Koenig et al. (1964) also reviewed previously published literature on the detection of circulating toxin in botulism patients. Circulating toxin (primarily serotype B) had been detected in select patients from 2 to 25 days after consumption of contaminated food and was rarely detected in type A botulism patients (Koenig et al., 1964). The authors suggested that serotype-specific differences in the persistence of circulating toxin might be attributed to their unique avidities to target tissues. Circulating toxin is generally detected only at very low levels at or immediately prior to death in lethally intoxicated patients (Ono et al., 1970).

Efforts have been made to determine the kinetics of the accessory components of the progenitor toxin complexes after systemic absorption of BoNTs. Iida et al. (1970) found that circulating type E toxin was shown to exist in the 7S form after oral administration of the progenitor toxin to rabbits, suggesting that the larger toxin complex dissociated at some point during or after absorption from the gastrointestinal tract. Similar findings were reported on the absorption and persistence of progenitor type A toxin in the rat; the mean sedimentation value of

toxin in the lymph after intraduodenal instillation was 7.9S, significantly lower than that of the crystalline toxin (Heckly et al., 1960).

29.6.2 Inhalation toxicity

29.6.2.1 Toxin persistence in the circulation and transit to target tissues

Very limited data are available on the persistence of BoNTs in the circulation following inhalation exposure in any animal species. These data indicate that circulating toxin can be detected soon after exposure but is subsequently cleared rapidly from the circulation. Park and Simpson (2003) reported on the time course for appearance (and amount) of either purified BoNT/A or type A HC in the circulation of mice after intranasal exposure. Maximum serum levels were observed at 2 h postexposure for both proteins, although the peak values were higher for BoNT/A than for HC. Rapid clearance was observed over the next few hours.

An earlier study showed that type A toxin could be detected primarily in the lungs and liver rather than the serum of guinea pigs after i.n. exposure (Sergeyeva, 1962). The same group reported on the correlation between administered toxin dose and detection of toxin in the blood, lungs, and liver of guinea pigs intoxicated via the i.n. route (Sergeyeva, 1966). Type E toxin was detected in the lungs of guinea pigs after i.n. administration of two lethal doses, while toxin appeared in the blood or liver only following i.n. administration of at least five lethal doses. The organ distribution patterns were similar in guinea pigs after inhalation exposure to types A, B, or C toxins (Sergeyeva, 1966). These studies did not address the potential for persistent toxin detection in the lymph after inhalational intoxication, despite the fact that other routes of exposure result in significant absorption into the lymphatics.

While scant literature is available on persistence and distribution after inhalation exposure, several studies have evaluated the systemic behavior of parenterally administered toxins. One group investigated toxin persistence in serum and tissue distribution in white mice following i.v. administration of 1000 lethal doses of ^{35}S-labeled type B toxin (Pak and Bulatova, 1962). Mice were sacrificed at 20, 60, and 150 min after toxin administration, and blood and tissues were harvested for toxin distribution analysis. These mice showed symptoms of severe intoxication, including atypical breathing patterns and paralysis, at 150 min postexposure. Toxin levels (as determined by radioactivity) were highest in the lung 20 min after toxin injection, followed by the liver, heart, kidneys, intestines, and brain (Pak and Bulatova, 1962). Radioactivity levels in the blood, as well as the liver, heart, intestines, and brain, were further reduced after 60 min posttoxin injection. Serum toxin concentrations were lower than those detected in any other tissue at all times (Pak and Bulatova, 1962). The authors concluded that the toxin rapidly escaped from blood to various other tissues, suggesting the capacity for unimpeded passage of the toxin through the vasculature and cellular membranes.

Somewhat slower kinetics for toxin clearance from the circulation were observed in dogs following parenteral [i.v., i.p., or intramuscular (i.m.)] exposure to type A toxin (House et al., 1964). Serum toxin persistence was evaluated in mongrel dogs receiving 8000−10,000 mouse units/kg of type A toxin. Peak serum toxin levels were detected 5 h after i.p. administration (13% of injected dose), 12 h after i.m. administration (9% of the injected dose), and within only 3 min after i.v. administration (79% of the injected dose) (House et al., 1964). The relative clearance kinetics were slower after i.m. and i.p. exposure than for i.v. administration, as serum toxin levels were identical 22 h after injection via all three rounds (approximately 6% of the injected dose). Some serum toxin activity could be detected by the mouse lethality assay for 2−4 days after parenteral administration. Serum toxin patterns were also evaluated in rhesus monkeys following i.v. administration of type A toxin (Stookey et al., 1965). Serum toxin levels dropped by about 50% of maximum within 16−24 h after i.v. injection, and previous exposure did not affect toxin clearance rates after the administration of subsequent doses.

Another study investigated circulating toxin levels in weanling pigs (5−12 weeks old) following parenteral administration of toxin types A, B, C1, and D (Smith et al., 1971). Toxin was cleared from the circulation less than 24 h after i.v. injection of type B (560 $MIPLD_{50}$/kg), type C1 (5,000 $MIPLD_{50}$/kg), or type D (60,000 $MIPLD_{50}$/kg) toxin. In contrast, toxin could consistently be detected in the serum over the entire 4-day period prior to death in pigs injected with serotype A (21,400 $MIPLD_{50}$/kg) (Smith et al., 1971). Serum toxin levels were 100 MIP_{50}/mL at 24 and 48 h after injection of type A toxin, 30 $MIPLD_{50}$/mL after 3 days, and 10 $MIPLD_{50}$/mL after 4 days. These findings indicated serotype-specific differences in the persistence of circulating BoNTs, at least in systemically intoxicated pigs.

Although these studies provide some insight into the persistence of circulating toxin after parenteral administration, they do not necessarily reflect the behavior of absorbed toxin after respiratory exposure. The route of administration may not have a significant impact on the behavior of toxin once absorbed into the serum and lymph, but the patterns and kinetics of absorption into the circulation might be quite different after inhalational versus parenteral exposure. Respiratory exposure could lead to a different proportion of toxin taken up into the

circulation, lymphatics, or both over a given time period than that seen after systemic injection. Such discrepancies might affect both the quantitative persistence of circulating toxin and its transit to peripheral target tissues. At this point, information is not yet available on the homing and distribution of toxins to target nerve tissues. The available literature also provides no insight on the mechanisms by which toxin is removed from the circulation, either through extravasation and uptake in target tissues or by metabolic processes. In the future, such data will be important in characterizing the pathogenesis of botulism after respiratory intoxication and other routes of exposure.

29.7 Mechanism of action

ACh release from presynaptic vesicles depends upon a propagated action potential, localized depolarization at the presynaptic motor endplate, proper SNARE complex formation (i.e., SNAP-25, syntaxin, and synaptobrevin), and SV docking with the presynaptic membrane (see neuromuscular transmission in the absence of BoNT; Fig. 29.4). Regardless of the exposure route, BoNTs lead to inhibition in the release of ACh from peripheral cholinergic nerve terminals resulting in flaccid paralysis (Simpson, 1986; see Fig. 29.5). The specific target for BoNT/A and /E is the 25-kDa vesicle-docking protein SNAP-25; BoNT/A cleaves the last nine residues, whereas BoNT/E cleaves a larger 26-residue fragment from the C-terminus of this protein (Blasi et al., 1993; Montecucco et al., 1994). The target of BoNT/B is the small transmembrane protein synaptobrevin/VAMP located on the surface of small SVs (Schiavo et al., 1995). The enzymatically active portion of the 150-kDa BoNT is the 50-kDa LC; the role of the 100-kDa HC involves binding to cholinergic nerve endings and intracellular penetration via receptor-mediated endocytosis (Simpson, 1986, 2004; Montecucco et al., 1994).

29.7.1 Heavy chain

The HC of the BoNTs has been shown to mediate toxin binding and internalization at cholinergic nerve terminals (Daniels-Holgate and Dolly, 1996; Simpson, 2004). The mostly β-strand-containing carboxy-terminus of the HC appears to be directly involved in toxin binding, while the mostly α-helical amino-terminal region mediates

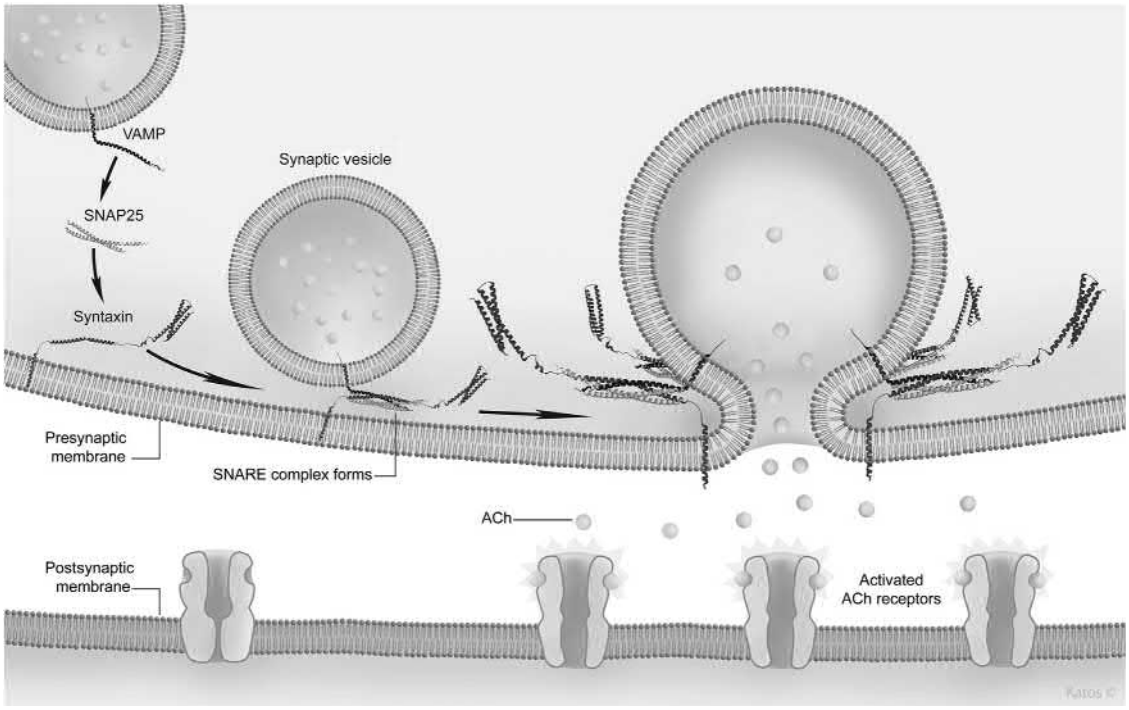

FIGURE 29.4 Neuromuscular transmission in the absence of BoNT. A nerve impulse is transmitted to the effector (muscle) cell by neurotransmitter liberated at the synapse. When the action potential arrives at the axonal terminus to depolarize the presynaptic membrane, Ca^{2+} ions enter through voltage-dependent Ca^{2+} channels. Ca^{2+} ions facilitate the fusion of SVs, containing the neurotransmitter ACh, with the presynaptic membrane. Three SNARE proteins (syntaxin, synaptobrevin, and SNAP-25) are critical for SV fusion. So long as the SNARE complex is intact, ACh releases by exocytosis, diffuses across the synaptic cleft, and binds to postsynaptic muscle-type nicotinic ACh receptors. Binding of ACh makes the sarcolemma of the muscle cell more permeable to sodium, which results in membrane depolarization. Excess ACh is hydrolyzed by the enzyme cholinesterase bound to the synaptic cleft basal lamina. ACh breakdown is necessary to avoid prolonged activation of ACh receptors. *Illustrations are copyright-protected and printed with permission from Alexandre M. Katos.*

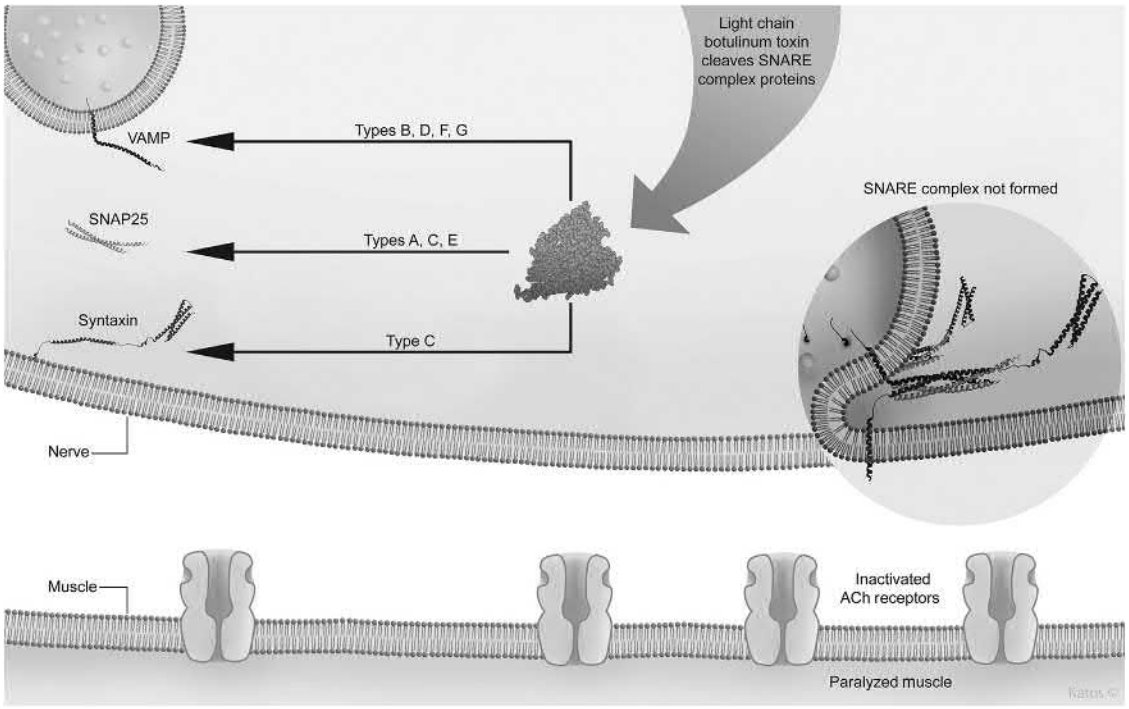

FIGURE 29.5 Neuromuscular transmission in the presence of BoNT. The catalytic LCs of the various serotypes cleave specific SNARE proteins. The SNARE complex does not form if any of the proteins are cleaved. In the presence of BoNT LC inside the axonal terminus, SVs will not fuse with the presynaptic membrane, ACh will not be released, and the muscle will not contract, resulting in paralysis at the NMJ. *Illustrations are copyright-protected and printed with permission from Alexandre M. Katos.*

translocation across the endosomal membrane (Simpson, 2004). Through mechanisms that have yet to be fully characterized, the toxins gain entry into the nerve terminal through receptor-mediated endocytosis followed by pH-induced translocation from the endosome to the cytosol. The ability of the Hn region to form transmembrane ion channels raises the possibility that they are intimately involved in translocating the toxic moiety into the cytoplasm (Koriazova and Montal, 2003). Once translocated into the cytosol, the toxic fragments exert their paralytic effects by inhibiting ACh release from NMJs as well as other peripheral cholinergic sites, including sympathetic and parasympathetic ganglia and postganglionic parasympathetic synapses (Lamanna, 1959; Simpson, 2004).

29.7.2 Light chain

These paralytic effects have been attributed to the proteolytic activity of BoNT LC on protein substrates required for vesicular exocytosis. BoNT LC inhibits neurotransmitter exocytosis through its zinc-dependent endoproteolytic activity. The LCs of the various neurotoxin serotypes possess distinct molecular targets within the peripheral cholinergic nerve terminals (Schiavo et al., 1992, 1993a,b, 1995). The endoproteolytic activities of the different toxin LCs produce similar flaccid paralytic effects.

The intracellular proteins SNAP-25, syntaxin, and synaptobrevin (or VAMPs) normally interact with each other in mediating neurotransmitter release from cholinergic and other nerve terminals (see Fig. 29.4). Toxin types B, D, F, and G cleave the VAMPs, while types A, C1, and E act on SNAP-25; type C1 toxin also cleaves syntaxin (Dong et al., 2003). The functions of the various neurotoxins are even more specialized, in that one toxin type can cleave its substrate at a different site than that targeted by other toxin serotypes. For example, BoNT/A cleaves SNAP-25 between residues 197 and 198, resulting in the loss of 9 amino acids, while BoNT/E cleaves the same protein between residues 180 and 181, thereby removing 26 amino acids (Schiavo et al., 1993a).

Although the LCs of both BoNT/A and /E target SNAP-25, these two serotypes exert significantly different potencies and paralytic profiles in cultured neurons and in vivo. A potential molecular basis for this discrepancy was established by the finding that these neurotoxins target different cleavage sites within the SNAP-25 protein. BoNT/A cleavage generates a 197-residue truncated protein (P197) by cleaving the last 9 amino acids from the C-terminus of SNAP-25 while BoNT/E cleavage produces a 180-residue species (P180) by removing the final 26 residues (Schiavo et al., 1993a). A series of studies by Keller et al. (1999) and Keller and Neale (2001) provided

additional insight into the molecular mechanisms associated with the potent and persistent action of type A neurotoxin relative to type E.

Serotype-specific cleavage events provide insights into the differential activities of the toxins at nerve terminals. In some cases, substrate cleavage studies also revealed important information regarding interspecies differences in the activity of certain toxins. BoNT/B was shown to block neuromuscular transmission by cleaving VAMP proteins between residues Q76 and F77 in humans and mice (Bakry et al., 1997). However, the rat VAMP1 (synaptobrevin) protein sequence differs at this critical cleavage site, in that the glutamine at position 76 is replaced by a valine, rendering the region more resistant to proteolysis by BoNT/B (Bakry et al., 1997; Verderio et al., 2006). On the other hand, rats and mice were shown to have similar susceptibilities (body weight adjusted) to i.m. injection of type A toxin; rats have also been shown to be much more resistant than mice to type F toxin (Kauffman et al., 1985).

The specific paralytic profiles associated with each of the BoNTs are typically attributed to their unique proteolytic activities within the nerve terminal. These activities are known to be mediated by the LC components of the various neurotoxins. The various nontoxic components within the multimeric progenitor toxin complexes have traditionally been considered accessory proteins that primarily function to increase neurotoxin stability and, in some cases, to facilitate absorption. Yet studies in the recent past have suggested a potential role for the HA constituents in enhancing the endopeptidase activity of the LC (Cai et al., 1999; Sharma and Singh, 2004). It is widely believed that pure BoNT/A requires either proteolytic nicking or chemical reduction for significant SNAP-25 cleavage activity. However, new evidence suggests that the type A progenitor toxin complex is apparently highly active even in nonreduced form (Cai et al., 1999). Further research is needed to substantiate this preliminary work and to establish a more detailed understanding of the prerequisites for LC proteolytic activity.

A recent study by Sharma and Singh (2004) provided additional support for the expanded roles of at least one neurotoxin-associated protein within the type A progenitor complex. The HA-33 component, representing 25% of the accessory protein content of progenitor neurotoxin, significantly increases the proteolytic activity of both BoNT/A and /E in vitro and in rat synaptosome preparations. The addition of HA-33 to nonreduced BoNT/A leads to a 21-fold increase in GST-SNAP-25 fusion protein cleavage activity in vitro and a 13-fold enhancement of endopeptidase activity in rat synaptosomes (Sharma and Singh, 2004). Similar enhancement of proteolytic activity was seen when HA-33 was added to BoNT/E both in vitro and in rat brain synaptosomes.

The enhancement of SNAP-25 cleavage activity by HA-33 in rat brain synaptosomes was taken as evidence that the neurotoxin and the accessory protein both gain entry to the nerve terminal (Sharma and Singh, 2004). The possibility that an accessory component of the progenitor toxin complex could exert direct effects on LC endopeptidase activity within the nerve terminal could have important implications with respect to neurotoxin function in vivo.

Two recent reports revealed additional layers of complexity regarding the mechanisms involved in the distinct durations of action associated with the different toxin serotypes. Fernández-Salas et al. (2004) investigated the subcellular localization of BoNT/A, /B, and /E LC-GFP fusion proteins following overexpression in several different mammalian cell lines. The LC/A fusion protein was shown to localize within discrete plasma membrane compartments in both neuronal (PC12) and nonneuronal (HEK293, HeLa, and HIT-T15) cell lines, while LC/B was detected throughout the cell and LC/E was primarily found within the cytosol.

29.8 Toxicity

29.8.1 Lethality

BoNTs are the most potent substances known to humans. A comparison of the lethal nature of BoNTs in relation to other toxic chemicals and substances discussed throughout this book is provided in Table 29.2. The toxicity associated with oral exposure of a given species to BoNTs is significantly lower than that resulting from parenteral administration (see Table 29.3).

The susceptibility of various animal species to parenteral intoxication does not provide adequate indication of their sensitivity to gastrointestinal exposure (Lamanna, 1961). The estimated human LD_{50} of approximately 1 ng/kg for parenteral botulinum intoxication is similar to that reported for most laboratory animals (Arnon et al., 1995; Middlebrook and Franz, 2000). In contrast, the relative susceptibilities of humans and other animal species to oral intoxication vary significantly (Morton, 1961). A clinical review of human botulism reported that the ingestion of as little as 0.05−0.1 μg of BoNT/A may be sufficient to cause death in humans (Cherington, 1998). Human lethal doses have also been extrapolated from primate studies, yielding an oral lethal dose of approximately 70 μg for crystalline type A toxin for a 70-kg human (Arnon et al., 2001). The lethal human respiratory dose is estimated to be 0.7−0.9 μg and the i.v. or i.m. dose is 0.05−0.15 μg (Middlebrook and Franz, 2000; Arnon et al., 2001).

29.8.2 Oral toxicity

An earlier report suggested that humans are more susceptible than monkeys to type A toxin by the oral route based on toxin dose estimates in foodborne botulism case studies (Morton, 1961). This same study also summarized the susceptibility of numerous other animal species to oral botulinum intoxication. Mice, monkeys, and guinea pigs were considered highly susceptible, while chickens, rabbits, horses, dogs, rats, and cattle were classified as more resistant, and ferrets, mink, and hogs were deemed resistant. The oral lethal doses of type A toxin in guinea pigs (1000−3000 MIPMLD) and monkeys (2000 MIPMLD) (Morton, 1961) are similar to the estimated oral lethal dose for humans (7000 MIPMLD).

Morton (1961) provided evidence for an estimated human oral lethal dose of much less than 3500 MIPMLD for type B toxin. This estimate was based on an earlier report describing a fatal type B human botulism case resulting from the ingestion of 3500 MIPMLD in toxin-contaminated cheese (Meyer and Eddie, 1951). A man weighing 104 kg consumed approximately 70 g of contaminated cheese; repeated tests of the cheese indicated that it contained only 50 MLD/g of type B toxin. The patient first developed somewhat atypical disease symptoms of nausea, vomiting, diplopia, dysphagia, phagodynia, and instability within 7 h of exposure (Meyer and Eddie, 1951). The man was later hospitalized and developed symptoms more characteristic of foodborne botulism within 18−20 h. He died 57 h after toxin ingestion despite receiving 35,000 units each of both type A and B antitoxins (Meyer and Eddie, 1951). Therefore, it was determined that 3500 MIPMLD is much greater than the minimum lethal dose of type B toxin for humans due to the rapid onset of illness and severity of disease (Morton, 1961). The same study reported a woman who died from botulism 42 h after consuming a small piece of toxin-contaminated pear.

29.8.3 Inhalation toxicity

Naturally occurring botulism cases in humans and other animal species are almost exclusively associated with the ingestion of toxin- or spore-contaminated foods. The level of knowledge in the published literature on toxin absorption following inhalational exposure is, therefore, much more limited than that associated with gastrointestinal intoxication. The potencies of inhaled BoNTs have been investigated in several experimental animal species. In a review of the early literature on this topic, Morton (1961) reported comparatively similar ratios (5.9:1) of oral to respiratory toxicity (the comparative lethal doses for toxin administered via the oral versus the respiratory route) for type A toxin in guinea pigs and mice. Iakovlev (1958) concluded that guinea pigs were more susceptible than mice to type A toxin by inhalation because they succumbed to intoxication after a shorter incubation period (1−2 days, vs 3−4 days for mice). Several technical reports established more specific guinea pig inhalation toxicity data for serotypes A through E (Jemski, 1960, 1961b).

29.8.4 Clinical toxicity

The natural occurrence of human foodborne and infant botulism translates into a wealth of information on the clinical signs and symptoms of disease. This information can be compared to the array of physiological and pathological findings in various species of experimental animals after oral administration of BoNTs. The ability of inhaled BoNTs to produce illness has also been documented in humans and in several experimental species. The primary neurophysiological signs and symptoms associated with respiratory exposure parallel those observed in cases of foodborne botulism; however, infants display a unique clinical picture of botulism. In addition, the various toxin serotypes are usually associated with analogous clinical presentations, with the most severe cases of foodborne botulism being caused by the ingestion of type A toxin.

Exposure to BoNT via oral or inhalational routes results in symptoms indicative of an inactive peripheral cholinergic system due to inhibition of ACh release from the nerve terminal. The time to onset of disease depends on the amount of toxin ingested and ranges from several hours to a few days after oral exposure (Lecour et al., 1988; Arnon et al., 2001). Prominent signs and symptoms of intoxication common to all serotypes and various routes of exposure include the following, in order of descending frequency: dysphagia, xerostomia, diplopia, dysarthria, fatigue, ptosis of the eyelids, constipation, arm weakness, leg weakness, gaze paralysis, blurred vision, diminished gag reflex, nausea, facial palsy, dyspnea, emesis, tongue weakness, sore throat, dizziness, dilated or fixed pupils, abdominal cramps, reduced or failed reflexes, nystagmus (involuntary rapid eye movement), diarrhea, ataxia, and paresthesia (reviewed by Arnon et al., 2001).

29.8.4.1 Foodborne botulism

Human foodborne botulism presents as an acute, symmetric, flaccid paralysis that generally involves multiple cranial nerve (CN) palsies initially, termed *bulbar involvement*. Early symptoms involve paralysis of the motor components of the CNs. The motor components are derived from cell bodies located in the brain, with axons that exit the cranium to control muscles, glandular tissue,

or specialized muscle in the heart and gastrointestinal tract. Paralysis by BoNTs leads to ptosis and dilated pupils (CN III); disconjugate gaze and blurred vision (CN III, IV, VI); facial droop or palsy (CN VII); dysphagia, dysarthria, and absence of gag reflex (CN IX, X); tongue weakness (CN XII); and weakness of neck strap muscles (CN XI). Botulism patients typically develop difficulty in seeing, speaking, or swallowing in the early phases of intoxication. As paralysis extends caudally, toxic signs and symptoms include loss of head control, hypotonia, generalized weakness, and flaccid paralysis or floppy appearance (infants and children). In infants and young children exposed to BoNT, floppy appearance and constipation may be the only presenting signs to warrant a diagnosis of BoNT exposure, since obtaining a reliable history may not be possible in this population.

Loss of the gag reflex and dysphagia may require intubation and mechanical ventilation. Deep tendon reflexes are often lost during later stages of intoxication, and death in untreated patients results from airway obstruction or inadequate tidal volume (Arnon et al., 2001). Respiratory failure is the most serious clinical manifestation of botulism, and the decline in mortality associated with foodborne botulism is primarily due to improvements in ventilatory support (Lecour et al., 1988). Around 60% of botulism patients in the United States require mechanical ventilation at some point during their hospitalization and treatment (Varma et al., 2004). In severe botulism cases (as in the previously mentioned case of the Florida physician involving research grade type A toxin instead of BOTOX for facial muscle paralysis), respiratory support may be required for prolonged periods of time, and autonomic dysfunction may persist for a period ranging from months to years (Mackle et al., 2001).

Other clinical forms of the disease share many of these signs and symptoms. The presentation and duration of the disease are coupled to the relative persistence of the toxin in blocking the release of ACh at peripheral nerve synapses. Although untreated botulism is potentially deadly, the availability of antiserum has dramatically reduced the mortality rates for the common clinical manifestations of the disease. Severe cases of foodborne botulism may still require ventilatory support for over a month, and neurological symptoms can sometimes persist for more than a year (Mackle et al., 2001).

29.8.4.2 Infant botulism

The characteristic symptoms of infant botulism are poor sucking, constipation, generalized weakness, floppy appearance, and respiratory insufficiency (Cox and Hinkle, 2002). Infant botulism may quickly progress to respiratory failure if not treated. The development of the intestinal flora has been demonstrated to suppress the germination and growth of *C. botulinum* spores in mice (Sugiyama and Mills, 1978). Ingestion of honey by infants is the classic scenario cited in infant botulism; therefore, honey is not recommended in this susceptible population (Arnon et al., 1998).

29.9 Risk assessment

BoNTs present a very real threat to the public health and are the most toxic substances known to humans. In a military or bioterrorist incident, intoxication by BoNT is likely to occur by inhalation of aerosolized toxin or by ingestion of contaminated food or beverages (Franz and Zajtchuk, 1997; Sobel et al., 2004). Although municipal water systems are considered to be safe from BoNT attacks, due to chlorination and dilution, it is not known whether current water treatments adequately decontaminate the toxin. Furthermore, bottled mineral water and milk (Sobel et al., 2004; Kalb et al., 2005) are obvious targets for terrorist groups. The vulnerability of the nation's milk supply was highlighted in a recent modeling study, where its complex distribution system would magnify the consequences of poisoning by BoNT (Kalb et al., 2005; Wein and Liu, 2005). BoNTs are a serious threat to the US national security due to their potency, remarkable stability, and persistence in the body.

Wein and Liu (2005) modeled a bioterror attack using BoNTs on the nation's milk supply. Modeling of toxins for dispersal into a liquid medium has been previously computed in a terrorist scenario (Dembek et al., 2005) involving a water fountain and contamination at a recreational center (CDC, 1999). Wein and Liu's assessment estimates the amount of toxin required, critically evaluates entry points into the milk supply industry, and details deficiencies in our current detection capabilities required to thwart such an attack (Wein and Liu, 2005).

The most prevalent BoNTs isolated in human botulism are serotypes A, B, and E. The ability of serotypes C and D, in addition to F, to paralyze human skeletal muscle should also be noted (Hilmas, unpublished). Complicating matters is the fact that all BoNTs remain stable in common beverages and retain significant potency for prolonged periods of time (>90 days) at room temperature and in biological fluids (human whole blood and serum) at physiological temperatures (Hilmas et al., 2006b; Williams et al., 2007). In addition, BoNTs possess a remarkable ability to remain within the nerve terminal for extended periods. Keller et al. (1999) showed BoNT protein detectable by western blot for 90 days in rat spinal cord cultures.

Stability of the BoNT protein should be considered in an assessment of the threat posed by intentional release of the toxins. In addition to the remarkable persistence of the toxin in biological fluids and beverages described

previously, BoNT remains a potent environmental threat. BoNT/A was subjected to desiccation to simulate the residue of an intentional release. Following 28 days of drying, the toxin still possessed remarkable paralytic properties (Williams et al., 2007).

The duration of muscle paralysis following intoxication by BoNT/A exceeds that resulting from exposure to other BoNT serotypes (Keller et al., 1999; Fernández-Salas et al., 2004). The remarkable persistence of BoNT/A action has led to its widespread use in the treatment of disorders of muscle tone and movement (Jankovic and Brin, 1997). Although a long duration is desirable in clinical use, the prolonged action of BoNT/A would also make intoxication by this serotype difficult to treat, particularly if it is used as a bioweapon (Franz and Zajtchuk, 1997). The duration of intoxication by BoNT/E is relatively brief (several weeks), whereas BoNT/B is of intermediate duration (Keller et al., 1999). The basis for the differences in serotype persistence is currently unknown. In any case, a bioterrorist attack, involving the most lethal substance known to humankind, would overwhelm the limited resources (i.e., mechanical ventilators) available to treat botulism patients.

29.10 Treatment

There are currently seven known antigenic serotypes of botulinum toxin, designated with the letters A through G, whereby antitoxin to one type does not cross-neutralize any of the others. Only early administration of antitoxin antibody in cases of suspected botulism will minimize the neurologic damage but will not reverse any existing paralysis. Paralysis could persist for weeks to months, and the available treatment consists of supportive care including fluids, TPN, and mechanical ventilation.

29.10.1 Antitoxin

The administration of a heterologous antitoxin was one of the first therapeutic approaches developed for botulism patients and remains the most effective when initiated in the early stages of intoxication. The primary limitation of antitoxin treatment was established in some of the earliest published reports on experimental botulism. One of these reports evaluated the pathogenesis of oral intoxication and the efficacy of antitoxin therapy in monkeys (Dack and Wood, 1928). Antitoxin treatment was not effective when administered after symptoms of botulism were already apparent, despite the fact that circulating toxin could still be detected in many of the animals.

Oberst et al. (1967) investigated the effectiveness of antitoxin therapy, artificial respiration, and supportive treatment in rhesus monkeys after IV type A toxin injection. These treatments were administered to the animals, either alone or in combination, after signs of intoxication were observed. Only one in six monkeys survived after receiving antitoxin injections alone as treatment for overt intoxication with 2.5 LD_{50} of type A toxin (Oberst et al., 1967). A combination of antitoxin therapy and supportive treatment initiated soon after the development of toxic signs protected 8 of 10 animals from death after i.v. injection of 4−5 LD_{50}. Artificial respiration prolonged survival in monkeys with respiratory paralysis but was ineffective as a primary treatment after lethal intoxication; no animals receiving only artificial respiration survived intoxication with 5−24 LD_{50} (Oberst et al., 1967). Untreated animals developed overt signs of intoxication within 20−38 h and died 32−135 h after toxin injection.

While antitoxin treatment was generally ineffective in experimental animals displaying significant clinical signs, several case studies of foodborne botulism indicated that antitoxin therapy remained potentially beneficial in humans even after the onset of illness. Iida et al. (1970) reviewed the high efficacy of antitoxin therapy in type E botulism outbreaks associated with contaminated fish consumption in Japan. A mortality rate of only 3.5% was observed among 85 antitoxin-treated patients in 9 recent foodborne botulism outbreaks, while a rate of 28.9% was reported among 135 untreated patients in 19 previous outbreaks. Iida et al. (1970) noted that all moderately and seriously ill patients in a 1962 foodborne type E botulism outbreak survived after antitoxin treatment. Hatheway et al. (1984) reported on the effectiveness of trivalent (ABE) antitoxin therapy during a 1978 outbreak of type A botulism. Four of seven patients with confirmed disease from type A toxin ingestion were treated with two to four vials of trivalent antitoxin (Hatheway et al., 1984). All four treated patients survived, although one of these individuals continued to suffer from severe paralysis and required ventilatory assistance for several months.

The current CDC therapy for the public is an FDA-approved, bivalent, botulinum equine antitoxin against serotypes A and B. The trivalent antitoxin against types A, B, and E is no longer available. In cases of exposure to any of the other botulinum toxin serotypes, the US Army can provide an investigational heptavalent (ABCDEFG) equine antitoxin, but the time required for typing a toxin subtype would limit its effectiveness in certain cases, such as an outbreak. A parenteral vaccine against the toxin is currently available, but the need exists for newer, nonparenteral vaccines that could be administered orally or via inhalation.

29.10.2 Treatment for infant botulism

Administration of equine antitoxin is not recommended for preexposure prophylaxis. The heterologous serum of antitoxin therapy can lead to a high frequency of adverse

reactions. The equine antitoxin available for use in humans has been reported to cause adverse reactions, such as anaphylaxis, in over 20% of treated patients (Lewis et al., 1980). This problem has been circumvented in the development of a safer approach to the treatment of infant botulism using plasma isolated from human subjects repeatedly immunized with pentavalent toxoid. Equine antitoxin is not used as a treatment for infant botulism due to the high risk of serious adverse reactions and the possibility of long-term sensitization to horse serum-based therapeutics (Arnon et al., 1998). An antiserum product termed BabyBIG (botulism immune globulin), derived from human volunteers immunized with pentavalent toxoid, is available for infant botulism patients. Intravenous BabyBIG therapy has proven extremely effective in counteracting the toxic effects of *C. botulinum* colonization in infants and in avoiding the risk of adverse reactions to equine antitoxin. It is also most effective when administered within 24 h of a high-dose aerosol exposure to the toxin (Gelzleichter et al., 1998a,b).

29.10.3 Vaccines

There are as yet no FDA-approved vaccines to prevent botulism. An investigational pentavalent botulinum toxoid (PBT) product, developed at Fort Detrick, Maryland, is available for persons at risk for botulism (i.e., laboratory workers and soldiers). While determined to be safe and immunogenic, PBT is not useful, nor is it recommended, for postexposure prophylaxis. Antitoxin titers do not develop until a month after the third dose in the vaccine schedule. PBT is reserved for employees at high risk for BoNT exposure, not for the general population. Several factors limit the usefulness of PBT as a vaccine for inoculating the general population. These include a declining potency and immunogenicity in recent years, the need to take multiple doses to maintain titers, and the limited supply of the vaccine.

29.11 Concluding remarks and future directions

The toxicity of botulinum toxins leading to paralysis is due to their ability to block ACh release from peripheral cholinergic nerve endings (Simpson, 2004). Once ingested or inhaled, the toxin binds to epithelial cells, transports to target tissues via the circulatory system, targets the NMJ, and penetrates cellular and intracellular membranes. BoNTs bind to the lipid bilayer of the neuronal cell surface, gain access by receptor-mediated endocytosis, and cleave polypeptides involved in exocytosis of ACh. As a result, botulism leads to a descending flaccid paralysis, starting usually in the bulbar musculature to involve deficits in sight, speech, and swallowing. Paralysis eventually progresses beyond CN palsies to include generalized muscle weakness and loss of critical accessory muscles of respiration. If untreated, death is inevitable from airway obstruction secondary to paralysis of pharyngeal, diaphragm, and accessory respiratory muscles, as well as loss of the protective gag reflex.

The CDC-recommended therapy for the public is a trivalent equine antitoxin against types A, B, and E. In cases of exposure to other BoNT serotypes, the US Army can provide an investigational heptavalent (ABCDEFG) antitoxin. However, the antitoxins are in limited supply and would need to be retrieved from stockpiles. Therefore, the development of safe and effective postexposure therapeutic compounds for BoNT intoxication is of paramount importance to serve the requirements of the military and civilian populations. In conjunction with drug-discovery efforts, there is a parallel exigency to develop appropriate animal models to test the usefulness of various strategies for protection against BoNT intoxication.

29.11.1 Development of animal model test systems

29.11.1.1 Inadequacies of current animal model test systems

Currently, a large number of animal models (mice, rats, guinea pigs, rabbits, and nonhuman primates) have been used for BoNT research, and it is not clear which species is the most appropriate. This is especially problematic since there are marked species differences in the relative potencies of the different serotypes and in their latency of action (the effect of BoNT/B in mice, rabbits, or guinea pigs vs rats; Erdal et al., 1995; Hilmas et al., 2006a). Mice, in particular, are desirable in BoNT research because they offer the most favorable balance between the scientific needs of the experiment and consistency with the existing literature. A variety of mouse strains and sexes have been used for other BoNT studies. The mouse LD_{50} is still used to quantitate the purity of BoNT batches and is the basis of the international standard used in serum neutralization assays of BoNT antitoxin. The mouse phrenic nerve–hemidiaphragm assay has been used to measure the effect of BoNTs on skeletal muscle contraction, and the doses necessary for inhibition are well characterized. The mouse has further advantages over other rodent species like rats.

Rats are not a valuable test system for BoNTs, as they are widely recognized as being insensitive to serotype B (Verderio et al., 2006). On the other hand, skeletal muscles of CD-1 mice, Hartley guinea pigs, and New Zealand White rabbits have similarities to humans, in that their muscles are sensitive to serotypes A, B, C, D, and E (Hilmas et al., 2006b). In vivo and in vitro physiological

assessments of BoNT action in rat have also proved to show inconsistent and erroneous results. In vivo experiments using the rat extensor digitorum longus (EDL) muscle assay showed sensitivities of rat muscle to the B serotype at low doses (10 MU, corresponding to approximately 1−10 pM) (Adler et al., 1996), despite the wide body of literature on the rat to the contrary. In addition, ex vivo rat phrenic nerve−hemidiaphragm preparations are insensitive to BoNT/B, even at very high concentrations in the nanomolar range (Williams et al., 2007).

Another physiological model to evaluate therapeutic candidates against BoNT intoxication is the rat toe spread assay. The rat toe spread assay is problematic as a model test system, however. First, it will not allow for the evaluation of therapeutic candidates against the B serotype since rats are insensitive to BoNT/B. Second, the rat toe spread assay does not involve focal application of BoNT; neighboring muscles are paralyzed due to local diffusion of toxin from the site of i.m. injection. Toe spread in the rat is mediated predominantly by digiti minimi abductor muscles and to a lesser extent by the EDL, the actual muscle injected in the assay. Intramuscular injection of rat EDLs with BoNT will primarily paralyze the EDL and, to a lesser extent, the digiti mini muscles, the true abductors of toe spread, by local diffusion. Therefore, EDL muscles injected with BoNTs would tend to show an erroneously early recovery of toe spread as the primary effectors of toe spread recover sooner compared to injected EDL muscles. To date, there is no acceptable in vivo model to test the efficacy of inhibitory compounds.

29.11.1.2 Advantages of the mouse hemidiaphragm assay

Current approaches to the inhibition of BoNT activity involve a number of strategies, each with potential advantages and disadvantages. Ultimately, model test systems that can incorporate each of these potential approaches are needed to evaluate the relative merit of potential therapeutic compounds. Since the presynaptic terminal is the primary target for BoNTs, a test system based on toxin action at presynaptic terminals is indicated. Such systems should permit testing of all relevant aspects of toxin (internalization, activity, and overcoming the inhibition of transmitter release), should be simple and reliable, and should permit rapid evaluation of novel therapeutics or their precursor compounds.

Due to the high sensitivity of mammalian synapses to the actions of BoNTs, due in part to the presence of high-affinity binding sites for toxin on the cell surface and to the intracellular presence of the appropriate enzymatic substrates, the test model systems should be of mammalian origin. Muscle is the ideal test system for BoNT since it is the most sensitive in vivo target for neurotoxin action. In addition, inhibition of the diaphragm muscle is the proximal cause of death in botulism (Simpson, 1986). Furthermore, a positive result with BoNT on muscle implies that the toxin is correctly folded and the binding, catalytic, and translocation domains are all intact. Enzyme-linked immunosorbent assays (ELISAs), on the other hand, detect only components of the toxin and may provide positive results when the toxin has in fact lost its ability to intoxicate (Kalb et al., 2005). The mouse phrenic nerve−hemidiaphragm assay is a favorable model test system to evaluate therapeutics against BoNT-induced paralysis.

Chapter 30

Onchidal and fasciculins

Arturo Anadón[1], María-Rosa Martínez-Larrañaga[1] and Luis G. Valerio[2]
[1]Department of Pharmacology and Toxicology, Faculty of Veterinary Medicine, Complutense University of Madrid, Madrid, Spain,
[2]Toxicology Expert, Ellicott City, MD, United States

30.1 Introduction

Onchidal and fasciculins are natural toxins that produce their toxicity in mammalian systems primarily by virtue of acetylcholinesterase (AChE) inhibition. AChE hydrolyzes acetylcholine (ACh), thereby regulating the concentration of the transmitter at the synapse. Termination of activation normally depends on dissociation of ACh from the receptor and its subsequent diffusion and hydrolysis, except in diseases where ACh levels are limited or under AChE inhibition, conditions that increase the duration of receptor activation (Silver, 1963).

The toxins and toxicants that inhibit AChE are called *anticholinesterase (anti-ChE)* agents. They cause accumulation of ACh in the vicinity of cholinergic nerve terminals, and thus, are potentially capable of producing effects equivalent to excessive stimulation of cholinergic receptors throughout the central nervous system (CNS) and peripheral nervous system (Long, 1963). Nevertheless, several members of this class of compounds are widely used as therapeutic agents; others that cross the blood–brain barrier (BBB) have been approved or are in clinical trial for the treatment of Alzheimer's disease (AD). The treatment approaches in the neurodegenerative pathology of AD continue to be primarily symptomatic, with the therapeutic strategies based on the cholinergic hypothesis, and specifically on AChE inhibition (Lane et al., 2004).

AChE can be classified in several ways. Mechanistically, it is a serine hydrolase. Its catalytic site contains a catalytic triad—serine, histidine, and an acidic residue—as do the catalytic sites of the serine proteases (such as trypsin), several blood clotting factors, and others. However, the acidic group in AChE is a glutamate, whereas in most other cases, it is an aspartate residue. The nucleophilic nature of the carboxylate is transferred through the imidazole ring of histidine to the hydroxyl group of serine, allowing it to displace the choline moiety from the substrate, forming an acetyl-enzyme intermediate. A subsequent hydrolysis step frees the acetate group. Understanding of the catalytic properties of the protein has assisted in our understanding of its inhibition by organophosphate (OP) and carbamate (CM) inhibitors. However, several questions remain to be answered regarding AChE catalysis, such as the mechanism behind the extremely fast turnover rate of the enzyme (Fair et al., 1994). Despite the fact that the substrate has to navigate a relatively long distance to reach the active site, AChE is one of the fastest-reacting enzymes (Nair et al., 1994). One theory to explain this phenomenon has to do with the unusually strong electric field of AChE. It has been argued that this field assists catalysis by attracting the cationic substrate and expelling the anionic acetate product (Ripoll et al., 1993). Site-directed mutagenesis, however, has indicated that reducing the electric field has no effect on catalysis. However, the same approach has indicated an effect on the rate of association of fasciculin, a peptide that can inhibit AChE and produce muscle fasciculations (Shafferman et al., 1994).

Naturally occurring irreversible inhibitors of AChE are toxins that are often selective inhibitors of protein function, and this property can often be exploited for a variety of purposes (Pita et al., 2003). For instance, physostigmine (also called eserine), is a naturally occurring alkaloid reversible inhibitor of AChE that has been used in understanding the kinetic mechanism of AChE. Through its action at both the central and peripheral cholinergic receptors, physostigmine reverses anticholinergic activity and ameliorates the coma, delirium, and seizures that accompany severe toxicity. Antidotes for such poisoning have been developed to accelerate enzyme regeneration. The slow reactivation of AChE is the basis of the use of physostigmine and pyridostigmine (a physostigmine derivative) as a prophylactic in anticipation of the

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00030-1

use of these toxins. It is argued that the psychological stress associated with warfare impaired the integrity of the BBB, allowing the peripheral-acting inhibitor of AChE to penetrate the brain, where it activated AChE transcription (Kaufer et al., 1998). For further details on toxins/toxicants and the BBB, see Chapter 48, Blood–brain barrier damage and dysfunction by chemical toxicity.

30.2 Background

This chapter covers natural agents that prolong the existence of ACh after it is released from cholinergic nerve terminals. Natural toxins are chemical agents of biological origin (including chemical agents and proteins), and can be produced by all types of organisms; such is the case for onchidal and fasciculins. Although a chemical and a protein, respectively, onchidal and fasciculins share the same toxic effect of inhibiting AChE, which is concentrated in synaptic regions and is responsible for the rapid catalysis of the hydrolysis of ACh. As such, the natural toxins onchidal and fasciculins can produce disorders of neuromuscular transmission that are clinically categorized as either presynaptic or postsynaptic; some toxins simultaneously affect both sites. Chemical agents associated with neuromuscular transmission syndromes include the fasciculins, crotoxin, taipoxin, tubocurarine, and OP compounds (Anadón and Martínez-Larrañaga, 1985).

These aforementioned natural anti-ChE agents can be developed for a different purpose, including extensive application as toxic agents (i.e., potential chemical weapons). One of the first interesting structures with cholinergic properties isolated from a marine source is onchidal. This compound was first isolated from the mollusk *Onchidella binneyi* and has an acetate ester similar to ACh. Upon isolation, onchidal was discovered as being an active, site-directed, and irreversible inhibitor of AChE (Abramson et al., 1989).

Neurotoxins from snake venoms have proved to be valuable tools for the understanding of synaptic transmission mechanisms. Likewise, the powerful inhibitory action of fasciculins against mammalian AChE makes them potentially useful for pharmacological and neurochemical research. Studies of their biochemical and electrophysiological effects on the CNS and biochemical characterization are now being carried out.

Natural toxins can be extremely potent, and many of them are effective at far lower dosages than conventional chemical agents. Natural toxins, as compounds of biological origin, are often classed as biological agents, but they are not infectious and are more similar to chemicals with respect to their military potential for tactical use; therefore, they should be considered to be chemical agents that could be used for warfare. The Chemical Weapons Convention (CWC 2003) (available at www.fas.harvard.edu/~hsp/cwc/cwcbyart.html) also includes natural toxins as chemical agents, specifically including the onchidal and fasciculin toxins in its control regime, along with other highly toxic chemicals.

30.2.1 Onchidal

Onchidal is a toxic component of a poisonous marine opisthobranch mollusk. Like other opisthobranchs, the *Onchidiacea* family of mollusks does not have the protection of a hard external shell as most mollusks do. They rely instead on the production of a defensive secretion. When the animal is disturbed, it emits a viscous fluid from specialized glands. In two species of *Onchidella* (*Onchidella floridanun* and *Onchidella borealis*), this defensive secretion has been shown to act as a deterrent to potential predators, including fish and crabs. Chemically, it is a simple lipophilic acetate ester (Fig. 30.1).

Onchidal has been identified as the major lipid-soluble component of the defensive secretion of mollusk *O. binneyi*, and it has been proposed as the compound responsible for the chemical protection of *Onchidella* species. *O. binneyi* is an opisthobranch mollusk that inhabits the rocky intertidal zone near the area of Baja California, Mexico. The defensive secretion was obtained in the field by squeezing the mollusk and collecting the mucus discharge in capillary tubes, exhibiting biological properties including feeding deterrence, and antibacterial and anticholinesterase activities. Large quantities of this material could be obtained after the extraction of intact animals with acetone (Ireland and Faulkner, 1978). However, the distribution of onchidal in different species of *Onchidella* was not reported and, apart from inhibiting the growth of *Staphylococcus aureus* (the IC_{50}value was between 0.21 and 0.63 μg/mL), which implies that onchidal is a potent inhibitor of Gram-positive microorganisms, no biological activity of onchidal was described. Additional studies demonstrated that onchidal is contained in several different species of *Onchidella* and that, once purified, it is toxic to fish (Abramson et al., 1989). Onchidal can be found in four of the eight known species of *Onchidella*

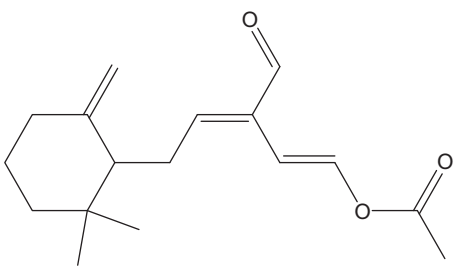

FIGURE 30.1 The chemical structure of onchidal.

collected from different countries (Table 30.1). In addition, the Abramson study found onchidal to be toxic to goldfish. Although goldfish are not potential predators of *Onchidella*, these results demonstrate that onchidal has a distribution and a biological activity consistent with its proposed role in the chemical defense of *Onchidella*.

30.2.2 Fasciculin

The venom of the eastern green mamba snake (*Dendroaspis angusticeps*, *Dendroaspis polylepis*, *Dendroaspis viridis*, *Dendroaspis jamesoni*), with a habitat almost exclusively arboreal, belongs to the three finger toxin family (3FTx), and contains a mixture of neurotoxic compounds, including postsynaptic cholinoreceptor α-neurotoxins, dendrotoxins, fasciculins, and muscarinic toxins (Hawgood and Bon, 1991). Forty-two different proteins were identified in the venom of *D. angusticeps*, in addition to the nucleoside adenosine. The most abundant proteins belong to the 3FTx (69.2%) and the Kunitz-type proteinase inhibitor (16.3%) families. Several subsubfamilies of the 3FTxs were identified, such as Orphan Group XI (Toxin F-VIII), AChE inhibitors (fasciculins), and aminergic toxins (muscarinic toxins, synergistic-like toxins, and adrenergic toxins) (Lauridsen et al., 2016). No α-neurotoxins were identified. Proteins of the Kunitz-type proteinase inhibitor family include dendrotoxins (Lauridsen et al., 2016). Effects at the NMJ include AChE inhibition by fasciculins and increased presynaptic release of ACh by dendrotoxins (polypeptides that facilitate ACh release in response to nerve stimulation; inhibit voltage-gated KV11, KV12, and KV16 potassium channels and block muscarinic receptors); together with the high ACh content of mamba toxin (6−24 mg/g), these effects are synergistic and enhance neurotoxicity and lethality. Moreover, the venom may contain other components that have a synergistic action with dendrotoxin.

Toxins that facilitate neuromuscular transmission are a characteristic component of mamba venom. The four known fasciculins bind to a peripheral regulatory anionic site of AChE in a noncompetitive and irreversible manner (Hawgood and Bon, 1991). The dendrotoxins comprise the second group of facilitatory neurotoxins and are present in most mamba venom (with the exception of *D. jamesoni*); they inhibit voltage-dependent K^+ channels in motor nerve terminals and facilitate ACh release at the NMJ. Postsynaptic toxins present in mamba venom bind to and block nicotinic acetylcholine receptors (nAChRs). The muscarinic toxins present in mamba venom are small proteins (7 kDa) that selectively bind to muscarinic cholinergic receptors and may constitute up to 1% of the venom protein (Adem and Karlsson, 1985; Jerusalinsky and Harvey, 1994). About 12 muscarinic toxins have been isolated. M1 toxin binds noncompetitively and with high affinity to the M_1 muscarinic receptor subtype. MTx1 and MTx2 show high affinity for both muscarinic M_1 and M_3 receptors; little is known about the receptor selectivity of MTx3 and MTx4. Dpα and Dpβ are also muscarinic agonists, displaying similar affinity for both the M_1 and M_2 receptor subtypes. The last two agonists, DpMTx and DvMTX, are selective muscarinic agonists present in the venom of some mamba species; these agonists also show affinity for the M_1 muscarinic receptor subtype.

The fasciculins are a family of closely related ~6750-Da peptides isolated from the venom of mambas (genus *Dendroaspis*), and are named after the long-lasting muscle fasciculations they produce in mice (Rodriguez-Ithurralde et al., 1983). They are potent and selective inhibitors of AChE. Fasciculins are 61-residue-long polypeptides. They share a three-looped structural motif with other toxins, such as α-neurotoxins, cytotoxins, and muscarinic toxins, directed to diverse specific targets. Four fasciculins are known (Table 30.2), which differ only by one to three residues and show selective and potent anti-AChE activity: Fas1 and Fas2 from the venom of *D. angusticeps* (the Eastern green mamba) contains 61 amino acid residues, including eight half-cystines (Rodriguez-Ithurralde et al., 1983), ToxC from the venom of *D. polylepis polylepis* (the black mamba, with a primarily terrestrial habitat) (Joubert and Taljaard, 1978), and Fas3, which was isolated from a particular batch of *D. viridis* (the Western green mamba) venom and found to have the same primary structure as ToxC (Marchot et al., 1993). No fasciculin has been found in other *D. viridis* venoms (Marchot et al., 1993), or in *D. jamesoni* (Jameson's mamba).

TABLE 30.1 Concentration of onchidal in different species of *Onchidella* (Abramson et al., 1989).

Organism	Collection site	Onchidal concentration (μg/animal)
Onchidella binneyi	Baja California, Mexico	230
Onchidella borealis	Central California, USA	33
Onchidella nigricans	New Zealand	18
Onchidella patelloides	Australia	42

TABLE 30.2 Types of fasciculin identified.

Fasciculins characterized	From the mamba snake venoms (Elapidae family) (*Dendroapsis* genus)
Fas1	*Dendroaspis angusticeps* (Eastern green mamba)
Fas2 (formally F_7 toxin)	*Dendroaspis angusticeps* (green mamba)
Fas3 (formally Toxin C)	*Dendroaspis polylepis* (black mamba)
Fas4	*Dendroaspis viridis* (Western green mamba)

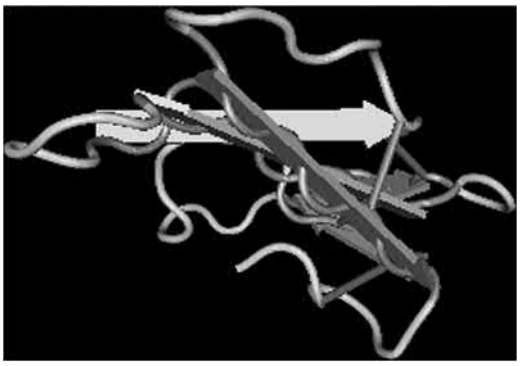

FIGURE 30.2 The 3-D protein structure of Fas1 derived from green mamba (*Dendroaspis angusticeps*) snake venom. *Obtained from the public domain at the U.S. National Library of Medicine, National Center for Biotechnology Information, MMDB.*

Angusticeps-type toxins constitute a group of toxins typical for mamba venoms. They consist of 59−61 amino acid residues and four disulfides, and show sequence homology with short-chain postsynaptic toxins and cardiotoxins, but they are immunochemically distinct from these toxins. Eight toxins of this type have been sequenced and structurally classified into four subgroups (Joubert and Taljaard, 1978). Pharmacological studies on these *angusticeps*-type toxins have revealed that only toxins F_7 and C, which belong to subgroup I, exhibit a potent inhibition of cholinesterase (ChE) of various tissues, except for that of chick skeletal muscle. Both F_7 and C stimulate mouse and toad skeletal muscles by their anti-ChE activity, as well as possibly by facilitating ACh release from nerve terminals (Lee et al., 1985). Fasciculins account for 3%−6% of the venom protein, and the relative proportion between Fas1 and Fas2 is about one-third (Cerveñanský et al., 1994).

The structural similarity between onchidal (an acetate ester) and ACh suggested that the toxicity of onchidal could result from inhibition of either nAChRs or AChE. Although onchidal (1.0 mM) did not prevent the binding of ^{125}I-α-bungarotoxin to nAChRs, it inhibited AChE in a progressive, apparently irreversible manner. The apparent affinity of onchidal for the initial reversible binding to AChE (K_d) was approximately 300 μM, and the apparent rate constant for the subsequent irreversible inhibition of enzyme activity (K_{inact}) was approximately 0.1 min^{-1}.

Fasciculins are a family of closely related peptides that are isolated from the venom of mambas and exert their toxic action by inhibiting AChE. The crystal structure of Fas2 from green mamba (*D. angusticeps*) snake venom was first resolved in 1992 (Le Du et al., 1992). The three-dimensional structure of Fas1, obtained from the US National Library of Medicine, National Center for Biotechnology Information, Molecular Modeling Database 3-D Structure Database (MMDB), is illustrated in Fig. 30.2.

Fasciculins belong to the structural family of three-fingered toxins from Elapidae snake venoms. Fasciculins selectively inhibit mammalian AChE with Ki values in the picomolar range and include the α-neurotoxins that block the nAChR and the cardiotoxins that interact with cell membranes. Elapid venoms contain AChEs, and typically affect peripheral nerves rather than the CNS because neurotoxins do not penetrate the BBB. The features unique to the known primary and tertiary structures of the fasciculin molecule were analyzed by Harald and colleagues (1995). Loop I contains an arginine at position 11, which is found only in the fasciculins and could form a pivotal anchoring point to AChE. Loop II contains five cationic residues near its tip, which are partly charge-compensated by anionic side chains in loop III. In contrast, the other three-fingered toxins show full charge compensation within loop II. The interaction of fasciculin with the recognition site on AChE was investigated by estimating a precollision orientation, followed by determination of the buried surface area of the most probable complexes formed, the electrostatic field contours, and the detailed topography of the interaction surface. This approach has led to testable models for the orientation and site of bound fasciculin.

30.3 Mechanism of action and biological effects

30.3.1 Onchidal

Onchidal belongs to the group of natural nonprotein neurotoxins and is an irreversible inhibitor of the AChE enzyme, with a novel mechanism of action. It has been suggested, however, that its toxicity could be a consequence of the inhibition of either nAChRs or the AChE enzyme. It was found that onchidal acts as an electrophile, reacting rapidly with the model nucleophile

n-pentylamine forming diasteromeric aminated pyrrole adducts. Onchidal and analogs reacted with the model protein lysozyme, forming covalent adducts and leading to protein cross-linking (Cadelis and Copp, 2018). The electrophilic reactivity of onchidal suggests a potential to induce DNA damage, which is discussed in Section 30.5.

Incubation of AChE with onchidal resulted in the production of acetate, demonstrating that onchidal was a substrate for AChE, and approximately 3250 mol of onchidal were hydrolyzed/mol of enzyme irreversibly inhibited. OP and CM inhibitors of AChE have partition ratios (mol of toxin hydrolyzed/mol of enzyme irreversible inhibited) that approach unit. Therefore, the relatively high partition ratio for onchidal suggests that the mechanism of inhibition utilized by onchidal may be distinctly different from other irreversible inhibitors (Walsh, 1984). The rate of hydrolysis of onchidal (K_{cat}) was 325 min^{-1}; this value is relatively slow, suggesting that onchidal is not a very good substrate. The ability of AChE to hydrolyze onchidal raised the question of whether inhibition of enzyme activity resulted from onchidal itself, or from a product of the enzymatic hydrolysis of onchidal. Enzyme kinetics revealed that onchidal was unable to completely inhibit higher concentrations of AChE. From the experiments performed by Abramson et al. (1989), onchidal was in molar excess and completely hydrolyzed. Thus, irreversible inhibition of enzyme activity resulted either from onchidal itself, or from a reactive intermediate produced during the hydrolysis of onchidal (Walsh, 1984).

In another investigation, irreversible inhibition of enzyme activity was prevented by co-incubation with reversible agents that either sterically block (edrophonium and decamethonium) or allosterically modify (propidium) the ACh site (Barnett and Rosenberry, 1977). Enzyme activity was not regenerated by incubation with oxime reactivators; therefore, the mechanism of irreversible inhibition does not appear to involve acylation of the active site serine.

Because onchidal is an acetate ester similar to ACh, and because cholinergic neurotransmission is often the site of action of natural products involved in chemical defense, Abramson et al. (1989) investigated the ability of onchidal to inhibit AChE and the nAChR. Although onchidal did not prevent the binding of ^{125}I-α-bungarotoxin to nAChRs, it was shown to be an active site-directed irreversible inhibitor AChE. The structure and pharmacology of onchidal suggest that inhibition of AChE results from a novel covalent reaction between onchidal and an amino acid within the ACh-binding site. The onchidal could potentially be exploited in the design of a new class of natural anti-ChE agents and in the identification of amino acids that contribute to the binding and hydrolysis of ACh.

30.3.2 Fasciculin

Various toxins in snake venoms exhibit a high degree of specificity in the cholinergic nervous system. The α-neurotoxins from the *Elapidae* family interact with the agonist-binding site on the nicotinic receptor. α-Bungarotoxin is selective for the muscle receptor and interacts with only certain neuronal receptors, such as those containing α7 through α9 subunits. Neuronal bungarotoxin shows a wider range of inhibition of neuronal receptors. A second group of toxins, the fasciculins, inhibits AChE. A third group of toxins, termed the *muscarinic toxins* (MT_1−MT_4), are partial agonists and antagonists for the muscarinic receptor. Venoms from the *Viperaridae* family of snakes and the fish-hunting cone snails also have relatively selective toxins for nicotinic receptors.

Other reversible inhibitors, such as propidium and fasciculin, bind to the peripheral anionic site on AChE. This site resides at the lip of the gorge and is defined by tryptophan 286 and tyrosines 72 and 124 (Taylor, 2001).

A large number of organic compounds reversibly or irreversibly inhibits AChE (Long, 1963), which binds either to the esteratic or the anionic subsite of the AChE catalytic site or to the peripheral site of the enzymes. Most are synthetic substances, sometimes with insecticidal properties. Few natural inhibitors of AChE are known and, to date, fasciculins are the only known proteinic AChE inhibitors. They have been shown to display a powerful inhibitory activity toward mammalian AChE. Iodination of Fas3 provided a fully active and specific probe of fasciculin-binding sites on rat brain AChE (Marchot et al., 1993). These authors demonstrate that fasciculins bind on a peripheral site of AChE, distinct from the catalytic site and, at least partly, common with the sites on which some cationic inhibitors and the substrate in excess bind; since phosphorylation of the catalytic serine (esteratic subsite) by [1,3-^{3}H]diisopropyl fluorophosphate can still occur on the Fas3. In the AChE complex, the structural modification induced by fasciculins may affect the anionic subsite of the AChE catalytic site.

Cholinesterases have a very different sensitivity toward fasciculins. AChEs from rat brain, human erythrocytes, and electroplax of electric eel (*Electrophorus electricus*) are inhibited by fasciculins with a Ki of about 10^{-11} M and pseudocholinesterases as human serum ChE are inhibited by fasciculins with a Ki of about 0.5 μM. A second group of enzymes is partially (10%−30%) inhibited by low concentrations (< 0.5 nM) of fasciculin. Increasing the concentration of fasciculins to a toxic level of about 1 nM inactivates the enzymes to 90%−110% of their initial activity. AChEs from guinea pig ileum, ventricle, and uterus behave similarly. A third group consists of enzymes insensitive to fasciculin; AChEs from chick

biventer cervicis muscle and brain and from insects, heads of *Musca domestica* (common housefly) and cobra (*Naja naja*) venom. The biochemical mechanism of fasciculins involves displacement of propidium from its binding site on AChE. Since propidium is a probe from a peripheral anionic site, it is concluded that fasciculins also bind to the same site. The different sensitivities of ChE to fasciculin should depend on the nature of their peripheral sites. Fasciculins are basic proteins of 61 amino acid residues and 4 disulfides, highly homologous to short α-neurotoxins and cardiotoxins. Indeed, a large number of AChE inhibitors are cations (e.g., neostigmine, physostigmine, and propidium).

The binding between fasciculin and AChE is strong, as indicated by a Ki of about 10^{-11} M. This should result from interaction of several amino acid residues in the toxin with the enzyme. A modification of one of these residues should not abolish the activity, but it should significantly decrease it. However, the decrease in activity can also depend on structural perturbations caused by the modification. Chemical modification and structural data suggest that Lys32 and Lys51 have a functional role (Cerveňanský et al., 1994). This author acetylated the amino groups of Fas2 with acetic anhydride. The monoacetyl derivatives of the ε-amino acids (Lys25, Lys32, Lys51, and Lys58) retained between 28% and 43% of the initial activity, and that of the α-amino group retained 72%. Acetylation of Lys25 that has the most reactive amino group decreased the activity by 65%, apparently without producing structural perturbation since the circular dichroism spectrum was not affected. The three-dimensional structure shows a cationic cluster formed by Lys32, Lys51, Arg24, and Arg28. A comparison of 175 sequences of homologous toxins shows that Lys32 is unique for fasciculin. Acetylation of lysine residues in the cluster had a large effect and reduced the activity by 72% (Lys32) and 57% (Lys51).

Fasciculins inhibit AChE from mammals, electric fish, and some snake venoms with Ki values in the picomolar to nanomolar range; in contrast, the AChEs of avian, insect, and some other snake venoms are relatively resistant, and high micromolar concentrations are required to inhibit mammalian butyrylcholinesterases (BuChE) (Marchot et al., 1993). Dissociation constants of Fas1 and Fas3 are twofold and 60-fold lower, respectively, than that of Fas2 for synaptosomal rat brain.

An examination of fasciculin association with several mutant forms of recombinant deoxyribonucleic acid (DNA)-derivated AChE from mice shows that it interacts with a cluster of residues near the rim of the gorge on the enzymes; the aromatic residues, Trp286, Tyr72, and Tyr124, have the most marked influence on fasciculin binding, whereas Asp74, a charged residue in the vicinity of the binding site that affects the binding of low-molecular-weight inhibitors, has little influence on fasciculin binding. The three aromatic residues are unique to the susceptible AChE and, along with Asp74, constitute part of the peripheral anionic site. Fasciculin falls into the family of three-loop toxins that include the receptor-blocking α-toxins and cardiotoxins. A binding site has evolved on fasciculin to be highly specific for the peripheral site on AChE. Acetylthiocholine affects rates of fasciculin binding at concentrations that cause substrate inhibition. In the case of the mutant ChE, where rates of fasciculin dissociation are more rapid, steady-state kinetic parameters also show ACh−fasciculin competition to be consistent with occupation at a peripheral or substrate inhibition site rather than the active center (Radic et al., 1994).

Fasciculin-induced inhibition of AChE is prevented by chemical modification of the enzyme at a peripheral site (Durán et al., 1994). The specific interaction of Fas2 with peripheral sites present in *E. electricus* AChE (Ki; 0.04 nM fasciculin) was investigated by chemical modification with *N*,*N*-dimethyl-2-phenylaziridium in the presence of active or peripheral anionic site protective agents. An enzyme was obtained that was compared to native AChE and was 10^6 times less sensitive to Fas2. This enzyme was fully inhibited by edrophonium and tacrine and was 25−170 times less sensitive to several peripheral site ligands. It seems Fas2 binding to an AChE peripheral site partially overlaps the site of other peripheral site ligands, including ACh.

30.4 Experimental and human toxicity

30.4.1 Experimental

Administration of Fas1 and Fas2 to mice at doses of 1−3 mg/kg and 0.05−2.0 mg/kg, respectively, after intraperitoneal (i.p.) injection caused severe, generalized, and long-lasting fasciculations (5−7 h), followed by gradual recovery to normal behavior. In vitro preincubation with fasciculins at concentrations of 0.01 μg/mL inhibited brain and muscle AChE up to 80%. Histochemical assay for AChE showed an almost complete disappearance of the black-brown precipitate at the neuromuscular endplate after in vitro incubation with fasciculins. Fasciculins represent a new type of AChE inhibitor exerting muscle fasciculations through a powerful inhibition of enzyme activity at the neuromuscular endplate, interfering with the normal hydrolysis of ACh molecules. Fasciculins have also been demonstrated to be powerful inhibitors of brain AChE (Rodriguez-Ithurralde et al., 1983).

The cause of death due to toxin F_7, an *angusticeps*-type toxin isolated from the venom of *D. angusticeps*, was studied in anesthetized mice (Lee et al., 1986). The carotid arterial blood pressure, electrocardiography, and the respiratory movements were recorded. Within a few

minutes after intravenous (i.v.) injection of F_7 (1 mg/kg), both the rate and amplitude of the respiratory movements decreased, and respiratory arrest took place within 15 min in most cases. Before respiratory arrest, marked bradycardia with various types of arrhythmia and oscillation of blood pressure were observed. Artificial ventilation could abolish these cardiovascular changes and maintain the blood pressure for a long period. Toxin F_7 caused a transient and slight increase in arterial blood pressure, which could be prevented by hexamethonium. Intracisternal application of toxin F_7 (1 mg/kg) caused long-lasting hypertension and bradycardia and the respiratory arrest time was significantly longer than after i.v. injection. A large dose (50 mg/kg, i.p.) of atropine, but not smaller doses (5−10 mg/kg), protected mice against respiratory failure induced by toxin F_7.

In rats, the phrenic nerve discharge was prolonged during respiratory depression. Since the toxin F_7 has a potent anti-ChE activity, it is concluded that the respiratory failure induced by toxin F_7 is peripheral in origin; this was chiefly, if not entirely, due to its anti-ChE activity. Despite its lack of α-neurotoxins, the venom of *D. angusticeps* is quite effective in killing mice rapidly after injection, as observed in acute toxicity experiments with crude venom, where the controls receiving 4 LD_{50s} of venom on average died within 10 min. Previous studies have highlighted two main toxic activities when *D. angusticeps* whole venom is tested in experimental systems. On various nerve-muscle preparations, this venom augmented the responses to indirect stimulation (Barrett and Harvey, 1979), possibly due to the combined action of dendrotoxins and fasciculins. Thus, the combined action of the various neurotoxin types present in *D. angusticeps* venom may result in a complex series of neuromuscular and cardiovascular effects. The combined action of these toxins results in effective prey immobilization despite the absence of the action of α-neurotoxins. The observation of this mixture's toxicity, that likely involves synergistic effects among the toxins, complicates the selection of the most relevant toxins toward which antibodies should be raised in order to abrogate venom toxicity (Lauridsen et al., 2016).

Strydom (1976) performed the purification of *D. polylepis polylepis* venom and found 12 low-molecular-weight proteins, of which 11 have subcutaneous LD_{50} values of less than 40 μg/g in the mouse. Clinically, mamba bites may not provoke a major local reaction. If neurotoxins are injected by the bite, clinical symptoms appear within minutes to hours.

30.4.2 Human

Envenomation by mambas cause rapid onset of perioral and generalized paresthesias, nausea, vomiting, hypersalivation, and hyperacusis followed by generalized weakness, ptosis, dysphagia, diaphoresis, goose flesh, and drowsiness. Despite a low number of human envenomations reported, *D. angusticeps* is classified as a "category 1" snake, which is the highest level of medically important snakebites, according to the WHO (WHO, 2016). Elapids are present in restricted areas of Africa. In particular they are found with high abundance in Kenya, Tanzania, Mozambique, Malawi, Eastern Zimbabwe, and the Republic of South Africa. Consequently, this snake species is of high epidemiological relevance to the region (WHO, 2016). Clinical features of severe envenomation by *D. angusticeps* can lead to rapid mortality within only 30 min of a bite (Spawls and Branch, 1995). The typical clinical manifestations include swelling of the bitten area, dizziness, nausea, difficult breathing, irregular heartbeat, and respiratory paralysis (Spawls and Branch, 1995). These life-threatening symptoms may escalate rapidly, but deaths are rare when effective antivenom is administered in a timely fashion. Clinical signs of impairment of neuromuscular transmission (ptosis, ophthalmoplegia, bulbar symptoms, or generalized weakness) dictate administration of antivenom (Ludolfph, 2000). The venom of *Elapidae* (coral snakes), is known to be a potential neurotoxin and may cause paresthesias, weakness, cranial nerve dysfunction, confusion, fasciculations, and lethargy. Often mild local findings, diplopia, ptosis, and dysarthria are common early symptoms. Patients die because of respiratory paralysis. In these cases, early and aggressive airway management is vital. Symptoms may be delayed by 8−12 h (Cameron, 2006).

Given the medical importance of *D. angusticeps*, it is necessary to have a thorough understanding of the composition of its venom, as well as of the underlying mechanisms for venom pathophysiology in human victims. Furthermore, preclinical assessment of antivenoms is critical for predicting the efficacy of snakebite envenoming therapy, which may be used to guide clinicians in the treatment of snakebites by *D. angusticeps*. Currently, only the SAIMR Polyvalent Snake Antivenom from the South African Vaccine producers is claimed to be effective against *D. angusticeps*. However, it is possible that other polyvalent antivenoms raised against the venoms of other mamba species may be effective in neutralization of *D. angusticeps* venom. The venom of *D. angusticeps* has not undergone a full proteomics evaluation, and its quantitative protein composition is not known. Nevertheless, several biochemical and pharmacological studies have been performed on different toxins from *D. angusticeps* venom (Harvey, 1990). These studies report that this venom contains several neurotoxins, such as the fasciculins and dendrotoxins (Harvey, 1990; Harvey and Anderson, 1991; Cerveñansky et al, 1991), which are unique to the *Dendroaspis* genus. This venom also

contains a number of other toxins of the three-finger toxin family (3FTx), such as muscarinic toxins, adrenergic toxins, and synergistic-type toxins (Blanchet et al, 2014).

30.5 Computational toxicology assessment

Toxicity databases and computer-assisted (in silico) computational predictive toxicology modeling are now becoming increasingly important to risk assessors when risk assessment of a chemical using experimental animal toxicological studies is unclear because the data are equivocal or even absent (Valerio, 2009; Bailey et al., 2005; Arvidson et al., 2008). There are many reasons for the development of in silico toxicology systems. Over 10 years ago a law passed by the European Union called Registration, Evaluation, Authorization, and restriction of Chemicals (REACH), entered into force on June 1, 2007. The goal of this regulation was to identify and more effectively avoid the risks that the toxic properties of chemicals pose to humans and the environment (Lahl and Gundert-Remy, 2008). Under REACH, firms that manufacture or import more than 1 ton of a chemical substance per year in the European Union are required to assess the chemical's potential toxicological or environmental adverse effects, and to register this information in a central database (Saiakhov and Klopman, 2008). REACH has had an impact on the widespread use of computational predictive modeling because it rules that no animal test should be used if it can be replaced with other techniques, such as reliable computer-based predictions (Lahl and Gundert-Remy, 2008; Saiakhov and Klopman, 2008). Therefore, the use of computer-assisted computational predictive toxicology software has attracted considerable attention worldwide because when applied under the appropriate circumstances, it is consistent with the 3Rs (reduce, refine, replace) concept for animal testing.

Since the acute and chronic toxic potentials of onchidal in experimental animal studies are rather limited, strategies using in silico assessment of its toxic potential could be envisioned. Computational-based strategies with pharmaceuticals and natural product toxins have already been developed for use in safety evaluation and risk assessment (Valerio, 2009, 2013; Valerio et al., 2007, 2013; Arvidson et al., 2010; Demchuk et al., 2008; Bailey et al., 2005; Valerio and Cross, 2012; Choi et al, 2013; Valencia et al, 2013). These strategies can be considered for an in silico risk assessment of onchidal. The electrophilic properties reported for onchidal (Cadelis and Copp, 2018), and as illustrated on its molecular structure (Fig. 30.1), raises the question of whether the structural features are associated with genotoxicity or carcinogenicity. Computational toxicology predictive systems were developed as an extension of Ashby-Tennant alerts that were based on compounds many of which bear electrophilic moieties. Therefore, the potential of onchidal to act as a mutagenic agent through direct DNA reactivity could be assessed using a computational model for DNA reactivity (i.e., an Ames test). One approach is to combine different predictive models for the same toxicological endpoint to determine if a consensus prediction regarding the mutagenic or other toxicological effects measured by a computer model is possible.

There are computational software that employ human rule-based approaches with software that utilize statistical algorithm-based predictions using quantitative structure−activity relationship (QSAR) models for the toxic potential of the compound of interest. There are computational models which are not based on a statistical association and these are referred to as structure−activity relationship (SAR) human expert systems, as predictions arise from the coding of a set of human expert knowledge into rules (i.e., structural alerts). If the outcome from a QSAR and SAR structural assessment with expert interpretation is negative, this can indicate that the assessment is sufficient to conclude there is no concern and to treat the compound as negative for the toxicological endpoint. If the outcome from the complementary in silico QSAR and SAR assessments is positive, then the compound could raise a concern to an assessor and potentially be prioritized for further standardized genetic toxicology testing or simply inform the risk assessment procedure.

