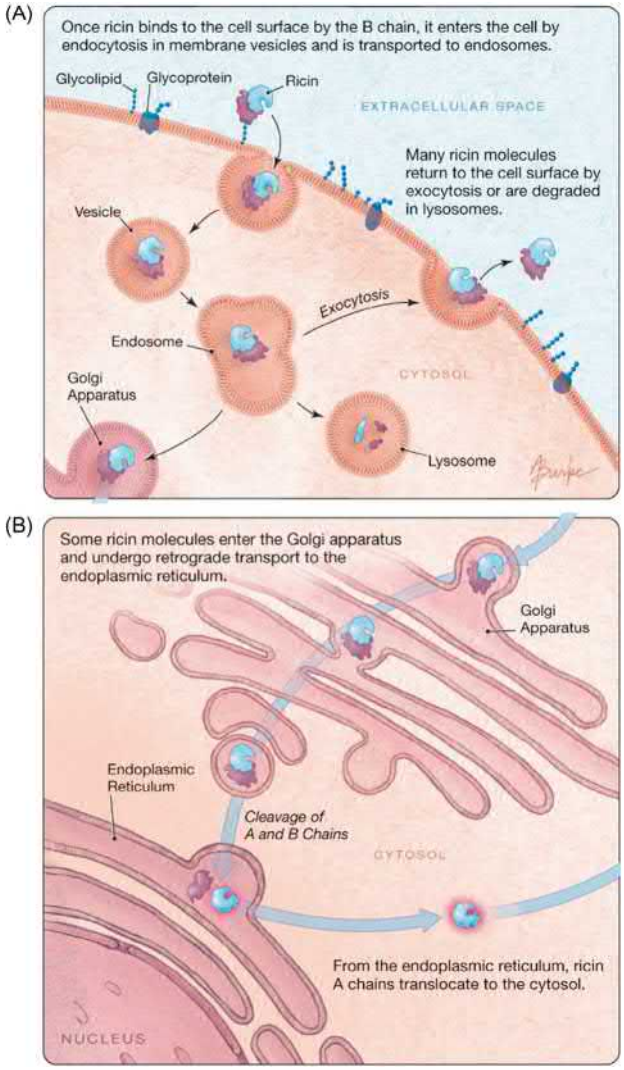

FIGURE 28.6 Example of the cellular internalization of ricin. The process involves endocytosis by coated pits and vesicles (A) or smooth pits and vesicles, followed by vesicle−endosome fusion (B). Ricin molecules can then return to the cell surface by exocytosis, or the vesicles may fuse to lysosomes for toxin destruction. *From Audi, J., Belson, M., Patel, M., 2005. Ricin poisoning: a comprehensive review. JAMA 294, 2342−2351.*

or, in some cases, return to the cell surface (Sandvig et al., 2004). For ricin molecules reaching the ER lumen, the disulfide bond connecting their A-chain and B-chain will be reduced, facilitating a partial unfolding of the A-chain (Kornfeld et al., 1991). The unraveling toxin protein will be translocated across the ER membrane via the Sec61p translocon, following the same pathway as that for incorrectly folded ER proteins targeted to the ER-associated degradation machinery (Simpson et al., 1999; Lord et al., 2003). Ricin molecules escaping the degradation machinery may find their way into the cytosol. These ricin molecules, and those crossing the trans Golgi network membrane into the cytosol, can refold into a

protease-resistant, enzymatically active structure (Lord et al., 2003). Just a single ricin molecule entering the cytosol of a living cell with a K_{cat} of 1500 min^{-1} can inactivate enough ribosomes to ultimately result in cell death (Endo et al., 1987).

28.7 *N*-Glycosidase activity of ricin

The ricin A-chain contains an enzymatically active site that recognizes and binds a highly conserved region in the large 28S rRNA of the intoxicated cell, referred to as the sarcin/ricin loop (Rajamohan et al., 2001). This loop is a very short stem-loop structure of the overall ribosome and the loop is located in domain VII, approximately 400 nucleotides from the 3′-end of the rRNA. Within the stem-loop, the ring of a single adenine (A_{4324}) becomes sandwiched between two tyrosine rings in the catalytic cleft of the ricin A-chain and is hydrolyzed at the carbon–nitrogen glycosidic bond by the *N*-glycosidase action of ricin (Endo et al., 1987). This particular site-specific RNA *N*-glycosidase activity is a common property of all identified type I and type II RIPs (Barbieri et al., 2006). The activity prevents the binding of elongation factors EF-1 and EF-2, resulting in the cessation of mRNA translation.

Although all RIPs exhibit *N*-glycosidase activity toward ribosomes, they display marked differences in substrate specificity. Most type I toxins exhibit very broad specificities, whereas type II toxins display a preference for animal ribosomes. Ricin, for example, is highly active against mammalian and yeast ribosomes but poorly active, or even inactive, against plant and bacterial ribosomes (Yoshinari et al., 1997). In contrast, pokeweed antiviral protein depurinates ribosomes from plants, bacteria, yeast, and various evolutionarily diverse animals (Rajamohan et al., 1999).

Both the RIP and ribosome in a RIP–ribosome interaction contribute to the apparent substrate specificity (Kurinov et al., 1999). Due to the universally conserved rRNA sarcin/ricin loop structure, differences in sensitivity to different RIPs may possibly reside within the associated ribosomal proteins that confer tertiary structure to the ribosome (Kurinov et al., 1999). These differences may either allow or prevent access of the RIPs to the sarcin/ricin loop. Vater et al. (1995) identified the rat liver ribosomal proteins L9 and L10e as the binding target of the ricin A-chain, whereas yeast ribosomal protein L3 has been identified as the binding factor for pokeweed antiviral protein. The specific interaction between pokeweed antiviral protein and L3 is most likely explained by the broad-spectrum activity of pokeweed antiviral protein toward ribosomes from species of different taxonomic groups, due to the highly conserved L3 in ribosomes (Rajamohan et al., 1999). Differences in activity and ribosome substrate specificity are also due to differences in the structure of different RIPs. This was demonstrated by an approach in which pokeweed antiviral protein–ricin A-chain protein hybrids were created and examined for activity on rabbit reticulocyte and *E. coli* ribosomes (Vater et al., 1995).

Experimental results demonstrated that the aminoterminal half of the hybrid proteins determines the substrate specificity. Structurally dissimilar surface polypeptide loops apparently do not play a role. In addition to the highly specific action on ribosomes, ricin and related RIPs have a less specific action in vitro on supercoiled double-stranded DNA, single-stranded DNA (ssDNA), and RNA substrates releasing multiple adenine residues and, in some instances, guanine residues (Wang and Tumer, 1999). RTA also catalyzes the hydrolysis of synthetic oligonucleotides as short as six base pairs, provided a GAGA tetra loop is present (Amukele and Schramm, 2004). Other reported RIP activities are lipase, chitinase, and superoxide dismutase (Xu et al., 2008). To date, activity against synthetic DNA or RNA oligonucleotides for the various RIPs has not been compared.

28.8 Signs and symptoms of ricin exposure

As with most biological warfare agents, ricin remains biologically active through several different modes of entry into a living animal, including ingestion, injection, and inhalation. Symptoms and toxicity, however, can vary dramatically with mode of entry (Olsnes, 2004). Response to cutaneous contact with ricin, however, is not particularly noteworthy. An urticarial, IgE-mediated allergic reaction may occur after handling the intact castor bean plant or exposure to castor bean dust or pomace. Irritation and the development of pseudomembranous conjunctivitis after ocular exposure to very low ricin concentrations are commonly reported. In humans, general signs and symptoms of ricin exposure include fever, fatigue, weakness, muscle pain, and dehydration.

Most of what is known about the effects of ingested ricin derives from animal studies, which reflect a 100-fold variation in lethal toxicity between the various animals studied. Of all tested animals, the chicken is the least sensitive and the horse is the most sensitive. In mice, the lethal dose for 50% of an animal test group (LD_{50}) is 20 mg/kg when ingested (Ishiguro et al., 1992). Absorption occurs within 2 h with uptake by both gastrointestinal lymphatic and blood vessels, and approximately 20%–45% of the ingested ricin is excreted unchanged in the feces (Ishiguro et al., 1992). The toxin accumulates mainly in the liver and spleen, with the onset of symptoms usually occurring within 4–6 h (Challoner and

McCarron, 1990; Ishiguro et al., 1992). Initial symptoms are nonspecific and may include abdominal pain, vomiting, diarrhea, heartburn, and oropharyngeal pain (Klaim and Jaeger, 1990). Without treatment, fluid losses may lead to electrolyte imbalances, dehydration, hypotension, and circulatory collapse. Blood chemistry changes can lead to leukocytosis, elevated transaminases and creatinine kinase activities, hyperbilirubinemia, renal insufficiency, and anemia. Postmortem findings of diffuse intestinal hemorrhagic lesions are common (Fodstad et al., 1976; Klaim and Jaeger, 1990).

The majority of the data for ricin injection derive from rodent studies (Beyer et al., 2009; David et al., 2009). The ricin LD_{50} in mice is approximately 5 μg/kg by injection (Fodstad et al., 1976). The highest concentration of ricin was found to localize to the spleen after either intravenous or intraperitoneal administration of ^{125}I-ricin, whereas the urine was found to be the major route of elimination. In general, for rodents, the majority of ricin excretion occurs in the urine over the course of the first 24 h (Blakey et al., 1988). The onset of nonspecific signs and symptoms, which may be similar to sepsis (fever, headache, dizziness, nausea, anorexia, hypotension, abdominal pain), occurs within 12 h after dosing. Abnormalities include elevated liver transaminases, amylase, and creatinine kinase activities, hyperbilirubinemia, myoglobinuria, and renal insufficiency, and these can progress to multisystem organ failure (Ishiguro et al., 1992; Bradberry et al., 2003). Postmortem findings are consistent in forensic case investigations as well as animal studies and include focal hemorrhage in the intestines, brain, myocardium, and pleura (Fodstad et al., 1976). The lymph nodes, kidneys, and intestines may also show signs of necrosis, hemorrhage, and edema (Flexner, 1897).

In cases of ricin inhalation, particle size can significantly influence lung deposition and lethality. Smaller particles typically deposit deeper into the respiratory tract, resulting in higher mortality. Larger particles deposit higher in the airways and can be swept up into the mouth by the mucociliary system and subsequently swallowed (Roy et al., 2003). The LD_{50} in mice exposed to ricin particles smaller than 5 μm is between 3 and 5 μg/kg (Wilhelmsen and Pitt, 1996). For monkeys, inhalation of 1- to 2-μm particles at 21–42 μg/kg results in progressive dyspnea 20–24 h after dosing (Wilhelmsen and Pitt, 1996). Postmortem findings typically include diffuse pulmonary edema with multifocal areas of necrosis and inflammation, and injury tends to be significantly worse in the distal airways and alveoli (Soler-Rodríguez et al., 1993; Griffiths et al., 1995; Wilhelmsen and Pitt, 1996; Brown and White, 1997). Toxicity results directly from the inhibition of protein synthesis, release of cytokine mediators, and direct injury to the epithelial membrane, with the primary targets of toxicity as the type I and type II pneumocytes (Soler-Rodríguez et al., 1993; Griffiths et al., 1995; Wilhelmsen and Pitt, 1996; Brown and White, 1997; Roy et al., 2003). Significant systemic absorption is usually not observed after inhalation, and toxicity is primarily limited to the respiratory tract (Soler-Rodríguez et al., 1993; Wilhelmsen and Pitt, 1996). Respiratory failure is likely to be the primary cause of morbidity and mortality in humans after ricin inhalation, and symptoms include severe lung inflammation with progressive cough, dyspnea, cyanosis, and pulmonary edema (USAMRIID, 2011).