The use of in silico toxicology methods has taken a real practical role and utility as a tool in facilitating decisions in chemical risk assessment. There are a variety of computational toxicology predictive software and data-mining databases available at either no cost or commercially for a fee (Choi et al., 2013; Valencia et al., 2013; Richard et al., 2008; Marchant et al., 2008; Saiakhov and Klopman, 2008; Shi et al., 2008; Mostrag-Szlichtyng et al., 2010). However, the information obtained from a predictive and data-mining in silico assessment must be used judiciously in order to serve its true purpose, which is to inform and support decision making as hazard identification is needed (Valerio, 2012; Arvidson et al., 2010).

In order to assess the potential toxicological effects of onchidal from a predictive computational toxicology standpoint, the author subjected the two-dimensional molecular structure of onchidal (1) to an in silico QSAR and SAR computational analysis using open source software; Toxtree 3.1.0 (toxic hazard estimation by decision tree approach) and VEGA-QSAR 1.1.4 The toxicological endpoints predicted by the Toxtree computational SAR assessment system included the in vitro mutagenicity (Ames test) alerts by ISS, and carcinogenicity (genotox and nongenotox) and mutagenicity rule base by ISS. The QSAR models employed that are available by

TABLE 30.3 The two-dimensional molecular structure of onchidal was analyzed by Toxtree (3.1.0) and VEGA-QSAR (1.1.4) computational software.

Model	Alert or prediction
Toxtree: In vitro mutagenicity (Ames test) alerts by ISS	QSA10 Ames α,β-unsaturated carbonyls
Toxtree: Carcinogenicity (gentox and nongenotox) and mutagenicity rule base by ISS	QSA24 gen a,b unsaturated alkoxy, structural alert for genotoxic carcinogenicity
VEGA-QSAR: Mutagenicity (Ames test) CONSENSUS model	Mutagenic score = 0.28 representing low to good reliability
VEGA-QSAR: Carcinogenicity model (IRFMN/ Antares)	Noncarcinogenic two of six compounds in the training set which are highly similar to onchidal are noncarcinogenic. Four similar compounds in the training set are carcinogenic but their structural similarity is low

Toxtree uses a knowledge base of human expert rules encoded into a decision tree to perform a computational toxicology prediction on hazard for specific endpoints. VEGA-QSAR uses statistical and artificial intelligence approaches with chemical training sets that are used to construct the models (Benfenati et al., 2013). The data shown in the table indicate onchidal is theoretically predicted to be positive for mutagenicity in the Ames test using both SAR and QSAR, and negative for carcinogenicity using the QSAR approach, but fired an alert for carcinogenicity using the SAR method.

VEGA-QSAR were the mutagenicity (Ames test) consensus model 1.0.2 and carcinogenicity model (IRFMN/ Antares) 1.0.0 (Table 30.3).

These computational results show that onchidal is predicted to be of concern for bacterial mutagenicity (Ames test) in both the SAR and QSAR model systems. The structural alert that fired in Toxtree was an α,β-unsaturated alkoxy feature, and VEGA-QSAR used an ensemble of models of which the consensus was the compound would be mutagenic if tested. Toxtree indicated that the α,β-unsaturated alkoxy feature on the molecule is also alerting for carcinogenicity. However, VEGA-QSAR's specified modeling method did not predict the compound to be carcinogenic. The prediction indicated there are several compounds in the training set that are noncarcinogenic and two that are carcinogenic, thus the conflict amounted to an overall negative prediction due to the degree of similarity of onchidal with noncarcinogenic compounds.

Onchidal has anticholinesterase effects (Anadón and Martínez-Larrañaga, 1985). Tachycardia as a result of anticholinergic has been suggested to increase or lead to arrhythmias (e.g., with low-potency antipsychotics; Huffman and Stern, 2003), and this could call for further analysis using additional specialized QSAR/SAR models designed for alerting to cardiovascular toxicity.

Overall, these in silico/computational toxicology models, as well as many others, are growing in interest of enhancing hazard identification of compounds where there is human exposure and data are lacking. These models represent structure-based assessments using QSARs and SARs that if used properly may help predict with considerable precision the toxicological and adverse effects of many classes of organic substances (Valerio, 2009; Valerio et al., 2013). As with all methods, these models have some limitations, and in this regard, the main consideration with predictive modeling is the quality of the data used to build it. Advanced efforts have been focused on data integration techniques to combine empirical data with theoretical predictions (Valerio, 2012, 2013; Nigsch et al., 2011). Clearly, building in silico tools directed at understanding human adverse effects can be helpful for assessing safety and risk parameters that are difficult and time-intensive to determine in animals or acquire from well-controlled human studies. Thus, if properly validated, described, and made available for broad consumption, the in silico approach has the potential to be helpful (Valerio, 2013; Valerio and Choudhuri, 2012). We anticipate that as the use of new informatics tools, standards, and predictive technologies expand, these enabling methods will help build groundbreaking efforts to transform toxicology so that there is a better understanding of the toxic effects of at-risk substances such as onchidal and fasciculins.

30.6 Treatment

Treatment primarily involves supportive care and the i.v. administration of antivenom as soon as possible after neurological symptoms develop. The antivenom is indicated for all confirmed Eastern coral snake bites (Western, no antivenom) (Cameron, 2006). The South African polyvalent elapid antivenom covers all African species of elapids. The development of novel antivenoms and recombinant neutralizing antibodies demands, of course, the identification of the most relevant toxins in these venoms.

Antidotal therapy for the toxic effects of ChE inhibitors, such as onchidal and fasciculins used as potential chemical warfare agents, is directed toward blocking the effects of excessive ACh stimulation and reactivating the inhibited enzyme.

Atropine in sufficient dosage effectively antagonizes the actions at muscarinic receptor sites (Taylor, 2001). Atropine is used in adults at doses of 1−2 mg i.v. and in pediatrics at a dose of 0.05 mg/kg i.v.; doubling this dose every 5 min (DeLisle, 2006). Larger doses are required to get appreciable concentrations of atropine into the CNS. Atropine is virtually without effect against peripheral neuromuscular compromise.

Anticholinergic poisoning is managed by i.v. physostigmine, a reversible anti-ChE agent. Through its action at both central and peripheral cholinergic receptors, physostigmine reverses anticholinergic activity and ameliorates coma, delirium, and seizures that accompany severe toxicity. The initial i.v. or i.m. dose of physostigmine is 2 mg, with additional doses given as necessary.

The aforementioned action of the anti-ChE agents, as well as all other peripheral effects, probably can be reversed by reactivators of ChE such as pralidoxime (pyridine-2-aldoxime methyl chloride) (2-PAM) in the treatment of onchidal and fasciculin poisonings. The velocity of reactivation of phosphorylated AChE by 2-PAM varies with the nature of the phosphoryl group, following the same sequence as the order for spontaneous hydrolytic reactivation. The usual dosages of 2-PAM are as follows:

- In adults, 1−2 g i.v. over 15−30 min, may repeat in 1 h if necessary or start a drip at 500 mg/h;
- In pediatrics, 25 mg/kg i.v. over 15−30 min., follow with continuous infusion of 10−20 mg/kg i.v. (DeLisle, 2006).

30.7 Concluding remarks and future directions

The natural toxins onchidal and fasciculins behave as anti-ChE agents. Onchidal is an active, site-directed irreversible inhibitor of AChE, and fasciculins are proteinic AChE inhibitors that bind to a peripheral regulatory anionic site of AChE in a noncompetitive, irreversible manner. Both toxins could be used in chemical defense as potential warfare agents.

There is limited information about the toxicity, toxicokinetics, and toxicological properties of onchidal, and additional data are needed to make a health-effect-based risk assessment of the natural compound. Although fasciculins are much better known, data on toxicological properties and toxicokinetics will be of interest and useful for risk assessments. This is the case even though it is generally accepted that the toxicity of this proteinic poison occurs at very low doses.

Onchidal and fasciculins are interesting natural compounds, and it is difficult to predict their toxicity. As demonstrated in this chapter, predictive in silico approaches using computational models can be used to help assess the nonclinical toxicity of chemical agents. The quality of computational toxicology assessments relates to the quality of data used to derive predictions and appropriate expert interpretation of the data. Because the in silico approach is tailored toward filling data gaps, and enhancing decision making, the paucity of human data on onchidal and fasciculins makes a clear case for the use of in silico predictive technologies. The future of computational assessments seems to be in enabling techniques that would facilitate integrating theoretical predictions with empirical evidence in order to strengthen contemporary decision analysis. A major challenge will be to predict the military potential and overall human impact of these natural toxins since their biochemical affinity for enzyme inhibition depends upon the amount and duration of human exposure, and data about human exposure are lacking.

30.8 Disclosures

The authors declare that there are no conflicts of interest.

Chapter 31

Cyanobacterial (blue-green algae) toxins

Jitendra K. Malik[1], Vijay K. Bharti[2], Anu Rahal[3], Dinesh Kumar[4] and Ramesh C. Gupta[5]

31.1 Introduction

Cyanobacteria, also known as blue-green algae, comprise a diverse group of photosynthetic prokaryotic bacteria that proliferate in a wide range of freshwater and marine environments including ponds, lakes, reservoirs, and slow-moving streams, when the water is warm and nutrients and plenty of sunlight are available. Cyanobacteria are morphologically and physiologically diverse and perform photosynthesis through the green pigment, chlorophyll-a, and often produce accessory photosynthetic blue pigments, called phycobilins or phycocyanins. They also produce red to brown accessory photosynthetic pigments called phycoerythrins. Based on the levels of phycobilins and phycoerythrins, the colors of cyanobacteria vary between different shades of blue and green and, less commonly, brown to red. Since many genera of cyanobacteria have the ability to produce toxins, they are of toxicological significance, affecting aquatic organisms and terrestrial species including wildlife, livestock, pets, and even humans with ingestion of contaminated water or seafood (van der Merwe, 2015; Buratti et al., 2017; Kaur, 2019).

Cyanobacteria may be benthic or pelagic and, based on their morphology, they represent one of the most diverse prokaryotic phyla. Cyanobacteria have been divided into five different morphological sections including unicellular colonies with binary fission, unicellular colonies with multiple fission, multicellular colonies, multicellular colonies with differentiated cells, and branched multicellular colonies with differentiated cells (Schirrmeister et al., 2011). They form colonies often large enough to be seen with the naked eye and, when numerous, may change the color of the water or form scum at the water surface. An algal bloom is dense proliferations of cyanobacteria in a water system. Cyanobacteria blooms are often called blue-green algae. Algal blooms having the potential to cause harmful effects are called harmful algal blooms (HABs). Blooms can last from a few days to many months. They have been increasing in size and frequency in most regions and are generally induced by an overabundance of nutrients in the water, with the two most common nutrients being fixed nitrogen and phosphate from agricultural and industrial sources. Contributing factors are low circulation and higher water temperature (Hudnell, 2010; Gkelis and Zaoutsos, 2014; van der Merwe, 2015).

Many cyanobacterial species are capable of producing a wide range of toxins. Eutrophication and also other environmental factors increase bloom formation, including low turbulence, stagnant water conditions, higher pH values, and higher temperature (Bláha et al., 2009). The occurrence of a cyanobacteria bloom does not necessarily indicate that there is production of toxin. Multiple genotypes of cyanobacteria can exist in a single bloom, and some produce toxins while others do not. Under some conditions, even cyanobacteria genotypes or species that can produce toxins do not always produce toxins. The growth of the cyanobacterial species and their cyanotoxin production are influenced by many environmental factors including temperature, light intensity, pH, nutrients, salinity, ultraviolet radiation, wind, trace metals, and environmental pollutants. The toxins produced by cyanobacteria are also regulated by limitations of nutrients (nitrogen, phosphorus, and carbon), light, heat, oxidants, and other components. Toxin production is generally more common during warm weather and abundant sunlight, but can occur at any time of the year. The environmental conditions that trigger or inhibit production of cyanotoxins are not fully understood and remain an active area of research

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00031-3

(Neilan et al., 2013; Boopathi and Ki, 2014; Szlag et al., 2015; van der Merwe, 2015). The production of toxin during HABs can be tremendously high and it has been documented that a HAB formed by microcystin-LR-producing *Microcystis aeruginosa* in a Kansas lake in 2011 produced toxin concentrations in the water of 126,000 ng/mL (van der Merwe et al., 2012). Such toxin concentrations in the water are highly significant taking into consideration that hepatotoxic effects in humans are possible following ingestion of 100 mL of water containing 20 ng/mL microcystin-LR (WHO, 2003). The spontaneous production of high concentrations of toxins in a natural environment, although somewhat sporadic, could make them accessible to harvesting for use as chemical weapons, requiring only simple equipment and low levels of technical capability. On the other hand, it is possible to obtain toxins from cyanobacteria produced in bioreactors, but this may require higher equipment investment and technical competence. Of toxins produced by cyanobacteria, saxitoxin or paralytic shellfish poison (PSP), which acts by blocking voltage-gated sodium channels, is listed as a Schedule 1 substance in the Chemical Weapons Convention. Other toxins produced by various genera of cyanobacteria may also pose credible threats based on their potency to produce deleterious effects, persistence in the environment, and widespread production in surface waters where they may be easily accessible (van der Merwe, 2015).

The cyanotoxins produced by freshwater cyanobacteria can be classified based on their origins, molecular structures, or adverse effects. They are generally grouped into major classes according to their toxicological targets, namely hepatotoxins (microcystins, nodularins, cylindrospermopsins), neurotoxins [anatoxin-a, anatoxin-a(s), saxitoxins], dermatotoxins (irritants), cytotoxins (aplysiatoxin, lyngbyatoxin-a), and endotoxins (irritants) (lipopolysaccharides) (Bláha et al., 2009).

31.2 Hepatotoxins

31.2.1 Microcystins and nodularins

31.2.1.1 Introduction

Microcystins are cyclic heptapeptides commonly produced by cyanobacteria genera *Microcystis*, *Anabaena*, *Planktothrix*, *Nostoc*, *Oscillatoria*, *Anabaenopsis*, and *Hapalosiphon*. They are called hepatotoxins because the liver is their primary target. Anthropogenic nutrient over-enrichment (eutrophication), but also other factors including expansion of intensive agriculture, rapid industrialization, and urbanization, seem to enhance the occurrence of microcystin-producing HABs in most regions. Microcystins have received increasing worldwide attention in the past decade because of their widespread and frequent occurrence, persistence in the environment, and their high potential to produce deleterious effects on human health.

Nodularins are mainly produced by *Nodularia spumigena* in brackish waters. They are similar to microcystins in structure and mechanism of toxicity and, for the purposes of this discussion, are considered equivalent to microcystins (Namikoshi et al., 1994; Chen et al., 2013a). In general, microcystin concentrations are correlated with cell density, even though high concentrations of cyanobacterial cells without toxin production are possible. The most common routes of human exposure to cyanotoxins are through the chronic and accidental ingestion of contaminated drinking water, inhalation or contact with the nasal mucous membrane, and dermal contact with toxins during recreational activities such as swimming, canoeing, or bathing. Other routes of exposure include consumption of contaminated vegetables, fruits and aquatic organisms, cyanobacterial dietary supplements, and the specific intravenous route caused by dialysis (Drobac et al., 2013).

31.2.1.2 Chemistry

Microcystins share a general cyclic heptapeptide structure which has the ability to resist physical and chemical factors (Fig. 31.1). The general structure of microcystins is cyclo-(-D-Ala-L-X-D-MeAsp-L-Z-Adda-D-Glu-Mdha), where Adda is (2S, 3S, 8S, 9S) 3-amino-9 methoxy-2,6, 8-trimethyl-10-phenyldeca-4,6-dienoic, D-MeAsp is D-erythro-b-methylaspartic acid, Mdha is *N*-methyldehydroalanine, and X and Z are variable L-amino acids (Sivonen and Jones, 1999; Massey et al., 2018; Yang et al., 2018a, b). The ADDA side chain is consistent between microcystin variants and can be used to quantify microcystins independent of the variant type. Based on combinations of X and Z, the two variable L-amino acids, more than 100 microcystin variants with different degrees of toxicity have been isolated from cyanobacterial blooms. Among the different variants, the most common are microcystin-LR, microcystin-RR, and microcystin-YR, and the X and Z variable amino acids for microcystin-LR, microcystin-RR, and microcystin-YR are leucine (L), arginine (R),

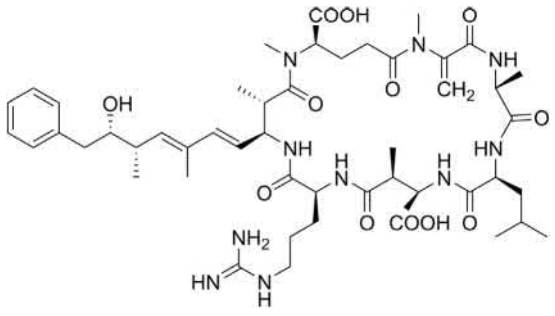

FIGURE 31.1 Microcystin chemical structure.

and tyrosine (Y) (Puddick et al., 2015; Yang et al., 2018a, b). Microcystin-LR is the most toxic, well studied, and abundant variant and is one of the most important algal toxins that has received worldwide attention (Zhou et al., 2013; Massey et al., 2018).

Microcystins are not actively secreted by cyanobacterial cells and therefore are strongly associated with cyanobacterial cells as long as the cells remain intact. However, microcystins may be released into the surrounding water after a bloom senesces or cyanobacterial cells are ruptured. Microcystins are stable, with a typical environmental half-life of 10 weeks. Under natural conditions, microcystins are resistant to physicochemical stresses, such as pH, temperature, and sunlight. However, the rate of breakdown is increased under direct sunlight, at high environmental temperatures ($>40^{\circ}C$), and at extremely low (<1) or high pH (>9) (Harada et al., 1996). Microcystin concentrations may be reduced by cooking in a microwave oven or by continuous boiling (Gutierrez-Praena et al., 2013). On the other hand, the concentration of free microcystins in muscle tissue from exposed fish may increase after boiling because of the release of phosphatase-bound microcystins (Zhang et al., 2010).

31.2.1.3 Toxic effects

The health effects of cyanotoxins are based largely on animal studies, usually mouse, rat, or pig, with some indirect data on humans obtained from forensic and epidemiological studies (Carmichael and Boyer, 2016; Greer et al., 2018; Massey et al., 2018). Only in a few cases have these studies been extended to chronic or teratogenic impacts on populations at risk (Meneely and Elliott, 2013). Our understanding of the toxicological effects of microcystins has been mainly based on microcystin-LR. The deleterious effects of other microcystin variants appear to be similar to those of microcystin-LR, but they differ in potency. Besides other factors, dose, potency, exposure route, duration of exposure, and intensity of exposure of cyanobacterial toxins employed in a particular laboratory animal species as well as interspecies variations in toxicokinetics and toxicodynamics can make the comparison with or extrapolating to the toxic effects of these toxins in other species challenging (Chen et al., 2018).

Exposure to microcystins represents a health risk to humans and many incidences of human exposure have been reported. The first confirmed human deaths from cyanotoxins occurred from intravenous exposure in a dialysis clinic in Brazil in 1996 (Jochimsen et al., 1998). Of 131 patients, 116 patients experienced visual disturbances, nausea, and vomiting. Consequently, 100 patients developed acute liver failure and this syndrome, now known as "Caruaru syndrome," resulted in 76 deaths. Of these, 52 deaths were a result of the dominant cyanobacterial toxins in the water supply reservoir, and it was concluded that the major contributing factor to death of the dialyses patients was intravenous exposure to microcystins (Carmichael et al., 2001).

The clinical effects of microcystin poisoning depend on the route of exposure, level of exposure, and the mixture of components involved in the exposure. In typical exposures of mammals to toxic blooms, low to mild exposure levels are associated with irritant effects, resulting in inflammatory responses in the skin, respiratory system, and gastrointestinal system. Higher exposure levels, particularly oral exposures, result in liver damage and, if the liver damage is severe, liver failure (Briand et al., 2003). The earliest detectable signs of liver damage include liver swelling and increased concentrations of liver enzymes such as alanine aminotransferase and aspartate aminotransferase in the blood. Early symptoms typically appear within minutes to hours of exposure and include inappetence, depression, and vomiting, followed by diarrhea, which may become extreme and hemorrhagic. Inappetence and depression become progressively worse. The final stages of lethal poisoning may be associated with recumbency and coma (van der Merwe et al., 2012; Kaur, 2019).

Microcystin-LR is a potential carcinogen for animals and humans, and is now classified as a potential class 2B carcinogen to humans. In addition to the liver, the testes has been considered as one of the most important target organs of microcystin-LR toxicity (Lone et al., 2015). Microcystins are one of the environmental carcinogens for the progression of colorectal carcinoma (Miao et al., 2016). Microcystins can also stimulate epithelial−mesenchymal transition (EMT) in colorectal cancer cells. During tumor progression, cancer cells acquire motility and an invasive property by regulating EMT that can lead to distant metastasis and are involved in embryonic development and cancer progression (Ren et al., 2017).

An important difference between exposures in aquatic organisms and terrestrial organisms is that exposures in aquatic environments often involve exposures to sublethal doses over days or weeks. In fish, exposures to microcystins cause cellular damage, particularly liver damage, similar to the effects seen in mammals (Tencalla and Dietrich, 1997). Mature fish are generally more resistant to microcystin toxicosis compared with juvenile fish. Although fish have the ability to avoid areas of accumulation of toxic algae, sublethal liver damage in fish is associated with accumulation of microcystins in fish food items such as mussels, snails, and zooplankton (Malbrouck and Kestemont, 2006). Fish are also susceptible to decreased water oxygen levels associated with the decay of algal scum, and this effect may also play a role in fish deaths (Ibelings and Havens, 2008).

Lower and higher concentrations of microcystin-LR-induced apoptosis and necrosis in lymphocytes,

respectively. In phagocytes, reorganization of the actin cytoskeleton, cell shrinkage, and filopodia disappearance were also observed, indicating immune system impairment (Rymuszka and Adaszek, 2013). Microcystin following epidermal exposure caused irritation of the skin. In cases of skin damage, faster penetration to deeper cell layers and absorption to the systemic circulation may be expected. Persistent toxic effects comprising of keratinocyte migration and cytoskeleton were only reported after longer exposures to the skin (Kozdeba et al., 2014).

31.2.1.4 Mechanism of action

Following ingestion and release from cyanobacterial cells, microcystins are absorbed into the portal circulation from the small intestine via bile acid transporters in the intestinal wall. Since the primary target cells for microcystins are in the liver, they are accumulated in hepatocytes via organic anion-transporting polypeptides (OATPs, OATP1B1, OATP1B3) in hepatocyte membranes. As a result of the abundance of OATPs expressed in the liver, the majority of ingested microcystin accumulates in hepatocytes. In addition to the liver, these cyanotoxins can affect other tissues including the kidneys, reproductive tissue, colon, and brain, that contain the appropriate OATPs (1A2, 1B1, 1B2, 1B3) (Carmichael and Boyer, 2016; Chen et al., 2016). OATP is also expressed in the blood−brain barrier, which may explain the neurological symptoms associated with human intoxication by microcystin in Brazil (Azevedo et al., 2002).

Microcystins are potent and irreversible inhibitors of protein phosphatases (PPs), mainly PP1 and PP2A. Inhibition of PPs leads to an increase in cell-phosphorylated protein load and subsequent deregulation of fundamental cellular processes and apoptosis. Microcystin-LR may also bind to ATP synthase, leading to hepatocyte apoptosis (Mikhailov et al., 2003). The microcystin-interacting PPs are ubiquitous and are found in all tissues and across species in mammals, plants, and bacteria. PPs reverse the active state of kinases through hydrolytic removal of the phosphoryl group from kinases. Inhibition of PPs also leads to changes in the cytoskeleton including hyperphosphorylation of cytokeratins, reorganization, disassembly of actin and microtubules, and ultimately disruption of cellular architecture (Huang et al., 2015; Zeng et al., 2015). Furthermore, PP2A inhibition also results in activation of the MAPK pathway (ERK1/2, JNK, p38) and apoptosis. Microcystin-LR impairs PP2A ability to bind tubulin and thus destabilizes the microtubules. The hepatotoxic effects of microcystin-LR proceed through alterations in cytoskeletal architecture and cell viability by MAPK activation, and hyperphosphorylation of p38, ezrin, and ERK1/2 (Komatsu et al., 2007; Kaur, 2019).

Microcystins produce toxicity mainly through oxidative stress, which was evident by marked alterations in cytotoxicity markers such as leakage of lactate dehydrogenase enzyme, lipid peroxidation, reactive oxygen species (ROS) generation, and antioxidant enzymes. Microcystin-LR also induces JNK activation, which affects enzymes involved in energy metabolism and mitochondrial dysfunction, ultimately resulting in apoptosis of hepatocytes and oxidative liver injury. Intracellular ROS production by microcystin-LR has also been shown due to a calcium-mediated loss of mitochondrial membrane potential. Microcystin-LR-mediated oxidative stress occurs with an increase in hydroxyl radicals and a subsequent induction of apoptosis-related genes p38, JNKa, and Bcl-2 in the liver of fish (Valério et al., 2016; Kaur, 2019). Calcium is known to be involved in the microcystin-mediated toxicity and may trigger mitochondrial dysfunction (Ding et al., 2001). In addition to calcium, ceramide is involved in microcystin-induced deleterious effects through regulation of the PP2A subunit, subcellular localization and inhibition, and cytoskeletal destabilization (Li et al., 2012). Chronic exposure to low-level microcystin-LR was found to inhibit fatty acid β-oxidation and hepatic lipoprotein secretion and promoted hepatic inflammation, leading to nonalcoholic steatohepatitis disease in mice (He et al., 2017).

Microcystins are capable of inducing deleterious effects in organs other than the liver including the kidneys, lungs, heart, and reproductive and immune systems (Massey et al., 2018). Oxidative stress and cytoskeletal disruption may interact with each other and jointly lead to apoptosis and renal toxicity induced by microcystins (Huang et al., 2015). Microcystins can cross the blood−brain barrier and blood−cerebrospinal fluid barrier and accumulate in the brain to induce neurotoxic effects, and neuroinflammatory and neurodegenerative disease due to the disruption of the mRNA levels involved in amino acid γ-aminobutyric acid (gabaminergic system), cytoskeleton, oxidative stress, and inhibition of PP1 and PP2A in the nerve cells (Li et al., 2012; Takser et al., 2016; Yan et al., 2017; Massey et al., 2018).

Microcystin-LR is classified as a possible class 2B carcinogen to humans. The ERK1/2 pathway, increased expression of protooncogenes namely cfos, c-jun, and c-myc in mouse, and p53 have been shown to be involved in microcystin-LR-induced tumor. Furthermore, microcystin-LR tumorigenesis was suggested to be regulated by NF-κB, interferon alpha (IFN-α), and tumor necrosis factor alpha (TNF-α) (Li et al., 2009; Christen et al., 2013; Valério et al., 2016). Microcystins may also produce alterations in expression of microRNAs in the liver to induce liver injury and influence liver tumor promotion (Yang et al., 2018a,b). Microcystins are associated

with the progression of colorectal carcinoma and can stimulate EMT in colorectal cancer cells (Miao et al., 2016; Ren et al., 2017).

Chronic exposure to low doses of microcystin can produce toxic effects on the male reproductive system due to a decrement of testosterone and testicular atrophy. Microcystins can lead to a decline in quality and viability of sperm, sperm abnormalities, and injury to the testes. Apoptosis can also be caused in Sertoli cells and Leydig cells (Ding et al., 2006; Chen et al., 2013b). Studies on the female reproductive system indicate that microcystins induced a direct reproductive toxicity resulting in decline of ovary weight, a decrease in primordial follicles, disturbance of estrus cycle, and decrease in serum progesterone (Wu et al., 2014). In cell culture models, microcystin-LR has been shown to induce Fas receptor, ligand, and NF-κB, which are important signals for apoptosis, and immune responses, and thus indicating its ability to modulate the immune system (Feng et al., 2011; Ji et al., 2011). Intraperitoneal administration of microcystin-LR in mice was demonstrated to increase thyroid hormones resulting in thyroid dysfunction. The glucose, triglyceride, and cholesterol metabolism were disrupted concurrent with symptoms of hyperphagia, polydipsia, and weight loss (Zhao et al., 2015).

31.2.1.5 Chemical warfare potential

Most microcystins are extremely toxic to freshwater bodies, marine ecosystems, and human health. Due to their capability to accumulate in aquatic species and food crops, they represent a health hazard in humans and animals through the food chain (Massey et al., 2018). Under favorable conditions including suitable nutritional levels and weather conditions, toxic concentrations can reach extremely high levels and represent an opportunity for the collection and storage of microcystins using widely available equipment and with minimal technical skill. The food supplies and water contaminated with microcystins represent significant human health risk. However, the major impact of such an event will be the cost associated with avoidance of exposure, including testing, water purification, and the procurement of alternative water and food sources (van der Merwe et al., 2012, van der Merwe, 2015). The most well-known occurrence of a harmful effect of microcystins is the first confirmed human deaths at a hemodialysis center following the use of contaminated dialysis water supplies (Azevedo et al., 2002). As a preventive measure to reduce risks caused by microcystins, the WHO recommends a provisional guideline value of 1 μg/L for microcystin-LR concentration in drinking water and a chronic tolerable daily intake of 0.04 μg/kg body mass per day for human consumption (Li et al., 2017). Although the potential efficacy of various chemoprotectants including antioxidant compounds and transport inhibitors to prevent or mitigate the toxic effects induced by microcystins has been investigated, there are no specific antidotes yet available for microcystin poisoning (van der Merwe, 2015; Guzmán-Guillén et al., 2017).

31.2.2 Cylindrospermopsin

31.2.2.1 Introduction

Cylindrospermopsin is an alkaloid cyanotoxin produced by several freshwater cyanobacteria genera, including *Cylindrospermopsis*, *Aphanizomenon*, *Anabaena*, *Lyngbya*, *Umezakia*, and *Raphidiopsis*. It is found worldwide in surface freshwaters and is a potential toxicant in drinking water supplies for a large human population, as well as animals (Guzmán-Guillén et al., 2013). It was first reported in 1979 after a hepatoenteritis outbreak occurred due to *Cylindrospermopsis raciborskii* bloom in the local drinking water supply in Palm Island, northern Queensland, Australia (Bourke et al., 1983).

31.2.2.2 Chemistry

Cylindrospermopsin is a polyketide alkaloid consisting of a tricyclic guanidine moiety combined with hydroxymethyluracil (Fig. 31.2). Due to its zwitterionic nature, cylindrospermopsin is a highly water-soluble compound. At present, there are five known structural variants of cylindrospermopsin, namely cylindrospermopsin, 7-epicylindrospermopsin, 7-deoxy-cylindrospermopsin, and the two recently characterized congeners, 7-deoxy-desulfo-cylindrospermopsin and 7-deoxy-desulfo-12-acetyl-cylindrospermopsin, which have been isolated from a Thai strain of *C. raciborskii* (Wimmer et al., 2014). Cylindrospermopsin is resistant to high temperatures, sunlight, and pH extremes. Unlike microcystins, cylindrospermopsin is often secreted from cyanobacterial cells into the surrounding water (Rucker et al., 2007). It bioaccumulates, particularly in organisms, in the lower level of the food chain, such as gastropods, bivalves, and crustaceans (Kinnear, 2010).

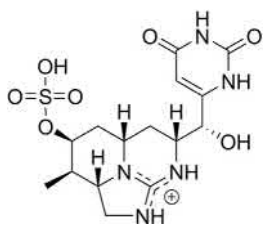

FIGURE 31.2 Cylindrospermopsin chemical structure.

31.2.2.3 Toxic effects

There are a number of worldwide reports on the impact of cylindrospermopsin exposure on human health. The toxin may produce a wide range of toxic effects. Cylindrospermopsin primarily targets the liver, but it is also a general cytotoxin that attacks the eyes, spleen, kidneys, lungs, thymus, heart, etc. (Guzmán-Guillén et al., 2017). A major outbreak of poisoning in humans with 148 cases occurred in 1979 near a reservoir on Palm Island, Queensland, Australia. The reservoir produced a dense bloom of cylindrospermopsin-producing *C. raciborskii* and the incident occurred a few days after treatment of the reservoir with copper sulfate to control the bloom. Finally, algal cell lysis and release of toxic cellular components occurred into the water. People in households connected to the reticulated water supply from the reservoir were affected with a syndrome that included liver and kidney damage, as well as severe gastroenteritis. Symptoms included hemorrhagic diarrhea, vomiting, fever, hepatomegaly, dehydration, electrolyte imbalances, acidosis, and hypovolemic shock. However, the potential role that copper sulfate water treatment could have played in the disease process remains uncertain. Intraperitoneal injection of extracts from *C. raciborskii* collected from the reservoir produced similar liver and kidney damage in mice (Hawkins et al., 1985). Cylindrospermopsin was also isolated from water used in dialysis in Brazil, which caused liver failure in dialysis patients. However, the role of cylindrospermopsin in the disease process was not clear because the water was also contaminated with toxic concentrations of microcystin (Azevedo et al., 2002).

C. raciborskii can cause mild skin irritation in some individuals, but the exact mechanism of action involved has not been elucidated. Although cylindrospermopsin outbreaks have been recently reported, there had been many instances of co-occurrence with other cyanobacterial toxins, making it difficult to confirm the relative contribution to symptoms. A similar outbreak, commonly known as "Barcoo fever," was reported in the Australian outback (Hayman, 1992). Pure cylindrospermopsin injected into tilapia caused progressive tissue damage over a period of 5 days in the liver, kidneys, heart, and gills (Gutierrez-Praena et al., 2013).

Administration of purified cylindrospermopsin by daily gavage in mice for 11 weeks increased the liver and kidney weight and alterations in hepatic and renal toxicity markers. Concomitant histopathological changes at the higher doses were also seen (Humpage and Falconer, 2003) Liver and kidney damage was consistently observed in laboratory rodents after exposure to acutely toxic doses of cylindrospermopsin-containing extracts. Typical liver pathology included lipid infiltration and necrosis, mostly in the periacinar region (Shaw et al., 2000). Dose-dependent DNA damage in mammalian cells has also been reported, which can be prevented by cytochrome P450 inhibitors, indicating an involvement of metabolic enzymes in progressing toxicity (Humpage et al., 2005). No reliable data on the cylindrospermopsin-mediated human carcinogenicity, genotoxicity, and reproductive/developmental toxicity are yet available (Kaur, 2019).

31.2.2.4 Mechanism of action

Cylindrospermopsin appears to be a molecule with a wide range of deleterious effects. Although the toxin primarily targets the liver, it is also a general cytotoxin that affects the eyes, spleen, lungs, thymus, heart, and lately the kidneys have been shown to be the more sensitive target of its toxicity (Guzmán-Guillén et al., 2017). Four sequential phases of hepatocyte damage were identified by a time series analysis, including protein synthesis inhibition, membrane proliferation, lipid infiltration, and necrosis. Kidney pathology included necrosis of the proximal tubules and protein accumulation in the distal tubules (Falconer et al., 1999). Studies using crude extracts reported higher potency and a wider range of effects compared with studies using purified cylindrospermopsin, indicating that other components also contributed to the adverse effects (Shaw et al., 2000).

Cylindrospermopsin is a potent inhibitor of protein synthesis in a concentration-dependent and irreversible manner, as confirmed both in in vivo and in vitro studies (Terao et al., 1994; Froscio et al., 2003), but the exact mechanism of action of the toxin has not been fully elucidated. A decrease in cylindrospermopsin toxicity by the administration of cytochrome P450 inhibitors has been reported, which suggests an alternative toxicity mechanism possibly through metabolite formation. Cylindrospermopsin has been shown to cause DNA fragmentation in vitro, and metabolic activation by a cytochrome P450 enzyme seems to be necessary for inducing this effect (Bazin et al., 2010). Recently, it has been shown that cylindrospermopsin induces upregulation of phase I biotransformation enzymes (CYP1A1, CYP1B1, ALDH1A2, and CES2) and phase II biotransformation enzymes (UGT1A6, UGT1A1, NAT1, and GSTM3) in human hepatoma HepG2 cells (Straser et al., 2013). In cell culture models, cylindrospermopsin has been shown to induce stress responses which resulted in the activation of the tumor suppressor protein p53 transcription factor (Bain et al., 2007).

Oxidative stress is one of the toxic mechanisms identified as being responsible for cylindrospermopsin toxicity. It is well known that cylindrospermopsin inhibits synthesis of glutathione, which is one of the major endogenous antioxidants that is produced by cells. In addition, cylindrospermopsin induced apoptosis in primary rat

hepatocytes and protein synthesis inhibition and increased ROS production were found to be involved in the cytotoxic effect elicited by the toxin (Lopez-Alonso et al., 2013). Cylindrospermopsin in subtoxic concentrations overexpressed proteins involved in DNA damage repair and transcription, including modifications of nucleosomal histones (Huguet et al., 2014). More recent experimental evidence using in vitro models of human bronchial epithelial cells showed that cylindrospermopsin is a potent cytotoxin causing significant inhibition of cell viability, which was accompanied by alterations in epithelial integrity and barrier function markers, along with activation of MAPK ERK1/2 and p38 (Kubickova et al., 2019).

31.2.2.5 Chemical warfare potential

Humans are more susceptible to the exposure to cylindrospermopsin as compared to other cyanotoxins, because up to 90% of total cylindrospermopsin is found outside the cyanobacterial cells (Rücker et al., 2007). The toxic effects of cylindrospermopsin are not yet fully established and additional data for hazard characterization purposes are required. It has been emphasized that research on various aspects including new emerging toxicity effects, the toxicity of analogs, or the potential interaction of cylindrospermopsin with other cyanotoxins, among others, remains very scarce (Pichardo et al., 2017). Despite the fact that the mechanisms of toxicity of cylindrospermopsin are not yet fully understood, ample evidence of its potential impact on human health exists, based on clinical cases, in vitro studies, and animal model studies (Poniedziałek et al., 2012). Owing to its increasing expansion worldwide and the increased frequency of its blooms, cylindrospermopsin is gaining increasing importance. The primary threats include contamination of drinking water supplies as well as food supplies.

31.3 Neurotoxins

31.3.1 Anatoxin-a

31.3.1.1 Introduction

Anatoxin-a is a very potent and fast-acting neurotoxin and is considered to be a major cyanotoxin of public health concern. It occurs worldwide in freshwaters and is produced by several genera of cyanobacteria, including *Anabaena*, *Aphanizomenon*, *Microcystis*, *Planktothrix*, *Raphidiopsis*, *Arthrospira*, *Cylindrospermum*, *Phormidium*, *Nostoc*, and *Oscillatoria*. Exposures occur mainly through consumption of contaminated drinking water but have also occurred from recreational use of lakes and through contaminated dietary supplements (Osswald et al., 2007).

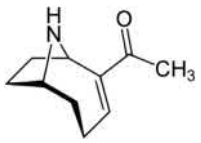

FIGURE 31.3 Anatoxin-a chemical structure.

31.3.1.2 Chemistry

Anatoxin-a is a bicyclic amine alkaloid (Fig. 31.3). It contains a homotropane scaffold that is derived from glutamic acid. Anatoxin-a is a chiral compound with asymmetric centers at C(1) and (5), and only one enantiomer has been reported from natural sources. The (+)-anatoxin-a enantiomeric form is naturally produced with a p*K*a of 9.4, indicating that it is mostly protonated under typical environmental pH conditions. Anatoxin-a is stable under sterile conditions but is susceptible to microbial biodegradation (Wonnacott and Gallagher, 2006). The half-life in a reservoir is reported to be 5 days under typical environmental pH conditions (Smith and Sutton, 1993). A structural analog, called homoanatoxin-a or methylene-anatoxin-a, has been isolated from *Oscillatoria formosa* (Skulberg et al., 1992). Small quantities of anatoxin-a are produced synthetically for use in acetylcholine receptor research.

31.3.1.3 Toxic effects

Anatoxin-a was originally called Very Fast Death Factor because of its rapid lethal effects, within 2–7 min, in laboratory mice. Acute deaths after exposure to anatoxin-a have been recorded in multiple species, including dogs, cattle, and wildlife, and interspecies differences in susceptibility to anatoxin-a have been observed even within animal types. Mallard ducks, for example, are more sensitive compared with ring-necked pheasants (Carmichael and Biggs, 1978). Anatoxin-a is rapidly absorbed from the gastrointestinal tract, as indicated by the rapidity of appearance of clinical effects after oral exposure. Clinical effects of poisoning may appear within minutes to hours after exposure and include loss of muscle coordination, muscle tremors and fasciculations, convulsions, and respiratory distress. The principal lethal effect is respiratory failure after loss of control over respiratory muscles (Osswald et al., 2007).

31.3.1.4 Mechanism of action

Anatoxin-a is an agonist of peripheral and central acetylcholine receptors, with a 100-fold selectivity for nicotinic receptors over muscarinic receptors. It binds to the acetylcholine receptor at the same position as acetylcholine (presynaptically and postsynaptically), causing sodium/potassium ion channels to open and induce a depolarizing blockade. Anatoxin-a is more potent than acetylcholine or

nicotine. Binding of anatoxin-a to the nicotinic acetylcholine receptors at neuromuscular junctions results in uncontrolled action potential propagation that manifests clinically as uncoordinated muscle contraction, muscle fatigue, and paralysis. The cholinesterase enzyme does not breakdown anatoxin-a, leading to persistent muscle stimulation (Wonnacott and Gallagher, 2006). Stimulation of nicotinic receptors in the cardiovascular system causes increased heart rate and blood pressure (Sirén and Feurstein, 1990). Stimulation of presynaptic nicotinic receptors in the central nervous system by anatoxin-a may also cause the release of neurotransmitters such as dopamine, which could further increase the susceptibility of postsynaptic receptors to overstimulation (Wonnacott and Gallagher, 2006). Central nervous system receptors are, however, less sensitive to anatoxin-a when compared with peripheral receptors.

31.3.1.5 Chemical warfare potential

Due to its high potency, fast action, and occasional availability of highly lethal concentrations of toxin during natural cyanobacterial blooms, anatoxin-a is potentially dangerous as a chemical warfare agent. Since anatoxin-a is vulnerable to rapid bacterial breakdown under nonsterile storage conditions, its intentional use is challenging without relatively sophisticated extraction and storage procedures (van der Merwe, 2015).

31.3.2 Anatoxin-a(s)

31.3.2.1 Introduction

Anatoxin-a(s) is a natural organophosphate analog produced by cyanobacteria in the genus *Anabaena*. The (s) in the name of anatoxin-a(s) refers to salivation, which is a characteristic sign of poisoning observed in laboratory rodents after exposure. Although anatoxin-a(s) has been less frequently reported, it was detected in animal toxicoses in Europe and the United States.

31.3.2.2 Chemistry

Anatoxin-a(s) is a cyclic *N*-hydroxyguanine with a phosphate ester moiety (Fig. 31.4) similar to typical synthetic organophosphate insecticides and chemical warfare nerve agents. No structural variants of anatoxin-a(s) have been described. Anatoxin-a(s) is susceptible to rapid degradation compared with other cyanotoxins (Matsunaga et al., 1989). The alkyl chain of anatoxin-a(s) (cyclic guanidines), which can be used as an intermediate in the total synthesis of anatoxin-a(s), was synthesized in both racemic and enantiomerically pure forms (Moura and Pinto, 2010). C-2, C-4, C-5, and C-6 of the anatoxin-a(s) are derived from the guanido carbon, C-5, C-4, and C-3 of L-arginine, respectively, and the three *O,N*-methyl groups originate from the tetrahydrofolate C_1 pool. *Erythro*-4-Hydroxy-L-arginine, a minor constituent of the cyanophyte, may be a precursor in the biosynthesis (Moore et al., 1992; Patocka et al., 2011).

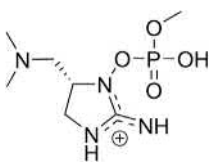

FIGURE 31.4 Anatoxin-a(s) chemical structure.

31.3.2.3 Toxic effects

Anatoxin-a(s) intoxication is characterized by severe cholinergic stimulation of both nicotinic and muscarinic receptors and clinical signs exhibited are indistinguishable from organophosphate poisoning. Muscarinic signs include salivation, lacrimation, urinary incontinence, and defecation, whereas nicotinic signs include muscle tremors and fasciculations, convulsions, and respiratory failure (Mahmood and Carmichael, 1986). The muscarinic effects of anatoxin-a(s) can be suppressed by atropine (Cook et al., 1990), but it is resistant to oxime reactivation due to the formation of an adduct on the acetylcholinesterase (AChE) enzyme (Hyde and Carmichael, 1991). Mice administered with *Anabaena flos-aquae* died within minutes due to respiratory arrest following convulsions. Prior to decreases in respiratory function, lowering of heart rate and blood pressure was also observed. As the inhibition of AChE enzyme was irreversible, surviving mice showed inhibition of erythrocyte cholinesterase for at least 8 days accompanied by twitching and fasciculations, indicating prolonged cholinesterase inhibitory action and toxic effects of anatoxin-a(s) at sublethal doses (Cook et al., 1991; Patocka et al., 2011; Miller et al., 2017).

31.3.2.4 Mechanism of action

Anatoxin-a(s) is a noncompetitive and irreversible inhibitor of AChE enzyme and, unlike the organophosphates, acts only on the peripheral nervous system in humans (Carmichael and Falconer, 1993). Similar to other organophosphate insecticides, anatoxin-a(s) is bioactivated via oxidative metabolism and ultimately binds to AChE enzyme. Acetylcholinesterase is present at all cholinergic synapses and is necessary for the inactivation of acetylcholine by hydrolysis. Inhibition of the enzyme therefore causes the acetylcholine level to build up at the receptor sites, triggering excessive stimulation of nicotinic and muscarinic receptors, resulting in persistent postsynaptic membrane depolarization (Cook et al., 1990). Since anatoxin-a(s) is a direct agonist at muscarinic receptors with indirect neuromuscular blockade, its effects can be blocked at least temporarily by atropine (Cook et al., 1989; Miller et al., 2017).

31.3.2.5 Chemical warfare potential

Similar to anatoxin-a, anatoxin-a(s) is a potential threat but its implementation will require relatively sophisticated procedures and equipment.

31.3.3 Saxitoxins

31.3.3.1 Introduction

Saxitoxins are often referred to as PSPs. Most human saxitoxin toxicoses have been associated with the ingestion of marine shellfish, which accumulate saxitoxins produced by marine dinoflagellates. Saxitoxins are also found in freshwaters and are produced by cyanobacteria in the genera *Anabaena*, *Aphanizomenon*, *Planktothrix*, *Cylindrospermopsis*, *Lyngbya*, and *Scytonema* (Wiese et al., 2010).

31.3.3.2 Chemistry

Saxitoxins are highly polar, nonvolatile, tricyclic perhydropurine alkaloids (Fig. 31.5) derived from imidazoline guanidinium. Various structural substitutions produce at least 57 analogs. Activity is mediated through positively charged guanidinium groups. Saxitoxins are heat-stable, particularly in slightly acidic environments, and are highly water-soluble. They are tasteless and odorless and are not destroyed by cooking (Trevino, 1998). Saxitoxins can bioaccumulate in freshwater fish such as tilapia (Galvão et al., 2009). Methods of synthetic saxitoxin production have been reported (Akimoto et al., 2013).

31.3.3.3 Toxic effects

The clinical presentation of saxitoxin poisoning varies depending on the level of exposure. High levels of exposure are usually related to ingestion of toxin-accumulating shellfish or fish, in association with toxin-producing dinoflagellate blooms (marine environments) or cyanobacterial blooms (freshwater environments). The lag time between exposure and the appearance of clinical signs is highly variable and can range from minutes to as long as 72 h. At relatively low exposure levels, moderate paresthesias, often described as a tingling sensation, are experienced around the mouth and extremities. Larger exposures lead to a spreading numbness of the mouth, throat, and extremities. High exposure levels may also cause acute muscle paralysis and respiratory failure (Garcia et al., 2004; Miller et al., 2017).

FIGURE 31.5 Saxitoxin chemical structure.

31.3.3.4 Mechanism of action

Saxitoxins are selective but reversible blockers of voltage-gated sodium channels. These toxins can cross the blood–brain barrier and cause sodium channel blockade in the central nervous system, contributing to paralytic effects (Wiese et al., 2010). They partially block L-type calcium channels, especially in the heart, and modify the voltage gating processes in potassium channels (Wang et al., 2003; Su et al., 2004). Therefore, early symptoms of a tingling sensation followed by paralysis and death usually occur due to suffocation or cardiac arrest (Miller et al., 2017).

31.3.3.5 Chemical warfare potential

Among cyanotoxins, saxitoxins only are listed in the Chemical Weapons Convention Schedule 1, where it is referred to as Agent TZ. Saxitoxins are also listed in the War Weapons List of the German War Weapons Control Act. There is a relatively high level of concern regarding saxitoxins as they are potent and stable, can be produced synthetically, and have been shown to be suitable for incorporation into ammunition. The regulatory control of saxitoxins gets rather complicated due to the ongoing need for its availability as an analytical standard in paralytic shellfish poisoning monitoring and risk management programs, and its use in medical research on voltage-gated sodium channels. Due to these requirements, saxitoxins are subjected to lower levels of restriction under the Chemical Weapons Convention when small quantities (5 mg or less) are to be used for diagnostic or medical purposes (van der Merwe, 2015).

31.4 Concluding remarks and future directions

Under favorable conditions for cyanobacteria proliferation, some cyanotoxins, in particular microcystins, can reach extremely high concentrations during HABs and these could be collected and stored with minimal technical sophistication and equipment. The use of such cyanotoxins with intention to contaminate water, food, and medical supplies represents a significant health and economic risk. Other cyanotoxins possessing high toxicity and infrequent availability during HABs such as cylindrospermopsin, anatoxin-a, and anatoxin-a(s) are potentially dangerous, but their intentional use is less likely due to their main limitations, such as unpredictable and occasional availability and relatively tedious extraction and storage procedures. The highest risk is represented by

neurotoxins with specific effects on the nervous system, such as saxitoxins, because they are listed in the Chemical Weapons Convention as a Schedule 1 compound. The listing of saxitoxins compared to other cyanotoxins is justified keeping in mind their high toxicity, stability, availability of synthetic methods for production, and suitability for incorporation into ammunition.

Chapter 32

Chemical warfare agents and the nervous system

Jing Liu[1,3], Linzzi K. Wright[2] and Carey N. Pope[3]

[1]*Preclinical Safety Assessment, Charles River Laboratories, Inc. Reno, NV, United States,* [2]*CCDC Chemical Biological Center, Aberdeen Proving Ground, MD, United States,* [3]*Department of Physiological Sciences, College of Veterinary Medicine, Oklahoma State University, Stillwater, OK, United State*

32.1 Introduction

Chemical warfare has a long history. One of the earliest forms of chemical warfare involved the application of natural toxins to the tips of arrowheads and spears, used by early civilizations in Europe, Asia, South America, and Africa and described in Greek and Norse mythology (Mayer, 2008). The various types of chemical warfare agents (CWAs) are now listed as scheduled chemicals (Schedules 1, 2, and 3) in the Chemical Weapons Convention (Organisation for the Prohibition of Chemical Weapons, OPCW). The use of CWAs in modern warfare began in World War I (WWI, 1914–18), during which chlorine gas, mustard gas, and phosgene (primarily dermal and/or pulmonary irritants) were used. Mustard gas was again used during WWII. A number of organophosphorus chemicals, targeting the cholinergic nervous system, were synthesized as potential CWAs during the 1930s and 1940s and are often referred to as "nerve gases," or more appropriately "nerve agents." There remains widespread concern for threats from CWAs, in particular the organophosphorus nerve agents, reinforced by their military use in the Iran-Iraq War of 1980–88, by terrorists in Japan in the mid-1990s, sarin munitions in 2013 and April 2017 in the Syrian conflict, and the use of the highly toxic nerve agent VX in the murder of Kim Jong-un's half-brother.

Worldwide concern over the use of organophosphorus nerve agents was particularly heightened by the more widespread military events in Syria. As noted above, a documented large-scale use of organophosphorus nerve agents occurred in August of 2013 in the Ghouta area of Damascus, Syria. Sarin was employed via surface-to-surface rockets with a considerable number of casualties. Although there are conflicting reports on the numbers, at least 3600 people presented to medical facilities with neurotoxic signs and symptoms and 588 fatalities were recorded by the Violations Documentation Centre, which reports to the United Nations (Dolgin, 2013; Enserink, 2013; Patrick et al., 2013).

The Syrian government reportedly possessed a stockpile of over 1000 tons of chemical agents and precursors including sulfur mustard, sarin, and VX. Another documented attack occurred later in Khan Sheikhoun, Syria. There have also been reports of the use of chlorine gas in the Syrian conflict. These concerns were being mitigated by efforts of the OPCW-United Nations joint mission in Syria, which targeted the removal and/or destruction of all priority chemicals in Syria by June 30, 2014. The OPCW stated on September 4, 2014, that 96% of that country's declared stockpile of chemical weapons had been destroyed.

The different types of CWAs can affect one or multiple major organ systems with systemic exposure. This chapter focuses on the nervous system as a target for CWAs. A brief overview of the nervous system, highlighting some of the special features that often contribute to its unique sensitivity to CWAs (and toxicants in general) is provided. Specific information on the effects of selected CWAs on the nervous system are discussed for illustration.

32.2 Overview of the nervous system

The nervous system can be divided into two major structural divisions: the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00032-5

the brain and spinal cord, covered by three "membranes"—the meninges. The outermost layer is the dura mater. The PNS consists of all parts of the nervous system that lie outside of the dura mater. The PNS can be classified based on functionality as the autonomic and somatic nervous systems. The autonomic nervous system, which can be further divided into the sympathetic, parasympathetic, and enteric divisions, regulates visceral functions and various processes that are not under voluntary control, while the somatic nervous system controls voluntary skeletal muscle activity. Maintenance of homeostasis and proper communication within and among these various components of the nervous system is critical for physiological coordination and normal functioning of the whole organism.

There are two basic types of cells in the nervous system: neurons ($\approx 10\%$ of the total number of cells) and glia ($\approx 90\%$ of the cells, including astrocytes, oligodendrocytes, NG2 cells, microglia, satellite cells, and Schwann cells). Neurons are highly specialized cells optimized for the conduction of electrical impulses to other nerve cells and to innervated tissues such as glands and muscles. In all neurons there exists a soma (cell body), dendrites (smaller branching structures), and an axon (electrical impulse-conducting fiber) that terminates in multiple endings and gives rise to specialized areas, that is, the presynaptic terminals. The junctional region between the presynaptic terminal and its target (innervated) cell is the synapse, where intercellular communication occurs, mediated by extracellular signal molecules (e.g., neurotransmitters) released by the presynaptic terminal. Anatomically, neurons can be classified into three basic types based on extensions of the dendrites and axon: unipolar, bipolar, and multipolar. Functionally, neurons can be characterized into afferent neurons (sensory neurons), efferent neurons (motor neurons), and interneurons. Afferent neurons conduct electrical impulses from tissues to the CNS, efferent neurons carry electrical impulses from the CNS to the tissues, and interneurons transmit information between neurons.

Despite having a markedly higher density in the nervous system, the glial cells were historically considered to provide metabolic and physical support for the neurons: this has been shown to be an oversimplification of the function of these types of cells. For example, astrocytes aid in the maintenance of homeostatic conditions of the extracellular fluid surrounding neurons by removing excess potassium ions. Microglia participate in phagocytosis following neuronal damage/degeneration. Oligodendrocytes and Schwann cells (found in the CNS and PNS, respectively) form the lipid-rich myelin layers around axons, which effectively enhance conduction down the axon and prevent the spread of impulses between juxtaposed axons. It is now recognized that glial cells play many important roles as key regulators of many aspects/processes associated with development, aging, and toxicology/pathology, such as synaptogenesis, reactive gliosis, immunoreactivity, and homeostasis of neurotransmitters (Aschner et al., 2002; Allen, 2013; Verkhratsky et al., 2014; Pajarillo et al., 2019).

Neurons are excitable cells undergoing dynamic phases of depolarization and repolarization as they mediate extracellular signaling. As with other cells, neurons maintain a resting potential across the plasma membrane, typically -60 to -75 mV, relative to the extracellular fluid. When fully excited, the membrane potential in a neuron exceeds a threshold voltage, which triggers a series of events that result in the initiation and propagation of an action potential along the axon to the terminal region. Each action potential begins with a rapid reversal of voltage from the negative resting potential to a positive potential (depolarization phase) and ends with an almost equally rapid change to a negative potential (repolarization phase). Once initiated, the action potential is self-propagated to the terminal region of the axon in an "all-or-none" (without decrement) fashion. When an action potential reaches the presynaptic terminal, voltage-gated Ca^{2+} channels open in response to depolarization, resulting in extensive influx of Ca^{2+} ions, which then trigger presynaptic vesicle exocytosis. The synaptic vesicles fuse with the plasma membrane and release their contents (neurotransmitters and other cosignals) into the synaptic cleft. Electrical impulses are thus transformed into chemical signals and thereby transduced from one (presynaptic) neuron to another (postsynaptic) neuron, muscle cell, or autonomic end organ through synaptic transmission.

Extracellular communication in the nervous system is typically mediated through synaptic transmission via the release of neurotransmitters and their subsequent binding to specific receptors. The transmitter−receptor interaction then generally elicits changes in ion channel permeability and/or second messenger formation in the innervated cell. Neurotransmitters can also interact with receptors located on the presynaptic terminal (either *autoreceptors* that are activated by the same transmitter or *heteroreceptors* that are activated by a different transmitter, released by a different neuron) to regulate presynaptic cell function, often by modulating further neurotransmitter release. Termination of synaptic neurotransmission is dependent upon the removal of neurotransmitter molecules from the synaptic cleft by either *enzymatic degradation* (e.g., by acetylcholinesterase in cholinergic neurons) or by *reuptake* into the presynaptic terminal (e.g., by a monoamine transporter in serotonergic neurons).

Classical neurotransmitters in the nervous system can be classified into the amino acids (e.g., glutamate, aspartate, GABA, glycine), the monoamines (e.g., catecholamines, serotonin, histamine), and acetylcholine. Adenosine triphosphate (ATP) and nitric oxide are

nonclassical neurotransmitters that often mediate cotransmission with other classical transmitters. Neurotransmitters typically mediate synaptic transmission in an anterograde fashion, that is, the transmitter molecules are released from a presynaptic terminal to diffuse across the synaptic cleft and bind to receptors on postsynaptic neurons or other types of cells to mediate unidirectional synaptic transmission.

In the last three decades, lipid metabolites known as endocannabinoids (eCBs) have gained attention as global neuromodulators, with the potential to influence a wide array of physiological and pathological processes (see reviews of Pacher and Kunos, 2013; Senst and Bains, 2014; Kendall and Yudowski, 2017). The eCBs are derived from membrane lipids that can modulate synaptic function in a *retrograde* fashion, that is, they are released by a postsynaptic cell but influence the activity of a presynaptic neuron. Anandamide (AEA) and 2-arachidonylglycerol (2-AG) are the two most prominent eCBs (i.e., endogenous lipid metabolites that directly bind/activate cannabinoid receptors). In the CNS, eCB signaling is mediated primarily by cannabinoid type 1 (CB1) receptors, a putative membrane transporter of eCBs, and enzymes involved in both synthesis (diacylglycerol lipase and *N*-acylphosphatidylethanolamine-specific phospholipase D) and inactivation (fatty acid amide hydrolase, FAAH and monoacylglycerol lipase, MAGL) of eCBs. Unlike classical neurotransmitters that are synthesized and stored in synaptic vesicles, the eCBs are synthesized "on demand" from arachidonic acid in the membrane lipids of neurons. Upon depolarization, the eCBs are synthesized and released from a postsynaptic neuron and then diffuse through the synapse to bind/activate CB1 receptors on the presynaptic terminal. The other major cannabinoid receptor subtype, CB2, primarily resides on immune cells, for example, activated microglia (Carlisle et al., 2002; Maresz et al., 2005), but eCBs may also modulate nervous system function by activating CB2 receptors on neurons (Morgan et al., 2009; García-Gutiérrez et al., 2012; Li and Kim, 2015). Endocannabinoid synthesis and release can also be stimulated in a receptor-mediated fashion by activation of the Gq protein-coupled metabotropic glutamate receptors and muscarinic M1 and M3 receptors. Termination of eCB signaling appears to require cellular reuptake via a carrier-mediated transport process. Following cellular reuptake, eCBs are enzymatically degraded. FAAH is distributed throughout the brain and appears to be primarily responsible for AEA hydrolysis, while MAGL is the primary enzyme involved in 2-AG degradation. Both FAAH and MAGL are intracellular enzymes and inhibition of either/both can lead to increases in eCB levels (Liu et al., 2013, 2015; Buntyn et al., 2017; Carr et al., 2014, 2017; Shin et al., 2019).

Depolarization-induced suppression of inhibition (DSI) and depolarization-induced suppression of excitation (DSE) are two forms of synaptic plasticity mediated by eCBs. In classical DSI, postsynaptic neurons release eCBs, which in turn decrease GABA release in presynaptic GABAergic neurons and disinhibit postsynaptic cell activity. In DSE, the eCBs reduce presynaptic glutamate release from glutamatergic neurons, leading to a net suppression of postsynaptic cell activity.

The nervous system is complex both anatomically and functionally. The extensive networks mediating intracellular and extracellular signaling make it highly vulnerable to disruption by many toxicants. Moreover, the nervous system possesses additional unique features that can contribute to its higher sensitivity to toxicants, including CWAs.

32.2.1 Special features of neurons and high energy demand

As noted above, neurons are composed of a cell body (or soma), extended, branching dendrites, and an elongated axon. Because of this structural complexity, most neurons have relatively large cell volumes compared to other cell types. The unique spatial features of neurons often require the synthesis of a large amount of proteins in the soma and their transport over long distances through processes of axonal transport. The Nissl substance, found exclusively in soma of neurons and formed by clusters of ribosomal complexes, synthesizes the large amount of proteins needed for these cells. Unlike other cells, neurons are particularly excitable, continuously generating and transmitting electrical signals along their axons and chemical signals across the intercellular synapses. The neurons, therefore, have an absolute requirement for a continuous and abundant supply of energy to support the need for synthesis of large amounts of proteins and neurotransmitters, for transport of proteins, cellular organelles, and cytoskeletal components to distant parts of the cell, and to maintain and restore ionic gradients affected by cycles of depolarization/repolarization.

The nervous system depends heavily on aerobic glycolysis to generate energy. The demand for oxygen and glucose is so high and sustained that even a brief interruption of oxygen and/or glucose may result in severe adverse consequences as there is essentially no reserve in the brain. The high oxygen requirement is associated with approximately 20% of total cardiac output going to the brain. Toxic agents that interrupt the supply of oxygen (e.g., carbon monoxide) or the utilization of oxygen (e.g., cyanide) can, therefore, produce catastrophic cellular and functional damage in the nervous system.

The nervous system is a lipid-rich environment. As noted above, many elongated axons in the CNS and PNS are insulated by concentric layers of myelin that facilitate conduction of electrical impulses. Because of the density of the lipids, myelinated axons can be more sensitive to lipophilic neurotoxicants. Moreover, axons in the adult CNS have very limited ability to regenerate after injury, at least partially because of myelin-associated inhibitory factors from oligodendrocytes and "glial scars" from reactive astrocytes. In contrast, axons in the PNS have a greater potential to regenerate and regrow after injury under the differential environment provided by Schwann cells.

32.2.2 Blood–brain barrier

Most of the adult brain and spinal cord is anatomically separated from the circulation by a continuous lining of specialized endothelial cells whose apposed surfaces form tight junctions. This, aided in part by associated glial cells, constitutes a *blood–brain barrier* (BBB), largely limiting passage of substances that are large and hydrophilic, unless there is an active transport mechanism for facilitating transfer across the cellular membrane. The BBB plays a pivotal role in protecting the CNS from various chemical challenges, especially larger, hydrophilic toxicants. In humans, this BBB is incompletely developed at birth, and even less so in premature infants. The barrier also does not exist in certain brain regions, for example, the area postrema, hypophysis, hypothalamic regions, pineal body, and the supraoptic crest. The deficiency of the BBB in these areas in the adult brain, and the incomplete BBB in the developing brain, can be important in differential sensitivity to chemicals. With many toxicants that are relatively hydrophobic (e.g., organophosphorus nerve agents) however, the BBB has little role in uptake and neurotoxicity. The integrity of the BBB can be compromised under certain conditions, for example, anesthesia, stress, metabolic and/or pathological disorders (e.g., adrenocorticoid hypertension, meningitis), leading to higher sensitivity to some neurotoxicants (see Kandel et al., 2013 for an extensive overview of nervous system structure and function).

32.3 Types of neurotoxicity

Based on the respective location of the original "lesion" elicited by a neurotoxicant, neurotoxic responses can be classified as neuronopathy, axonopathy, myelinopathy, or transmission-associated toxicity. *Neuronopathy* involves injury/death of neurons, with subsequent degeneration and loss of dendrites, axons, and myelin sheath (when present). Such neuronal degeneration is irreversible and can result in an encephalopathy with global dysfunction, dependent upon the neuronal population(s) affected. *Axonopathy* can be thought of as a "chemical transection" at some point along an axon, such that the distal segment degenerates but the soma remains intact. The critical difference between central and peripheral axonopathies is the ability of the axon to regenerate and reinnervate the "target" cell over time. A common, early clinical indicator of axonopathy is loss of peripheral sensations (e.g., glove and stocking paresthesia) and disruption in fine, distal motor control. *Myelinopathy* is a chemical-induced demyelination (i.e., loss of the myelin sheath) or intramyelinic edema (i.e., separation of the concentric layers of the myelin). Remyelination typically occurs with a much thinner myelin sheath and shorter intermodal distances than present before the toxic insult. *Neurotransmission-associated toxicity* typically occurs in the absence of any initial morphological change, but is related to toxicant-induced *neurochemical* changes within the synaptic region. Toxicants can disrupt neurotransmission by affecting presynaptic processes including neurotransmitter synthesis, transport, and/or storage in synaptic vesicles, neurotransmitter release, reuptake or degradation, by binding to presynaptic and/or postsynaptic receptors, by affecting ion flux in the presynaptic or postsynaptic cell, or by other mechanisms influencing signal transduction.

Neurotoxicity can also be classified based on the functions affected, for example, dysautonomia when the autonomic nervous system is disrupted, neuromuscular disorders when somatic motor neurons or the neuromuscular junction is affected, sensory neuropathy when sensory receptors or afferent sensory neurons are the primary targets, or cognitive deficits and mood/mental disorders when higher brain/cognitive functions are affected.

32.4 Selected chemical warfare agents that affect the nervous system

As briefly reviewed above, the nervous system possesses some unique anatomical, biochemical, and physiological characteristics that can contribute to its relatively higher sensitivity to xenobiotics, including CWAs. Many chemicals are potential weapons of mass destruction, including but not limited to organophosphate nerve agents, cyanides, mustards, arsenicals, and the natural products botulinum toxin and ricin. CWAs can adversely affect the nervous system either directly [i.e., the toxicant interacts with a receptor inside the nervous system (a molecular initiating event)] or indirectly (i.e., the disruption of nervous system function by a molecular initiating event outside the nervous system), leading to acute and/or chronic adverse neurological consequences.

32.4.1 Organophosphorus nerve agents

The organophosphorus nerve agents are widely recognized as CWAs and are among the most lethal CWAs ever developed. They are classified as either "G" or "V" series agents. The "G" agents including tabun (*O*-ethyl-*N*,*N*′-dimethylphosphoramidocyanidate; GA), soman (*O*-pinacolyl methylphosphonofluoridate; GD), sarin (isopropyl methylphosphonofluoridate; GB), and cyclosarin (cyclohexyl methylphosphonofluoridate; GF) are volatile and relatively nonpersistent, whereas the "V" agents such as VX (*O*-ethyl *S*-2-diisopropylaminoethyl methylphosphonofluoridate) are less volatile and relatively more persistent. Both the United States and the Soviet Union stockpiled many of these agents for military use during the Cold War. However, the first documented military use of nerve agents was not until the Iran-Iraq War of 1980−88. During this conflict, Iraqi troops employed sarin-containing munitions against both military personnel and civilians, confirmed by detection of trace amounts of a breakdown product, isopropyl methylphosphonic acid, in soil samples taken from a Kurdish village in northern Iraq (Macilwain, 1993). Subsequently, sarin was used in two separate terrorist attacks in Japan by a cult named *Aum Shinrikyo* (Divine Truth). The first attack on June 27, 1994, occurred in a residential neighborhood in Matsumoto, resulting in 56 hospitalizations and 7 deaths. The second attack on March 20, 1995, occurred in several subway cars in Tokyo, resulting in 796 hospitalizations and 12 deaths (Yanagisawa et al., 2006).

Among the victims of the sarin attack in Tokyo, Japan, 111 individuals were characterized as severely or moderately injured on admission to hospital on the day of the attack and exhibited miosis (99%), headache (75%), respiratory distress (63%), nausea (60%) and vomiting (37%), eye pain (45%), blurred or dim vision (40% and 38%, respectively), and seizures (approximately 3%) (Okumura et al., 1996). Changes in psychomotor functioning, visual perception and sustained attention, learning and memory, and mood (Yokoyama et al., 1998; Murata et al., 1997) were observed in 18 survivors, evaluated 6 − 8 months later. Depressive behaviors were reported in survivors between 6 months and 7 years after the attack. This included those who had not presented with symptoms of acute toxicity at the time of the incident (Araki et al., 2005). Yamasue and colleagues (2007) observed smaller regional white matter volumes and diffuse bilateral disruption of white matter integrity 5−6 years after the attacks. Miyaki and colleagues (2005) reported deficits in attention and gross motor speed 7 years after the attacks. Hoffman et al. (2007) reported that digit span, finger-tapping, and computerized posturography tests showed statistically significant differences between victims of the Tokyo attacks and controls, while the most consistent consequence was post-traumatic stress disorder.

Organophosphorus toxicants, including nerve agents, elicit acute toxicity primarily via inhibition of acetylcholinesterase, disrupting homeostatic regulation of acetylcholine-mediated cholinergic signaling in the CNS and PNS. Acetylcholine is synthesized in the presynaptic terminal by choline acetyltransferase using choline and acetyl CoA as substrates. Once synthesized, acetylcholine molecules are stored in the synaptic vesicles. Upon depolarization, the vesicles containing acetylcholine fuse with the presynaptic membrane and release acetylcholine into the synapse. The diffusible acetylcholine molecules then interact specifically with cholinergic (muscarinic and nicotinic subtypes) receptors on postsynaptic cell membranes to mediate signal transduction. Muscarinic receptors are G protein-coupled receptors that modulate the formation of second messengers [e.g., cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG), and inositol triphosphate (IP3)]. Five muscarinic receptor subtypes (M1−M5) have been identified and cloned. M1, M3, and M5 subtypes are coupled to phospholipase C (PLC) via G_q and increase the formation of DAG and IP3 upon activation, whereas M2 and M4 subtypes are coupled to inhibition of adenylyl cyclase via G_i and decrease the formation of cAMP. Nicotinic receptors are ligand-gated ion channels that generally increase Na^+ influx upon stimulation. Acetylcholine can also bind to presynaptic muscarinic and nicotinic receptors to modulate the further release of acetylcholine in a negative (or sometimes positive) "feedback" manner. Acetylcholine in the synapse is degraded very rapidly by acetylcholinesterase into choline and acetate. The choline molecules are transported back into the presynaptic terminal through a process known as *high-affinity choline uptake*, the rate-limiting step in acetylcholine synthesis. Acetylcholine, therefore, has only a transient opportunity to activate muscarinic or nicotinic receptors, either postsynaptically or presynaptically. Inhibition of acetylcholinesterase prevents the normally efficient breakdown of acetylcholine in the synapse, leading to acetylcholine accumulation and persistent/prolonged stimulation of cholinergic receptors, which in turn elicits signs and symptoms of cholinergic toxicity.

Many of the classical signs of cholinergic toxicity associated with organophosphate poisoning involve the PNS. The well-recognized cholinergic signs of excessive secretions (salivation, lacrimation, urination, and defection, abbreviated by the acronym SLUD) and other sensitive changes, for example, miosis, are the result of acetylcholinesterase inhibition and muscarinic receptor activation in peripheral tissues (Espinola et al., 1999). Other common signs of cholinergic toxicity, for example, muscle fasciculations, involve overstimulation of nicotinic receptors in peripheral tissues (Costa, 1988). However, the most debilitating effects of anticholinesterase exposures involve the CNS (Pope, 2006). Lethality from

organophosphate intoxication is typically due to depression of brainstem respiratory control centers, compounded by excessive airway secretions and dysfunction of diaphragm and intercostal muscles. Rickett and colleagues (1986) reported that one of the first signs of nerve agent-induced respiratory distress in cats was disruption of the normal firing of respiratory-related neurons in the pons medulla, followed by changes in airflow, diaphragm contraction, diaphragm electromyogram (EMG), and phrenic nerve activity. Spectral analysis of diaphragm EMG indicated that the functional integrity of the diaphragm in guinea pigs following soman exposure (15 μg/kg, s.c.) was not sufficiently compromised to produce respiratory distress despite signs of fatigue (Chang et al., 1990). These studies suggested that respiratory distress following nerve agent exposure is mainly due to disruption of central cholinergic signaling. Bajgar et al. (2007) reported that acetylcholinesterase activity in the pons medulla (i.e., the site of respiratory control centers) was more extensively inhibited by soman, sarin, and VX than acetylcholinesterase in many other brain regions.

While tremors can be elicited by excessive activation of nicotinic receptors in the PNS, whole body tremors can result from extensive acetylcholinesterase inhibition in the CNS, with activation of muscarinic receptors in the basal ganglia being of prominent importance (Espinola et al., 1999). With severe intoxications, seizures can be elicited that lead to irreversible neuropathology (Shih et al., 1991; Kadar et al., 1995; Dekundy et al., 2001, 2007). Shih and McDonough (1999) demonstrated that all five of the classic nerve agents (i.e., cyclosarin, sarin, soman, tabun, and VX) were capable of inducing seizures at lethal dosages. In the case of VX, however, the latency of seizure development was three to five times longer than with the other nerve agents. Soman-induced seizures occurred in rats only when cortical acetylcholinesterase inhibition was over 65% (Tonduli et al., 2001). Anticholinergics (e.g., atropine and biperiden) and benzodiazepines (e.g., diazepam and midazolam) were able to terminate nerve agent-induced seizures in guinea pigs when administered within 5 min of seizure onset, but a higher dose of each was typically required to terminate seizures induced by soman compared to other nerve agents (Shih et al., 2003).

Prolonged seizure activity (i.e., *status epilepticus*) following nerve agent exposure has been shown in several animal models to cause neuropathological lesions that are associated with long-term deficits in cognitive function and other neurobehavioral endpoints. Moderate to severe neuropathological lesions were reported in 70% of sarin- (Kadar et al., 1995) and 98% of soman-treated (McDonough et al., 1995) rats, when seizures lasted 20 min or longer. Pathological lesions were primarily noted in hippocampus, piriform cortex, and thalamus, but later progressed to other brain regions, for example, amygdala. Soman-induced *status epilepticus* in rats resulted in significant neuronal loss and neurodegeneration, in particular with GABAergic interneurons, in the basolateral nucleus of the amygdala. Moreover, this neuropathology was associated with increased anxiety-like behavior measured in the open-field test and the acoustic startle response, 14 days later (Prager et al, 2014). Spatial memory performance deficits in the Morris water maze were directly related to the severity of hippocampal lesions in soman-treated rats. Interestingly, no memory impairment was observed below a threshold of 15% neuronal loss (Filliat et al., 1999). Impaired contextual and cued fear conditioning (fear-based learning and memory) were observed in soman-treated rats and mice that experienced seizures and neuronal degeneration in different brain regions (Moffett et al., 2011; Coubard et al., 2008). These mice also showed anxiety-like behaviors measured in unconditioned fear tests (light/dark boxes and elevated plus maze). Deficits in cognitive function measured in a novelty test, the brightness discrimination task (Myhrer et al., 2005), and the stone maze (Raffaele et al., 1987) were reported in rats following soman-induced seizures associated with neuropathological lesions.

Nerve agents such as soman and other organophosphorus anticholinesterases can induce behavioral changes linked to anxiety- and depressive-like behaviors in animal models, at dosages that do not elicit seizures. A sublethal dosage of soman ($0.6-0.8 \times LD_{50}$) triggered anxiety-like behavior (measured in the open-field test and elevated plus maze) in guinea pigs (Mamczarz et al., 2010). Acute intoxication with diisopropylfluorophosphate (DFP, a prototype organophosphate and structural analog of sarin) in rats increased immobility and decreased active swimming behavior in the forced swim test (Wright et al., 2010).

DFP (9 mg/kg, i.m.) in atropine- and pyridostigmine-pretreated rats led to seizures and delayed (4−72 h) apoptotic neuronal cell death in the hippocampus, cortex, amygdala, and thalamus as shown by Fluoro-Jade staining, with reduced NeuN immunoreactivity at 24 h after dosing (Li et al., 2011). Interestingly, neuregulin isoforms (NRG-EGF, NRG-GGF2) reduced both neuronal injury and apoptosis in this model (Li et al., 2012). Moreover, a time-course study indicated that astrocytic immunoreactivity (GFAP) increased in a brain regional manner, with GFAP in hippocampus and piriform cortex increasing from 1−8 h, decreasing out to 24 h, and then showing a marked increase from 3 to 7 days after dosing. The results suggested that glial activation may be an early precedent of neuropathology in this model (Liu et al., 2012). A more recent study (Li et al., 2015) indicated that neuregulin-1 reduced microglial activation after DFP exposure. Microarray analysis suggested a reduction in proinflammatory cytokines including IL-1B and IL-6.

Flannery et al. (2016) and Hobson et al. (2019), using a similar DFP-rat model, studied the time course of immunohistochemical markers of neuroinflammation [GFAP and ionized calcium-binding adapter molecule 1 (IBA1)], along with PET imaging of the 18-kDa mitochondrial membrane translocator protein (TSPO). Neuroinflammation was noted in hippocampus and cortex from 3 days, peaking at 7 days and evident out to 21 days after dosing, and importantly was correlated with earlier seizure intensity. These and other results (Sisó et al., 2017; Guignet et al., 2019) confirmed a likely role for neuroinflammation in the delayed and persistent sequelae following OP anticholinesterase-induced seizures and acute cholinergic toxicity.

Chen et al. (2011) reported serotonergic-related changes in affective behaviors measured in the elevated plus maze, the Vogel's conflict test, the novelty-suppressed feeding test, and the forced swimming test in adolescent rats exposed to the common OP insecticide chlorpyrifos (10−160 mg/kg/day for 7 days, s.c.). Repeated exposure to another OP insecticide, methamidophos, in the drinking water at levels that did not elicit systemic toxicity induced depressive-like behavior in adult mice (Lima et al., 2009). Malathion exposure has also been reported to be associated with depressive-like behavior in rodents (Ramos et al., 2006; Brocardo et al., 2007; Acker et al., 2009).