The CDC recommends taking the following precautions when handling ricin in the laboratory (Centers for Disease Control and Prevention, 2014):

- Avoid any activity that places persons at risk for exposure, especially activities that might create aerosols or droplet dispersal.
- Follow laboratory safety practices to prevent exposure.
- Decontaminate laboratory benches after each use and dispose of supplies and equipment in proper receptacles.
- Avoid touching mucosal surfaces with gloved or ungloved hands and never eat or drink in the laboratory.
- Remove gloves before leaving the laboratory, dispose of gloves in a biohazard container, wash hands, and remove laboratory coat.

28.9 Field-forward biological agent detection

28.9.1 Immunoassays

Conventional assays used to detect biological toxins involve traditional biochemical techniques such as immunoassays based on antibodies raised against the toxin target. Immunoassays were first developed in the 1950s; 30 years later, the assays were in common use due to the development of standard reagents and automated assay readers (Ngundi et al., 2006). The immunoassay is a rapid and reliable technique for identifying a molecule that contains at least one antigenic moiety. Immunoassays rely on the inherent ability of an antibody to bind specific chemical groups on conformationally flexible antigens, such as carbohydrates, or specific molecular conformations in the case of large, conformationally rigid molecules, such as proteins. These chemical groups and conformations are referred to as antigenic determinants and epitopes, respectively. Antibodies are ideal for use in the detection of biological molecules, because they are produced against a specific determinant or epitope, which makes them highly specific and selective. Field-forward analysis for biothreat agents is limited to antibody-based tests and polymerase chain

reaction (PCR). The most commonly used tests are the ELISA and immunochromatographic tests typically referred to as hand-held assays (HHAs), as shown in Fig. 28.7.

Currently, the gold standard of immunoassays for toxin detection is the enzyme-linked immunosorbent assay (ELISA) (Hammond et al., 2006; Guglielmo-Viret and Thullier, 2007; Garber and O'Brien, 2008). In its simplest terms, the ELISA is a technique used to detect the presence of an antigen in a sample by affixing the sample contents to a solid support and visualizing the immobilized antigens with specific antibodies. Performing an ELISA involves at least one antibody with specificity for the target antigen. The sample is first immobilized to a solid support such as the surface of a polystyrene microtiter plate, either nonspecifically via direct adsorption or specifically via capture by another antibody specific for the target antigen that is affixed to the solid support. After antigen immobilization, a second mixture of antibodies sometimes referred to as detector antibodies is added to the complex with target antigens. Detector antibodies can be covalently linked to an enzyme or a chromophoric reporter group, or themselves can be detected by a secondary antibody linked to an enzyme or chromophoric reporter group. The labeling of the detector antibody allows for visualization of the antibody/antigen complex. Washing with a mild detergent solution typically is used between each step to remove nonspecific antibodies or other proteins. After a final wash, the assay is developed to visualize the results, either by addition of an enzymatic substrate to produce a color change or precipitate, or by irradiation of a specific wavelength of light in the case of chromophoric reporter groups.

The most recently developed technique aimed at enhancing immunoassay sensitivity is immune-PCR. The technique is markedly more sensitive than ELISA, primarily because it combines the detection specificity of an antibody with the amplification power of real-time PCR for a nucleic acid. The technique was first described by Sano et al. (1992). Realized limits of detection have surpassed ELISA by 10-fold to 10,000-fold. Typically, lateral flow immunochromatographic assays are used in field-forward situations due to lenient storage and equipment requirements (Pastoor et al., 2008). The problem with PCR-based assays is that they do not detect toxin protein, but they do detect copurifying DNA, which is not always present. Cell-based bioassays are sometimes used to confirm intact toxin-killing activity of the ricin in environmental samples (Brzezinski and Craft, 2007).

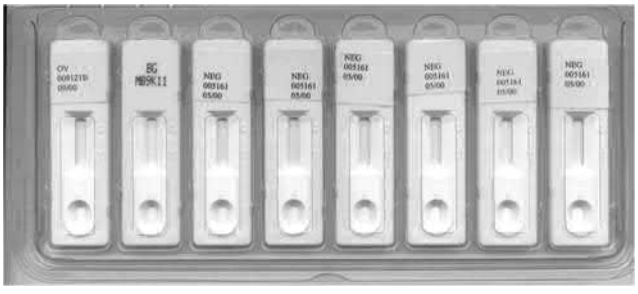

FIGURE 28.7 Photograph of an HHA packet.

The ricin toxin has been detected in tissue sections, some tissue specimens, nasal swabs, and fluids by using immunologically based methods to study animals and animal tissues (DOD, 1999; Brzezinski and Craft, 2007). Immunologically based methods applied to human and animal fluid specimens have the potential to measure ricin concentrations as low as 0.1 ng/mL (1.54 pmol/L) (Shyu et al., 2002a,b). However, such applications have not been clinically validated, and concentrations after toxic exposures are unknown. Reference laboratories such as the US Army Medical Research Institute of Infectious Diseases (USAMRIID) (Aberdeen Proving Ground, MD) and the CDC are currently adapting these and other analytic methods for application to human specimens. At the US Army Combat Capabilities Development Command Chemical Biological Center, Aberdeen Proving Ground, Maryland (CCDC CBC, Aberdeen Proving Ground, MD), matrix-assisted laser desorption-ionization mass spectrometry is used as a definitive method for identification in biological specimens, but this technique is not currently able to provide quantitative results. Technologies used for assessing enzymatic activity are the cell-free luciferase-based assay, the cell-based apoptosis assay, and a recently developed liquid chromatography tandem mass spectrometry (LC-MS) technique (Zamboni et al., 1989; Roen et al., 2013). Another technique that has been described measures the liberation of radio-labeled adenosine from RIP substrates resulting from their enzymatic activity. This technique has similar sensitivity to the LC-MS method with a range of 0.01−10 pmol, but it involves the hazards of radio-labeled nucleotides and is not readily transferable to field-forward use (Brigotti et al., 1998).

28.9.2 DNA-based assays: polymerase chain reaction

PCR is a technique for logarithmically amplifying a DNA sequence to the extent that a sufficient quantity of material may be available to detect through either fluorescence or gel electrophoresis. The technique was developed in 1993 by Kary Mullis, who was awarded the Noble Prize in Chemistry that year for his pioneering work (Bartlett and Stirling, 2003). As a result of its simplicity, PCR is a highly popular technique with a wide range of applications, including direct nucleic acid sequencing, genomic cloning, DNA typing, the detection of infectious organisms, site-directed mutagenesis, parental genetic disease research, and the analysis of allelic sequence variations (Sambrook and Russell, 2001).

Typically, when PCR is used as an identification technique, the target sequence to be amplified is a sequence of DNA known to be specific to one particular organism; this is referred to as template DNA. The complementary strands of the double-stranded template are separated at 95°C, and the temperature is lowered slightly to allow two 10- to 30-base pair (bp) ssDNA primers to anneal to their complementary strands of the template. DNA polymerase binds the primer–template hybrid and initiates synthesis of DNA complementary to the template from the primer in a 5′–3′ direction. This cycle of heating to denature the double-stranded template DNA, followed by annealing and extension of the primers by DNA polymerase, is typically repeated approximately 30 times to yield literally billions of copies of the original template (Antwerpen et al., 2008).

In the original PCR process, described by Mullis, *E. coli* DNA polymerase was used for DNA synthesis. The challenge presented by using the enzyme was that the 95°C melting step destroyed its polymerase activity, and the enzyme had to be replenished after the heating stage cycle. As a result, the original Mullis PCR process was very laborious and required vast amounts of DNA polymerase. The problem was resolved in 1986 by utilizing DNA polymerase from *Thermophilus aquaticus* bacterium that was discovered in Colorado hot springs. The bacterium was well-adapted to the extremely high water temperatures of the springs, and its DNA polymerase was found to endure the high temperatures required for PCR (Munster et al., 1986). The enzyme allows a series of 30–40 cycles of PCR amplification without the need of replenishing the polymerase and also reduces the associated potential for introducing contamination into the PCR assay. Moreover, because of its thermophilic origins, Taq polymerase functions optimally at approximately 72°C, allowing DNA synthesis to be performed at much higher temperatures than was possible with the *E. coli* enzyme. Because of the higher stringency of PCR primer annealing at the higher temperatures, the DNA template is copied with much higher fidelity, and the nonspecific products that had affected many previous PCR reactions are reduced (Saiki et al., 1988). One of the major disadvantages of Taq polymerase, however, is its low replication fidelity. Taq polymerase does not have a 3′–5′ exonuclease proofreading mechanism to replace base-pairing mismatches in the newly synthesized DNA strand; however, it does have a 5′–3′ exonuclease activity that allows real-time PCR (Luthra et al., 1998). The intensity of fluorescence emitted during the PCR reaction is monitored in real-time PCR, acting as an indicator of the degree of PCR amplification occurring during each PCR cycle. Thus, with newer real-time PCR instruments, reaction progress can be observed visually in real time.

The CDC and Department of Homeland Security Laboratory Response Network centers conduct PCR tests and time-resolved immunofluorescence assays to detect the ricin toxin in environmental specimens. Immunofluorescence is the immunoassay technique that uses a detector antibody or an antigen labeled with florescent dyes (Lim et al., 2005). Time-resolved fluorescence simply delays the time between excitation of the fluorescent dyes and quantifying resulting emission. The long-lived emissions of the fluorescent dyes are exploited to reject background signals such as sample autofluorescence as well as Rayleigh and Raman scatter (Marriott et al., 1991). Detection of the delayed emission leads to an increase in the signal-to-noise ratio of the dye, thereby lowering the detection limit of the assay. Time-resolved fluorescence also enhances separation of emission spectra from multiple dyes, thus improving assays that are multiplexed (Yan and Marriott, 2003).

Cell-based bioassays are sometimes used to confirm the intact toxin-killing activity of ricin in environmental samples because PCR-based assays cannot directly detect the toxin protein (Brzezinski and Craft, 2007).

Many of these technologies have the potential to quickly and conveniently determine whether an unknown sample possesses ricin activity and could greatly aid in the triage of victims after suspected ricin exposure. Furthermore, it would enable determination of the effective decontamination for a site. Technology of this nature may also greatly aid in an initial forensic investigation by immediately determining potency, and field-forward personnel could estimate the purity, grade, and the age of the weapon. Finally, a rapid screening assay for RIP activity would also prove beneficial for the pharmaceutical industry as a screening tool for genetically engineered ricin developed for cancer chemotherapeutics, and for basic researchers attempting to identify and characterize new and novel RIPs.

28.10 Concluding remarks and future directions

The assays for ricin described in this chapter are based on either ELISA detection of the toxin or DNA-based detection. Largely ignored is the fact that the lectin portion (B-chain) of the intact toxin could also serve as an analytical target. Carbohydrate-binding lectins bind to carbohydrate ligands with weak binding affinities, ranging in molar to submillimolar concentrations, even when preserving high specificities of the interaction. Lectins have the ability to distinguish a wide range of carbohydrate structures on the surface of cells. Their importance in cell recognition as related to mitogenesis, agglutination, and direction of cell cytotoxicity has been established (Sharon and Lis, 1989).

This specificity has been exploited to differentiate various cancer cells (Welty et al., 2006). Our understanding of the adsorption and distribution of the ricin toxin within the target organism could be greatly enhanced through the use of such techniques.

Chapter 29

Botulinum toxin

Rhian B. Cope
Australian Pesticides and Veterinary Medicines Authority, Australia

29.1 Introduction

The specific focus of this chapter is on the use of botulism and/or botulinum toxins as weapons. Botulism is a disease caused by the neurotoxins produced by an anaerobic, spore-forming *Clostridium botulinum* bacteria found in soil. The most common forms of naturally occurring human botulism include foodborne, infant, and wound botulism. Foodborne botulism is the most common form of the naturally occurring disease in humans. Foodborne botulism is caused by consuming foods contaminated with botulinum spores, which germinate and multiply into bacteria to produce neurotoxins in the food. Important sources of foodborne botulism include improperly preserved home-processed foods such as honey, corn, green beans, and beets. Less frequent sources are fish products and commercially processed foods. Infant botulism is often associated with eating honey contaminated with spores, but new evidence suggests that soil and dust brought into the house from the outside may also be a significant source of botulinum spores. Wound botulism occurs when spores contaminate a wound, germinate, and produce neurotoxins that are then absorbed into the bloodstream.

Regardless of the form of botulism, disease results from the intoxicating effects of potent neurotoxins. Botulinum neurotoxins (BoNTs) comprise a family of seven distinct neurotoxic proteins produced by immunologically discrete strains of *C. botulinum*. This family of neurotoxins has an estimated human LD_{50} of 1−3 ng/kg (Simpson, 2004; Sobel et al., 2004). Due to their extremely high toxicity, ease of production, and previous history of weaponization, the BoNTs have been designated as category A threat agents by the US Centers for Disease Control and Prevention (CDC). Category A agents are defined by the CDC as those that "result in high mortality rates and have the potential for major public health impact; might cause public panic and social disruption and require special action for public health preparedness."

While there are currently seven known antigenic serotypes of BoNT, only serotypes A, B, and E are predominantly associated with human intoxication. Intoxication by BoNTs leads to bilateral flaccid paralysis, involving skeletal muscle and structures innervated by autonomic fibers (Simpson, 1986; Shapiro et al., 1998). Death is inevitable if the intoxication is left untreated. The toxicity of BoNTs leading to flaccid paralysis of skeletal muscle is due to their ability to block acetylcholine (ACh) release from peripheral cholinergic nerve endings. Paralysis could persist for weeks to months (depending on the serotype), and the available treatment consists of supportive care including fluids, total parenteral nutrition (TPN), and mechanical ventilation. Death occurs when the diaphragm and intercostal muscles become sufficiently compromised to impair ventilation or when patients succumb to secondary infections following long periods of intensive care (Hatheway et al., 1984; Shapiro et al., 1998). In survivors the effects of what effectively amounts to denervation associated muscular atrophy can be severe and long-lasting.

29.2 Historical aspects

The weaponization of BoNTs continues to pose a serious concern. The toxins are highly lethal, easy to isolate, and easy to deliver. The modern development of BoNTs as offensive weapons began in the 1930s. During the occupation of Manchuria the Japanese fed lethal cultures of *C. botulinum* to prisoners as part of experiments conducted by its biological and chemical weapons program (Unit 731) (Harris, 1994; Hill, 1947). In response to intelligence indicating that Germany attempted to weaponize botulinum

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00029-5

toxins as a defense against invasion the United States formed the War Research Service in 1942. This service investigated the potential use of Anthrax and botulinum toxin-based weapons. At this time, the specific toxic agents and their mode of action were not fully understood (Dickson and Shevky, 1923). Thus the goals of the earliest research were to isolate and purify the toxin and determine its mode of action (Guyton and MacDonald, 1947). By June 1944 the United States had stockpiled sufficient quantities of botulinum toxin to allow for massive retaliation if German forces attempted to use biological agents in the European theater of World War II (Cochrane, 1947; Bernstein, 1987, 1990; Franz et al., 1997). The US code name given to BoNT at that time was "agent X." Subsequent work was conducted by the US at Camp Detrick. Based on President Richard M. Nixon's 1969–1970 executive orders (explicitly stated in National Security Decision Memoranda 35 and 44, 13) the US's offensive weapon stockpiles of BoNT were subsequently destroyed (Tucker and Mahan, 2009; Lebeda, 1997).

In 1975 the Convention on the Prohibition of the Development, Production and Stockpiling of Bacteriological (Biological) and Toxin Weapons and on Their Destruction came into force (OPBW, 1975). This convention prohibited the production of offensive toxins, including botulinum toxins. While the Soviet Union signed and ratified the convention, its biological warfare program, which included BoNT research, biological weapons development, and production, continued and was expanded in the post-Soviet era (Adams, 1995; Bozheyeva et al., 1999). Testing of botulinum-filled weapons occurred at the Soviet Aralsk-716 test site on Vozrozhdeniye (Renaissance) Island in the Aral Sea (Bozheyeva et al., 1999; Miller, 1999). The Soviet Union also attempted to transfer complete botulinum toxin genes into other bacteria (Alibek and Handleman, 1999). During the presidency of Boris Yeltsin, Russia, despite its treaty obligations, continued a large covert effort to effectively weaponize botulinum toxins (Alibek and Handleman, 1999).

Despite also being a signatory to the Biological Weapons Convention, Iraq acknowledged that it produced 19,000 L of concentrated BoNT and incorporated this material into weapons systems (UN, 1991; Zilinskas, 1997; Blix, 2004). Weapon delivery systems included 13 SCUD missiles, bombs, and tank sprayers. However, fortunately, these weapon systems were never used in combat. Iraq has subsequently claimed that its biological warfare stockpiles were destroyed.

Nonstate-sponsored terrorists have an interest in BoNTs (Brackett, 1996). Members of the Japanese Aum Shinrikyo cult made attempts to develop BoNT-based weapons following the political defeat of the party during the 1990 Japanese elections. While the cult is best known for the subway sarin attack in Tokyo in 1995, the organization was also responsible for an attempted biological weapons attack on the Kasumigaseki subway station 24 in the same year (Danzig et al., 2011; Sugishima, 2003). Investigations into the cult demonstrated that the organization was unable to effectively produce and weaponize BoNTs because the organization lacked the scientific expertise to correctly culture *C. botulinum* and to preserve the toxins.

Investigators have attempted to evaluate the consequences of a BoNT attack by a terrorist group by evaluating what would have happened if the Rajneeshee cult (the followers of the Bhagwan Shree Rajneesh who had carried out a biological attack to influence a local election) had used botulinum toxin instead of *Salmonella typhimurium* on salad bars in its 1984 attack in The Dalles, Oregon (Miller et al., 2001; Smith, 2006). Their conclusions were that many of the 751 who were poisoned during the incident would likely have died and the event would have very quickly overwhelmed the locally available medical resources.

Other approaches have been to model the effects of the 2006 foodborne botulism outbreak in Thailand (Ungchusak et al., 2007; Kongsaengdao et al., 2006; Witoonpanich et al., 2010; Hardin and Cohen, 1988; Dembek et al., 2007). During this outbreak 209 individuals were exposed to BoNT-contaminated food, of which 163 required medical examination, 140 required hospitalization, and 42 required respiratory support. Thailand lacked sufficient local stocks of BoNT antitoxin and stocks of these materials had to be donated and imported. The available donated supplies were only sufficient to treat 90 patients. For logistical reasons antitoxin treatment was delayed for 5–9 days following poisoning. The median duration of hospital admission was 6 days for patients without mechanical ventilation and 25 days for patients with mechanical ventilation. This incident demonstrated that apart from the technical and infrastructure needs associated with the provision of respiratory support, the management of mass BoNT incidents requires a complex range of medical expertise including neurologists, pulmonologists, respiratory care technicians, intensivists, cardiologists, infectious disease specialists, pharmacists, mental health specialists, and rehabilitation and referral services.

Wein and Liu (2005) mathematically modeled a BoNT attack utilizing the US milk supply. Because of biological and logistical factors milk represents a potentially ideal medium to disperse BoNTs amongst a large population. However, a significant limitation of this exposure scenario is that it may not adequately account for the use of pasteurization within the US milk supply chain, that is, introduction of BoNTs into the supply chain before pasteurization would likely substantially reduce the impact of such an attack (standard pasteurization at 72°C

for 15 s inactivates at least 99.99% of BoNT/A and BoNT/B and at least 99.5% of their respective complexes). Given how the US milk supply chain operates, incorporating large amounts of BoNTs into the supply following pasteurization with the objective of a widely dispersive bioterrorism attack is regarded as being difficult. Other exposure scenarios that have been modeled include BoNT distribution using a public drinking fountain and within a recreational facility (Dembek et al., 2005).

29.3 Background

29.3.1 Toxin structure and molecular function

The highly potent neurotoxins synthesized by the *C. botulinum* microorganism and several related clostridial species (*C. baratii*, *C. butyricum*, and *C. argentinense*) are the causative agents of botulism, a potentially lethal disease historically associated with the ingestion of contaminated food products. Seven different BoNTs, designated A through G, are currently known to be produced by various strains of clostridial bacteria; these neurotoxins are antigenically distinct but comparable in basic structure. The BoNTs are members of a superfamily of homologous proteins that also include tetanus neurotoxin. BoNTs are generated as single-chain polypeptides that are then posttranslationally modified (i.e., proteolytically nicked) to yield a disulfide bond-linked dichain structure composed of a heavy chain (H-chain or HC) and a light chain (L-chain or LC). Enzymes synthesized by these microorganisms themselves often mediate this cleavage, although the gastrointestinal enzymes of the host can also generate the dichain structure from the ingested toxin. The three-dimensional dichain protein structure of the purified toxin is provided (Fig. 29.1).

29.3.1.1 Function of heavy and light chains

The HC and LC of BoNTs each play critical roles in toxicity. HC is thought to mediate binding and internalization of the toxin at peripheral nerve synapses. LC, the toxic moiety, inhibits neurotransmitter exocytosis through its zinc-dependent endoproteolytic activity. The LCs of the various BoNT serotypes differ in their distinct molecular targets within the peripheral cholinergic nerve terminals (Schiavo et al., 1992, 1993a,b; Blasi et al., 1993). The endoproteolytic activities of the different toxin LCs produce similar flaccid paralytic effects, despite their distinct targets.