Anxiety and depression have also been reported in humans following organophosphate intoxication. A number of epidemiological studies have reported long-term neuropsychological or neuropsychiatric sequelae, such as anxiety and depression, with past anticholinesterase intoxication or exposure (Savage et al., 1988; Rosenstock et al., 1991; McConnell et al., 1994; Steenland et al., 1994; Yokoyama et al., 1998, 2002; Wesseling et al., 2002; Colosio et al., 2003; London et al., 2005; Roldan-Tapia et al., 2006). A cross-sectional survey conducted among 761 individuals, representing 479 farms in northeastern Colorado between 1992 and 1997, found that exposure to pesticides, in particular organophosphates, sufficient to cause self-reported poisoning symptoms was associated with a more than five times higher rate of depression, independent of other known risk factors (Stallones and Beseler, 2002). A mini review of 11 studies on depression in relation to pesticides revealed increased odds ratios (ranging from 2 to 6) for developing depression or other psychiatric disorders (Freire and Koifman, 2013). Wesseling et al (2010) reported an increased incidence of depression and anxiety, along with other psychological or psychiatric deficits, in workers exposed to organophosphates that had received medical attention 1−3 years prior to the study.

Thus, central actions of acute or repeated exposures to organophosphorus anticholinesterases can be critical in both acute and long-term neurological sequelae. While disruption of cholinergic neurotransmission is a hallmark of acute organophosphate poisoning, substantial evidence indicates disruption of noncholinergic signaling can contribute to the ultimate long-term outcome. Shih and coworkers (1991) reported that seizures elicited by soman were initially sensitive, but later resistant, to the antimuscarinic antidote atropine. Activation of glutamate signaling in limbic regions, for example, hippocampus, appeared particularly important in maintaining organophosphate-induced seizures (Lallement et al., 1991). These investigators observed a 78% increase in extracellular glutamate in the CA3 region of the hippocampus within 30 min of seizure onset, and a more robust early increase (180%) followed by a decline but more sustained increase in the hippocampal CA1 region after 50 min of seizure onset in soman-treated rats. Sparenborg and colleagues (1992) reported that the NMDA antagonist MK-801 (30, 100, or 300 μg/kg, i.m.) arrested soman-induced seizures in a dose-dependent manner, suggesting that NMDA receptor activation plays a critical role in the spread and persistence of nerve agent-induced seizures. Moreover, NMDA receptor antagonists blocked seizures elicited by some organophosphorus insecticides (dichlorvos and chlorfenvinphos; Dekundy et al., 2001, 2007). In contrast, it is reported that higher striatal dopamine and GABA levels were correlated with the severity of soman toxicity, seizure intensity, and epileptiform bursting (Cassel and Fosbraey, 1996; Jacobsson et al., 1997). The dopamine D1-like antagonist SCH23390 completely blocked soman-induced seizures (Bourne et al., 2001). The activation of noncholinergic signaling pathways, therefore, appears to participate in the expression of organophosphate toxicity, and brain regional differences in the activation of noncholinergic signaling may be important in the ultimate neurotoxic outcome.

More than 100,000 United States military personnel participating in the 1991 Gulf War were potentially exposed to low levels of cyclosarin and sarin following the destruction of a munitions storage facility at Khamisiyah, Iraq, in March 1991 (Smith et al., 2003). Roughly 30% of Gulf War veterans later reported various neurological and other symptoms collectively referred to as Gulf War illnesses (GWI), characterized by impaired cognition, depression, insomnia, ataxia, disorientation, joint/muscle pain, extremity paresthesias, fatigue, headaches, and respiratory, gastrointestinal, and dermatologic complaints (Haley et al., 1997; Steele et al., 2015; White et al., 2016). Deficits in motor dexterity and visuospatial abilities (Proctor et al., 2006) and a twofold increase in the incidence of brain cancer-related deaths (Bullman et al., 2005) were reported in these veterans. In addition, a reduction in the overall volume of white matter and an enlargement of the lateral ventricles were observed in the brains of some veterans (Heaton et al., 2007).

An extensive review (RAC, 2008) found a causal relationship between exposure to anticholinesterases (pyridostigmine and/or pesticides) and GWI, while a later Institute of Medicine review (IOM, 2010) concluded there was insufficient information to confirm that association. The fact that pyridostigmine was *intentionally* taken (suggested dose was 30 mg three times a day) and thus constituted a relatively high-level exposure compared to many other potential environmental chemical exposures is important. A number of studies published since 2010 continue to provide support for a role of pyridostigmine in GWI. For example, Steele and coworkers (2015) found an association between pyridostigmine use and increased odds for GWI in those veterans having genetic variants of butyrylcholinesterase (the "sister" enzyme of acetylcholinesterase) with low enzymatic activity. White and colleagues (2016) concluded that exposure to pesticides and/or to pyridostigmine was associated with neurological symptoms of GWI in Gulf War veterans potentially exposed to sarin and cyclosarin. In a rat model of GWI with prior pyridostigmine exposures, lipopolysaccharide challenge led to increased C-reactive protein levels compared to controls, attenuated cholinergic neurochemical responses, and impaired behavioral responses in contextual and fear-based learning paradigms (Macht et al., 2019). Thus, the causal relationship between anticholinesterase exposures including pyridostigmine and development of GWI remains a viable hypothesis supported by substantial evidence.

GWI is regarded as a chronic multisymptom illness or CMI (IOM, 2013). Treatment strategies for relatively nonselective, multisymptom clusters are being actively evaluated. The cause or causes of GWI have been extensively evaluated and remain uncertain, but more effective treatments may be realized in the absence of a mechanistic explanation for these conditions. Although exposure to the organophosphorus nerve agents, organophosphorus pesticides, and the carbamate anticholinesterase pyridostigmine have been suspected of playing some role in the neurological dysfunction in GWI (Brimfield, 2012; Sullivan et al., 2018; White et al., 2016), the evidence overall has been insufficient to firmly establish such relationships.

Reviews of medical records for Gulf War veterans and published field accounts revealed no clinical indications of classic, acute organophosphate intoxication (Riddle et al., 2003). Again, the lack of evidence for acute cholinergic signs in affected individuals, coupled with the very high sensitivity of acetylcholinesterase to inhibition by these toxicants and thus to cholinergic toxicity, may be a clue that noncholinergic mechanisms are important in the etiology of GWI.

Neuroinflammation has been implicated in the development of a variety of neurological conditions (Schwartz and Deczkowska, 2016; Hobson et al., 2019). A number of studies suggest a role for neuroinflammation in the etiology of GWI (O'Callaghan et al., 2015; Coughlin, 2017; Shetty et al., 2017; Locker et al., 2017; Carreras et al., 2018; Michalovicz et al., 2019). A noncholinergic signaling pathway that may participate in inflammation and other anticholinesterase-mediated effects is the eCB system. Endocannabinoid signaling participates in a variety of processes including thermoregulation, food intake, immunomodulation, perception (hearing, color, vision, taste), cognition (long-term potentiation, short-term memory), and motor function (locomotor activity, proprioception, muscle tone). Of particular importance in cholinergic toxicity, eCBs inhibit the release of a number of neurotransmitters (Gifford and Ashby, 1996; Gessa et al., 1997; Levenes et al., 1998; Miller and Walker, 1995; Cadogan et al., 1997; Cheer et al., 2004). Several studies have suggested that eCBs tonically inhibit acetylcholine release in hippocampus via CB1 receptors, that is, agonists reduce while antagonists increase the release of acetylcholine (Gifford and Ashby, 1996; Gifford et al., 2000; Tzavara et al., 2003; Degroot et al., 2006; Gessa et al., 1997; Kathmann et al., 2001). Interestingly, acetylcholine release in the striatum is unaffected by eCB agonists/antagonists or by deletion of the CB1 gene in mice (Gifford et al., 2000; Kathmann et al., 2001). Thus, differential effects of eCBs on acetylcholine release in different brain regions may be important.

Endocannabinoid-mediated inhibition of GABA and glutamate release from presynaptic neurons via DSI and DSE may also play an important role in the expression of organophosphate toxicity. As mentioned above, higher levels of striatal GABA and limbic glutamate levels have been correlated with more severe signs of organophosphate toxicity (Lallement et al., 1991, 1992; Cassel and Fosbraey, 1996; Jacobsson et al., 1997). Furthermore, the $GABA_A$ receptor antagonist bicuculline is proconvulsant when directly administered into limbic regions but is anticonvulsant when microinjected into the striatum (Turski et al., 1989, 1991). Thus, changes in GABAergic and glutamatergic signaling and their modulation by eCBs could have regional-specific effects on neurological function after organophosphate intoxication.

While eCBs can regulate the release of acetylcholine and other neurotransmitters, organophosphorus toxicants may also affect eCB signaling, either indirectly through acetylcholinesterase inhibition (and neuronal depolarization/activation of M1/M3 receptors) or directly through binding to cannabinoid receptors and/or inhibiting cannabinoid metabolizing enzymes (Quistad et al., 2001, 2002, 2006; Segall et al., 2003; Nallapaneni et al., 2006, 2008). Chlorpyrifos oxon, paraoxon, and DFP inhibit CB1 receptor binding and the activities of FAAH and MAGL in vitro, with chlorpyrifos oxon being more potent. In

vivo, DFP inhibited FAAH but had little effect on MAGL or CB1 binding (Nallapaneni et al., 2008). Liu and colleagues (2013) reported that both chlorpyrifos and parathion (the parent compounds of chlorpyrifos oxon and paraoxon, respectively) inhibited FAAH and MAGL in vivo, with more extensive inhibition of FAAH by both compounds. Extracellular levels of eCBs in rat hippocampus were increased by both chlorpyrifos and parathion at dosages that inhibited >80% of hippocampal acetylcholinesterase activity.

Pharmacological manipulation of eCB signaling has been shown to affect both acute and long-term toxicity of organophosphates. The mixed CB1/CB2 receptor agonist WIN 55,212-2 (1.5 mg/kg, i.p.) reduced acute paraoxon toxicity with a single dose, but increased toxicity if paraoxon was given after repeated WIN 55,212-2 dosing (daily for 7 days; Nallapaneni et al., 2006). Liu and Pope (2015) showed increased cholinergic toxicity in rats exposed to either chlorpyrifos oxon or paraoxon and then challenged with the CB1 receptor antagonist/inverse agonist AM251. Farizatto and coworkers (2017) reported that paraoxon reduced synapsin IIb levels and elicited oxidative damage to proteins (4-hydroxynonenal-protein adducts) in hippocampal slices in vitro, which were reversed by the FAAH inhibitor AM5206. Moreover, preexposure to AM5206 in rats blocked paraoxon-induced seizures, reduction in synapsin IIb, and oxidative changes in the hippocampus and cortex. Acute DFP toxicity was reduced by WIN 55,212-2, as well as by inhibitors of FAAH and MAGL (URB597 and URB602, respectively), and the eCB reuptake inhibitor (AM404; Nallapaneni et al., 2008). As noted before, acute DFP exposure induced changes in the forced swim test in rats used extensively in tests for antidepressant efficacy. The combination of URB597 and URB602 reversed some DFP-induced changes in the forced swim test (Wright et al., 2010). Interestingly, the CB1 receptor antagonist/inverse agonist AM251 decreased parathion-induced toxicity in rats while having no influence on functional signs of chlorpyrifos (Liu et al., 2013). Thus, eCB signaling may play differential roles in toxic outcome of organophosphates based on the modulation of different neurotransmitter systems, possibly related to the time of onset and the duration of the neurotoxic response.

A number of studies have reported that young animals are generally higher in sensitivity to the acute toxicity of organophosphorus insecticides (Benke and Murphy, 1975; Pope et al., 1991; Moser, 2011; Padilla et al., 2000; Pope and Liu, 1997; Zheng et al., 2000). Interestingly, based on acetylcholinesterase inhibition and functional/behavioral changes, young rodents can actually be less sensitive to repeated anticholinesterase exposures, due to the differential rates of recovery of acetylcholinesterase activity after inhibition by an organophosphorus toxicant (Chakraborti et al., 1993). With lower level, repeated exposures to the pesticide chlorpyrifos in postnatal rats [0.5−1.0 mg/kg/day from postnatal day (PND) 10−16], eCB metabolism (by inhibiting FAAH) was affected in dosages that in most cases did not affect acetylcholinesterase activity and was associated with increased brain and peripheral tissue anandamide and 2-arachidonoyl glycerol levels and changes in anxiety-like behaviors (Carr et al., 2014, 2017; Buntyn et al., 2017).

Relatively less is known regarding the neurochemical and toxicological consequences of organophosphorus nerve agents in young individuals. Wright and coworkers (2016) reported that rats at PND 7, 14, 21, and 70 were more sensitive than at PND 28 and 42 to lethality from subcutaneous exposure to tabun, sarin, soman, and cyclosarin, but no age-related differences in sensitivity were observed with VM, VX, or Russian VX. Wright et al. (2017) also reported higher sensitivity to inhalation exposures to sarin in PND 14 rats, and again, with lowest sensitivity in the adolescent rats (PND 28). Miller et al. (2015) showed that PND 21 rats exposed to $1.2 \times LD_{50}$ soman that developed status epilepticus also had decreased brain acetylcholinesterase activity, especially in the basolateral amygdala. Soman-induced seizures in PND 21 rats were also associated with fear-learning deficits and increased anxiety at 30 days post-exposure, and reduced volume of the amygdala and hippocampus at 30 and 90 days despite no signs of neuronal degeneration in the brain at 1 or 7 days. Meanwhile, Scholl et al. (2018) reported that seizure severity was age-dependent: PND 14 rats exposed to sarin or VX showed no EEG seizure activity, while seizure activity increased in severity as a function of age in PND 21, 28, and 70 rats.

While we and others have focused on the role of endocannabinoids in modulation of organophosphorus anticholinesterase toxicity, an important issue is the increasing legal medical and recreational use of phytocannabinoids (in marijuana) in the United States and other countries. As the psychoactive phytocannabinoids can interact with the same cannabinoid receptor signaling pathways as the endocannabinoids, there is concern for how eCB signaling may be disrupted by cannabis use, in children or in adults, and how that could influence the sensitivity to an organophosphate through disruption of endocannabinoid-mediated neuromodulatory mechanisms (Nallapaneni et al., 2006; Liu and Pope, 2015; Farizatto et al., 2017). Further, the classical neuromodulatory role of CB1 receptor activation by endocannabinoids and phytocannabinoids (e.g., THC) influences synaptic signaling by modulating neurotransmitter release. In the presence of acetylcholinesterase inhibition, reducing further acetylcholine release can putatively reduce cholinergic toxicity. In contrast, activation of CB2 receptors has little to do with regulating neurotransmitter release but can play an

immunomodulatory role that could be important in some later responses to anticholinesterase exposures (Haugh et al., 2016; Mastinu et al., 2018). Moreover, THC as well as the nonpsychoactive phytocannabinoids, for example, beta-caryophyllene, can activate CB2 receptors while the endocannabinoid-like metabolites oleoylethanolamide and palimitoylethanolamide activate PPAR alpha receptors (Guzmán et al., 2004; O'Sullivan, 2007; Lindsey et al., 2019). As PPAR activation can also modulate inflammatory processes, all of these actions have the potential to modulate neuroinflammation that may be important in the later neurological complications of an acute anticholinesterase intoxication. With a number of studies implicating neuroinflammation in the delayed and persistent neurological sequelae following anticholinesterase intoxication, both endocannabinoids and phytocannabinoids may modulate the progression of delayed neuroinflammatory processes. These neuroinflammatory pathways may have importance in the ultimate outcome of acute organophosphate intoxication and in the etiology of GWI.

Organophosphorus anticholinesterases have the potential to markedly disrupt nervous system function, eliciting a broad range of acute and long-term effects. While acetylcholinesterase has been considered as the primary target of these toxicants, and downstream changes in cholinergic signaling have been the main focus in understanding mechanisms and exploring countermeasures, noncholinergic pathways following acetylcholinesterase inhibition may play a prominent role in the ultimate chronic outcome following organophosphate exposure.

32.4.2 Cyanides

Cyanides have been used for their toxic potential since ancient Roman times. Cyanogen chloride, cyanogen bromide, and hydrogen cyanide are important cyanide-containing compounds of potential use as CWAs. The use of cyanides in chemical warfare was not realized until WWI. Due to their high volatility, however, these compounds rarely achieve lethal atmospheric concentrations except in enclosed spaces (Lee, 1997). Hydrogen cyanide was used for mass extermination of prisoners in concentration camps by the Nazis during WWII. Other forms of cyanide-containing compounds have also been used for malicious purposes. For example, potassium cyanide was illicitly placed in capsules of Extra Strength Tylenol, leading to seven deaths in the Chicago area in 1982 (Dunea, 1983).

Signs of cyanide exposure include agitation, dizziness, headache, and mental confusion followed by cardiac disturbances, loss of consciousness, respiratory distress, seizures, and death. While cyanide exposure is often fatal, there are reports of long-term effects with sublethal intoxications. Finelli (1981) described a 30-year-old male, 1 year after an attempted suicide with cyanide, who developed choreiform movements in his extremities and impairment in the movement of his left hand. Similarly, Carella et al. (1988) reported a 46-year-old woman who drank a beverage poisoned with cyanide and later developed a dystonic posture of the mouth and tongue that was deviated to the right and twisted. Computed tomography scans showed that both individuals had lesions in the basal ganglia.

Although there are a number of reports on the neuropathological consequences of cyanide exposure including necrotic lesions in the cerebellar gray matter of dogs (Haymaker et al., 1952) and demyelinating lesions in the corpus callosum and optic nerves of rats (Lessell, 1971), its neurobehavioral sequelae have received relatively little attention. D'Mello (1986) reported that a single exposure to sodium cyanide (4 mg/kg, s.c.) impaired swimming ability in guinea pigs. Mathangi and Namasivayam (2000) demonstrated that repeated exposure to sodium cyanide (2 mg/kg/day $\times$ 30 days, i.p.) impaired T-maze performance in rats, along with a reduction in dopamine and 5-hydroxytryptamine levels in the hippocampus.

The primary mode of action for cyanide-induced toxicity is inhibition of cytochrome oxidase, the terminal enzyme of the electron transport chain. Inhibition of cytochrome oxidase leads to cytotoxic hypoxia, with a shift from aerobic to anaerobic metabolism, a decrease in ATP synthesis, and an increase in lactic acid production (Way, 1984). The CNS is particularly sensitive to the toxic effects of cyanide due to both extremely limited anaerobic metabolic capacity and high energy dependence. Ikegaya and colleagues (2001) showed that the inhibition of cytochrome oxidase activity following oral administration of potassium cyanide (10 mg/kg) in rats was highest in brain compared to other organs. Thus, not only is the CNS particularly sensitive to cyanide-induced hypoxia and energy deficit, but the target enzyme itself in the CNS may be more sensitive to inhibition by cyanide compared to enzyme in other tissues.

Oxidative stress may also play a critical role in cyanide-induced toxicity. Potassium cyanide (7 mg/kg, s.c.) decreased the activities of catalase, glutathione peroxidase, and superoxide dismutase in mouse brain (Ardelt et al., 1989). Potassium cyanide also stimulated the formation of reactive oxygen species and increased levels of malondialdehyde in a number of neuronal cell types including cerebellar granule cells (Gunasekar et al., 1996), primary cortical cells (Li et al., 2002), and rat pheochromocytoma (PC-12) cells (Kanthasamy et al., 1997). Johnson and colleagues (1986) proposed that a rise in intracellular Ca^{2+} levels following potassium cyanide exposure was responsible for the formation of reactive oxygen species. In support of this, Gunasekar and

colleagues (1996) reported that removal of Ca^{2+} from the culture medium blocked the formation of reactive oxygen species in cerebellar granule cells exposed to potassium cyanide (100 μM). Moreover, antioxidants (Muller and Krieglstein, 1995), Ca^{2+} channel blockers (Johnson et al., 1987), cyclooxygenase-2 (COX-2) inhibitors (Li et al., 2002), as well as NMDA receptor antagonists (Gunasekar et al., 1996) and phospholipase A2 inhibitors (Kanthasamy et al., 1997) all blocked the formation of reactive oxygen species in neuronal cell lines exposed to potassium cyanide.

Cyanide-induced cell death may involve selective activation of apoptosis or necrosis in different brain regions or neuronal populations. Mills and colleagues (1999) reported that cyanide induced cell death in mouse brain via apoptosis in the cortex, but through necrosis in the substantia nigra. Similarly, Prabhakaran et al. (2002) reported that cyanide elicited cell death via apoptosis in primary cortical cells but by necrosis in primary mesencephalic cells. While potassium cyanide (400 μM) increased the formation of reactive oxygen species in both cell types, the rates of formation and the nature of the reactive oxygen species varied. Furthermore, catalase and superoxide dismutase decreased the formation of reactive oxygen species in cortical cells but not in mesencephalic cells. These findings suggest that the selective vulnerability of different neuronal populations to cyanide may be related to differences in their susceptibility to oxidative stress.

Dopaminergic neurons are highly sensitive to oxidative stress, possibly due to dopamine auto-oxidation to quinones and other reactive oxygen species (Basma et al., 1995; Ben-Shachar et al., 1995). Kanthasamy and colleagues (1994) reported that mice repeatedly exposed to potassium cyanide (6 mg/kg, twice a day for 7 days, s.c.) had a reduced number of TH-positive cells, indicating a loss of dopaminergic neurons in the substantia nigra. Approximately 30% of the cyanide-treated mice exhibited decreased locomotor activity and akinesia, which were alleviated by the administration of L-DOPA (100 mg/kg, i.p.). Cassel and Persson (1992) reported that levels of striatal dopamine and its metabolite HVA were rapidly decreased in rats exposed to sodium cyanide (20 mg/kg, i.p.). However, the in vivo synthesis of dopamine, measured as the rate of L-DOPA accumulation after neuronal decarboxylase inhibition, was increased in these rats. Kiuchi and colleagues (1992) noted that perfusion of sodium cyanide (2 mM) into rat striatum produced a transient but marked increase in DA release. In addition, dopamine D1 and D2 receptor binding in the striatum was decreased in rats after the administration of sodium cyanide (2 mg/kg, i.p.) (Cassel et al., 1993). Given that Parkinson's disease is a condition characterized by the selective loss of dopaminergic neurons in substantia nigra and the depletion of striatal dopamine levels (German et al., 1989), these findings suggest that cyanide exposure may lead to the development of parkinsonian-like signs or symptoms.

Both glutamatergic and GABAergic neurons may be involved in the development of seizures after cyanide exposure. There is a strong correlation between whole-brain Ca^{2+} levels and cyanide-induced seizures in mice (Johnson et al., 1986). Patel and colleagues (1992) demonstrated that NMDA receptor activation was responsible for the rise in intracellular Ca^{2+} levels, contributing to cyanide-induced toxicity in cultured hippocampal neurons. Yamamoto and Tang (1996, 1998) reported that cyanide-induced seizures in mice were blocked by MK-801 (2 mg/kg, s.c.) and the morphological changes observed in cerebrocortical neurons exposed to potassium cyanide (1 mM) were blocked by 2-amino-7-phosphonoheptanoic acid (AP7; 1 mM): both are selective NMDA receptor antagonists. Persson and colleagues (1985) reported that striatal GABA levels were decreased in rats exposed to sodium cyanide (20 mg/kg, i.p.), and these decrements were associated with an increased susceptibility to seizures (Cassel et al., 1991). Similarly, Yamamoto (1990) reported that whole-brain GABA levels were markedly decreased and Ca^{2+} levels were increased in cyanide-treated mice exhibiting seizures. All these findings suggested that increased glutamatergic activity and/or decreased GABAergic activity may contribute to the development of seizures following cyanide exposure.

32.4.3 Sulfur mustard

Sulfur mustard (2,2′-dichlorethyl sulfide; HD) is a classical blister agent and an effective incapacitating chemical. It was first used as a CWA in WWI during a German attack on British troops at Ypres, Belgium, in 1915. Subsequently, it has been used in a number of military conflicts, including the Iran-Iraq War of 1980–88 (Marshall, 1984). During this conflict, Iraqi troops employed sulfur mustard against both military personnel and civilians. Approximately 40,000 victims of sulfur mustard have been documented among the Iranian and Kurdish populations (Hay, 2000; Khateri et al., 2003).

Sulfur mustard exerts local actions on the eyes, respiratory tract, and skin followed by systemic actions on the nervous, cardiac, gastrointestinal, and hematopoietic systems (Dacre and Goldman, 1996). A moderate exposure to sulfur mustard can cause blisters, conjunctivitis, erythema, lacrimation, nausea, and respiratory inflammation; whereas a severe exposure can cause blindness, bronchitis, bronchopneumonia, corneal damage, leucopenia, seizures, and death. Sulfur mustard is a strong alkylating agent that reacts with thiol, amino, carboxyl, hydroxyl, and primary phosphate groups in DNA and other macromolecules. Alkylation of DNA activates chromosomal

poly(ADP-ribose) polymerase (PARP), reducing the intracellular supply of NAD^+ and thus inhibiting glycolysis and causing cell death (Papirmeister et al., 1985). More recently, it was suggested that oxidative stress also may play a critical role in sulfur mustard-induced toxicity (Naghii, 2002). Jafari (2007) demonstrated that high dosages of sulfur mustard (> 10 mg/kg, i.p.) decreased the activities of catalase, glutathione peroxidase, glutathione S-transferase, and superoxide dismutase in rat liver and brain, leading to impairment of antioxidant defense systems.

There is limited information available on the effects of sulfur mustard on the CNS. The majority of the victims exposed to sulfur mustard during the Iran-Iraq War seeking medical treatment at European hospitals had anxiety, confusion, headache, and lethargy, with the potential of these neurological symptoms related to indirect effects (Balali-Mood and Hefazi, 2006). A cohort study conducted on 495 Iranian civilians revealed that individuals exposed to sulfur mustard exhibited a significantly higher incidence of depression, anxiety, hostility, and obsessive-compulsive behavior compared to age-matched counterparts 20 years after exposure (Roshan et al., 2013). Lethal dosages of sulfur mustard (> 10 mg/kg, s.c.) caused hyperexcitability followed by unsteadiness of gait, muscular weakness, and seizures in dogs (Lynch et al., 1918). Philips and Thiersch (1950) reported that lethal dosages of 2,4,6-tris(ethylenimino)-*S*-triazine (> 125 mg/kg, i.p.), which has an ethylenimine moiety analogous to sulfur mustard, caused similar effects in mice. Although the mechanism responsible for these effects is unknown, it is interesting to note that sulfur mustard induced acetylcholinesterase activity in neuroblastoma cell cultures, suggesting that cholinergic signaling potentially plays a role in its effects on the CNS (Lanks et al., 1975).

Brimfield (2012) suggested that recent studies provided evidence that sulfur mustard metabolism by NADPH-cytochrome P450 reductase could be important in the context of mixture exposures such as those that occurred in the Gulf War setting. In essence, carbon free radicals formed by this reaction could inhibit electron transport, with potential for oxidative stress exacerbation in the nervous system and other tissues. While sulfur mustard is typically thought of as a blister agent, clinical and experimental data suggest that it has the potential for eliciting both acute and long-term neurotoxic effects and may interact in a complex manner with multiple chemical coexposures.

32.4.4 3-Quinuclidinyl benzilate

3-Quinuclidinyl benzilate (QNB) (1-azabicyclo[2.2.2]oct-3-yl hydroxy(diphenyl)acetate; BZ) is a potent, atropine-like glycolic acid ester that blocks muscarinic receptors in the CNS and PNS (Spencer, 2000). During the 1950s, QNB was explored by both the United States and the Soviet Union as a potential antidote for organophosphorus anticholinesterases. However, the marked hallucinogenic actions of QNB led to its potential use as a CWA (Marshall, 1979). Saddam Hussein used QNB against the Kurds in July 1995 (Gaillard et al., 2014) and the Yugoslav People's Army allegedly used QNB leading to hallucinations and irrational behavior against Bosnian refugees fleeing from the town of Srebrenica (Hay, 1998; Gaillard et al., 2014).

QNB acts as a potent, competitive inhibitor of acetylcholine at muscarinic receptors located in the brain, heart, exocrine glands, and smooth muscles in various organs, resulting in a confused mental state with delusions, hallucinations, mental slowing, erratic behavior, a decrease in intestinal motility and tone, inhibition of bronchial and salivary secretions, and sweating, mydriasis, and tachycardia (Ketchum, 1963). Early studies demonstrated QNB was a potent and selective ligand for muscarinic receptors. Yamamura and Snyder (1974) showed that the inhibition of [^{3}H]-QNB binding to homogenates of rat brain by muscarinic drugs correlated with their pharmacological potencies, whereas nicotinic and noncholinergic drugs had negligible affinity. Kuhar and Yamamura (1976) reported that the injection of [^{3}H-]QNB into rat brain led to its localization to muscarinic receptors in the cerebral cortex, hippocampus, nucleus accumbens, and striatum. In addition, Jovic and Zupanc (1973) reported that the subcutaneous administration of QNB (5−20 mg/kg) to rats decreased oxygen consumption in the cerebral cortex and medulla oblongata. Interestingly, while QNB as a radioligand appears to bind to all known subtypes of muscarinic receptors, some evidence suggests that it has selectivity for the M2 subtype of muscarinic receptors when administered in vivo (McRee et al., 1995). QNB, thus, can produce a variety of neurological effects, presumably through the antagonism of cholinergic muscarinic receptor signaling in the CNS and PNS.

32.5 Concluding remarks and future directions

The nervous system has a number of biochemical, physiological, and anatomical characteristics that can make it particularly sensitive to CWAs. Indeed, many CWAs, in particular the nerve agents, can elicit debilitating and devastating neurotoxic responses. In some cases, these neurotoxic effects are elicited by direct interaction with specific target molecules within the nervous system, while in other cases actions on other organ systems can lead to indirect impairments of neurologic functions. The global importance of the continuous neuronal regulation of vital

physiological processes throughout the body makes the nervous system an effective target for disruption by CWAs. Thus, knowledge of mechanisms by which CWAs elicit neurotoxicity can aid in seeking and designing effective countermeasures against CWA exposures.

33.1 Introduction

Behavioral changes in humans exposed to highly toxic organophosphorus (OP) compounds, called nerve agents, have been discussed in numerous reports. The incidence of behavioral effects is higher in individuals who have been severely exposed to nerve agents, but they may also occur in individuals who have received a low-level exposure below those producing convulsions and other severe clinical signs of toxicity. The behavioral effects usually start within a few hours and last from several days to several weeks or months. The most frequent symptoms include feelings of uneasiness, tenseness, and fatigue. Exposed individuals may be forgetful and generally display impaired memory and learning, poor comprehension, decreased ability to communicate, and occasional mild confusion.

There are a few reports describing behavioral changes in subjects accidentally exposed to nerve agents. They reported sleep disturbance, mood changes, fatigue, jitteriness or tenseness, an inability to read with comprehension, difficulties with thinking and expression, forgetfulness, a feeling of being mentally slowed, depression, irritability, giddiness, poor performance in arithmetic tests, minor difficulties in orientation, and frightening dreams. It was observed that the complex of central nervous system (CNS) symptoms may not fully develop until 24 h after exposure. In addition, no correlations between the presence or severity of symptoms and the degree of acetylcholinesterase inhibition were seen. Most of the effects of exposure disappear within 3 days. It was concluded that not only severe but also mild intoxication of nerve agents may cause behavioral and psychological disturbances. In general, the behavioral effects have not been permanent but have lasted from weeks to several months, or possibly several years. Long-term behavioral effects after poisoning with nerve agents or organophosphorus insecticides have been reported (Karczmar, 1984; Levin and Rodnitzki, 1976; Loh et al., 2010). These reports are based on clinical observations, which are occasionally supported by psychological studies.

33.2 The methods used to evaluate the behavioral effects of nerve agents

33.2.1 Functional observatory battery

The functional observatory battery is a noninvasive and relatively sensitive type of neurobehavioral examination of 40 sensory, motor, and automatic nervous functions. Some are scored (Table 33.1), and others are measured in absolute units (Frantik and Hornychova, 1995). The first evaluation is made when nerve agent-exposed or control rats are in the home cage. The observer evaluates each animal's posture, palpebral closure, and gait, and the presence or absence of convulsions is noted. Each rat is then removed from the home cage and briefly held by the observer. The presence or absence of spontaneous vocalization, piloerection, and other fur and skin abnormalities, as well as irritability, is noted. Lacrimation and salivation are also observed. Other signs such as exophthalmus, crustiness around the eyes, or emaciation are recorded too. The animals are then placed on a flat surface that serves as an open field. For a period of 3 min, the frequency of rearing responses is recorded. During the same time, gait characteristics are noted and ranked, and activity, tremor, convulsions, and abnormal posture are evaluated. At the end of the third minute, the number of fecal boluses and urine pools on the absorbent pad is registered. A reflex test that consists of recording each rat's response to the frontal approach of the blunt end of a pen, a touch of the pen to the posterior flank, and an auditory click stimulus is then used. The responsiveness to a pinch on

TABLE 33.1 Functional observational battery.

Marker	Scored values only									
	−2	−1	0	1	2	3	4	5	6	7
Posture				Sitting or standing	*Rearing*	*Asleep*	Flattened	Lying on side	Crouched over	Head bobbing
Catch difficulty				Passive	*Normal*	Defense	Flight	Escape	Aggression	
Ease of handling				Very easy	Easy	Moderately difficult	Difficult			
Muscular tonus	Atonia	Hypotonia	*Normal*	Hypertonia	Rigidity	Fasciculations				
Lacrimation			*None*	Slight	Severe	Crusta	Colored crusta			
Palpebral closure				*Open*	Slightly	Half-way	Completely shut	Ptosis		
Endoexophthalmus		Endo	*Normal*	Exo						
Piloerection			*No*	Yes						
Skin abnormalities			*Normal*	Pale	Erythema	Cyanosis	Pigmented	Cold	Injury	
Salivation			*None*	Slight	Severe					
Nose secretion			*None*	Slight	Severe	Colored				
Clonic movements			*Normal*	Repetitive	Nonrhythmic	Mild tremors	Severe tremors	Myoclonic	Clonic	
Tonic movements			*Normal*	Contraction of extensors	Opisthotonus	Emprosthotonus	Explosive jumps	Tonic convulsions		
Gait			*Normal*	Ataxia	Overcompensation of hindlimb movement	Feet point outwards from body	Forelimbs are extended	Walks on tiptoes	Hunched body	Body is flattened against surface
Gait score				*Normal*	Slightly impaired	Somewhat impaired	Totally impaired			
Mobility score				*Normal*	Slightly impaired	Somewhat impaired	Totally impaired			
Arousal (level of unprovoked activity)				Very low	Sporadic	Reduced	*Normal*	Enhanced	Permanent	
Tension			*None*	Partial (ears)	Stupor					

(*Continued*)

Stereotypy			*None*	Head weaving	Body weaving	Grooming	Circling	Others		
Bizarre behavior			*None*	Head	Body	Self-mutilation	Abnormal movements	Others		
Approach response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Touch response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Click response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Tail-pinch response				No reaction	*Normal*	Slow reaction	Energetic reaction	Exaggerated reaction		
Pupil size		Miosis	*Normal*	Mydriasis						
Pupil response			No reaction	*Normal reaction*						
Righting reflex				*Normal*	Slightly uncoordinated	Lands on side	Lands on back			

the tail and the ability of the pupils to constrict in response to light are then assessed. These measurements are followed by a test for the aerial righting reflex, then by the measurements of forelimb and hindlimb grip strength, body weight, rectal temperature, and finally hindlimb landing foot splay. This entire battery of tests requires approximately 6–8 min per animal. Motor activity data are collected using an apparatus for testing a spontaneous motor activity of laboratory animals. The animals are placed in the measuring cage for a period of 10 min and their movements (total horizontal activity, stereotypical activity, rearing, jumping, scratching, and total vertical activity) are recorded.

33.2.2 Performance on the RAM task

RAM sessions are conducted using an eight-arm commercially available radial maze measuring 137.2 cm in diameter. The center of the maze is a plastic octagon hub measuring 26.67 cm across, with a Plexiglass lid and wire grid floor. A Plexiglass arm with a wire mesh floor is attached to each of the eight sides of the hub. The entrance to each arm contains a motorized guillotine door allowing access to and from the hub. Each arm's runway contains two floor-mounted switches, which are depressed by the weight of the rat when present in the proximal and distal portion of the runway, respectively. The terminal portion of each arm contains a food dispenser, for delivering food pellets, connected to a trough that is outfitted with the photoemitter/detector that can detect access by the rats. Experiments are controlled and monitored using a commercial hardware interface and a microcomputer using the L2T2S software control system (Coulbourn Instruments). For the RAM task, four of eight arms are "baited," meaning that a single food pellet is available upon a nose-poke into the food trough at the terminal portion of each arm. Each rat is randomly assigned a maze configuration of four baited arms from 37 possible configurations, excluding more than two consecutive baited arms. The same configuration of baited arms is used for a specific rat for each of the sessions, but different configurations can be used for different rats. Sessions begin with the rat placed in the center hub compartment and the doors to the eight arms are raised. The rat is then free to explore the maze to obtain the food rewards available from the four baited arms. The session is terminated when the rat obtains all four food rewards or when 15 min have elapsed. If a rat does not complete the maze within 15 min, a completion time of 15 min is assigned and errors are analyzed. Failure to complete the maze, however, is infrequent and only occurs during the initial few sessions in the maze. No familiarity training with the maze is conducted prior to the first session. The major dependent variables characterizing performance on the RAM task are the time to complete the maze and the number of errors made. Errors are designated when a rat chooses an unbaited arm (reference memory error) or when a rat returns to a baited arm after obtaining the food reward (working memory error) (Genovese et al., 2006).

33.2.3 Acoustic startle response and prepulse inhibition

The animals are tested for acoustic startle response and prepulse inhibition in the SM100 Startle Monitor system. The system is programmed for six types of white-noise burst stimulus trials: no stimulus (background, 60 dB), prepulse (70 dB), pulse (100 and 120 dB), and prepulse plus pulse (70 dB + 100 dB and 70 dB + 120 dB). Each trial type is presented 10 times in 10 blocks. Stimuli are presented in random order to avoid order effects and habituation. The intertrial interval can vary from 9 to 16 s. All animals are regularly handled before individual tests in order to minimize handling-related stress. Animals are pair matched according to baseline values into experimental groups using the average of the response to 100 and 120 dB. The tested animals are restrained loosely in holders that are placed on a sensing plate transforming movements of the body (jerks) into an analog signal through an interface. Finally, the percentage of prepulse inhibition measurements is calculated as the difference between the pulse alone, multiplied by 100. Percentage scores are typically used to minimize the effect of individual variation of startle amplitude on prepulse inhibition (Mach et al., 2008).

33.2.4 Performance on the Y-maze

Cognitive functioning can be tested using a Y-maze with averse motivation by a strong electric footshock, evaluating learning and spatial memory (Koupilova et al., 1995). The Y-maze is a plastic box consisting of a square start area (285 × 480 mm) separated by a Plexiglass sliding door from two trapezoid, black and white arms—the choice area (140 × 324 mm). The grid floor in the start and choice area is electrifiable. The animal is placed on the start area and after 48 s electric footshocks (60 V, 50 Hz, duration 0.5 s) are applied at 5-s intervals. The rats try to avoid the shock by escaping to one of two arms. In the case of a rat moving to the wrong (dark) arm, the rat fails to avoid further footshock. The animals are taught spatial discrimination with the preference of the black or white arm in the Y-maze. The latency to enter the correct arm is measured and the number of wrong entries is counted. Before exposure to a nerve agent, the rats are trained to avoid footshock by moving to the correct (white) arm in the Y-maze. It usually takes 4 weeks of training to reach the criterion of 80% or more correct

averse behaviors (moving to the correct arm) within less than 1.5 s. During the training, 10 sessions (two trials/session) per week lasting 4 min each are realized. The exposure starts the day after the animals reach this criterion. The latency time to enter the correct arm by nerve agent-exposed rats and the number of entry errors are compared to the values obtained from the control rats exposed to pure air instead of a nerve agent.

33.2.5 Performance on the T-maze

Cognitive functioning can be also tested using a T-maze, consisting of five segments, a starting and a goal compartment to evaluate learning, spatial memory, and spatial orientation (Koupilova and Herink, 1995). The rats are trained with a food reward, to run through the maze in less than 10 s without entering the side arm. The time necessary to reach the goal box is recorded. Before exposure to a nerve agent, the rats are trained to reach the goal box as soon as possible by moving to the correct segment in the T-maze. It usually takes 4−6 weeks of training to reach the criterion of 80% or more correct behavior. The exposure starts the day after the animals reached this criterion. The time of reaching the goal box by nerve agent-exposed rats is compared to the values obtained from the same rats immediately before nerve agent exposure and from control rats exposed to pure air instead of a nerve agent.

33.2.6 Performance on the Morris water maze

The water maze (WM) is often used for the evaluation of effects of various compounds on memory functions, that is, memory formation, consolidation, and retrieval effects due to its advantages and broad utilization. The Morris WM is a widely used measurement of visuospatial learning that has been demonstrated to have high validity in identifying the cognitive effects of various brain lesions and the effects of drugs used to treat cognitive deficits (Morris, 1984; Myhrer, 2003). Special motivation such as food and water deprivation is not required for the WM performance. The effect of odor cue is eliminated in the WM. In addition, rats are forced to swim in the WM. They cannot choose whether or not to move, so failure to respond is not a confound (Shukitt-Hale et al., 2004). The place learning version with a submerged platform can be used for working memory tests (Myhrer, 2003). The WM can be used to measure spatial learning and memory in the case of the evaluation of cognitive impairment in rats because of the mentioned advantages. In addition, a visuospatial learning task is sensitive to cholinergic dysfunction and, thus, deficits in visuospatial processing have been recognized as some of the negative consequences in organisms chronically exposed to OPC (Roldán-Tapie et al., 2005).

The rats perform cognitive tasks that require spatial learning and memory—the ability to acquire a cognitive representation of location in space and the ability to effectively navigate the environment in the WM (Shukitt-Hale et al., 2004). Memory alterations appear to occur mostly in secondary memory systems and are reflected in the storage of newly acquired information (Bartus et al., 1989; Joseph, 1992). It is thought that the hippocampus mediates allocentric spatial navigation (i.e., place learning) and that the prefrontal cortex is critical to acquiring the rules that govern performance in particular tasks (i.e., procedural knowledge), while the dorsomedial striatum mediates egocentric spatial orientation (i.e., response and cue learning) (McDonald and White, 1994; Oliviera et al., 1997).

The WM consists of a black circular pool (180 cm diameter × 80 cm high) filled to a depth of 25 cm with room temperature water (Raveh et al., 2002). The pool is imaginarily divided into four compartments numbered clockwise 1−4. The black antireflective circular escape platform (15 cm diameter) is placed into compartment 1 or 4, 20 cm off the pool wall. The platform is sunk 2 cm below the water surface, so that it is not visible from to the rat via the water mirror effect. A yellow rectangle (30 cm × 40 cm) is fixed on the pool wall, immediately close to the platform, as the spatial conditional cue (Robinson et al., 2004). Its place is variable according to the platform. Another dark rectangle is randomly fixed on the pool wall in different compartments (without platform) as the negative conditional cue. Around the pool, there are several stable extramaze cues in the room that the rat could use to navigate the maze (Morris, 1984). However, the impact of extramaze cues is not significant due to high maze walls.

33.2.7 Performance on the passive avoidance test

Passive avoidance is a fear-motivated test classically used to assess short-term or long-term memory on small laboratory animals (rats, mice). Basically, passive avoidance working protocols involve timing of transitions, that is, time that the animal takes to move from the white compartment to the black one after a conditioning session in which entry into the black compartment is punished with a mild inescapable electrical shock. The animal's position is detected using high-sensitivity weight transducers providing more effective and reliable detection of animal responses (zones entries) than systems based on photocell beams or on grid floor displacements. The measured parameter is a latency to enter the black compartment.

A two-compartment step-through passive avoidance apparatus is usually used. The apparatus (430 × 220 × 190 mm) is divided into bright and dark compartments by a removable divider. The divider is a tunnel with an automatic door. Using a software-controlled magnetic switch, this door can be closed automatically. The gate has to be opened manually at the start of the experiment. Each compartment is equipped with a light (2.2 W). The ceiling also contains a common loudspeaker to deliver a sound signal (10 kHz fixed, max. 100 dB). The animal's position inside the cage is monitored with the help of infrared light barriers. After a specified time interval following drug administration, passive avoidance training is performed. The animals are placed in the bright compartment and allowed to explore for 30 s, at which point the guillotine door is raised to allow the rat to enter the dark compartment. When the animal enters the dark compartment, the guillotine door is closed and an electrical footshock (0.1−3.0 mA) is delivered. Training sessions are conducted twice (double-trainings) during the light phase of the 12-h day/night cycle. The second double-training session is carried out immediately after the first. The animals are placed in the bright compartment and allowed to explore for 30 s, and then the guillotine door will raise. The latency to enter the dark compartment is recorded for up to 300 s (Gacar et al., 2011).

33.2.8 Performance on the Barnes maze

The Barnes maze tests spatial learning and memory (Pompl et al., 1999). It consists of a platform (91 cm in diameter) that is elevated 91 cm from the ground with 20 holes (5 cm in diameter) equally spaced around the outer perimeter of the platform to include one "escape hole" under which is a small escape box. Posters with black and white geometric shapes are used as spatial cues and placed on the walls surrounding the maze (Sharma et al., 2010). Two lights and a camera are positioned above the apparatus to provide light and record the animals' movements, respectively. After a 10-min acclimatization period, the animals are transported to the maze in an opaque cup and placed in the center of apparatus. After 30 s, the cup is lifted and a 5-min trial begins. Each animal is placed in the maze for four trials with 15−25 min between trials (Sharma et al., 2010). Latency to escape (a measure of spatial learning and memory), the number of head pokes into the perimeter holes (a measure of error), and the primary latency to head poke into the escape hole (Sharma et al., 2010; Patel et al., 2014) are recorded using ANY-maze software. If the animal successfully escaped (defined as staying in the escape hole for 15 s), the test ended and the animal remained in the hole, covered by the experimenter, for 30 s to reduce anxiety (Fox et al., 1998). If the animal did not successfully locate the escape hole within the testing period, it is picked up and placed in the escape hole, where it remains for 1 min (Fox et al., 1998; Cheng et al., 2014).

33.3 Long-term behavioral effects of acute high-level exposure to nerve agents

Many of the data regarding long-term neurological sequelae to exposures to cholinesterase inhibitors in humans have been gathered following accidental exposures to OP compounds (pesticides as well as nerve agents). Nevertheless, the extrapolation from these exposures to prediction of effects from nerve agents is difficult for several reasons:

- The cholinergic crisis caused by acute, severe intoxication with OP pesticides is generally much longer than that caused by OP nerve agents;
- OP pesticide-induced delayed peripheral neuropathy can be caused by nerve agents only at doses many times greater than the LD_{50} (Davis et al., 1960);
- A delayed manifestation of OP poisoning has not been described after administration of nerve agents to animals or in instances of nerve agent poisoning in humans (Sidell, 1997).

There have been descriptions of the acute effects in humans that follow high-dose exposure ($\geq LD_{50}$) to the nerve agents soman, sarin, and VX (Inoue, 1995; Nakajima et al., 1997; Nozaki et al., 1995). A similar cluster of behavioral symptoms (anxiety, psychomotor depression, intellectual impairment, and sleep disturbance) was observed in the immediate period following resolution of the acute signs of intoxication that then slowly faded with time, sometimes taking months to be fully resolved. The CNS symptoms noted following short-term exposure of humans to diisopropyl fluorophosphate (DFP) were excessive dreaming, insomnia, jitteriness and restlessness, increased tension, emotional lability, subjective tremulousness, nightmares, giddiness, drowsiness, and mental confusion. CNS symptoms were correlated with the depression of red blood cell acetylcholinesterase (AChE; EC 3.1.1.7) to 70% − 60% of original activity and they disappeared within 1−4 days (Grob et al., 1947). It was also noted that more severely exposed individuals and those with multiple exposures tended to display persistent symptoms that included forgetfulness, irritability, and confused thinking, although the duration of these persistent symptoms was never clearly defined (Holmes and Gaon, 1956). These CNS symptoms are virtually identical to those that have been reported to occur following high-level exposure to nerve agents. It was shown in the study of human sarin poisoning that sarin-induced behavioral effects were virtually identical to those reported for DFP.

These effects coincided with the depression of plasma ChE and red blood cell AChE activity to approximately 60% and 50%, respectively, of original activity (Grob and Harvey, 1958). The behavioral symptoms such as anxiety, psychomotor depression, a general intellectual impairment consisting of difficulties in concentration and retention, and sleep impairment generally involving insomnia due to excessive dreaming were also described during human poisoning with the nerve agent VX (Bowers et al., 1976).

Exposure to high doses of OP compounds including nerve agents has been demonstrated to result in severe brain neuropathology that involves not only neuronal degeneration and necrosis of various brain regions (Lemercier et al., 1983; McLeod et al., 1982; Petras, 1981) but also persistent severe alteration in behavior and cognitive incapacitation, especially impairments of learning and memory (Bushnell et al., 1991; McDonald et al., 1988). The most significant injury caused by OP poisoning is neuronal degeneration of the hippocampus that is associated with spatial learning and memory. Therefore, impairment of cognitive functions, especially incapacitation of learning and memory, belongs to the most frequent central signs of acute OP poisoning (Marrs, 1993; McDonald et al., 1988). In addition, the adverse effects of OP compounds on cognition functions, such as learning and memory, may persist for quite some time after termination of toxicant exposure. The results from several studies have demonstrated the presence of OP compound-induced learning impairments several days after the classic signs of OP toxicity have subsided (Buccafusco et al., 1990; Bushnell et al., 1991; McDonald et al., 1988). Behavioral effects are typically evident before the occurrence of physical symptoms. These effects were associated with whole-blood ChE inhibitions of $>60\%$. It was also found that severe poisoning with OP compounds causing general tonic-clonic convulsions altered Ca^{2+} dynamics that could underlie some of the long-term plasticity changes associated with OP compound toxicity. These changes demonstrated in hippocampal neurons can be responsible for the long-term behavioral toxicity of OP compounds (Deshpande et al., 2010, 2016).

Several studies of the long-term effects of sarin exposure on victims from Japan have been published. Exposure to nerve agents in humans was found to produce effects that include cognitive deficits and memory loss (Hatta et al., 1996; Hood, 2001; Okudera, 2002). Eighteen victims of the Tokyo subway incident were evaluated at 6–8 months postexposure (Yokoyama et al., 1998). Sarin-exposed individuals scored significantly lower than controls on a digit symbol substitution test, and scored significantly higher than controls on a general health questionnaire (GHQ, psychiatric symptoms) and a profile of mood states (POMS, fatigue). The elevated scores on the GHQ and POMS were positively related to increased PTSD (posttraumatic stress disorder) scores and were considered to be due to PTSD (Yokoyama et al., 1998). There have been two brief reports of severely poisoned nerve agent victims (one sarin and one VX) in Japan who experienced retrograde amnesia, possibly due to prolonged periods of seizures and/or hypoxia (Hatta et al., 1996; Nozaki et al., 1995). Symptoms related to sarin exposure in Japan still existed 1–3 years after the incident and included fatigue, asthenia, shoulder stiffness, and blurred vision (Abu-Qare and Abou-Donia, 2002).

The existence of long-term behavioral effects following acute exposure to high doses of nerve agents and OP pesticides was verified many times with the help of laboratory experiments on animals. There are numerous studies in animals showing that survivors of high-level OP exposure can experience subtle but significant long-term neurological and neuropsychological outcomes that are detectable months or even years following recovery from acute poisoning (Brown and Kelley, 1998). Three months after severe paraoxon exposure, the surviving rats exhibited a despair-like state, anhedonia-like condition, increased anxiety, and impaired recognition memory (Deshpande et al., 2014). Exposure of animals to nerve agents was shown to produce neurotoxicity in the CNS areas associated with cognition and memory functions (Koplovitz et al., 1992; Petras, 1994). There are a few studies that have revealed changes in the brain following sublethal nerve agent exposure that involve not only the cholinergic system but also the glutamatergic system (Lallement et al., 1992; McDonough and Shih, 1997). Excitotoxic injury caused by increased levels of glutamate has repeatedly been shown to cause cognitive dysfunction (O'Dell et al., 2000). Therefore, the disruption of cognitive functions, especially spatial and working memory, seems to be the most frequent and most observable behavioral effect of nerve agent poisoning. In addition, acute and repeated administration of OP compounds induced anxiogenic and depression-like responses. This fact was assessed on the elevated plus-maze and forced-swim tests, which are validated animal models to observe for anxiety and depression-like behavior (Assissi et al., 2005). These studies show changes in the brain following sublethal nerve agent exposure that lead to memory and attention deficits that normally involve the hippocampus (Hatta et al., 1996; Miyaki et al., 2005; Nishikawi et al., 2001). The role of the hippocampus in complex visuospatial learning and memory has been well established. The high concentration of NMDA and AMPA glutamate receptors, which play a key role in hippocampal-mediated learning and memory, also make the hippocampus highly vulnerable to glutamate-induced excitotoxic injury from nerve agent poisoning (Filliat et al., 2007; Lallement et al., 1992; Shih et al., 1990).

Following a high-dose exposure (above 0.5 LD_{50}), seizures are a prominent sign of nerve agent intoxication and these prolonged seizures can produce neural lesions

(McDonough and Shih, 1997). Thus, neurological and behavioral deficits are predictable long-term effects following exposure to such doses of nerve agents. Animals exposed to high (convulsive) doses of nerve agent can develop spontaneous seizures, and display hyperactive and aggressive behavior and profound deficits in learning and/or performance of a variety of behavioral tasks. Animal studies have demonstrated deficits in acquisition of several types of operant tasks, performance of serial probe recognition task, maze learning, and passive avoidance learning following acute poisoning with nerve agents (McDonough et al., 1986; Modrow and Jaax, 1989; Raffaele et al., 1987).

The inhalation exposure to high-level sarin-induced impaired memory processes in rats seen at 1 month postexposure with no recovery of cognitive function during the 6-month follow-up period. In the open field, sarin-exposed rats showed a significant increase in overall activity with no habituation over days. In a working memory paradigm in the WM, the same rats showed impaired working and reference memory processes with no recovery. These data suggest long-lasting impairment of brain functions in surviving rats following a single sarin exposure. Animals that seem to fully recover from the exposure, and even animals that initially show no toxicity signs, develop some adverse neurobehavioral changes with time (Grauer et al., 2008). These findings are in accord with reports on long-term behavioral impairment following exposure to OP pesticides used in agriculture (Wesseling et al., 2002). Similarly, long-term follow-up of victims of the sarin attacks in Japan demonstrated neurological as well as emotional and cognitive changes up to 7 years postexposure (Miyaki et al., 2005; Ohbu et al., 1997; Yokoyama et al., 1998).

Generally, according to high-dose exposure studies, animals exposed to nerve agents that exhibit seizures that are not promptly controlled develop brain damage and subsequent neurobehavioral problems. Animals that do not develop seizures or those that are rapidly and effectively treated with drugs that stop the seizures suffer no brain lesions and display no long-term neurobehavioral deficits. Besides classic antidotes (atropine, oximes, benzodiazepines), other drugs, such as the centrally acting anticholinergic drug scopolamine and a new anticonvulsant drug imidazenil, are effective in eliminating or at least reducing behavioral toxicity of nerve agents (Che et al., 2011; Wang et al., 2012).

33.4 Chronic behavioral effects of single or repeated low-level exposure to nerve agents

Anticholinesterase compounds such as nerve agents can alter behavioral functions even after small subtoxic doses. There are very few data on human exposures. Based on the data describing the signs and symptoms in accidentally exposed humans, some long-term health effects, including behavioral effects of repeated subclinical exposures to OP compounds, were observed (Wesseling et al., 2002). When workers were exposed to small amounts of nerve agents, they showed mild toxic signs of exposure including CNS effects such as insomnia, excessive dreaming, restlessness, drowsiness, and weakness (Craig and Freeman, 1953). It was shown that psychological symptoms are probably more common than usually recognized and may persist in more subtle forms for much longer (days, weeks) than physical symptoms (Sidell and Hurst, 1997). Recently, a dose−response association was found between low-dose exposure to sarin and cyclosarin inhalation during the 1991 Gulf War and impaired neurobehavioral functioning as well as subtle CNS pathology as revealed by MRI study (Heaton et al., 2007; Proctor et al., 2006). It is interesting that functional impairments were detected even in people who initially developed only mild or no signs of sarin or cyclosarin toxicity. These data correspond to the published epidemiological studies showing alterations in cognitive functions, impaired memory, and concentrations in humans after chronic low-dosage occupational exposure to OP insecticides (Parrón et al., 1996; Stephens et al., 1995). An increased amount of forgetfulness and difficulties in thinking, exposure-related increases in work-related tension, sleep disturbance, restlessness, and nervousness have been documented among sheep farmers exposed to OP pesticides (Beach et al., 1996; Stephens et al., 1995). Recently published meta-analysis of 14 studies which fulfilled strict criteria for inclusion and data from more than 1600 participants, found an association between subthreshold OP exposures and impaired neurobehavioral functions. The domains of cognition most affected included attention, working memory, executive function, visuospatial ability, and visual memory (Ross et al., 2013).

Based on experimental animal data, the progression of signs, their neuropharmacological basis, and the toxic consequence elicited from acute high-dose exposures have been well characterized (McDonough and Shih, 1993; Shih et al., 2003). However, much less is known about the long-term effects of repeated low-dose nerve agent exposure. Several comprehensive reviews on the long-term health effects of low-level nerve agent exposure have been published (Moore, 1998; Romano et al., 2001). There are prospective animal studies that support the argument that chronic or repeated exposures to OPs at levels that are not associated with acute toxicity can indeed result in a variety of sustained deficits in delayed matching performance, sensorimotor gating, spatial learning and retention, recognition memory, and cognitive flexibility. They have been reported in association with

low-level exposures to OPs (Terry et al., 2012; Yan et al., 2012).

It is known that a significant, clinically manifested AChE inhibition in the CNS leading to the neuronal degeneration of some brain regions including the hippocampus, associated with spatial learning and memory, is not necessary for clinically manifested cognitive impairments. This fact corresponds with earlier published data about neurological and neurophysiological outcomes detectable months or even years following recovery from acute OP poisoning (Savage et al., 1988; Yokoyama et al., 1998). It is very difficult to find the real reason for the memory impairments in the case of low-level nerve agent exposure. Recently, a temporal relationship has been demonstrated between OP-induced impairment in performance of a spatial memory task and the protracted decrease in the expression of cholinergic receptors in specific brain regions (including the hippocampus) following the asymptomatic exposure to OP compounds (Stone et al., 2000). Nerve agent-induced impairment of cognitive functions is probably caused by subsequent desensitization and internalization of cholinergic receptors as a reaction of nerve agent-exposed organisms on hyperstimulation of cholinergic receptors, especially in parts of the brain with a high density of cholinergic synapses, such as the hippocampus (McDonald et al., 1988; Stone et al., 2000). This means that a decrease in the number of cholinergic receptors in the hippocampus following low-level exposure to OPs without significant AChE inhibition could cause memory impairments.

However, noncholinergic pathways may also be involved in OP-induced alteration of behavioral functions. The above-mentioned prospective studies support the argument that chronic or repeated exposures to OPs at levels that are not associated with acute toxicity can indeed result in cognitive deficits. The neurobiological substrates of these persistent behavioral effects of OPs have not been fully elucidated but substantial evidence now suggests that cholinesterase inhibition alone is insufficient as an explanation. It has been suggested that interactions of OPs with noncholinesterase targets may contribute to the more delayed and persistent effects observed following chronic or repeated exposures (Costa, 2006). The list of noncholinesterase targets for OPs is growing and now includes a variety of proteins, receptors, and enzymes (Casida and Quistad, 2005; Terry, 2012). There are other serine hydrolases that could be the secondary targets of these agents (Casida and Quistad, 2005; Rocha et al., 1999). Studies carried out in AChE knockout mice have also shown that some OP-induced effects, including behavioral effects, are independent of their cholinergic effects (Duysen et al., 2001). It is supposed that low levels of OP compounds induce changes in the brain dopaminergic and serotoninergic systems and that these changes may help to explain the various neuropsychological symptoms associated with low-level OP exposure. It was shown that the nerve agent sarin can induce significant long-term changes on the monoamine activity in different brain structures of mice. These effects of sarin on the monoaminergic neurotransmitter systems suggest that OPs exert some of their long-lasting toxic effects including behavioral effects via noncholinergic mechanisms (Oswal et al., 2013). OP compound-induced impairment of cognitive functions may involve multiple mechanisms of action which may be due to deficits in axonal transport, mitochondria, and neurotropic factors (Terry, 2012). Many results indicate that the threshold for neurotoxic consequences may be surpassed during repeated exposure to subthreshold doses of OPs (Singh et al., 2016; Terry et al., 2014). It was described that OP compound-induced cognitive deficits may be related to persistent functional changes in brain neurotrophin and cholinergic pathways (Terry et al., 2011). Additionally, the influence of diet on the behavioral toxicity of nerve agents was demonstrated (Langston and Myers, 2011). It was found that diet composition exacerbates or attenuates the behavioral toxicity of nerve agents in exposed rodents. The exacerbated behavioral toxicity of nerve agents in animals fed a glucose-enriched diet could be due to inactivation of esterases including AChE, BuChE, CAE, and PON by glycation or glyco-oxidation or by increased acetylcholine synthesis and/or its utilization (Myers and Langston, 2011). On the other hand, a ketogenic diet attenuates behavioral toxicity of nerve agents. The mechanism responsible for this effect is unknown but there is considerable evidence that the ketogenic diet has neuroprotectant and anticonvulsant properties by altered energy or altered neurotransmitter (GABA) synthesis (Bough and Rho, 2007). In addition, a moderate benefit of choline supplementation against behavioral toxicity of nerve agents was observed (Langston and Myers, 2011). Moreover, the influence of genetic background on the toxicity of nerve agents was also demonstrated (Matson et al., 2018a). The available data suggest genetically determined differences in susceptibility or resistance to nerve agent-induced toxicity, including behavioral toxicity. Some genetic markers for organophosphorus susceptibility (variants of the gene paraoxonase 1, cytochrome gene variants, butyrylcholinesterase gene variants) in humans have also been identified and confirmed in rodent models (Furlong, 2007; Povey et al., 2007; Lockridge, 2015). Thus, genetic background plays an important role in behavioral, neurological, and physiological responses to nerve agent exposure. This fact was supposed by the assessment of mouse strain differences in toxic response to sarin. It was found that BALB/cByJ and FVB/NJ strains were the most resistant strains, while DBA/2J was the most sensitive mouse strain (Matson et al., 2018b).

In the literature available on repeated low-dose exposure to nerve agents, soman is the nerve agent studied most often. Mice, rats, guinea pigs, and primates have been used to investigate repeated low-dose soman exposure. The effects of repeated soman exposures ranged from performance decrements on a well-learned compensatory tracking task (Blick et al., 1994b) to development of attention deficits (Gause et al., 1985) and hyperreactive responses to handling (Shih et al., 1990). In addition, a single subcutaneous exposure of guinea pigs to sublethal doses of soman triggered long-lasting anxiogenesis and decreased locomotor activity (Mamczarz et al., 2010).

Unlike soman, the amount of literature regarding the effects of repeated low-level exposure to sarin is rather sparse and sometimes conflicting. Rhesus monkeys exposed to low levels of intramuscular sarin showed no signs of adverse health or long-term behavioral effects (Burchfiel et al., 1976). In contrast, it has been observed in rats and mice that intraperitoneal injections of subtoxic doses of sarin or soman decreased locomotor activity and altered behavior on the plus-maze and elevated horizontal bridge tests (Baille et al., 2001; Nieminen et al., 1990; Sirkka et al., 1990). Single as well as repeated low-level inhalation exposure of rats to sarin produced a deficit on the RAM spatial memory task. The deficit was resolved during the first 3 weeks of acquisition (Genovese et al., 2009). It was also shown that repeated low-level inhalation of sarin in rats at clinically asymptomatic doses was disruptive to neurophysiological function and caused long-term memory impairments (Kassa et al., 2001a,b). The results of the study related to the measurement of sarin-induced alteration of behavioral and neurophysiological functions at 3 months following low-level sarin inhalation exposure of rats showed a significant alteration of mobile activity and gait characterized by ataxia and an increase in stereotypical behavior. These signs were observed in rats repeatedly exposed to sarin at clinically asymptomatic doses or singly exposed to sarin at doses causing mild muscarinic signs of exposure. These animals had awkward hindlimbs and their mobility was markedly diminished (Kassa et al., 2001d). Spatial discrimination in the Y-maze was also altered in rats exposed to low levels of sarin. While spatial orientation of rats singly exposed to clinically asymptomatic doses of sarin was significantly influenced for a short time only (1 or 2 h following exposure), the rats repeatedly exposed to clinically asymptomatic doses of sarin showed a decrease in Y-maze performance for a relatively long time (until the third week following the exposure) (Kassa et al., 2004). The significant impairment of spatial memory of rats exposed to clinically asymptomatic concentrations of sarin was also observed when cognitive functions were evaluated with the help of T-maze performance. Rats exposed to low-level sarin showed a significant decrease in T-maze performance for a short time (until the first day following the exposure). In addition, the effects of low-level sarin inhalation exposure were dose dependent. When the rats were exposed to low-level sarin causing moderate signs of poisoning, their time of passage through the maze was more lengthened at 1 and 2 h following the inhalation exposure compared to the rats exposed to clinically asymptomatic levels of sarin (Kassa et al., 2001c).

A single exposure to another nerve agent, cyclosarin, at concentrations that do not produce convulsions or severe clinical signs of toxicity can also produce performance deficits on learned behavioral tasks. However, with repeated exposure, the deficits are not persistent and recovery is complete. In addition, exposure concentrations not producing any evaluated clinical signs of toxicity, other than temporary miosis (in the case of inhalation exposure), do not produce performance deficits on behavioral tasks (Genovese et al., 2006). Asymptomatic exposure of rats to VX vapors can produce only minor performance effects on previously learned behavioral tasks and on the acquisition of a new behavioral task (Genovese et al., 2007).

Reports in the literature of animal studies show that nerve agents can be administered repeatedly with minimal overt neurobehavioral effects if care is taken in choosing the dose and time between doses (Sterri et al., 1980, 1981). Repeated low-level nerve agent exposure made the cognitive impairments longer and higher compared to single nerve agent exposure. Repeated exposure to low doses of soman can produce small, transient performance decrements only, most likely due to the development of a physiological and behavioral tolerance to low levels of ChE activity (Blick et al., 1994a,b). Nevertheless, a progressive and long-lasting inhibition of AChE in the CNS following repeated administration of low doses of soman was demonstrated (Hartgraves and Murphy, 1992). This study was corroborated by Olson et al. (2000) using sarin. Generally, repeated or long-term exposure to low levels of nerve agents can cause neurophysiological and behavioral alterations (Abu-Qare and Abou-Donia, 2002).

Rats repeatedly exposed to sarin at doses corresponding to $0.5 \times LD_{50}$ (three times per week, s.c.) showed an increase in acoustic startle and a decrease in distance explored in the open field 2 weeks after sarin exposure. On the other hand, no effect of sarin exposure on passive avoidance was noted at the same time after sarin poisoning. Brain regional AChE was not affected at any time after sarin exposure, but muscarinic receptors were downregulated in the hippocampus, caudate putamen, and mesencephalon in the sarin group at 2 weeks postexposure.

Thus, downregulation of muscarinic receptors in the hippocampus as a reaction to acetylcholine accumulation at muscarinic receptor sites based on AChE inhibition can be considered a cause of behavior performance deficits, especially disruption of cognitive functions (Scremin et al., 2003). In addition, protracted impairment of cognitive functions in rats exposed repeatedly to low-level OP compounds may be associated with a decreased rate of AChE recovery in the hippocampus (Prendergast et al., 1997).

The results from several studies have demonstrated the presence of OP-induced learning impairments several days after the behavioral signs of OP toxicity have subsided (Bushnell et al., 1991; McDonald et al., 1988). Chronic exposure to OP compounds can also result in specific long-term cognitive deficits even when signs and symptoms of excessive cholinergic activity are not present (Prendergast et al., 1998). Thus, the significant, clinically manifested AChE inhibition in the CNS leading to the neuronal degeneration of some brain regions, including the hippocampus, is not necessary for the clinically manifested cognitive impairments. This conclusion corresponds with earlier published data about neurological and neurophysiological outcomes detectable months or even years following recovery from acute OP poisoning (Savage et al., 1988; Yokoyama et al., 1998). A current study attempts to show a temporal relationship between OP-induced impairment in performance of a spatial memory task and the protracted decrease in the expression of cholinergic receptors in specific brain regions caused by asymptomatic exposure to an OP compound (Stone et al., 2000). In addition, low-level OP-induced memory impairment may be associated with a decreased AChE recovery in the hippocampus relative to the cortex. This decreased rate of enzyme recovery may contribute to hippocampal toxicity underlying protracted impairment of working memory and other cognitive functions (Prendergast et al., 1997).

Repeated or chronic low-level nerve agent exposure can cause a prolonged inhibition of extracellular AChE leading to a prolonged increase in extracellular acetylcholine (ACh). The prolonged availability of ACh in the synaptic clefts results in feedback inhibition on muscarinic, presynaptic receptors to decrease further ACh release (Russell et al., 1985). The greater ACh release in the nerve agent-exposed group may be due to the known downregulation of muscarinic receptors in response to chronic nerve agent exposure (Churchill et al., 1984). Neurochemical analyses showed that normal brain neurotransmitter and receptor homeostasis is disrupted even at 10–12 days after 2 weeks of chronic nerve agent exposure at least in the striatum but probably throughout the whole cholinergic system in the brain (Shih et al., 2006).

33.5 Concluding remarks and future directions

Exposure to high doses of nerve agents has been demonstrated to result in severe brain neuropathology that involves not only neuronal degeneration and necrosis of various brain regions, but also persistent severe alterations in behavior and cognitive functions, especially impairment of learning and memory. The most significant injury caused by nerve agent poisoning is neuronal degeneration of the hippocampus, which is associated with spatial learning and memory. Therefore, impairment of cognitive functions, especially incapacitation of learning and memory, belongs to the most frequent central signs of acute nerve agent poisoning. In addition, the adverse effects of nerve agents on cognitive functions, such as learning and memory, may persist for a relatively long time following the termination of nerve agent exposure.

Behavioral alterations and impairments of cognitive functions were found following acute exposure to nerve agents with the absence of any classic signs of cholinergic toxicity. It was shown based on the experimental results that not only convulsive doses but also clinically asymptomatic doses of nerve agents can cause subtle long-term neurophysiological and neurobehavioral dysfunctions. The neurological and neurophysiological outcomes are detectable months or even years following the recovery from acute poisoning. It probably means that systems other than the cholinergic nervous system can be involved in nerve agent-induced long-term signs of alteration of neurological and neurophysiological functions. Thus, it will be necessary in the future to find new markers describing noncholinergic outcomes of low-level nerve agent exposure.

The long-term behavioral toxicity of nerve agents, especially the alteration of cognitive functions (T-maze, Y-maze, Morris maze test) due to nerve agent-induced delayed toxicity, seems to be connected with the neuropathological damage observed in the hippocampus. Thus, neuropathology of the hippocampus connected with the alteration of cognitive functions can occur after high-level as well as repeated or long-term low-level nerve agent exposure.

Neurochemical analysis of repeated or low-level nerve agent exposure provokes the suggestion that the prolonged nerve agent-induced alteration in brain chemistry may be a pharmacological basis for neurobehavioral changes. Thus, it is necessary to follow brain homeostasis during acute as well as chronic nerve agent exposure.

Repeated or long-term exposure to low levels of nerve agents can cause neurophysiological and behavioral alterations due to downregulation of muscarinic receptors in the hippocampus as a reaction to acetylcholine accumulation at muscarinic receptor sites based on AChE

inhibition. This phenomenon is considered to be the cause of behavior performance deficits, especially disruption of cognitive functions.

Chapter 34

The respiratory toxicity of chemical warfare agents

Alfred M. Sciuto[1] and Urmila P. Kodavanti[2]

[1](Retired), Biochemical and Physiology Branch, Analytical Toxicology Research Division, US Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD, United States, [2]Public Health and Integrated Toxicology Division, Center for Public Health and Environmental Assessment, US Environmental Protection Agency, Research Triangle Park, NC, United States

34.1 Introduction

Chemical warfare agents (CWAs) play a significant role in the defense preparation plans of major military organizations worldwide. Human CWA exposure produces unique pulmonary and systemic health effects. The exposure/response relationships have been characterized to some extent, but many of the precise mechanisms are extremely complex and unknown. The physiology, biochemistry, and toxicology of CWA exposure has been studied for decades, but more recently, the interest in this topic has been rejuvenated due to increased threat for potential use of CWAs and development of countermeasures. The health studies involve acute and chronic exposure effects to high or low doses of various agents. The landscape for the administration of medical therapies has evolved from these studies. However, recent history has shown that some of the focus of chemical defense has shifted to the biological agents that have attracted much attention with the deadly anthrax attacks in the early part of this century. While many of these agents pose a different kind of threat with regard to their potential use, this chapter deals specifically with the more common CWAs, including traditional nerve agents such as sarin, soman, and tabun; vesicants such as sulfur mustard; riot control agents (RCAs); metabolic poisons such as cyanide; and choking agents such as phosgene and chlorine. Many of the agents discussed here, while not necessarily regarded as valid CWAs in current plans and scenarios, remain legitimate terrorist weapons.

In an attempt to elucidate the site-specific targets of toxicity and to define the physiological, biochemical, and toxicological mechanisms of an inhalation exposure, rodent models have been extensively utilized. This has been the case with practically all studies that investigate the adverse effects of an inhalation challenge. While these models are extremely useful as a first attempt to identify exposure/response effects, rodents do not accurately represent humans in terms of respiratory structure and function. Therefore, the extrapolation of rodent data to humans should be made carefully with regard to the toxicity of CWAs. The agents discussed herein manifest their toxicities based on the capability of the exposed animal to distribute, detoxify, metabolize, excrete, and override the deleterious effects of an agent challenge, regardless of route of exposure. However, when the toxic load overwhelms the system, potentially adverse outcomes are imminent.

34.2 History of chemical warfare agents use

The use of CWAs on the battlefield gained significant recognition during and after World War I. An excellent and comprehensive history of the use of CWAs is presented by Hilmas et al. (2008) and Salem and Tourinsky (2008). The historical use of CWAs stems from work with plant poisons by the ancient Egyptians and Indian civilizations nearly 5000 years ago. One of the earliest recorded uses of chemical warfare was that of Greek fire, as noted in the Ebers Papyrus 3500 years ago. Greek fire may have consisted of pitch, quicklime, and sulfur naptha. Arsenic-based and phosgene-like toxic smokes and "flaming concoctions" were used throughout history by the Greeks, Chinese, and Romans before the common era (BCE) to achieve victories in such settings as the Peloponnesian Wars (431–404 BCE) against tribal

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00034-9

mountain rebels, and the Turks over 2000 years ago, respectively. During the fifteenth century, Leonardo da Vinci proposed the use of shells filled with copper acetate, sulfur, and arsenic as a weapon to be fired against enemy ships to disable the crew by directly affecting their lung. Similar toxic smokes were used during the Thirty Years War (1618–48). The use of chlorine gas was suggested during the US Civil War (1861–65), but it was not actually manifested under battlefield conditions until World War I. By far, the most extensive use of CWAs on the battlefield occurred during World War I. Both Germany and the Allies used projectiles filled with chlorine, phosgene, diphosgene, and sulfur mustard. These were used singly or in combinations, such as chlorine used with phosgene. These agents were well suited for use, as they generally tended to be heavier than air, and as such, caused extensive mortality and morbidity. In the mid-1930s, during the Italian-Ethiopian War, sulfur mustard (and possibly chloropicrin (PS) and phosgene) were used. In the intervening years between World War I (1914–18) and World War II (1939–45), significant effort was put into developing therapies and physical barrier protection, such as masks and suits, for the possibility of the chemical warfare attack by warring nations in future conflicts. Although CWAs were stockpiled during World War II, none were used. The development of more deadly chemical agents—namely those of the organophosphorus nerve agents—occurred during this period.

In the 1960s, during the Vietnam War, the United States used defoliating agents such as Agent Orange to uncloak the enemy. While the planned use of sulfur mustard was not applied on the battlefield, the United States implemented the use of nonlethal RCAs. In the Yemen Civil War, the Egyptians used mustard gas, phosgene, nerve agents, and RCAs on a regular basis from 1963 to 1967. In the mid-1980s, sulfur mustard and nerve agents were used by the Iraqis on Iranian troops, causing massive casualties and deaths. Over 35 years later, the survivors of these gas attacks continue to have exposure-related health issues. More recently, in 2002, the Russians used the incapacitating agent fentanyl to subdue Chechnyan terrorists holding Russian civilians hostage in a movie theater. This attempt to defuse the situation resulted in over 118 deaths due to asphyxiation. In 2007, terrorists exploded homemade chlorine canisters, causing numerous casualties in Iraq. Even more recently, in 2013, there was the alleged use of the nerve gas sarin by the Syrian government in the Syrian Civil War that presumably killed hundreds of civilians. Virtually all these agents, regardless of their route of exposure, can injure the respiratory system.

34.3 The respiratory system

The structure of the respiratory system is complex, so the effects produced by inhaled CWAs can vary depending on the chemistry and deposition efficiencies of these substances. The respiratory system is comprised of the airway compartment, to transport air, and the alveolar compartment, to perform the gas-exchange function. The airway begins with the nose, which through the pharynx carries air to the trachea, divides into two main bronchi and then several small bronchioles within each lung. Epithelial cells of different types line the airways and perform cell-specific functions. The pseudostratified, columnar ciliated cells predominate in the airways, and while guiding the airflow, function to remove particles encountered through inhaled air. Dome-shaped, secretory cells within small airways (known as *Clara cells*) secrete uteroglobin, possess drug-metabolizing enzymes, and function as stem cells to replenish lost ciliated epithelial cells. In addition, goblet cells produce and secrete mucus at the apical surface of the airway epithelium. The mucous layer helps remove particulates and pathogens via mucociliary clearance and modulates the innate immune response. The thickness of the mucous layer is proportional to the diameter of the airway and the density of goblet cells in a given area. At the basal sector of the airway epithelial cells is the basement membrane, which supports the epithelial cells and interstitial space and allows communication to the smooth muscle layer. Dendritic cells that project between airway epithelial cells function as antigen-presenting cells which, upon recognition of antigens (particulate, microbial, or soluble substances), produce innate and humoral responses (Cook and Bottomly, 2007). Sensory, vagal C-fibers innervate the airways at the airway epithelium and evoke a classical reflex reaction when stimulated, leading to bronchoconstriction and coughing, which in turn enhances parasympathetic tone, causing bradycardia and hypotension (Pisi et al., 2009). The airway surface layer is the first to encounter inhaled soluble and insoluble respirable toxicants that pass through the nose after inhalation.