BoNT serotype A is the most well characterized of the different serotypes in terms of both structure and function. Early biochemical efforts led to its crystallization, and this crystalline form was used in numerous animal studies

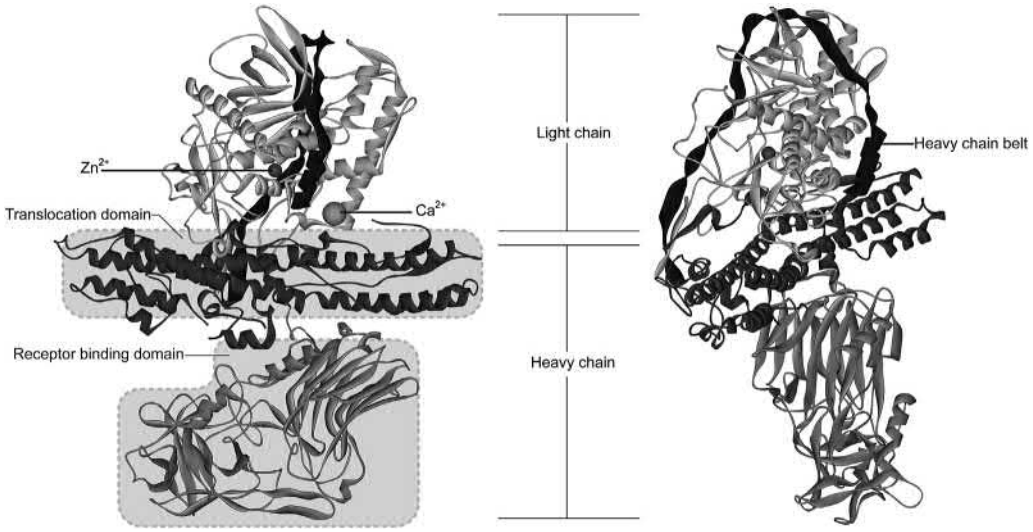

FIGURE 29.1 Three-dimensional structure of botulinum toxin serotype A (BoNT/A). BoNT/A (1296 amino acids), rendered as a ribbon structure, is depicted in two views. BoNTs are synthesized as a single polypeptide and nicked by bacterial proteases to form a dichain molecule. The 50-kDa LC, with 448 residues, and the 100-kDa HC, with 848 residues, are linked by a disulfide bond. All BoNTs comprise three major domains: a receptor-binding domain (C-terminal end of HC), a translocation domain (N-terminal end of HC), and a zinc-binding metalloprotease domain on LC. All seven BoNTs exhibit conserved sequences, but they are also antigenically distinct at the same time. The LC seems to be held in place by the translocation belt of HC (Brunger et al., 2007). The belt spans residues 492–545 in BoNT/A and 481–532 for BoNT/B and wraps around the catalytic domain of the LC. Brunger et al. (2007) suggest that the belt acts as a surrogate pseudosubstrate inhibitor of the LC protease and acts as a chaperone during translocation across the endosome membrane into the cytosol. The belt occludes access to the active site of LC, thereby holding the unreduced holotoxin in its catalytically inactive state. The sphere represents the bound Zn^{2+} at the LC active site. The structure of BoNT/A holotoxin was provided free of copyright restrictions from the Research Collaboratory for Structural Bioinformatics (RCSB) Protein Data Bank (PDB) (Berman et al., 2000; PDB ID: 2nz9; Garcia-Rodriguez et al., 2007) and rendered using Accelrys DS Visualizer 2.0 software.

on the pathogenesis of botulism. Crystalline type A toxin has a sedimentation constant of 19S (around 900 kDa), which is far larger than the combined size of the HC and LC components (Simpson, 1981). This large progenitor toxin form was shown to dissociate under moderately alkaline conditions, releasing the derivative (7S) or neurotoxin component (Heckly et al., 1960; Sugii et al., 1977a, b; Chen et al., 1998). The derivative neurotoxin has a molecular weight of 150−160 kDa, representing the combined size of the H- and L-chains. Additional work led to the finding that the dichain molecules comprising the various neurotoxins are often released as higher-order polypeptide complexes. The crystalline type A progenitor toxin consists of the 7S neurotoxin and one or more noncovalently linked accessory proteins. These nontoxic components of the progenitor toxin complex were later identified as three different hemagglutinins (HAs) and a nontoxic nonhemagglutinin (NTNH) protein.

29.3.1.2 Accessory proteins of the progenitor toxin complex

The accessory proteins of the progenitor toxin serve to enhance the stability of the toxin to ensure uptake from the gut. The NTNH component of the multimeric type A toxin complex is encoded by a single gene upstream of the neurotoxin locus, while three different HA proteins have been characterized in association with BoNTs. All *C. botulinum* serotypes have been shown to produce neurotoxin complexes with the NTNH and HA proteins.

29.3.2 Overview of botulinum neurotoxin action

After gaining entry to the lymphatics and circulation via the gastrointestinal tract, BoNTs function as potent neuromuscular blockers. The cellular and molecular mechanisms involved in toxin absorption, transit to specific target tissues, escape from the vasculature, and uptake within peripheral cholinergic nerve terminals have yet to be fully characterized. However, each of the neurotoxins has been shown to block vesicular neurotransmitter release at peripheral cholinergic synapses through the endoproteolytic cleavage of proteins associated with the exocytosis machinery (Schiavo et al., 1993a,b, 1995; Blasi et al., 1993). At peripheral cholinergic nerve endings, BoNT binding to high-affinity receptors leads to acceptor-mediated endocytosis and low pH-induced translocation across the endosomal membrane into the cytosol. The carboxy-terminal region of the toxin HC appears to mediate binding at the nerve synapse, while the amino-terminal domain controls translocation. The LC is held in close association with the HC by an amino acid belt. The LC of each toxin functions as a zinc-dependent endoprotease, cleaving at least one of three soluble *N*-ethylmaleimide-sensitive fusion protein attachment receptor (SNARE) proteins involved in neurotransmitter release.

Stimulus-evoked, calcium-dependent release of ACh from the cholinergic synapse normally occurs through the formation of a fusion complex between ACh-containing vesicles and the intracellular leaflet of the nerve terminal membrane (Arnon et al., 2001). This synaptic vesicle (SV) fusion complex consists of several proteins of the SNARE family, including a 25-kDa synaptosomal associated protein (SNAP-25), vesicle-associated membrane protein (VAMP, or synaptobrevin), and the synaptic membrane protein syntaxin. Other SNARE proteins have been identified as components of membrane transport systems in yeast and mammals but have not been implicated as targets for BoNTs. Meanwhile, type A and E neurotoxins cleave SNAP-25, while types B, D, F, and G act on VAMP and type C1 toxin cleaves both syntaxin and SNAP-25. Neurotoxin-mediated cleavage of any of these substrates disrupts the processes involved in the exocytotic release of ACh and leads to flaccid paralysis of the affected skeletal muscles.

29.3.3 Clinical forms of botulism in humans and animals

Exposure to BoNTs can produce lethal disease in humans and other animal species. Six different clinical forms of human botulism have been described in the literature (see Table 29.1), including (1) foodborne botulism, (2) infant botulism, (3) wound botulism, (4) an adult form of infant botulism, (5) inadvertent systemic botulism, and (6) inhalation botulism (reviewed by Cherington, 1998; Middlebrook and Franz, 2000; Arnon et al., 2001). Botulism is the result of either an infectious process involving elaboration of toxin from the colonizing clostridial organism, or a noninfectious process. Infant and wound botulism are the most prevalent infectious forms of botulism. Although rare, an adult form of infant botulism has been documented; gastrointestinal colonization in adults may be enabled by alterations in normal gastrointestinal flora resulting from antibiotic treatment (Cherington, 1998). Foodborne and inhalational exposures have noninfectious etiologies and are the result of ingesting or inhaling preformed toxin. Although only one inhalational botulism incident has been reported in humans, this incident demonstrates that humans are susceptible to respiratory intoxication similar to that which has been experimentally produced in many laboratory species (reviewed by Middlebrook and Franz, 2000). Finally, the emergence of a multitude of therapeutic applications for BoNTs has led to infrequent cases of inadvertent systemic botulism resulting from local toxin injection (reviewed by Arnon et al., 2001).

TABLE 29.1 Clinical forms of botulism.

	Infectious			Noninfectious		
	Infant	**Wound**	**Adult colonization**	**Foodborne**	**Inhalational**	**Inadvertent systemic**
Cause	Colonization of immature intestinal tract	Wound colonization resulting from contact with contaminated material	Intestinal colonization secondary to disruption of normal intestinal flora	Ingestion of preformed toxin in contaminated food products	Respiratory exposure to toxin aerosols or droplets	Systemic toxin uptake after therapeutic toxin administration
Susceptibility	Young infants (2–4 months of age) prior to establishment of normal intestinal flora	Self-administering users of i.v. drugs (often black tar heroin)	Antibiotic-treated patients	All exposed individuals	All exposed individuals	Patients treated with local toxin injections

29.3.4 Infectious forms of botulism

29.3.4.1 Infant botulism

Infectious botulism is a consequence of ingesting or inhaling clostridial spores that colonize the large intestines, germinate, and elaborate toxin into the bloodstream. Infant and wound botulism are the most prevalent infectious forms of botulism. Infant botulism comprises the majority (72%) of reported human botulism cases in the United States, while most of the remaining cases involve foodborne and wound botulism (Mackle et al., 2001). Infants are especially susceptible to infant botulism. Infants were found to be uniquely susceptible to gastrointestinal colonization due to a lack of well-established competing gut flora (Arnon et al., 1995). While infant botulism can be acquired by inhaling spores, this differs markedly from inhalational botulism, which results from inhaling preformed aerosolized toxin and not spores. Clostridial spores do not pose a threat in older infants or most adults (Arnon et al., 1995, 1998; Cox and Hinkle, 2002).

29.3.4.2 Wound botulism

Wound botulism involves growth of *C. botulinum* spores in a contaminated wound with in vivo toxin production (Weber et al., 1993). It accounts for less than 25% of all botulism cases. The majority of wound botulism cases are caused by serotype A and the remainder by serotype B (Shapiro et al., 1998). The neurological symptoms of wound botulism differ little from those of foodborne botulism except for the general absence of gastrointestinal symptoms. From its discovery in 1943 until 1996, only 111 incidents of wound botulism were documented (Merson and Dowell, 1973; CDC, 1998; Shapiro et al., 1998); among the 100 laboratory-confirmed cases, 83 cases were type A, 16 cases type B, and one a mixture of type A- and B-producing organisms (CDC, 1998). Risk factors for wound botulism include deep wounds, avascular areas, compound fractures, and crush injuries of the hand. Although a rare form of naturally occurring BoNT intoxication, it most recently occurred in Maryland as a result of a construction worker receiving a contaminated, compound fracture of the femur after falling into an excavated pit (Hilmas, personal observation). Wound botulism also occurs in intravenous (i.v.) drug users as a result of bacterial colonization at needle puncture sites or nasal/sinus lesions secondary to cocaine snorting (MacDonald et al., 1985). From 1986 through 1996, 78 cases of wound botulism were reported, and the majority of cases were linked to black tar heroin, introduced intravenously.