The terminal airways, called *respiratory bronchioles* in humans, lead into small alveolar sacs, which are lined with type 1 and type 2 alveolar epithelial cells. Thin type 1 epithelial cells cover the alveolar surface, while cuboidal type 2 cells function to secrete proteins and surfactant material that is stored in lamellar bodies. The pulmonary arteries, which bring blood from the heart to the lung for oxygenation, form a capillary network surrounding the alveolar sacs. Type 1 cells are close to the capillary walls, allowing the diffusion of carbon dioxide from the blood to the air and oxygen from the air to the blood to occur (Galambos and Demello, 2008; Herzog et al., 2008). Myofibroblasts are found within the interstitial tissue supporting the alveolar compartments and capillary network and are involved in various functions, including synthesis of collagen, elastin, and other extracellular matrix proteins. The alveolar sacs, interstitial matrix, and capillary

network are encapsulated by the pleural mesothelial layer, which provides anatomical structure to each lung.

The surfactant material produced within type II cells is composed of about 80% phospholipids and about 20% neutral lipids and proteins. Once secreted, it layers thinly over the entire alveolar epithelial surface and provides stability to the alveoli, prevents collapse, and preserves patency. In addition to maintaining surface tension, surfactants play an important role in host defense. Of the four surfactant proteins (SPs), SP-A, SP-B, SP-C, and SP-D, SP-A and SP-D play a role in host defense, whereas hydrophobic SP-B and SP-C are involved in the adsorption and spreading of the surfactant material along the alveolar lining (Griese, 1999; Enhorning, 2008). Alveolar macrophages within the alveoli protect the lung from inhaled pathogens by engulfing bacteria, particles, damaged surfactants, and dead neutrophils or other cells after an acute lung injury. In addition, macrophages perform important innate immune functions by expressing cytokines that are involved in mounting an inflammatory response, as well as in the resolution of inflammation. A variety of warfare agents and pathogens can produce acute lung injury and alveolar edema and lead to respiratory collapse when exposures are encountered at high levels.

34.4 Pulmonary agents

Practically all CWAs can be classified as airway and lung toxicants. When inhaled, CWAs can penetrate to various levels of the respiratory system, from the nasal passages to the lung periphery, and cause toxicities specific to lung cells. More importantly, the development of many CWAs were specifically designed to cause significant mortality and morbidity due to compromised respiratory function. These include phosgene, chlorine, diphosgene, and chloropicrin, all of which were used either singly or in combination during World War I and other conflicts worldwide. While, these compounds may be found in old agent stockpiles, both phosgene and chlorine pose industrial and occupational hazards because they are also employed in many industrial chemical manufacturing processes. They are also toxic combustion by-products. Their heavy industrial usage classifies them as toxic industrial compounds (TICs), with the significant potential to affect large residential or rural areas if exploited. In this chapter, we describe the respiratory toxicity of the known warfare agents for which inhalation is the primary route of exposure.

34.4.1 Arsine

Arsine (also known as *arsenic trihydride, arsenous hydride*, and *hydrogen arsenide*) has been described as the most toxic form of arsenic. Its chemical formula is AsH_3, and it has a molecular weight of 77.95. It is 2.5 times as dense as air, which makes it highly suitable for a "state-of-the-art" trench-type warfare agent. Arsine most likely would now be classified as a low toxicity and high persistence CWA, at a level equivalent to chlorine (Table 34.1). However, due to its low toxicity (10 times less toxic than phosgene), its battlefield usage was halted during World War I. It is colorless and can have the mild odor of garlic. AsH_3 is soluble in chloroform and benzene, but only slightly soluble in water. Currently, arsine gas is used in the microchip industry to plate semiconductors with arsenic. Other workplace activities where arsine is used are for galvanizing, soldering, etching, and lead plating. Arsine is a strong reducing agent and can be formed through the following arsenide, Zn_3As_2, and acid hydrolysis reaction (Eq. 34.1):

$$Zn_3As_2 + 6H^- \rightarrow 2AsH_3 + 3Zn^{2+} \qquad (34.1)$$

34.4.1.1 Exposure physiology

The single most important route of exposure to arsine is through inhalation. Generally, no discomfort occurs from exposure to arsine, as it is a nonirritating compound. The extent and nature of the symptoms depend largely upon the concentration and duration of exposure. Romeo et al. (1997) report that exposure levels of 10−32 mg/m^3 for up to several hours may produce symptoms consistent with arsine toxicity (described next). An earlier study (Morse and Setterlind, 1950) indicated that exposures ranging

TABLE 34.1 Classification of CWAs and their military symbols based on environmental persistence and lethality.

Potency	High persistence	Low persistence
Low lethality	Sulfur mustard (HD), lewisite (L), mustard-lewisite (HL), nitrogen mustard (HN1−3), cyanogen chloride (CK), diphenylchloroarsine (DA), arsine (AsH_3), chlorine (Cl_2)	*o*-Chlorobenzyl-malonitrile (CS), dibenz(*b*,*f*) − 1,4-oxazepine (CR), chloracetophenone (CN), chloropicrin (PS)
High lethality	Soman (GB), cyclosarin (GF), VX	Phosgene (CG), sarin (GB), tabun (GA), hydrogen cyanide (AC)

from 23 to 970 mg/m^3 may be lethal to humans. Many symptoms are latent in nature. Within 1−24 h after inhalation at a high concentration, persons become ill and may experience hematuria (the voiding of dark, bloody urine). Massive hematuria may lead to anuria, which can become fatal. Within 24 h, symptoms may also include headache, vomiting, muscle weakness, dyspnea, nausea, confusion, wheezing, and jaundice. Fowler and Weissberg (1974) have shown that arsine causes tachycardia, tachypnea, hepatic enlargement, and abdominal rigidity and tenderness. In severe cases, acute respiratory distress syndrome (ARDS) could become evident along with hyperthermia, hypotension, and paresthesias in the extremities. According to the Centers for Disease Control and Prevention (CDC), high levels of inhaled arsine can also produce convulsions, loss of consciousness, paralysis, and respiratory failure, ultimately leading to death. Pulmonary edema and circulatory collapse may also result in a fatal outcome. However, at low concentrations of 10 ppm for 6 h/day for 4 days, arsine exposure to pregnant mice and rats resulted in no developmental effects (Morrissey et al., 1990). The chronic effects of arsine poisoning include renal injury, polyneuritis, memory loss, and agitation. The most significant finding of arsine toxicity is the fulminant lysis of erythrocytes. It has been reported that arsine at estimated concentrations of 750−1500 ppm × min will cause extensive hemolysis (Caravati and Dart, 2004). The LCt_{50} for arsine gas is estimated to be 5000 mg × min/m^3 (Seto, 2011).

34.4.1.2 Exposure biochemistry

The effect of arsine on the blood has been studied in several animal inhalation exposure models. Blair et al. (1990a,b) exposed male and female mice to arsine at concentrations totaling 9−900 ppm administered for 6 h/day for 5 days over 13 weeks. Pathophysiological results at the highest total dose showed significant decreases in hematocrit (HCT) and hemoglobin (HGB) with increases in mean corpuscular hemoglobin at 5 days postexposure. Between 15 and 90 days, a regenerative process appeared to have been activated by elevated reticulocytes and mean corpuscular volume. At 90 days, denatured proteins such as Heinz bodies were present. Also at 90 days, the formation of methemoglobin suggests that the oxidation of ferrous heme iron (Fe^{2+}) to ferric heme iron (Fe^{3+}) had occurred. When red blood cells (RBCs) were exposed to arsine gas in vitro, reduced glutathione (GSH) levels were diminished by 60% after a 4-h exposure (Blair et al., 1990a,b). The authors concluded that an enhanced oxidative environment may be the source of the oxidation of membrane-bound sulfhydryl groups on the HGB molecule. This conclusion was corroborated to some extent by the addition of the sulfhydryl inhibitor *N*-ethylmaleimide, 2 h after arsine exposure, which resulted in less hemolysis (Rael et al., 2000). Ionic gradient hemostasis is also affected by arsine exposure in RBCs. Rael et al. (2000) have shown that intracellular K^+ and Mg^{2+} decreased, whereas Na^+, Cl^-, and Ca^{2+} increased. Based on these data, the increase in Ca^{2+} influx may be responsible for arsine-induced hemolysis of RBCs. However, the role of oxidized GSH and an amplified oxidizing environment has been questioned by some investigators as the primary reason for arsine-induced hemolysis (Hatlelid et al., 1995; Winski et al., 1997). Pulmonary toxicity of arsine has not been reported, although inhalation exposures have been used in many studies, except for one where intraperitoneal (i.p.) injections of dimethylarsine and trimethylarsine have resulted in lung tumor formation (Yamanaka et al., 2009).

34.4.1.3 Exposure histopathology

A search of literature did not reveal any lung pathological reports for arsine gas toxicity. As stated earlier, the most prominent event following an inhalation challenge is erythrocyte hemolysis.

34.4.2 Chlorine

Similar to phosgene, chlorine is considered a "choking" agent. Under ambient conditions, chlorine, also known as *dichlorine* (molecular weight/MW = 71), is a pungent, noncombustible, yellow-green gas. Chlorine is heavier than air, which enables it to settle in low-lying areas, making it a possible persistent agent, and yet it does not have the toxicity of phosgene (Table 34.1). It is slightly soluble in water in which it can form hydrochloric and hypochlorous acids (HOCl). Chlorine can also bind with alkenes, alcohols, and ammonia. Due to high electronegativity, chlorine can react with numerous biomolecules present in cells and tissues. Reactions with Cl_2 can occur by either radical or ionic processes that form one or two chlorine atom bioproducts. As a nonmetal halogen, Cl_2 is not formed in nature due to its high reactivity. After fluorine and oxygen, it is the third most electronegative element. It was one of the first widely used CWAs, having been employed early in World War I. Presently, the majority of exposures to chlorine occur through accidental occurrences such as train derailments, industrial process failures, and recently, the intentional use of these substances by terrorists in Iraq in 2007 (Weill, et al., 1969; Hilmas, et al., 2008; Van Sickel et al., 2009).

34.4.2.1 Exposure physiology

The principal route of exposure to chlorine is through respiration. Chlorine is classified as a pulmonary irritant that can affect both the central and peripheral airway compartments. Unlike phosgene, chlorine may not obey Haber's

rule; that is, that a constant concentration × time ($[C] \times t$) product leads to a consistent physiological/toxicological outcome (Hoyle et al., 2010). Acute lung injury is not necessarily caused by chlorine itself, but by the aqueous reaction products formed in the mucus membrane of the airways. These include chlorine dioxide, chloramine, and HOCl. General sequelae include, but are not limited to, lacrimation, rhinorrhea, conjunctival irritation, cough, sore throat, laryngeal edema, dyspnea, stridor, pulmonary edema, and ARDS, all of which can lead to respiratory collapse. Furthermore, inhalation leads to abrupt airway bronchoconstriction, increased airway resistance along with decreased compliance, epithelial cell necrosis, and microvascular permeability. Chlorine exposure has also been linked to irritant-induced asthma, or what is commonly known as *reactive airways dysfunction syndrome (RADS)*. RADS is characterized by airway hyperreactivity, fibrosis, and airway obstruction. Thus, the responses to chlorine are generally nonspecific, as they are with most irritant compounds. The LCt_{50}, the amount of chlorine inhalation needed to cause 50% mortality in exposed animals or humans, is estimated to be 19,000 mg × min/m^3 (Seto, 2011).

To understand the physiological and mechanistic responses to chlorine inhalation, exposure-response studies have been conducted in rodents. Acute respiratory responses following exposure of female mice to chlorine were examined by Morris et al. (2005). In this study, mice were exposed for 15 min at total chlorine concentrations ranging from 12 to 57 ppm × min. It is not surprising that in obligate nose-breathers, the results indicate that chlorine was scrubbed with excellent efficiency in the upper respiratory tract (URT) at 97%. Resistance in the URT beginning at 15−17 days after exposure was also significantly higher with chlorine than with deep lung irritants. The RD_{50} (the 50% reduction in respiration rate as measured by frequency), at 57 ppm/min of chlorine was significantly increased from baseline to twofold during the last 6 min of 15 min total exposure. Mo et al. (2013) reported an impairment of lung antimicrobial activity in male mice exposed to a total concentration of 14,400 ppm × min chlorine and then challenged with *Aspergillus fumigatus* 24 h postexposure. In these mice, significant increases in the recruitment of lymphocytes, monocytes, and neutrophils were measured compared to chlorine exposure alone. The authors show that increased neutrophils and concentrations of reactive oxygen species (ROS) may be responsible for the inability of exposed mice to mount an immune challenge to *A. fumigatus*.

34.4.2.2 Exposure biochemistry

Chlorine inhalational damage is not restricted to particular cell types, such as epithelial cells. Injury caused by inhaled chlorine can be complex and may involve multiple pathways. The loss of vascular tone following chlorine exposure has been linked to dysfunctional nitric oxide (NO)−dependent mechanisms and resulting vasodilation (Honavar et al., 2011). To address the role of NO, Honavar et al. (2014) found that when rats were exposed to a total chlorine concentration of 12,000 ppm × min, isolated pulmonary artery studies showed disruption of vascular tone due to disrupted NO signaling. The balance between endothelial nitric oxide synthase (eNOS)- and inducible nitric oxide synthase (iNOS)-derived NO was disrupted by chlorine. The expression and activation of eNOS and iNOS through the interaction between p38 MAPK- and PI3/AKT-dependent pathways may also have an effect on endothelial permeability in lung injury. However, the precise mechanism by which eNOS and iNOS might be linked to functional impairment of pulmonary vascular tone, and bronchoconstriction is not well understood.

Exposure to chlorine in mice induces inflammatory pathways, resulting in the recruitment of neutrophils and the production of cytokines such as GROα/CINC/KC, IL-6, and TNFα (Tian et al., 2008; Song et al., 2011). Li et al. (2013) have determined that exposure of mice to chlorine gas, 400 ppm × 30 min upregulates unfolded protein response (UPR) in the lung for up to 6 h postexposure. UPR elements are regulated by a defensin-like peptide through the disruption of iron homeostasis. The authors speculate that inflammatory mediators such as TNFα, IL-6, and hepcidin might also be involved. The link between UPR elements and inflammation has been demonstrated in other studies (Xue et al., 2005). Chlorine exposure also affects regulatory Na^+ channels in epithelial lung cells (Lazrak et al., 2012). Epithelial Na^+ channels (ENaC), which are present on the apical surface, were inhibited in mouse lung slices and Type II epithelial cells after exposure to 400 ppm × 30 min of Cl_2. The data suggests that Cl_2-activated ERK1/2 expression (extracellular signal-related kinase) in Type II cells in vitro and in vivo might be involved. The data suggests that Cl_2 exposure results in compromised Na^+ regulatory activity, partly responsible in fluid clearance mechanisms. Postexposure treatment with reactive species scavengers ameliorated the problem (Xue et al., 2005). The common thread among these studies is that chlorine-induced inflammation produces reactive intermediates and induces cytokine release, which can ramp up destructive pathophysiological responses. Chloramine, a reactive by-product of chlorine metabolism, is also capable of initiating reactive processes. The degree of chlorine-induced injury and lung inflammation has been shown to differ between mouse strains (Tian et al., 2008).

34.4.2.3 Exposure histopathology

In humans who have died from severe chlorine exposure, postmortem results have shown the presence of massive pulmonary edema, ulcerative bronchiolitis, and

cardiotoxicity (White and Martin, 2010). In mice exposed to chlorine at 400 ppm × 15 min, profound changes in lung pathology were observed (Hoyle et al., 2010). This study looked at lung damage through a range of concentrations over various points in time that produced a constant concentration × time ($[C] \times t$) product. There was significant damage to the airway epithelium. At 6 h postexposure, the injury was more widespread, encompassing large airways and causing denudation. At 24 h postexposure, sloughed epithelial tissue fragments were present in the airway lumen. There was also evidence of neutrophilic inflammation that is consistent with inhaled chlorine toxicity. The magnitude of the histopathological response was not necessarily $[C] \times t$-dependent. These data corroborate a comparable study by Tian et al. (2008) where similar histological responses were observed. However, at a later time point after exposure (48 h) repair processes are likely activated. Thus, exposure to high concentration of chlorine can produce profound lung injury and pathology.

34.4.3 Phosgene

Phosgene (also known as *carbonyl dichloride, carbon dichloride oxide, carbon oxychloride, chloroformyl chloride, dichloroformaldehyde*, and *dichloromethanone*), whose chemical formula of $COCl_2$ (MW = 98.9) was used as a CWA during World War I. In addition to its weapons applications, it has a variety of industrial uses, such as in the synthesis of pharmaceuticals and organic materials (Wyatt and Allister, 1995). Because of its potential for toxicity, phosgene is often produced and used captively in the same chemical facility to avoid potential hazard. Although it is less toxic than nerve gases such as sarin and tabun, it is still regarded as a viable CWA because it is so easy to produce. Phosgene is generally produced in industry by the interaction of carbon monoxide and chlorine gas, using activated carbon as a catalyst. It can also be produced from chloroform in the presence of oxygen and ultraviolet (UV) light. When phosgene reacts with water, it decomposes into hydrogen chloride (HCl) and carbon dioxide. Accidental exposures to phosgene in humans at high concentrations cause pulmonary edema, sensory irritation, and associated rapid breathing (Diller, 1985a). Patients complain of dyspnea upon exertion and reduced ability to exercise for several months to years after an accidental exposure. Normalization of lung function can take several years (Diller, 1985b).

34.4.3.1 Exposure physiology

Phosgene can be widely and easily dispersed by the wind. Being heavier than air, it tends to sink into trenches and ditches making it fairly nonpersistent on the ground (Table 34.1). Phosgene is deposited in deeper regions of the lung, as opposed to nitrogen oxide, sulfur oxide, and chlorine, which are more water-soluble and are deposited primarily in the upper airways. Inhaled phosgene causes chest pain, burning throat, and persistent cough. It affects numerous metabolic pathways critical to cell and tissue survival. The average LCt_{50} of phosgene in acutely exposed rats has been reported to be 1741 $mg/m^3 \times min$ (Pauluhn, 2006a). The respiratory toxicity of phosgene is well studied in laboratory rodents, and large animal species such as dogs and sheep. There is a steep acute $[C] \times$ time mortality relationship for phosgene gas in rats (Pauluhn et al., 2007).

Exposure to phosgene was associated with early bronchoconstriction, an obstructive injury pattern, and disruption of mechanical rhythm of breathing, which were largely attributed to the progressive production of pulmonary edema in mice (Sciuto et al., 2003). Increased expiratory resistance and decreased dynamic compliance were noted in rats exposed to phosgene (Ghio et al., 2005). In pigs exposed to a high concentration of phosgene, a transient decrease in oxygen saturation and cardiac stroke volume index was observed during the exposure period, while significant decreases in arterial pH, P_aO_2, and lung compliance were noted 6 h after exposure (Brown et al., 2002). Thus, the acute physiological effects are likely mediated by sensory irritation and lung edema.

34.4.3.2 Exposure biochemistry

Once inhaled, phosgene penetrates deep into the alveolar region, where it transits through the airway surface and is hydrolyzed to CO_2 and HCl; however, it has been shown that the concentration of HCl is not sufficient enough to produce the damage that is typically seen after an acute phosgene exposure (Pauluhn et al., 2007). In contrast to soluble gases, the less-soluble phosgene gas penetrates the lower respiratory tract without marked retention in the conducting airways. It has been hypothesized that phosgene-induced acylation of nucleophilic amino, hydroxyl, and sulfhydryl moieties of the fluid components of the alveolar lining, rather than HCl itself, results in rapid alveolar injury and inflammation (Pauluhn et al., 2007). Through this acylation reaction, phosgene instantaneously interacts with antioxidants such as GSH, resulting in its depletion (Sciuto et al., 2003, 2005). It has been proposed that surfactant destabilization and generation of reactive oxidation by-products results in rapid intra-alveolar pulmonary edema. The surfactant abnormalities have been presumed to initiate events leading to acute respiratory failure (Mautone et al., 1985).

Many experimental studies have investigated transient surfactant abnormalities soon after phosgene exposure (Jugg et al., 1999). The surfactant, a mixture of lipids and

proteins, performs an important function of maintaining surface tension between air liquid interphase within the alveoli and prevents alveolar collapse. It also regulates innate immune response and host defense (Wright, 2003). Proteins leaked from the vasculature into the alveoli due to phosgene-induced damage to the surfactant and alveolar cells can further inactivate surfactant material. Upon exposure to phosgene, increases in the bronchoalveolar lavage fluid (BALF) levels of proteins are attained on day 1, while lipids increase on day 3, suggesting that these proteins are the likely cause of surfactant destabilization, leading to further vascular leakage, inducing apoptosis, and inflammatory signaling cascade via an innate immune response (Pauluhn et al., 2007). Evidence from studies using large animal models such as dogs and pigs suggests that phosgene inhalation causes a high-permeability type of lung edema brought on by high surface tension and the compensatory interstitial perimicrovascular hydrostatic pressure, resulting in alveolar flooding (Pauluhn, 2006a,b). It has been postulated that the latency between phosgene entry into the lung and edema are due to the time required for increased fluid distribution between interstitial, lymphatic, and perimicrovascular compartments within the alveoli. The alveolar epithelial and interstitial cells (but not endothelial cells) are the primary targets of phosgene-induced injury, further supporting the hypothesis that pulmonary edema results from a pressure gradient across the air liquid interphase (reviewed in Pauluhn et al., 2007).

Increased pulmonary edema induces a sequence of events that results in the release of inflammatory cytokines, apoptosis, extravasation of inflammatory cells, and inflammation that is linked to extracellular matrix remodeling and fibrosis observed in a number of studies, specifically those involving low-level, longer duration exposures. The degree of inflammation and subsequent fibrosis could be directly related to the concentration of phosgene, the longevity of exposure, and the type of laboratory animal model being exposed (Kodavanti et al., 1997; Pauluhn et al., 2007). The removal of pulmonary liquid and inflammatory cells may facilitate quick reestablishment of the homeostasis. A number of processes, such as mucociliary clearance, fluid clearance through pulmonary circulation, and inflammatory cell signaling, are initiated within alveolar and lower airway structures. Although acute pulmonary toxicity of phosgene is fairly well established, there are no effective antidotes other than supportive management of symptoms. A number of different therapeutic approaches have been tested experimentally (Sciuto and Hurt, 2004).

34.4.3.3 Exposure histology

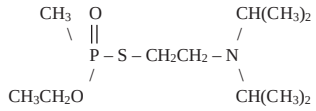
Histopathological lesions have been reported after an acute exposure to phosgene, which are characterized by alveolar and interstitial edema, hemorrhage, fibrin deposition, alveolar and interstitial flooding, and inflammatory cell infiltration. Focal bronchiolar and terminal airway degeneration and necrosis have also been reported. Resolution of inflammation and edema have been noted in a number of animal studies (Gross et al., 1965; Hatch et al., 2001; Duniho et al., 2002). At relatively low concentrations and longer exposures, phosgene can induce alveolar inflammation and fibrosis in a concentration-dependent manner (Kodavanti et al., 1997). The histologic changes in the bronchioalveolar regions in rats exposed to phosgene at 0.1 ppm for 4 weeks were characterized by a small but apparent thickening and mild inflammation, which were progressive with increased concentrations. Masson's trichrome staining indicated increased collagen deposition at the terminal bronchiolar sites and increased pulmonary hydroxyproline, a measure of collagen deposition, at high concentration of 1 ppm. These lesions were also seen in animals exposed for 12 weeks and persisted after a 4-week nonexposure recovery period. Histological changes, including collagen deposition after long-term phosgene exposure, have also been reported by Pauluhn (2006a). Histopathology in pigs exposed to high concentrations of phosgene revealed areas of widespread pulmonary edema, petechial hemorrhage, and bronchial epithelial necrosis (Brown et al., 2002). Thus, phosgene-induced injury is likely to cause pulmonary fibrosis and scarring of the peripheral lung tissue, which might affect breathing.

34.4.4 Nerve agents

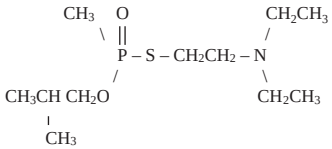
The nerve agents consist of a family of compounds whose role in chemical warfare was to cause significant morbidity and mortality among soldiers. As such, the most likely application of nerve agents was initially for military purposes. However, as recently as 2013, nerve agents were allegedly used against civilians in conflicts in the Middle East (Sellstrom et al., 2013). The syntheses and development of nerve agents took place in Germany between World War I and World War II. Nerve agents are highly toxic and are classified as organophosphates (OPs). OPs are esters of phosphoric acid and are the most toxic of the known chemical CWAs. Members of this family also include parathion, malathion, and mipafox, which are commonly used worldwide in agriculture as well.

The principal chemical varieties of chemical warfare nerve agents are shown in Fig. 34.1. Nerve agents are generally odorless and colorless. See Table 34.2 for physical chemical characteristics. Sarin (GB), tabun (GA), cyclosarin (GF), and soman (GD) are known as the *G agents*, where *G* denotes "Germany." These agents volatilize fairly rapidly. Whereas the *V agents* (where *V* denotes "venomous"), such as *O*-ethyl *S*-[2-(diisopropylamino)ethyl]

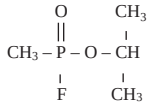
A. VX (*O*-ethyl *S*-(2-(diisopropylamino) ethyl) methlyphosphonothioate)



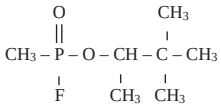
B. VR (*O*-isobutyl *S*-[2-(diethylamino)ethyl] methylphosphonothioate)



C. Sarin ([GB], isopropyl methylphosphonofluoridate)



D. Soman ([GD], pinacolyl methylphosphonofluoridate)



E. Tabun ([GA], ethyl *N*-dimethyl phosphoroamidocyanidate)

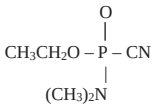


FIGURE 34.1 Chemical structures of nerve agents.

methylphosphonothioate (VX) and VR, are classified as nonvapor hazards. VR (also known as *Russian VX*) is a close stereoisomer of VX. Classifying V agents as nonvapor threat agents may not be entirely appropriate, as these agents can penetrate the airways if they adhere to dusts, mists, and fog particles, thereby causing significant effects. As a class of threat agents, they are meant to be used as offensive weapons and can be delivered via rockets, bombshells, mortar rounds, and other devices. Usually dispersion is in the forms of sprays, aerosols, and vapor, and possibly the combination of aerosol and vapor. The toxicity response produced by a mixture of OPs can be multifaceted with respect to how these agents are absorbed and deposited in the airway. Punte et al. (1958) makes the statement that OPs in the aerosol form may be more toxic than an equivalent amount delivered by a gas exposure. Owing to their rapid uptake, nerve agents can be absorbed by inhalation, dermal, ocular, and oral routes of exposure. The neuronal effects of nerve agent intoxication include physiological, toxicological, and biochemical responses, which are well studied, but the pulmonary effects are less well examined. These effects are common to all the agents with structural similarities, as shown in Fig. 34.1.

Regardless of the route of exposure, nerve agents cause a variety of physiological and toxicological effects, as discussed next. Many of these occur within minutes of exposure, especially with the more volatile G agents. Studies involving inhaled nerve agents have been conducted for many years with a range of animal models. Many factors affect the toxicity response—for example, whole-body exposure versus head-out or nose-only, animal species, agent type, time of day of exposure, duration of exposure, aerosol versus vapor (as these enter the airspaces at different rates and in different locations), dilution vehicle used, agent concentrations and particle size (in the case of an aerosol), and most important, the target tissue dose. Pulmonary toxicities of different classes of nerve agents are described next.

34.4.4.1 Volatile agents

G agents include GA, also known as ethyl dimethylamidocyanophosphate, EA1205 (tabun); GB, known as isopropyl methylphosphonofluoridate, trilone, MFI, TL1 618, T144, and T2106 (sarin); and GD, known as pinacolyl methylphosphonofluoridate (soman). They are among the most toxic CWAs. Listed in descending order of ease of volatilization, it is GB, GD, and GA. GA is colorless and may have a fruity odor, which can change to bitter almonds (similar to cyanide) upon decomposition. GA is soluble in organic solvents such as ethanol, diethyl ether, and chloroform. Hydrolysis of GA can produce cyanide and hydrocyanic acid. GA has a $t_{½}$ of 8.5 h at a pH of 7 in an aqueous solution. GB is colorless and odorless, and it is the most volatile of the G agents. It is miscible in water and, like GA, is hydrolyzed in both acidic and basic conditions. This rapidly acting compound has a $t_{½}$ of about 1.5 min. at a pH of 11 and 25°C. However, one report shows an estimated $t_{½}$ to be 40 h (Garigan, 1996). GB comes in two enantiomeric forms (+) and (−), with the (+) form twice as toxic as the (−) form (Christen and Van den Muysenberg, 1965). GD is also a colorless liquid with a fruity odor. It is about 20% soluble in water at 25°C. In water at 20°C, and a pH of 7, it hydrolyzes with $t_{½}$ of about 80 h. GD has two isomers, C(±)P(−) is more toxic than C(±)P(+), each possessing different rates of hydrolysis, with C(±)P(+) being faster. GF and GA are the least studied of the G agents and will not be discussed herein. Chemical properties of the G agents are shown in Table 34.2.

34.4.4.2 Exposure physiology

Considerable valuable and relevant data have come from many experimental models using the inhalational approach to assess G agent toxicity. The organ distribution of G agents can take on different patterns following exposure with regard to the volume of distribution. GB is distributed to the brain, kidney, liver, and blood plasma of mice (Little et al., 1986). Within the brain, both GA and

GD are detected in the hypothalamus (Wolthis et al., 1986). GD can partition into fat, which delays the morbidity response in animals. In addition to distribution, elimination pathways of nerve agents consists of covalent binding and enzymatic hydrolysis. A number of studies have examined the toxicity of these agents. Van Helden et al. (2004) exposed marmosets and guinea pigs to low vapor concentrations of GB, 7–150 μg/m^3 over 10–300 min, to determine the earliest physical response to exposure. Results showed that GB, at levels that were undetected by the fielded alarm systems used, produced significant neuronal effects in the exposed animals. This suggested that acute effects of GB can occur at very low levels. Lung microinstillation exposures of guinea pigs for 4 min to GB caused increased weight loss, lung edema, decreased O_2 saturation, decreased peak inspiratory and expiratory flows, and increased minute volume within 4 h (Conti et al., 2009). Decreased flows are indicative of increased airway resistance. High-dose inhalation exposure to GB (a total dose of 130–150 mg/m^3 × min over 10 min) caused severe bronchoconstriction in rats (Gundavarapu et al., 2014). Che et al. (2008) showed that microinstillation exposure of GB in guinea pigs caused immediate inhibition in BALF in acetylcholinesterase (AChE) activity, followed by a reversal of this effect within an hour despite continued inhibition of blood AChE. This was likely due to the high lipophilicity and rapid absorption of GB. In a 3-month study using rats exposed to GB vapor at 33–35 μg/L for 10 min daily, Allon et al. (2005) determined that there was an increased vulnerability to cardiac arrhythmias after each challenge to GB. This study pointed to the potential of delayed effects of GB exposure; however, long-term consequences of single high-dose GB exposures are not well studied. In a limited study, Husain et al. (1993) showed that mice exposed to nebulized GB at 100 mg/m^3 × min per day for 10 days developed muscular weakness of the limbs and slight ataxia on day 14. GB and GD exposure-response effects on hemodynamics and lung function were assessed in baboons following an inhalation challenge. GD at 13.14 μg/kg and GB at 30 μg/kg were vaporized into the upper airway of baboons. Both agents caused increased development of apnea due to decreased phrenic nerve signals, cardiac arrhythmias, and a decrease in mean systemic blood pressure (Anzueto et al., 1990).

In an acute in vivo guinea pig lung microinstillation model, Katos et al. (2009) demonstrated that exposure to GD produces prominent respiratory dynamic changes. At 24 h postexposure, tidal volume increased along with respiratory frequency. In contrast to the study by Conti et al. (2009), peak inspiratory flow was increased, possibly suggesting agent-specific effects on lung airflow patterns. Using a head-out vapor exposure system, Perkins et al. (2013) investigated the toxicity of inhaled GD at concentrations ranging between 520 and 1410 mg × min/m^3 in the conscious rat. All animals exposed to the higher

two doses died. Significant increases in BALF protein occurred with dose-dependent inhibition of AChE activity in the lung and brain within 24 h after challenge. Cholinergic crises were evident based on dose-dependent changes in cholinergic symptoms compared to controls. It can be presumed that the systemic effects of acute nerve agent exposure may be more likely when the RBC−AChE levels drop by 75%−80% (Sidell and Somani, 1992). Systemic OP-induced depletion of AChE could be directly responsible for increases in mortality resulting from heightened convulsive and seizurogenic activity. However, a number of studies have shown the effects independent of AChE inhibition. Willems (1981) demonstrated that in OP pesticide-exposed individuals, there was no correlation between AChE inhibition and the extent of neuronal symptoms. Moreover, an acute noninhalation exposure study with sarin, VX, and soman in male and female guinea pigs demonstrated that respiratory toxicity of these compounds did not correlate with AChE activity (Fawcett et al., 2009). Mutagenicity studies with GB and GD have shown that they do not produce adverse effects in the Ames *Salmonella*, Chinese hamster ovary, and mouse lymphoma assays. However, GA was deemed slightly mutagenic in the Chinese hamster ovary and Ames bacterial system assays (Nasr et al., 1988; Goldman and Dacre, 1989).

Thus far, human data have largely come from low-dose exposure of volunteers and from nonfatal accidental exposures. Exposed humans have experienced coughing, wheezing, rhinorrhea, and nonexertional and exertional dyspnea, along with a feeling of increasing pressure in the thoracic region. Craig and Freeman (1953) provided evidence that accidental exposure to GA or GB causes behavioral changes, sleep disturbances, fatigue, and mood changes. Indeed, the concentrations of these agents required to produce mortality in humans are not precisely known. However, the estimated LCt_{50} of GA, GB, and GD are believed to be 150, 70−100, and 40−60 mg × min/m^3, respectively.

34.4.4.3 Exposure biochemistry

The nerve agents are known to bind and functionally disable AChE regardless of the agent form (i.e., vapor or spray) or the route of exposure. The extent of AChE inhibition is a function of dose and duration of exposure, basically the product of $[C] \times t$. AChE is found at the synaptic junctions of nerve endings and is responsible for hydrolyzing excess acetylcholine (ACh), which is critical to synaptic nerve transmission. The failure to metabolize or break down ACh causes an accumulation of ACh at the nerve terminals, leading to increased cholinergic stimulation and many of the toxidromic symptoms typical of nerve agent poisoning, known medically as a *cholinergic crisis*. Increased cholinergic stimulation leads to persistent stimulation of muscarinic receptors (M_1−M_3 in the lung) within the parasympathetic neurons. In mammalian species, parasympathetic nerves innervate the airways. Muscarinic receptors belong to the G-protein coupled receptor family presenting throughout the airways. Overstimulation of muscarinic receptors initiates increased salivation, lacrimation, urination, and defecation (commonly known as *SLUD*), along with bronchoconstriction, bradycardia, increased nasal secretions, emesis, and dyspnea. Nicotinic receptors, a member of the ligand-gated ion channel family, occur in the somatic or sympathetic nervous system and are also affected by OPs. Symptoms include tachycardia, mydriasis, fasciculations, meiosis, skeletal muscle paralysis, hypertension, slurred speech, irritability, fatigue, impaired judgment, insomnia, and diaphragmatic weakness. More severe poisoning is associated with more profound central nervous system (CNS) responses such as ataxia, convulsions, seizures, and death by asphyxiation.

Neurotransmitter pathways may be directly involved in the sequelae of G agent-induced toxicity. In the CNS, G agents can also act directly on glutamate receptors. Chebabo et al. (1999) demonstrated in an in vitro model that nM amounts of GB reduced the amplitude of gamma-aminobutyric acid (GABA), which is a neurotransmitter. It has been suggested that overstimulation of glutamatergic receptors by GD in the brain may be responsible for the modulation of seizure activity (Lallement et al., 1991a,b). Affected neurotransmission pathway may have far-reaching consequences on behavior and induction of convulsions. For an in-depth discussion of nerve agent exposure-response effects and case histories, refer to the excellent overview by Sidell et al. (2008). Some investigations have centered on the effects of repeated exposure to nerve agents. Kalra et al. (2002) studied the effects of subclinical repeated inhalation nose-only exposures to GB of 0.2 and 0.4 mg/m^3 on immune cell responses in rats. GB exposure suppressed T-cell mitogenesis, conconavalin A, and anti-αβ-T receptor-dependent antibody-forming cell responses. In addition, there was a reduction in glucocorticoid production. Their data indicated that repeated exposures to GB over 5−10 days caused changes in T-cell responsiveness mediated by GB's effect on the autonomic nervous system.

Inhaled G agents cause significant respiratory problems. The respiratory effects occur within minutes and clinically can resemble a severe asthmatic attack. A nerve agent-induced death is normally linked to pulmonary dysfunction. Enhanced secretions are the result of vagal efferent activity resulting from increased ACh concentration, substance P, and vasoactive intestinal peptide release. The inhalation of a high concentration of vapor will result in loss of consciousness, apnea, flaccid

paralysis, and seizures (status epilepticus) within a period ranging from seconds to several minutes. Peak effects can occur within 30 min, followed by an asphyxiating death (Berkenstadt et al., 1991).

One of the major differences between the principal nerve agents GA, GB, and GD is associated with aging of the AChE enzyme. This AChE aging is basically a chemical reaction resulting in the complexation of the nerve agent with the AChE enzyme that prevents the reactivation of the enzyme. GB-complexed AChE ages over about 5 h, whereas GD takes only minutes (Garigan, 1996). Aging half-time estimates can vary depending on the experimental model used such as in vitro versus in vivo (Sidell et al., 2008).

In addition to binding with AChE, the detoxification process can lead to interaction of OPs with other cholinesterases such as butyrylcholinesterase (BuChE) and carboxylcholinesterase (CaChE) in the plasma and tissues. Levels of these enzymes can vary from organ to organ. In humans, CaChE is present in cells rather than in plasma, as is measured in other animal species. OPs can also interact with other enzymes such as paraoxonase and arylesterase. For a more comprehensive review of these secondary effects, see Casida and Quistad (2004).

Exposure to G agents in particular GD may change the antioxidant-to-oxidant ratio by affecting free-radical scavenging pathways that are abundant in mammals. Klaidman et al. (2003) showed that an intramuscular injection of GD in rats decreased protein sulfhydryls in the piriform cortex and the hippocampus during seizures at 1 h postexposure, whereas at 24 h, postexposure GSH levels decreased nearly 50% in the piriform cortex. These results suggest that free-radical formation may be contributing to seizurogenic pathophysiology. Furthermore, subcutaneous challenge to GD increased lipid peroxidation and formation of nitrogen oxides within 30 min of administration in rat brain, especially the hippocampus, thalamus, and medulla-pons (Jacobsson et al., 1999). Since the medulla-pons region controls respiration, it is likely that neuronal mechanisms might also contribute to respiratory effects of OPs. Despite the fact that the two models cited here do not involve the inhalation route of exposure, it is clear that once the agent crosses into the systemic circulation, similar physiological responses occur regardless of the route of exposure.

Exposure to G agents can also cause changes in transcriptional pathways. For instance, RamaRao et al. (2011) showed that GD caused perturbations in the phosphorylation levels of cAMP response element binding protein (CREB), c-Jun, and NF-κB, all of which control a variety of pathological processes. Dillman et al. (2009) demonstrated using microarrays that GD markedly modulated p38 mitogen-activated protein kinase (MAPK) and extracellular receptor kinase (ERK) signaling pathways. While these were not inhalation studies, it should be noted that once the agent enters the systemic circulation, multiple comparable side effects are initiated and propagated. Exposure to G agents causes perturbations in calcium regulatory signaling pathways, which can affect a variety of physiological responses. Destabilization of protein kinase C, which is responsible for brain ion fluxes and eventual neurotransmitter release at different rates in various brain regions, suggests that brain regions respond differently to nerve agent challenges. Exposure to GB also induces inflammatory gene expression within the lung. GB increases lung tissue expression of IL-2, TNFα, IL-1β, hypoxia-induced factor HIF-α, and eotaxin 24 h following exposure, suggesting a cytokine surge resulting from highly active inflammatory processes (Gundavarapu et al., 2014). For these and other nerve agent-induced expression changes in inflammatory processes, see RamaRao and Bhattacharya (2012).

34.4.4.4 Exposure histopathology

Inhalational effects of G agents on lung tissue following exposure can range from basically none to severe based on the $[C] \times t$ of exposure. In rats exposed to 768 mg × min/m^3 aerosolized GB, major changes in the pathology at 4 days after exposure were observed. Primary changes were seen in the epithelial lining of the lobar bronchi. Lung histology showed increases in interstitial mononuclear cells and thickening of the alveolar septa. Masses of exudate, inflammatory cell infiltration, and bronchial epithelial damage were also seen (Pant et al., 1993). In a study featuring 10-day repeated exposure to GB, on day 14 postexposure spinal cord pathology showed clear evidence of degenerative axons (Husain et al., 1993). Brain lesions and cardiomyopathy were observed in rats exposed to GD or GB in a subcutaneous injection model (Singer et al., 1987; Tryphonas and Clement, 1995). In Perkins et al. (2013), rats exposed to 4−6 min GD vapor at 600 mg × min/m^3 had compromised lung tissue pathology compared with controls. At 24 h after exposure, alveolar hemorrhage, inflammation, and histiocytosis scored twofold higher than controls. Neutrophilic exudate and alveolar destruction were also observed. An intramuscular challenge with GD showed astrocytic degeneration, neuronal necrosis, and liquefaction necrosis of the CNS. The cerebral cortex, limbic system, thalamus, and substantia nigra appeared to be targets of toxicity in the rat (Tryphonas and Clement, 1995). Pulmonary pathology changes after systemic administration of nerve agents are not well characterized.

34.4.5 Nonvolatile agents

Nonvolatile agents, such as VX and its structural isomer VR, have the same molecular weight (as shown in

Table 34.2) and are not considered to be vapor hazards. As a result, they are judged to be low inhalational threats to humans (the agents, listed in order of volatility are GB, GD, GA, VX, and VR). Most research on V agents have centered on VX, which is considered the "gold standard" against which the toxicities of all other agents (GA, GB, and GD) are compared.

VX is an odorless and colorless compound when in pure form. It is an oily liquid that is slightly soluble in water. These characteristics are largely responsible for its capacity to be classified as a persistent agent (Table 34.1). Although VX and VR are similar in structure, Collins et al. (2013) demonstrated in a rat aerosol exposure model that after a single 10-min exposure to VX or VR, the VR lethal concentration was nearly half that of VX (367 versus 632 mg × min/m^3) making it more toxic. These data support results from an earlier study by Chang et al. (2002), where they conclude that it may take higher doses of atropine to treat those exposed to VR. While there may be differences between VR and VX in terms of lethality, the physiological, biochemical, histopathological, and toxicological outcomes are very similar. Therefore, unless specifically pointed out, mostly VX data are reported. The reported estimates of lethality for VX is 40 mg × min/m^3 (Seto, 2011).

34.4.5.1 Exposure physiology

While VX and VR pose more of a percutaneous threat, exposure by inhalation should be given more serious consideration, as the agent can directly come into contact with airway surfaces when bound to mists, dust particles, fog, and other substances. As a result, entry into the airspaces can be accelerated. Exposure of airway surface can lead to almost immediate reactions culminating in respiratory failure if the $[C] \times t$ product is sufficiently high. Bronchoconstriction, a hallmark of nerve agent exposure, in animals caused by the inhaled V agents most likely is a result of mechanisms common to those of G agents. Bronchospasms may be caused by local effects on the respiratory center of the CNS, as opposed to direct effects. It is likely that more persistent agents have a tendency to deposit in the lung compartment and are slowly released over time as previously described for GD. Exposure to VX or VR produces similar hypercholinergic effects such as SLUD, incapacitation, seizures, and cardiorespiratory depression (bradycardia, dyspnea, and convulsions).

Lung exposure studies in animals using microinstilled VX have provided evidence of the nature of pulmonary effects. In guinea pigs exposed for 5 min to VX doses ranging between 50 and 90 μg/m^3, acute effects varied from an increase in lung wet/dry weight ratio with increases in the numbers of macrophages/monocytes in BALF at 24 h postexposure (Wright et al., 2006). In a similar exposure model of local pulmonary instillation of VX, Graham et al. (2006) demonstrated that BuChE activity, although inhibited at 5 min postexposure, was quantifiably present in BALF at 24 h postexposure even at the highest dose of VX. The authors speculate that the presence of BuChE, which is synthesized in the liver and circulates in the plasma, may be a marker of damaged air−blood barrier integrity at later time points. Katos et al. (2007) found a significant inhibition of AChE in the esophagus and intestine following microinstilled VX in the lung. From these studies, it is apparent that VX can localize to the gastrointestinal tract, causing an "irritable bowel-like" condition as a result of its likely clearance through the gut. In guinea pig studies investigating the long-term effects of a 10 min. VX exposure on changes in pulmonary respiratory dynamics, Rezk et al. (2007) demonstrated that end-expiratory pause (EEP); that is, the length of time between the end of expiration and the beginning of the inspiratory cycle was increased at 48 h postexposure. This study also indicated that most of the altered respiratory function returned to near control levels by day 7, except for EEP. EEP did return to normal levels by day 18. These data suggest that VX can persist in the body due to tissue-specific compartmentalization and produce long-term effects.

A direct 10-min intratracheal VX exposure of anesthetized rats, bypassing the nose (preventing neuronal translocation to brain through nose), resulted in acute lung injury and tissue damage, suggesting direct tissue-specific effect. In this work, VX aerosol was administered at 514 mg/min/m^3 and produced significant increases in BALF protein concentrations at 6 and 24 h after exposure, suggesting the prevalence of pulmonary edema. Airway resistance was significantly increased at 20 min and 6 h postexposure at all VX concentrations tested and at the two highest doses, 343 and 514 mg × min/m^3, 24 h postexposure (Peng et al., 2014). The authors concluded that VX inhalation impairs pulmonary function through an obstruction associated with increased pause, expiration time, and nearly a 50% decrease in expired flow rate, decreased respiratory rate and tidal volume, leading to a drop in minute ventilation. These are all indicators of airway flow obstruction. VX inhalation could transiently disturb lung function through airway smooth muscle spasm, paralysis, or both, and when combined with mucus oversecretion, could result in respiratory failure; however, the precise mechanisms are not well understood.

Additionally, a preliminary assessment of the VX exposure effects on cellular profiles in BALF was undertaken. Study time points were 3, 6, 24 h, and 1 and 2 weeks postexposure. Blood analyses indicated that VX exposure at 343 mg × min/m^3 increased circulating white blood cells (WBCs), erythrocytes (RBCs), HCT, HGB,

neutrophils, platelets (PLTs), and eosinophils at 6 h post-VX inhalation compared with naïve controls. Lymphocytes, basophils, monocytes (MONO), HCTs, and RBCs remained elevated at 1 week. Monocytes and PLTs continued to be elevated at 2 weeks after exposure compared to naïve controls (Sciuto, 2014). While further work is needed in this area to determine how these changes are associated with pulmonary pathology and the chronicity of the damage, these data indicate that variable effects of V agent inhalation on cell populations are not limited to acute effects. This substantiates the fact that V agents may deposit in tissues and get released over a long period of time after a single exposure. It is also possible that there may be a lag-time in the immune response induced by V agent exposure as part of a compensatory mechanism.

34.4.5.2 Exposure biochemistry

Limited published studies are available investigating the effects of V agent exposure on biochemical pathways. Similar to G agents, V agents likewise inhibit blood and lung tissue AChE activity. In the aerosolized VX rat exposure model of Peng et al. (2014), blood AChE activity was decreased 41% at 343 and 52% at 514 mg × min/m^3 24 h postexposure. Lung tissue AChE activity was also inhibited by VX. However, using a similar exposure model testing the effects of VR, AChE mRNA transcription in the lungs was up-regulated by 19% for 143 and 30% for the 286 mg × min/m^3 VR groups compared to vehicle at 24 h (Sciuto, 2014). Up-regulation of lung tissue AChE mRNA may indicate the cellular response to accumulation of nonfunctional enzyme. In addition, we observed by immunohistochemistry a positive staining for iNOS in alveolar epithelial cells together with decreased staining of surfactant D in lung tissue 24 h postinhalation exposure to 514 mg × min/m^3 VX.

In these VX aerosol inhalation studies, Western blot analyses showed that xanthine oxidoreductase, an enzyme-producing superoxide, is activated in response to VX inhalation exposure at 343 mg × min/m^3. VX inhalation also triggered IL-6 expression in rat lung tissue. In VR-exposed rats, lung lavage assays showed decreased GSH concentration and superoxide dismutase (SOD) activity, which indicates a local oxidative stress environment. Western blot analyses of lung tissue 6 h postexposure demonstrated an increased expression of xanthine oxidase, increased IL-1β expression, and activation of phosphorylation of p38 and Akt suggesting stimulation of inflammatory mechanisms.

34.4.5.3 Exposure histopathology

There is minimal if any lung damage within 24 h after VX exposure in rats. Lung and tracheal lesions were generally less severe in the 3- and 6-h VX postexposure groups than in the 24-h VX postexposure groups consistent with its delayed effects. This delay could be due to the time it takes for extravasation of inflammatory cells, such as neutrophils and macrophages (Peng et al., 2014). The tracheal lesions in these animals showed evidence of ulceration accompanied by neutrophilic inflammation and necrotic epithelial lining (necrotic membrane). Similar findings were observed in a VX-exposed guinea pig inhalation model (Nambiar et al., 2007). Peng et al. (2014) also showed that at high levels of inhaled aerosolized VX, exposure produced prominent alterations in airway and lung pathology at 24 h in the rat. A 10-min exposure to 514 mg × min/m^3 VX-induced architectural changes in the trachea and lung. The most significant findings were perivascular inflammation, histiocyotsis, alveolar exudate, alveolar epithelial necrosis, septal edema, and bronchiolar inflammatory infiltrates.

VX exposure also causes lung parenchymal pathology. VX-induced histological changes are persistent for 1−2 weeks postexposure. In general, the pulmonary histologic changes described are likely secondary to nebulized agents. The prevalence of lesions suggest that VX, when administered by inhalation at concentrations of 171 and 343 mg × min/m^3, can induce mild but persistent pulmonary changes over several days postexposure. Wright et al. (2006) showed similar patterns in the lungs of guinea pigs microinstilled with VX for 5 min.

34.4.6 Cyanides

Cyanides were used as CWAs and are potential terrorist agents (Magnum and Skipper, 1942; NRC National Research Council, 1999). Cyanides are also used industrially for electroplating and the extraction of gold and silver. They can be released into the atmosphere from volcanoes, fungi, and bacteria. Common food items such as pears, peach, sweet potatoes, peas, apples, and lima beans are sources of cyanogenic compounds.

34.4.6.1 Exposure physiology

The cyanides, formerly known as "blood agents," consist of hydrogen cyanide (NATO code designation AC, HCN: MW 27.04) and cyanogen chloride (CK, ClCN: MW 61.5). The common metabolic by-product is the toxic CN^- anion, which is largely a systemic toxicant. Vapors from these agents are heavier than air and spread across the ground like phosgene and can pose a problem in low-lying, confined areas (Table 34.1). A mild exposure to these agents through the inhalation route can cause headache, loss of consciousness, ataxia, and confusion. Palpitations and respiratory tract irritation with labored breathing (dyspnea) can lead to hyperpnea in some cases.

For exposures classified as severe, serious CNS effects may occur. These include coma, seizures, and mydriasis. Dysrhythmias, low blood pressure, and eventual life-threatening cardiac arrest may follow. The occurrence of pulmonary edema followed by respiratory insufficiency can be a late manifestation following a severe inhalation exposure episode. The toxic load of inhaled HCN can be enhanced through its effect on increased minute volume (Purser et al., 1984).

Animal studies have provided evidence of the tissue distribution of inhaled cyanide. These studies have indicated that the target organs are the lung and heart, followed by the brain; all highly perfused. For example, in the rat following an acute inhalation exposure to HCN, the highest concentrations were measured in the blood, brain, heart, and lung with very little in the liver (Ballantyne, 1983). The estimated human inhaled 50% lethal concentration of HCN is 2500−5000 mg × min/m^3 and for cyanogen chloride, it is approximately 11,000 mg × min/m^3. These data indicate that via the inhalation route, the cyanides are less toxic compared to their effects as systemic poisons (McNamara, 1976).

34.4.6.2 Exposure biochemistry

It is well known that HCN vapor readily penetrates the epithelium with little difficulty due to its low ionization and low molecular weight. This allows for the rapid absorption through pulmonary alveolar membrane during exposure. The basic metabolic chemical reactions involving CN^- have been studied for decades (Sykes et al., 1981). CN^- binds to and inactivates enzymes involved in oxidative phosphorylation within mitochondria. The mitochondria are the primary target organelles involved in HCN poisoning. Lethal cytotoxic anoxia results from the interaction of CN^- with cytochrome c-oxidase, which is an important regulator of cellular respiration. This reaction, which occurs within minutes, inhibits aerobic metabolism by binding to the binuclear heme center. Additionally, there is loss of the formation of ATP, which is critical to supplying cells with the energy required for normal cellular processes (Keilin, 1929; Klein and Olsen, 1947). This adverse reaction prevents the binding of electrons to the molecular oxygen. As such, aerobic cell metabolism is halted even in the presence of well-oxygenated blood. In a futile attempt to regain the loss of ATP, cells increase glycolysis, especially in organs rich in mitochondria, such as the brain and heart. This results in metabolic acidosis characterized by increase in lactic acid. This, along with severely decreased ATP production, is responsible for dampened neurotransmission and altered perceptive abilities (Lindalh et al., 2004). In the brains of mice exposed to cyanides, lactic acid increases, and accumulation of adenosine diphosphate (ADP) and phosphates also lead to overall CNS metabolic impairment (Estler, 1965; Isom et al., 1975). CN^- can be removed through metal-complexing interactions with cobalt, molybdenum, and organic compounds prior to cell entry. Cyanide also forms cyanomethemoglobin as a result of its interaction with methemoglobin within erythrocytes. This process can remove cyanide from the plasma. Detoxification of CN^- occurs through the formation of the less acutely toxic thiocyanate (SCN) via the mitochondrial enzyme rhodanese which catalyzes the transfer of a sulfane sulfur atom from sulfur donors to sulfur acceptors (Eq. 34.2). The end reaction with the formation of SCN^- is generally irreversible.

$$CN^- + S_2O_3^{2-} \rightarrow SCN^- + SO_3^{2-} \qquad (34.2)$$

β-mercaptopyruvate-cyanide transulfurases, which are present in the liver, kidney, and blood are also capable of detoxifying cyanides forming SCN^- (Westley et al., 1981, 1983). A third enzymatic system present in the kidney may likewise play a role in the detoxification of CN^-. The sulfotransferase, called *cystathionine* γ-lyase, has been shown to be effective in cyanide-clearing processes (Wrobel et al., 2004).

34.4.6.3 Exposure histopathology

Inhalation exposure to cyanide-forming agents leave scant identifiable markers of tissue or cellular damage in target organs such as the lung, heart, and brain following challenge. This is mostly because once in the body, it diffuses rapidly into the bloodstream and acts essentially as a systemic toxicant, regardless of route of exposure. Several earlier animal studies showed that acute or repeated exposure to CN^- causes neuropathological changes, such as gray matter necrosis and degenerative changes in ganglion and Purkinje cells, in dogs (Haymaker et al., 1952). Encephalopathy and optic nerve neuropathy are other sites of toxicity following inhalational exposure (Hirano et al., 1967; Lessel, 1971). Thus, inhalational exposure might result in more severe neuronal impact, since the brain is rich in mitochondria.

34.4.7 Riot control agents

RCAs, also known as *sternutators* (from the Latin term meaning "sneezing") and *lacrimators*, consist of a specific class of irritant compounds. Agents (and NATO codes) in this class are 2-chlorobenzylidene malononitrile (CS: MW 188.6), dibenz (*b,f*)−1:4-oxazepine (CR: MW 195.3), oleoresin capsicum (OC: MW 305.4), 10-chloro-5,10-diphenylaminochlorarsine (DM: MW 277.6), chloropicrin (PS: MW 164.4), and 1-chlorocaetophenone (CN, also known as MACE: MW 154.6). Some of these agents, such as PS, DM, and CN, are CWAs (Fig. 34.2).

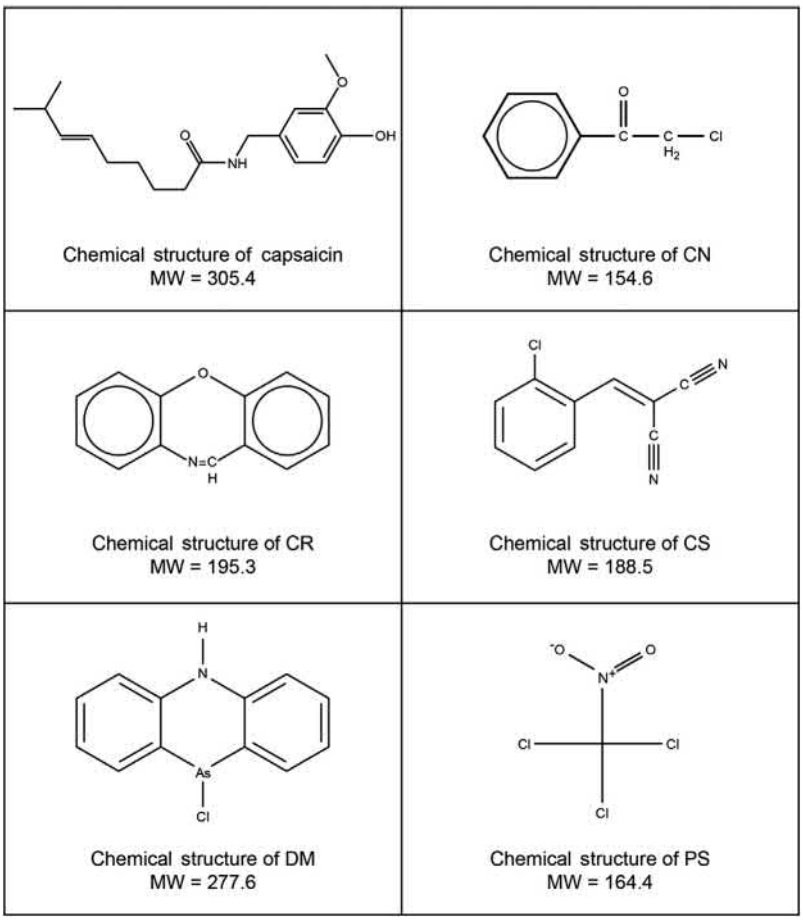

FIGURE 34.2 Chemical structures and formula weights of the most commonly studied RCAs.

RCAs have the general characteristics of causing rapid incapacitation, ease of dissemination, and relative low toxicity. They are usually disseminated as mists, aerosols, smoke, or volatilized M18 thermal grenades. They have been used widely as CWAs (Hilmas et al., 2008; Salem et al., 2008). CN was the original tear gas, which eventually was replaced by CS. In general, these agents possess actions that are short-lived, with the exposed becoming adapted to the effects within about 30 min of exposure. However, death has been known to occur with high doses and in confined spaces. Pharmacologically, they fall across classes that include emetics, hypnotics, serotonin antagonists, neuromuscular blockers, and sedatives. The toxicological effects of RCAs are readily apparent in various anatomical areas, such as the eye, gastrointestinal tract, nasal, oral and neuronal tissues, lung, and skin. Complex interactions among the sites described make RCAs potent candidates for crowd dispersion and control. Even though all of these anatomical sites are critical with regard to aftereffects, we will focus primarily on inhalation toxicology. For an outstanding and extensive review of RCA toxicity, see Olajos and Salem (2001).

34.4.7.1 2-Chlorobenzylidene malononitrile

CS is a white crystalline solid with a relatively low solubility in water, but a rapid rate of hydrolysis. It is soluble in most polar organic solvents. Harris (1993) describes RCAs as nonlethal, making them most effective as crowd dispersants on unprotected personnel. RCAs can enter the respiratory tract in the form of vapor or aerosol.

34.4.7.1.1 Exposure physiology

When inhaled, these agents are capable of sensory nerve receptor irritation, causing the Kratschmer reflex, which may result in cessation of respiratory function. Initial responses include sneezing, coughing, a burning sensation, and excessive rhinorrhea. Additional responses can also include dizziness and disorientation. While these are protective mechanisms to reduce the effects of inhalation, they may be accompanied by bradycardia and biphasic changes in aortic blood pressure. The half-life of CS following inhalation is less than 30 s (Olajos and Salem, 2001). Because of its low water solubility CS is environmentally persistent (Table 34.1). To further increase environmental persistence for up to 2 weeks, two hydrophobic

forms were synthesized, CS1 and CS2, which are rapidly absorbed from the respiratory tract. In rat inhalation studies, repeated exposure to CS1 caused aggressive behavior and hyperreactivity. In other studies with concentrations reaching 25,000–68,000 mg × min/m^3, there were no changes in blood electrolyte levels; however, pulmonary edema and necrosis of the respiratory and gastrointestinal tracts were observed in the rats that died after CS exposure. Death most likely consisted of the combined result of hypoxia, circulatory failure, and obstructed airways (Salem, et al., 2006). In human volunteers, exposures to a range of CS concentrations showed no evidence of deleterious changes in airway resistance, vital capacity, or tidal volume (Beswick et al., 1972). The LCt_{50} values for humans have been estimated to range between 25,000 and 100,000 mg × min/m^3 (WHO (World Health Organization), 1970). However, there have been no reported human mortalities due to CS exposure. The high levels of estimated concentrations of CS required to be lethal in humans clearly places it in the low lethality category (Table 34.1). While lethality is not measured during the course of human exposure, CS exposure has been linked to RADS, which can result from a single intentional exposure (Hu and Christiani, 1992). The respiratory irritation effects of CS exposure may be linked to the release of bradykinin (McNamara et al., 1969; Cucinell et al., 1971).

34.4.7.1.2 Exposure biochemistry

As noted previously, CS is rapidly absorbed during inhalation. It has a very short half-life and is metabolized and detoxified in the blood and other organs. Its disappearance follows first-order kinetics, and it spontaneously hydrolyzes to form malononitrile, which is then metabolized to thiocyanide (Nash et al., 1950). However, it is believed that in the case of inhalation exposure, the amount of formed thiocyanide may have little if any role in human toxicity (Ballantyne, 2006). Metabolites can be found in the blood only after high exposures. CS is an SN_2-alkylating agent with active halogens, which react with nucleophilic sites. A common metabolite 2-chlorobenzaldehyde was found in the blood of rodents and humans after exposure. CS reacts rapidly with plasma proteins and GSH, all of which are possible cofactors responsible for detoxification (Cucinell et al., 1971). Sulfhydryl-containing enzymes, such as lactic dehydrogenase, pyruvic decarboxylase, and glutamic dehydrogenase, are targets of the alkylating effects of CS (Lovre and Cucinell, 1970). The i.p. administration of CS to rats results in its excretion in the urine as mercapturic acid (Rietveld et al., 1983). It is not known if this occurs following inhalation. On the other hand, it has been reported that aerosol exposure to CS leads to an excretion of thiocyanate. The release of cyanide has also been shown to occur following i.p. injection in the rat (Frankenberg and Sorbo, 1973).

34.4.7.1.3 Exposure histopathology

Overall, CS does not produce significant respiratory tract or systemic lesions. In mice and rats, exposure to CS caused squamous metaplasia of the olfactory epithelium and hyperplasia and metaplasia in the respiratory epithelium. In 1990, the National Toxicology Program (NTP) tested CS for genotoxicity and carcinogenicity and found no evidence of either effect in rodents (NIH (National Toxicology Program), 1990). In inhalation experiments using rats and hamsters, with CS concentrations ranging between 150 and 750 mg/m^3 and lasting from 30 to 120 min, a small degree of lung pathology was seen for up to 28 days postexposure. The hallmark of exposure at high levels in the lung was congested alveolar capillaries, pulmonary edema, and hemorrhagic lesions. Secondary effects in extrapulmonary organs were renal tubular and hepatic cellular necrosis (Salem et al., 2006). In 120-day inhalation studies using guinea pigs, acute alveolitis was observed (Ballantyne and Callaway, 1972; Ballantyne and Swanston, 1978).

34.4.7.2 Dibenz (b,f) − 1:4-oxazepine (CR)

CR is a pale yellow solid with a strong, pepperlike odor. Exposure-effect responses of CR are similar to CS. CR is the most potent lacrimator with the least toxicity. It is the parent compound of the antipsychotic drug loxapine (Blaine, 2003).

34.4.7.2.1 Exposure physiology

Upon inhalation, CR is rapidly absorbed through the lung and into the bloodstream. It has a plasma half-life of about 5 min (Upshall et al., 1977). CR can be dispersed as an aerosol or as grenade-generated smoke. For the most part, animals exposed to CR exhibit physical dysfunctions such as ataxia, loss of coordination, tachypnea, and convulsions. In human volunteers, low-level CR aerosol exposure produced bronchoconstriction and increased pulmonary blood flow within about 20 min (Ashton et al., 1978). These effects are believed to be due to the stimulation of irritant receptors, the effects of which usually subside within an hour after exposure. Ballantyne studied the effects of inhaled CR aerosol and CR smoke in rats. Concentrations ranged between 13,050 and 428,000 mg × min/m^3. Excessive nasal discharge and blepharospasms occurred, which also subsided in about 60 min (Ballantyne, 1977). No mortalities were recorded. Investigations involving the effects of CR exposure on teratogenicity (specifically, embryo toxicity) revealed no adverse developmental toxicology (Upshall, 1974).

Carcinogenicity and genotoxicity assessment using various strains of *Salmonella typhimurium* reverse mutation tests, CHO gene mutation system (V79/HGPRT), mouse lymphoma assay (L5178Y/TK + /TK −), and micronucleus testing also indicated no toxicity (Colgrave et al., 1979). Data from Kumar et al. (1995, 2006) provides evidence that CN is much more toxic than CR at the 5% LC_{50} level and upon repeated exposure in rats and mice.

34.4.7.2.2 Exposure biochemistry

In rat tissue, CR is metabolized to 4-, 7-, and 9-hydroxylactams via oxidative processes, followed by ring hydroxylation and sulfate conjugation, and then excreted via urine (French et al., 1983). Metabolites and excretion profiles of CR are similar among many species regardless of exposure route. Intravascularly dosed mice suggested rapid uptake of CR from the blood and into the kidney, small intestine, bile, and liver, which was in line with data from rats indicating rapid absorption, hepatic metabolism, and renal excretion (French et al., 1983).

34.4.7.2.3 Exposure histopathology

CR administered by aerosol inhalation at 68,400 mg × min/m^3 did not cause lethality in mice, rabbits, or guinea pigs (Ballantyne, 1977). However, congestion in the capillaries and alveolar hemorrhaging were noted. Pattle et al. (1974) exposed rats to CR at a concentration of 115,000 mg × min/m^3 to determine whether a high concentration produced adverse effects on cell organelles such as lamellar bodies. Electron microscopy indicated no effects of inhaled CR on lamellar bodies. Colgrave et al. (1979) exposed animals to a range of CR aerosols at dosages from 78,200 to 161,300 mg × min/m^3 and reported no abnormalities in the lung. However, subsequent assessment after microscopic examination revealed mild lung congestion, hemorrhage, and emphysema. Long-term effects of inhaled CR aerosol were conducted in hamsters and mice using dosages of 204 ppm (5 min), 236 ppm (8.6 min), and 267 ppm (15.8 min) 5 days/week for 18 weeks. Survivors were sacrificed and dissected 1 year after exposure, with the only pathology being chronic laryngeal inflammation (Marrs et al., 1983).

34.4.7.3 10-Chloro-5,10-diphenylaminochlorarsine (DM-adamsite)

DM, an organoarsenical compound, is a yellowish-green crystalline solid with low volatility. DM and other compounds, such as PS, diphenylchloroarsine (DA), and diphenylcyanoarsine (DC), are known as *vomiting agents*. DM is considered odorless, but it can contain a faint odor of bitter almonds. It is more soluble in organic solvents, such as benzene, toluene, and alcohols, than in water. It can be released as a dry powder using thermal or explosive techniques.

34.4.7.3.1 Exposure physiology

Respiratory effects of inhaled DM include increased nasal congestion, salivation, coughing, and sneezing. Irritation of the mucous membranes of the eyes and airway lining can occur. Persistent vomiting and headaches are also exhibited after DM exposure. Compared to other RCAs, the effects of inhaled DM can take as long as 3 min and last up to several hours (BMOD British Ministry of Defense, 1972). Punte et al. (1962) studied the effects of a number of RCAs in animals that were exposed for periods ranging from 5 to 90 min. With DM, there were no abnormalities observed below concentrations of 500 mg × min/m^3. Estimated LCt_{50} values were as follows: for mouse, 22,400 mg × min/m^3; rat, 3700 mg × min/m^3; and guinea pig, 7900 mg × min/m^3.

Striker et al. (1967) exposed nonhuman primates to various $[C] \times t$ levels of DM. An inhaled dose of 2565 mg × min/m^3 was well tolerated except for one animal that exhibited nasal discharge. At a dose level of $[C] \times t$ of 8540 mg × min/m^3, nasal discharge and facial erythema were noted, but these symptoms were resolved by 24 h post-exposure. When the exposure dose was increased to 28,765 mg × min/m^3, hyperactivity ensued, with significant nasal discharge and respiratory distress in all animals. Striker et al. (1967) concluded that death in some animals was caused by respiratory failure. In human volunteers, doses thought to cause adverse physiological responses such as nausea and vomiting were tested. Some studies found that humans can tolerate DM in the range of 22−92 mg/m^3 for at least 1 min with a 50% tolerance level of up to 220 mg/m^3 (Punte et al., 1962). In this study, the definition of tolerability was the desire to vacate the exposure space as quickly as possible. From these studies and others, it was shown that exposure to inhaled DM produced a range of effects including pain in the eyes, throat, nose, and upper airway; coughing; and salivation similar to a cholinergic response seen with nerve agent exposure. If the exposure is severe enough and sufficient in duration, death may ensue. There is one known human death caused by inhaled DM (Owens et al., 1967). Exposure times of 5−30 min at concentrations of 1130−2260 mg/m^3 ($[C] \times t$ of 5650 to 67,800 mg × min/m^3) were estimated. For the most part, this is well above the estimated LCt_{50} of 11,000 mg × min/m^3 for humans reported by Sidell et al. (1997a,b).

34.4.7.3.2 Exposure biochemistry

There is only one study that suggests the possible metabolic and detoxification fate of DM (Haas et al., 2004). As an organoarsenical compound, it would seem likely that its toxicity may be linked to the metabolism of arsenic. Through the oxidation of As (III) by manganese peroxide, DM is broken down into As (V). This reaction releases chloride with the subsequent incorporation of two oxygen molecules into the parent compound (Haas et al., 2004).

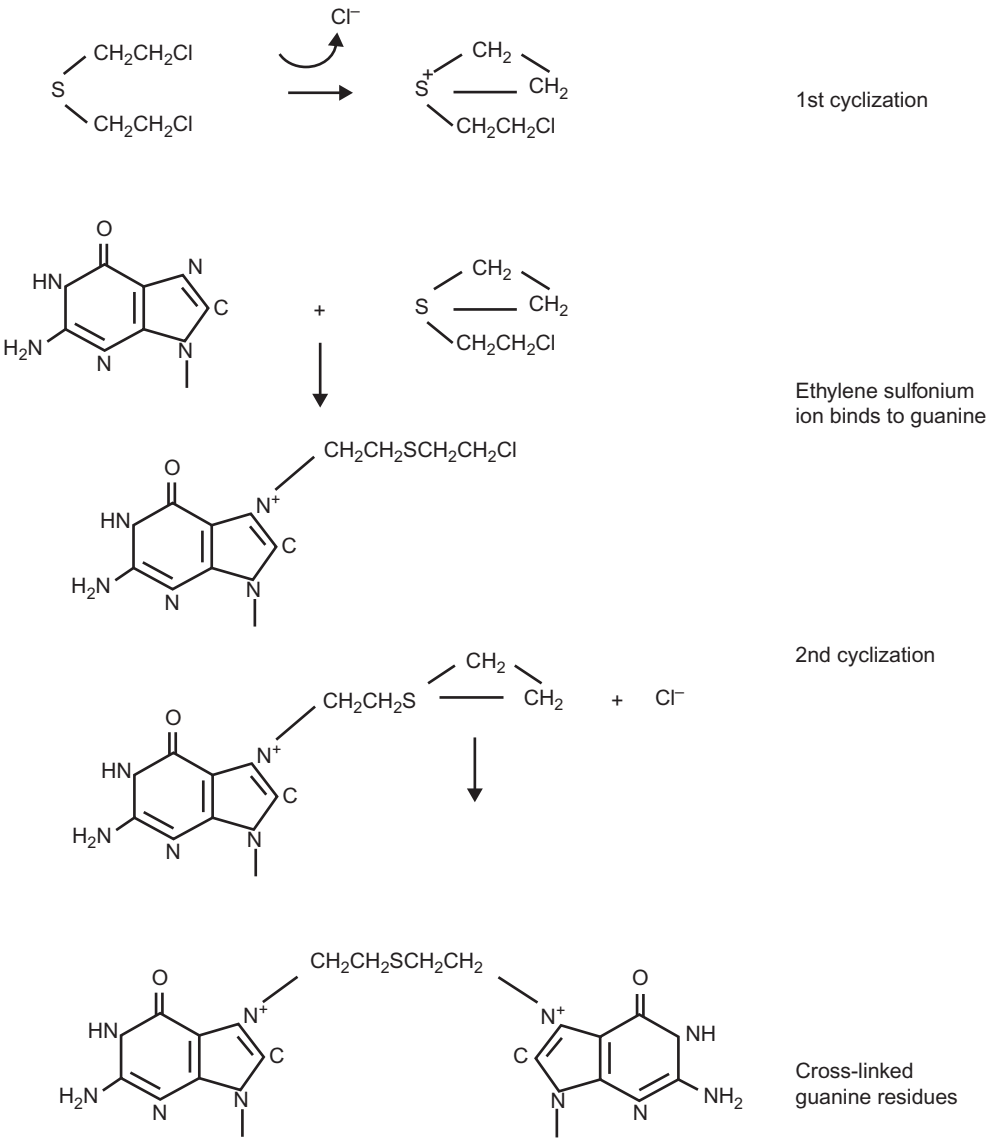

FIGURE 34.3 Reactive chemical mechanisms involved in HD hydrolysis, formation of sulfonium ion, and the alkylation of DNA through guanine cross-linked residues.

Arsenic released in the metabolic process with a specific valance state could inhibit succinic dehydrogenase activity and cause the uncoupling of oxidative phosphorylation and reduced ATP levels.

34.4.7.3.3 Exposure histopathology

As stated previously, there remains little doubt that the target organ showing significant and consistent debilitating effects of inhaled DM is the lung. In DM-exposed nonhuman primates, gross postmortem examination showed evidence of edematous and severely congested lungs, whereas microscopic evaluation revealed ulceration of the tracheobronchial tree and alveolar edema (Striker et al., 1967). In the human death mentioned previously, postmortem analysis revealed edema of the subcutaneous tissue of the neck, mediastinum, pleura, and pericardium, along with emphysematous bullae widespread in the lung. Histologically, bronchopneumonia, hemorrhage, pseudomembrane formation in the trachea and bronchi, and congestion were observed throughout the entire respiratory tract (Owens et al., 1967).

34.4.7.4 Oleoresin of capsicum (OC—pepper spray)

OC is a reddish-brown, oily resin derived from capsicum plants, commonly known as nightshade (Fig. 34.3). Capsaicinoids can exist in several derivative forms such as dihydrocapsaicin, homocapsaicin, and nordihydrocapsaicins. Capsaicinoids are isolated through volatile extraction of the dried, ripened fruit of chili peppers. Once dried, the OCs are predominantly capsaicin, and also nordihydrocapsaicin and homocapsaicin (Salem et al., 2006).

However, other potentially irritating components are present, such as acids, esters, and phenolic agents. Capsaicins at high concentrations can cause a variety of potent effects such as dermatitis, nasal, ocular, pulmonary, and gastrointestinal tissue injury. The active ingredient of capsaicin is 8-methyl-*N*-vanillyl 1,6, nonenamide.

34.4.7.4.1 Exposure physiology

Like all other RCAs, aerosol-dispersed OC causes erythema; burning of the eyes, nose, and throat; sneezing; coughing; and blepharospasm. Acute exposure to inhaled OCs results in pulmonary edema, bronchospasm, respiratory arrest, hypertensive crises, and hyperthermia. OC causes excitement, convulsions, dyspnea, and death due to respiratory failure. While pepper spray is considered relatively safe, fatalities have been reported due to airway obstruction (Synman et al., 2001). Inhalation of capsaicin activates the Kratschmer reflex, as mentioned earlier, accompanied by bradycardia, apnea, and a biphasic rise and fall of aortic blood pressure. The pulmonary effects of capsaicin may be species-related. In guinea pigs exposed to capsaicin via aerosol, bronchoconstriction occurred, suggesting both a vagal-cholinergic as well as a noncholinergic local axonal reflex (Buchan and Adcock, 1992), whereas in cats using a similar exposure method, bronchoconstriction was determined to be due to a direct vagal-cholinergic response (Adcock and Smith, 1989). Glinsukon et al. (1980) determined the LD_{50} in several animal species using various routes of delivery. The concentrations ranged from 0.56 mg/kg intravenously (i.v.) to 1.6 mg/kg by intratracheal instillation. An LCt_{50} value for capsaicin of 13,000 mg/m^3 × min has been published by Seto (2011).

34.4.7.4.2 Exposure biochemistry

One of the mechanisms responsible for capsaicin toxicity is the stimulation of neurons consisting of neuropeptide-containing afferent nerves that are capable of activating specific vanilloid receptors (Szallasi and Blumberg, 1999). Stimulated nerves are of the Aδ and C fiber-unmyelinated types. The activation through ligand-gated mechanisms opens cation channels (Marsh et al., 1987) and increases the influx of Ca^{2+} and Na^{+} in cells, which leads to depolarization and the release of neuropeptides such as substance P. Protective reflexes are activated via autonomic motor neurons. Other transmitters of biological responses to capsaicin included calcitonin gene-related peptide (CGRP) and neurokinin A (a tachykinin), both of which are released from neurons and are responsible for pain transmission and neurogenic inflammation. For an extensive list of capsaicin-sensitive markers, see Holzer (1991).