29.3.4.3 Child or adult botulism from intestinal colonization

Gastrointestinal colonization in adults or children by clostridia bacteria does not typically take place except in circumstances where the normal flora has been altered by antibiotic treatment (Cherington, 1998). Botulism results from in vivo production of toxin, analogous to the pathogenesis of infant botulism (Chia et al., 1986). Support for this form of botulism is provided by the demonstration of prolonged excretion of toxin and *C. botulinum* in stool, by the demonstration of *C. botulinum* spores but not preformed toxin in suspected foods, or both.

29.3.5 Noninfectious forms of botulism

29.3.5.1 Foodborne botulism

Worldwide, BoNT intoxication is most commonly associated with food poisoning. In the early 19th century, the effects of botulism were observed to be associated with the consumption and handling of meat products. Thus, German physician Justinus Kerner described what he termed "sausage poisoning" (Erbguth, 2004). It was later in the 19th century that the term *botulism* was used, from the Latin *botulus*, meaning "sausage." Foodborne botulism results from ingesting preformed toxin in food contaminated with toxin spores. Inadvertent and inhalational botulism, two other noninfectious forms of botulism, also involve exposure to preformed toxin. Outbreaks of foodborne botulism in the United States result from eating improperly preserved home-canned foods (CDC, 1995). The majority of cases of foodborne botulism are due to serotypes A, B, and E. From 1990 through 1996, type A accounted for 44.6% of foodborne outbreaks in the United States, followed by type E (35.7%) and type B (12.5%) (CDC, 1998). The prompt recognition of such outbreaks in the United States and early treatment with serotype-specific botulinum antitoxin has limited the number of casualties, severity of the disease, and the case-to-fatality ratio. Mortality from foodborne botulism has declined from 60% (CDC, 1998) in 1950 to less than 10% of clinical cases (Shapiro et al., 1998).

29.3.5.2 Inhalational

Because humans are relatively resistant to gut colonization by the *C. botulinum* microorganism, oral and inhalational exposures to preformed neurotoxin are likely to present the greatest threats with respect to intentional dissemination. The ability for inhaled BoNTs to produce illness has been documented in humans and in several experimental species. Only one incident involving inhalational intoxication in humans has been reported. Three laboratory workers presented with physical and neurological symptoms after accidental respiratory exposure to aerosolized type A toxin (Middlebrook and Franz, 2000; Arnon et al., 2001). These patients were all successfully treated with antiserum, gradually recovering from their weakness and visual disturbances over the next several days. After inhalational exposure, the neurotoxins are absorbed from the respiratory tract into the lymphatics and circulation for transport to peripheral cholinergic synapses (reviewed by Simpson, 2004). The pathogenesis following neurotoxin absorption is thought to be similar for both the respiratory and gastrointestinal exposure routes. Thus, the primary neurophysiological signs and symptoms associated with respiratory exposure parallel those observed in cases of foodborne botulism.

29.3.5.3 Inadvertent systemic botulism

The therapeutic indications for BoNTs are numerous. They are used in the treatment of ophthalmological disorders (strabismus, Duane's syndrome, esotropia/exotropia), movement disorders (focal dystonias, blepharospasm), spasticity, neuromuscular disorders, pain (headache, myofacial pain), disorders of the pelvic floor (anal fissures), ear/nose/throat disorders, cosmetic applications (wrinkles), and hyperhidrosis. The recent explosion in new indications for BoNTs in the treatment of a wide range of medical conditions also brings the possibility of medical errors in BoNT dosing. Systemic botulism may result from injection of excessive doses of the potent neurotoxin. The most infamous case of systemic botulism involved the paralysis of four Florida patients, including a doctor, who were treated with BoNTs for wrinkles. The physician used formulations of type A from Toxin Research International, Inc., which were approved by the US Food and Drug Administration (FDA). The research grade type A neurotoxin was apparently sold to the doctor and reconstituted to be thousands of times more potent than the typical dose used in BOTOX for paralyzing facial muscles. Later testing estimated that the raw bulk toxin that was used contained between 20,000 and 10 million units of botulinum toxin. In comparison, a typical vial of BOTOX from Allergan, Inc. contains only 100 units (CIDRAP (Center for Infectious Disease Research and Policy, 2004)). All three patients and the physician were injected with the toxin preparation; they developed severe systemic botulism requiring mechanical ventilation. While all four survived the superlethal dose of type A toxin, several of the patients experienced a syndrome involving chronic gastrointestinal symptoms and discomfort months after exposure.

29.3.6 Human intoxication

The basic syndrome of BoNT intoxication is similar for all naturally occurring forms, as well as for inhalation exposure, and does not vary appreciably among serotypes (Hatheway et al., 1984; Simpson, 1986; Jankovic and Brin, 1997). Based upon documented laboratory evidence, human BoNT intoxication is caused by exposure primarily to serotypes A, B, E, and (to a much lesser extent) to serotype F; disease manifests mostly as a result of foodborne, infant, and wound botulism (Simpson, 1986). BoNTs are also lethal when inhaled in aerosolized form, although this is not generally observed in nature.

The various toxin serotypes are usually associated with analogous clinical presentations. Paralysis proceeds in a descending fashion after an initial bulbar involvement. The earliest symptoms of botulism typically include visual disturbances, followed by dysphagia, dysphonia,

and dysarthria, reflecting an especially high susceptibility of cranial efferent terminals to BoNT action (Jankovic and Brin, 1997). A descending generalized skeletal muscle weakness may then develop, progressing from the upper to the lower extremities. Involvement of the diaphragm and intercostal muscles can lead to ventilatory failure and death unless appropriate supportive care is provided (Shapiro et al., 1998).

29.4 Epidemiology

29.4.1 Foodborne botulism

Human foodborne botulism outbreaks have typically been linked to the consumption of toxin-contaminated home-prepared or home-preserved foods (Maselli, 1998). The vast majority of foodborne botulism cases are attributed to toxin types A, B, or E. Maselli (1998) reports that type B is the most prevalent (52%) in the United States, followed by type A (34%) and type E (12%), while the CDC (1998) suggests 37.6% of all foodborne botulism outbreaks since 1950 were caused by type A, 13.7% by type B, 15.1% by type E, 0.7% by type F, and 32.9% were unidentified with respect to toxin type. Outbreaks of type F and G botulism are rare (Sonnabend et al., 1981; Maselli, 1998; Richardson et al., 2004), and only anecdotal reports of isolated type C1 and D botulism cases can be found in the published literature (e.g., Lamanna, 1959).

The natural epidemiology of foodborne botulism provides additional insight into the similarities and discrepancies between the human disease and that represented in various animal models. In the United States, around 25% of reported human botulism cases are classified as foodborne and 72% are infant (Mackle et al., 2001). Human type A and B foodborne botulism cases occur worldwide and constitute the vast majority of reported human intoxications (Maselli, 1998). The majority of other botulism cases are attributed to serotype E and are typically associated with the consumption of contaminated seafood. Generalizations have been made regarding the geographic distribution of the most common *C. botulinum* strains within the United States. Most human foodborne botulism outbreaks occurring west of the Mississippi are due to type A toxin; type B strains are more prevalent east of the Mississippi, while type E strains are typically isolated to Alaska and the Pacific Northwest (Arnon et al., 2001; Richardson et al., 2004).

Several clinical and epidemiological reports have evaluated the worldwide geographic distributions of human foodborne botulism cases. A review of 13 outbreaks between 1970 and 1984 identified geographic differences in the toxin serotypes associated with human foodborne botulism cases. Type B botulism was predominant in Portugal, Spain, France, and several other European countries (Lecour et al., 1988). Interestingly, the low mortality rate associated with human type B foodborne botulism (8.8%, vs 24.3% for type A and 30.8% for type E in the United States from 1950 to 1979) did not correlate with the high oral toxicity for type B toxin in mice (Ohishi et al., 1977; Sugii et al., 1977a,b,c). Serotype E was linked to botulism outbreaks in select regions such as the Baltic countries (Lecour et al., 1988) and typically resulted from the consumption of contaminated fish (Maselli, 1998).

Type F toxin was associated with only two reported outbreaks of human foodborne botulism prior to 1998 (Maselli, 1998). The first of these outbreaks occurred in Denmark (on the island of Langeland) and was attributed to a contaminated liver paste product (Richardson et al., 2004). The second outbreak, in 1966, affected three individuals in California and was associated with homemade venison jerky (Richardson et al., 2004). While a few other type F botulism cases have been reported, they are generally thought to have resulted from intestinal colonization and type F toxin production by another related species, *C. baratii* (Richardson et al., 2004). A recent report of a type F botulism case in California provided some additional insight into this uncommon toxin serotype and the associated clinical disease (Richardson et al., 2004). The patient described in this report presented with typical signs and symptoms, including ptosis, dysphagia, and weak extremities. Although the source of the ingested toxin was not conclusively determined, the exposure was tentatively linked to shellfish consumption, and type F toxin was subsequently detected in the patient's stool (Richardson et al., 2004). Human type F botulism cases may have been underreported in the past since some laboratories did not test culture isolates for the presence of *C. baratii*, which also produces type F toxin.

Type G toxin-producing clostridial organisms (*C. argentinense*) have been detected in several soil samples from a South American cornfield (Maselli, 1998), but only one reported outbreak of type G botulism (in Switzerland) has been identified in the published literature (Sonnabend et al., 1981). Certain aspects of this outbreak draw questions as to whether it was truly associated with type G intoxication. Type G organisms were isolated from all four affected adults and an 18-week-old infant, suggesting that the intoxications were due to ingestion and subsequent colonization by type G spores (Sonnabend et al., 1981). Type G toxin was detected at low levels of two to seven mouse intraperitoneal lethal dose 50 ($MIPLD_{50}$)/mL in the serum of three out of the four lethally intoxicated adults, all of whom died suddenly sometime after the presumed foodborne intoxication. Type A toxin was also detected in two of these individuals, suggesting that the intoxications may have involved colonization either by a mixed set of clostridia or by a unique strain producing multiple toxins

(Sonnabend et al., 1981). Alternatively, detection of dual serotypes could have been an artifact of the culture or testing methods. Soil samples taken from the area indicated the presence of only type A clostridial organisms (Sonnabend et al., 1981). Regardless, the occurrence of human type G botulism is rare, and the relative susceptibility of humans to colonization and intoxication from this serotype is not clear.

Species-specific patterns of susceptibility to different toxin types are common in both naturally occurring and experimental foodborne botulism. These differences do not necessarily facilitate identification of the most appropriate animal models from the human condition, but they may help to eliminate highly variant species. For example, mink were reported to be relatively resistant to toxin types A, B, and E (Yndestad and Loftsgard, 1970), which are responsible for the vast majority of human botulism outbreaks (Maselli, 1998; Arnon et al., 2001). Weanling pigs, on the other hand, were shown to be moderately resistant to types A, C1, E, and F and highly resistant to type D toxin (Smith et al., 1971). Experimental and epidemiological studies have identified one persistent difference in the epidemiology of botulism in humans compared to many other animal species. Few reports citing human outbreaks of types C and D are available. One of these reports mentions two type C outbreaks and one type D outbreak in humans, but provides no source for these cases (Lamanna, 1959). More recent reports of human types C or D botulism have not been found in the literature, and it is widely assumed that human foodborne intoxications are rarely, if ever, associated with these toxin types. In contrast, naturally occurring botulism of both types is quite common among domestic and wild animal species, and several studies have established the susceptibility of various laboratory species to experimental types C and D botulism.

The effect of C and D toxin serotypes, as well as A, B, and E, on human intercostal muscle have been studied (Anderson and Hilmas, 2015). All serotypes showed a similar ability to produce complete muscular paralysis in ex vivo human intercostal muscle. Intercostal muscle was excised from patients receiving a thoracotomy and intercostal muscle flap procedure. The muscle was removed tendon to tendon by surgical excision without electrocautery and dissected into multiple bundles with their associated intercostal nerves. The nerve−muscle units were placed in a vertical twitch bath and stimulated at 0.03 Hz (0.2-ms pulses of supramaximal strength) using a novel nerve clamp electrode to illicit an indirect muscle twitch. Potent toxins (1 nM) from various serotypes were added to the bath after confirming the stability of control muscle responses. In each case, twitch tensions declined to negligible amplitudes by 1 h after direct toxin application to the tissue bath.

Several nonhuman primate species are known to be susceptible to types C1 and D toxins both in nature and as experimental models. A large natural outbreak of type C botulism was reported in a troop of captive *hamadryas* baboons in 1989 (Lewis et al., 1990). The outbreak resulted in the deaths of 36 animals, including 3 adult males, 6 subadult males, 17 adult females, and 10 subadult females. Additional animals displayed mild to moderate symptoms that resolved themselves over a period of several days (Lewis et al., 1990). As with human foodborne botulism, various age groups and both sexes were affected, and no macroscopic lesions were apparent. Serum samples and gastric contents taken from ill animals contained type C1 toxin, although the source of the toxin was not identified (Lewis et al., 1990). The authors speculated that humans are probably also susceptible to type C1 toxin. The reason for the relative lack of human type C botulism cases remains unknown. It has been suggested that serotype C is often associated with carrion, providing a possible explanation for the absence of reported human cases. At least two other outbreaks of naturally occurring type C botulism in nonhuman primates were previously reported, one in squirrel monkeys (*Saimiri sciureus*) and capuchin monkeys (*Cebus capucinus* and *Cebus olivaceus*) (Smart et al., 1980) and the other in gibbons (*Hylobates lar*) (Smith et al., 1985).

In addition to nonhuman primates, most other animal species that show some sensitivity to botulinum intoxication are in fact susceptible to toxin serotypes C1 and D. Several rodent species are susceptible to oral intoxication with most botulinum toxins, including types C1 and D (Jemski, 1961a,b; Cardella et al., 1963; Sergeyeva, 1966; Sugiyama et al., 1974; Smith, 1986; Gelzleichter et al., 1999; Middlebrook and Franz, 2000). The majority of botulism outbreaks in cattle have also been attributed to toxins C1 and D. Cattle intoxication is typically associated with the ingestion of contaminated bones and other carcass remains; their apparent susceptibility to types C and D botulism might simply be due to frequent ingestion of decaying material that is primarily contaminated with these toxin types. A recent study indicated that cows are also uniquely sensitive to i.v. injection of type C1 toxin (Moeller et al., 2003). The high susceptibility of cattle to type C botulism is not dependent on exposure route, although the specific factors contributing to their sensitivity are not known.

A recent outbreak of type C botulism among farmed mink and foxes in Finland underscores the need to consider not only the quantitative susceptibility of various species to the toxins but also the potential epidemiological significance of interspecies differences in dietary patterns. Lindstrom et al. (2004) reviewed the Finland incident, which was the largest documented type C botulism outbreak in fur production animals. Over 52,000

animals developed illness after consumption of feed product that was contaminated with over 600 MLD of type C1 toxin per gram. This feed consisted of acidified slaughter by-products from poultry, beef, and fish (Lindstrom et al., 2004). According to national regulations, these by-products were acidified with an organic acid to yield a final pH of 4.0 or lower. Such processing would inhibit the growth of many microorganisms but would not necessarily result in significant toxin inactivation. Over 44,000 of the 52,000 affected animals died, and the death rate among all potentially exposed animals was almost 22% (Lindstrom et al., 2004).

The large number of animals affected and the high lethality associated with the outbreak could be considered indicative of the high susceptibility of the affected species to foodborne type C botulism. This high susceptibility might appear to be in stark contrast to that of humans due to the scarcity of type C cases in humans. However, the Finland outbreak provides a clear indication that dietary differences between species may play a significant role in these epidemiological patterns. Humans would be far less likely to consume slaughter by-products (including intestinal tissues), as opposed to higher-quality beef, poultry, and fish products. Moreover, the preparation of such products for human consumption would generally involve cooking rather than acidification. Thus, the influence of dietary habits must be taken into consideration when evaluating interspecies differences in epidemiological patterns for the various toxin serotypes.

It remains possible that humans generally do not consume the types of foods that are typically subject to contamination with type C1 and D toxins. Some researchers continue to speculate that humans are likely to be susceptible to both serotypes because they lead to botulism in monkeys, both in nature and after experimental oral exposure. Alternatively, humans might display a unique pattern of physiological susceptibility to the different toxin types. Lack of human susceptibility to type C1 and D intoxication could be attributed either to poor absorption of these specific toxins from the human gastrointestinal tract or to resistance of human cholinergic nerve terminals to the activity of these toxins. One cell culture study provided some support for the latter explanation. Type C1 neurotoxin was shown to bind with high efficiency to mouse neuroblastoma cells and to hybridomas of mouse neuroblastomas and rat gliomas, but not to human neuroblastoma cell lines (Yokosawa et al., 1989). Yokosawa et al. (1989) suggested that reduced binding of type C1 toxin to human versus mouse neuroblastoma cells could provide one explanation for the lack of type C botulism cases in humans.

Another potential explanation for the unique epidemiology of human botulism was provided in a study of botulinum toxin binding and transcytosis across polarized monolayers of two human colon carcinoma cell lines (T-84 and Caco-2). Substantial binding of iodinated BoNT/A and BoNT/B to human colon carcinoma cells was observed, while minimal binding of type C1 neurotoxin was detected (Maksymowych and Simpson, 1998). Both types A and B neurotoxins were also efficiently taken up, transcytosed, and released, by the polarized human carcinoma cells, whereas minimal transcytosis of type C1 neurotoxin was observed. The patterns of neurotoxin transcytosis (A and B, but not C1) observed in these human gut epithelial cell lines correlate with human susceptibility to foodborne botulism (Maksymowych and Simpson, 1998). The authors speculated that since human tissues are fully sensitive to the neuromuscular blocking properties of C1 neurotoxin (Coffield et al., 1997; Eleopra et al., 2004), the relative absence of human foodborne type C botulism could be due to the inability of this toxin to penetrate from the gut to the general circulation. Human susceptibility to type C1 and D neurotoxins remains unclear; however, clarification of this issue will be important in interpreting data derived both from in vitro studies on toxin transcytosis and from animal models for oral intoxication.

29.5 Pathogenesis

29.5.1 Overview of pathogenesis

BoNTs are a group of immunologically distinct but closely related bacterial proteins that act as potent inhibitors of synaptic transmission in skeletal muscle. Inhibition of ACh release from the presynaptic terminal of the neuromuscular junction (NMJ) is thought to be the sole mechanism involved in the toxins' lethal action (Simpson, 1986) and therefore the cause of botulism. The pathogenesis of intoxication is not completely understood but is generally thought to involve a multistep process to interrupt the normal vesicular release of ACh from the presynaptic motor nerve terminal. In a process of transcytosis, ingested or inhaled BoNT must first cross a barrier (either intestinal or pulmonary epithelial cells) to gain access to the circulation (see intestinal absorption of BoNT; Fig. 29.2). Once in the circulation, BoNT travels to its major target, the presynaptic membranes of alpha motor neurons at NMJs and neuroeffector junctions. Toxin binding through its HC to a cell surface receptor on the presynaptic motor nerve ending is followed by internalization via an endocytotic vesicle, acidification of the endosome, conformational change allowing cleavage of the enzymatically active LC from a bound HC, and release of LC toxin into the cytoplasm. Here, the LC cleaves one of the integral members of the SNARE complex (SNAP-25, VAMP, or syntaxin), proteins involved in exocytosis of ACh (Simpson, 1986, 2004; Black and

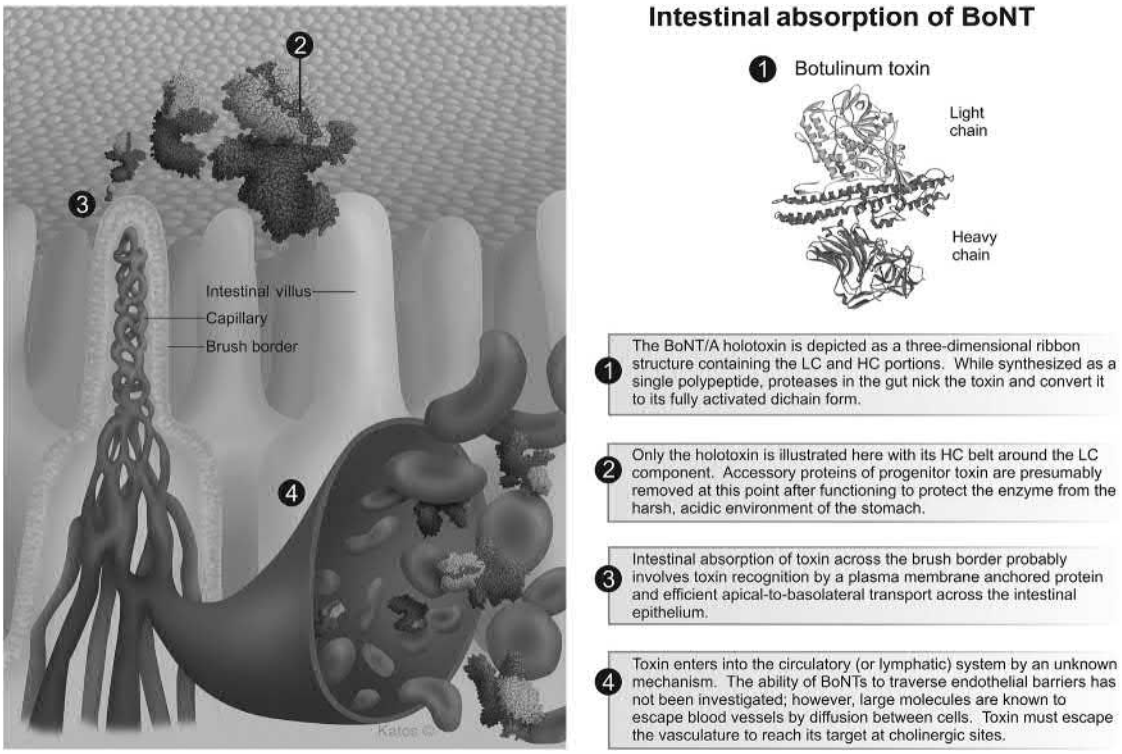

FIGURE 29.2 Intestinal absorption of BoNT. Neurotoxin present in the gut lumen as a result of foodborne (ingested toxin) or infant botulism (toxin synthesized by clostridial spores) must cross the epithelial membrane to reach the circulatory and lymphatic systems. The toxin presumably binds to an as-yet-unidentified receptor on the intestinal villus epithelium that is linked to an efficient transport process. Progenitor toxin contains nontoxic HA and NTNH accessory proteins, which are probably shed from the protein prior to entry across the intestine brush border. Progenitor toxin is thought to be too large for any significant rate of paracellular diffusion (Simpson, 2004). The ability of botulinum holotoxins without accessory proteins to traverse endothelial barriers has not been investigated; however, large molecules are known to escape blood vessels by diffusion between cells. Toxin escapes the circulatory system and reaches peripheral (and possibly central) cholinergic sites. These include NMJs, ganglia of the sympathetic and parasympathetic nervous system, postganglionic parasympathetic sites, and postganglionic sympathetic sites that release ACh. *Illustrations are copyright-protected and printed with permission from Alexandre M. Katos.*

Dolly, 1986; Blasi et al., 1993; Montecucco et al., 1994; Schiavo et al., 1995). BoNT thereby prevents docking of SVs with presynaptic plasma membrane by selective proteolysis of synaptic proteins. Each stage in BoNT action provides a potential point for pharmacological intervention.