Mediator-induced inflammatory processes can lead to increased vascular permeability, neurogenic inflammation of airways and blood vessels, chemotaxis, and bronchospasm (Smith and Topford, 1999). Furthermore, capsaicin activates the vanilloid receptor family TRPV1 (transient receptor potential cation channel subfamily V) within sensory neurons. Activation of these receptors leads to prolonged refractory periods and to a nonconducting desensitization. One study suggests that TRPV pathways may not be entirely responsible for all of the adverse reactions caused by capsaicin (Holzer, 1991).

34.4.7.4.3 Exposure histopathology

There have been no reports or reviews assessing the histopathology results from an inhalation challenge to capsaicins or OCs. The only data from toxicity studies was from Glinsukon et al. (1980), who found visceral organ hyperemia without hemorrhage, gastric desquamation, and increased mucus.

34.4.7.5 Chloropicrin (PS)

PS produces many of the effects consistent with RCAs. In addition, it has been classed with choking agents such as phosgene and chlorine due to its effect on the upper airways. PS is an oil ranging from colorless to light green, with a stinging odor classified as aniselike. It has low solubility in water, but it is readily soluble in most solvents such as acetone and chloroform. At high temperatures, PS decomposes to phosgene, nitrogen dioxide, and other irritants. During World War I, it was labeled as a choking agent and mixed with sulfur mustard to lower its freezing point. PS is a lung irritant and is used as a soil fumigant for its biocidal and fungicidal properties. As a result of commercial usage, exposure threats are by way of the inhalation and dermal routes in persons living and working within the operational area (O'Malley et al., 2004).

34.4.7.5.1 Exposure physiology

Mechanisms of PS toxicity are not that well understood. Largely, PS is irritating to the respiratory system, mucous membrane, gastrointestinal tract, skin, and eyes. Airway inflammation, lacrimation, nausea, and vomiting are the hallmarks of exposure. In severe respiratory exposures, pulmonary edema can ensue, ultimately causing death. In mice inhalation studies, Buckley et al. (1984) assessed the RD_{50} (the dose of material required to cause a 50% reduction in respiration rate), which was 8 ppm with exposures of 6 h/day over 5 days. Exfoliation, ulceration, and necrosis of the respiratory epithelium were observed. The estimated LCt_{50} is 2000 mg × min/m^3. A 20-min exposure to PS in pigs and cats resulted in an LD_{50} value of 800 mg/m^3 or 16,000 mg × min/m^3, respectively; and for mice, 15,840 mg × min/m^3 over a 4-h exposure (NIOSH

(National Institutes of Occupational Safety and Health), 2007). For humans, the permissible exposure limit (PEL) established by the National Institute of Occupational Safety and Health (NIOSH)/Occupational Safety and Health Administration (OSHA) for a work-related, time-weighted average is 0.7 mg/m^3 (1 ppm = 6.72 mg/m^3). With regard to the capacity of PS to be genotoxic, carcinogenic, or both, studies have shown mixed results.

34.4.7.5.2 Exposure biochemistry

As with several RCAs, the absorption, distribution, metabolism, and excretion of PS are not well elucidated. However, in two studies by Sparks et al. (1997, 2000), data indicated that PS can form adducts with thiol groups. After oral or i.p. injection in mice, PS is rapidly absorbed and distributed to the blood, liver, and kidneys. Metabolites identified include thiophosgene dichloronitromethane, chloronitromethane, and nitromethane. Castro et al. (1988) and Sparks et al. (1997, 2000) both suggest that enzymatic reactions may be driven by β-lyase, cytochrome P-450s, and GSH-S-transferases. Additional evidence suggests that PS may be converted to raphanusamic acid (Sparks et al., 1997).

34.4.7.5.3 Exposure histopathology

In postmortem assessment of exposure to inhaled PS, Buckley et al. (1984), recorded that PS was only one of several inhalants that produced lower respiratory tract lesions. In a case of homicidal poisoning resulting in an exposure to PS, spotty discoloration and pulmonary edema were found in the postmortem examination (Gonmori et al., 1987). Death in this case occurred within 3−4 h of exposure.

34.4.7.6 1-Chloroacetophenone (CN)

CN is a gray, crystalline solid compound with the odor of apple blossoms. Known also as Mace, it was specifically developed as an RCA. A potent lacrimator, it was developed just after World War I. As a vapor, it is 5 times heavier than air. Dissemination of CN can be achieved by grenade, steam dispensers, projectile cartridges, and aerosols.

34.4.7.6.1 Exposure physiology

CN is a much more effective lacrimator than either CS or CR, causing serious injury to the ocular targets. Blepharospasm, corneal edema, erosion, and ulceration, as well as focal hemorrhages, can occur. As a potent skin toxicant it produces severe skin edema. Irritation of the airway, including sneezing, coughing, nasal secretions, and congestion, may persist for up to 20 min. after a challenge. The primary cause of death is from damage to the lung.

34.4.7.6.2 Exposure biochemistry

The LCt_{50} for several species using the aerosol delivery method are as follows: dog, 7033 mg × min/m^3; rat, 8878 mg × min/m^3; and guinea pig, 7984 mg × min/m^3. Multiple exposures using nonhuman primates and guinea pigs demonstrated that lethality decreases with repeated exposures over days or weeks, suggesting adaptation to CN toxicity. Using guinea pigs, dogs, and nonhuman primates in a similar experimental design, with a 10-day concentration totaling 88,000 mg × min/m^3, mortality was observed in animals. In one of the few comparative inhalation studies, Ballantyne and Swanston (1978) performed acute toxicity testing on rats, mice, guinea pigs, and rabbits using CN and CS aerosols. The duration of exposure ranged from 15 to 60 min, with lethality occurring within 14 days. The respective LCt_{50} values for these animals were 8750, 18,200, 13,140, and 11,480 mg × min/m^3. For all species, CN was much more toxic than CS. Equitoxic doses of CN and CS produced similar findings using the i.v. and i.p. challenge routes. These data suggests that for appropriate toxicity screening, multispecies and multiagent comparisons are critical. For further toxicological reviews, see McNamara et al. (1969).

CN has been shown to increase lung sphingomyelin and decrease phosphatidylcholine and ethanolamine in rats (Kumar et al., 1995). Based on the increased bacterial retention in the lung in mice exposed to CN, the authors concluded that CN might increase susceptibility to infection. This may be attributed to the immunotoxic effects of CN through altered, T-cell-mediated macrophage functions (Kumar et al., 1992).

34.4.7.6.3 Exposure histopathology

Animals exposed to high concentrations of CN that resulted in mortality at 48 h showed evidence of tracheal congestion and pulmonary edema (Ballantyne and Swanston, 1978). Histopathology revealed congestion of alveolar capillaries and intrapulmonary veins, inter- and intra-alveolar hemorrhages, and excessive secretions in the bronchioles. CN was reported to produce degeneration in the epithelium of the bronchiole and alveolar septal-wall thickening and the presence of an increased number of mononuclear cells in rats (Kumar et al., 1995). Necrosis of the liver, kidney, small intestine, and spleen were also observed.

34.4.8 DA and DC

As previously stated, DA and DC are known as *vomiting agents*. Like other RCAs, they manifest their toxicity by

irritating the airway mucous membranes, as well as the eyes. Irritation results in sneezing, coughing, vomiting, and headache. They have a bond between trivalent arsenic and chlorine (in the case of DA) or cyanide (in the case of DC) and are less toxic than CN.

DA, a sternutator, is a white crystalline solid with a MW of 265. As was noted for DM, the toxicity of these compounds is attributable to the presence of arsenic in the form of As (III). The general, physiological outcome of exposure to organoarsenicals can be manifested as severe conjunctival membrane irritation, swelling of the cornea, and sloughing of respiratory mucosa forming mucus plugs in the lower airways. DA can produce these effects, and it leads to death if exposure occurs in unventilated and confined spaces (Ochi et al., 2004). Studies by Ishii et al. (2004) postulated that metabolic by-products of DA and DC, such as diphenylarsenic acid, might be associated with developmental abnormalities in humans. The estimated LCt_{50} values for DA and DC are 15,000 and 10,000 mg $\times$ min/m^3, respectively (Seto, 2011). It should be noted, however, that the toxicity of DA as a CWA is lower than the vesicants discussed next. Limited information is available on the pulmonary toxicity of these agents.

34.4.9 Vesicating agents

Sulfur mustard was used extensively in World War I and was responsible for thousands of casualties. The most recent significant intentional use of vesicants was that of sulfur mustard (HD) during the Iran–Iraq war (1984–88). Vesicants are compounds that produce chemical burns. Members of this group of vesicating agents include HD, lewisite (also known as *Agent L*) (an arsenical) and phosgene oxime (CG). CG exposure produces hivelike, urticarial skin reactions on contact. HD is a persistent agent as it can remain on the soil for more than a day (Table 34.1). Persistence is dependent on pH, soil type, and hydrophilicity. At high temperatures, such as those that occur in the desert (38–49°C), it is a considerable inhalation hazard. There is a great deal of literature regarding the toxicology, physiology and biochemistry of HD.

34.4.9.1 Sulfur mustard—bis-(2-chloroethyl) sulfide (HD)

Sulfur mustard, or mustard gas, is a colorless oil with a MW of 159. Impurities can cause HD to give off a garlic-like odor. It is 5.4 times as dense as air, which enables it to settle in trenches (and hence making it well suited for war). Although it is a low volatility agent, the HD vapor was responsible for about 80% of the chemical exposure deaths during World War I. HD has also been known as "Yellow Cross," "Lost," "S-Lost," "H," or "Yperite." Because HD is denser than water and does not readily hydrolyze, it can remain a threat for a while in various aqueous environments and has caused skin blisters when handled many years after submergence (Aasted et al., 1985; Wulf et al., 1985). The formation of fluid-filled blisters by HD can cause immediate tissue damage yet latent pain that may take several hours. Clinical effects may occur hours later.

34.4.9.1.1 Exposure physiology

Although skin is considered to be an important route of exposure for HD, many of the fatalities ascribed to HD exposure during World War I and the Iran–Iraq war were the result of inhalation. Inhaled HD is largely absorbed in the upper airway and rarely penetrates to the lung parenchyma unless the concentration or duration of exposure are sufficiently high. In humans, following inhalation exposure to HD, reports have identified bronchopneumonia, chest tightness, and, in long-term survivors, chronic bronchitis, lung fibrosis, productive cough, and chronic obstructive pulmonary disease (Ghanei and Harandi, 2007). Injury can develop slowly, becoming much more intense over time. One important issue with HD-induced lung damage is the proper maintenance of blood oxygenation. Hypoxia is usually secondary to inflammation and bronchitis. Other consequences following exposure include tracheobronchial stenosis and life-threatening pseudomembrane (casts) formation. Leukopenia can also occur several days after exposure and suggests compromise of the immune pathway that can progress to suppressed bacterial clearance and sepsis. HD exposure has also been shown to affect the CNS. Most of the casualties observed following an inhalation exposure to HD were from pulmonary damage generally due to complications of bronchopneumonia, sepsis, and immunosuppression. Experiments done in animals decades ago employed various routes of administration, including inhalation, which produced convulsions, hyperactivity, and abnormal movements (Vedder and Vedder, 1925). Anderson et al. (1996) demonstrated the formation of mucus casts within 24 h of exposure in a HD vapor rat inhalation model. Casts can cause ventilation perfusion mismatch due to clogged airspaces and lead to respiratory failure. Heully and Gruninger (1956) reported that three children accidently exposed to HD had abnormal muscular activity with one child alternating between coma and agitation. Two of these children died.

In large animal studies, such as with swine, 6 h after a 10-min exposure to HD vapor from 67 to 157 μg/kg body weight resulted in respiratory acidosis, increased shunt fraction, and hypoxemia at the higher concentrations. Elevated bronchoalveolar lavage (BAL) levels of IL-8 and IL-1β were measured in the high-dose exposed

animals suggesting a pro-inflammatory stimulation associated with airway injury (Fairhall et al., 2010). The LCt_{50} of HD has been estimated to be 1500 mg × min/m^3 (Seto, 2011).

34.4.9.1.2 Exposure biochemistry

The mechanism of biotransformation of HD has been elucidated. Once HD enters the target organ and blood, it forms an intermediate sulfonium ion which is transformed into a carbonium ion considered to be a strong electrophilic species capable of reacting with highly nucleophilic sites (Fig. 34.3). These are robust alkylating agents that react with cellular constituents, such as SH^- and NH^- in DNA, RNA, lipids, and proteins. Byrne and Stites (1995) have shown that HD forms crosslinks with cysteine residues in proteins. HD reacts with RNA and DNA molecules at such sites as N7 guanine, N3 adenine, and O^6-guanine. The O^6 position is particularly critical for the action of O^6-alkyl-guanine-DNA-alkyltransferase in DNA repair (Ludlum et al., 1986) (Fig. 34.3). HD also forms DNA crosslinks. Kehe and Szinicz (2005) have discussed the likely role of HD in alkylating membrane-bound proteins and enzymes. Zhang et al. (1995) have assessed the effects of HD on basement membrane components. Their results indicated that HD can alkylate and form crosslinks with membrane adhesion molecules such as laminin. This may have important consequences in the case of a high-dose inhalation exposure to HD, whereby it can reach and directly affect the alveolar epithelial cell layer. Bone marrow, a site of cell proliferation, is also a target of HD toxicity (Dacre and Goldman, 1996). In 2008, Kan et al. provided some evidence that there may be causal link between the inhalation of HD and cancer in rats exposed to a single high dose of HD (3 mg total dose over 10 min) (Kan et al., 2008). The conclusions of this limited study have yet to be supported by continued research. However, the results obtained may provide the incentive for future studies.

In rodent studies using intravascularly administered radiolabeled HD, distribution occurred in highly perfused organs such as the kidney, heart, liver, intestine, and lung within 1 h after injection (Maisonneuve et al., 1994). These organs are sites of biotransformation. Capacio et al. (2008) showed that HD-plasma protein adducts can be measured in the blood following a single 10-min exposure to graded increases of HD in a rat aerosol inhalation model.

The role of GSH in detoxification of HD has been somewhat controversial. Sciuto et al. (2007) have shown that there may be a biphasic response to HD intoxication. Testing for pulmonary toxicity using an intravascular HD injection model in rats, it was shown that at 1 h postexposure, BAL revealed a dose-dependent inflammatory stage that decreased over time from 3 to 24 h. Macrophage inflammatory protein (MIP-2) was the predominant chemokine in the BAL followed by IL1β, IL10, and TNFα. A second phase involved changes in the antioxidant response pathway, which was mostly affected at 6 h post-challenge. HD exposure increased BALF protein, GSH, and the activities of GSH peroxidase (GPX), catalase, GSH reductase, and SOD (Sciuto et al., 2007). Laskin et al. (2010) summarized that in some animal models of acute lung injury with HD and HD-like compounds, antioxidant markers such as GPX and GSH increased, suggesting enhanced endogenous compensatory antioxidant activity. Brimfield et al. (2012) investigated mustard-induced, oxygen free-radical formation in an *in vitro* system using the spin-trapping technique. They concluded that the presence of peroxyl and hydroxyl free radicals could arise only when oxygen is reduced by carbon-based mustard radicals. The electron paramagnetic resonance (EPR) ROS signals disappeared by adding catalase and SOD to the reaction system.

Increased autophagy has also been reported in rats exposed to HD. Increases in LC3B-II and LC3B I were noted in rat lungs as early as 6 h and as late as 48 h post-exposure (Malaviya et al., 2010). Since this process might involve mitochondria, it is possible that HD might induce alterations in cell energy and metabolism (Uchiyama et al., 2008, from Malaviya et al., 2010). Dillman et al. (2005) showed that apoptotic pathways are also activated within 3 h of intravascular injection of HD in rats. This damage subsequently resulted in enhanced expression of proteins that arrest cell cycle progression and enhance programmed cell death. Presumably, apoptotic activation in the face of extensive DNA damage may be intended to avert multiple mutations that could lead to cancer formation. It is also apparent that tissue and cell damage is dose-related and does not appear to decrease over time, suggesting a long-term effect in the lung from a single HD challenge.

It is apparent from battle casualties (most recently from the Iran−Iraq war) that both soldiers and civilians continue to suffer debilitating compromised lung function 30 + years after initial exposure (Ghanei and Harandi, 2007). However, the long-term consequences of HD inhalation exposure have not been well examined in animals. Mortality at 3−8 and 15−19 weeks following a single HD intravenous exposure (3 mg over 10 min) occurred in rats (Fig. 34.4). This dose approximately translates to LCt_{70} and LCt_{80}, respectively, over these time intervals. The data indicated that rats surviving a first phase with respect to lethality are not completely free of problems later. These data are supported by depressed respiratory function, which also suggests a link with temporal morbidity outcomes. Results from this long-term study in HD-exposed rats also revealed compromised respiratory function and symptoms of chronic

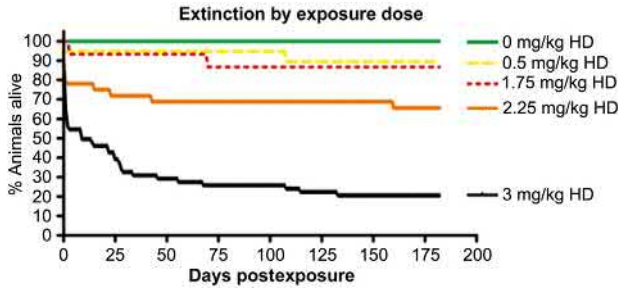

FIGURE 34.4 Shown here are 26-week survival curves of male rats exposed to a single 10 min inhaled HD. Concentrations represent the total dose delivered during exposure. Data indicate a delay in lethality based on dose. Exposures were done via intratracheal administration of aerosol in ventilated and anesthetized animals to avoid scrubbing in the nasal passages and providing a direct challenge to the lung. To control the rate of aerosol delivery, ventilation parameters (such as the tidal volume and the respiratory rate) were held constant for all exposed animals. *Data from Olivera, D., Sciuto, A.M. Unpublished research results.*

obstructive pulmonary disease in rats that are similar to those described in soldiers and civilians exposed to HD during the Iran−Iraq war.

Biomarkers of HD exposure have focused on blood and urine evaluations. Historically, the metabolite thiodiglycol (TDG) was used as an indicator of exposure. However, the significance of linking TDG to HD exposure became problematic since TDG levels in the urine can be naturally elevated as a result of normal metabolism. However, as analytical techniques improved, more refined analyses revealed other metabolites that were indicative of actual HD exposure. In a large swine HD inhalation study, the monosulfoxide β-lyase metabolite of HD [1-methylsulfinyl-2-[2(methylthio) (ethylsulfonyl) ethane] (MSMTESE)] was discovered in the urine (Fairhall et al., 2010). MSMTESE was present for up to 6 h postexposure following a single 10-min inhalation challenge to 158 μg/kg HD. The detection of MSMTESE in the urine served as a valid biomarker for an HD inhalation exposure in this model.

34.4.9.1.3 Exposure histopathology

In 15-year survivors of the Iran−Iraq war, histopathological examination of lung tissues revealed evidence of increased asthma, chronic bronchitis, emphysema, airway stenosis, bronchiectasis, and lung cancer, and possibly lung fibrosis as well. The contributions of smoking and the presence of preexisting pulmonary disease as potential confounders against these conclusions were not taken into account.

34.4.9.2 Lewisite—b-chlorovinyldichloroarsine (agent L)

Lewisite (also called *Agent L;* MW = 207.3) is a colorless, oily liquid. Impure Agent L may have a faint odor of geraniums and could be blue-black in color. It is classified as a blistering, but not vesicating, agent due to its effects on the skin and eyes. Compared to HD, Agent L forms fluid-filled blisters accompanied by immediate pain. Exposure occurs through inhalation, ocular, or dermal routes. After acute dermal exposure, the liver, gallbladder, urinary bladder, lung, and kidneys are affected as well (Snider et al., 1990). The appearance of blisters can begin at any time, ranging from seconds to minutes based on exposure $[C] \times t$. Lesions resulting from various exposure routes are similar to HD. Hydrolysis products are more persistent than HD, and it is about 10 times as volatile. It is soluble in organic solvents and is readily absorbed by paint, rubber, and porous surfaces. As an organoarsenical, the enhanced reactivity of Agent L is linked to labile chlorine atoms, trivalent arsenic, and its capacity to form multiple chemical bonds with proteins. Agent L contains about 0.8−1.3 mg/mL of arsenic.

34.4.9.2.1 Exposure physiology

Exposure to Agent L can occur through oral, dermal, ocular, ingestion, and inhalation pathways. Lewisite shock is observed following exposures to high levels. This mostly results from protein and plasma leakage from the capillaries, hypotension, and hemoconcentration. Agent L can readily penetrate the skin in both vapor and liquid form, causing systemic exposure; as little as 0.5 mL can cause serious problems, and at 2 mL, lethality can occur in humans. Vapor inhalation causes rhinorrhea, violent sneezing, and irritation to the nasal passages. These may be followed by expectoration of blood and coughing. According to Sidell et al. (1997a,b), Agent L does not cause bone marrow damage or immunosuppression. Clinically, large doses of arsenical compounds may lead to leukopenia. Since trivalent arsenic, As (III), is a major metabolite of Agent L, acute exposures might cause neurological damage. These may include loss of memory, problems in concentrating, anxiety, and confusion (Rodriguez et al., 2003). The inhaled LCt_{50} is estimated to be 1500 mg × min/m^3 in mammalian species (Seto, 2011). These are close to earlier estimates of inhalation studies in mice, where the LCt_{50} for a 10-min exposure was 1900−2000 mg × min/m^3 (Silver and McGrath, 1943).

Currently, there is insufficient data on the carcinogenic effects of Agent L. Combustion by-products of Agent L, such as arsenic trichloride, vinyl chloride, and arsenic trioxide, have the potential to induce cancer. Arsenic trioxide and vinyl chloride are labeled Class A carcinogens by the U.S. Environmental Protection Agency (US EPA US Environmental Protection Agency, 1984). However, it is not known if Agent L has any direct effect on cancer development. See Goldman and Dacre (1989) for a more detailed review on the chemistry of lewisite toxicity.

34.4.9.2.2 Exposure biochemistry

Agent L will react with water to form chlorovinylarsenous acid (CVAA), which is slowly converted to arsinoxide. Metabolites can be found in the urine after exposure (Waters and Williams, 1950). It is highly distributed systemically, even after inhalation, due to its high lipophilicity. The reaction by-products include unstable chlorine atoms, As (III), and carbon. It is most likely that the metabolite As (III) is responsible for the observed systemic toxicity. As (III) can react as a nucleophile on thiol groups in proteins and lipids, particularly on lipoic acid, eventually forming alkylarsine sulfides. The binding of Agent L to sulfhydryl-containing proteins and enzymes inhibit pyruvate dehydrogenase activity, which is critical to glucose and fatty acid metabolism (Black, 2008). Agent L metabolites produce antioxidant imbalance, calcium metabolism imbalance, lipid peroxidation associated with oxidative stress, membrane impairment, and ultimately cell death (Sidell et al., 1997a,b). Fidder et al. (2000) incubated labeled Agent L with human erythrocytes and found that 25%–50% of the bound isotope formed protein adducts at cysteine residues of 93 and 112 of the β-globin molecule (Noort et al., 2002). The major excretion by-products of Agent L, including CVAA, are quantifiable markers in the blood that can be useful in detecting exposure.

34.4.9.2.3 Exposure histopathology

There have been very limited studies on the toxicity of inhaled Agent L, specifically in the lungs. Decades ago, Vedder and Vedder (1925) showed that in dogs exposed to Agent L, considerable nasal secretions, lacrimation, vomiting, and labored breathing were present until death. At postmortem, lungs were found to be edematous, with pseudomembranes extending from the nasal area to the bronchi. Airway mucosa was congested and edematous. Bronchopneumonia was also present. No other studies have systematically examined pulmonary pathological changes in animals exposed to Agent L.

34.5 Concluding remarks and future directions

The potential for human exposure due to intentional use or accidental release of CWAs and toxic industrial chemicals will likely persist for many years. History has shown that exposure to these chemicals, regardless of the source, can be problematic for both civilians and military personnel. As such, continued study of the toxicity of these agents is of the utmost importance. All agents have the potential to cause significant morbidity and mortality by way of severely compromised pulmonary physiological homeostatic processes. The key target organ is the lung, and in many cases, regardless of the exposure route, respiratory failure is the cause of death. Subsequent exposure-related effects can involve altered respiratory function, compromised vital cellular metabolic/detoxification pathways, mitochondrial toxicity, hematotoxicity, and CNS toxicity. Other effects include immune response and associated release of cytokines and chemokines, altered antioxidant/oxidant pathways, increased free-radical formation, destruction of lung solute transport channels, and disruption of adaptive repair processes. All of the processes discussed here appear to be affected in a concentration-dependent manner; often with a latency period. For example, vesicant inhalation significantly alters the architecture of the lung to the extent that attempts to counteract the effects of damage through the innate repair process are compromised, leading to an obstructive pulmonary disorder.

The works cited herein show that although progress has been made in elucidating the toxicological, physiological, biochemical, and histopathological processes responsible for respiratory toxicity, much more effort is required to understand chemical-specific mechanisms and develop effective therapeutic measures. Three major issues will need to be addressed by future studies: (1) the development of a reliable, and appropriate animal inhalation exposure systems and the availability of human relevant animal models; (2) examination of molecular mechanisms to identify potential therapeutic targets; and (3) assessment of the long-term effects of inhaled CWAs. It is hoped that future efforts in this area will lead to the successful determination of therapeutic windows, treatment modalities, and effective medical countermeasures. A single therapeutic medical intervention likely will not be sufficient, but combinational therapies may be needed to counter the respiratory and systemic toxicities of CWAs.

Acknowledgments

We thank Dr. Gary Hatch and Dr. Michael Madden (EPA) for their critical review of this manuscript.

The US army experimental studies cited herein were approved by the Animal Care and Use Committee at the U.S. Army Medical Research Institute of Chemical Defense, and all procedures were conducted in accordance with the principles stated in the *Guide for the Care and Use of Laboratory Animals* and the Animal Welfare Act of 1966 (P.L. 89–544), as amended. The views expressed in this article are those of the author(s) and do not reflect the official policy of the army, the Department of Defense, or the US government.

The research described in this article has been reviewed by the Center for Public Health and Environmental Assessment, EPA, and approved for publication. Approval does not signify that the contents necessarily reflect the views and the policies of the agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

Chapter 35

The cardiovascular system as a target of chemical warfare agents

Csaba K. Zoltani
Emeritus, ARL, Aberdeen Proving Ground, MD, United States

35.1 Introduction

The use of chemical warfare agents (Schwenk, 2018; Ciottone, 2019; Pitschmann, 2014) produces a multipronged attack on the affected organs. Alleviation requires consideration on a level that previously was not considered necessary. The presence of xenobiotics is primarily expressed by dysregulation of heart function. An early marker, changes in the electrocardiogram (ECG), is noticeable immediately. Ancillary indicators, that is, changes in the metabolites of body fluids, emerge but are delayed. Gene reprogramming, alterations in biochemical pathways, peptide hormones, and cytokines may also be present.

This section lists the usual conventional markers of a xenobiotic attack on the cardiac system. In the concluding section of this chapter, an approach to dealing with the latest and more dangerous effects of potential attack methods is presented. It points to, and describes, the therapeutic modus operandi that needs to be adopted. The propounded approach promises a heretofore unavailable insight into the dynamics of the poisoning taking place.

35.1.1 Potential indicators

To deal with the affected cardiovascular system, consideration needs to be given to one or more of the critical items listed in Table 35.1.

35.1.1.1 Troponin level changes (cTnT/cTnI)

Troponin is one of the proteins that regulate cardiac contractions. Following injury, typically when oxygen demand is not met, myocardial necrosis occurs. Egress of troponin is one of the accepted validators for myocardial infarction (MI). Located on the myofibrillar filament of the cardiac muscle, troponin contains three subunits, troponin T, troponin I, and troponin C. Excitation−contraction of the heart is regulated by the cTn complex. On contraction, the myosin filament pulls the actin filament using ATP (adenosine triphosphate) to power the contraction. The actin filament is regulated by cTnC, a calcium-binding protein, while cTnI inhibits contraction in the absence of Ca^{2+} binding to cTnC. ATPase activity of actomyosin is inhibited by cTnI. A troponin I level above 0.40 ng/mL is considered to be an indicator of probable cardiac ischemia. After damage, the myocyte sheds cTn into the circulating blood after several hours.

Troponin release is also caused by a number of other pathological conditions, in addition to coronary diseases. Decreased ventricular ejection fraction correlates with cTn elevation, as well as strenuous physical activity. In cases of renal failure, cTnT concentrations rise. Troponin increases in heart failure (HF) as well as under inflammatory conditions such as myocarditis (Korff et al., 2006; Sebastian et al., 2018).

35.1.1.2 Creatine kinase and lactate dehydrogenases, markers of tissue damage

Tissue damage is marked by the release of intracellular enzymes into the serum. Creatine kinase (CK) enzyme, found in the heart and also skeletal muscle tissue, increases due to muscle damage. Lactate dehydrogenase (LDH) enzymes, responsible for catalyzing the conversion of pyruvate to lactate, are significant markers. High levels of LDH indicate lactate accumulation and tissue damage. LDH deficiency, on the other hand, points to rhabdomyolysis, characterized by muscle necrosis with the release of intracellular constituents into the circulation. An increase in free ionized cytoplasmic and mitochondrial calcium is observed due to depletion of ATP, the usual energy

TABLE 35.1 Selected cardiac response effects due to xenobiotics.

Activated	Effect	Measurable	References
Troponin release	Myocarditis	Myocarditis	Korff et al. (2006)
	Heart failure	Heart failure	
	Renal failure	Renal failure	
Natriuretic peptide	Bioregulation	Congestive HF	Pandit et al. (2011)
	Contractility		
	BNP upregulation		
C-reactive protein	Thrombus formation	LV dysfunction	Sproston and Ashworth (2018), McFadyen et al. (2018)
	Suppresses the thrombo-regulatory pathway	Low-grade inflammation	
Ischemia-modified albumin	Low binding for transition metals	Hypoxia, acidosis,	Oran and Oran (2017), Gaze (2009)
		Na^+-K^+ pump	
Creatine kinase and lactate dehydrogenase	Myocardial tissue damage, rhabdomyolysis	Lactate accumulation	Moghadam-Kia et al. (2016)
Parathyroid hormone	Bioregulator, myocardial contractility	Hypocalcemia, cardiac hypertrophy	Fujii (2018)

source, and goes hand in hand with dysfunction of the Na^+/K^+-ATPase and Ca^{2+}ATPase pumps. The ATP depletion causes myocyte injury and release of various muscle enzymes. An increase of intracellular calcium produces an increase in muscle cell contractility and production of reactive oxygen species (ROS).

Earlier the CK test was used to diagnose heart attacks, but has been replaced. Increased CK levels usually mark myopathies (muscular disorders) of various causes. In rhabdomyolysis, CK levels are considerably increased. Chemical and biological injury to muscles can cause rapid breakdown of muscles. Toxins act similarly.

35.1.1.3 Brain natriuretic peptide

BNPs are hormones secreted by myocytes from the cardiac ventricles in response to stretching, that is, to changes in pressure inside the heart, on cardiac stretch receptors. Upon release, BNPs activate the atrial natriuretic factor receptors NPRAs and to a lesser degree NPRBs. These decrease the vascular resistance, thereby decreasing the blood pressure. An increase in BNP designates left ventricular dysfunction that is also helpful for diagnosis of HF (Maisel et al., 2002).

35.1.1.4 C-reactive protein

C-reactive protein (CRP) is a component of a set of proteins that the immune system produces as a response to inflammatory challenges. CRP is markedly increased by trauma or infection, thereby it is a predictor of future cardiovascular events. Generally, CRP values higher than 3 mg/L suggest elevated vascular risk.

35.1.1.5 Parathyroid hormone

Xenobiotic effects may cause unexpected cardiac changes by the parathyroid hormone (PTH; Fujii, 2018; Wu et al., 2018). The PTH, produced by parathyroid cells, among other functions regulates calcium, phosphate, and vitamin D metabolism. PTH enhances myocardial contractibility through increased entry of calcium ions by activation of voltage-dependent calcium channel influx that also affects the SA node of the heart and thus the heart rate.

PTH also promotes apoptosis of cardiomyocytes. Excess PTH hormone leads to cardiac hypertrophy and HF. The PTHrP/PTH-1 receptor participates in bioregulation of cardiomyocyte function also as part of the pathological process in the myocardium. Ischemic injury activates this signaling system that induces muscle-relaxant effects (Monego et al., 2009) that influence cardiovascular homeostasis. When PTH secretion is low, hypoparathyroidism causes hypocalcemia, with immediate signatures in the cardiac function.

35.1.1.6 Ischemia-modified albumin

Myocardial ischemia (MI) produces hypoxia, acidosis, and destruction of the Na^+-K^+ pump, resulting in the formation of ischemia-modified albumin (IMA) by

cleavage of the amino acids of the HSA (human serum albumin) N-terminal. IMA has low binding affinity for transition metals (Oran and Oran, 2017). In a short period of time following MI, there is a drastic increase in the IMA level measurable before myocardial necrosis. IMA levels are now used as a biomarker (Kader and Wahab, 2017; Gaze, 2009).

Depending on the situation, the cardiac system can also be affected by various chemicals including cyanide, as discussed in Section 35.5, and arsenic and ricin discussed in Section 35.6.

The palette of military warfare agents, their modes of action at the cellular level, including a description of their expression in the changed morphology of the tissue and modified electrical state (Romano et al., 2008; Ellison, 2008), follows. The expressed effects of poisons on the heart are dose related. The references give a good summary of the expected effects of each of the anticipated conditions. ECGs (Wexler et al., 1947; Karki et al., 2004; Delk et al., 2007), illustrating the effect of the toxicants, are given where available. New biomarkers, miRNAs, short noncoding RNA sequences that regulate gene expression and control cellular processes, are revolutionizing the detection and treatment of cardiotoxicity and are discussed in a separate section. Approaches to therapy and recommended antidotes for some of the discussed toxicants are also given.

35.1.2 Hazard models

Current approaches gaging the effect of warfare agents on cardiac function assume a primary effect of the attacking medium. With new agents, several effects acting concurrently need to be considered to gage the overall impact. Initially, the Cox Impartial Hazards Model may be appropriate, but with the availability of additional data, to gage how the factors impact multivariable Cox regression analysis would be a possible approach.

This chapter describes how the heart is affected by and reacts to various chemical warfare agents (Balazs, 1981; Baskin, 1991; Acosta, 2001). The next section gives an overview of the anatomy and functioning of the heart (Opie, 1998) with an emphasis on the components most vulnerable to the presence of toxins. The importance of cardiac neuronal changes as possible indicators of exogenous effects is underscored. The normal electrical state and signature of cardiac toxicity are contrasted.

35.2 Background

35.2.1 Cardiac anatomy

The timed delivery of oxygenated blood to all parts of the body is the function of the four-chambered pump, the heart. It is enclosed in a double-layered sac, the pericardium, with the inner layer, the visceral pericardium, anchoring the heart, and the outer layer attached to the sternum. A cardiac skeleton anchors the four heart valves, the atria, and the ventricles. The thick wall separating the two ventricles, the interventricular septum, houses the Purkinje fibers, which play an important part in the electrical activity of the heart.

Deoxygenated blood from the body enters the heart by the vena cava and empties into the right atrium. Through the tricuspid valve, blood then transits into the right ventricle and via the pulmonic valve enters the lungs, where it is oxygenated. It returns to the heart through the pulmonary veins and the atrium to the left ventricle. This muscular pump redistributes the oxygenated blood to all parts of the body.

The heart is mediated by an electrical system that is easily disturbed by toxicants, which change the timing, flow, and magnitude of the electrical pulses and thus interfere with the required pumping action. The activity of the heart is myogenic, that is, the activity is initiated by the heart itself. Various components of the heart, the sinoatrial (SA) node, atrioventricular (AV) node, and the Purkinje fibers are capable of pacemaker activity. Healthy atrial and ventricular tissue does not engage in pacemaker activity. The primary pacemaker is the SA node, but in diseased or affected states the secondary pacemakers take over.

The SA node lies in the right atrium, in an epicardial location and functions as the primary source of the electrical impulse formation. It consists of specialized muscle cells, smaller than ventricular cells containing few contractile elements. Due to its location, the action potential generated traverses the atria first, causing the primary contraction. The action potential is relayed to the AV node, the conduit for the electrification of the ventricles. The signal must pass through the AV node, otherwise the atria and the ventricles are electrically insulated from each other. A time delay in transmission is needed for the atria to be emptied of blood.

The AV node is a subendocardial right atrial construct that is located within a fibrous stroma in the triangle of Koch. It is connected to both sympathetic and parasympathetic nerves. The bundle of His arises from the distal section of the AV node and goes to the summit of the ventricular septum. It is the only nonpathologic electrical conduction between the ventricles. The bundle of His divides into the left and right bundle branches, which then become the Purkinje fibers that interweave the contractile cells of the ventricle and speed the excitation throughout the ventricles.

The action potential of the cardiac myocytes is initiated by an inward sodium current in both the atria and the ventricles with inward calcium currents contributing to

the upstroke in the SA and AV nodes. Slow inward currents result in lower resting and activation potentials. In the latter, membrane potentials range from −40 to −70 mV and the activation threshold lies in the range of −30 to −40 mV and shows phase 4 depolarization. These cells are modulated by acetylcholine (ACh) and catecholamine. The duration of the action potential depends on the outgoing potassium current durations, with the inward calcium currents of lesser importance. It is longest in the Purkinje fibers. Resting potentials of atrial and ventricular cells range from −80 to −90 mV, with activation thresholds in the −60 to −70 mV range. Impulse conduction ranges up to 300 V/s in atrial and ventricular cells and up to 900 V/s in the Purkinje tissue.

35.2.2 Innervation of the heart

The autonomic nervous system guides the electrical and mechanical functions of the heart (Klabunde, 2012). The heart is innervated by both the sympathetic and parasympathetic systems, which have opposite effects and are activated reciprocally. They play important roles in arrhythmia susceptibility. Sympathetic stimulation originates from the intermediolateral column of the thoracic spinal cord. Its neurotransmitter, norepinephrine, is released from neurons of the postganglionic fibers of stellate ganglia and epinephrine is released from the adrenal medulla. Both act on cardiac β-adrenergic receptors. Beta-adrenergic receptors of the myocardium play an important role in regulation of heart function. They belong to G-protein-coupled receptors that normally bind to norepinephrine released by sympathetic adrenergic nerves. Receptors that bind catecholamine will stimulate the sympathetic nervous system, for example, increasing the heart rate.

Sympathetic nerves are predominantly on the epicardial surface. Receptors for norepinephrine on cardiac muscle are of the β-adrenergic type. Postganglionic sympathetic neurons innervate the SA and AV nodes, the conduction system, and the myocardial fibers in the ventricles. Epinephrine is the primary endogenous catecholamine produced in the adrenal medulla and regulates organic metabolism. It stimulates β_1 receptors, enhances ventricular contractility, and enhances SA nodal cell phase 4 depolarization, that is, impulse generation.

The cholinergic, that is, parasympathetic system, acts through the vagal nerves by release of ACh that opposes the sympathetic stimulation. Parasympathetic preganglionic neurons originate in the medulla. Parasympathetic fibers terminate mainly on cells of the atria. Parasympathetic innervation is denser in the SA and AV nodes than the left ventricle. The right vagus nerve innervates the SA node. The neurotransmitter ACh and adenosine promote susceptibility to atrial fibrillation and shorten atrial refractoriness. Excessive stimulation causes bradyarrhythmia. The left vagus nerve innervates the AV node, where excessive stimulation results in AV block. Receptors for ACh are of the M2 muscarinic type and ACh binding to muscarinic receptors inhibits cAMP production. ACh has a negative chronotropic effect (slows the heart), slows conduction (negative dromotropic effect), and also has a negative inotropic effect (decreases the strength of contraction). The latter is through activation of the current $I_{K,ACh}$ resulting also in a shortening of the action potential. ACh has three actions on cardiac muscle: (1) it activates ACh-sensitive K-current, $I_{K,ACh}$; (2) it inhibits the voltage, time-dependent inward calcium current I_{Ca}; and (3) it inhibits the hyperpolarization-activated inward current I_f, important for pace making. Ventricular muscle is not affected by vagal stimulation.

There are anatomical physiological differences between the sympathetic and parasympathetic systems. The parasympathetic ganglia lie within or close to the organ that postganglionic nerves innervate, while sympathetic ganglia lie closer to the spinal cord. There is limited parasympathetic innervation of the ventricles compared to the atria. The vagal nerve fibers are mostly intramural. The heightened adrenergic activation in the ventricles is potentially arrhythmogenic. All catecholamine receptors are metabotropic. They act by initiating metabolic processes affecting cellular functions. β-Adrenergic receptors, receptors for epinephrine and norepinephrine, act by stimulatory G proteins to increase cAMP in the postsynaptic cell. cAMP binds to and activates protein-kinase enzyme.

Disturbed balance between the parasympathetic and the sympathetic systems can result in disturbances in cardiac function. As discussed later, chemical warfare agents play an important role in disturbing this balance.

35.2.3 Neuropeptides

Vasoactive intestinal peptide (VIP), a neurotransmitter, is found in extrinsic and intrinsic nerves of the heart. VIP is released by the vagal nerve, and its effect is to increase the pacemaker current I_f and pacemaker rates (Chang et al., 1994; Accili et al., 1996). VIP release takes place under high-frequency stimulation. As an internal brake, it limits the ability of ACh to excessively suppress the sinus node and other pacemakers. It also has an effect on the calcium-activated potassium channel.

VIP acts as a parasympathetic neurotransmitter in its involvement in the postsynaptic control of the heart. VIP is exactly opposite in its action to that of ACh. Vagal activity, causing release of ACh, slows the heart but corelease of VIP leads to tachycardia due to VIP preferring receptors leading to an increase in adenylate cyclase and an accumulation of cAMP.

Neuropeptide Y (NPY) suppresses the pacemaker current I_f. Colocalized with norepinephrine in sympathetic nerve terminals on the heart, it is released with catecholamines during sympathetic neural activation. NPYs on cardiomyocytes have surface membrane-binding sites and suppress contractility in concentrations from 10^{-9} and above. In ventricular myocytes, the L-type Ca^{2+} current, as well as the delayed rectifier potassium currents, are suppressed.

35.2.4 Energetics of the heart

The heart requires a continuous supply of energy to be able to sustain its pumping action. Most of the energy is derived from fatty acids. Under ischemic or anaerobic conditions, glycolysis comes into play, consuming large amounts of glucose with the adverse effect of the formation of lactic acid (Jafri et al., 2001).

More than 95% of the metabolic energy is used in the form of ATP. Its concentration in a myocyte is about 10 mM. ATP is synthesized by oxidative phosphorylation in the mitochondria. There, acetyl CoA is broken down to CO_2 and hydrogen atoms. Electrons are pumped out to form a proton gradient across the mitochondrial membrane. The protons reenter the mitochondria and combine with oxygen, eventually forming water.

The glycolytic pathway under hypoxic conditions produces only a limited amount of ATP. Pyruvate formed in glycolysis is transported into the mitochondria where CO_2 is formed through cellular respiration. From each glucose molecule, 28 ATP molecules are formed in anaerobic glucose metabolism. The heart also has an energy reserve in the form of phosphocreatine (PCr), which is an immediate precursor of ATP. In the reverse Lohman reaction, CK favors the maintenance of ATP concentration at required levels. The energy released during hydrolysis of the phosphoanhydride bond in ATP powers energetically unfavorable processes, such as the transport of molecules against a concentration gradient. During conditions of hypoxia, ATP is first degraded to adenosine diphosphate, then to adenosine monophosphate (AMP), and then to adenosine. The latter diffuses into the circulating blood where the adenosine concentration rapidly increases under conditions of cellular damage. The action of adenosine is antiinflammatory as well as inhibitory.

35.2.5 Electrophysiology

The SA node, consisting of spindle-shaped cells, initiates the electrical activity of the heart. From its location in the right atrium in proximity to the superior vena cava, the electrical activity spreads to the atria whose cells are larger than those of the SA. The pulse from the atria spreads to the AV node, the gateway to the ventricles. The atria and the ventricles are electrically isolated. The AV node also slows down the electrical activity, giving the atria time to fill. The bundle of His is the upper end of the electrical path, which through the Purkinje fibers allows the electrical signal to activate the ventricles and thus to pump the blood.

Each cell's activity goes through four phases of the action potential (Grant, 2009). The morphology of each type of cell is different. Also, the kinds of electrolytes moved, and their quantity and speed, are dictated by environmental conditions, detailed in Carmeliet and Vereecke (2002). Xenobiotic interference with the transmission of the ions changes the electrical homeostasis, and commences the breakdown in the state of the tissue. The membrane currents, pump, and exchanger of importance in this regard are given in Table 35.2. Anionic chloride currents, especially those activated by swelling, play an important role in cyanide intoxication (Baumgarten and Clemio, 2003).

35.3 Signatures of cardiac toxicity

35.3.1 The electrocardiogram as a diagnostic tool for poisoning

35.3.1.1 Recorded morphological changes on the electrocardiogram

At present, morphological changes in an ECG are insufficient to make a definitive diagnosis of a poisoning but are useful in giving guidance as to which of the ion currents are affected and thus to the possible nature of the toxicity (Yates and Manini, 2012). Without access to and comparison with a preincident ECG and the multitude of factors that need to be considered, the diagnosis may be erroneous. On the other hand, poisons cause definite changes in timing and morphology of the ECG of affected individuals (Delk et al., 2007; Gussak et al., 2004; Dalvi et al., 1986; Zoltani and Baskin, 2007) and thus an ECG constitutes an important tool in the initial evaluation.

Disequilibrium in the electrolyte balance can provide diagnostic clues. For example, hyperkalemia causes tall T-waves in leads II, III, V_2 to V_4, when the potassium balance exceeds 5.5 mmol/L. In conjunction, the amplitude of the P wave is reduced and QRS is widened. Hyperkalemia is usually present when the amplitude of the T-wave is higher than that of the R-wave. With increasing potassium concentration, P-waves widen and eventually disappear. Accentuated hyperkalemia results in asystole.

TABLE 35.2 Membrane currents, pump and exchanger of importance.

Current	Function/origin	Effect
I_{Na}	Voltage-gated Na^+ current	Depolarization
I_{K}^+	Voltage-gated K^+ channel	
I_{Ca}^{2+}	L-type Ca^{2+} current	
I_{Cl^-swell}	Activated by cell swelling	Cell swelling
$I_{K,ATP}$	Activated by fall in intracellular ATP	Fall in ATP
I_f	Hyperpolarization-activated current carried by Na^+ and K^+ in sinoatrial and AV node cells and His-Purkinje cells and contributing to phase 4 depolarization	
$I_{K,ACh}$	Parasympathetic control of the heart	ACh
Na^+/K^+-ATPase	Moves Na^+ out, K^+ into cell against concentration gradient using ATP for energy	
Na/Ca	Exchanges intracellular Ca^{2+} for extracellular Na^+	Responsible for DAD

Hypokalemia results in decreased T-wave amplitude and ST-segment depression; however, accurate QT interval measurement is difficult. Malignant ventricular arrhythmias result when potassium concentrations become very low. Hypercalcemia shortens the QT interval, while hypocalcemia produces ST-segment prolongation.

Left bundle branch block is characteristic of poisoning and is defined (Zimetbaum et al., 2004) as QRS >0.12 s with delayed intrinsicoid deflection in the V_1, V_5, and V_6 leads greater than 0.05 s. The risk of arrhythmia is greatest when QRS is ≥ 0.11 s. Right bundle branch block greater than 0.12 s is a fairly good predictor of arrhythmic death.

Blockade of potassium, sodium, calcium channels, β-adrenergic receptor sites, and the Na^+/K^+-ATPase pump change the ECG and may give an indication of the type of poisoning present in the tissue (Delk et al., 2007).

Reductions in the outward potassium ion flow prolong QT, a harbinger of torsade de pointes (TdP), and ventricular fibrillation (VF). Sodium channel blockers delay the entry of sodium ions, widening the QRS complex. In extreme cases, asystole ensues. A subsidiary event may be ventricular tachycardia degenerating into VF.

For control of tachyarrhythmia, calcium channel blockers are used. Blockade of these channels decreases contractility and SA and AV node depolarization. Blocking β_1 receptor sites within the myocardium reduces the intracellular calcium concentration and contractility. The potassium concentration is increased, an undesirable effect when the β_2 receptors are blocked. Inhibition of the Na^+/K^+-ATPase pump results in $[K^+]_o$ and intercellular $[Na^+]_i$ increases, in turn increasing the intracellular calcium concentrations.

35.3.1.2 Long QT

An important predictor of arrhythmia is changes in the duration of the QT trace, the time for ventricular repolarization, displacement of the ST-segment, and changes in the pattern of T-waves that may sometimes be seen as a T and U wave (Roden, 2008). This can be linked to ventricular tachycardia, including TdP, an abnormal heart rhythm. On the ECG it is expressed by twisting of the QRS complex around the isoelectric line. Lengthened QT increases the time available for intracellular calcium accumulation, enabling early afterdepolarization (EAD) in the Purkinje fibers, and activates calmodulin (CaM) and calmodulin kinase (CaMK). CaMK is believed to enhance afterdepolarization, triggering the TdP. CaMK increases L-type calcium channel activity. Anderson (2006) reported that inhibition of CaMKII can prevent cellular arrhythmia where QT prolongation is present (Zoltani and Baskin, 2007).

During the plateau phase of the action potential, there is a delicate balance between the L-type Ca^{2+} channels and the slowly and rapidly activating cardiac delayed rectifier currents, I_{Ks} and I_{Kr} (Chen et al., 2016). Due to the slow onset of I_{Ks} activation during the rectification of I_{Kr}, a limited amount of repolarizing current flows. The L-type Ca^{2+} channels are time-dependently inactivated while an outflowing potassium current takes place. With a net outflow of ions, repolarization takes place. It is critical that the I_{Kr} deactivates slowly. Thus, small changes in the inward or outward conductance, that is, the amount of current leaving or entering, has a deciding influence on the length of the repolarization. The effect of poisons on these processes plays an important role in determining the QT-segment length.

35.3.2 Biochemical markers of tissue injury

35.3.2.1 Conventional biomarkers

Protein markers released into the bloodstream have been used as indicators of cardiac injury. The current gold-standard marker is troponin. Three types of troponin, as well as elevated CK−MB levels, and peripherally myoglobin, are used as indicators of cardiac tissue damage (Apak et al., 2005; O'Brien, 2008). Biomarkers of HF (Mittmann et al., 1998), including natriuretic peptides that increase in response to wall stress and ST2, reflective of ventricular remodeling and cardiac fibrosis, may be evident as a consequence of toxicity, and are detailed by Maisel (2012).

The cardiac troponin complex consists of three parts. Troponin T (cTnT) facilitates contraction, troponin I (cTnI) inhibits actin−myosin interactions, and troponin C binds to calcium ions. Troponin I and T are specific to the heart but cTnT is also expressed by injured skeletal muscle. In the course of cell damage, cardiac troponin is released from myocytes, facilitated by increased membrane permeability that allows smaller troponin fragments to traverse the membrane. Complicating the use of troponin levels is the fact that in cases where there is cardiac injury without cardiac cell membrane disruption, serum troponin levels can increase. Also, altered ion homeostasis may not be reflected in troponin levels.

In cancer patients undergoing high-dose chemotherapy, elevated troponin I and CK−MB are predictors of ventricular systolic dysfunction, and thus indicators of cardiac damage. Immunological ultraviolet-array is used for determination of the level of CK−MB, where an elevation greater than twice normal is taken as an indicator of myocardial infarction. Cardiac troponin is measured by electrochemiluminescent immunoassay. Cardiac impairment is indicated by the presence of troponin. The release of the enzyme has been linked to a mismatch between oxygen demand and expenditure in the tissue, lessening of the time available for diastolic coronary perfusion, catecholamine release, and intense sympathetic stimulation. Warfare agent-associated cardiac toxicity is characterized by these conditions.

Is the increased level of troponin due to damage to the heart muscle? In-depth studies note that stroke victims without acute myocardial infarction have elevated troponin levels. Severe renal dysfunction may also cause it. Thus, until convincing proof is presented for noncardiac causes, an increase in the presence of marker enzymes can be taken as an indicator of damage due to toxins in the cardiac tissue.

CK is a protein necessary for ATP generation. One of its forms, CK−MB, is found mainly in the myocardium and upon tissue damage, such as myocardial infarction (MI), becomes elevated. It takes up to 24 h for the elevated level to reach its peak. A difficulty resides in the fact that unlike troponin, an assay does not distinguish between cardiac and skeletal muscle damage. Also, in about a third of MI cases, while CK−MB levels stay neutral, troponin elevation is noted. The normal level of troponin in the blood for troponin I is less than 10 μg/L and troponin T less than 0.1 ng/mL, while for CK−MB it is less than 3.0 ng/mL. For humans, normal CK is in the range of 55−170 IU/L (international units per liter) but is less specific than CK−MB for cardiac tissue damage.

35.3.2.2 miRNA

Traditional biomarkers lack tissue specificity—and their appearance in body fluids is time-delayed. For example, troponin levels are elevated between 3 and 12 h after myocardial injury. Recently microRNAs have gained acceptance as alternate biomarkers (Sahu, 2013; Gidlof et al., 2013; Vickers et al., 2014; Yamakuchi, 2012). Their tissue specificity, sensitivity, stability, and timeliness underlie their usefulness and have opened new therapeutic approaches. These noncoding RNAs play an important role as gene expression regulators, and miRNAs regulate fundamental cellular functions and toxicological outcomes. The number of identified miRNAs is large and regulates the majority of mRNAs.

miRNAs are short, 22 nucleotides long, and modulate protein expression by binding to mRNA, thereby inhibiting translation or targeting them for degradation. As regulators of physiological processes, they play an important part in the developing pathology (Kim, 2013; Vacchi-Suzzi et al., 2013).

Biogenesis of miRNAs starts in the nucleus of the cell where miRNA genes are transcribed by RNA polymerase into primary miRNAs. The Drosha enzyme then creates the precursor miRNA. After export to the cytoplasm, cleavage by the Dicer enzyme produces the miRNA. The mature miRNA is incorporated into RISC, the RNA-induced silencing complex. The miRNA of the RISC complex binds to the target messenger RNAs, preventing translation. After myocardial infarction, for example, miRNA levels increase signaling-reduced systolic function, where the left ventricle ejection fraction is $<50\%$. Microvesicles shed from the cell, that is, exomes, export the miRNAs and transport them to other locations, in effect constituting the intercellular communication and thereby regulating genetic function and protein generation (Romaine et al., 2015).

In drug toxicity (Yokoi and Nakajima, 2013), as well as oncology, miRNAs are becoming useful tools in making diagnoses. As shown in Section 35.7, miRNAs offer new therapeutic approaches for warfare agent-caused cardiac toxicity. For further details on cardiac toxicity biomarkers, readers are referred to Zoltani (2019).

35.4 Indices of the toxicity of warfare agents

35.4.1 Classes of warfare agents

Three broad classes of warfare agents are considered: organophosphate nerve agents (Newmark, 2007; Munro et al., 1994), the cyanides (Baskin et al., 2009), and a third general category that is less weaponized but whose effects are important as potential terror agents, the arsenics and ricin. An excellent overview of chemical warfare agents is given by Marrs et al. (2007).

Respiratory tract irritants, such as phosgene and vesicants, and including sulfur mustard, have a subsidiary cardiac impact but the mode of disability is acute lung injury.

The classes of nerve agents of primary interest are the "G" agents, first synthesized in Germany. Denser than air, these agents hug the ground and represent a vapor hazard due to their volatility. Tabun (GA), sarin (GB), and primarily soman (GD) are those most widely used. "V" (venomous) agents were developed in the United Kingdom. VX is more toxic than the G agents. Cyanides are less weaponized but also of concern. Arsenic and ricin are more terror threats than battlefield weapons. Novichok, developed in the Soviet Union, is the most potent nerve agent but there is little public information available.

35.4.2 Background

Chemically induced cardiac failure has been the subject of a number of works. Baskin (1991) and Acosta (2001) give an overview of the subject. Hypoxia is one of the effects of the decreased availability of ATP, which depresses muscle contraction. The energy that is supplied by the phosphate bonds is possible only as long as aerobic glycolysis and oxidative phosphorylation are maintained. Under anoxic conditions, this is no longer possible and with the adrenergic stimulus continuing, calcium accumulation in the mitochondria leads to impairment of function, eventually causing dose-related lesions (Suzuki, 1968).

35.4.3 Signatures of toxicity

Warfare agent-supplied xenobiotics disturb cardiac homeostasis. Changes of concern include the following:

- Morphological tissue changes;
- Enhanced neural stimulation;
- Release of neuropeptides;
- Activation of usually dormant cardiac currents;
- Alteration in the storing and movement of ions;
- Disturbances in energy use and storage.

Ferrans et al. (1969) noted ultrastructural changes in myofibrils, including mitochondrial swelling and disorganization. Catecholamines also produce changes in the activity of oxidative enzymes. The decline in the activity progresses to the point where necrosis is evident. Ancillary effects include loss of myocardial potassium and an increase in interstitial fluid. Intracellular calcium overload also develops, as noted by Fleckenstein et al. (1974). It has been hypothesized that necrosis due to catecholamine overload may be caused by a defect in energy supply needed for the maintenance of cellular processes.

At low concentrations, the catecholamines, epinephrine, and norepinephrine exert positive inotropic effects on the myocardium. High concentrations, however, can cause cardiac lesions (Inoue et al., 1998). Even physiologic concentrations, when extended over time, lead to cardiac damage, as shown by Szakacs and Mellman (1960). The LD_{50} of norepinephrine in rats is 680 mg/kg, but at doses as low as 0.02 mg/kg, focal necrotic lesions are produced.

The oxidation product of catecholamine is adrenochrome, whose accumulation has also been linked to myocardial necrosis, as well as morphological and subcellular alteration (Yates and Dhalla, 1975). Administration of adrenochrome to rats also induced heart arrhythmias. Free radicals may also contribute to these processes. It has been suggested that catecholamines may activate β-adrenergic receptors, stimulating adenylate cyclase, and thus elevating cAMP. This in turn activates protein kinase, increasing the phosphorylation of slow calcium channels, possibly resulting in an overflow of calcium, leading to necrosis preceded by swollen sarcoplasmic reticulum, altered enzymatic activities, and lower ATP.

Cyanide primarily blocks oxidative phosphorylation and ATP production. Every heart beat uses up to 2% of the energy available to the cell. Arsenic primarily causes a long QT (LQT) interval on the ECG, by blocking the fast potassium current, an action that is a precursor to VF. The activation of dormant currents by the presence of xenobiotics, including cell swelling, radically changes the electrical homeostasis of the tissue (Zoltani and Baskin, 2007).

35.4.4 Nerve agents

There is a difference in distribution of nerve agents for different organs of the body as well as different locations within the heart. Roth et al. (1993) detail the effects on the heart. Aspects of neurotoxicity are discussed in detail in Omahen (2011).

35.4.4.1 Mechanism of action

Nerve agents are OP compounds, which irreversibly inhibit AChE, leading to ACh accumulation, and cause overstimulation of muscarinic and nicotinic ACh receptors.

TABLE 35.3 Toxicities of weaponized agents.

Agent	LCt_{50} (mg min/m^3)	ICt_{50} (mg min/m^3)	LD_{50} (mg/kg)
GA	400	300	14.28
GB	100	75	24.28
GD	70		5.0
VX	50	35	0.1428
Cyanide	2500–5000		1.1

The effect at the SA node, the primary heart control site, is inhibitory and bradycardia results. VX primarily affects neurotransmitter receptors, those of norepinephrine, and also affects the central nervous system unrelated to AChE inhibition. The balance between nicotinic receptor potentiating effects and muscarinic effects at parasympathetic postganglionic fibers determines the effect of nerve gases on the heart.

Toxicants change the homeostatic distribution and timing of the presence of electrolytes, enzymes, and other constituents of myocytes and their environment. These changes affect and determine the current flow, in turn affecting the electrical state and possibly signaling the onset of electrical instability. Table 35.3 shows toxicities of weaponized nerve agents.

35.4.5 Electrocardiographic signature of organophosphates

Disturbances in the electrical activity of the heart caused by xenobiotics are readily discernible in a surface electrocardiogram (Yurumez et al., 2009; Dalvi et al., 1986; Chuang et al., 1996). OPs cause QT prolongation on the ECG that subsequently can degenerate into TdP. In one reported OP case, 79.7% had QT prolongations with ST-segment and T-wave abnormalities (Karki et al., 2004; Rubinshtein et al., 2002). Changes are ultimately expressed in arrhythmia, VF and TdP, and severe disturbance of the energy homeostasis of the heart. Second-degree AV heart block as well as ST-T wave alterations (Balali-Mood and Saber, 2012) have also been observed.

An initial indicator of an impending arrhythmia is prolongation of the QT interval. The lengthening can be caused by a reduction in the outward currents or increased inward currents, that is, imbalance of inward and outward currents during the second and third phases of the cardiac cycle, namely, the I_{Kr}, I_{Ks}, $I_{Ca(L)}$, and I_{Na} currents. These currents can generate EAD and trigger activity at the end of repolarization. Primary sites are the Purkinje fibers and the mid-myocardial M cells. In the Purkinje fibers, at higher positive resting potentials than the ventricles, blockade is voltage dependent, with an increased block in the depolarized tissue. The failure of complete repolarization leads to dispersion of refractoriness and enhanced arrhythmogenicity. Acquired LQT interval involves pause-dependent or short–long–short RR interval sequences on the ECG, and enhancement of sympathetic nervous system tone. LQT is favored in cases of severe bradycardia, hypokalemia, and conditions that lead to EAD. LQT may not be a sufficient condition for TdP. Stimulation of adrenergic receptors plays a significant role but it can enhance or inhibit afterdepolarization.

The electrical activity of the heart is modulated by hormones and neurotransmitters. Xenobiotics disturb their balance. The parasympathetic system releases ACh and the sympathetic system releases catecholamines (norepinephrine and epinephrine). These bind to α and β types of receptors. α_1-Receptors are present on the postsynaptic member of the organ and mediate vasoconstriction and stimulation of Na^+/K^+-ATPase, the Na^+/Ca^{2+} exchanger, and the Na^+/H^+ exchanger. This affects the I_{KATP} and inhibits the I_{Na^+} and I_{to}. The α-receptor stimulation thus effectuates depolarization and the α_2-receptor inhibits norepinephrine release.

Cardiac β_1-receptors and atrial and ventricular β_2-receptors take part in a positive inotropic response. Inhibition of catecholamines at β-adrenergic receptor sites interrupts the production of cAMP and inhibits calcium influx, producing a negative inotropic effect that yields a reduction in heart rate.

The main effect of adrenergic stimulation is to enhance the intracellular adenylyl cyclase activity. This in turn increases cyclic AMP levels. Protein kinase A is modulated and activates calcium and potassium channels. Phosphorylation of the calcium channel increases the inward current leading to EAD.

β_1-Adrenergic stimulation increases the activity of the Na^+/K^+ pump and inhibits EAD. Hyperpolarization of resting membrane potential counteracts automaticity, leading to a decrease in heart rate. α_1-Adrenergic stimulation hyperpolarizes membranes, and enables EAD and TdP by blocking potassium channels. Release of norepinephrine enhances α_1-adrenergic stimulation, facilitating EAD (Schomig et al., 1995). In long QT, increased sympathetic discharge may induce both bradycardia and TdP. Increased adenosine increases ventricular refractoriness and sympathetic tone, setting the conditions for reentrant arrhythmias. Hypokalemia prolongs cardiac action potential and may be the precursor of EAD. The net outward potassium currents are reduced and the inward calcium current is increased.

35.4.5.1 Toxic effects of organophosphates on the heart

The anticholinesterase effects of OP nerve agents depend on the sites where they act. The muscarinic effects in the heart act through the parasympathetic system, while the nicotinic effects act through the sympathetic system. Agents like tabun, sarin, and soman, analogous to acetylcholine, are capable of changing the receptor sites, which increases the conductance of electrophysiological signals related to the enhancement of neuromuscular function. VX, on the other hand, counteracts the effect of ACh, interrupting neuromuscular function.

ACh is a neurotransmitter that is present in the parasympathetic nervous system and is stored in vesicles. Its function, under normal circumstances, is terminated by AChE that is present in both the pre- and postsynaptic membranes. OPs inhibit AChE by electrophilic (a reactant which accepts an electron pair from a molecule with which it forms a covalent bond) attack of the enzyme. The neurotoxicity of OPs was exploited in the development of nerve gases. The key to the understanding of OP inhibition of AChE is the enzyme's serine hydroxyl group behavior. Normally, it attacks ACh at the carboxyl carbon yielding a covalent bond between the enzyme and the ACh substrate. The transiently acetylated enzyme is next hydrolyzed and the active enzyme site is regenerated. The active serine hydroxyl group is attacked by the electrophilic phosphorus of the OP instead of the ACh. A covalent, nonhydrolyzable bond is formed between the enzyme and the OP, leaving the enzyme in an inactivated form. Release of an alkyl chain further strengthens the phosphorus−enzyme bond. With AChE inactivated, the amount of ACh present increases, resulting in overstimulation of the tissue. The pathophysiological effects that result can be explained by the overabundance of ACh. Overstimulation of muscarinic receptors in the heart leads to bradycardia.

35.5 Specific warfare agents of concern regarding the heart

35.5.1 Currently the most widely used agents rely on organophosphate compounds

The heart may be affected by both muscarinic and nicotinic effects. In the former, stimulation of the parasympathetic nerve endings occurs, while in the latter, excess ACh on the nicotinic receptors is of importance. The cardiovascular effects are tachycardia caused by overstimulation of the sympathetic system, bradyarrhythmia, AV block, hypotension and QT prolongation, VF, and TdP (Grmec et al., 2004).

OP intoxication manifests itself in three phases. First, a nicotinic phase hypertension and sinus tachycardia occurs. This is followed by sinus bradycardia and parasympathetic overstimulation and ST-segment changes on the ECG and rhythm disturbances. During the last phase, TdP and sudden cardiac death occur. According to Ludomirsky et al. (1982), a QTc (QT corrected for heart rate) of 580 ms signals high probability of sudden cardiac death. Roth et al. (1993) give further insight from actual cases.

A breakdown of actual cardiac symptoms for OP poisoning in hospital admissions is given by Karki et al. (2004). Sixty-seven percent of the acute OP cases had QT prolongation, 24% experienced ST-segment elevation, and 17% had inverted T-waves. Nine percent had atrial tachycardia, 9% ventricular tachycardia, and 4% had VF. Sinus tachycardia was observed in 35% of admissions, while sinus bradycardia was noted in 28%. Noting that acidosis and electrolyte derangement play a major role in the development of cardiac events, they recommend "atropine in adequate doses very early in the course of the illness" as the strategy to be implemented. Table 35.4 summarizes the effect of OP on the electrophysiology of cardiac tissue.

OPs are known to induce time-delayed neurotoxicity. This is due to the inhibition of an esterase in nerve tissue, neuropathy target esterase (NTE), that is also found in muscle and blood cells. The NTE level in the blood is an indicator of the inhibition of the enzyme. Inhibition of NTE and aging, the process of following the OP binding to an active esterase site that prevents the reactivation of the site, is important for selection of an antidote against certain OP nerve agents. It is of primary concern for novichok. There is little information available on its neurotoxicity and cardiac toxicity.

35.5.1.1 VX

The most toxic nerve agent available in the Western world is VX. It is an inhibitor of AChE, which acts by increasing the ACh at the nerve synapses. Toxicity sets in when more than 50% of the AChE enzyme is inhibited. The $AChE_{50}$ value for VX is taken as 0.023 mg/kg for an

TABLE 35.4 Effect of OP on the electrophysiology of cardiac tissue.

AChE	Lesions				Second messenger (VIP, others)
	Anoxia	Acidosis	Modulated ion concentration	Release of catecholamines	
ACh overload causes bradycardia, slows conduction in AV, prevents hydrolysis $[Ca^{2+}] \uparrow \rightarrow I_{K,ACh} \uparrow$	Lowers ATP, cAMP; ATPase inhibition $I_{K,ATP} \uparrow$ (activated), AP shortened	pH ↓, Na^+/H^+ exchange ↑, [ATP] ↓, $[K^+]_o \uparrow$, reduces I_{Kr} by increasing rate of deactivation, shifts voltage dependence of activation to more positive potentials, $g_K \uparrow$	$[K^+]_o \uparrow$effect on velocity of propagation, inexcitability	Prolongs AP, $[Na^+] \uparrow$, Na^+/K^+-ATPase antagonized DAD enhanced difference for α, β receptors	Adenylate cyclase activation
Antagonizes adenylyl cyclase		Cytoplasmic $[Ca^{2+}] \uparrow$slows repolarization, reduces max. diastolic potential	$[Na^+] \uparrow Na^+/K^+$ pump inhibition, Na^+/Ca^{2+} exchanger $\rightarrow Ca^{2+}$ influx	α stimulation: reperfusion arrhythmia, calcium overload, gap junction conductance ↓, exchanger stimulation, activates Na^+/K^+ pump	$I_f \uparrow$, cAMP ↑, → HR ↑OP reduces cAMP $\rightarrow Ca^{2+}$ influx, inhibits adenylate cyclase, stimulates ATP, $I_K \uparrow$, affects $I_{Ca(L)}$, EAD, DAD → arrhythmia
Arrests cAMP synthesis, depresses I_f (pacemaker current)		$I_{Ca(L)} \downarrow$, $I_{Na} \downarrow$ (inactivation of fast Na^+ channel), decreased excitability, CO_2 accumulation	$[Ca^{2+}] \uparrow Na^+/Ca^{2+}$ exchanger ↓reduced SR uptake		
ACh inhibits adenylate cyclase			$[Mg^{2+}] \uparrow$(hydrolysis of ATP), activates enzymes, reduces $I_{Ca(L)}$, I_{K1}, $I_{K,ACh}$, I_{KATP}, I_{Ks}	β stimulation: adenylate cyclase, elevates cAMP, increases calcium influx, I_f activation, triggered activity improves modal conduction	

[...], Concentration; ↑, increase; ↓, decrease; →, yields; $I_{(.)}$, ionic current with the subscript denoting the channel type; *DAD*, delayed afterdepolarization; *EAD*, early afterdepolarization; *g*, conductivity of the tissue; SR, sarcoplasmic reticulum.

oral dose (Sidell, 1974). Activity of RBC-AChE (red blood cell acetylcholinesterase) and plasma butyrylcholinesterase (BChE) are other markers of toxicity of OPs. In tests on human volunteers, 1 μg of VX/kg by i.v. infusion showed a depression in AChE activity of more than 50%, but for these tests no cardiac symptoms were recorded. VX produces intense stimulation of nicotinic ACh receptor ion channels and muscarinic ACh receptors. Though not recorded in human volunteer tests, cardiac effects are known to take place, based on animal studies. VX exposure produces positive inotropic effects. Arrhythmia was noted in rats and dogs (Robineau and Guittin, 1987). In guinea pigs treated with VX, delayed afterdepolarization was found (Corbier and Robineau, 1989). In rats the effect of VX is ascribed to inhibition of the cardiac Na^+/K^+-ATPase α_1 isoform. At 1 μM concentration, the inhibition is 35% (Robineau et al., 1991). Physostigmine, hyoscine, and HI 6 were investigated as antidotes (Wetherell et al., 2007; Munro et al., 1994).

35.5.1.2 Tabun

GA, a unitary chemical munition, inhibits AChE, the enzyme responsible for the breakdown of the neurotransmitter ACh. When inhaled, its toxicity is half that of sarin. It depresses plasma and RBC-AChE activities significantly in the blood. At 20%−25% of red blood cell AChE baseline, the effect of the nerve agent becomes noticeable. There is no evidence of systemic toxicity other than the cholinesterase activity (Parker et al., 1990; Munro et al., 1994).

GA has not been shown to produce OPIDN (organophosphorus-induced delayed neurotoxicity) except at extremely high doses. The cardiac effect of GA conforms to OP-caused arrhythmias and AV block.

35.5.1.3 Sarin

Sarin was involved in terrorist attacks in Japan. The increase in sympathetic and parasympathetic tone results in tachycardia, ST-segment modulation (Abraham et al., 2001), and arrhythmia. Recently, Watanabe et al. (2013) also described acute effects of a sarin-like OP agent, bis (isopropyl methyl) phosphonate, on cardiovascular parameters in artificially ventilated, anesthetized rats. Findings revealed that powerful stimulation of sympathetic and parasympathetic nerves resulted in modulation of heart rate and blood pressure. Inhibition of cholinesterase within the neuroeffector junction also affects nerve impulse transmission by direct action. Direct action on muscarinic or nicotinic ACh receptors (Somani et al., 1992) is observed when the blood level of sarin exceeds the micromolar level. Sarin inhibits RBC-AChE 80%−100% as well as plasma-BChE between 30% and 50% (Grob and Harvey, 1958). It also binds to another serine-containing enzyme aliesterase or carboxylesterase, thereby reducing its concentration for AChE inhibition in rats (Gupta et al., 1991).

Sarin exhibits OP-delayed cardiotoxicity possibly due to epinephrine-induced arrhythmias (Allon et al., 2005; Morris et al., 2006). This hypothesis is supported by Khositseth et al. (2005) who showed that epinephrine changes T-waves in the ECG where AT prolongation already exists.

35.5.1.4 Soman

The most widely used nerve agent, GD, exerts a defining effect on cardiovascular function. Myocardial degeneration and necrosis were noted by Britt et al. (2000) in soman-exposed rhesus macaques. Generally, upon contact, bradycardia and modulated cardiac output are followed by hypotension and changes in the ECG. Notably, AV conduction modulation, QT extension, T-wave and ST-segment changes characteristic of myocardial infarction, and ACh-induced coronary vasospasm are noted. For OP's cardiac effects, important references include Sidell (1974), Kiss and Fazekas (1983), and Anastassiades and Ioannides (1984). McKenzie et al. (1996) also showed that in swine a dose of $2 \times LD_{50}$ soman i.v. increased coronary sinus plasma ACh by 314% and decreased coronary blood flow to 55% of control. The evidence indicates OP-caused deaths are due to ACh-induced coronary vasospasms that culminate in MI. This is seen as VF on the ECGs. The Food and Drug Administration (FDA) approved pyridostigmine bromide as a pretreatment for soman poisoning (Newmark, 2007).

35.5.1.5 Novichok

In open literature, little is known about these agents developed in the Soviet Union. They are assessed to be 5 to 10 times more toxic than VX (Ellison, 2008; Chai et al., 2018). The toxicity of these binary agents does not rely primarily on the inhibition of AChE, but it is thought that it causes permanent neuropathy. Consequently, conventional nerve agent antidotes may not ameliorate its toxicity. Reactive oximes such as potassium 2,3-butanedione monoximate may be useful in detoxification. No published information is available on cardiac pathologies caused by novichok agents, but general effects of its use in terrorist poisoning have been published (BBC, 2018).

35.5.2 Antidotes for organophosphate nerve agents

Enzymatic hydrolysis (where enzymes cleave bonds in molecules with the addition of water) is a primary route for elimination of nerve agents. Specifically, treatment for OP intoxication includes atropine, a muscarinic receptor antagonist, an anticonvulsant such as diazepam, and a cholinesterase reactivator, an oxime. It has been found that drug-induced inhibition of ACh release and accumulation in the synaptic cleft, such as adenosine receptor antagonist early in OP intoxication, improves the chances of survival. Some AChE reactivators, such as bispyridinum oximes, HI 6 and HLö 7 with atropine, are quite effective. Oximes can reactivate acetylcholinesterase by attaching to phosphorus, subsequently divorcing from the AChE enzyme. A large number of other oximes were also investigated (Balali-Mood and Saber, 2012).

35.5.3 Cyanide

Classified as a blood agent, cyanide is usually deployed as hydrogen cyanide and cyanogen chloride. Considerable literature exists on the effects of cyanide (Suzuki, 1968; Baskin et al., 2009). Cyanide binds irreversibly to its target sites. In the human host it preferentially accumulates in the hypothalamus and neural tissue. Its concentration in red blood cells is much greater than in plasma. The lethal dose is of the order of 1 mg/kg or inhalation of 50 mL of hydrogen cyanide gas.

35.5.3.1 Toxicity

Cyanide binds to Fe^{3+} in heme-containing proteins. This inhibits the terminal cytochrome complex IV of the electron transport chain. The block lock of complex IV by cyanide depletes ATP, culminating in cell death. Oxygen is unable to reoxidize the reduced cytochrome a3. Thus, cellular respiration is inhibited as well as ATP production, in essence depriving the cells, tissue, and ultimately the whole body of oxygen. Hypoxia evolves into metabolic

acidosis and decreased oxygen saturation. The extent of lactic acidosis indicates the severity of the cyanide poisoning. In a collapsed individual, plasma lactate is an indicator of cyanide poisoning. In severe cyanide poisonings, up to 98% of the cyanide in the bloodstream is tightly bound to red blood cells. The ancillary response is myocardial depression and decline in cardiac output. Bradycardia, hypotension, and cardiac arrhythmia then develop into VF and cardiovascular collapse.

In severe cyanide poisonings, autonomic shock due to the release of biogenic amines plays a role. The coronary arterial vasoconstriction, resulting in an increase in central venous pressure, leads to the observed shock-like state that is not attributable to inhibition of cytochrome oxidase. In the liver, CN is metabolized by rhodanese to thiocyanate, which is excreted in the urine.

Hypoxia is one of the signatures of cyanide poisoning. In CN poisoning, as in ischemia, oxidative metabolism is blocked and acidosis is enhanced. Acidosis depresses contractility and metabolism, while sparing ATP supplies.

A dose of 0.54 mg of hydrogen cyanide per kg of body weight is fatal, with an average of 1.4 mg. Data indicate that the heart absorbs the second highest amount of cyanide per organ weight. On the other hand, in sublethal exposure, cyanide-fed rabbits (Okolie and Osagie, 2000) do not show the hemorrhaging in the cardiac tissue noted by Suzuki (1968). Cyanide also causes a decline in $[K^+]_i$, that is, significant hypokalemia and an increase in $[Na^+]_i$. These changes were not reflected in the skeletal muscle. Cyanide caused a decline in ATP, the energy source of the cell, to less than 10% of the normal value, which activates the otherwise dormant potassium channel and the outward current I_{KATP}. These changes result in shortening of the AP and a decrease in the contraction.

Cyanide also causes endogenous catecholamine release (Schomig et al., 1995; Inoue et al., 1998). Inoue et al. (1998) also point out that cyanide-produced depolarization increases intracellular calcium due to the suppression of the potassium channels and activation of the voltage-dependent calcium channel. Anoxia induces suppression of the sodium pump and activates cation channels due to the decrease in ATP. A further consequence of the presence of cyanide in the tissue is inhibition of the Na^+/Ca^{2+} exchanger (NCX) (Ju and Allen, 2005). NCX is important for the pacemaker currents. Metabolic inhibition of NCX reduces the firing rate of pacemaker cells.