29.5.2 Toxin stability

29.5.2.1 Biological stability of the toxins in the gastrointestinal tract

A major factor to consider in botulism is the stability of both the organism and the toxin. A variety of factors can affect the stability of ingested BoNTs within the gastrointestinal tract. The oral potency of the toxins is closely related to their ability to withstand the conditions found in these biological compartments prior to absorption into the lymphatics and general circulation. The stability of BoNT preparations, therefore, has been examined in the gastrointestinal compartments of intoxicated animals, as well as under different enzymatic and acidic conditions in vitro. Some of the earliest work on BoNT intoxication indicated that the stability and resulting potency of type A toxin vary both qualitatively and quantitatively in different rodent species (Minervin and Morgunov, 1941).

Several groups have evaluated the influence of ingested foods on the gastrointestinal stability and potency of BoNTs. Lamanna and Meyers (1959) reported that the ingestion of protein- or fat-containing foods prior to oral type A exposure in mice resulted in a moderate increase in toxicity. The mechanisms by which food intake enhanced toxin potency were not clarified; however, the relatively small observed increases (twofold) could have been due to normal experimental variation in determining oral toxicity values. The same study demonstrated that fluorescein-labeled type A toxin was quickly destroyed in the stomachs of mice. Crystalline and purified toxins form stable complexes with albumin and other proteins found in food and serum (Lamanna and Meyers, 1959). Albumin was later shown to prevent loss of potency when type A toxin was exposed to a wide range

of pH values (Zacks and Sheff, 1967). This observation was consistent with the more recent finding that the enzymatic activity of BoNT/A was enhanced in the presence of albumin (Schmidt and Bostian, 1997).

Subsequent studies expanded upon this early work by investigating the stability of other toxin types and preparations in solutions having different pH values and other conditions similar to those encountered in the gastrointestinal tract. Type C1 toxin was stable in most acidic and basic environments, as significant inactivation (as indicated by loss of toxicity in a mouse lethality assay) was observed only following exposure to extreme pH values (i.e., pH 1.8 and 12) (Halouzka and Hubalek, 1992). Progenitor type E toxin was more stable than its derivative (purified) form, which was subject to rapid inactivation when exposed to pH values less than 4.0 (Sakaguchi and Sakaguchi, 1974). This study demonstrated that type E progenitor toxin dissociated either during or after gastrointestinal absorption in mice, as only the derivative component could be detected in the blood and lymph following oral administration of the progenitor form.

Similar findings on the relatively high stability of progenitor versus derivative forms of the other toxin serotypes have been reported in other studies. Types A, B, and F progenitor toxins were more stable under conditions of low pH, as well as more resistant to digestion by pepsin and papain, than their corresponding derivative toxins (Sugii et al., 1977a,b).

The derivative forms of toxins A and B were almost completely inactivated after 10 min of peptic digestion at pH 2.0, while the progenitor forms retained over 60% toxicity after an 80-min treatment (Sugii et al., 1977a). Crystalline type A toxin was shown to be partially resistant to proteolysis by trypsin, retaining 25% of the potency of control-treated toxin even after a 72-h trypsin digestion at 37°C (Coleman, 1954). The crystalline toxin was more readily inactivated by digestion with pepsin at pH 1.4 and chymotrypsin at pH 6.5. Interestingly, another group reported that the potency of type A toxin was weakened by 80% after a 5-h incubation in phosphate buffer (pH 7.5), while toxins C1 and D maintained 100% toxicity under the same conditions (Miyazaki and Sakaguchi, 1978). These findings demonstrate both serotype- and enzyme-dependent effects on the in vitro stability of the BoNTs that are also likely to affect their persistence in the gastrointestinal tract. A similar pattern of stability among the various BoNT forms in gastrointestinal juices isolated from different animal species has been demonstrated (Sugii et al., 1977a). The progenitor forms for all toxin serotypes retained significant toxicity in comparison to their derived holotoxin counterparts.

Epitope mapping experiments suggested that the nontoxic component of the intact progenitor toxin complex covers a large portion of the binding domain of the neurotoxin (Chen et al., 1998). Toxin interaction studies also revealed that the purified neurotoxin adheres to lipid monolayers, while the progenitor complex is not subject to significant adsorption to the same monolayers. This observation led to speculation that the protective nontoxic components (HA and NTNH) may also facilitate progenitor toxin transit through the gastrointestinal tract by minimizing neurotoxin adherence to lipid membranes (Chen et al., 1998). On the other hand, toxicity studies suggest that adherence to lipid membranes is not critical for neurotoxin absorption since the intact progenitor complex is generally much more potent by the oral route than the purified neurotoxin. Moreover, the neurotoxin has been shown to protect the agglutination capacity of the associated nontoxic HA components within the progenitor toxin complex (Chen et al., 1998).

Importantly, the nontoxic HA components of the progenitor complex appear to protect the neurotoxin from proteolysis and degradation under pH extremes while the agglutinating activity of the nontoxic component is maintained by the presence of the neurotoxin. The type A progenitor toxin complex contains several HA components that might contribute to protecting the neurotoxin from degradation. One of these HA components, referred to here as *HA-33* (or *HA1* in some studies), was shown to interact directly with type A neurotoxin and to significantly increase its resistance to enzymatic proteolysis in vitro (Sharma and Singh, 2004). The authors of this work hypothesized that HA-33 provides protection against enzymatic degradation either by blocking the accessibility of protease-sensitive sites on BoNTs or by inducing structural changes within the neurotoxin itself.

Collectively, these studies offer important insight into the relative stability of the BoNTs within the gastrointestinal tract based upon their resistance to inactivation under various enzymatic conditions. In general, toxin stability directly correlates with the presence of the accessory HA and NTNH components of the multimeric progenitor toxin complex. These proteins appear to function in protecting the neurotoxin from degradation or inactivation. The various toxin serotypes also display unique resistances to enzymatic digestion although the basis for these differences is not known.

29.5.3 Oral intoxication: toxin absorption from the gastrointestinal tract

29.5.3.1 Role of progenitor toxin accessory proteins

The role of the nontoxic accessory proteins within the progenitor toxin complexes is not fully understood. They appear to function in protecting the ingested toxins from degradation and in facilitating absorption from the

gastrointestinal tract. Functional characterization of the HA and NTNH proteins has been advanced by biochemical techniques for generating toxin preparations containing only select components of the progenitor complex. These 7S toxins are relatively sensitive to proteolytic degradation and denaturation in the stomach (Schiavo et al., 1992). The auxiliary HA and NTNH proteins within the multimeric complex have been shown to dramatically increase the stability of the associated neurotoxin during transit through the gastrointestinal tract (Ohishi et al., 1977; Sugii et al., 1977a,b,c). The multimeric complex is then thought to readily dissociate either in the intestine or after absorption into the circulation. Most studies suggest that the accessory proteins do not appear to have any involvement in the activity of the toxins at peripheral nerve terminals. Thus, the HA and NTNH components are likely to be dispensable in disease pathogenesis after parenteral or respiratory exposure, where the toxins bypass the harsh conditions of the gastrointestinal tract.

29.5.3.2 Role of enterocytes

Both absorptive enterocytes and Peyer's patch-associated M cells have been implicated in toxin transcytosis from the gastrointestinal tract after oral exposure. Peyer's patches are collections of lymphoid tissue that are part of the gut-associated lymphoid tissue. M cells are found not only in the intestinal tract, but also in the respiratory epithelium overlying bronchus-associated lymphoid tissue. Park and Simpson (2003) indicate that knockout mice deficient in Peyer's patch-associated M-cell complexes are still susceptible to both oral and respiratory botulinum intoxication and the development of HC-specific antibody responses. Based upon these results, the authors suggest that M cells are not likely to be involved in toxin uptake and processing from the respiratory tract. In addition, both cell types have comparable transcytosis rates (M cells are five times as efficient in transcytosis than intestinal enterocytes), but enterocytes greatly outnumber M cells; therefore, gastrointestinal enterocytes are the predominant cell types involved in toxin uptake and processing from the gastrointestinal tract.

Maksymowych and Simpson (1998) used transwell culture systems with various transformed epithelial cell lines to evaluate the fate of the HA components of type A progenitor toxin complex. Radiolabeled preparations of both BoNT/A and HA were taken up by cultured T-84 human colon carcinoma cells by bulk endocytosis. However, efficient delivery across the T-84 cells was observed only for the neurotoxin.

29.5.4 Respiratory intoxication

The potential threat posed by aerosolized botulinum toxins is emphasized by their ease of production, their extremely high potency relative to other biological toxins, and their use in various weaponization programs over the past several decades (Arnon et al., 2001). This threat, along with the relative lack of information on respiratory toxicity and pathogenesis in humans, has fueled research on inhalational botulism in several animal models, including mice, rabbits, guinea pigs, mongrel dogs, and rhesus monkeys.

29.5.4.1 Toxin absorption from the respiratory tract

The relative persistence and absorption of the toxins following experimental respiratory exposure have been investigated in a few animal species. An early literature review suggests that type A toxin is more potent in mice by the respiratory route than by subcutaneous (s.c.) administration but less potent by the intraperitoneal (i.p.) route (Morton, 1961).

Guinea pigs were shown to be highly sensitive to inhaled botulinum toxins when compared to other rodent species. Respiratory penetration and retention of inhaled toxin are higher in guinea pigs than mice (Lamanna, 1961). Toxin could be detected in the lungs of guinea pigs after intranasal (i.n.) administration of only two mouse lethal doses of type E toxin, although detection in the blood or liver required higher doses (Sergeyeva, 1962, 1966). Guinea pigs were also reportedly more susceptible than mice to type A toxin by inhalation because shorter incubation periods were observed in guinea pigs prior to the onset of acute disease (Iakovlev, 1958).