Cyanide poisoning is marked by metabolic acidosis and a large anion gap. The latter is a consequence of the blocked oxidative phosphorylation and the increased rate of glycolysis. Maduh et al. (1990) showed that cyanide also affects H^+ and thus the pH of the tissues. In turn, the Ca^{2+} transport process is disrupted, leading to a rise in cystolic $[Ca^{2+}]$. Acidification depolarizes the cell membrane and changes the potassium conductance.

Cyanide also exerts a strong influence on the vagus nerve and thus on the VIP that under normal conditions exerts a strong inotropic and chronotropic effect. VIP stimulates adenylyl cyclase activity. In ventricular myocytes, VIP potentiates voltage-gated Ca^{2+} channel currents and also acts on pacemaker currents.

As shown by Goldhaber et al. (1991), contractile failure, that is, twitch shortening, is caused by cyanide. It is said to be due to failure of activation of the Ca^{2+} current. Electrocardiographic manifestations of CN poisoning are shown in Katzman and Penney (1993), and Wexler et al. (1947) described in Zoltani et al. (2004), and summarized in Table 35.5.

The ECG of an individual (Wexler et al., 1947) executed by inhalation of cyanic acid revealed that, initially, between the first and third minutes, a heart rate slowing was discernible with the disappearance of the P-wave. Later the heart rate increased slightly. T-waves showed an increase in amplitude and a marked shortening of the ST-segment. One subject, unlike some others in this cohort, showed normal AV conduction until ventricular tachycardia and VF developed.

35.5.3.2 Antidotes for cyanide poisoning

Bhattacharya and Flora (2015) and Cummings (2004) described the following approaches:

1. Use of a nitrite (oxidizing agent such as sodium nitrite) to change the ferrous ion of hemoglobin to a ferric ion. The created methemoglobin binds cyanide forming cyanmethemoglobin. One drawback, however, is that impairment of oxygen transport occurs, i.e. that is, the amount of hemoglobin available is reduced. Amyl nitrite to generate methemoglobin is no longer preferred, since it does not bind enough cyanide.
2. Sulfur donors for conversion of cyanide to thiocyanate by rhodanese or other sulfur transferases, that is, a source of sulfur. For moderate poisoning, sodium thiosulfate is the usual choice.
3. Use of cobalt chemistry that chelates the cyanide directly, such as hydroxocobalamin.
4. Hydroxocobalamins, precursors to vitamin B_{12}, are preferred in France and elsewhere in Europe. Hydroxocobalamin binds cyanide to form cyanocobalamin. It does not interfere with tissue oxygenation but large doses are required to be effective.
5. In the United Kingdom, dicobalt edentate, which chelates the cyanide directly, is preferred, but assurance that cyanide poisoning is present is needed since this antidote contains cobalt, which can be toxic.

TABLE 35.5 Effect of CN on the electrophysiology of cardiac tissue.

P	QRS	ST	T	Remarks	Reference
Disappearance (auricular arrest)	Change in amplitude, right axis deviation	Shortening, disappear	Incr. amplitude, origin of T-waves on QRS	0.11–0.20 mg/kg NaCN, inhalation, AV dissociation, HR↓, BBB, initial bradycardia, AV block, asystole	Wexler et al. (1947) (man)
	Lengthened	Absent or depressed, elevated after 20 s	Increased, decreased over time, T starts on top of R, diphasic, negative	0.4–0.8 mg/kg NaCNHR↓, bradycardia, Wenckebach, heart block, V-flutter, VF	Leimdorfer (1950) (cats)
		Short, shifted toward T-wave	Tall T, surpassing R, sometimes inverted	0.1 mg/kg NaCN, bradycardia, incomplete AV blockade, VF	Paulet (1955) (dog)
	Abnormal	Elevated, shortened	T-wave beginning high on QRS	0.3–0.6 g sodium nitrite as antidote with sodium thiosulfate, atrial fibrillation	De Busk and Seidl (1969) (man)
	Narrow QRS	Nonspecific ST-T changes in anterior chest leads, shortened ST-segment	Fusion of T-wave into QRS, sharp rise of T-wave	Sinus tachycardia, acidosis with high anion gap	Chin and Calderon (2000) (man)
	Q-wave present in lead III, persisted after treatment of acidosis	Deviation of 4 mm in leads II, III, aVF, 2 mm in V_6, ST depression of 2–4 mm in V_1–V_4, I, aVL leads, normalization of ST-segment in precordial leads	T-wave inversion in II, III, aVF, V_5 and V_6 leads	Acidosis, CN level of 3 μg/mL, anion gap present	Sanchez et al. (2001) (man)

35.6 Other terror agents

35.6.1 Arsenic

Arsine blood agents were first developed for battlefield use during World War I. Due to difficulties with dispersion, they were never used. Arsenic, however, has potential use as a terror agent (Ellison, 2008; Sidell et al., 1997).

Arsine is the simplest compound of arsenic. It is colorless and 2.5 times denser than air with an odor resembling garlic. Arsine binds to hemoglobin of the red blood cells, destroying them. Poisoning kills by allosteric inhibition of metabolic enzymes. Arsenic disrupts ATP production. Arsenic inhibits pyruvate dehydrogenase, uncoupling oxidation phosphorylation. Arsenic poisoning also occurs through arsenic–oxygen compounds, especially arsenic trioxide, As_2O_3 (ATO), which is 500 times more toxic than pure arsenic (Yamazaki et al., 2006).

ATO has been effectively used as a remedy for relapsed acute promyelocytic leukemia, but with the side effect that it causes QT interval prolongation, possibly heralding ventricular arrhythmia (Chiang et al., 2002). Abnormalities in $I_{Ca(L)}$ in myocytes were also noted (Sun et al., 2006). ATO's direct effect on cardiac repolarization with its effect on I_{Kr} was noted by Haverkamp et al. (2000). ATO also causes cellular Ca^{2+} overload and augments APD (action potential duration) (Yamazaki et al., 2006). Chronic arsenic exposure leads to QT prolongation, blockage of I_{Kr}, TdP, and T-U alternans, and changes in the T-wave result (Little et al., 1990; Ficker et al., 2004).

It has been suggested that potassium ion channel alteration induced by arsenic may be related to hERG (Vandenberg et al., 2012), trafficking defects. ECG changes in arsenic poisonings have been reported by Fennel (1981). The T-waves are domed. ECG changes,

especially where arsenic involvement is not severe, are reversible. Hemodialysis and BAL (dimercaprol) therapy (to remove excess lead) have been found to be effective. Sun et al. (2006) suggest that choline can normalize QT interval abnormality by inhibiting $[Ca^{2+}]_i$ and $I_{Ca(L)}$ in ventricular myocytes when ATO is present. Arsenic intoxication results in widened QRS by 0.06 s and prolonged QT (Ahmad et al., 2006). Ventricular tachycardia and VF have been reported by St Petery et al. (1970).

35.6.2 Ricin

Ricin (*Ricinus communis*), a toxic glycoprotein derived from the castor bean, causes hypotension and myocardial hemorrhage. The Centers for Disease Control and Prevention (CDC) lists it as a category B agent due to its easy availability as a terrorist weapon. Only a limited amount of information is available in the open literature on ricin's effect on the heart. The medical files of Georgi Markov, the Bulgarian journalist, assassinated in London with what was assumed to be ricin, are not publicly available (Crompton, 1980; Aggarwal et al., 2017). He suffered complete atrioventricular conduction block.

Ricin is a glycoprotein made up of two chains linked by a disulfide bond. Its toxicity results from one of the chains inhibiting protein synthesis by irreversibly inactivating eukaryotic ribosomes. The lethal dose of ricin has been set at 1−20 mg/kg of body weight (Bradberry et al., 2003). Christiansen et al. (1994) performed extensive experiments on rabbits. Their main findings include the following:

1. Ricin caused vasodilatation and increased endothelial-dependent vascular relaxation resulting in hypotension.
2. Ricin disturbed calcium homeostasis leading to cell necrosis.
3. Ricin reduced both systolic and diastolic left ventricular function.
4. Ricin caused myocardial hemorrhage.

Balint (1974) and later Zhang et al. (1994) found that at the lethal dose in rabbits, ricin caused hemorrhage and necrosis. Christiansen et al. (1994) found that the release of norepinephrine from sympathetic nerves in the vasculature is not impaired by ricin. The CDC, under signs and symptoms of ricin poisoning that may be encountered, cite cardiovascular collapse (hypovolemic shock).

ECG abnormalities in children who ingested castor beans have been noted by Kaszas and Papp (1960). These include QT interval lengthening, repolarization changes, and intraventricular conduction disturbances. Crompton (1980) later reported on experiments on pigs that experienced hemorrhagic lesions and an abnormal ECG due to ricin. Genes of ricin toxicity have been identified suggesting therapeutic targets (Moreau et al., 2011). At the present time, no antidotes or effective therapy are available to counteract the effects of ricin.

35.7 Therapeutics under development

Chemical warfare agents almost instantaneously affect the cardiac system. miRNA signatures give rapid and conclusive evidence of the affected site and degree of involvement. Predominantly, though not exclusively, the injury turns off genes, expressed through miRNAs. Thus, modulating the genetic response to overcome dysregulation of miRNAs, therapy aims to normalize miRNA expression, silence those that are overexpressed, and replace those that are downregulated.

The heart expresses a large number of miRNAs (Wang, 2011; Zhou et al., 2018) that have been correlated with the genes that affect the heart's varied functions, including electrophysiology. Many miRNAs have a large number of target genes. The change in the value of the particular miRNA from normal reflects not only the injured organ but also the degree of injury. Thus, for example, changes in the ECG can be related to particular miRNAs.

A common sign of cardiac injury is up- or downregulation of miRNAs. An effective countermeasure is inhibition of the affected miRNAs. AMOs (anti-miRNA oligonucleotides), single-stranded 2′-*O* methyl-modified oligonucleotides fragments that are antisense to its target miRNA have been used. The methyl group improves the binding to RNA. AMO acts by base-pairing, producing loss-of-function of the miRNAs. Multitarget AMO (MT-AMO) enables a single AMO fragment with the capability of targeting multiple miRNAs. miRNA sponges are similar, but contain multiple binding sites for an miRNA seed family.

miRNA inhibitors bind to complementary mRNA sequences that result in posttranscriptional gene silencing. Engineered oligonucleotides, antagomirs, and miRA erasers and sponges are currently preferred. Anti-miRNAs contain the reverse sequence of a mature miRNA that is able to reduce the endogenous levels of the miRNA. In addition, it must be cell permeable, stable, and able to bind to the selected miRNA with high probability.

miRNAs play a role in cancer pathogenesis. miRNAs that function as tumor suppressors may be downregulated by disease while oncogenes are upregulated. mRNA targets of these miRNAs have been identified. This suggests that genes involved with atrial and VF can also be modulated. In fact, miR-1 changes in the myocardium of normal hearts have induced arrhythmias (Kim, 2013; Su et al., 2017).

TABLE 35.6 Warfare agent-induced cardiac pathologies.

Cardiac syndrome	Physical syndrome	Dysregulated miRNA	Cellular expression	References

Vascular	Inflammation, vasodilation, hemorrhage	miR-126	Endothelial cells promote vascular homeostasis, release factors including NO	Yamakuchi (2012)
		miR-17		
		miR-146a		

In view of a quantifiable association of miRNA and gene expression, cardiac injury caused by warfare agents may be amenable to therapies based on miRNAs.

HF, ischemia, modulated ion flow, and vascular inflammation have specific associated miRNAs, as shown in Table 35.6. A pathological condition, caused by an injury, may reflect several conditions, thus the miRNA expression profile may not be unique.

Ischemia upregulates several miRNAs, including the miR-15 family. As shown by Hullinger et al. (2012), oligonucleotides can effectively suppress expression of miR-15, reduce infarct size, and remodel after ischemic injury.

Tissue-specific regulation of miRNAs has been achieved by adenoviruses, enabling continuous replacement. It has also been successfully used in gene therapy to overcome tumor genesis. Considerable detail on miRNA therapy is given by van Rooij (2011) and Thum (2011).

In replacement therapy, to restore the loss of function caused by a warfare agent, miRNA mimics can be used to reintroduce miRNAs into affected cells that also reactivate pathways and target silenced genes. Lipoproteins would be the preferred means to introduce the encapsulated miRNA to achieve these ends.

For resolution of warfare agent-caused cardiotoxicity, miRNA approaches, with specificity and timeliness, offer a myriad of opportunities.

35.8 Concluding remarks and future directions

Per organ weight, the heart is the second most preferred depository for several of the warfare agents used. Disturbance of the electrical homeostasis, the cellular energy production, and breakdown of the electrical control network within the tissue are mostly affected.

35.8.1 Current concerns

Areas that need further insight include the following:

- Chemical warfare agents cause miRNA concentration changes in body fluids; tissue specificity and time of appearance of the changes after exposure need to be correlated with conventional biomarkers and electrophysiologic markers, such as ECG changes;
- Means of reactivation, that is, overcoming "aging" caused by OP-based agents;
- Nanoparticles that carry medicines show promising results; their use to counteract xenobiotic poisoning needs to be exploited;
- Role of NTE in cardiac toxicity.

Human data for various cardiotoxic scenarios is unavailable. The means of prompt identification of the particular xenobiotic causing poisoning remains an urgent

task. Progress in metabolomics, the identification biomarkers that result from metabolic changes caused by the presence of xenobiotics, will enable the development of chip-based rapid-responding assaying devices. Hopefully, this chapter will be an incentive to follow up on the approach outlined here that has tremendous potential for the understanding and treatment of cardiac toxicity.

35.8.2 Potential future scenarios

Advent of weapons systems that create changes beyond muscarinic and nicotine effects pose new challenges to the preservation of cardiac function. Synthetic biology-enabled weapons produce biochemicals by novel metabolic pathways and modification of the human microbiome. Use of CRISPR, the gene-editing tool, by means of viruses can cut human DNA and cause, among others, cardiac misfunction. Dysbiosis and disease as a weapon need to be considered as outlined in detail in National Academies of Sciences, Engineering, and Medicine (2018) and by Dando (2015).

Morphological changes leading to an alteration in cellular ionic balance affect automaticity and conductivity as well as unequal parasympathetic and sympathetic activity leading to possible arrhythmia.

Peptide bioregulators that control normal biological processes, like toxins, are weaponizable substances. Tachykinins cause rapid loss of blood pressure. Endothelin is a potent vasoconstrictor peptide that stimulates the contraction of blood vessels. Toxins are quick-acting blockers of cellular metabolism affecting conduction of nerve impulses. T-2 mycotoxin or the botulinum toxins are more dangerous than soman or VX.

35.9 A new approach

The effectiveness of the newest chemical warfare agents has undergone remarkable improvements. The altered miRNA induced by these compositions evokes or silences genes that make the ensuing tissue activity more difficult to counteract. To determine an effective therapy, the miRNA signature produced by the attacking substance must be known. miRNAs regulate gene expression at the posttranscriptional level by binding to the 3' untranslated region of the target mRNAs. miRNA is tissue specific and molded by the transcription process. Cardiac-specific miRNA expressions and signatures for specific cardiac dysfunctions (Ikeda et al., 2007; Small et al., 2010) are known.

Signatures of dysregulated miRNA of affected tissue need to be determined. The potential damage is remedied by modifying the newly established miRNA. Among the available choices, it can be determined by "next-generation sequencing." It is one of the preferred techniques (Shendure and Hanlee, 2008; Liu 2018) although it is elaborate. It needs to turn off genes that the xenobiotic turned on and substitute by replacement a new miRNA, that could also be a synthetic miRNA, an miRNA mimic. Implementation offers several possibilities. Use of nanoparticles, as in drug delivery, is an option. Use of inorganic material carriers, such as ferric oxide or positively charged thiolated gold or magnetic nonviral nanoparticles (Schade et al., 2014), has been proposed. Thereby the introduced miRNA restores the suspended and desired miRNA activities.

Essentially, the procedure consists of three steps:

1. Identify the miRNA of the system that the xenobiotic created;
2. Delete the miRNA that was introduced;
3. Determine and install the desired miRNA.

This procedure has not been previously used on cardiovascular systems targeted by chemical warfare agents.

Considerable new information, currently not used, could upgrade therapeutic processes. Recently, circular RNA has received attention. Formed by back-splicing of one or two exons, it results in a covalently closed molecule. Known as circular RNA (circRNA), they participate in cardiac pathophysiological processes and also have been proposed as biomarkers. CircRNA can also act, by interacting with RNA-binding proteins, as miRNA sponges to regulate transcription.

The xenobiotic effect of circRNA in cardiac tissue needs to be explored. These tissue- and pathologic-specific molecules are more stable than linear RNAs and protected from degradation by exonucleases. Exploration of the biogenesis and function of circRNAs, a potential biomarker in cardiovascular disease, is an active area (Aufiero et al., 2019; Gomes et al., 2018; Holdt et al., 2018).

Chapter 36

Ocular toxicity of chemical warfare agents

Patrick M. McNutt, Tracey A. Hamilton, Megan E. Lyman and Marian R. Nelson
Department of Toxicology, US Army Medical Research Institute of Chemical Defense, MD, United States

36.1 Introduction

Vision is the dominant sense in humans. In healthy individuals the visual system contributes to approximately 80% of perception and cognition. The eye and the accessory visual structures (e.g., the conjunctiva, lacrimal apparatus and eyelids) are developmentally and structurally complex, and proper vision is critically dependent on the functional integration of diverse tissues with distinct morphological and cellular properties. The intricate internal architecture and exposed location of the eye render it highly susceptible to injury by a wide array of toxins and toxicant agents, with the severity of injury influenced by factors such as dose, physicochemical properties, and environmental conditions. Manifestation of injury is further modulated by the specific interactions of each agent with the various physiological and biochemical microenvironments of the eye. In some cases, recovery from intoxication may be critically influenced by the regenerative capacity of individual ocular tissues. In this chapter, we summarize what is known about the toxicological and toxicokinetic effects of ocular exposure to a wide array of traditional chemical warfare agents (CWAs), including several biological toxins. Although the primary concern is usually the long-term protection of vision, even CWAs that manifest with short-term and reversible ocular symptoms can cause a temporary incapacitation that has profound effects on lifestyle. In some cases, acute ocular symptoms may serve as prodromic markers of exposure or predicative of future pathophysiologies. Thus, understanding the toxicological mechanisms underlying both acute and chronic ocular responses to CWA exposure is critical to predictive diagnosis of the potential impact on the visual apparatus and development of therapeutic strategies.

Traditionally, CWAs are divided into seven general categories based on their toxicological properties: vesicants, biological toxins, blood agents, tear agents, nerve agents, incapacitating agents, and choking agents (Table 36.1; Romano et al., 2008). Vesicants are a class of highly reactive alkylating compounds that catastrophically disrupt cellular functions by forming covalent adducts with proteins, ribonucleic acid, and deoxyribonucleic acid. In contrast, organophosphorus nerve agents (OPNAs) block acetylcholinesterase (AChE) activity, causing synaptic accumulation of acetylcholine (ACh) and overstimulation of cholinergic receptors. The resulting cholinergic toxidrome potentiates sympathetic signaling, resulting in distinctive but reversible changes in the pupillary apparatus, the lens, and possibly the retina. Incapacitating agents work in a variety of ways; antimuscarinics such as 3-quinuclidinyl benzilate (BZ) elicit an anticholinergic toxidrome, disrupting vision through loss of accommodation, decreased depth of field, ciliary muscle paralysis, and mydriasis. Blood agents interfere with oxygen delivery and oxygen utilization, causing acute cytotoxicity due to progressive tissue hypoxia and necrosis. The tear agents are nonlethal, lacrimating agents that rapidly irritate mucosal membranes and peripheral ocular nerves, causing an acute discomfort that is typically transient and reversible. The conjunctiva is particularly susceptible to blood agents and tear agents because of its exposed location and extensive innervation. Ocular toxicities can also result from exposure to diverse biological toxins, including botulinum neurotoxins (BoNTs), a family of potent neuroparalytic toxins produced by the *Clostridium* genus of bacteria; ricin, a transcriptional blocker extracted from the castor bean; and *Streptococcus* enterotoxin B (SEB), a bacterial superantigen. Finally, we propose a toxidromic-based approach for classifying chemical toxicities with the goal of assessing acute and chronic risks and simplifying treatment strategies.

Cyclosarin	GF	3-Quinuclidinyl BZ	BZ
VX	VX	**Biological toxins**	
VR	VR	Botulinum Neurotoxins	X
Novichok		Ricin	W
Choking agents		Staphylococcal Enterotoxin B	UC
Phosgene	CG	Saxitoxin	TZ
Diphosgene	DP	Tetrodotoxin	PP
Chlorpicrin	PS		

36.2 Background

36.2.1 The structure of the eye

The eye is constructed of three layers (or tunics) which play key roles in enabling the entry and visual processing of light. Each layer is separated by fluid-filled chambers which provide nourishment as well as structural support (Fig. 36.1). The outer layer of the eye includes the sclera, conjunctiva, cornea, and corneal limbus. As a result of their exposed locations, these tissues are primary targets for CWAs. The white, opaque sclera is a tough fibrous connective tissue layer containing interlacing type I collagen bundles and elastic fibers that give the eye its shape. The anterior surface of the sclera is covered by the conjunctiva, a layer of stratified columnar epithelial cells that produce mucus to help lubricate the eye. The conjunctiva is richly supplied with blood vessels and is highly susceptible to inflammation. At the front of the eye is the cornea, a transparent and avascular yet highly innervated tissue. The cornea is responsible for protecting the eye against insults such as injury and infection. It also provides roughly two-thirds of the total refractive power of the eye and is therefore the major refracting lens of the eye (Meek et al., 2003). The corneal limbus, which is located at the junction between the conjunctiva and cornea, plays an essential role in sustaining and repairing the corneal epithelium. Limbal cytotoxicity, therefore, has

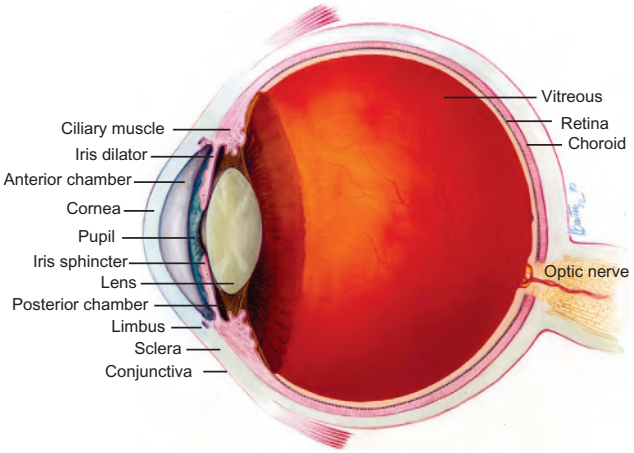

FIGURE 36.1 Anatomy of the eye.
Diagram of the human eye, labeled with the structures involved in ocular toxicity following exposure to CWAs. *Modified with permission from National Eye Institute, National Institutes of Health, reference number NEA04.*

severe consequences to corneal function, as discussed in the next section.

Between the cornea and the uveal tissues is the anterior chamber, which contains a watery fluid called the aqueous humor (AH). The anterior chamber exerts positive pressure against the posterior corneal surface (a.k.a., intraocular pressure) that shapes the cornea. Together the

cornea and the AH form an outer lens that plays the most significant role in refracting light toward the center of the eye. The AH also provides nourishment for the tissues lining the anterior chamber, and consequently is rich in metabolites (Goel et al., 2010). The AH is continuously secreted by the ciliary epithelium at a rate of 3 μL/min (in humans), and flows from the posterior chamber through the iris into the anterior chamber, exiting the eye primarily via the trabecular meshwork, where it is absorbed into the bloodstream. The entire volume is replaced every 90 min (Goel et al., 2010). Penetration of CWAs through the cornea results in intracameral exposure, which can cause systemic toxicity and/or produce biomarkers through adduct formation between CWAs and intracameral proteins that subsequently can be detected in plasma (Romano et al., 2008; McNutt et al., 2012a,b). AH production and drainage are critical to normal ocular function, and even short-term functional disruption has profound negative effects on corneal integrity and vision. Long-term disruption can result in complete loss of vision.

The middle layer of ocular tissues includes the choroid, iris, lens, pupillary apparatus, and ciliary body. General inflammation of these tissues is called *uveitis* or *iritis*. The choroid is the inner vascular layer of the eye, underlying the sclera. The primary function of the choroid is to provide oxygen and nutrients to the retina. While the high degree of choroidal vascularization renders the choroid prone to inflammation, it is largely isolated from direct exposure to most CWAs as a consequence of its deep intraocular location. The narrow space delineated by the iris, lens, and ciliary structures is known as the posterior chamber. The iris is a contractile diaphragm that controls the pupillary aperture and therefore the amount of light that enters the eye. Pupil size is regulated by two iris muscles: the pupillary sphincter, which is responsible for constriction of the pupil, and the pupillary dilator, which is responsible for dilation of the pupil. These muscles are innervated by sympathetic ("fight or flight") and parasympathetic ("rest and relax") nerves that determine constriction and dilation, respectively. The lens is a crystalline structure that focuses light on the retina. The autonomic nervous system controls focus (accommodation) by changing the shape of the lens under the control of ciliary muscles. Since changes in pupil size and accommodation are principal ocular symptoms associated with exposure to many CWAs, neuro-ophthalmic processes are described in greater detail in the section below.

The majority of the volume of the eye consists of the vitreous chamber, which is filled with a transparent, gelatinous mass of extracellular matrix material similar to the corneal stroma. This mass, which is known as the vitreous humor, holds the retina in position. The retina is comprised of 10 layers of nervous tissue containing millions of hierarchically organized light receptors that are connected to the brain by the optic nerve. Because of the physicochemical barriers that reduce CWA penetration to the rear of the eye, the retina is not susceptible to CWA toxicity, with the exception of systemically distributed neurotoxic CWAs that affect retinal function and information processing.

Finally, the ocular adnexa (not shown) are tissues that provide a supportive environment to the globe. Adnexal tissues include the lacrimal glands, which are located beneath the outer portion of the upper eyelid, the eyelids, and extraocular muscles. The lacrimal glands produce tears that help lubricate and moisten the eye and flush foreign matter that may contact the surface of the eye. They also contain proteases and cytokines that regulate the activation and fate of stromal cell populations upon disruption of the epithelial barrier. The eyelids facilitate corneal wetting, protection, and flushing, while the extraocular muscles control convergence, allowing the eyes to synchronize and to provide binocular vision.

36.2.2 Effects of ocular structure on regenerative capacities

The cornea and conjunctiva are generally the first ocular tissues encountered by external agents, and thus are the most common target of chemical toxicities. In fact, the extent of CWA absorption, penetration, and reactivity with conjunctival or corneal tissues is a major determinant of ocular injury (Jester et al., 2001; Maurer et al., 2002). Corneal function is critically dependent on the ability of the corneal epithelium and corneal endothelium to maintain stromal deturgescence by controlling fluid ingress at the anterior and posterior margins of the cornea, respectively. Disruption of either barrier results in corneal edema, increased production of proinflammatory mediators, and entry of matrix-active enzymes into the stroma. Disruption of both boundaries can have devastating effects on vision, eliciting a persistent corneal edema that may progress to corneal degeneration, and ultimately require surgical intervention (Eagle et al., 1989; Alomar et al., 2011). Agents that disrupt the full-thickness integrity of the cornea can cause diverse corneal pathologies, including stromal scarring, endothelial toxicity, recurrent corneal lesions, and corneal perforation (Fig. 36.2).

Given the susceptibility of the cornea to chemical toxicity and the devastating consequences of corneal dysfunction to proper vision, the regenerative capacity of the cornea represents the most significant repair mechanism for preservation of vision after ocular exposure to CWAs. The cornea is composed of five histologically distinct layers with different regenerative capacities: corneal epithelium, Bowman's layer, stroma, Descemet's membrane

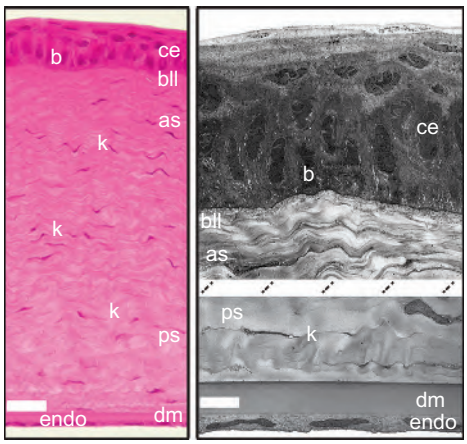

FIGURE 36.2 Structure of the cornea.

Unpublished data.

(DM), and corneal endothelium (Fig. 36.2). The corneal epithelium is a stratified epithelium with five to seven cell layers that provides a dynamic physical barrier between the external environment and intraocular space. Tight junctions among the different layers of corneal epithelial cells form a highly impermeable barrier to tear film and microorganisms (Klyce, 1972). The basal epithelial cells have several important functions, including the secretion of matrix factors, establishment of hemidesmosomal attachments to focal adhesion complexes in the anterior stroma, and proliferation to generate new epithelial cells. Anterior to the basal epithelial cells are the wing-like suprabasal cells. Over time, the suprabasal cells move superficially and terminally differentiate into the outer layers of squamous epithelial cells. These cells are shed from the ocular surface during normal wear and tear and are replaced by the steady superficial migration from underlying epithelium. Thus, homeostasis of the corneal epithelium is critically dependent on mitotic renewal.

Regeneration of the corneal epithelium primarily relies on a small population of limbal epithelial stem cells (LESCs) located in the basal region of the limbus. Although LESCs slowly cycle during homeostasis, they can become highly proliferative in response to corneal injury, undergoing asymmetric division to produce daughter transit amplifying cells that migrate into the basal layer of the corneal epithelium and undergo limited proliferation to replace corneal epithelial cells lost during normal exfoliation or due to injury (Ordonez and Di Girolamo, 2012). The limbal niche is highly vascularized, and factors that regulate niche function are delivered via multiple sources, including systemic circulation, tear film, AH, support cells in the LESC niche, keratocytes in the stroma, and corneal epithelial cells. Adverse conditions, such as chemical injury or persistent inflammation, can disrupt niche function, leading to a constellation of symptoms known as *limbal stem cell deficiency* (*LSCD*; Ahmad, 2012; Osei-Bempong et al., 2013). Dysregulation of the LESC niche has severe consequences for the corneal epithelium, which in turn evokes symptoms of corneal failure, such as invasion of goblet cells from the conjunctiva into the cornea, neovascularization, chronic inflammation, recurrent corneal erosions, keratitis, corneal ulceration, and stromal scarring.

Beneath the corneal epithelium is the corneal stroma, which encompasses over 99% of the corneal volume. The stroma is a highly ordered tissue composed of tightly packed collagen fibrils that are structured by proteoglycans into lamella (Hassell and Birk, 2010). This uniform packing is essential for rendering the stroma transparent to light. Maintenance of the stroma in a deturgescent state by the barrier functions of the corneal endothelium and corneal epithelium is a key factor in preserving lamellar organization. Disruption of either barrier increases corneal hydration and disrupts lamellar structures, causing aberrant light refraction through the stroma (Eagle et al., 1989). Under normal conditions, the stroma is sparsely populated by keratocytes, a quiescent population of mesenchymal cells that secretes transparent corneal material. Keratocytes exhibit variable responses to corneal injury, depending on their proximity to the injury (West-Mays and Dwivedi, 2006; Wilson, 2012). After a penetrating injury to the cornea, nearby keratocytes undergo apoptosis, prompted by the stromal influx of signaling molecules from the tear film or AH. More distant keratocytes undergo a fibroblastic transformation, become active, begin to proliferate, and start synthesizing matrix metalloproteinases that assist in tissue remodeling and/or scar formation (Hassell and Birk, 2010).

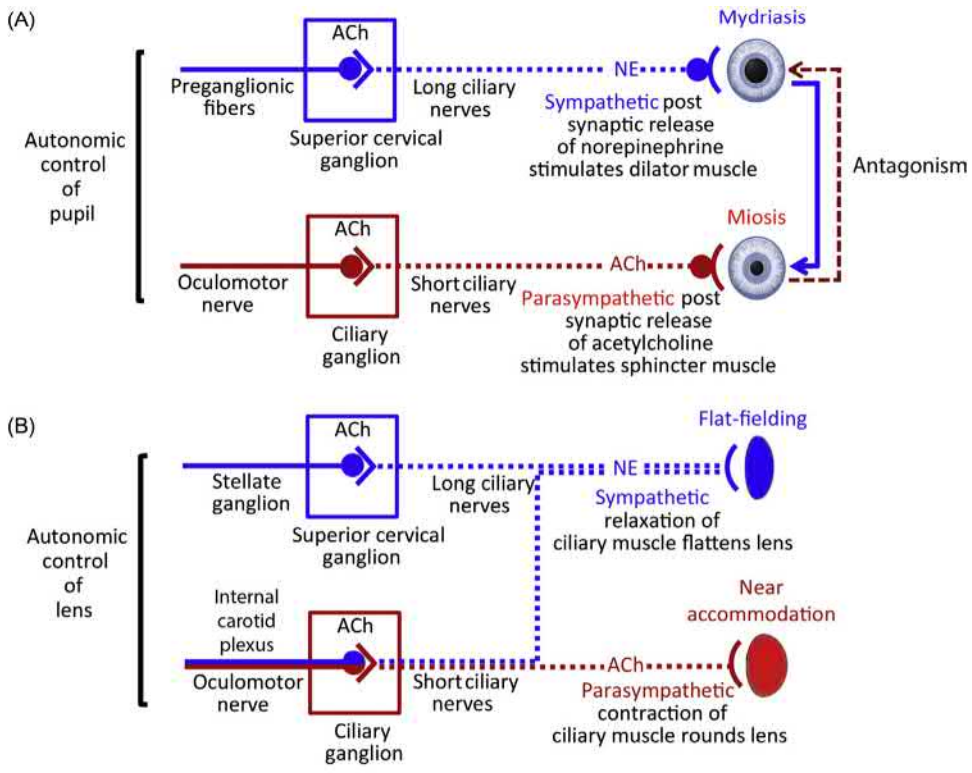
The corneal endothelium is a monolayer of cells on the DM that regulate corneal nutrition and turgescence by balancing a semipermeable barrier activity with active ion transport mechanisms. Since adult human corneal endothelial cells (CECs) do not appear to proliferate in vivo, the corneal endothelium has limited ability to recover from cytotoxic injury (Joyce et al., 1996; Senoo and Joyce, 2000). Under normal conditions, gaps in the CEC monolayer are rapidly filled by the spreading of proximal cells, driven by morphologic changes that compensate for endothelial cell loss. Once the focal CEC density falls below the threshold level required for endothelial function (estimated to be 1000−2000 cell/cm^2) (Joyce et al., 1996), the corneal endothelium can no longer maintain the stroma at the proper level of turgescence, resulting in a persistent corneal edema that, in turn, causes secondary keratopathies such as anterior segment inflammation,

epithelial bullae, and LSCD (Eagle et al., 1989; Petroll et al., 1995). Thus, while endothelial function can be restored after a mild injury by CEC spreading, recovery from more severe endothelial lesions may be limited by the repair capacity of the human endothelium.

36.2.3 Importance of neurological function to vision

Ocular function is extensively integrated with afferent and efferent neurological activity. For example, autonomic neurons control the activity of intrinsic ocular muscles (the sphincter pupillae, the dilator pupillae, and the ciliary muscle), which determine focal accommodation and pupil size. Autonomic neurons also control the function of the lacrimal glands. Neuronal afferents in the eye include sensory neurons from the conjunctiva and cornea, reflexive contributions to the iris, ciliary muscle, and eyelids, and the densely innervated retina. Finally, extraocular muscles and eyelids are controlled by cholinergic motor neuron inputs.

Under normal conditions, pupil size and focal accommodation result from a balance between sympathetic (adrenergic) and parasympathetic (cholinergic) nerve inputs (Fig. 36.3) (Levin and Kaufman, 2011). Autonomic control over pupil dilation is mediated by sympathetic postganglionic neurons originating from the superior cervical ganglion and synapsing with the iris dilator muscle. Stimulation of the sympathetic pathway results in the release of norepinephrine onto α-adrenergic receptors on the sphincter dilator, dilating the pupil and increasing the activation of light receptors in the retina. The short ciliary parasympathetic nerves project from the ciliary ganglion to form cholinergic synapses with the iris sphincter. Stimulation of the parasympathetic pathway results in pupillary constriction (miosis), reducing light input and causing tunnel vision. The dilator and sphincter muscles are also antagonistic, such that inhibiting one pathway allows the other pathway to become dominant. The system is further complicated by differential expression of stimulatory and inhibitory receptors in the uveal muscle tissues, presumably coordinating the complex



(C) Representative effects of neuro-ophthalmic agents on autonomic nervous system balance

- Organophosphorus nerve agents potential cholinergic signaling, shifting the balance toward parasympathetic dominance.
- BZ block cholinergic signaling, shifting the balance towards sympathetic dominance.
- Low doses of systemic botulinum block cholinergic release, shifting the balance toward sympathetic dominance.
- High doses of systemic botulinum block cholinergic and adrenergic release, producing tonic and poorly responsive pupils that are not dominated by either autonomic pathway.

FIGURE 36.3 Autonomic nervous system inputs to the pupil and the lens.
Diagram depicting the balance between sympathetic and parasympathetic signaling to the pupil (A) and lens (B), and summarizing how agents causing neuro-ophthalmic toxicity can alter this balance (C).

interplay of sympathetic and parasympathetic inputs (Whikehart, 2003).

Control over lens accommodation by the ciliary muscle is coordinated with pupil size and binocular convergence to optimize focus. The ciliary muscle receives both parasympathetic and sympathetic inputs from the ciliary ganglion via the short ciliary nerves. Postganglionic sympathetic signals result in the release of norepinephrine onto the ciliary muscle, activating β-adrenergic receptors and relaxing the muscle, which in turn optimizes refractive power for far vision. In contrast, parasympathetic activation activates muscarinic receptors, causing ciliary muscle contraction and rendering the lens more spherical for near-focus.

Given the extensive role that neurological function plays in proper vision, it is not surprising that exposure to CWAs that directly or indirectly alter neurological behaviors can result in ocular symptoms (Table 36.2). In fact, CWAs can be grouped into three general categories based on pathogenic mechanisms of ocular toxicity: (1) nonspecific, cytotoxic mechanisms; (2) nonspecific, noncytotoxic mechanisms; and (3) specific disruption of neuro-ophthalmic functions (Table 36.2). This novel grouping is useful in assessing the toxidromic progression (and treatments thereof) associated with each group of agents. For example, ocular exposure to Category 1 cytotoxic agents involves a common set of symptoms, including proinflammatory responses, chemosis, corneal lesions, corneal edema, limbal dysfunction, and the possibility of corneal ulceration at very high doses. Independent of the etiogenic agent, clinical management of these symptoms is essentially the same: supportive care to reduce the acute injury followed by pharmacologic and surgical treatments to facilitate corneal repair. Exposure to Category 2 agents requires supportive care, but rarely warrants more extensive regenerative therapies. In contrast, Category 3 neuro-ophthalmic modulators manifest by modulating either the activities of innervating ocular neurons or the ability of effector tissues to respond to neuronal signals. This modulation can be specific to particular neuronal subtypes, such as with cholinergic agonists or antagonists, or can be nonspecific, such as with blood agents. Although countermeasures for Category 3 toxidromic agents would be dependent on the type of agent, one common treatment might be drugs that antagonize cholinergic signaling to reverse myosis.

36.3 Ocular toxicities of specific chemical warfare agents

36.3.1 Selection of agents discussed

The list of CWAs, CWA derivatives, and potential CWAs with ocular toxicity is lengthy, and providing a comprehensive review is beyond the scope of this chapter. To constrain this discussion, representative CWAs were chosen from (1) traditional chemical and biotoxin threat agents identified by the US Department of Defense (DOD) and the Centers for Disease Control and Prevention (CDC); (2) Schedule 1A−3A substances, as described in the 1993 United Nations Convention on the Prohibition of the Development, Production, Stockpiling, and Use of Chemical Weapons and on their Destruction, also known as the 1993 Chemical Weapons Convention (CWC); and (3) representative chemicals of toxidromic families. While only a subset of potential CWAs are discussed, the overall objective of this chapter is to consider these limited examples as part of a generalizable approach to classify and treat ocular exposure to novel chemicals with shared physicochemical properties and/or toxidromic effects.

36.4 Vesicants (Group 1)

Sulfur mustard, nitrogen mustard, and lewisite are CWC Schedule 1A substances. These substances have few legitimate applications, if any. The largest section of this chapter will focus on the vesicant class of CWAs for three reasons. First, the vesicants pose the most significant threat to the eyes, with the development of irreversible, vision-threatening injuries following severe exposures. Second, the clinical, biological, and functional

consequences of ocular exposure to vesicants have been extensively researched. Third, the vesicants have a high potency against ocular tissues, and ocular injury can occur at doses that produce minimal systemic or cutaneous effects. Given the importance of eyesight in the sensory armature, ocular exposure to vesicants can incapacitate victims for days to months and incur a profound degree of psychological distress.

36.4.1 The mustard gases

Sulfur mustard (HD; $C_4H_8Cl_2S$) and nitrogen mustard (HN-1; $C_6H_{13}Cl_2N$) are highly reactive adducting compounds that exert their cytotoxic effects through a combination of genotoxicity, production of reactive oxygen species, direct interference with protein function, and disruption of metabolism. Although the mustards are well known for their cutaneous blistering effects, the ocular injury is clinically distinct from the cutaneous injury, influenced by factors unique to the eye, including structure, biochemical composition, and regenerative mechanisms. The tactical implications of HD use on troop morale and combat capability are poignantly captured in the John Singer Sargent painting *Gassed*, based on the artist's first-hand observations of a German mustard gas attack on British troops on August 21, 1918, in which he depicted lines of vesicant-blinded troops moving slowly toward casualty stations (Fig. 36.4). Harry L. Gilchrist, the medical director of the Gas Service, US Army Expeditionary Force, described a similar phenomenon following a mustard attack on US soldiers (Gilchrist and Matz, 1933):

> *At first the troops didn't notice the gas and were not uncomfortable, but in the course of an hour or so, there was marked inflammation of their eyes. . . . by the time the gassed cases reached the casualty clearing station, the men were virtually blind and had to be led about, each man holding on to the man in front with an orderly in the lead.*

The combination of HD's physicochemical properties, latent period of injury, and severe clinical effects rendered HD to be the most effective CWA during World War I, earning it the moniker of "king of battlefield gases" (Fitzgerald, 2008; Ganesan et al., 2010). HD was responsible for 77% of all gas injuries in World War I (Hughes, 1942). Large-scale deployment of HD during World War I and the Iran–Iraq War (1980–88) resulted in well over 600,000 casualties, with estimates of 75%–90% of HD casualties presenting with ocular injuries (Papirmeister et al., 1991). HD was also deployed in a number of smaller conflicts between 1917 and 1997, including by Egypt against North Yemen during 1963–67, Italy against Ethiopia from 1935 to 1940, and the Soviet Union against China in 1934 and again in 1936–37, although there is significantly less information about the consequences of HD use during these conflicts (Tuorinsky, 2008).

36.4.1.1 Toxicokinetics of the acute ocular mustard injury in human victims

Eyes are roughly 10-fold more sensitive to HD injury than are skin or pulmonary tissue. This increased sensitivity is largely attributable to the high metabolic rate of corneal epithelial cells, rendering them highly sensitive to chemical agents, and the large aqueous–mucous interface between the corneal surface and the tear film, which is a very effective sink for liquid and particulate contaminants as well as gas absorption (Pickard, 1919; Solberg et al., 1997; Safarinejad et al., 2001). Therefore, it is not surprising that approximately 75%–90% of HD casualties develop ocular symptoms, with 10% presenting with severe ocular damage (Pickard, 1919; Pechura and Rall, 1993). For example, of 998 victims exposed during the production of sulfur mustard at Edgewood Arsenal from September 1941 to March 1943, 78% developed acute ocular injuries (Uhde, 1946). A similar ratio held true for battlefield casualties during World War I and the Iran–Iraq War (Tuorinsky, 2008).

The spectrum of ocular injury among sulfur mustard victims is primarily the product of exposure time and concentration, with clinical outcomes ranging from mild conjunctivitis to chronic advanced corneal disease and loss of

FIGURE 36.4 *Gassed*, by John Singer Sargent. *Reprinted with permission from the John Singer Sargent Gallery.*

vision (Pechura and Rall, 1993). A remarkable series of low-dose HD exposure experiments involving live human military volunteers provided rigorous concentration:time (Ct) data for the acute phase of ocular mustard injury (Reed et al., 1918; Walker et al., 1928; Guild et al., 1941; Anderson, 1942; Smith and Dunn, 1991). Based on these experiments, ocular exposure to HD can be detected from exposure to 5–30 $mg \cdot min/m^3$. This dose produces a mild conjunctival injection without corneal involvement that resolves within days. Exposure to 60–75 $mg \cdot min/m^3$ HD causes conjunctivitis, corneal irritation, and photophobia (Mandel and Gibson, 1917; Mann and Pullinger, 1944; Gates and Moore, 1946; Balali-Mood and Hefazi, 2005). In some cases, exposure to 60 $mg \cdot min/m^3$ HD produces incapacitating ocular injuries that require supportive care for up to 2 weeks. Battlefield exposures and accidental exposure at ammunition plants provided additional data on outcomes at higher HD doses. At doses exceeding 100 $mg \cdot min/m^3$, severe intraocular injuries characterized by corneal edema, keratitis, ocular pain, blepharospasm, uveitis, neovascularization, and corneal perforation develop at greater than 100 $mg \cdot min/m^3$. The resulting corneal epithelial vesication and corneal edema require weeks to months to heal. Doses of 200 $mg \cdot min/m^3$ cause corneal edema, corneal opacity, eyelid edema and severe blepharospasm, and require months to heal. At doses exceeding 400 $mg \cdot min/m^3$, severe corneal damage develops that requires months of hospitalization. At these doses, blindness can rapidly develop due to corneal scarring and corneal ulceration. Based on these experiments, the minimum incapacitating vapor dose was estimated to be 60 $mg \cdot min/m^3$ and the median incapacitating dose (ICt_{50}) was estimated to be 100–200 $mg \cdot min/m^3$ (Project Coordination Staff, 1946; Reutter and Wade, 1994). Estimates of battlefield air concentrations of mustard gas during World War I were 19–33 mg/m^3. Under these conditions, the minimum incapacitating dose would be exceeded within 2 min, and a 5- to 10-min exposure would incapacitate 50% of soldiers (Solberg et al., 1997). Note that ocular exposure to neat HD in its liquid form, which is more concentrated than saturated HD vapor, dramatically increases the risk of corneal ulceration and vision loss, and therefore is far more dangerous than vapor-induced injury (Papirmeister et al., 1991).

Approximately 90% of soldiers and workers exposed to sulfur mustard in World War I initially presented with symptoms of conjunctivitis, photophobia, and blepharospasm. The subsequent injury progression was observed to follow one of three clinical trajectories (Classes I–III), which differed based on the nature of the symptoms and the recovery time (Table 36.3) (Hughes, 1945b). Class I injuries occurred in 75% of those with ocular presentation, involving mild symptoms without corneal involvement or significant chemosis that resolved within 1–2 weeks. Based on the Ct data presented here, Class I injuries are caused by doses ranging from 5 to 60 $mg \cdot min/m^3$. Class II injuries occurred in 15% of the victims, and correspond to a dose of 100–200 $mg \cdot min/m^3$. Class II injuries involve eyelid, conjunctival lesions and corneal lesions, and result in incapacitation lasting 4–6 weeks. Signs of the Class II injury include chemosis, corneal edema, epithelial erosions, severe ocular pain, blepharospasm, and photophobia. Class III injuries occurred in 10% of victims and are caused by exposure to more than 200 $mg \cdot min/m^3$. Class III injuries are characterized by severely affected eyes, with significant corneal involvement. Symptoms include severe ocular pain, reduced vision, blepharospasm, uveitis, edematous eyelids, limbal necrosis, chemosis, corneal erosions, and corneal edema. Class III was further subdivided into Class IIIa and Class IIIb. Class IIIa victims presented with moderate corneal symptoms, with a prognosis of 6 weeks to 3 months before soldiers could return to duty. In contrast, Class IIIb victims exhibited severe corneal changes resulting in

TABLE 36.3 Summary of ocular manifestations and healing times following exposure to SM vapor.

Injury class	Estimated dose ($mg \cdot min/m^3$)	Characteristic ocular manifestations	Symptomatic recovery
Class I	12–70	Conjunctival injection and ocular irritation, without lacrimation, blepharospasm, or photophobia	1–2 weeks
Class II	100–200	Above symptoms plus mild corneal involvement, such as corneal edema and epithelial vesication. Symptoms appear 6–12 h after exposure, including edema and epithelial erosions	6–12 weeks
Class III	>200	Corneal swelling, edema, and epithelial lesions, with destruction of limbal blood vessels at higher doses. MGK may develop. At very high doses, penetrating corneal ulcers occur	Months to never

disability of more than 3 months, and possibly causing complete loss of vision. Of the 939 ocular casualties caused by accidental exposures in mustard gas production factories in England, 10.4% presented with Class III symptoms, but only 1% developed Class IIIb corneal lesions (Hughes, 1945a).

36.4.1.2 Evidence for a delayed ocular mustard injury in human victims

Starting in the late 1920s, reports appeared of a late-onset complication in survivors of severe HD ocular injuries, in which ostensibly healed eyes developed a "delayed keratitis" from 8 to 25 years after exposure (Pechura and Rall, 1993). It was initially noted that following recovery from the acute lesion, which took 4–6 months, some patients remained largely asymptomatic for a decade or longer. However, approximately 1% of survivors subsequently developed a progressive ulcerative corneal disease that did not heal, characterized by photophobia, lacrimation, recurrent corneal erosions, idiotypic keratitis, decreased corneal sensitivity, and progressive corneal degeneration. As of 1939, approximately 300 victims of the severe form of mustard gas keratopathy (MGK) were described in the literature (Phillips, 1940). In 1944, it was reported that MGK developed intermittently in Class III-injured veterans over a period of 8–17 years after initial exposure, with a sudden increase in incidence from 17 to 25 years (Mann, 1944). Strikingly, of the 84 patients with delayed-onset HD injuries that were involved in that study, 76 were believed to have fully recovered from the acute injury prior to clinical re-emergence.

Additional evidence for the late-onset injury accumulated among survivors of the Iran–Iraq War, which represented the first instance of the prolonged deployment of HD munitions during the modern era, producing 50,000–100,000 military and civilian casualties (Willems, 1989; Khateri et al., 2003). Medical follow-up of this population using modern clinical methods has been illuminating with regard to the scope and progression of the acute and late injuries. In the largest available study, 34,000 survivors of HD injury were screened 13–20 years after exposure (Khateri et al., 2003). While 60.7% of survivors had no ocular symptoms, 35% were classified as having mild symptoms, involving persistent conjunctival irritation; 3.6% as having moderate symptoms, involving corneal opacities, mild corneal edema, and band keratopathy; and 0.7% as having severe symptoms, which included corneal melting and neovascularization. In a separate, nonoverlapping study involving 134 patients examined 17–22 years after exposure, 83% of survivors presented with ocular complications, which included burning (69%), photophobia (64%), blepharitis (28%), tearing (12%), corneal ulceration (12%), and retinal and conjunctival complications (4.5%) (Namazi et al., 2009). In another study specifically evaluating ocular injury in 40 veterans from 16 to 20 years after a single, high-dose exposure, 39 reported persistent ocular sequelae, including chronic conjunctivitis (17.5%), corneal thinning (15%), limbal ischemia (12.5%), corneal opacity (10%), corneal vascularization (7.5%), and corneal epithelial defects (5%) (Balali-Mood et al., 2005). A total of six patients exhibited severe corneal involvement and were diagnosed with the severe form of MGK.

This delayed ocular HD injury is predominantly associated with Class III exposures and exhibits latencies ranging from 1 to 40 years (Solberg et al., 1997; Balali-Mood and Hefazi, 2005). Onset is typically abrupt, characterized by the appearance of photophobia, tearing, and corneal and limbal lesions. However, the etiology of the late HD injury is still unknown. Corneal tissues removed from MGK victims during surgical interventions or postmortem exhibit signs of chronic inflammation, corneal thinning and ulceration, neovascularization, and corneal degeneration, suggesting a persistent injury that is beyond the healing capacity of the cornea (Richter et al., 2006; Javadi et al., 2007; Kanavi et al., 2010). Without a clear understanding of the etiopathogenesis of chronic HD injury, treatments have been mostly palliative in nature. Surgical interventions such as corneal keratoplasty and limbal stem cell transplants have had mixed outcomes, with successes largely restricted to mild cases of MGK (Richter et al., 2006; Javadi et al., 2007, 2011; Baradaran-Rafii et al., 2013).

36.4.1.3 Toxicokinetics of the acute and late-onset ocular mustard injuries

The acute symptomatic progression of the ocular HD injury is well described (Mann and Pullinger, 1944; Tuorinsky, 2008). The duration of the latent period between exposure and the appearance of ocular clinical symptoms is inversely correlated to the severity of exposure (Tuorinsky, 2008). At vapor doses below 60 $mg \cdot min/m^3$, the latent period is typically 4–12 h. At vapor doses exceeding 60 $mg \cdot min/m^3$, the latent period may be 3 h or less. Symptoms typically appear within an hour after exposure to liquid sulfur mustard. Following the latent period, the earliest symptoms of injury are sensations of grit in the eyes, ocular soreness, lacrimation, conjunctival injection, chemosis, and corneal injection. In Class II or III injuries, the corneal epithelium sloughs from the basement membrane within 6–12 h, leading to severe pain, photophobia, corneal edema, and impaired vision. By 24 h, corneal edema has increased the thickness of the cornea up to 300%, disrupting vision and

causing corneal pain. After a week, corneas begin to show clinical improvement with subsiding edema. Class II injuries subsequently develop superficial corneal vascularization, secondary corneal edema, and recurrent corneal symptoms that persist for several weeks before ultimately resolving.

The progression of healing in more severely injured eyes is less straightforward. A review of dose−response data and case studies enabled clinicians to identify three clinical trajectories among Class III-injured eyes: (1) injury resolution similar to Class II, but over a period of months and without the subsequent reoccurrence of corneal symptoms; (2) a chronic injury that develops immediately after the acute injury and fails to heal; and (3) delayed-onset lesions that appear 1−40 years after exposure (Duke-Elder, 1972; Papirmeister et al., 1991; Javadi et al., 2005, 2007). The latter two trajectories are collectively referred to as MGK. Although the relationship between the chronic and delayed-onset forms of MGK is unclear, the severe form of each involves an idiotypic, noninfectious keratitis with secondary keratopathies such as persistent epithelial lesions, corneal neovascularization, and progressive corneal degeneration (Khateri et al., 2003; Mousavi et al., 2009). Since both the chronic and delayed-onset forms of MGK result from a severe corneal exposure and share similar symptoms, it may be that a common pathophysiological mechanism is involved, despite temporal differences in clinical onset.

The pathogenic mechanisms responsible for MGK are unknown, but the most common clinical sequelae include recurring corneal epithelial lesions, corneal neovascularization, a progressive corneal degeneration, and frequent impairment or loss of vision (Solberg et al., 1997; Javadi et al., 2005; Balali-Mood and Hefazi, 2006). In a study restricted to 48 veterans suffering chronic ocular symptoms, 31 (64.6%) developed MGK directly from acute injury (i.e., the chronic form), whereas the delayed-onset form developed in 17 (35.4%), with latencies ranging from 1 to 15 years (Javadi et al., 2005). Limbal lesions were present in 81% of the MGK eyes, suggesting that development of limbal stem cell disorder is a common sequelae of MGK. Corneal signs included scarring (87.5%), neovascularization (70.8%), thinning (58.3%; resulting in corneal perforation in 4.2% of patients), and recurring epithelial defects (31.3%). In a separate study involving 149 seriously eye-wounded veterans, 90% of casualties with chronic ocular symptoms who were followed for 10−15 years showed no improvement, and in many cases, the injury became progressively worse (Ghasemi et al., 2009). According to these studies and many others, the delayed HD injury is usually progressive and difficult to clinically manage (Safarinejad et al., 2001). Not surprisingly, chemical warfare survivors with ophthalmologic complications suffer from a significantly lower quality of life as a consequence of their chronic injuries (Mousavi et al., 2009).

36.4.1.4 Mechanistic studies of sulfur mustard toxicity

Animal models have been used to study the pathogenesis of acute and chronic HD ocular injuries for over 70 years (Mann and Pullinger, 1944; Pechura and Rall, 1993; Ruff et al., 2013). One of the most productive models is an in vivo vapor exposure model in rabbits. The rabbit cornea is structurally similar to that of the human, and at functionally equivalent doses, rabbit and human eyes exhibit nearly identical lesions (Mann and Pullinger, 1944; Gates and Moore, 1946). Recently, a rabbit vapor HD exposure model was shown to produce dose-dependent, multiphasic corneal injuries with sequelae similar to those observed in human victims (Kadar et al., 2001; Milhorn et al., 2010; McNutt et al., 2012a,b).

Using the rabbit vapor exposure model, the progression of structural, biochemical, and molecular changes during acute injury and the transition to MGK were elucidated. Briefly, exposed corneas develop an acute lesion within 1 day, characterized by vesication of the corneal epithelium, stromal keratocytosis, corneal edema, and CEC loss. The corneal epithelium then undergoes a robust healing response, regenerating an intact, stratified epithelium with rudimentary hemidesmosomal attachments to adhesion plaques in the anterior stroma by 7 days after the exposure. Grossly, corneas appear to be healing from 1 to 2 weeks (the quiescent phase), with few clinical symptoms other than lingering edema. Resolving corneas subsequently undergo a rapid decrease in corneal thickness, reaching baseline levels by 6 weeks; a time frame that is similar to Class II or IIIa injuries in humans (Fig. 36.5) (Kadar et al., 2001; McNutt et al., 2012a,b). In contrast, the failure of corneal edema to resolve at 3 weeks and beyond is the earliest clinical marker of MGK onset. Histopathological markers of MGK include recurring basal epithelial cell cytotoxicity, basement membrane zone degeneration, loss of LESCs, inflammatory cell infiltration, elevation of cytokines, persistent endothelial failure, delayed in-migration of keratocytes, stromal degeneration, and redundant deposition of basement membrane components caused by cyclical attempts to regenerate the epithelium (Kadar et al., 2001; McNutt et al., 2012a,b). Secondary pathologies, such as epithelial bullae formation, recurring corneal erosions, neovascularization, and LSCD, subsequently develop, further interfering with stable repair of the ocular surface. Postexposure, steroid-based antiinflammatory protocols reduce and postpone the appearance of late injury. However, they do not prevent late injury, suggesting that anti-inflammatory drugs fail to treat the central pathologies responsible for MGK onset (Amir et al., 2000; Kadar et al., 2009; Gordon et al., 2010).

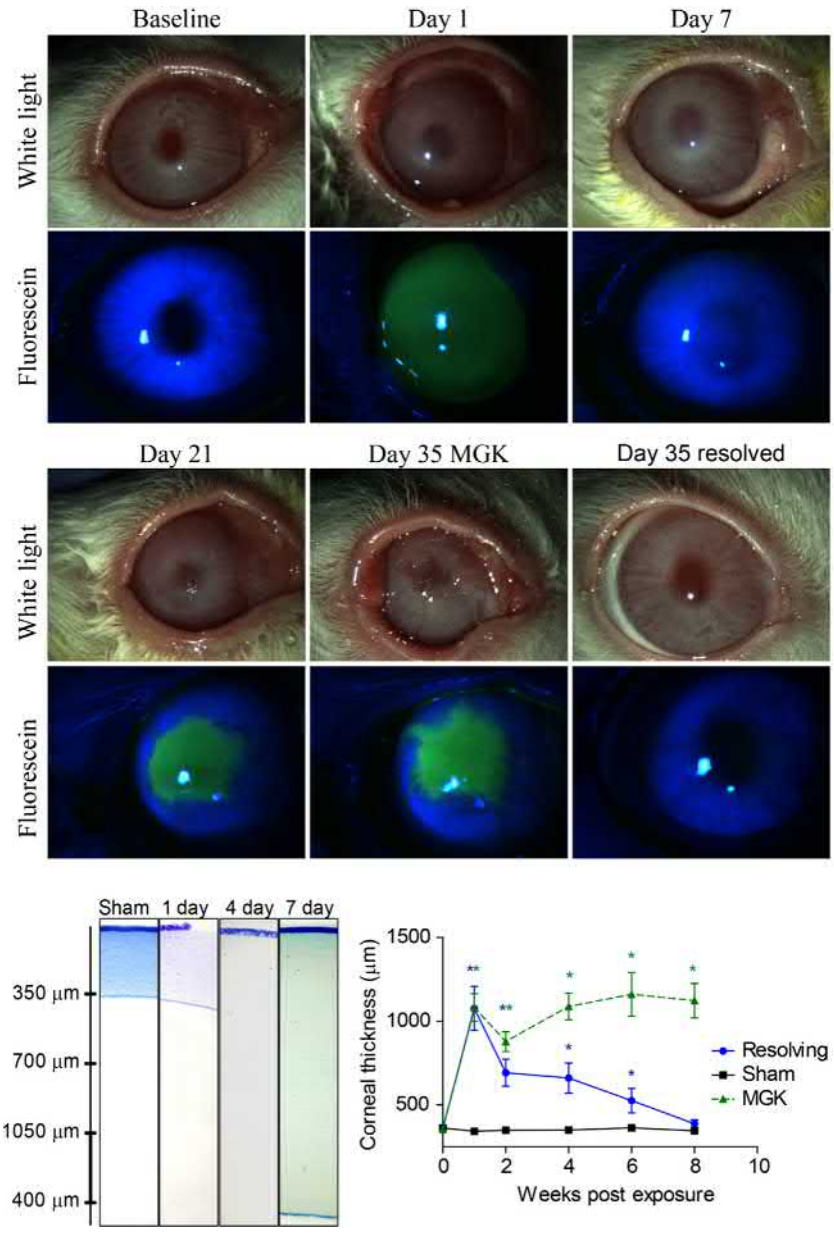

FIGURE 36.5 Development of acute and MGK injuries in HD vapor-exposed rabbit eyes.
(Top panels) Rabbit eyes were exposed to HD vapor for 2.5 min and evaluated by slit-lamp examination using fluorescein uptake as a measure of epithelial vesication. All panels are from the same animal. Note the transient recovery of an impermeable epithelial cap by 7 days, only to be followed by a recurring epithelial lesion by 21 days in an MGK cornea. Middle right represents a resolved eye, which appeared to have fully healed. (Bottom left) Histology demonstrating massive increase in corneal edema during the first week, a result of cytotoxicity in the corneal epithelium and endothelium. Note: lesion margin in the epithelium of the 1 d cornea. (Bottom right) Longitudinal changes in corneal edema in resolving versus MGK eyes. Note the biphasic transition at 2 weeks in MGK corneas.

The distinct pathophysiology of MGK revealed in these studies suggests the involvement of injury processes that operate on different time scales and in different corneal compartments than during the acute injury. However, all studies identified persistent edema as a primary causative factor underlying MGK onset.

36.4.1.5 Etiogenesis of the delayed ocular sulfur mustard injury: current theories

Damages to the corneal limbus and the corneal endothelium have emerged as pathophysiologies that may be critically involved in MGK onset, progression, or both. Both pathologies are consistent with clinical observations in human MGK corneas and are spatiotemporally expressed in such a way as to contribute to the long-term corneal HD injury (Baradaran-Rafii et al., 2010; Jafarinasab et al., 2010).

In a clinical study of 35 Iranian patients diagnosed with MGK, all MGK eyes exhibited LSCD (Baradaran-Rafii et al., 2010). Similar symptoms were observed in rabbit eyes expressing MGK symptoms, including goblet cell invasion (an indicator of limbal destruction) and a significant reduction of LESCs (Kadar et al., 2011, 2012). Interestingly, LESC loss did not appear to occur during

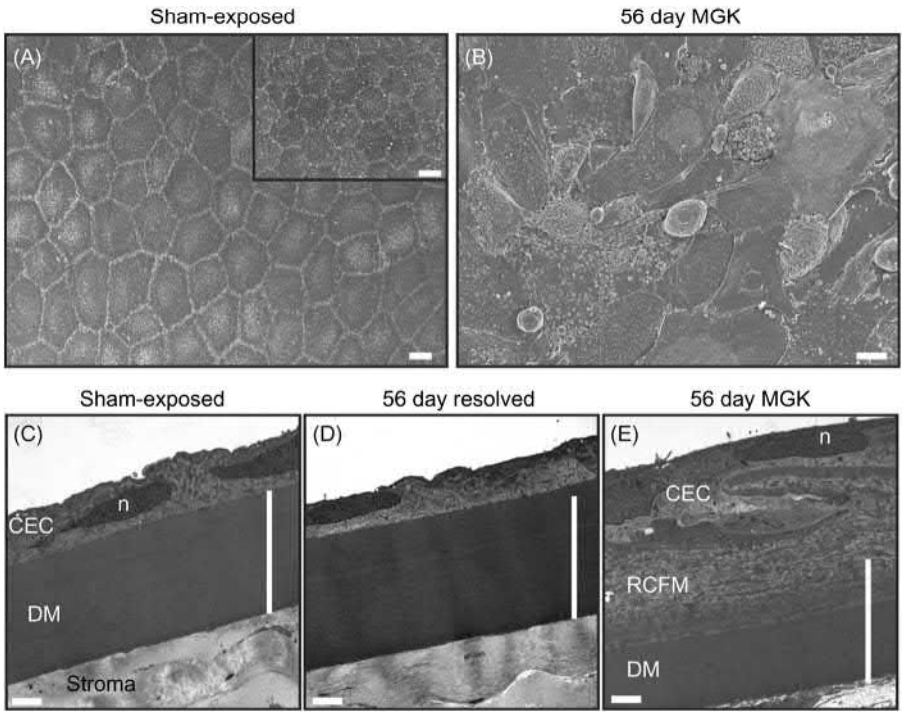

FIGURE 36.6 Ultrastructural evidence of endothelial cytotoxicity.
(A and B): Scanning micrographs showing CEC morphologies in resolved (A) and MGK corneas (B−D) 8 weeks after SM exposure. Inset in (A) is a sham-exposed cornea at the same magnification, highlighting the increased size of CECs in resolved corneas. Note evidence of ongoing cytotoxicity and a delayed healing response in (B). Scale bars = 10 μm. Transmission micrographs of posterior cornea comparing ultrastructure of sham-exposed (C), resolved (D), and MGK (E) corneas 8 weeks after SM exposure. Note the extensive thickening of the posterior DM and formation of a retrocorneal fibrous membrane in the MGK cornea. For comparison, the vertical white lines represent the full thickness of the DM in sham-exposed controls. Labels: corneal endothelial cell (CEC); nucleus (n); Descemet's membrane (DM); retrocorneal fibrous membrane (RCFM). Scale bars = 2 μm.

the acute phase following HD exposure; rather, it developed concurrent with the appearance of MGK symptoms. These data suggest that dysfunction of the LESC niche is a delayed phenomenon that occurs after the acute injury. A proinflammatory response and nerve damage were found in the corneal limbus of both rabbits and humans during MGK onset, implicating their involvement in the initiation of the late ocular injury (Javadi et al., 2005; Kanavi et al., 2010; Kadar et al., 2011). Regardless of the causal relationship between LSCD and MGK, LSCD is a clinically important aspect of MGK and the delayed loss of LESCs raises the possibility of a postexposure therapeutic window during which limbotrophic treatments could preserve LESCs.

A second important pathology that was recently described is failure of the corneal endothelial barrier due to CEC loss. Early reports of HD toxicity included endothelial cell toxicity and uveitis in Class III injuries, suggesting that HD can penetrate through the cornea to the anterior chamber (Mann and Pullinger, 1944; Hughes, 1945b). Evidence of endothelial toxicity was identified in human MGK corneas, including reduced CEC density with increased variability in size and morphology (Jafarinasab et al., 2010). More recently techniques such as transmission electron microscopy, in vivo confocal microscopy, functional assessment of the barrier, and immunocytochemistry were used to demonstrate that corneal endothelial toxicity is associated with acute injury and MGK corneas, but not resolved corneas (McNutt et al., 2013). MGK corneas exhibited an idiotypic endothelial injury characterized by focal CEC loss, abnormal CEC morphologies, and a diffusively thickened DM (Fig. 36.6). In contrast, resolved corneas exhibited a normal-appearing corneal endothelium. Notably, other clinical endotheliopathies involving the rapid loss of large quantities of CECs, such as aphakic bullous keratopathy, produce secondary keratopathies that are strikingly similar to MGK, including epithelial bullae, delayed LSCD, and corneal inflammation (Taylor et al., 1983; Eagle et al., 1989; Alomar et al., 2011).

The potential involvement of endothelial toxicity in the late HD injury is intriguing for several reasons. First, it provides a mechanism to explicate the dose dependence of MGK onset, based on the permeation of sufficient doses of HD through the cornea to cause injury to the corneal endothelium. Second, it proposes that the clinically biphasic injury progression observed during the acute phase is an epiphenomenon arising from the differential healing capacities of the corneal epithelium and corneal endothelium. Furthermore, the limited ability to heal large endothelial lesions may contribute to the prolonged recovery time following Class III ocular injuries. Third, it provides a single pathology to explain both the chronic and delayed-onset forms of MGK. For example, in this model, the chronic form of MGK would be caused by the inability to restore an intact endothelial barrier, resulting in untreatable corneal edema. Alternatively, in the delayed-onset form of MGK, the delayed loss of CECs (i.e., as a consequence of aging, or due to delayed cytotoxic mechanisms such as genotoxicity) from an endothelium

that is already diminished due to HD injury eventually results in endothelial failure and corneal decompensation. Additional implications of this hypothesis include the possibilities that therapies to restore the endothelium may mitigate the likelihood of MGK and that quantitation of endothelial loss may provide a diagnostic to identify corneas likely to develop MGK. Although many questions remain regarding the extent to which endothelial cytotoxicity and LSCD contribute to the acute injury and MGK, it is encouraging that mechanistic studies have moved beyond the corneal epithelium to study HD-induced injury processes in other corneal tissues.

36.4.2 Lewisite

Lewisite (L; $C_2H_2AsCl_3$) was first synthesized in 1904 and stockpiled by the United States, Germany, and Japan during World War II. Although lewisite is considerably more potent than HD, it produces immediate symptoms of physical discomfort, which rendered it relatively ineffective as a standalone CWA. However, lewisite was found to increase the environmental persistence of HD by depressing its freezing point at lewisite concentrations that had no apparent physiological effect, and therefore lewisite stockpiles were retained for several decades.

The toxicological effects of ocular exposure to lewisite are mediated by the interaction of inorganic arsenite (AsO_3^{3-}) with thiol groups of biologically active proteins, including dihydrolipoic acid (DHA). DHA is a cofactor in several critical enzyme systems critically involved in energy production, and disruption of DHA inactivates these enzyme complexes. For example, As^{3+} interaction with the E3 component of the pyruvate dehydrogenase complex prevents the conversion of pyruvate to acetyl-CoA, impairing ATP production and resulting in energy depletion, metabolic failure, and cytotoxicity (Young, 1999). Though lewisite injury progression can be mitigated by treatment with sulfhydryl-containing competitive antagonists of lewisite, such as 2,3-dimercaptopropanal (aka, British antilewisite; BAL), an ocular formulation of BAL is not currently available (Vilensky and Redman, 2003). Ocular neutralization of lewisite is very time-critical; unless BAL is topically administered with 2–5 min, lewisite eye injuries are irreversible.

36.4.2.1 Toxicokinetics of ocular lewisite injuries

The distinctive toxicokinetic effects of lewisite exposure on ocular tissues produces an injury progression that is very different from the mustards (Ottinger et al., 1973; Romano et al., 2008; Tuorinsky, 2008). Unlike the latency associated with mustard exposure, lewisite causes rapid ocular irritation, lacrimation, blepharospasm, and chemosis. Eye pain occurs immediately, reaching its peak in 4–8 h. Corneal vesication, perforation, and blindness are observed following instillation of as little as 1 μL of neat lewisite to the corneal surface (Pechura and Rall, 1993). Vapor administration of 0.15 $mg \cdot min/m^3$ causes significant conjunctival injection and swelling of the eyelids, whereas corneal injuries occur at concentrations as low as 2.5 $mg \cdot min/m^3$. Permanent eye damage occurs at concentrations as low as 15.2 $mg \cdot min/m^3$. Lewisite can be detected by smell at about 14–23 mg/m^3; thus, permanent ocular injury is likely within 1 min of olfactory detection (Gates et al., 1946). At high vapor doses or following liquid droplet exposure, delayed effects develop in the cornea within 6–24 h, including vesication of the corneal endothelium, full-thickness keratocytosis, corneal edema, inflammatory cell infiltration, neovascularization, corneal perforation, and blindness.

Despite the 20- to 30-fold higher toxicity of lewisite than mustards, the ocular injuries caused by field exposure to lewisite vapor are predicted to be less significant than HD (Gates et al., 1946). Because ocular irritation is almost immediate even at low concentrations of lewisite, the rapid onset of blepharospasm, ocular pain, and edema at low concentrations causes the eyes to close involuntarily, reducing the total ocular exposure.

Lewisite is very lipophilic, and ocular absorption has been reported to elicit toxicological responses in the ciliary body and iris (Young, 1999). At similar doses, it is significantly more efficient than HD at evoking corneal edema (Pechura and Rall, 1993). At high doses, lewisite-exposed eyes rapidly develop miosis and severe uveitis, indicating that lewisite penetrates to the inner chambers of the eye (Pechura and Rall, 1993). Since lewisite efficiently permeates the cornea to produce acute toxicity in posterior ocular tissues, it is also likely to cause CEC toxicity. This is consistent with a 1947 report that first described acute symptomatic similarities between the mustards and lewisite, despite their distinctive modes of actions (Adler et al., 1947). Notably, this study also reported the focal loss of CECs following liquid instillation of lewisite directly to the corneas of rabbits. It is currently unknown if lewisite exposure produces the equivalent of a late HD injury. While delayed-onset ocular effects analogous to severe HD-exposed eyes were not reported in lewisite-exposed rabbits, rabbits were only followed for 30 days after exposure (Mann et al., 1946).

36.4.3 Phosgene oxime

Although technically considered a vesicant, phosgene oxime (CX; Cl_2CNOH) does not produce blisters, and thus it is more appropriately considered an urticant, or nettle agent. Phosgene causes significant pain on exposed skin and eyes through an unknown mechanism. Eyes rapidly develop conjunctivitis, lacrimation, lid edema, and

blepharospasm after mild exposures, while more severe exposures can result in keratitis, iritis, corneal perforation, and blindness (Romano et al., 2008). In general, eye lesions are fairly similar to those caused by lewisite. Phosgene oxime ocular injury has not been well studied, and long-term consequences of exposures are unknown.

Inhalational injury studies conducted in humans are limited to a controlled study with informed volunteers (Malatesta et al., 1983). This study reported that a vapor concentration of 1 mg/m^3 was the limit of physiological detection. Exposure to 3 $mg \cdot min/m^3$ was defined as the minimum effective concentration, eliciting conjunctival irritation. In the same study, mice, guinea pigs, and rabbits exposed to 3000−15,000 $mg \cdot min/m^3$ phosgene oxime displayed agitation, respiratory difficulty, and intense lacrimation within 30 min. These symptoms appeared to resolve within 72 h, although no supportive histology or histopathology data were published.

36.5 Nerve agents

Schedule 1A OPNAs include the G-series agents, the V-series agents, and novichok agents (Table 36.1). OPNAs inactivate AChE by alkyl phosphorylation of a serine hydroxyl group at the esteratic site of the enzyme (Romano et al., 2008). Once conjugated to AChE, the nerve agent eventually loses an alkyl side chain by hydrolysis in a process known as *aging*, further enhancing the stability of the enzyme−nerve agent complex. Whereas reactivators such as the quaternary ammonium oxime family can restore function to nonaged AChE, there is currently no way to reactivate aged AChE in vivo, and thus recovery of cholinergic function mainly depends on synthesis of new enzyme. Functionally, OPNA inhibition of AChE prolongs the residency of the ACh neurotransmitter in the synapse, resulting in the excessive stimulation of postsynaptic receptors. In the peripheral nervous system, toxidromic progression is mediated by cholinergic overstimulation of several types of receptors, including nicotinic receptors at neuromuscular junctions; nicotinic receptors at autonomic ganglia; muscarinic receptors at parasympathetic efferents onto smooth muscles; and muscarinic receptors on adrenal glands and sweat glands. Unlike the severe pathologies resulting from ocular exposure to the cytotoxic ocular irritants, the neuro-ophthalmic effects of exposure to OPNAs are fully reversible.

Ocular symptoms are among the earliest and most sensitive indications of the cholinergic toxidrome caused by exposure to nerve agent vapor, including tearing, pupillary constriction (miosis), and loss of accommodation. Ocular symptoms of a cholinergic toxidrome can manifest at vapor doses that do not cause evidence of other toxicities, and therefore can serve as an early physiological marker of exposure to nerve agents (Baker and Sedgwick, 1996). For example, the most reliable indicator of exposure after the Tokyo sarin attack was miosis, which was observed in 90% of victims (Wiener and Hoffman, 2004). Ocular toxicity by OPNAs is specifically mediated by overstimulation of muscarinic receptors and excessive excitation of parasympathetic signaling within the eye, causing contraction of the pupillary sphincter and ciliary muscle and overstimulation of the lacrimal glands, resulting in the clinical symptoms of miosis, blurred vision, and tearing (Romano et al., 2008).

The first intraocular effect of nerve agents is miosis resulting from overstimulation of parasympathetic muscarinic receptors on the pupillary sphincter muscle. This causes the iris to contract and reduces light input into the eye (see Fig. 36.2) (Soli et al., 1980; Dabisch et al., 2005). The second intraocular target of nerve agents is the ciliary muscles that control lens accommodation. Overstimulation of the ciliary muscles alters the lens shape, decreasing focal accommodation and blurring vision. Overstimulation of cholinergic nerve terminals in the retina may also contribute to visual disruption (Voigt, 1986). The final ocular targets of OPNA exposure are the parasympathetic inputs to the lacrimal glands, increasing tearing.

The miotic effect of OPNAs is primarily attributed to ocular absorption rather than systemic distribution, because percutaneous exposure does not cause miosis until near-lethal doses (Table 36.4; Romano et al., 2008). In contrast, OPNA exposure on or near the eye will cause miosis at very low concentrations (Hurst, 2007). Together, these suggest that the relatively privileged environment of the inner eye is more susceptible to direct absorption of nerve agent and drugs than to systemically circulated compounds. Furthermore, they indicate that the

onset of tearing with miosis, in the absence of pain, is a prodromic indicator of exposure to OPNAs.

36.6 Psychomimetic incapacitating agents

Incapacitating agents are defined by the Department of Defense as "an agent that produces temporary physiological or mental effects, or both, which will render individuals incapable of concerted effort in the performance of their assigned duties" and are not intended to be lethal (Romano et al., 2008). The development and use of psychomimetics as incapacitating agents are reflected in diverse apocryphal stories, driven in part by the testing of lysergic acid diethylamide (LSD), phencyclidine (PCP), and 3-quinuclidinyl benzilate (BZ) on military volunteers at Aberdeen Proving Ground (McFarling, 1980; National Research Council, 1984). Collectively, the incapacitating agents are an unusual category of CWAs, with varied physicochemical characteristics and psychogenic effects. Incapacitating agents involve a spectrum of psychogenic effects, including agents that act as stimulants, depressants, psychedelics, and deliriants. Psychomimetic agents that have been specifically described in a military context include muscarinic antagonists, cannabinoids, indoles, and anxiogenics.

The only psychomimetic chemical explicitly listed in the CWC is BZ, a Schedule 2A agent. BZ is an anticholinergic glycolate related to atropine that competitively antagonizes postjunctional muscarinic receptors at ganglia as well as parasympathetic innervations onto smooth muscle and exocrine glands. By blocking the ability of muscarinic receptors to respond to the synaptic release of acetylcholine, BZ inhibits parasympathetic signaling and drives the ocular nerves toward sympathetic dominance. This shifts the pupillary balance toward mydriasis, failure of accommodation, and lacrimal paralysis. Thus, BZ effects on the eye are the opposite of the OPNAs, resulting in mydriasis, the loss of near-focus, and dry eye. Similar to nerve agents, once normal cholinergic signaling is restored, the ocular effects of BZ are fully reversed.

Unlike the prodromic effects of many agents on the ocular system, ocular symptoms of BZ inhalation occur secondary to more general signs of intoxication, such as incoordination, confusion, and slurred speech (Sidell et al., 1997). Although minimal human dose–response data is available for ocular symptoms of BZ exposure, relevant studies were conducted in other species. The effective species-specific concentration:time values for mydriasis following inhalational exposure of BZ were less than 130 $mg \cdot min/m^3$ in dogs, 70 $mg \cdot min/m^3$ in monkeys, and 40 $mg \cdot min/m^3$ in rabbits (Ketchum, 1963; McNamara, 1963). At incapacitating doses (estimated to be 8 μg/kg), central effects persist in humans for 3–4 days; however, the persistence of ocular effects after such treatments was not described.

36.7 Blood agents

The principal blood agents are hydrogen cyanide (AC; HCN) and cyanogen chloride (CK; NCCl). These agents are Schedule 3 toxic chemicals according to the CWC. Schedule 3A substances have legitimate, large-scale industrial uses; therefore, large stockpiles are likely available for repurposing as CWAs.

Cyanide is one of the least toxic of the lethal CWAs. The inhalational LCt_{50} values for AC and CK are estimated to be 2500–5000 and 11,000 $mg \cdot min/m^3$, respectively (Simeonova, 2004). The cyanide ion (CN^-) is the toxic moiety, mediated primarily by its great affinity for the heme a_3 moiety of cytochrome c-oxidase in mitochondria, a key component in oxidative respiration. This interaction blocks the last stage in the electron transfer chain, resulting in cellular hypoxia and a shift of aerobic to anaerobic cellular respiration, and in turn causing cellular ATP depletion and lactic acidosis. Therefore, tissues with high metabolic demands, such as neurons and cardiac cells, are key targets for toxicity. At lethal doses, death occurs within 6–8 min (Sidell et al., 1997).

Exposure to blood agents has two distinct effects on the eye, depending on the route of exposure. The retina and optic nerve are principal symptomatic targets of acute systemic cyanide exposure, with mydriasis commonly occurring at sublethal cyanide exposure and vision failure developing at higher doses. This is due to the metabolic inhibition of highly active neurons secondary to vascular distribution of the CN^- ion. The appearance of fixed and dilated pupils is common late in the toxidromic progression, but this is likely to result from the general loss of autonomic neuronal function rather than ocular-specific toxicity (Grant and Schuman, 1993).

Alternatively, topical administration of blood agents to the ocular surface results in local absorption and toxicity, primarily concentrated in anterior ocular tissues such as the conjunctiva and lacrimal glands. Thus, topical exposure to the blood agents elicits mild ocular symptoms, primarily characterized by lacrimation and conjunctival irritation. In animal studies, the administration of sodium cyanide (1.7–5.3 mg/kg/day) to the inferior conjunctival sacs of rabbits resulted in immediate conjunctival irritation and lacrimation (Ballantyne, 1983b). In a separate study, rabbits that were administered 0.9 mg/kg of hydrogen cyanide to the conjunctival sacs developed general keratitis (Ballantyne, 1983a). These two experiments involved the administration of lethal doses of cyanide in liquid form directly to the conjunctiva, which is likely to lead to the very rapid cytotoxicity of local nerves, blood

vessels, and epithelial cells. Exposure to sublethal concentrations of cyanogen chloride vapor similarly caused intense conjunctival irritation, severe blepharospasm, and lacrimation.

36.8 Choking agents

The choking agents are chloropicrin (PS; CCl_3NO_2), phosgene (CG; $COCl_2$), and diphosgene (DP; $ClCO_2CCl_3$). These agents injure the nose, throat, and lungs, causing pulmonary edema and respiratory distress (Dembek, 2007). Although diphosgene has very similar physiochemical properties to phosgene, it readily condenses to a liquid and is therefore easier to handle and store. The ocular irritation caused by all three agents occurs at doses that are equivalent to the limit of olfactory detection. The acute symptoms of ocular exposure to phosgene and diphosgene (and possibly chloropicrin) are due to their hydrolysis to hydrogen chloride (HCl), creating what is essentially a chemical burn (Dembek, 2007). The longer term respiratory symptoms are primarily due to hydrolysis as well as acylation, resulting from reaction of phosgene with nucleophilic moieties on macromolecules, such as amino, hydroxyl, and thiol groups. Acylation denatures lipid and protein and disrupts enzymatic function and appears to play a more significant role than hydrolysis in longer term pathophysiologies. In contrast, the mechanism of action for chloropicrin is not well understood, but may involve an oxidative reaction with biological thiols, such as glutathione and hemoglobin.

Although there is a paucity of acute human data containing ocular pathogenesis and toxicokinetics caused by phosgene or diphosgene, ocular irritation involving burning, conjunctivitis, and lacrimation was reporteded within 20 min of exposure to 12 mg/m^3 phosgene (Bast and Bress, 2002). Concentrations of 30−40 mg/m^3 result in severe ocular irritation. Although phosgene's poor water solubility means that minimal hydrogen chloride is produced by hydrolysis, even small quantities are sufficient to elicit an initial irritation to the eyes, nasopharynx, and respiratory tract. Contact with liquid phosgene may result in corneal opacities and delayed perforation, consistent with a chemical burn injury and presumably resulting from the effects of HCl on the cornea.

Human exposure concentrations and times are better described for chloropicrin, which is roughly one-third as lethal as phosgene with an estimated median lethal dose of approximately 20,000 $mg \cdot min/m^3$. At low concentrations chloropicrin causes profuse lacrimation and conjunctivitis. At high concentrations it is severely irritating to the lungs, eyes, and skin. Thus, the primary effects observed with short- and long-term exposure to chloropicrin are sensory and respiratory irritation. The most likely route of ocular exposure is conjunctival and corneal absorption. Ocular irritation occurs prior to other symptoms of exposure, including respiratory irritation, and manifests at doses that are below the limit of olfactory detection. Studies in human volunteers indicate that lacrimation and blepharospasm are apparent at 5.0 $mg \cdot min/m^3$, conjunctival irritation is apparent at 10−100 $mg \cdot min/m^3$, and intolerable ocular irritation develops at 500 $mg \cdot min/m^3$ (Fries and West, 1921; Prentiss and Fisher, 1937). These studies are consistent with more recent findings following an industrial accident in California that produced a plume of chloropicrin with estimated air concentrations between 0.17 and 1.0 mg/m^3 (Barry et al., 2010). Of the 324 residents who reported symptoms consistent with chloropicrin exposure, 93.2% presented with ocular symptoms such as lacrimation, ocular pain, and burning.

36.9 Riot control agents

Riot control agents (RCAs), also called *irritants*, *lacrimators*, and *tear gas*, produce transient discomfort and eye closure that render the recipient temporarily incapable of fighting or resisting. The RCAs in use today are CS (2-chlorobenzalmalononitrile; $C_{10}H_5ClN_2$), CN (mace; C_8H_7ClO), CR (dibenzoxazepine; C_8H_7ClO), OC (oleoresin capsicum; $C_{18}H_{27}NO_3$), and various combinations of these agents. The RCAs share several characteristics that make them very effective as nonlethal agents, including rapid onset, with symptoms developing within seconds of exposure; a short duration of effect, with recovery occurring within 30 min after the end of exposure; and a high median lethal concentration with a low effective concentration meaning that they cause acute incapacitation without long-term effects or disabilities (Table 36.5) (Olajos et al., 2004). The eye is the most sensitive organ to RCAs, and although each RCA has slightly different effects, they all produce sensations of conjunctival and corneal burning, tearing, blepharospasm, and conjunctival injection. Barring direct application of solid RCAs to the eye or mechanical injury from the deployment of RCAs, the ocular symptoms are transient and fully reversible. Although RCAs are not considered to be CWAs according to the 1925 Geneva Convention, President Gerald Ford signed Executive Order 11850, banning the use of RCAs in war, except in defensive actions, without the advance approval of the president. Thus, although RCAs are incapacitating agents, they are not considered *military* incapacitating agents. However, since RCAs are increasingly being deployed in other contexts and can theoretically be deployed in a military capacity, we will address them here.

RCAs are distinguished based on two general mechanisms of action. The C agents (CS, CN, and CR) are SN_2-alkylating agents that react readily with sulfhydryl-containing enzymes,

TABLE 36.5 Toxicological parameters of RCAs.

Compound	Ocular irritancy	Rate of action	Irritancy threshold (mg/m^3)	Intolerable concentration (mg/m^3)	Lethal concentration ($mg \cdot min/m^3$)
CS	Profound	Instantaneous	0.004	5	25,000
CN	Profound	Instantaneous	0.3	35	14,000
CR	Profound	Instantaneous	0.002	1	100,000
OC	Profound	Instantaneous	–	–	–
Chloropicrin	High	Rapid	2–9	50	20,000

Source: Modified from Olajos, E.J., Woodhall, S., 2004. Riot control agents and acute sensory irritation. In: Olajos, E.J., Woodhall, S. (Eds.), Riot Control Agents and Acute Sensory Irritation. CRC Press LLC, Boca Raton, FL.

such as lactate dehydrogenase. For example, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme in the pyruvate decarboxylase system. These agents act as peripheral sensory irritants, which act primarily upon the eyes, respiratory tract, and skin. Despite small differences in potency, the C agents are similar in that exposure results in the near-instant ocular irritation, burning, and swelling of the conjunctiva, with uncontrolled lacrimation, blepharospasm, and increased intraocular pressure. The use of CS has largely replaced CN due to being significantly more effective as a sensory irritant, but much less toxic. Ocular irritancy studies for the C agents were conducted in various animal species and in human volunteers (Punte et al., 1963; Ballantyne and Swanston, 1978). Generally, these studies were consistent in showing that exposure to low concentrations of CS was immediately irritating and rapidly became incapacitating at higher doses, but significant corneal toxicity did not occur until very high concentrations were achieved. For example, instillation of 5%–10% CS to the corneal surface caused acute conjunctivitis, chemosis, keratitis, neovascularization, epithelial lesions, and corneal inflammation. The mechanism of injury at high concentrations is unknown, although it is speculated that the alkylating properties of the C agents disrupt protein structure. The poor water solubility of C agents limits their principal mode of action to the corneal epithelium. The potential for ocular irritation from CS is less than with CN; however, prolonged exposures to both results in conjunctivitis and photophobia (Ballantyne et al., 1974).

The second class of RCAs is the capsaicins, represented by OC and its derivatives. The capsaicins are naturally occurring compounds of the capsicum plants, which include chili peppers and jalapenos. Capsaicin binds TRPV1, a vallinoid type I receptor that is activated by elevated temperature (43°C) or abrasion. TRPV1 is expressed by nociceptor neurons in the eye, and TRPV1 activation elicits symptoms of pain. Clinical signs of exposure to OC include lacrimation, transient conjunctivitis, redness, burning, pain, swelling, and blepharospasm. If applied directly to the eye, OC can cause neurogenic inflammation, insensitivity to chemical and mechanical stimuli, and loss of the blink reflex (Olajos and Salem, 2001). Generally, not much is known about the general toxicity of capsaicins, but because they are widely used in food products, they are believed to exhibit low ocular toxicities.

36.10 Biological toxins

Although there is ongoing disagreement over whether biotoxins should be classified as biological warfare agents (BWAs) or CWAs, biotoxins are clearly more similar to CWAs in their deployment, clinical manifestation, and medical management. Three categories of biotoxins are discussed below, each of which exhibits a distinctive mechanism of action: neurotoxins, metabolic toxins, and bacterial superantigens.

36.10.1 Botulinum neurotoxins (BoNTs)

BoNTs are highly lethal bacterial toxins produced by the *Clostridium* species, a family of bacteria that lives in the soil and in low-oxygen conditions. Clinical manifestations of botulism can occur following the ingestion, inhalation, or injection of preformed toxin or by productive infection of toxin-producing strains. There are currently eight known BoNT serotypes (/A–/H), of which /A, /B, /E, /F are commonly associated with human disease (Simpson, 2004; Dover et al., 2013). The toxin is expressed as a single 150-kDa peptide, which is post-translationally nicked to produce a dichain composed of a 100-kDa heavy chain (HC) and a 50-kDa light chain (LC) linked by a disulfide bond (reviewed in Simpson, 2004). HC mediates binding to presynaptic receptors and entry of toxin into the neuron via synaptic endocytosis. Acidification of the endosome triggers the HC to form a pore in the endosome membrane that allows translocation of the LC from the lumen to the neuronal cytosol. LC then targets and cleaves one or more of three soluble NSF attachment

protein receptor (SNARE) proteins with exquisite specificity: synaptosomal-associated protein 25 (SNAP-25; BoNT/A, /C, /E); vesicle-associated membrane proteins 1−3 (VAMP1−3; BoNT-/B, /D, /F, /G); or syntaxin (BoNT/C). The neuronal SNARE proteins are essential components of the synaptic exocytosis mechanism, and their cleavage prevents functional assembly of the ternary complex, thereby blocking neurotransmitter release. The combination of efficient neuronal targeting and presynaptic activation renders BoNTs the most potent substances known, with estimated human median lethal doses as low as 0.1−1 ng/kg.

BoNTs interfere with the synaptic release of ACh from several types of cholinergic neurons, including motor neurons, preganglionic neurons, parasympathetic neurons, and some sympathetic neurons, such as those that innervate sweat glands. Furthermore, although there is a partial selectivity for cholinergic synapses, BoNT can also impair neurotransmission at other types of synapses, including adrenergic and noradrenergic sympathetic synapses (MacKenzie et al., 1982). Chemical denervation of autonomic signaling can occur at ganglia, which are cholinergic; at the synaptic fasciculation, where the neuron releases neurotransmitter onto the smooth muscle cells; or in both locations. Thus, the effects of intoxication on ocular behavior can vary based on dose and time after intoxication. Prominent neurologic findings in all forms of botulism include diplopia, blurred vision, and dilated pupils with weak pupillary responses. Tear production may be reduced because of peripheral parasympathetic cholinergic blockade, and ptosis is common.

The speed at which nerve terminals are intoxicated is closely related to neuronal activity, since higher rates of neurotransmitter release correspond to increased toxin uptake. Consequently, ophthalmic manifestations are among the earliest signs of clinical presentation (Konig et al., 1975; Levy et al., 1991). Common findings include accommodative paresis (59%), blurred vision (89%), mydriasis (52%), and photophobia due to paralysis of the cholinergic terminals of the parasympathetic nerves. Impairment of tear production results from paralysis of the autonomic nerves innervating the lacrimal glands, leading to dry eye. Paralysis of the extraocular muscles is also an early symptom, producing double vision (diplopia, 59%), fixed gaze (36%), nystagmus (56%), and drooping eyelids (blepharoptosis, 80%). Manifestations at very high doses include tonic pupils that are poorly responsive to light, suggesting significant paralysis of both autonomic pathways. Supersensitivity of the iris sphincter muscle to muscarinic agonists is a characteristic in severely intoxicated eyes, suggesting that antagonistic signaling via the sympathetic pathway is also impaired (Caya, 2001).

Unlike nerve agent, which stimulates the parasympathetic pathway, or BZ, which blocks the parasympathetic pathway, botulinum chemically denervates both signaling pathways at high doses, leading to poorly responsive or tonic pupils. In contrast, at lower systemic doses, BoNT preferentially blocks cholinergic neurotransmitter release, resulting in the dominance of the sympathetic signaling pathway.

The shellfish poison saxitoxin (STX) and the pufferfish poison tetrodotoxin (TTX) are also biological neurotoxins. Both toxins antagonize the voltage-gated sodium channels responsible for the rising phase of an action potential in neurons, thereby preventing action potential propagation and reducing or eliminating neurotransmitter release. Both toxins are exceedingly potent, with intravenous LD_{50} values of 10 and 8 μg/kg, respectively. The inhalational LD_{50} value for STX is estimated to be 5 $mg \cdot min/m^3$ (the equivalent value for TTX is not available). Although there are minimal data on toxic effects following topical exposure in healthy eyes, in principle the conjunctiva and corneal epithelium should provide an effective barrier to ocular absorption. Interestingly, topical administration of STX or TTX to deepithelialized corneas or by subconjunctival injection produces a long-lasting anesthetic effect, without causing ocular irritation or corneal edema (Duncan et al., 2001). In contrast, systemic administration can paralyze the ocular neurons, blocking pupillary light responses, spontaneous or reflexive eye openings, and gaze (Lan et al., 1999). At intermediate doses, patients may experience blurred vision, darkened vision, and loss of accommodation, with temporary blindness occurring at higher doses. There do not appear to be any chronic complications from ocular paralysis resulting from exposure to TTX or STX, and, upon recovery, oculomotor coordination, pupillary responses, and visual acuity were reported to be physiologically normal. These data suggest that the corneal epithelium and endothelium act as effective barriers to prevent the transcorneal absorption of TTX or STX, and therefore, ocular responses to aerosol exposures are more likely to result from inhalation and systemic distribution than from direct corneal absorption.

36.10.2 Ricin

Ricin is a heterodimer glycoprotein isolated from the castor bean. After nonspecific internalization into a wide variety of cells, ricin cleaves a glycosidic bond on the 60S subunit of eukaryotic ribosomes, preventing protein synthesis and causing cytotoxicity within 8 h. The median LD_{50} of ricin is around 22 μg/kg in humans from injection or inhalation. There is little information available on the ophthalmic manifestations of ocular exposure to ricin; however, topical administration to the eye is severely irritating, causing chemosis and conjunctivitis (Hunt, 1918; Grant and Schuman, 1993). Ocular instillation of 100 μg

to rabbits, guinea pigs, or mice causes extensive ocular inflammation that may lead to permanent corneal damage and blindness. It is unlikely that ricin can penetrate into the globe, and therefore the direct action of ricin must occur principally at the ocular surface (Strocchi et al., 2005).

36.10.3 *Staphylococcus* enterotoxin B (SEB)

SEB is a 23- to 29-kDa polypeptide in the bacterial superantigen family that cross-links the major histocompatibility class II receptor and T-cell receptors. This short-circuits the antigen processing and presenting mechanism, stimulating the release of pathologic levels of proinflammatory cytokines while failing to activate regulatory feedback signaling (Ahanotu et al., 2006). Prior to the 1975 Biological Warfare Convention (the biological equivalent of the CWC), SEB was studied by the United States as a biological agent that could be used to incapacitate soldiers in the battlefield. SEB was an attractive potential BWA because it can easily be aerosolized, is stable, and at low doses can cause widespread systemic damage when inhaled. In most circumstances, aerosol exposure results in a profoundly incapacitating illness lasting as long as 2 weeks, but it does not cause death (Sidell et al., 1997). SEB-induced ocular injuries are described only three times in the literature,; in all instances, exposures occurred when laboratory workers placed contaminated material in the near proximity to their eyes. Symptoms appear within 1−6 h, and included significant eyelid edema, periocular swelling, and acute conjunctivitis with discharge. Symptoms resolved within a week, although at least one patient appeared to exhibit continued hypersensitivity when in laboratories where SEB experiments were being conducted. These suggest that casualties resulting from an inhalational exposure may present with ocular toxicities that can be acutely incapacitating although, as with ricin, primarily localized to the ocular surface (Rusnak et al., 2004).

36.11 Concluding remarks and future directions

A wide array of CWAs and biological toxins exhibit acute ocular toxicities. The mode of action of these agents can be groupedinto three general categories: those that exhibit acute cytotoxic activity; those that stimulate symptomatic distress without directly causing cytotoxicity; and those that modulate neuro-ophthalmic signaling, thereby causing incapacitation, without directly injuring corneal tissues. The exquisite sensitivity of the eye to many of these agents enables the rapid appearance of ocular manifestations to serve as prodromic indicators of exposures. In the case of the CWAs that are most injurious to the eye—namely, vesicants—considerable research is still needed to identify therapeutic modalities that protect against long-term, progressive sequelae that can result in loss of vision. The ocular toxicities of the remaining agents are mild or reversible under most circumstances, and thus only temporarily incapacitating. However, one cannot discount the acute psychological distress of ocular pain or impaired vision, particularly if the causative agent is unknown and the prognosis is unclear. Thus, while most CWAs have transient and reversible effects on vision, preservation of vision remains a serious concern for a subset of potential agents.

37.1 Introduction

The skeletal muscles account for about half of a mammal's body weight, and, as a result, they receive proportionately large amounts of administered doses of chemicals. Skeletal muscle is a target organ for a variety of chemicals and toxic effects can range from minor muscle weakness or slight pain to complete paralysis. Skeletal muscles present major targets for the toxicity of organophosphate (OP) nerve agents, exceeded only by the brain. Morbidity and mortality associated with OP intoxication occur due to the effects of these compounds on skeletal muscles in general and the muscles of respiration in particular. Deaths from overdose of OPs are due in part to respiratory paralysis following depolarization of the neuromuscular blockade. Understanding the skeletal muscle system in the context of OP poisoning is essential, but it is also very complex because different muscle fiber types often respond differently, even to the same OP compound. The distinct features of slow and fast muscles are the most fascinating research aspects of skeletal muscles.

Both cholinergic and noncholinergic elements are present in the skeletal muscles, and are directly or indirectly modulated by OP nerve agents. Motor innervation plays an important role in the regulation of many properties of skeletal muscles, including neuromuscular activity. Changes in the activities of acetylcholinesterase (AChE) and choline acetyltransferase (ChAT) appear to greatly modulate neuromuscular activity and can modify neuromuscular transmission. At the cholinergic synapse, AChE plays an important role in the removal of acetylcholine (ACh) from the synaptic cleft. Inhibition of this enzyme by OP nerve agents profoundly modifies neuromuscular transmission, as seen in twitch potentiation, fasciculation, muscular weakness, and muscle cell death by necrosis or apoptosis. Because of their high metabolism, skeletal muscles are very vulnerable to OP-induced oxidative/nitrosative stress due to excess free radical generation. The importance of skeletal muscles has been recognized for decades because of their involvement in intermediate syndrome (IMS) and tolerance development related to the toxicity of OP pesticides. OP-induced effects on skeletal muscles can occur at one or multiple sites (the nerve fiber, the nerve terminal, the junctional cleft, the motor endplate, and the myofibrils). This chapter describes structural and functional aspects of skeletal muscles in the context of OP nerve agent toxicity.

37.2 Behavioral effects

Exposure to sublethal sign-producing doses of an OP nerve agent exerts prominent motor, behavioral, and autonomic symptoms. The motor symptoms are fasciculations, fibrillations, and body tremors. Fasciculations and fibrillations occur due to antidromic neural discharge from excess junctional ACh, while tremors are of a central origin (Gupta et al., 1986; Misulis et al., 1987). OP-induced behavioral studies indicate that different nerve agents [e.g., soman, sarin, tabun, and *O*-ethyl *S*-[2-(diisopropylamino)ethyl] methylphosphonothioate (VX)] require different concentrations to produce equitoxic effects, degree of AChE inhibition, and myonecrosis. Acute symptoms of equal severity in male Sprague-Dawley rats by soman, sarin, tabun, and VX can be achieved at doses of 100, 110, 200, and 12 μg/kg, administered subcutaneously (s.c.), respectively (Gupta et al., 1987a,b, 1991). Based on the equitoxic doses, VX is the most toxic and tabun is the least toxic OP nerve agent.

With an acute dose of soman (100 μg/kg, s.c.) rats exhibited signs of toxicity, such as salivation, muscle fasciculations, and severe tremors, within 5−15 min.

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00037-4

Signs of maximal toxicity appeared within 20−30 min, and persisted for about 4−6 h. Thereafter, the intensity is reduced to a mild form, but the signs of toxicity can still be observed after 24 h. Rats usually become free of overt signs after 72 h. With VX, onset of symptoms and appearance of maximal severity are delayed by approximately 20 min compared to other nerve agents (Gupta et al., 1987a,b, 1991). During peak toxicity of soman, signs such as complex posturing movements and tremors are indicative of pronounced CNS effects compared to moderate peripheral muscle fasciculations. Muscle fasciculations superimposed upon this activity are less prominent than the signs of gross motor unit activity. This is in contrast to the OP compound diisopropylphosphorofluoridate (DFP), which exerts greater peripheral activity with fasciculations and fewer central toxicity signs (Gupta et al., 1985, 1986, 1987a,b). This suggests that AChE inhibitors differ in their propensity to produce central or peripheral effects and that peripheral effects are required for muscle necrosis (Gupta et al., 1985, 1986, 1987a,b; Misulis et al., 1987).

37.3 Cholinergic system

Key elements of the cholinergic system include a neurotransmitter, ACh; an enzyme, AChE, which hydrolyzes ACh; and an enzyme, ChAT, which synthesizes ACh. All skeletal muscles contain these cholinergic components, but their quantities can significantly vary from muscle to muscle; that is, fast fiber-containing muscle has greater values than slow fiber- or mixed fiber-containing muscle.

37.3.1 Normal activity of acetylcholinesterase and its molecular forms

AChE (E.C. 3.1.1.7), in the muscle, is partly concentrated in the endplate region; that is, 20%−40% of the total amount found in the whole muscle (Hall, 1973; Younkin et al., 1982). Using a histochemical technique, Müntener and Zenker (1986) demonstrated the presence of AChE in the sarcoplasm of limited areas in sections of normal rat muscles. Normal activity of AChE varies from muscle to muscle; that is, higher AChE activity is found in fast fiber- (type II fibers in general, and type IIB fibers in particular) than in slow fiber-containing (type I fiber) muscle. Enzyme activity in mixed-fiber muscle (such as diaphragm) is found between the values of slow and fast muscles (Table 37.1). AChE plays an essential role in the removal of ACh at the neuromuscular junction (NMJ). Inhibition of AChE activity, which results in the accumulation of ACh, profoundly modifies neuromuscular transmission by producing fasciculations and twitch potentiation. At high rates of stimulation, the muscle is unable to maintain a normal contraction, and muscle hyperactivity often ensues in muscle fiber necrosis.

AChE exists in nerves and muscles in a range of globular and asymmetric molecular forms. A wide variety of sedimentation profiles have been established for AChE molecular forms in different mammalian muscles (Massoulie and Bon, 1982). The variations seen in the ratios of these molecular forms between different muscles are wide and complex. Qualitative and quantitative variations exist among different species, as well as the young versus adults (Barnard et al., 1984). In the rat extensor digitorum longus (EDL, a fast-twitch muscle), the G_1 (4S), G_4 (10S), and A_{12} (16S) molecular forms are predominant, while in the soleus (SOL, a slow-twitch muscle) and diaphragm (a mixed muscle), a fourth major molecular form is also present, called the A_8 (12S). In rat SOL, the majority of the total AChE activity is contributed by the 12S and 16S forms, whereas in the diaphragm, it is 4S and 10S, and in the EDL, it is 4S (Grosswald and Dettbarn, 1983a,b; Patterson et al., 1987) (Table 37.2).

In the rat, the 16S form is found in high concentrations at the endplates, and it is thought to be involved in neuromuscular transmission. The different molecular forms of AChE in SOL and EDL have apparent K_m values similar to that found in the diaphragm muscle (Grosswald and Dettbarn, 1983a,b). There appears to be no difference between catalytic sites of the molecular forms of AChE in fast-EDL and slow-SOL muscles, despite the different molecular form patterns and activity in these muscles.

TABLE 37.1 Normal values of AChE and BuChE activity in rat skeletal muscles.

Muscle	AChE activity (μmol substrate/g/h)	BuChE activity (μmol substrate/g/h)
EDL (fast fiber muscle)	105.8 ± 1.0	9.7 ± 0.8
Soleus (slow fiber muscle)	60.1 ± 1.2	10.3 ± 0.3
Diaphragm (mixed-fiber muscle)	78.3 ± 1.6	10.2 ± 0.2

The substrates used were acetylthiocholine iodide and butyrylthiocholine iodide for AChE and BuChE activity, respectively. Each value represents mean ± SEM ($n = 5–6$).

TABLE 37.2 Total AChE activity and percent contribution of molecular forms to total AChE activity in rat skeletal muscles.

			Molecular forms			
		Total activity	A_{12} (16S)	A_8 (12S)	G_4 (10S)	G_1 (4S)
EDL	w/ PI	93.8 ± 7.5	18.7 ± 1.8	–	26.4 ± 3.5	54.9 ± 4.1
	w/o PI	102.9 ± 4.7	18.7 ± 1.6	–	30.2 ± 2.8	51.1 ± 3.1
Soleus	w/ PI	53.6 ± 4.7	26.8 ± 1.9	33.7 ± 2.3	15.2 ± 1.0	24.3 ± 0.9
	w/o PI	61.4 ± 5.3	25.9 ± 2.2	33.0 ± 2.2	16.3 ± 1.3	24.8 ± 1.4
Diaphragm	w/ PI	81.4 ± 6.1	26.9 ± 1.4	14.2 ± 0.9	28.8 ± 0.3	30.1 ± 1.7
	w/o PI	89.5 ± 4.9	24.6 ± 1.8	14.8 ± 0.9	29.7 ± 1.7	30.9 ± 1.5

Activity values are expressed as μmol ACh hydrolyzed/g/h tissue for total activity and as a percentage of the total distribution for molecular forms. Values are the mean ± SD ($n = 6–8$ muscles); w/ PI, protease inhibitors present; w/o PI, protease inhibitors absent. No statistical significance was found comparing the presence versus absence of protease inhibitors for values of the individual molecular forms or total activities.

37.3.2 Inhibition of acetylcholinesterase and its molecular forms by nerve agents

Following an acute exposure to OP nerve agents, signs of cholinergic toxicity may appear within a few minutes and are caused by irreversible inhibition of AChE activity in neuronal tissues. Inhibition of AChE causes excess accumulation of ACh at central and peripheral synaptic sites, leading to failure of neuromuscular, respiratory, and cardiovascular functions. For some OP compounds, a close relationship exists between the severity of toxic signs and the inhibition of AChE during the acute phase of intoxication. The observable toxic effects usually do not persist for more than 4–6 h, while recovery of AChE activity occurs at a much slower rate, such as 7–14 days or even 3–4 weeks, depending on the tissue and inhibitor.

Gupta et al. (1987a) demonstrated that selective inhibition of AChE activity in skeletal muscles was apparent within 1 h of soman administration (100 μg/kg, s.c.) in rats when SOL showed the maximum inhibition (87%), whereas EDL showed the least inhibition (47%). AChE activity in skeletal muscles was maximally depressed during the following 3–6 h, the time when animals showed severe signs of toxicity. Recovery was clearly apparent during the next 3–7 days in all three skeletal muscles (SOL, EDL, and diaphragm); 7 days after soman treatment, enzyme recovery was greater than 90% in EDL and diaphragm compared to 75% in SOL. Within 1 h, all molecular forms of AChE were reduced to less than 10% of control in SOL and diaphragm (Fig. 37.1). In EDL, the 16S form, mainly localized at the NMJ, was not affected at this time, while the 10S form was completely inhibited and the 4S form was reduced to 50%. Further inhibition was seen after 24 h but even then the 16S form was the least inhibited in EDL. After 3 days of soman treatment, the AChE molecular forms in all three muscles showed signs of recovery. This was particularly evident in the 16S form in EDL and diaphragm, where it appeared to be approximately 75% of controls. In the SOL, the 16S form had recovered to only about one-third of the control when measured after 3 days; 7 days after soman, the 16 and 4S forms in the EDL and diaphragm had fully recovered. The activities of the 10S EDL form and the 10 and 12S diaphragm forms were still reduced, while in the SOL the activity of all forms remained below the control.

In similar experiments, tabun (200 μg/kg, s.c.) produced differential AChE inhibition in various skeletal muscles (SOL = diaphragm > EDL), which was similar to that seen with soman (Gupta et al., 1987a,b). The varying degrees of AChE inhibition in the skeletal muscles treated with tabun, however, correlated well with the observed difference in the number of myonecrotic lesions; that is, the greater the AChE inhibition (during the initial 24-h period), the higher the number of lesions found in the diaphragm and SOL. EDL, with a low level of AChE inactivation, had the smallest number of lesions. This observation was in agreement with a similar pattern of histochemical observations following soman and sarin administration (Meshul et al., 1985; Gupta et al., 1987a, 1991). The reason for this difference in susceptibility to a particular nerve agent may be due to: (1) variations in the location of AChE in different muscles (Grosswald and Dettbarn, 1983a), (2) changes in ACh release due to a different firing pattern (Misulis et al., 1987), and (3) pharmacokinetic variables, which influence the delivery of a particular OP compound. With tabun toxicity, inhibition and recovery of AChE molecular forms, especially the 16S form associated with the NMJ (endplate region),

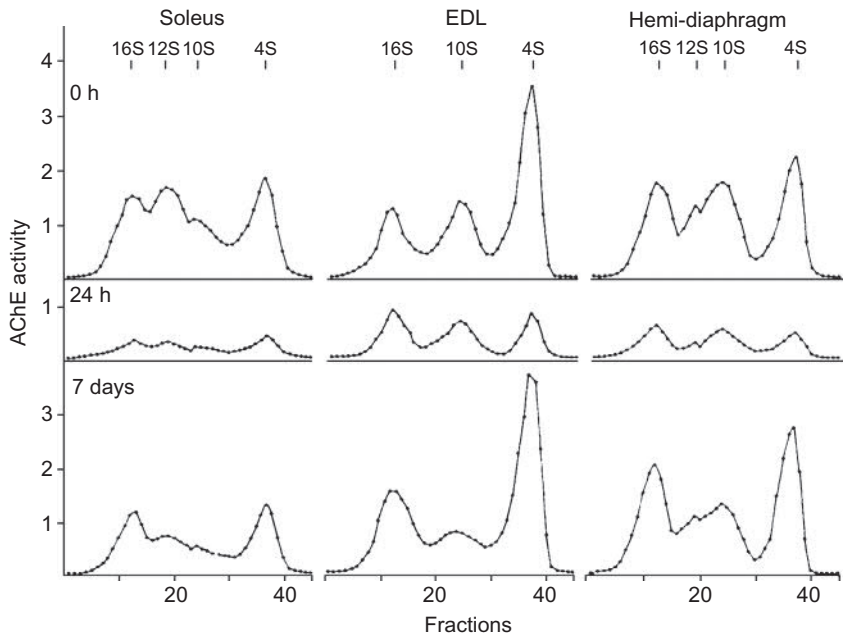

FIGURE 37.1 Representative profiles of the activity of the AChE molecular forms in the SOL, EDL, and hemidiaphragm muscles. Profiles at the top of each column are from untreated muscles, followed by profiles of activity of AChE molecular forms of muscles 24 h and 7 days after receiving an acute dose of soman (100 μg/kg, s.c.). The AChE activity scale is in arbitrary units based on the micromole substrate hydrolyzed/min by the enzyme activity in each fraction. The sedimentation values of the AChE molecular forms are given in the profiles of untreated muscles above the associated peaks. Sedimentation values were determined by the location of the added sedimentation standards, β-galactosidase (16.0S), catalase (11.1S), and alkaline phosphatase (6.1S), following velocity sedimentation of the gradients.

corresponded well with the appearance and disappearance of necrotic lesions. The delay in the molecular form's return to normal is due to the fact that the heavier molecular forms (16, 12, and 10S) are based on an assembly of the monomeric 4S form. Synthesis of the 4S form increases when the assembly of the heavier forms lags behind.

Following an acute exposure to sarin (110 μg/kg, s.c.), AChE activity in skeletal muscles was reduced to 23% in SOL and 48% in diaphragm within 1 h, while EDL AChE was significantly unaffected. By 24 h, however, a still-greater inhibition was seen for these muscles, and in EDL, AChE activity was reduced to 43%. In an early phase, recovery of AChE was rapid, but still not complete when measured after 7 days of treatment. Activities of the AChE molecular forms, after 1 h of sarin injection, were significantly depressed in the SOL and diaphragm, while those in the EDL showed significant inhibition only after 24 h (Fig. 37.2). By day 7 in SOL, activities of the 4 and 10S molecular forms of AChE had recovered to higher than control levels, while in the diaphragm, a significant shift toward the 4S molecular form had taken place so that the AChE profile resembled that of a control EDL. In EDL, the activity of 4 and 16S molecular forms recovered at a faster rate than the 10S molecular form.

Following VX administration (12 μg/kg, s.c.), within 1 h, AChE activity of all three skeletal muscles was reduced to between 8% and 17% of control with incomplete recovery by the end of 7 days. At the same time, VX caused significant inhibition in the activity of all molecular forms in all three muscles (Fig. 37.3). In EDL, the activity of 4 and 10S showed significant recovery 24 h later, while those of SOL and diaphragm remained inhibited. By day 7, the activity of all forms had recovered and an excess of activity was seen in the 4S form of EDL and diaphragm, shifting the latter profile toward that of the EDL and contributing a higher protection to the total AChE activity.

37.3.3 Butyrylcholinesterase

Butyrylcholinesterase (BuChE, E.C. 3.1.1.8) activity in skeletal muscles is significantly lower than AChE activity (Table 37.1). Also, unlike variable AChE activity, all three muscles (SOL, EDL, and diaphragm) contain equal levels of BuChE activity. Following soman administration (100 μg/kg, s.c.) in rats, maximal inhibition of BuChE activity in skeletal muscles was observed after 24 h. At this time, SOL was greatly affected (98%), followed by the diaphragm (87%) and EDL (60%). A rapid recovery of BuChE was noticed during 48−72 h after soman treatment and enzyme activity returned to baseline values when measured after day 7 (Gupta et al., 1987a).

Tabun (200 μg/kg, s.c.) caused significant inhibition of BuChE activity within 1 h in skeletal muscles (SOL, EDL, and diaphragm, 14%, 50%, and 35% remaining activity, respectively), but maximal inhibition appeared after 3 h in SOL (6% remaining activity), and after 24 h in diaphragm and EDL (7% and 11% remaining activity, respectively) (Gupta et al., 1987b). Unlike AChE, the recovery rate of BuChE appeared to be rapid, as the enzyme activity in the diaphragm and EDL recovered to baseline values by day 7. At this time, SOL BuChE activity remained significantly inhibited. After 1 h of sarin

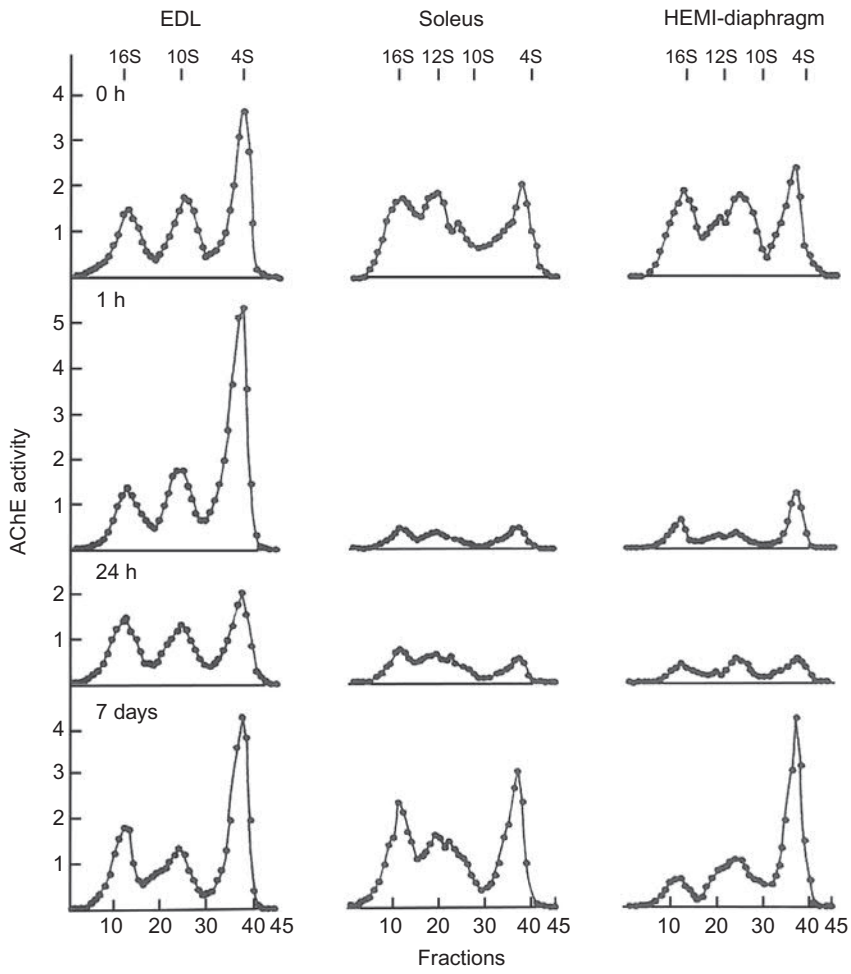

FIGURE 37.2 Representative profiles of the AChE molecular forms in the EDL, SOL, and hemidiaphragm muscles from rats following an acute sublethal injection of sarin (110 μg/kg, s.c.). Profiles at the top of each column are from untreated muscles, and subsequent profiles show the activity of the AChE molecular forms 1 h, 24 h, and 7 days, respectively, after sarin treatment. For further details, see Fig. 37.1.

administration (110 μg/kg, s.c.), BuChE activity was significantly inhibited in the SOL and EDL (78% and 79% remaining activity, respectively), but not in the diaphragm. With sarin, maximal BuChE inhibition was noted after 24 h in SOL, EDL, and diaphragm (39%, 71%, and 43% remaining activity, respectively). In similar studies, within 1 h VX (12 μg/kg, s.c.) caused significant and maximal inhibition of BuChE in all three muscles (29%, 60%, and 60% remaining activity, respectively). When measured after 24 h, EDL and diaphragm showed marked recovery, while SOL still had 41% inhibition. All three muscles showed complete recovery of BuChE when measured after 7 days.

37.3.4 Choline acetyltransferase

Existence of ChAT (acetyl-CoA-choline *O*-acetyltransferase, EC 2.3.1.6) in skeletal muscles is probably of neural origin, and its activity varies among skeletal muscles. ChAT activity can be altered by increased or decreased neuromuscular activity. It appears that neuromuscular activity exerts a regulatory influence on neuronal production of ChAT. Alterations in ChAT activity in response to variations in muscular activity represent changes in enzyme synthesis, although the effects on catabolism of the enzyme or on exoplasmic transport of enzyme to the nerve terminal cannot be ruled out. Acute exposure to DFP (1.5 mg/kg, s.c.) caused insignificant increase, while repeated administration at a low dosage (0.5 mg/kg/day for 5 days) resulted in significant increase in ChAT activity (diaphragm 140%, EDL 150%, and SOL 156%). A significant increase in ChAT activity was noted even after 2 weeks of repeated administration.

37.3.5 Acetylcholine receptors

Acetylcholine receptors (AChRs) are of two types: muscarinic (mAChR) and nicotinic (nAChR), based on the agonist activities of the natural alkaloids, muscarine and nicotine, respectively. These receptors are functionally different. The muscarinic type being G-protein-coupled receptors mediate a slow metabolic response via second

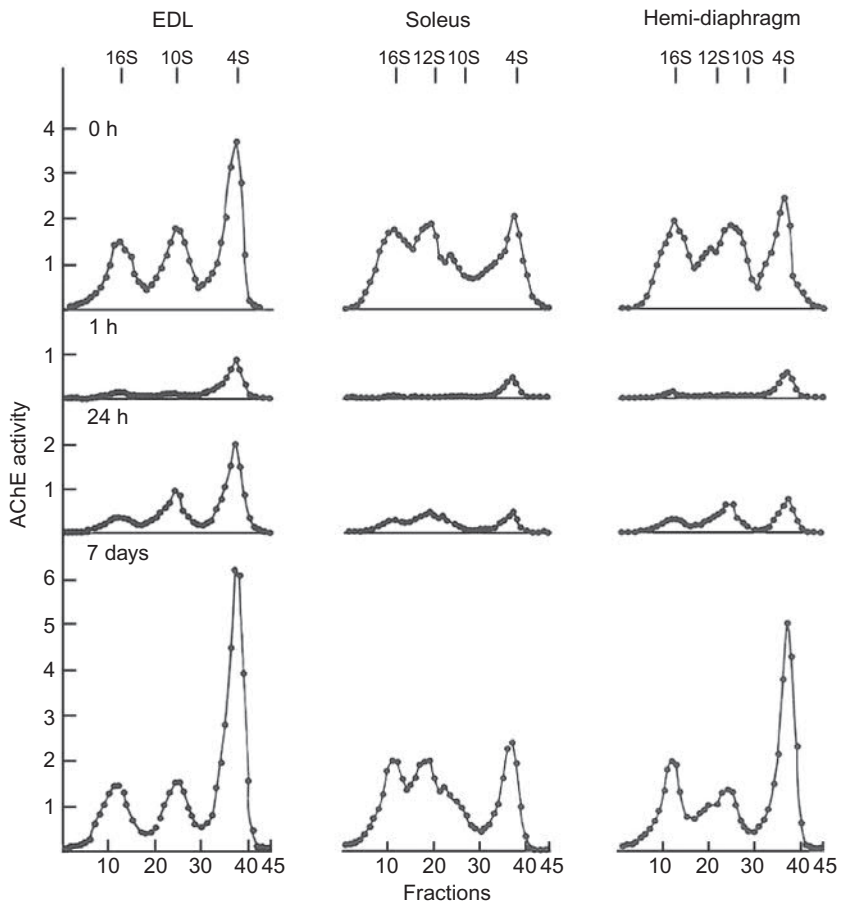

FIGURE 37.3 Representative profiles of the activity of the AChE molecular forms in the EDL, SOL, and hemidiaphragm muscles from rats following an acute, sublethal injection of VX (12 μg/kg, s.c.). For further details, see Fig. 37.1.

messenger cascades, while the nicotinic type are ligand-gated ion channels, which mediate a fast synaptic transmission of the neurotransmitter. Skeletal muscles are enriched with nAChRs and are devoid of mAChRs.

The nAChRs, with a molecular mass of 290 kDa, are composed of five receptor subunits (α, β, δ, ε, and γ) arranged symmetrically around the central pore. Adult muscle is composed of α2βαδγ, whereas fetal muscle has α2βδε (Mishina et al., 1986). Experimental studies in the late 1970s revealed that in relatively immature muscle cells, the AChRs are distributed uniformly over the entire sarcolemma (Bevan and Steinbach, 1977). At about the time of the initial innervation, aggregations/clusters of AChRs appear, in addition to the relatively low-density receptors (Braithwaite and Harris, 1979). During the course of embryonic development, the low-density receptors disappear, and almost all AChRs in the adult muscle fibers are localized to the region of the NMJ (Fambrough, 1979). Sohal and Boydston (1982) suggested that neither the total receptor content nor the ability of the receptors to cluster seems an essential element for the formation and maintenance of the morphological aspects of the NMJs or for the growth and maturation of the muscle. It is yet to be established what exactly, if any, role nAChRs have in the formation of the NMJ.

At the mammalian NMJ, where nAChRs are localized, stimulation of the presynaptic nerve causes release of the neurotransmitter ACh from the nerve terminals. Released ACh diffuses across the gap, separating nerve and muscle cells and interacts with specific receptors associated with the postsynaptic muscle membrane to produce increased membrane permeability to some cations. When two molecules of ACh bind to an nAChR, a conformational change occurs in the receptor, resulting in the formation of an ion pore. The nAChRs are a family of cationic channels whose opening is controlled by ACh and nAChR agonists and they are the key molecules in cholinergic nicotinic transmission at the NMJ. At this site, the opening of a pore produces a rapid increase in the cellular permeability of Na^+ and K^+ ions, resulting in the depolarization and excitation of the muscle cell, thereby producing a muscular contraction. Adult vertebrate muscle fibers are highly

sensitive to ACh only in the region of the NMJ. Muscle fibers of fetal and neonatal rats are also sensitive to ACh in regions outside the NMJ.

Excessive ACh or long-acting cholinomimetic agents can produce muscle paralysis due to prolonged depolarization of the endplate, a phenomenon referred to as depolarization block. Prolonged transmitter (ACh) receptor (nAChR) interactions, as a result of the high concentrations of accumulated ACh, produce a depolarization block, similar to that seen with agents such as decamethonium. Furthermore, there is a possibility of the same postjunctional area being activated repeatedly, resulting in desensitization of receptors (desensitization block). These forms of neuromuscular block usually produce muscle weakness and paralysis.

The binding site for cholinergic effectors is believed to reside primarily in the α-subunits. Evidence for this fact is based on affinity-labeling experiments in which analogs of ACh [bromoacetylcholine and 4-(-*N*-maleimidophenyl) trimethylammonium] have been shown to label only the α-subunits. Receptors also demonstrate high-affinity binding of the polypeptide α-neurotoxins, such as α-bungarotoxin (αBT), which interacts specifically and in an essentially irreversible manner with nAChRs. At the nAChRs, αBT competes for binding with both cholinergic agonists (e.g., carbamylcholine chloride and decamethonium bromide) and antagonists (e.g., curare) Berg et al. (1972) reported binding of αBT to AChRs in rat diaphragm muscle and found that 90% of the binding that occurred was "endplate-specific."

Some of the toxic effects of OP nerve agents and pesticides are unrelated to inhibition of AChE. However, the exact mechanism by which OP nerve agents and other anti-AChE compounds affect nAChRs is yet to be elucidated. Some of the biochemical and morphological alterations have been attributed to an excess amount of ACh in the synaptic cleft resulting from AChE inactivation. Many anti-AChE agents have been shown to produce postsynaptic morphological, biochemical, and electrophysiological alterations in adult mammalian skeletal muscle after acute and long-term treatment (Fenichel et al., 1972; Laskowski et al., 1977; Hudson et al., 1978). Normally, at the motor endplate, the small electrical nerve impulse releases ACh, which diffuses across the synaptic membrane and attaches to the postsynaptic receptors on the muscle membrane. However, during AChE inhibition by OPs, unhydrolyzed ACh does not diffuse from the cleft, but repeatedly combines with postsynaptic receptors. The prolonged presence of ACh in the synaptic area appears to cause some of the myopathic changes. This was supported by observations of paraoxon, causing antidromic firing and increasing spontaneous miniature endplate potential (MEPP) frequency to 38 times the control rates (Laskowski and Dettbarn, 1971).

Gupta et al. (1986) demonstrated that an acute exposure to DFP (1.5 mg/kg, s.c.) changed neither nAChR density (B_{max}) nor the affinity constant (K_D) in the diaphragm muscle. Subchronic DFP treatment (0.5 mg/kg/day, s.c., for 5 days) caused a marked decrease in B_{max} (56%), without a significant change in K_D. Chronic treatment with anti-AChEs reduced the total number of nAChRs by 42%−45% in the endplate region (Chang et al., 1973). Later studies revealed that in sublethal doses, OPs induce symptoms that cannot be solely attributed to AChE inhibition, indicating a direct interaction with postsynaptic nAChRs (Menking et al., 1990). Tattersall (1990) investigated the effects of DFP, sarin, soman, VX, and echothiophate on the nAChR ion channel at the adult mouse muscle endplate by using single-channel recording techniques. DFP, sarin, and soman had no effect on open times at concentrations up to 100 μM, but echothiophate and VX were found to have voltage- and concentration-dependent, open-channel blocking at concentrations of 1−50 μM. In similar experiments, Bakry et al. (1988) demonstrated that OP nerve agents and echothiophate bind to AChRs, inhibit or modulate binding of radioactive ligands to these receptors, and modify events regulated by them. The OPs also bound to allosteric sites on the nAChR (identified by inhibition of ^{3}H-phencyclidine bonding), but some bound also to the receptor's recognition site (identified by inhibition of ^{125}I-αBT binding). Soman and echothiophate in micromolar concentrations acted as partial agonists of the nAChR and induced receptor desensitization. On the other hand, VX acted as an open-channel blocker of the activated receptor and also enhanced receptor desensitization. Membrane fragments from torpedo electric organs were used to determine these interactions using ^{3}H-phencyclidine as a probe. The results were consistent with the hypothesis that OPs bind to, and irreversibly phosphorylate, an allosteric site on the ion channel associated with the nAChR.

In the context of OP toxicities, it needs to be emphasized that for a normal muscle contraction, the ratio of AChE to nAChRs is crucial in determining the minimum AChR density. Since the AChE recovers at almost the same rate as do the AChRs, a balance of AChE to AChR is maintained over the postsynaptic surface during recovery. A relatively constant ratio of AChE to AChR is very important for maintaining normal neuromuscular function.

37.4 Noncholinergic system

37.4.1 Muscle excitotoxicity

Involvement of the cholinergic neurotransmitter ACh in muscle excitotoxicity has been known for a long time.

There is also mounting evidence showing the presence of glutamatergic machinery (receptors, transporters, and glutamate itself) at the NMJ (Pinard and Robitaille, 2008). It has been suggested that glutamate and ACh are coreleased at the NMJ. Glutamate might be a mediator or modulator of neuromuscular transmission. Glutamate receptors present at the NMJ are predominantly an *N*-methyl-D-aspartate (NMDA) subtype. Furthermore, it was demonstrated in in vivo studies that a noncompetitive NMDA receptor (NMDAR) antagonist, known as memantine, blocks muscle fasciculations induced by AChE inhibitors (DFP, soman, sarin, tabun, and VX), suggesting an involvement of NMDARs (Gupta and Dettbarn, 1992; McLean et al., 1992). Of course, memantine exerts several additional pharmacological actions, including nAChR blockage. Unlike the well-understood role of cholinergic excitotoxicity, the role of glutamate excitotoxicity is yet to be established in AChE inhibitor-induced muscle toxicity.

37.4.2 Oxidative/nitrosative stress

Although the exact mechanism underlying skeletal muscle damage by OP nerve agent-induced hyperactivity still remains unclear, evidence clearly indicates that free radicals play an important role. During normal conditions, free radicals are generated at a low rate and subsequently taken care of by the well-developed scavenger and antioxidant systems. However, during exhaustive hyperactivity of the skeletal muscles caused by anti-ChE, excessive amounts of reactive oxygen species (ROS) and reactive nitrogen species (RNS) (hereafter referred to collectively as ROS) are generated and exceed the capacity of the muscle defense system, thus producing oxidative stress. Excessively generated ROS can cause muscle injury by reacting with cellular components, such as membrane phospholipids, mitochondrial enzymes/proteins, and nucleic acids. Consequently, this leads to skeletal muscle cell apoptosis/necrosis, inflammation, and loss of cell viability.

A causal relationship appears to exist between excitotoxicity, ROS, lipid peroxidation, and muscle cell injury/death. One of the well-recognized targets of ROS-induced injury is peroxidation of lipids and the formation of prostaglandin F_2-like compounds, such as F_2-isoprostanes (F_2-IsoPs) (Milatovic et al., 2019). Studies have shown that the assay of these compounds provides an accurate measure of lipid peroxidation (Roberts and Morrow, 2000; Dettbarn et al., 2001). Quantification of F_2-IsoPs and nitric oxide (NO) in skeletal muscles (SOL, EDL, and diaphragm) has provided strong evidence that AChE inhibitor-induced toxicity initiates lipid peroxidation and muscle cell injury (Dettbarn et al., 2001; Gupta et al., 2001a,b; Milatovic et al., 2001). Yang and Dettbarn (1998) found a significant increase of F_2-IsoPs in diaphragm muscle (156%) 1 h after DFP injection (1.7 mg/kg, s.c.), when muscle hyperactivity was maximal.

The primary reason for the increased generation of ROS appears to be a decreased rate of ATP synthesis in the mitochondria, which is related to a loss of cytochrome oxidase (COX) activity. COX is the terminal complex in the mitochondrial respiratory chain, which generates ATP by oxidative phosphorylation. During intense muscle hyperactivity, the activity of COX is reduced, leading to an increase in the electron pressure within the electron transport chain and to increased ROS production (Yang and Dettbarn, 1998). More than 90% of O_2 consumption in the cells is catalyzed by COX. The chance of intermediary products, such as superoxide anion, hydrogen peroxide, and the hydroxyl radical, escaping is small under conditions where COX remains active. A reduced capacity of this enzyme, however, increases the risk for an incomplete reduction of O_2 and further O_2 radical formation.

Xanthine oxidase (XO) is another enzyme that contributes to increased ROS generation. During normal conditions, 80%–90% of native XO exists as xanthine dehydrogenase (XD), but during metabolic stress and increased Ca^{2+}, XD is converted to a reversible oxidase form. XO uses molecular O_2 instead of NAD^+ as an electron acceptor. Molecular O_2 is thereby reduced and the superoxide radical (O_2^-) is formed. During hyperactivity of the muscle by AChE inhibitors, regeneration of ATP is insufficient, not due to the lack of O_2, but due to greater utilization and impaired synthesis of ATP (Gupta et al., 1994, 2000a,b, 2001a, 2002). Unlike ischemia, O_2 is present during oxidative stress caused by prolonged contractile activity. This suggests that subsequent to the conversion of XD to XO, O_2 is continuously univalently reduced to superoxide anions. This occurs during oxidative stress when ATP utilization exceeds the rate of ATP synthesis during increased muscle activity. Yang and Dettbarn (1998) provided direct evidence for the role of COX and XO in muscle injury by its hyperactivity, showing that during DFP-induced muscle hyperactivity, a decrease in COX activity and an increase in XO activity occurred. The NAD(P)H oxidases can also be the major O_2^--generating sources in contracting skeletal muscle (Sakellariou et al., 2014). Blockage of muscle fasciculations prevented these enzyme changes.

Another ROS contributing to oxidative stress is peroxynitrite ($ONOO^-$), which is formed by the reaction of NO with superoxide (O_2^-). $ONOO^-$ has the potential to modify biomolecules through several different mechanisms and is a good candidate for mediation of the NO-dependent pathophysiological process. Under normal conditions, NO is widely regarded as a multifunctional messenger/signaling molecule and is thought to have two

physiological functions in skeletal muscle. The first is to promote relaxation through the cGMP pathway, and the second is to modulate muscle contractility that depends on reactive oxygen intermediates. At the NMJ, NO appears to be a mediator of: (1) early synaptic protein clustering, (2) synaptic receptor activity and transmitter release, and (3) downstream signaling for transcriptional control (Blottner and Luck, 2001). NO has also been demonstrated to modulate excitation−contraction coupling in the diaphragm muscle (Reid et al., 1998). Within skeletal muscle cells, all three known nitric oxide synthase (NOS) isoforms (neuronal, nNOS; endothelial, eNOS; and inducible, iNOS) are present, but nNOS, which is Ca^{2+} dependent, seems to predominate, and is concentrated at the sarcolemma and postsynaptic surface of the NMJ (Stamler and Meissner, 2001). In a recent study, NOS has been demonstrated to play the role of mechanosensor in skeletal muscle fibers (Smith et al., 2002). Neuronal NOS in skeletal muscles is involved in the regulation of metabolism and muscle contractility. Kobzik et al. (1994) reported for the first time that the NOS activity of individual muscles could be correlated primarily with type II fibers (being highest in the EDL), while Frandsen et al. (1996) found the distribution of nNOS homogeneous.

Data presented in Table 37.3 show the levels of citrulline (determinant of NO/NOS) in skeletal muscles of control rats and those treated with an acute dose of DFP (1.5 mg/kg, s.c.). In control muscles, markedly higher citrulline levels were found in the SOL, followed by the EDL and diaphragm. The observed higher level of NO in the SOL could be due to a greater activity of NOS. Within 1 h of DFP exposure, when rats exhibited signs of peak severity and maximal reduction of AChE activity (90%−96%), the levels of citrulline were maximally increased (272%−288%), and remained significantly elevated in all three muscles (>twofold) when measured after 2 h. The finding of elevated NO by DFP-induced muscle hyperactivity (Gupta et al., 2002) was supported by previous studies showing that increased muscle contractility generates significantly greater quantities of ROS/RNS (Yang and Dettbarn, 1996; Clanton et al., 1999). A significant increase in NO is known to cause the inhibition of mitochondrial function and thereby appears to be the cause of the impaired synthesis of ATP.

37.4.3 High-energy phosphate depletion and myonecrosis

The interest in the role of energy metabolites (especially ATP) in chemical-induced mitochondrial cytotoxicity has been reinvigorated, since ATP appears to be a switch to decide whether cells die from apoptosis or necrosis. Muscle necrosis is probably caused by increased contractile activity in individual muscle fibers. Ca^{2+} is believed to regulate mitochondrial oxidative phosphorylation, thereby contributing to the maintenance of cellular energy homeostasis (Glancy et al., 2013). In normal cells, the mitochondrial Ca^{2+} content is relatively low compared to that in the cytoplasm. However, abnormally high cytosolic Ca^{2+} levels (due to NMDAR activation and impaired Ca^{2+} extrusion, which is an energy-dependent process) perturb many cellular processes. The major changes include: (1) reduced COX activity, (2) increased XO activity, (3) mitochondrial damage due to excessive mitochondrial Ca^{2+} accumulation, (4) reduced ATP synthesis, and (5) increased production of O_2^- and NO^-, resulting in increased $OONO^-$ formation. The extreme vesiculation and disruption of the sarcoplasmic reticulum (SR) under the endplate, as well as the swollen mitochondria may reflect Ca^{2+} overloading of the muscle Ca^{2+}-binding capacity, which could result in high sarcoplasmic Ca^{2+} levels, which in turn leads to necrosis (Salpeter et al.,1982). The control of intracellular Ca^{2+} concentration is of great importance to muscle fibers, and a transient rise leads to contraction. An increased net influence of Ca^{2+} forces the mitochondria and SR to maintain Ca^{2+} homeostasis by sequestering the excessive amounts of this ion. This is an energy-consuming process and occurs in preference to ATP formation. The ensuing lack of energy ultimately causes the free sarcoplasmic Ca^{2+} to rise and

an excessive ROS formation, leading to necrosis. The energy required for muscle contraction is derived from the breakdown of ATP. As soon as ATP is broken down, it is promptly restored in the so-called Lohmann reaction at the expense of phosphocreatine (PCr).

Data of high-energy phosphates (i.e., ATP and PCr) and their metabolites in the skeletal muscle of control rats and those treated with an acute dose of DFP (1.5 mg/kg, s.c.) are shown in Table 37.4. Analyses of control muscles revealed the levels of ATP and PCr to be higher in the EDL, followed by the diaphragm and the SOL. The values of energy charge potential (ECP = ATP + 0.5ADP/TAN) in SOL, EDL, and diaphragm were 0.86 ± < 0.01, 0.91 ± < 0.01, and 0.86 ± < 0.01, respectively. At the time of maximal severity (i.e., 1 h after DFP exposure), the levels of ATP, total adenine nucleotides (TAN = ATP + ADP + AMP), PCr, and total creatine compounds (TCC = PCr + Cr) were maximally reduced in all three muscles, and they remained reduced to the same degree after 2 h. Similar results were found with soman toxicity.

Depletion of energy-rich phosphates (ATP and PCr) by AChE inhibitors occurs due to impaired synthesis and greater utilization of ATP during muscle hyperactivity. In fact, the time course of necrosis correlates with the reduced levels of PCr, the reduction of which may have been the result of an increased demand for energy and a low rate of ADP phosphorylation, caused by an increased level of sarcoplasmic Ca^{2+}. AChE inhibitor-induced increases in NO (Table 37.3) can exert cellular toxicity primarily by depleting energy stores through multiple mechanisms: (1) by prolonging poly-(ADP-ribose) polymerase activation; (2) by inhibiting mitochondrial enzymes, such as COX, aconitase, and creatine kinase (CK); and (3) by inhibiting the glycolytic enzyme phosphofructokinase. NO, at nanomolar concentrations, can directly and specifically inhibit mitochondrial respiration by competing with molecular O_2 for binding to COX, thereby causing an inhibition of ATP synthesis (Brown and Cooper, 1994). Other factors that contribute to the decline of energy metabolites may include damage to mitochondria, a higher rate of ATP utilization needed to generate NAD^+ in the ADP-ribosylation of nuclear proteins, enhanced influx of sarcoplasmic Ca^{2+}, an increased number of contractile protein cross-bridges, and the release of ATP in concert with ACh from the nerve terminals. The net effect of AChE inhibitor-induced muscle hyperactivity is a reduced cellular energy level.

37.5 Muscle activity—electromyography

AChE inhibitors (DFP, 1.5 mg/kg, s.c.; or soman, 100 μg/kg, s.c.) at a toxic sign-producing sublethal dose elicit prominent motor, behavioral, and autonomic symptoms. As mentioned earlier, the motor symptoms are fasciculations, fibrillations, and body tremors. Fasciculations and fibrillations are due to

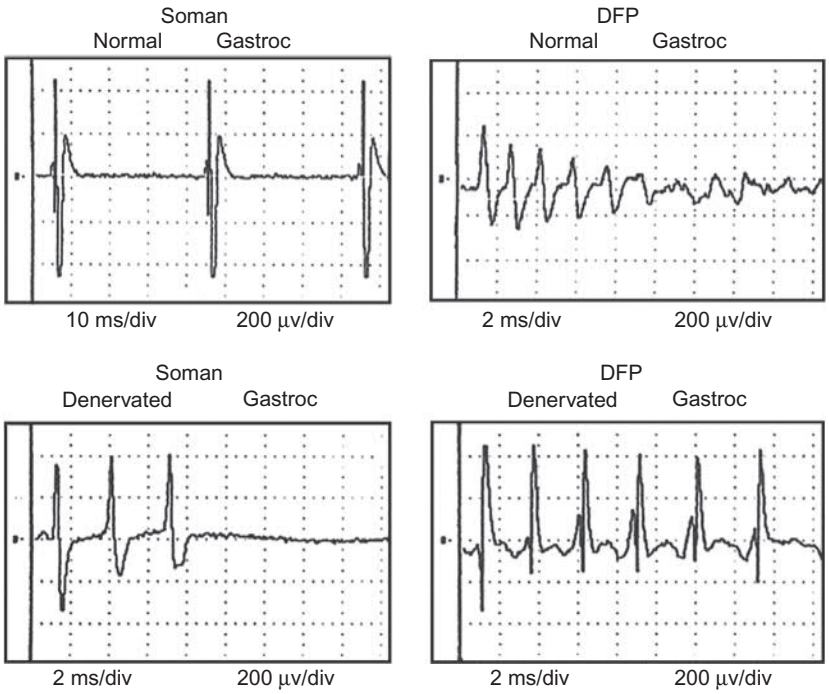

FIGURE 37.4 EMG recordings from normal and acutely denervated lateral gastrocnemius in response to soman (100 µg/kg, s.c.) or DFP (1.5 mg/kg, s.c.). Left, soman; right, DFP; top, non-denervated muscle; bottom, denervated muscle. Note the difference in time base and voltage scale. The differing morphology of the normal DFP waveform occurs due to electrode orientation and distance from the muscle fiber and does not represent a systematic difference between the effects of individual agents.

antidromic neural discharge from excess junctional ACh, while tremors are of a central origin. Misulis et al. (1987) demonstrated a difference in the pattern of motor symptoms in rats treated with soman or DFP. Soman produces complex posturing movements and tremors affecting virtually the entire body, while DFP produces movements that are similar to fasciculations or myokymia. Muscle fiber necrosis is also more frequent at symptom-producing doses of DFP than equivalent doses of soman. This suggests that the AChE inhibitors differ in their propensity to produce central or peripheral effects and that peripheral effects are required for muscle necrosis.

Electromyographic (EMG) findings indicate that soman and DFP produce different responses (Fig. 37.4). The majority of the motor symptoms induced by soman are due to impulses descending from the CNS, and a proportion of these symptoms are epileptiform activity. This activity is not generated at spinal levels. In contrast, DFP produces motor symptoms mainly by peripheral action that depends on a functioning nerve terminal (Misulis et al., 1987). Anderson (1987) also demonstrated that DFP and soman have opposite effects on skeletal muscle contracture during tetanic stimulation. DFP significantly decreased the ability of rat skeletal muscle to maintain a contracture. Soman, on the other hand, increased muscle force in a frequency-dependent manner. The opposite actions of DFP and soman on muscle contractility might be the consequence of a difference in effects of these two agents on postsynaptic muscle ACh receptors. The finding of Anderson (1987), which indicated an increase in contracture following soman, was somewhat surprising in view of the work of Dettbarn (1984) and Gupta et al. (1987a,b), who reported that soman is as effective as other AChE inhibitors in producing muscle necrosis (Table 37.6). However, Meshul et al. (1985) reported that soman appears to spare motor endplates from structural damage and thereby may account for maintaining muscle function (Anderson, 1987). Thus, different AChEIs can produce opposite effects on muscle contracture.

37.6 Muscle fiber histopathology

By using actomyosin ATPase reaction, analysis of untreated rat SOL revealed predominantly type 1 fibers with a few type 2A and 2B fibers. In contrast, EDL is composed predominantly of type 2 fibers with few type 1 fibers. The total fiber numbers are approximately 1800 in SOL and 2500 in EDL (Gupta et al., 1989).

OP pesticides and nerve agents and some carbamates in a single sublethal dose are known to cause fasciculations and induce myopathy (histopathological changes) in the diaphragm, SOL, EDL, sternomastoid, gastrocnemius, triceps, and tibialis of experimental animals. Pathological changes in skeletal muscles by AChE inhibitors are observed in the region adjacent to the motor endplate. Patterson et al. (1987) determined the necrotic lesions by assessing endplates in skeletal muscles of rats acutely intoxicated with DFP (1.5 mg/kg, s.c.). In SOL, these are found only in the midsection of the muscle, while in EDL, the endplates are found throughout the muscle

TABLE 37.5 Number of necrotic fibers following a single sublethal injection of DFP (1.5 mg/kg, s.c.).

Time after DFP administration	Soleus		EDL		Diaphragm	
	AChE	Lesions	AChE	Lesions	AChE	Lesions
Control	100%	0	100%	0	100%	0
1 day	24%	27 ± 6[a]	17%	64 ± 11[a]	13%	308 ± 58[a]
2 day	24%	39 ± 9[a]	14%	71 ± 12[a]	13%	333 ± 63[a]
3 day	39%	5 ± 1[a]	31%	49 ± 5[a]	25%	174 ± 35[a]
7 day	65%	0	53%	0	69%	0

Values of AChE activity are expressed as % remaining activity of control (100%); numbers of lesions are presented per cross section from the mid-belly region of muscle; data are presented as the means ± SEM ($n = 5–10$).

TABLE 37.6 Necrotic fibers in skeletal muscles of rats following a sublethal dose of soman, sarin, tabun, or VX.

Time (posttreatment)	Muscle	Number of lesions/1000 fibers			
		Soman (100 μg/kg, s.c.)	Sarin (110 μg/kg, s.c.)	Tabun (200 μg/kg, s.c.)	VX (12 μg/kg, s.c.)
1 h	DIA	0	9 ± 1	6 ± 2	26 ± 5
	SOL	0	12 ± 4	9 ± 2	16 ± 3
	EDL	0	0	0	0
6 h	DIA	3 ± 2	100 ± 30	48 ± 12	233 ± 45
	SOL	13 ± 3	111 ± 38	21 ± 4	97 ± 17
	EDL	0	0	0	23 ± 10
24 h	DIA	260 ± 48	435 ± 154	302 ± 32	322 ± 49
	SOL	48 ± 9	101 ± 24	66 ± 14	99 ± 20
	EDL	1 ± 0	103 ± 45	33 ± 5	28 ± 14
3 days	DIA	74 ± 24	490 ± 66	541 ± 31	305 ± 78
	SOL	9 ± 3	135 ± 42	192 ± 29	186 ± 37
	EDL	0	18 ± 17	66 ± 12	79 ± 16
7 days	DIA	0	216 ± 69	40 ± 10	75 ± 12
	SOL	0	237 ± 61	28 ± 4	62 ± 7
	EDL	0	30 ± 11	3 ± 1	27 ± 11

Value are means ± SEM of necrotic lesions ($n = 5$).

length. In EDL, the fibers are innervated at different levels throughout the length of the muscle, while in SOL, the nerve makes functional contact just in the midsection. No endplates or lesions are found outside this area. Gupta et al. (1985, 1986) found the highest number of lesions in all three muscles (diaphragm, SOL, and EDL) of rats within 24–48 h after a single injection of DFP (1.5 mg/kg, s.c.), when the inhibitory effect on AChE activity was also maximal (Table 37.5). The diaphragm muscle had the highest number of lesions, followed by the EDL and SOL.

Data on soman- (100 μg/kg), sarin- (110 μg/kg), tabun- (200 μg/kg), and VX = induced (12 μg/kg) pathological changes in skeletal muscles of rats are presented in Table 37.6. Following soman treatment, the number of necrotic fibers in the SOL and the diaphragm was found

to increase for up to 24 h, and no new lesions appeared thereafter. By day 7, these two muscles appeared to have fully recovered from the soman effect. In EDL, no morphological changes were seen at any time. While the acute toxic effects of tabun are more or less similar to soman, there are also some significant differences between these two agents. Unlike soman, tabun caused prolonged AChE inhibition and progressive development of muscle necrosis over a period of 3 days. While the primary toxic effect of tabun occurs due to inhibition of AChE activity, some of the differences seen in regard to other nerve agents may be due to additional actions of the cyanide group that is released during AChE inhibition. The inhibitory effect of CN on oxidative metabolism could result in reduced de novo synthesis, delaying synthesis of AChE, and prolonged inhibition of Ca^{2+} sequestration into the SR of skeletal muscles. Therefore, in the context of OP nerve agent-induced myopathy, soman, sarin, tabun, or VX caused the greatest number of lesions in the diaphragm, followed by the SOL, and then in the EDL during the first 24–48 h (Gupta et al., 1987a,b, 1991). With all four OP nerve agents, the greatest number of lesions occurred in animals exhibiting severe muscle fasciculations (Gupta et al., 1986, 1987a,b, 1991; Inns et al., 1990; Bright et al., 1991). By day 7, muscles recovered from soman-induced myopathy, but not from any other nerve agents since the necrotic lesions were still evident.

The earliest lesions are focal areas of abnormality in the subjunctional section of the muscle fiber adjacent to the motor endplate, including eosinophilia and sarcoplasmic swelling (Laskowski et al., 1977; Gupta et al., 1985, 1986; Patterson et al., 1987). Mitochondria are disrupted as evidenced by clumping of highly reactive material of lactate dehydrogenase (LDH) and reduced nicotinamide adenine dinucleotide reactions. These focal changes progress to a breakdown of subjunctional fiber architecture, loss of striations, and then phagocytosis. Longitudinal sections reveal that necrosis affects only a small segment of fiber lengths. During the latter stages, progressively greater lengths of muscle fibers are affected (Gupta et al., 1986; Patterson et al., 1987). Serial cross sections of 10 μm thickness indicate that the number of lesions correlates with the greatest density of endplates (Patterson et al., 1987). The longer the lag between injection and sacrifice, the greater the extent of the lesions. A significant increase in blood CK activity coincides with the appearance of myonecrosis, indicating destruction of the muscle membrane (Sket et al., 1989; Gupta et al., 1991, 1994).

Subjunctional changes in the muscle fibers, such as supercontraction of subjunctional sarcomeres, as well as disruption of cytoarchitectural organization, are always present (Gupta et al., 1986, 1987a,b, 1991; Inns et al., 1990; Bright et al., 1991). The initial changes are in the mitochondria which first swell and then show lysis of the central cristae. Myelin figures beneath the endplate are frequently observed, while the region more distal to the endplate is less affected. The nucleoli of the muscle cell nuclei are enlarged and move to the periphery of the nucleus. This myopathy can be induced with OP prototype DFP (Gupta et al., 1986; Misulis et al., 1987; Patterson et al., 1987, 1988; Sket et al., 1991a,b), or the OP nerve agents soman, sarin, tabun, and VX (Gupta et al., 1987a,b, 1991; Inns et al., 1990; Gupta and Dettbarn, 1992).

Laskowski et al. (1975) reported ultrastructural changes in the subsynaptic folds that were quite varied, even between muscle fibers from the same diaphragms of rats acutely treated with paraoxon. The fact that some endplates were totally degenerated after 2 days of paraoxon treatment, while others appeared almost normal even after 5 days, indicates that some endplates are more resistant than others. The most consistent change at the endplates was the presence of vesicular structures in the synaptic clefts. Some regions of the subsynaptic folds contained varying sizes of vacuoles and vesicles. There appears to be a wide variation in the severity of the lesions in the subsynaptic folds even in the same muscle. After 2 days of paraoxon treatment, the muscle surrounding the motor endplate often showed less cytoarchitectural organization than control muscles. Myelin figures beneath the endplate were frequently observed, while the region of muscle distal to the endplate was less severely affected.

Regardless of the diversity in OP structures, it is evident that induced myopathy is dose-dependent and rests on both a critical duration and degree of AChE inhibition. The higher number of necrotic lesions found with faster rates of AChE inactivation indicates the involvement of ACh in the generation of myopathy (Wecker et al., 1978a,b; Gupta et al., 1986, 1987a,b, 1991). Regardless of the OP involved, AChE inhibition of more than 80% for about 2 h is necessary to initiate severe muscle fiber necrosis. AChE inhibition resulting in an excess of ACh and its prolonged functional interactions with the nAChRs are responsible for producing lesions. However, some anticholinesterase (anti-ChEs) agents have been shown to interact directly with the nicotinic receptors (Tattersall, 1990, 1992). The OP compounds acting directly on postsynaptic membranes or on components of the muscle cell were also considered in the etiology of myopathy (Laskowski and Dettbarn, 1971). However, the prior injection of either tubocurarine or α-bungarotoxin can prevent development of the myopathy and indicates that neither the OP per se nor ACh by itself causes the damage; rather, the damage is due to changes in transmitter–receptor interaction. Tubocurarine and α-bungarotoxin, by occupying

the postjunctional receptors, prevent the ACh from interacting with the receptor. The primary defect is at both presynaptic and postsynaptic sites. This not only supports the concept of an abnormal neurotrophism as a mechanism of myopathy, but also allows the possibility that the primary defect is in the cholinergic system of nerve and muscle.