Although inhalational botulinum intoxication was investigated in other animal species, these studies have not provided specific data on toxin absorption. The behavior of BoNTs in the respiratory tract was only recently investigated. Park and Simpson (2003) studied the properties of pure BoNT/A neurotoxin both in vivo and in vitro using mice and pulmonary cell culture models, respectively. Mean survival times were compared in mice receiving various doses of pure BoNT/A either i.n. or i.p. Pure BoNT/A was found to be a potent i.n. poison, although the toxicity (as determined by mean survival time) associated with i.p. administration was somewhat higher. Mean survival times in mice were less than 100 (i.p.) or 600 min (i.n.) after administration of 0.1 μg pure toxin; 75 (i.p.) or 400 min (i.n.) for 1 μg toxin; and 120 min (i.n.) for 10 μg toxin (Park and Simpson, 2003). As seen with oral and parenteral routes, a linear relationship existed between the log of the intranasal dose administered and the geometric mean survival time. The HA and NTNH component of the progenitor toxin did not enhance toxicity, establishing different requirements for the stability and absorption of inhaled versus ingested toxin (Park and Simpson, 2003).

Transwell experiments were also performed to investigate BoNT/A transcytosis across a human pulmonary

adenocarcinoma cell line (Calu-3), the MDCK cell line, and a primary rat alveolar epithelial cell line (Park and Simpson, 2003). Efficient BoNT/A transcytosis in both directions across polarized Calu-3 monolayers was observed, while toxin transcytosis occurred at a much lower rate across MDCK cells. These findings were in agreement with previous work demonstrating that the efficiency of BoNT/A transcytosis across MDCK monolayers was much lower than that observed across gut epithelial cells (Maksymowych and Simpson, 1998). BoNT/A transcytosis was also observed across primary rat alveolar cells, although at a slightly slower rate than that seen for the human adenocarcinoma cells (Park and Simpson, 2003). While the LC of BoNT/A was not essential for transcytosis, HC apical−basolateral (A−B) and basolateral−apical (B−A) transcytosis rates were somewhat lower than those of intact BoNT/A for both Calu-3 cells (HC 53% lower than BoNT/A for A→B; 45% lower for B→A) and rat alveolar cells (HC 62% lower for A→B; 17% lower for B→A). The transcytosis process was shown to involve an active-energy-dependent mechanism and was significantly inhibited by toxin preincubation with immune serum (Park and Simpson, 2003).

An important caveat to consider when evaluating the relevance of these in vitro studies is the use of pulmonary adenocarcinoma and alveolar epithelial cell lines in modeling respiratory absorption. It is generally believed that systemic absorption of inhaled particles is more likely to occur within the distal regions of the respiratory tract; therefore, particles must pass through thinner membranes in the deep lung and are less susceptible to nonabsorptive particle clearance (Lamanna, 1961). Some potential also exists for significant particle absorption from the nasopharyngeal and tracheobronchial regions of the respiratory tract; the cell lines utilized in these in vitro studies clearly do not account for this absorption potential. Importantly, investigators in the field have recently sought to characterize the specific cell types involved in toxin absorption from the respiratory tract.

M cells are found not only in the intestinal tract, but also in the respiratory epithelium overlying bronchus-associated lymphoid tissue. The studies of Park and Simpson (2003) indicate that M cells are not the major players in transepithelial transport of toxin across the respiratory epithelium. Additional studies directly investigating the absorption of inhaled BoNTs do not exist.

29.5.5 Toxin binding and uptake into target tissues

The remaining steps of BoNT pathogenesis following neurotoxin absorption are thought to be similar for both the respiratory and gastrointestinal exposure routes. After oral or inhalational exposure, the neurotoxins are absorbed from the gut or respiratory tract, respectively, into the lymphatics and circulation for transport to peripheral cholinergic synapses (Simpson, 2004). Fig. 29.3 illustrates the NMJ, a major target for the actions of BoNTs. BoNTs are taken up presynaptically at the endplate region of NMJs (Verderio et al., 1999) and at other cholinergic synapses. Toxin binding involves high-affinity presynaptic receptors. These receptors have recently been identified as a combination of polysialogangliosides, SV protein 2 (SV2), and synaptotagmin (Verderio et al., 2006). Each serotype displays an affinity for a unique combination of receptors. For example, BoNT/B recognizes synaptotagmin II (and I) and ganglioside lipids (Dong et al., 2003) (see Fig. 29.3).

BoNT/A involves recognition of SV2C, SV2A, and SV2B (Dong et al., 2003); binding to SV2C also involves a lipid. After toxin binding, the complex is internalized by what is believed to be a clathrin-mediated endocytotic process.

29.6 Toxicokinetics

The onset of symptoms in botulism depends upon the amount of toxin ingested or inhaled and the related kinetics of absorption. Time to onset can range from as short as 2 h to as long as 8 days, although symptoms typically appear between 12 and 72 h after consumption of toxin-contaminated food (Lecour et al., 1988; Arnon et al., 2001). In a review of 13 foodborne botulism outbreaks involving 50 patients from 1970 to 1984, the incubation period ranged from 10 h to 6 days (Lecour et al., 1988).

29.6.1 Foodborne toxicity

29.6.1.1 Toxin persistence in the circulation and transit to target tissues

Case reports of human foodborne botulism incidents offer some information on toxin persistence and transit after oral exposure in humans. Koenig et al. (1964) reported that circulating toxin was detected in five out of six patients suffering from type E botulism after consuming contaminated fish by the mouse lethality assay on serum samples collected from the patients from 1 to 10 days after foodborne exposure. Serum from one of the patients who rapidly succumbed to disease contained approximately 8 $MIPLD_{50}$/mL; extrapolation of this value yields an estimate that 20,000−24,000 human LD_{50}s were in this individual's circulation (Koenig et al., 1964). The toxin isolated from the serum of these clinically ill patients was not further activated in vitro by trypsin treatment. This observation was in agreement with other studies demonstrating cleavage of the single-chain prototoxin

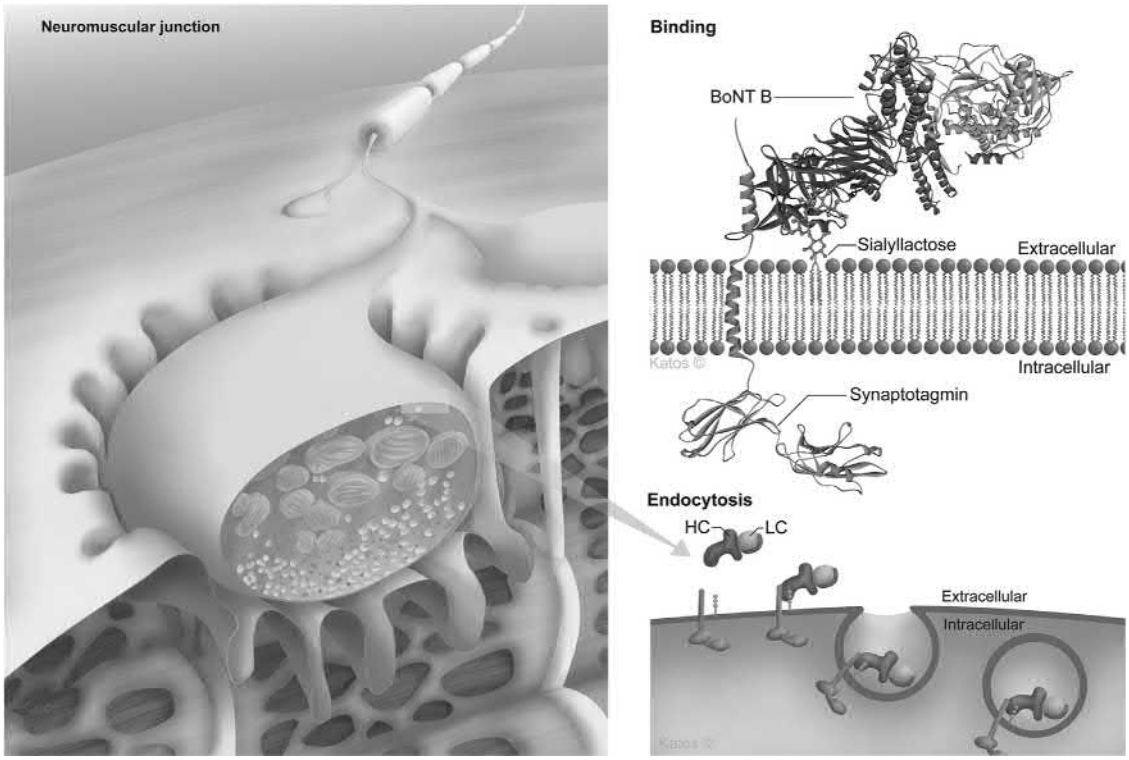

FIGURE 29.3 Toxin binding and internalization at the NMJ. (Left panel) A mammalian NMJ is illustrated with the alpha motor neuron innervating skeletal muscle at specialized junctional folds in the membrane (Couteaux and Bourne, 1973). Invaginations of the T system are also illustrated at the level of transition between the A and I bands. The axon loses its myelin sheath and dilates to establish irregular contact with the muscle fiber. Muscle contraction begins with the release of ACh from SVs (tiny spheres) at the motor endplate region. ACh binds to postsynaptic, muscle-type nicotinic ACh receptors and causes an increase in the permeability of the sarcolemma. This process is propagated to the rest of the sarcolemma and ultimately to the sarcoplasmic reticulum (SR) by the T system. An increase in SR permeability liberates calcium ion (Ca^{2+}) stores, resulting in the sliding of illustrated muscle filaments and muscle contraction. BoNTs bind and internalize at the presynaptic side of the NMJ (Verderio et al., 1999). Release of BoNTs into the cytosol results in inhibition of ACh release and flaccid paralysis of innervated muscle. [Top-right panel (toxin binding)] A three-dimensional ribbon structure of BoNT/B is illustrated. The receptor-binding domain of BoNT/B HC binds to synaptotagmin (Syt-II) and ganglioside (sialyllactose) receptors of the presynaptic motor endplate. Each BoNT serotype binds to a different set of receptors in the membrane (Verderio et al., 2006). [Bottom-right panel (endocytosis)] Receptor-mediated endocytosis of BoNT/B holotoxin is illustrated in this panel. The remaining steps in BoNT toxicity involve acidification of the endosome, pH-induced conformational change in the toxin, translocation of BoNT LC across the endosomal membrane with the aid of BoNT HC, and proteolytic degradation of target SNARE proteins by LC. *Illustrations are copyright-protected and printed with permission from Alexandre M. to the active dichain form within the gastrointestinal tract. Importantly, circulating toxin was not detected in a patient with minimal disease 11 days after ingestion of contaminated food (Koenig et al., 1964). Six out of seven individuals who had consumed the contaminated fish but did not develop clinical illness also lacked circulating toxin. Circulating toxin, therefore, was detected much more consistently in symptomatic patients associated with this outbreak than in subjects who were unaffected after toxin ingestion (Koenig et al., 1964).