Evidence for the involvement of locally elevated levels of ACh was confirmed since denervation prevented myopathy or nAChR blockade with α-bungarotoxin (Wecker and Dettbarn, 1976; Dettbarn, 1984). It was clearly demonstrated that transection of the phrenic nerve to the rat hemidiaphragm prevented myopathic development, while in the contralateral innervated hemidiaphragm, the number of lesions increased. Thus, the common denominator is muscle hyperactivity, such as fasciculations (Gupta et al., 1986, 1987a,b, 1991; Adler et al., 1992). The longer the muscle hyperactivity lasts, the greater the number of necrotic muscle fibers found.

There is ample evidence that ACh accumulation is involved in causing Ca^{2+} influx into skeletal muscle fibers during anti-ChE poisoning. Experiments with sarin (25−150 μg/kg, s.c.) in mice revealed a similar role of Ca^{2+} in muscle fiber damage (Inns et al., 1990). Ca^{2+} increase was found in the diaphragm of those mice to which sarin had been administered at doses of 50 μg/kg or above. Ca^{2+} accumulation, which was confined to the region of the motor endplates, occurred earliest and remained the longest in the diaphragm from those animals receiving the highest doses of sarin. Generally, Ca^{2+} accumulation can be detected on day 1 after injection and none after day 7. This observation coincides with the duration of appearance and disappearance of muscle lesions. It was suggested that Ca^{2+} is among a series of events that ultimately lead to myonecrosis. Mitochondrial damage by excessive Ca^{2+} is expected to cause a partial or complete depletion of ATP synthesis and consequently excessive generation of oxygen- and nitrogen-free radicals and eventually myotoxicity (Gupta and Dettbarn, 1987, 1992; Gupta et al., 2001a,b, 2002). Taken together, following an acute exposure to an OP compound at a higher dose, a causal relationship exists between a critical level of AChE inhibition, Ca^{2+} accumulation, depletion of ATP, and appearance of muscle fiber necrosis.

Chronic exposure (30−60 days) of rats to paraoxon, at doses (0.05−0.1 mg/kg, s.c./day) that do not produce parasympathomimetic effects, led to necrosis of muscle fibers in diaphragm muscle, which was qualitatively similar to that following the administration of a single high dose of paraoxon (0.23 mg/kg, s.c.). The lesion was characterized by the presence of central nuclei, fiber splitting, and breakdown of fiber architecture followed by phagocytosis and necrosis. With either dose, AChE inhibition occurred in the endplate regions, not in the nonendplate regions (Wecker and Stouse, 1985).

37.7 Muscle cytotoxicity biomarkers

37.7.1 Creatine kinase and creatine kinase isoenzymes

CK catalyzes the synthesis of ATP and PCr in a reverse Lohmann reaction. Normal distribution of CK and its isoenzymes in the skeletal muscle of untreated control male Sprague-Dawley rats is shown in Table 37.7. The findings revealed that the fast-muscle EDL had the maximal CK activity, followed by diaphragm, with the lowest in the SOL. Electrophoretic separation of CK isoenzymes in all three muscles revealed the existence of only CK-MM isoenzyme. Further separation of CK-MM isoenzyme for subforms showed only CK-MM3 in all three muscles. Compared to muscles, serum had very little CK activity; however, the CK consisted of three distinct isoenzymes: CK-BB (15.3%), CK-MB (3.9%), and CK-MM (80.8%).

TABLE 37.7 Normal distribution of CK and CK isoenzymes in skeletal muscles and serum of rats.

	Total CK	CK isoenzymes		
		CK-BB (CK-1)	CK-MB (CK-2)	CK-MM (CK-3)
Soleus	2,062,800 ± 71,065 (100)	ND	ND	2,062,800 ± 71,065 (100)
EDL	4,659,125 ± 185,583 (100)[a,b]	ND	ND	4,659,125 ± 185,583 (100)[a,b]
Diaphragm	3,018,240 ± 110,777 (100)	ND	ND	3,018,240 ± 110,777 (100)
Serum	3769 ± 240 (100)	576 ± 45 (15.3)	148 ± 17 (3.9)	3086 ± 209(80.8)

Values expressed in terms of IU/L are presented as means ± SEM ($n = 4–6$); numbers in parentheses are percentages of isoenzymes to total CK activity (100%); ND, none detected.
[a] *Significant difference between EDL and soleus* ($P < .001$).
[b] *Significant difference between EDL and diaphragm* ($P < .001$).

Further electrophoresis of the serum CK-MM isoenzyme revealed the presence of three subforms: CK-MM1 (6.3%), CK-MM2 (24%), and CK-MM3 (69.7%) (Gupta et al., 1994). Literature abounds showing that the CK-MM3 subform secretes from muscles into the plasma, where it converts into the MM2 and MM1 subforms by carboxypeptidase-N2 (CPN-2).

Within 1 h of exposure to carbofuran (1.5 mg/kg, s.c.), CK activity was significantly reduced in the SOL, while it increased in the diaphragm. At the same time, activities of CK and all three CK isoenzymes were significantly elevated in serum. An important finding was that carbofuran or methyl parathion caused a shift in the serum CK-MM subform; that is, higher sequential conversions of CK-MM3 subform to CK-MM2 and CK-MM2 to CK-MM1, possibly due to enhanced CPN-2 activity (Gupta et al., 1994).

37.7.2 Lactate dehydrogenase and lactate dehydrogenase isoenzymes

LDH catalyzes the synthesis of lactate and pyruvate in a reversible reaction and is commonly used as a biomarker of cell damage or death. Normal distribution of LDH and its isoenzymes in skeletal muscles of rats revealed that, in controls, LDH activity was found to be highest in the EDL, followed by the diaphragm, and lowest in the SOL (Table 37.8). Compared to muscles, the enzyme activity was meager in serum. Interestingly, all three muscles and serum contained all five electrophoretically distinct LDH isoenzymes, although with varying quantities. Each muscle presented a characteristic LDH isoenzyme pattern. For example, EDL contained a large proportion of LDH-5 (62.6% of total activity) and very little LDH-1 (3.5%). SOL, on the other hand, had a very small amount of LDH-5 (11.3%) and about 20% each of the other four isoenzymes (LDH-1−LDH-4). In general, values of LDH isoenzymes in diaphragm were intermediate to the EDL and SOL. Diaphragm had predominantly LDH-5 and LDH-4 (40% and 27.7%, respectively). In control serum, isoenzyme LDH-5 was 87% of the total LDH activity (100%).

Total LDH activity was significantly enhanced in EDL, diaphragm, and serum by carbofuran (1.5 mg/kg, s.c.) or methyl parathion (5 mg/kg, i.p.) within 1 h of injection. Each AChE inhibitor caused a marked elevation of all five isoenzymes in serum, with maximum increases in LDH-1 and LDH-4 (threefold). Unlike serum, muscle LDH isoenzymes depicted variable patterns by carbofuran or methyl parathion intoxication. A significant decline in ATP appears to be the mechanism involved in leakage of cytoplasmic/mitochondrial enzymes into the circulation (Gupta et al., 1994).

37.8 Skeletal muscle involvement in tolerance development

Repeated application of OP nerve agents or pesticides for a prolonged period in concentrations that initially do not produce obvious symptoms of toxicity can lead to a limited degree of adaptation, as seen in a reduction of the duration and intensity of muscle fasciculations, muscle fiber necrosis, and behavioral tolerance (Wecker and Dettbarn, 1976; Gupta et al., 1985, 1986). Various cholinergic mechanisms in skeletal muscles underlying this phenomenon have been well-documented, including: (1) reduced cholinergic-binding sites of muscarinic and nicotinic receptors, (2) reduced uptake of choline, and (3) stimulation of AChE synthesis (Gupta et al., 1985, 1986). In an in vivo subchronic study (DFP, 0.5 mg/kg, s.c./day for 14 days) in male rats, Gupta and Dettbarn (1986) demonstrated complete recovery of protein synthesis in skeletal muscles (SOL, EDL, and diaphragm) during the tolerance phase (day 14) from inhibition of protein synthesis observed during the toxicity phase (day 5). Further, during the toxicity phase (day 5), inhibition of in vivo protein synthesis was comparable to that seen from an acute dose of DFP (1.5 mg/kg, s.c.). Additional mechanisms that may contribute to general tolerance are the availability of other serine active site enzymes, such as carboxylesterase (CarbE) and BuChE. Although the functional role of these enzymes is unknown, binding to and inhibition of these enzymes reduce the free concentration of inhibitors that otherwise would have been available to interact with AChE (Gupta et al., 1985). This is supported by studies showing that the toxicity of OPs can be potentiated by inhibition of CarbE, and tolerance to soman develops when plasma CarbEs recover during chronic exposure (Sterri et al., 1981).

A major mechanism causing adaptation to the necrotic action of DFP at the NMJ is the reduction of nAChRs (B_{max}, 56%) without significant change in affinity constant (K_D). This loss of receptors can also explain the disappearance of fasciculations that was observed between days 3 and 5 of treatment (Gupta et al., 1986). Whether presynaptic receptors regulating fasciculations are involved in this process remains to be determined. Changes in the postsynaptic receptor density could occur as an adaptation mechanism of the cell to the excessive cholinergic stimulation caused by AChE inhibition. The loss of ACh receptors may be caused by a reduction of junctional folds (Laskowski et al., 1975) on which most of the nicotinic ACh receptors are located. Changes in the ionic milieu, especially increases in Ca^{2+} caused by the increased neuromuscular activity during DFP-induced fasciculations, may be involved in the loss of secondary junctional folds. In essence, at the NMJ, the two major mechanisms leading to adaptation are: (1) an increased

TABLE 37.8 Normal distribution of LDH and LDH isoenzymes in skeletal muscles and serum of rats.

	Total LDH	LDH isoenzymes				
		LDH-1 HHHH	LDH-2 HHHM	LDH-3 HHMM	LDH-4 HMMM	LDH-5 MMMM
Soleus	72,720 ± 2484 (100)	14,962 ± 476 (20.7)	19,054 ± 617 (26.3)	16,118 ± 692 (22.2)	14,254 ± 1332 (19.5)	8316 ± 890 (11.3)
EDL	207,300 ± 22,945 (100)[a,b]	7290 ± 1890 (3.5)[a,b]	12,300 ± 2033 (5.9)[a,b]	18,105 ± 1498 (8.7)	40,420 ± 4100 (19.5)[a,b]	129,870 ± 15,298 (62.6)[a,b]
Diaphragm	129,120 ± 4828 (100)	17,020 ± 504 (13.2)	17,498 ± 571 (13.5)	16,190 ± 780 (12.6)	26,738 ± 1080 (27.7)	51,680 ± 3081 (40.0)
Serum	740 ± 28 (100)	9.8 ± 1.4 (1.3)	17.4 ± 2.0 (2.3)	10.2 ± 1.2 (1.4)	38.0 ± 3.8 (5.2)	643 ± 65 (87.0)

Values expressed in terms of IU/L are presented as means ± SEM ($n = 4–6$); numbers in parentheses are percentages of isoenzymes to total LDH activity (100%).

recovery of AChE activity as a result of de novo synthesis (Gupta et al., 1986), (2) a reduction in nAChR binding sites (Gupta et al., 1985, 1986, 1987a,b), and (3) modification of ACh release from presynaptic sites (Carlson and Dettbarn, 1988).

37.9 Skeletal muscle involvement in intermediate syndrome

OP insecticide-induced IMS was reported for the first time in human patients in Sri Lanka in 1987 (Senanayake and Karalliedde, 1987; Karalliedde and Henry, 1993). Thereafter, this syndrome has been reported in South Africa (1989), Turkey (1990), Belgium (1992), India (2003), and many other countries. IMS is clearly a separate entity from acute cholinergic crisis and delayed neuropathy. IMS is a life-threatening complication of OP poisoning, which most commonly occurs 48−72 h after exposure. Thus far, IMS has not been documented with OP nerve agents. Clinically, IMS is characterized by acute respiratory paralysis and weakness in the territories of several cranial motor nerves, neck flexors, and facial, extraocular, palatal, nuchal, and proximal limb muscles. Despite severe AChE inhibition, muscle fasciculations and muscarinic receptor-associated hypersecretory activities are absent. Based on EMG findings from OP-poisoned patients and experimental studies on laboratory animals, it has been found that the defect in IMS is at the neuromuscular endplate and postsynaptic levels, but the effects of neural and central components in muscular weakness have not been ruled out. EMG in the early stages reveals marked decrements at low rates of repetitive nerve stimulation and increments at a high rate, suggesting diverse types of impaired neuromuscular transmission. IMS seems to be due to persistent AChE inhibition at the endplate, presumably leading to combined presynaptic and postsynaptic impairment of neuromuscular transmission. Very little is known about the type of damage at the motor endplate or about risk factors associated with IMS. For details on the involvement of muscles in IMS, see De Bleecker (2006).

37.10 Prevention/treatment of myopathy

Various pharmacologic and therapeutic drugs have been tested to prevent or treat myopathy. Drugs effective in the treatment of neuromuscular signs of anti-ChE toxicity include: (1) oximes that reactivate the phosphorylated AChE (Thiermann et al., 2005; Marrs and Vale, 2006), (2) subparalyzing and paralyzing doses of *d*-tubocurarine (Clinton and Dettbarn, 1987; Patterson et al., 1987), (3) atropine sulfate/atropine methyl nitrate (Patterson et al., 1987; Clinton et al., 1988), (4) diazepam, and (5) creatine phosphate (Clinton et al., 1988). In several studies, reversible AChE-inhibiting carbamates, atropine, or anticonvulsants were given with oxime to achieve an optimal effect. Some of the drugs, including AChE reactivators, muscarinic and nicotinic ACh receptor blockers, NMDAR antagonists, anticonvulsants, and antioxidants, are described here briefly in terms of their prophylactic/therapeutic efficacy. It should be noted that some of these agents, however, produce toxicity when given for an extended period of time, thereby limiting their utility.

37.11 Acetylcholinesterase reactivators and acetylcholinesterase receptor blockers

The standard treatment of nerve agent-induced muscle toxicity calls for reactivation of the phosphorylated AChE with an oxime. Oximes such as obidoxime [bis(4-formylpyridiniomethyl) ether dioxime, also known as Toxogonin], pralidoxime (2-pyridine aldoxime methochloride/2-PAM), and a few others have been found very effective when given in combination with other drugs such as atropine, *d*-tubocurarine, and diazepam. The effectiveness of pretreatment with oximes varies with the chemical structures of the nerve agents and depends on the time after exposure. For example, it has been established that asoxime chloride (HI-6) effectively reactivates AChE inhibited by soman, while TMB-4 is known as one of the most efficient reactivators of tabun-inhibited enzyme. In in vivo studies, Jovanovic (1983) evaluated the effects of two bis-pyridinium oximes (BDB-27 and HGG-12) on neuromuscular blockades induced by nerve agents (sarin, soman, tabun, and VX) in rats, and the effectiveness was compared with the two most potent oximes (HI-6 and TMB-4). It was found that BDB-27 was equal or superior to HI-6 in sarin, soman, and VX, and to TMB-4 in tabun-poisoned animals. The potency of HGG-12 was equal to HI-6 only in soman poisoning, but it was much less pronounced against neuromuscular blockades induced by the other nerve agents. In general, oxime therapy becomes progressively ineffective with time due to changes in the enzyme−inhibitor complex, which loses an alkyl radical. This so-called aged phosphorylated enzyme complex is resistant to oxime reactivation (Radic and Taylor, 2006). Thus, prevention of formation of the enzyme−inhibitor complex seems to be one of the preferred strategies in the treatment of myopathy.

The best pretreatment should include agents that prevent access of the nerve agent to AChE without affecting its activity, or a combination of drugs that would decrease the release of ACh from nerve terminals and partially

block access to the nicotinic and the presynaptic and postsynaptic muscarinic receptors. So far, timely administration of atropine sulfate or atropine methyl nitrate, in combination with an oxime (such as 2-PAM) or diazepam, is currently the treatment of choice for OP poisoning (Marrs and Vale, 2006). Atropine modifies ACh receptor interaction at the NMJ postsynaptically by shortening the opening time of the ion channel, and possibly by lowering Na^+ conductance. Atropine sulfate has been observed to reduce motor activity and muscle necrosis caused by AChE inhibitors (Clinton and Dettbarn, 1987). Atropine methyl nitrate is four times more potent than atropine sulfate in its peripheral effects and has been confirmed to ameliorate peripheral motor activity caused by AChE inhibitors (Clinton et al., 1988). Atropine methyl nitrate (16 mg/kg, s.c.) failed to ameliorate the central effects of both soman and DFP due to its quaternary structure that hinders its passage across the blood–brain barrier (Clinton et al., 1988).

Earlier studies with *d*-tubocurarine and atropine indicated that nicotinic and muscarinic ACh receptor blockers can modulate the release of ACh induced by an inhibitor of AChE (Carlson and Dettbarn, 1988). The effects of these drugs, whether inhibiting or stimulating ACh release, are concentration dependent and determined by the frequency of nerve activity (Bowman, 1980; Wessler et al., 1987a,b). Therefore, drugs that reduce axonal hyperexcitability by decreasing the amount of ACh released from the nerve terminals without interfering with normal transmission, provide another pretreatment possibility. Protection against DFP-induced myopathy was achieved using small concentrations of atropine sulfate (16 mg/kg, s.c.) or atropine methyl nitrate (16 mg/kg, s.c.) and *d*-tubocurarine (75 μg/kg, s.c.) that prevented fasciculations and muscle necrosis without interfering with normal neuromuscular function (Patterson et al., 1987). In this study, pretreatment agents acted presynaptically by preventing DFP-induced backfiring and muscle fasciculations, possibly by reducing the release of ACh. The protective drugs in the concentrations used had no significant effect on the normal characteristics of conduction and transmission. Carlson and Dettbarn (1988) showed that *d*-tubocurarine or atropine sulfate in subparalytic concentrations prevented the increases in MEPP frequency when given prior to an AChE inhibitor, or attenuated the increased frequency to normal when given after the increase of frequency. At a subparalytic dose *d*-tubocurarine (50 μg/kg, i.v.) is known to suppress fasciculations by preventing repetitive firing of nerve terminals. Furthermore, *d*-tubocurarine and atropine sulfate reduced Ca^{2+} influx and ACh release (through presynaptic receptors), which is associated with repetitive activity, as seen during AChE inhibitor-induced antidromic firing.

37.11.1 *N*-Methyl-D-aspartate receptor antagonist

In a series of in vivo experiments, rats receiving a sublethal dose of soman (100 μg/kg, s.c.), sarin (110 μg/kg, s.c.), tabun (200 μg/kg, s.c.), VX (12 μg/kg, s.c.), or DFP (1.5 mg/kg, s.c.) developed seizures and severe muscle fasciculations within 15–20 min that lasted for about 4–6 h. Marked inhibition of AChE activity and necrotic lesions in skeletal muscles (SOL, EDL, and diaphragm) became evident between 1 and 24 h postinjection and persisted for several days. Pretreatment of rats with a NMDAR antagonist memantine HCl (18 mg/kg, s.c.), given in combination with atropine sulfate (16 mg/kg, s.c.) 60 and 15 min prior to DFP or nerve agents, respectively, significantly attenuated AChE inhibition and prevented myonecrosis and muscle fasciculations, as well as other signs of behavioral toxicity. No muscle fasciculations were seen at any time (Gupta and Dettbarn, 1992).

Protection of AChE inhibition was greater when memantine was given prophylactically than therapeutically. It is noteworthy that memantine itself does not influence normal activity of AChE in non-OP-treated animals. Although the precise mechanism involved in reduction of AChE inhibition by memantine against nerve agents is yet to be elucidated, spontaneous reactivation as the cause of the remaining high-enzyme activity was ruled out since the enzyme activity was determined within a short period of time; that is, 1 h after acute intoxication with soman, sarin, tabun, VX, or DFP (Gupta et al., 1986, 1987a,b, 1991; Gupta and Dettbarn, 1992), and AChE activity remained low when only atropine sulfate (16 mg/kg, s.c.) was used. McLean et al. (1992) revealed that memantine did not prevent inhibition of AChE by edrophonium, an anionic site inhibitor, or by decamethonium, a peripheral site inhibitor. Thus, memantine appears to bind to a different modulatory site to protect this enzyme's activity. Stojiljković et al. (2019) described that the mechanism of the antidotal effect of memantine against soman poisoning appears to be a combination of AChE protection and NMDA receptor-blocking action. The other mechanisms by which memantine might have attenuated AChEI's toxicity may include the following:

- Reduced reflex excitability of both flexors and extensors (Wand et al., 1977);
- Reduced high frequency of repetitive activation of peripheral nerves by reducing the permeability of Na^+ and Ca^{2+} in axonal membranes (Wesemann and Ekenna, 1982; Wesemann et al., 1983);
- Blockage of nicotinic ACh receptor–ion channel complex (Masuo et al., 1986);

- Prevention of neural hyperexcitability (McLean et al., 1992);
- Central muscle relaxation (Grossmann and Jurna, 1977);
- Reduced seizures by uncompetitive NMDAR blockage (Danysz et al., 1994; Carter, 1995; Parsons et al., 1999; Stojiljkovic et al., 2019);
- Prevention of cellular energy depletion (Gupta and Goad, 2000);
- Prevention of oxidative/nitrosative stress (Gupta et al., 2005).

Although not all of these mechanisms have been investigated in the protection of OP nerve agent-induced myopathy by memantine, it appears that memantine provides protection by multiple mechanisms. It needs to be mentioned that no significant change occurred in AChE activity in skeletal muscles of OP-untreated rats receiving memantine and atropine sulfate. Prophylactic administration of memantine and atropine sulfate also blocked the AChEI-induced increase in levels of citrulline and F_2-isoprostanes, markers of NO synthesis and lipid peroxidation, respectively (Milatovic et al., 2005). Memantine has the advantage of providing prophylactic benefits without producing sedation or any other side effects. Thus, memantine may prove to be a superior drug to many other agents.

37.11.2 Anticonvulsants and anesthetics

The prevention and treatment of OP-induced myopathy are both complex since individual AChEIs differ in their major sites of action. As mentioned earlier, soman-produced muscle hyperactivity was generated mainly in the CNS, while DFP-induced hyperactivity arose approximately equally from the CNS and the peripheral nervous system and NMJ. Clinton et al. (1988) reported that in the case of both soman (90 μg/kg, s.c.) and DFP (1.5 mg/kg, s.c.) poisoning, ketamine (25 mg/kg, s.c.) reduced centrally generated motor activity, while atropine methyl nitrate (16 mg/kg, s.c.) and sodium phenytoin (15 mg/kg, i.v.) had no significant effect. It was suggested that the effectiveness of ketamine may alter patterns of neuronal firing by reducing high-frequency neuronal discharges that are characteristic of seizures (MacDonald and McLean, 1986). Ketamine is known to act on sodium channels by producing a dose-dependent reduction of inward sodium current in a manner similar to that of local anesthetics, with a resultant suppression of high-frequency neuronal bursts, which are manifested as excess muscle activity seen with OP poisoning. Since ketamine and drugs in its class also have specific anticholinergic effects at both nicotinic and muscarinic (more potent at nicotinic than at muscarinic) receptors (Kloog et al., 1977), it may be a direct antagonist in the CNS against the cholinergic activation caused by AChEIs (Gupta et al., 1987a,b). Additionally, ketamine can inhibit excitation–contraction coupling within the muscle by altering Na^+ conductance at the muscle membrane (Marwaha, 1980a,b).

The anticonvulsant phenytoin did not reduce central motor activity induced by either soman or DFP (Clinton et al., 1988). Phenytoin suppresses sustained high-frequency neuronal firing through a membrane potential-dependent blockade of Na^+ channels with resulting inhibition of nonsynaptic events involved in epileptogenesis (MacDonald and McLean, 1986; Yaari et al., 1986). The failure of phenytoin to control the seizures induced by AChEIs suggests that they may not result from the same mechanisms of epileptogenesis as seizures produced by maximal electrical shock, against which phenytoin is most effective. Conventional anticonvulsant compounds have been reported to provide limited protection against nerve agent-induced seizures and muscle necrosis when given therapeutically (Lipp, 1972; Clinton et al., 1988). Sedation, tolerance, and abuse potentially limit prophylactic use of benzodiazepine compounds, however.

In animal models, clonidine (an alpha2 adrenergic agonist) has also been reported to prevent nerve agent-induced seizures (Buccafusco et al., 1988). Prophylactic use of clonidine may be limited by the marked ataxia and sedation produced by this drug in effective concentrations.

37.11.3 Antioxidants, spin-trapping agents, and creatine

Scavenging or prevention of the ROS generation originated through various excitotoxicity mechanisms are of particular interest. An antioxidant such as the lipid-soluble vitamin E (α-tocopherol) is an excellent blocker of ROS production, as it extracts hydrogen and interrupts lipid peroxidation. Vitamin E mainly acts as a chain-breaking antioxidant and radical scavenger, protecting cell membranes against oxidative damage. There are reports demonstrating that vitamin E concentrates in the mitochondria, the major site for the generation of ROS, as well as energy metabolites. Therefore, vitamin E regulates ROS production, maintains oxidative phosphorylation in mitochondria, and accelerates the restitution of high-energy metabolites.

A synthetic spin-trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is capable of scavenging many types of free radicals. This compound is widely used to trap

TABLE 37.9 Protective effect of PBN against DFP-induced fasciculations, AChE inhibition, and necrosis in rat EDL.

	Control	DFP[a]	PBN + DFP[b]	DFP + PBN[c]
Fasciculations	−	+	−	+
Necrotic fibers/cross section of muscle	2 ± 2	82.55 ± 2.98*	0**	67.0 ± 4.59
AChE activity	12.17 ± 0.73 (100%)	3.70 ± 0.35* (30%)	10.85 ± 0.59** (89%)	2.97 ± 0.17 (24%)

Activity of AChE is expressed in terms of nmol/mg protein/min and number of necrotic fibers/1000 muscle fibers. Ranking of fasciculations: −, absent; +, high frequency affecting all muscles. Values are means ± SEM of five muscles.
*Significant difference between control and DFP-treated rats ($P < .01$).
**Significant difference between DFP-treated rats and PBN + DFP-treated rats ($P < .01$).
[a]*DFP (1.7 mg/kg, s.c.) was given 1 h before sacrificing the rats.*
[b]*PBN (300 mg/kg, i.p.) was given 30 min before DFP (1.7 mg/kg, s.c.).*
[c]*PBN (300 mg/kg, i.p.) was given 20 min after DFP (1.7 mg/kg, s.c.) administration.*

ROS in a variety of physical, chemical, and biological studies using electron magnetic resonance spectrometry. PBN is known to be concentrated in the mitochondria, where it reacts with ROS and forms stable adducts, thereby maintaining normal levels of energy metabolites. In addition, PBN has other pharmacological actions, such as: (1) reversible Ca^{2+} channel blockade (Anderson et al., 1993), (2) direct reversible interaction with AChE against phosphorylation by DFP (Zivin et al., 1999; Milatovic et al., 2000a,b), and (3) protection of COX activity (Milatovic et al., 2001).

Pretreatment with PBN (75, 150, or 300 mg/kg, i.p.) 30 min prior to DFP injection (1.7 mg/kg, s.c.) in a dose-dependent manner protected AChE activity from inhibition, and prevented muscles from undergoing necrosis and rats from fasciculations (Milatovic et al., 2000a,b) (Table 37.9). The protective mechanism of PBN is proved to take place due to its ROS/RNS scavenging property (Gupta et al., 2000a, 2001b). Treatment with PBN 20 min after DFP exposure neither prevented fasciculations nor protected AChE activity. While the role of PBN as an antioxidant is well established, its prophylactic effect against excitotoxicity induced by an AChEI is due to its protection of AChE from critical inhibition (Milatovic et al., 2000a,b). Unlike PBN, vitamin E neither prevented DFP-induced muscle fasciculations nor protected AChE. Both vitamin E and PBN concentrate in the mitochondria, so they can regulate ROS production, maintain oxidative phosphorylation, and accelerate restitution of high-energy metabolites (Gupta et al., 2001a,b).

Since the major energy sources are ATP and PCr, an increase of both compounds in muscles through administration of creatine appears to sustain ATP levels under stress conditions. This is supported by the findings that rats pretreated intravenously with PCr showed reduced muscle necrosis that otherwise would have been seen following DFP treatment. PCr did not attenuate the DFP-induced muscle fasciculations that generated the necrosis (Clinton and Dettbarn, 1987).

37.12 Concluding remarks and future directions

Skeletal muscles are the target of a variety of chemicals, especially OP nerve agents. These agents modulate structural and functional properties of the muscles, and the toxic effects can range from minor chest pain, muscle cramps in the legs, complete paralysis, and even death. Both in vivo and in vitro data strongly implicate that OP nerve agents initially exert acute toxicity by excitotoxicity involving not only the cholinergic system, but also processes associated with noncholinergic mechanisms. These processes include the glutamatergic system, excess generation of free radicals (ROS/RNS), and alterations in antioxidants and the scavenging system, causing oxidative stress, lipid peroxidation, high-energy phosphate depletion, and muscle necrosis. Wide variations exist between slow and fast fiber-containing muscles, and they further appear to respond differently to each OP nerve agent. Available sensitive biomarkers are indicative of cytotoxicity and mitochondrial toxicity (Gupta et al., 2019). Myopathy induced by AChE-inhibiting OP nerve agents is a serious concern, since it is untreatable in most circumstances. Instead, prevention seems a better option. More potent AChE reactivators need to be developed for better therapeutic efficacy against OP nerve agent-induced myopathy.

Acknowledgment

The authors would like to thank Robin B. Doss for her technical assistance in the preparation of this chapter.

38.1 Introduction

Skin integrity is in part determined by the interaction of a number of proteins that form a continuum of molecules linking together to ensure the epidermis and dermis are tightly attached to one another. These macromolecules include the keratins that form the intermediate filaments in the cytoplasm of keratinocytes, integrins which are made of two subunits and found in the hemidesmosomes of the basal keratinocyte membrane, and a variety of laminins, collagens, and their receptors, situated both in the basement membrane that separates the epidermis from the dermis, and in the dermis itself. Any chemical agent that disrupts this continuum of linking proteins will result in a breach in skin integrity and ensuing histopathology (Uitto et al., 2007). One such compound is the alkylating agent sulfur mustard [bis(2-chloroethyl) sulfide; SM], which causes detachment of the epidermis from the dermis. Skin exposure to SM starts a complex series of events with a host of normal skin responses to wounding which interact with, influence, and regulate each other to result in cutaneous toxicity. Various mediators of injury that regulate inflammation, immune responses, cell death, and a number of signaling pathways have been implicated in the process. This chapter describes our current knowledge of the cutaneous actions of SM, discussing the basic mechanism of action and mediators involved, to provide for the reader a comprehensive understanding of the histopathology of SM-exposed skin. The injury process is described, and SM-induced skin injury is compared to other types of wound injury. Additionally, various skin-injury models and potential therapeutic countermeasures are discussed.

38.2 Background

38.2.1 Military use

Sulfur mustard, a vesicant or blistering agent, has been used intermittently as a chemical warfare agent since 1917 when Germany first introduced it as a weapon against British soldiers in Ypres, Belgium. Subsequently in the 1930s it was reported as having been used by Italy against Abyssinia (Ethiopia), Poland against Germany, and Japan against the China. During the 1960s, SM was allegedly used by Egypt against Yemen. The last well-documented use in the 1980s was by Iraq against Iran and the Kurds (Papirmeister et al., 1991c). Noteworthy is the completed destruction of Libya's sulfur mustard stockpile in 2013, as overseen by the Organization for the Prohibition of Chemical Weapons (OPCW) and the United Nations. Recently however, chemical weapons, including sulfur mustard, have been used in the ongoing (2011−present) Syrian civil war.

38.2.2 Wound repair

Repair of the simplest skin wound requires the coordination of a number of physiological processes and events. The tissue injury causes blood vessel disruption and an activation of the inflammatory pathway that releases a battery of mediators. Reepithelialization requires activation of additional pathways and the initiation of specific events at specific times, such as extracellular matrix (ECM) remodeling and the proliferation and migration of keratinocytes. If these events are not precisely coordinated, the end result can be delayed healing and/or scar

formation. Since the repair process is complicated, a review of the wound-healing events in dermal injury might be helpful. There are at least three phases to wound healing following dermal injury (Gurtner et al., 2008). (1) Inflammation (first 24–48 h): this phase occurs early and involves activation of the coagulation cascade, inflammatory pathways, and immune system. These biological processes involve an attempt to maintain homeostasis by preventing blood and fluid loss, removing dead tissue, and preventing infection. (2) Wound repair phase (2–10 days after injury): this phase involves the proliferation and migration of several cell types. Keratinocytes migrate over the injured dermis, endothelial cells proliferate to form new blood vessels, and fibroblasts differentiate into myofibroblasts in order to initiate wound contraction. (3) Remodeling phase (2–3 weeks postinjury): this phase results in the final wound repair. All the activated cellular processes turn off. Many cell types undergo apoptosis or leave the wound site. The ECM is remodeled and resumes normal functions.

These same basic phases are applicable to injury caused by SM, but the pathology frequently is more severe than other types of dermal wounds and the basic timing of the various phases may be extended in SM injury (Papirmeister et al., 1991b; Dacre and Goldman, 1996; Balali-Mood and Hefazi, 2006). Normal clothing provides little protection to the skin from a liquid or vapor exposure to SM. Once in contact with the skin, the lipophilic properties of SM allow it to rapidly penetrate the epidermal barrier, while its high reactivity and bifunctional nature lead to alkylation of a wide range of molecules (Fig. 38.1). The ultimate injury caused by SM is highly dependent on the dose and length of exposure, resulting in a wide range of histopathology. Erythema, resembling sunburn, may be the mildest and earliest form of skin injury, occurring 2–48 h post-SM exposure (USAMRICD, 2007). The erythema may be accompanied by pruritus or burning pain and small vesicles may eventually develop which coalesce to form bullae (Fig. 38.2). Fluid-filled blisters increase in size, their color ranging from yellowish to tan. The fluid itself does not contain active alkylating agent, nor does it have vesicating properties. When SM is applied as a liquid, the exposure concentration is even higher than a vapor application and severe lesions are more likely. The resultant wounds are prone to secondary infections and may cause chronic ulcers that are resistant to wound repair. There may be permanent pigmentation changes in the skin after exposure to SM. Clearly, the effects of SM on skin are complex and involve many systems and pathways. The following sections address the mechanism of action of SM and the systems and pathways involved in an organized way.

38.3 Pathogenesis

The bulk of what is known about human skin injury from SM has been gathered from victims of the military use of the compound (Requena et al., 1988; Balali-Mood and Hefazi, 2006; Hefazi et al., 2006). Nevertheless, there are several reports where the cutaneous vesicating effects of SM were studied experimentally in human subjects (Papirmeister et al., 1991b; Dacre and Goldman, 1996).

In one comparative study (Daily et al., 1944) 12 volunteers had forearm vapor cup applications of SM, trifunctional nitrogen mustard (HN3), and lewisite. The conclusions were that SM exposure caused the largest vesicles formed, the earliest peak vesication, the longest healing time, and the most severe final scar. Lewisite was the second most potent agent and HN3 the least potent, although the HN3 lesions had the most edema of the three vesicants examined. The results confirmed the previously published studies which followed the development of skin pathogenesis after topical exposure to SM.

Clinical injury by SM has been extensively reviewed and will be summarized here. Sulfur mustard injury to human skin begins almost immediately after exposure when the highly reactive bifunctional SM directly alkylates resident proteins. However, recognizable skin pathology does not usually occur for several hours to a day after exposure. The very first physical sign of SM exposure is usually erythema which may or may not be associated with itching (Papirmeister et al., 1991b). This is often followed later by distinct fluid-filled blisters that break open and become covered with a scab. Many researchers have noted that the blisters resemble those formed by epidermolysis bullosa (EB), a genetic or acquired skin pathology that results in a separation of the epidermis from the dermis (Chang et al., 2018a). In both SM exposure and EB, there may be multiple rounds of blistering and healing in an individual (Balali-Mood and Hefazi, 2005; Pillay, 2008). In fact, some of the therapeutic agents for EB are being tested as potential medical countermeasures against SM injury. These will be addressed later.

38.3.1 Cytotoxicity of sulfur mustard

While stable in lipophilic solvents, SM has a half-life of only 24 min at room temperature in aqueous physiological solutions since it rapidly reacts with water to form thiodiglycol and HCl. This rapid activation of SM in an aqueous environment also allows it to react with small molecules of biological interest, as well as proteins, carbohydrates, lipids, RNA, and DNA (Bartlett and Swain, 1949; Papirmeister et al., 1991a; Debouzy et al., 2002; Noort and van der Schans, 2002). The initial reaction involves the formation of a cyclic ethylene sulfonium ion which readily targets reactive groups on skin components, including sulfhydryls, phosphates, ring nitrogens, and carboxyl groups. As a bifunctional alkylating agent, SM forms monofunctional adducts and intra- and intermolecular cross-links. Since it is so reactive and indiscriminate in its molecular targets, SM affects many pathways and is cytotoxic on many levels. There are at least three independent mechanisms of cytotoxicity that have been proposed and each will be addressed in separate sections.

38.3.1.1 Alkylation of DNA/poly(ADP-ribose) polymerase activation

A major target of SM alkylation is DNA, with which it can form both monofunctional adducts and bifunctional cross-links (Papirmeister et al., 1991a; Debiak et al., 2009), which can persist in affected skin for at least 21 days (Batal et al., 2013). A DNA damage response, initiated by the kinases ATM, ATR, and DNA-dependent protein kinase leads to cell cycle arrest (Lin et al., 1996; Long et al., 2016; Blackford and Jackson, 2017) allowing for a variety of DNA repair processes to ensue. Although the monofunctional adducts, typically at the N7 position on guanine, are a more prevalent consequence of SM exposure, DNA cross-links, especially between complementary strands, are most cytotoxic (Walker, 1971; Jowsey et al., 2012; Batal et al., 2013). The myriad pathways available to remove adducts and repair strand breaks produced by SM include both nucleotide excision repair (NER) and base excision repair (Matijasevic and Volkert, 2007; Jowsey et al., 2009), as well as those pathways more specific for double-strand breaks: nonhomologous end joining (NHEJ), homologous recombination (HR), and the alternate endjoining mechanisms, microhomology-mediated end joining and single-strand annealing (Sallmyr and Tomkinson, 2018). While rates and fidelity of repair differ among these pathways, and their dominance varies according to many factors, including the species and phase of the cell cycle, current information suggests that HR is perhaps the most important mechanism for sulfur mustard exposure, with NER and NHEJ pathways playing a supportive role (Jowsey et al., 2012).

SM-induced DNA damage also triggers activation of a family of nuclear repair enzymes called poly(ADP-ribose) polymerases (PARPs) (Papirmeister et al., 1985; Shall and de Murcia, 2000). While low levels of PARP activation may signal repair, excessive activity can deplete cells of PARP's required cofactor, NAD^+. Depletion of NAD^+ in turn inhibits ATP production, which is essential for metabolism (Martens and Smith, 2008). Apoptosis or necrosis may result, depending upon the level of ATP depletion, cell type, and other factors (Rosenthal et al., 2001). Preventing the depletion of NAD^+ by interfering with PARP activation has been the rationale for testing PARP inhibitors as therapeutic countermeasures (Debiak et al., 2009). Recent studies confirm that SM induces poly-ADP ribosylation in the HaCat keratinocyte cell line (Liu et al., 2016; Mangerich et al., 2016). Furthermore, ABT-888, a clinically relevant PARP inhibitor, reverses NAD^+ depletion produced by SM in these cells and reduces SM-induced edema in the mouse ear vesicant model (MEVM) pointing to the potential utility of selective PARP inhibitors in SM-induced injury (Liu et al., 2016).

38.3.1.2 Reactions with glutathione/oxidative stress

There is considerable evidence to support the hypothesis that oxidative stress plays a key role in the cutaneous vesicating actions of SM. Under homeostatic conditions, a net reducing environment is maintained in tissues by the presence of glutathione (GSH), which serves as a buffer against cytotoxic electrophiles and reactive oxygen species (ROS). Excess H_2O_2 is eliminated by glutathione peroxidase at the expense of GSH. Depletion of intracellular GSH allows the accumulation of oxidants, including H_2O_2, which become abundant and actively contribute to lipid peroxidation and other types of cellular damage. Dermatotoxic agents such as ultraviolet radiation (UVA) and psoralens have been shown to deplete intracellular GSH, resulting in cellular toxicity (Wheeler et al., 1986). The propensity of SM to react with sulfhydryls is thought to lead to a concentration-dependent depletion of reducing equivalents within cells. Electron paramagnetic resonance studies have suggested that SM and related vesicants can interact with key intracellular reductases to produce mustard-free radicals as an intermediate to ROS generation (Brimfield et al., 2009, 2012). In other tissues, SM exposure has been shown to reduce GSH, glutathione peroxidase, and glutathione reductase activity, potentially contributing to the depletion of reduced glutathione (Husain et al., 1996; Jafari, 2007; Pohanka et al., 2011, 2013). In addition, inflammatory cells, which infiltrate into the skin in response to SM-induced injury, generate additional ROS that contribute to oxidative stress (Droge, 2002). This information raises the possibility that oxidative stress plays a role in the vesicating actions of mustard alkylating agents.

Several reports more directly support the notion that GSH depletion and oxidative stress are important mechanisms of cutaneous toxicity induced by SM and its vesicating analogs. Cutaneous glutathione peroxidase gene expression is increased following SM treatment in the MEVM, suggesting that this enzyme is important in reducing oxidative stress due to SM exposure (Buxton et al., 2001). Treatment with the monovalent mustard analog, 2-chloroethyl ethyl sulfide (CEES), has been shown to significantly deplete GSH in mouse and human keratinocyte cell lines (Tewari-Singh et al., 2011). Furthermore, depletion of intracellular-reduced glutathione by buthionine sulfoxamine sensitizes keratinocytes treated in vitro with SM (Simpson and Lindsay, 2005) or CEES (Tewari-Singh et al., 2011).

There is more direct evidence from both in vivo and in vitro studies that CEES produces oxidative stress. CEES application to the dorsal skin of SKH-1 hairless mice led to time- and dose-dependent increases in oxidative damage to tissue proteins as evidenced by modification by lipid peroxides, radical adduction, and the formation of protein carbonyls (Pal et al., 2009). Increased DNA oxidation, detected as the formation of 8-hydroxy-2-deoxyguanosine (8-OHdG), was also a consequence of CEES exposure. Subsequent studies with the JB6 mouse keratinocyte cell line and primary fibroblasts in culture confirmed the ability of CEES to increase 8-OHdG and also increase both mitochondrial and cytosolic superoxide generation (Inturi et al., 2011). A report using mouse PAM212 keratinocytes in three-dimensional air−liquid interface cultures demonstrated concentration-dependent increases in hydrogen peroxide and protein carbonyl formation after topical application of CEES (Black et al., 2010a). These changes were accompanied by increases in the relative mRNA of Cu, Zn-SOD, catalase, thioredoxin reductase, and several glutathione-*S*-transferases (GSTs), suggesting a compensatory cellular response to oxidative stress.

There are likewise demonstrations that an increase in the antioxidant cellular capabilities of in vitro skin models reduces susceptibility to mustard alkylating agents. Several reports show a protection from SM, HN2, or CEES toxicity by activators of the transcription factor, Nrf2 (Gross et al., 2006; Abel et al., 2011; Udasin et al., 2016), as well as suggest that iodine, an agent demonstrated to protect the skin from HN2, may act via this mechanism (Ben-Yehuda Greenwald et al., 2017). Nrf2 translocates to the nucleus under conditions of electrophilic or oxidative stress and binds to the antioxidant responsive element, leading to increased transcription of antioxidant/electrophilic response genes (Li and Kong, 2009). Important mechanisms that are enhanced include the synthesis and availability of GSH, GST activity, and cellular efflux transporters. Finally, a variant of the HaCaT human keratinocyte line with increased resistance to SM has recently been developed (Schmidt et al., 2016). These cells, which also show resistance to cancer chemotherapeutic agents of several classes and to H_2O_2, are distinguished by having significantly higher resting GSH levels as well as a more robust rebound in GSH levels after SM exposure (Rothmiller et al., 2018a). In summary, there is now compelling evidence that the loss of cellular reducing equivalents and the increase in oxidative stress are key contributors to cutaneous toxicity by SM and its vesicating analogs.

38.3.1.3 Reactions with glutathione/calcium homeostasis

Depletion of GSH also affects calcium homeostasis; treatment of primary human epidermal keratinocytes with buthionine sulfoxamine depressed the level of reduced glutathione but increased intracellular Ca^{2+} (Ray et al., 1993). Neuroblastoma cells treated in vitro with 0.3 mM

SM maintained high cell viability for nearly 9 h, which then decreased with time. The decrease in cell viability was prefaced by an increase in free intracellular calcium that occurred between 2 and 6 h postexposure (Ray et al., 1995). Intracellular free calcium is a well-recognized marker of cell stress (Ruff and Dillman, 2007). Induction of intracellular calcium is thought to contribute to apoptosis induced by SM exposure in keratinocytes in vitro (Rosenthal et al., 2003). Despite these findings, Sawyer's group has shown that the sensitivity of primary human keratinocytes to SM was unaffected when calcium was reduced using chelators or increased using the membrane ionophore ionomycin (Sawyer and Hamilton, 2000). These findings suggest that although calcium levels are significantly altered by SM treatment, modulation of calcium alone is neither necessary nor sufficient for SM-induced apoptosis.

38.3.2 Inflammation

Inflammation is one of the major driving forces of the skin pathology caused by SM exposure. The contribution of cytokines to the inflammatory events is well established and their signaling pathways are important targets of medical intervention for potential countermeasures of vesicant injury (Joseph et al., 2016; Wagner et al., 2019). The literature linking inflammation and wounding is so extensive as to fill a book by itself. This section will therefore only present an overview of the inflammatory response to dermal skin injury. In short, cytokines signal via several pathways, including Akt, ras, Death Domain, MAP/Erk, and Janus kinase (Jak) (O'Shea and Murray, 2008; Weber et al., 2010; Kalliolias and Ivashkiv, 2016). The latter, JAK-signal transducer and activator of transcription (Stat) pathway, is a major regulator of all the cell types involved in inflammation and they can be either positive or negative mediators to the inflammatory process. Both proinflammatory and antiinflammatory events are under the influence of the Jak-Stat pathways and hundreds of cytokine receptors are regulated via these pathways, including more than 40 type I and type II cytokine receptors, and receptors for interleukins, interferons, growth stimulating factors, leptin, erythropoietin, and many more (O'Shea and Murray, 2008).

As for vesicant-injured skin, the inflammatory response appears to be biphasic. This is based upon our years of experience in addition to others who reported that inflammation played a minor role in the initial events of SM-induced cutaneous injury, but had much greater importance at later stages (Papirmeister et al., 1991b). Indeed, in another examination, the authors argued that inflammation may be more significantly involved in the vesication (blistering) event than previously believed, with inflammatory cells and mediators contributing directly to the formation of the primary lesion (Cowan and Broomfield, 1993). More recently, Joseph et al. (2011) documented a correlation between markers of inflammation and DNA damage with structural changes in skin following SM exposure.

Numerous accounts, from both in vivo and in vitro studies, have now documented a rise in a number of inflammatory cytokines in response to SM. Applications of SM in the MEVM have resulted in induction of IL-1β, IL-6, TNFα, and GM-CSF within 6 h (Sabourin et al., 2000; Wormser et al., 2005; Chang et al., 2018b). While IL-1α was not detected in these studies, its inducibility by SM vapor was confirmed in experiments in which the backs of hairless mice were exposed (Ricketts et al., 2000). Further, relative mRNA levels of IL-1β, IL-6, IL-8, and TNFα have been demonstrated to significantly rise within 24 h of SM vapor treatment in full-thickness skin biopsies from weanling pigs (WPs; Sabourin et al., 2002). Studies with cultured human keratinocytes have shown that these cells respond directly to SM with the production of cytokines. Interleukins-1β, -6, -8, and TNFα were detectable in culture media from these cells 24 h after treatment with 100−300 μM SM (Arroyo et al., 2000). Cultured skin fibroblasts have also been shown to express TNFα in response to SM. The chemotactic activity of keratinocyte-derived IL-8 could initiate the transmigration of circulating granulocytes into SM-exposed tissues where they could contribute to the primary lesion. Other cytokines may be involved in priming and activation of the recruited immune cells. While cytokine induction may occur via several means, there is now ample evidence that the inflammatory transcription factor NF-κB is one such pathway activated by SM (Atkins et al., 2000; Minsavage and Dillman, 2007; Rebholz et al., 2008). In fact, enhanced synthesis of the aforementioned cytokines in resident skin cells may occur as a result of this NF-κB activation (Ghosh et al., 1998). More recently, evidence has been provided that the p38/MAP kinase pathway is also important in SM-induced cytokine production by human keratinocytes (Ruff and Dillman, 2010).

Additional inflammatory mediators have been detected in cutaneous tissues as a consequence of SM injury. These include free arachidonic acid (Lefkowitz and Smith, 2002) and its cyclooxygenase (Rikimaru et al., 1991; Dachir et al., 2004) and lipoxygenase products (Tanaka et al., 1997). Furthermore, the increased capillary permeability observed would allow a variety of circulating inflammatory participants, such as complement components, kininogens, etc., to enter the dermal interstitium (Rikimaru et al., 1991). Clearly, vesicant injury involves a host of inflammatory mediators similar to those seen in other types of wounds, where individual cytokines have been singled out as potential therapeutic targets.

38.3.3 Protease activation

While there may be protease involvement in the initial SM injury, most studies have viewed the participation of serine and matrix metalloproteases (MMPs) in SM injury as a downstream event since MMPs in particular regulate various inflammatory and repair processes (Parks et al., 2004). The regulatory role confounds the potential use of MMP inhibitors as therapeutic agents because of their beneficial role in wound repair and remodeling. Increased protease activity following SM exposure has been reported in vitro in human peripheral blood lymphocytes (PBLs) (Cowan and Broomfield, 1993) and human epidermal keratinocytes (Smith et al., 1991), ex vivo in rabbit skin organ cultures (Higuchi et al., 1988; Woessner et al., 1990) and human skin explants (Rikimaru et al., 1991; Lindsay and Rice, 1996), in vivo in hairless guinea pig (HGP) skin (Cowan et al., 1993, 1994; Kam et al., 1997), and in vivo in the mouse ear (Powers et al., 2000) and hairless mouse (HM; Casillas et al., 2000a). The continued assessment of proteolytic activity in animal models is useful for characterizing specific proteases important to SM injury and for identifying effective protease inhibitors with therapeutic use in reducing or eliminating tissue injury caused by SM cutaneous exposure. The relationship between SM-increased protease activity and the subsequent vesication that occurs in SM lesions remains unclear, but emerging literature implicating protease involvement is consistent with the known ability of proteases to degrade basement membrane components in vitro and in vivo. Inhibition of these proteases should reduce the extent of the injury, promote a more rapid recovery, and provide a useful adjunct to other therapeutic strategies aimed at preventing SM-induced degenerative pathophysiological events (Cowan et al., 1993).

38.3.4 Apoptosis

Mechanisms underlying SM-induced apoptosis have been carefully explored using primary cultures of human keratinocytes. Treatment of keratinocytes with 100−300 μM SM resulted in activation of both caspase 8, which initiates the Fas-dependent death receptor pathway, and caspase 9, which initiates the mitochondrial apoptotic pathway (Rosenthal et al., 2003). Fas and Fas ligand (FasL) were upregulated in a concentration-dependent manner by SM leading to activation of caspase 3, the central executioner protease. Transfection of immortalized keratinocytes with a dominant negative Fas-activated death domain resulted in a blunted caspase response to SM. Microvesication and tissue injury produced in vivo by SM exposure of transfected cells after grafting onto athymic nude mice was also reduced by this treatment.

Changes in intracellular calcium levels are known to activate the mitochondrial pathway of apoptosis. A key regulator to Ca^{2+}-dependent proteins is calmodulin. SM has been shown to cause a time-dependent induction of calmodulin in keratinocytes (Simbulan-Rosenthal et al., 2006). Moreover, depletion of calmodulin using antisense probes attenuated SM-induced activation of caspases involved in the mitochondrial pathway of apoptosis. Both antisense and pharmacological inhibition of calmodulin prevented SM-induced nuclear fragmentation in the keratinocytes. Bad, a proapoptotic Bcl-2 family member present in an inactive phosphorylated form in viable cells, was also activated by SM. Furthermore, cyclosporine A, a selective inhibitor of calcineurin, a Bad phosphatase, inhibited SM-induced keratinocyte apoptosis. These results suggest that calcium-dependent activation of Bad may be a mechanism by which SM induces apoptosis in keratinocytes.

Another potential signal for SM-induced cell death is endoplasmic reticulum (ER) stress. An accumulation of unfolded proteins in the ER will trigger multiple corrective mechanisms, which, if unsuccessful, will lead to caspase-12-dependent apoptosis (Oyadomari and Mori, 2004). Using the MEVM, Chang et al. (2013) have identified specific molecular markers indicating induction of ER stress within 24 h of SM exposure.

One form of cellular demise common to epithelial cells is detachment-initiated apoptosis, also referred to as anoikis (Frisch and Francis, 1994). Epidermal keratinocytes rely on signals derived from the surrounding ECM for survival. It is possible that loss of these signals plays a role in SM-induced epidermal cell injury, and that cell detachment from the basal lamina precedes cytotoxicity. Several lines of evidence support this possibility. First, SM can alter the dynamics of cytosolic proteins that exert control over the attachment of cells to the basement membrane. For example, SM can modify intracellular actin microfilaments and keratin intermediate filaments known to be important in maintaining epithelial cell connections with the basal lamina. Thus, Hinshaw et al. (1999) reported that SM causes changes in the actin microfilament architecture and morphology of human keratinocytes within 3 h of exposure. This was associated with a significant decrease in keratinocyte adherence without evidence of cytotoxicity. In addition, Werrlein and Madren-Whalley (2000) found that SM caused rapid, significant decreases in immunodetection of keratins 5 and 14, an intermediate filament pair found in undifferentiated keratinocytes. In both in vivo (Gunhan et al., 2004) and in vitro studies with human keratinocytes (Dillman et al., 2003), and with purified proteins (Hess and FitzGerald, 2007), keratins 5 and 14 have been found to be alkylated by SM as well as nitrogen mustard (mechlorethamine, HN2) and CEES, the monofunctional analog of SM. Sites

of alkylation may be similar to dominantly acting mutations in keratins 5 and 14 that are known to be responsible for the human blistering disorder, EB simplex, in which, like SM-induced blistering, basal epidermal cells are targeted (Fuchs, 1997). The keratin cytoskeleton of basal keratinocytes links to the hemidesmosome and makes connections, through plectin, with the β4 cytoplasmic tail of integrin α6β4, thereby strengthening adhesion to the basement membrane via laminin-332 (Giancotti and Tarone, 2003). Alkylation of keratins 5 and 14 could cause aggregation and loss of function of the intermediate filament network and serve as a prelude to basal cell separation from the basement membrane. Likewise, as has been hypothesized, SM-induced proteolytic degradation of laminin-332 could provide the basis for blistering that occurs following SM exposure (Jin et al., 2016; Chang et al., 2018a).

In addition to its actions on epidermal cells, SM can directly alkylate ECM proteins in the skin, a process that can also alter the ability of basal keratinocytes to maintain vital connections with the basement membrane. In support of this idea, Gentilhomme et al. (1998) showed that SM treatment of human dermal equivalents reduced the ability of naïve keratinocytes to deposit laminin at the dermal−epidermal interface. In addition, Zhang et al., found that treatment of fibronectin and laminin with SM interfered with the ability of human epidermal keratinocytes to adhere to these matrix proteins (Zhang et al., 1995a,b). This inhibitory action was determined to be alkylation-dependent, because it could be prevented by cotreatment with SM scavengers. Sulfur mustard and nitrogen mustard also reduce cell and tissue immunoreactivity for laminin-332, as well as integrin α6β4 and collagen XVII (also known as bullous pemphigoid antigen), two hemidesmosomal components that are critical for keratinocyte adherence (Smith et al., 1997c, 1998; Zhang and Monteiro-Riviere, 1997; Werrlein and Madren-Whalley, 2000; Kan et al., 2003). Interestingly, each of these proteins, like keratins, has been implicated in human blistering disorders involving separation of the epidermis at the dermal−epidermal junction (Pulkkinen and Uitto, 1998; Yancey, 2005; Chang et al., 2018a). These findings suggest that SM can alter the interaction of basal cells with matrix proteins critical for basement membrane detachment. The alteration may occur by reducing protein functionality, decreasing protein expression, or increasing protein degradation. By whichever mechanism, a negative alteration in these critical anchoring components could lead to basal cell detachment and initiate anoikis.

38.3.5 Signal transduction pathways

Sulfur mustard exposure induces the activation of many molecular signaling pathways (reviewed in Ruff and Dillman, 2007). These pathways mediate many responses including inflammation, cell proliferation, cell differentiation, and apoptosis. Some that involve inflammation include the transcription factor NF-κB and p38 MAP kinase. NF-κB is a transcription factor that is induced within 2−4 h after SM exposure (Minsavage and Dillman, 2007). Dillman has suggested that this delayed induction is due to a nontraditional pathway of stimulation, whereby p90RSK phosphorylates IκB or the p65 subunit of NF-κB (Ruff and Dillman, 2007). The MAP kinase p38 is activated in response to damaging stimuli, including heat, UVA, and proinflammatory stimuli. Dillman's group and others have noted an increase in activation of p38 by phosphorylation and demonstrated that inhibition of p38 phosphorylation resulted in a decrease in SM-induced proinflammatory cytokine production in vitro (Kehe et al., 2009). However, the importance of NF-κB or p38 activation in mediating SM cutaneous injury has not been demonstrated in vivo. Also, while important for understanding SM-mediated toxicity, these pathways are difficult to target pharmacologically.

38.4 Models of dermal sulfur mustard exposure

38.4.1 Introduction

Although there has been considerable investigation of SM therapies since the publication of Bruno Papirmeister's landmark compilation of *Medical Defense Against Mustard Gas* nearly 30 years ago, no suitable pharmacological treatment for SM exposure to the skin has been approved (Papirmeister et al., 1991c). The field has dramatically changed direction from strategies and therapies based on protection from SM exposure to therapies designed to subvert the blistering process and increase the rate of wound healing. New pharmaceutical strategies will be increasingly focused on combination therapies such as bifunctional drugs that target multiple processes in blister formation and the wound-healing process, together with increased recognition of the importance of pharmaceutics.

Although many advances have been made in the production of skin barrier protection or postexposure skin decontaminants [such as skin exposure reduction paste against chemical warfare agents and reactive skin decontamination lotion (RSDL), respectively], drug countermeasures against vesicants remain a subject of intense investigation. The primary treatment strategy following exposure to vesicants such as mustard gas is decontamination. However, given the high reactivity of SM, there is a very short timeframe (3−5 min) in which decontamination can be effectively accomplished (reviewed in Vogt et al., 1984 and Wormser, 1991); and some studies

suggest that an extractable reservoir persists for much longer. Furthermore, because SM exposure does not cause immediate pain or noticeable effects, exposure is often not recognized until the effective window for decontamination has passed. Therefore, much research has focused on the identification of treatments that can be performed after exposure has occurred. These treatments can be directed at any stage during the progression of injury resulting from vesicant exposure, including before or after blister formation. This chapter focuses on the progress that has occurred in the 30 years since Papirmeister's publication (Papirmeister et al., 1991c).

38.4.2 Model systems for screening sulfur mustard

In vitro and in vivo models for SM have substantially improved over the past 5 years. Experimental animal models have different skin characteristics including a reduced barrier for chemical penetration as compared to human skin (Bartek et al., 1972). The reduced barrier results in greater systemic toxicity in animals, complicating other measures of cutaneous injury. Despite these difficulties, animal models have displayed great utility, and surrogate endpoints such as microblister (epidermal−dermal separation) formation or edema are established biomarkers for measuring the efficacy of candidate compounds.

A systematic characterization of animal models including the euthymic HGP, WP, the MEVM, and the HM showed that SM-induced subepidermal blister formation and epidermal cell death in all models tested (Smith et al., 1997b). Hairless mice are useful models of human skin; the absence of hair on the skin and increased skin thickness reduce the rapid penetration of toxicants (Walter and DeQuoy, 1980). Thus, the HM has emerged as an effective model for characterizing vesicant injury mechanisms and for early screening of candidate therapeutics (Blank et al., 2000; Casillas et al., 2000a; Ricketts et al., 2000; Sabourin et al., 2003; Pal et al., 2009; Tewari-Singh et al., 2009, 2010, 2011, 2013, 2014a; Anumolu et al., 2011; Dorandeu et al., 2011; Jain et al., 2011; Joseph et al., 2011; Vallet et al., 2012).

First characterized in 1967, the HGP has been the most widely used model for vesicant exposure (Marlow et al., 1990a,b; Mershon et al., 1990; Yourick et al., 1991, 1992, 1993, 1995; Cowan et al., 1993, 1994; Graham et al., 1994; Smith et al., 1995;Kim et al., 1996; Kam et al., 1997; Millard et al., 1997; Dachir et al., 2010; Benson et al., 2011). Like human skin, SM-treated HGPs experience defects in epithelial cell regeneration, basement membrane modifications, and increased necrosis and apoptosis, making them a good model for therapeutic testing (Kan et al., 2003; Dachir et al., 2006). There is one report utilizing the rabbit ear as a model of SM injury, however, we know of no reports further developing this model to screen candidate antivesicants (Zlotogorski et al., 1997).

The MEVM is performed by application of vesicant to the inner (medial) side of the ear (Casillas et al., 1997). Edema can be quantified by measuring 8 mm diameter ear punch biopsy weights. Microscopic investigation shows clear histopathologic changes that include edema, epidermal−dermal separation, and necrosis. These effects occur in a dose-dependent manner. This model has been used to screen many compounds and remains the most cost-effective live animal screen available (Casillas et al., 2000b; Dachir et al., 2002, 2004; Babin et al., 2003; Casbohm et al., 2004; Sabourin et al., 2004; Wormser et al., 2004a,b, 2005; Kiser et al., 2005; Amitai et al., 2006; Dillman et al., 2006; Kumar et al., 2015; Liu et al., 2016; Achanta et al., 2018; Chang et al., 2018b; Tumu et al., 2018). Furthermore, the benefits of a fully sequenced mouse genome and wide range of antibodies available make this model superior. Systemic effects do occur, as physiological and toxicological effects are detected in the contralateral (untreated) ear of animals (Babin et al., 2000).

WPs and minipigs have also been used extensively for SM-induced skin injury (Lindsay and Rice, 1995; Brown and Rice, 1997; Graham et al., 1999, 2000; Chilcott et al., 2000; Logan et al., 2000) (Fig. 38.3) due to established similarities between human and pig skin (reviewed in Graham et al., 2005). Erythema was found to peak at 24 h after a 15-min vapor exposure, with maximal edema occurring at 48 h postexposure (Smith et al., 1996, 1997b; Graham et al., 1999). The dermal−epidermal junction was also damaged at 48 h, with laminin-5 (renamed laminin-332) showing a progressive decrease in protein expression following SM injury (Smith et al., 1997c). Furthermore, inflammatory markers including IL-8, IL-6, IL-1β, and MMP-9 are induced within 72 h of treatment with SM (Sabourin et al., 2002). The WP is also used as a model of wound debridement to enhance repair (Graham et al., 2002a,b, 2006; Reid et al., 2007; Dalton et al., 2008), as discussed in greater detail later in this chapter.

The isolated perfused porcine skin flap (IPPSF) model is an effective in vitro model for SM exposure, characterized extensively by Monteiro-Riviere's laboratory (King and Monteiro-Riviere, 1990). Skin flaps consist of isolated, perfused skin with intact dermis and epidermis maintained by microcirculation in a system that mimics normal blood flow. Unlike other animal models, gross blisters are obtained, with blister-induced epidermal−dermal separation occurring at the upper lamina lucida (Monteiro-Riviere and Inman, 1995, 1997; Riviere et al., 1995). This model has allowed for several

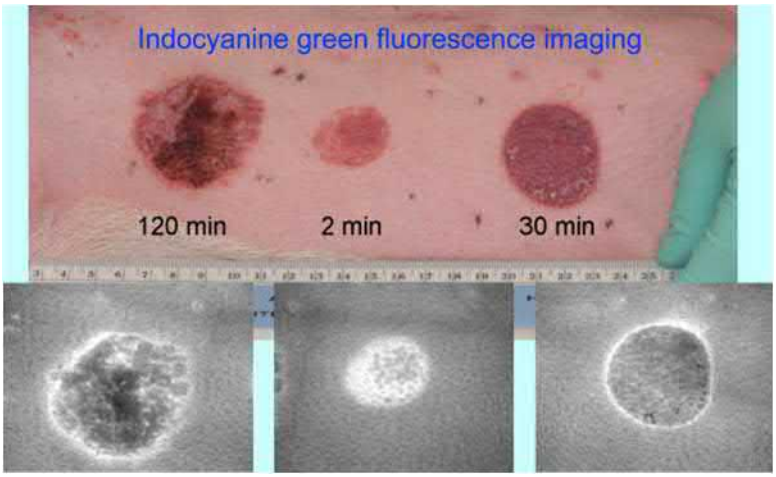

FIGURE 38.3 Weanling pig skin stained with indocyanine green following 48 h exposure to SM. *Reprinted from Graham, J.S., Chilcott, R.P., Rice, P., Milner, S.M., et al., 2005. Wound healing of cutaneous sulfur mustard injuries: strategies for the development of improved therapies. J. Burns Wounds 4, e1, in accordance with the Creative Commons Attribution License. (Graham et al., 2005)*

interesting experiments which could not have otherwise been performed. For example, the flow rate and composition of perfusing media can be altered: a higher flow rate is associated with increased blister formation, whereas increased glucose in the perfusion medium has been shown to block the formation of microvesicles and blisters (Riviere et al., 1997). Whether increased glucose can protect against blister development in live animals has not been tested. No reports using this model have been published since 2004.

Cell lines have been used to test vesicant toxicity and the efficacy of therapies. These studies are impacted by the differences in solubility of the vesicants, with CEES and SM being lipid soluble, and NM being water soluble, and all chemicals being quite reactive with water. Still, due to their ease of use, cell lines remain an important early screen for many toxic agents and there have been efforts to further develop as models for use with vesicants. HaCaT cells are immortal adult human skin cells that differentiate and proliferate easily in vitro. A cell line resistant to SM was developed in order to identify biological pathways that might offer protection against vesicants. The line was developed by serial culture in the presence of gradually increasing concentrations of SM over 40 months. This line, named HaCaT/SM, showed an 8.2-fold increase in LC^{90} (Schmidt et al., 2016). It showed smaller nuclei perimeter, higher clonogenicity, and altered gene expression. The cell line was found to be resistant to other alkylating agents and cytotoxic drugs (Schmidt et al., 2018b), and showed higher glutathione levels, survival against H_2O_2 treatment, and lower expression of nrf2 and its targets GCLC and GST (Rothmiller et al., 2018a). The microRNA MiR-181 was also induced and was thought to contribute to the resistance of this line (Rothmiller et al., 2018b).

HaCaT cells have also been tested in coculture with THP-1 immune cells in an effort to identify and characterize the immunological component of vesicant injury using a cell line system (Balszuweit et al., 2014). Treatment of HaCaT cells with SM in the presence of THP-1 cells increased necrosis, apoptosis, and inflammation in HaCaT cells. However, if the THP-1 cells were added following SM exposure, the increased signs of cellular injury were not evident, suggesting that the THP-1 cells were responding to SM treatment directly. Necrosulfonamide, an inhibitor of necroapoptosis, blocked the induction of proinflammatory cytokines when given to cocultures of HaCaT and THP-1 cells treated with SM, suggesting a role for immune cell death and release of these cytokines, which then impact HaCaT cells (Menacher et al., 2019). Diclofenac reduced necrosis, apoptosis, and inflammation in the cocultured cells treated with SM (Menacher et al., 2018), and the herbal remedy berberine provided similar protection (Lang et al., 2018). The efficacy of the antiinflammatory drugs in preventing SM injury suggests that this method may allow for screening of other drugs for SM injury that function via the same mechanism. Furthermore, removal or addition of the THP-1 cells allows for distinction of the molecular pathways affected.

In addition to cell lines, artificial human skin has been used to test the effects of SM (Petrali et al., 1993). Human skin equivalent, commercially available as EpiDerm, is a fully differentiated artificial human skin with both a dermis and an epidermis (Monteiro-Riviere et al., 1997). Full-thickness models (EpiDerm-FT) have been evaluated for their potential use in SM models as well, in particular focusing on the dermal−epidermal junction and basement membrane components (Hayden et al., 2009). Studies by our laboratories demonstrated CEES-mediated gene induction in EpiDerm-FT and demonstrated the usefulness of this model in histological evaluation following vesicant exposure (Black et al., 2010b, 2011). EpiDerm-FT might also be used as an in vitro

assay for screening of potential medical countermeasures against vesicants, such as was done with liposome-encapsulated glutathione (Paromov et al., 2011).

Administration of the vesicants themselves is also an area of consideration. Whereas SM and CEES are both lipid soluble, NM is water soluble. For lipid-soluble compounds, the chemicals may be placed directly on the skin, or a vapor cup model may be used in which a cup is placed over a portion of skin and the vapor pressure of the agent results in skin exposure over a fixed surface area. Different strategies must be used for NM as it is water soluble and has negligible vapor pressure. A cutaneous patch model has been developed for NM exposure in the skin. This model using a glass microfiber filter delivery system with a semiocclusive patch that allows for easier application of NM over defined areas of the skin (Composto et al., 2016).

38.4.3 Decontamination

Skin decontamination can be an effective means of reducing or preventing injury from SM exposure when conducted within minutes of exposure (Sidell et al., 1997; Chan et al., 2013). Most SM decontamination strategies focus on its removal with solvents or adsorption of SM to inert substances, since preventing skin penetration of sulfur mustard is the most important factor. Even simple techniques such as washing with soap and water are effective (Aasted et al., 1987; Rejaei et al., 2010; Weibrecht et al., 2012; Chan et al., 2013; Graham and Schoneboom, 2013). Washing with a variety of other substances has been suggested, including kerosene, oil, gasoline, surgical spirits, and neutral sodium hypochlorite (Sollmann, 1919a,b; Chiesman, 1944; Jelenko, 1974; Gold et al., 1994; Wormser et al., 2002). Fuller's earth, a binding agent, is a well-established and effective means for the decontamination of exposure to liquid sulfur mustard, however, it is difficult to contain and uncomfortable to apply. Fuller's earth is clay-rich soil commonly used to purify hydrophobic materials, including oils and greases (Chilcott et al., 2001), and functions by binding in a near-irreversible manner to SM, therefore, preventing its absorption, association, and reaction with skin components. While Fuller's earth is a common standard to which other decontamination agents are tested, modifications of this compound and other related clay-like materials may be more efficacious (Lyle et al., 1984, 1986, 1987; Joiner et al., 1987). Other items, including flour and talcum powder, were shown to be effective in reducing the progression of injury (Van Hooidonk et al., 1983). However, decontamination is ineffective in cases of vapor exposures to SM, which occur over a longer time period (McNamara, 1960). These results suggest that nearly anything that could adsorb a hydrophobic product would be effective in reducing SM injury.

Another strategy for decontamination is active chemical neutralization, whereby the SM undergoes a chemical reaction to prevent its reaction with outside components. There have already been successes with this type of approach, with the best example being RSDL, a product approved for military use by the United States and a number of other nations (FDA, 2003), and recommended for mass civilian exposure (Mengs et al., 2012). RSDL has been demonstrated to be as effective as Fuller's earth in its decontamination properties (Taysse et al., 2007, 2011). The first generation of this product was composed of a solution of potassium 2,3-butanedione monooximate and its free oxime, diacetyl monooxime, in a mixture of monomethyl esters of polyethylene glycol. The solvent portion of the lotion is designed to solubilize chemical weapons away from the skin, while the oxime component readily reacts with mustards and with nerve agents, producing less toxic products (Sawyer et al., 1991a,b; Sun et al., 2015). In domestic pigs, treatment with RSDL 5 min after exposure to SM resulted in significantly less injury observed 3 days postexposure (Taysse et al., 2007).

Other approaches to chemical neutralization include the use of sodium thiosulfate as a reducing agent to function by reacting with activated SM (Hatiboglu, 1960; Owens and Hatiboglu, 1961; Bonadonna and Karnofsky, 1965; reviewed in McKinley et al., 1982). Original studies (WW1-1970) focused on its use as an injectable drug to prevent the bone marrow suppression seen with exposure to SM and related mustard agents. Systemic administration of this and other antioxidant molecules such as *N*-acetyl cysteine is discussed later in this chapter. Another thiol, 2,3-dimercapto-propane sulfonic acid, showed protection against injury in mice exposed to SM vapor (Pant et al., 2000).

Decontamination can also be accomplished by the application of creams containing fluorinated cross-linker monomers (Liu et al., 1999). Deactivation occurs when substances within the cream actively react with and decontaminate the agents. Care should be taken with administration of these creams, since they can trap chemical agents on the skin and prevent natural off-gassing. This may result in enhanced injury if inadvertently applied after exposure to a chemical agent. In some cases, perfluorinated creams have produced an 18-fold reduction in the rate of skin absorption (Chilcott et al., 2002).

Once dermal absorption of SM has occurred, it is generally accepted that SM is irreversibly bound to skin constituents, and therefore cannot be removed from the skin through the methods discussed above. However, some investigators suggest that there remains some fraction of unreacted SM in the skin, in what is often described as a skin reservoir. This reservoir is thought to contribute to ongoing injury by continually releasing SM, allowing

further damage to occur. Indeed, recent studies demonstrated that application of ^{14}C-labeled SM was extractable from an in vitro pig skin model for up to 6 h, however, the extract was not further evaluated to show skin toxicity (Dalton et al., 2004; Hattersley et al., 2008). Future work might focus on targeting this reservoir to prevent ongoing damage; no therapies are currently available for this purpose.

38.4.4 Treatment of blisters

The prolonged pathology observed in SM injury suggests two pathological mechanisms: an ongoing toxicity that contributes to a step-wise progression culminating in blister formation, and a healing process that has been subverted. This is quite unlike the wound healing of thermal injuries. Aspiration (removal of the fluid within the blister) and deroofing (removal of the epidermal layer that constitutes the roof of the blister) are the main courses of action taken for larger, coalesced blisters, in order to promote the healing process (reviewed in Jenner and Graham, 2013).

Physical debridement of tissues, the surgical removal of tissue beyond the epidermal (roof) layer, enhances the rate of wound healing (Graham et al., 2005) (Table 38.1). The slow rate of healing suggests that SM-modified proteins or other cellular components are preventing the normal healing process (Eldad et al., 1998). SM-mediated cross-linking of structural proteins such as laminins may not be easily repaired and may contribute to a delayed wound-healing response (Zhang et al., 1995a). This could occur by promoting prolonged inflammation or by preventing the normal wound closure event that occurs as dermal cells migrate across and repair the blister area. Early studies demonstrated that SM-induced lesions in the skin of WPs or Yucatan miniature pigs underwent faster wound healing when treating lesions by debridement after exposure to SM, whether the debridement was performed by CO_2 laser or surgically (Smith et al., 1997a,b,c; Rice et al., 2000; Graham et al., 2002a). Furthermore, when combined with skin grafting, debridement promotes wound repair (Graham et al., 2002b; Rice, 2003; Evison et al., 2006; Dalton et al., 2008).

A 2018 report of an accidental human exposure to SM in the laboratory was effectively treated with debridement (Schmidt et al., 2018a). In this case, a laboratory worker synthesized SM for use in creating a new type of plastics. After accidentally spilling it on his lab coat, the technician removed his coat but was unaware that the underlying clothing was also contaminated until 30 min after exposure. His abdomen and left forearm were exposed, with the abdomen forming a 2-cm red patch. Two hours after exposure, the lesions were treated with H_2O_2 and cortisone. Five hours postexposure, the patient presented with pronounced reddening of his abdomen, with blisters forming at 9 h. The patient presented at the Center for Severe Burn Injuries in Hamburg, Germany, for treatment. At this point and beyond, photographs were taken of the injury and its healing process (Fig. 38.4). Over the course of 12 days, the abdominal lesion progressed as a second-degree burn without further healing. The wound was excised and skin grafting was done 14 days postexposure using skin from the patient's right thigh. The wound healed without complications (Fig. 38.4). The wound was not completely debrided, and the region that was grafted with skin has a different coloration than the region that healed on its own (Fig. 38.4, +1-year panel).

Interestingly, the patient returned to the hospital 14 months after the incident due to his concern that SM might lead to carcinogenesis. He requested complete removal of the affected region and a second skin graft. The surgery was performed, and the wound healed with less scarring and noticeable difference in skin color (Fig. 38.5, +1-year panel). Physicians performed skin biopsies prior to the surgery to evaluate whether malignancy had occurred. The excised tissue was free of inflammation and showed no signs of malignancy. Skin biopsies showed normal dermis and epidermis structure. DNA hypermethylation was observed in the regions that were exposed to SM, however. Four years after the accident, which was 22 months after the second surgery, the physicians noted that the scars were mature, stable, and freely moveable. This case provides an example of two treatment approaches in the same individual.

38.5 Therapeutics

38.5.1 Antioxidants

Chemical scavengers may be used to inactivate free radical forms of SM or the oxygen or nitrogen radicals thought to be formed as a consequence of SM activation. If given early enough after SM exposure, such scavengers might directly deactivate SM and perhaps reduce the reservoir of SM present in the skin. However, scavengers seem to have efficacy beyond the lifetime of SM itself in the skin, suggesting that other physiological mechanisms such as inflammation and oxidative stress might be reduced by these agents (reviewed in Papirmeister et al., 1991c). Scavengers have mostly been tested for their ability to reduce leukopenia and death due to the systemic effects of mustard exposure, rather than the reduction of skin injury (reviewed in Papirmeister et al., 1991c). Although most work has focused on scavengers as therapeutics in pulmonary exposures where ongoing oxidative stress contributes to toxic outcomes such as pulmonary fibrosis or chronic obstructive pulmonary disease, there has been limited research on their efficacy in treating cutaneous injury.

TABLE 38.1 Comparison of dermabrasion (debridement) strategies for enhancing the rate of SM-induced skin injury repair.

Therapy	Time of administration	Agent route	Species/ system	Efficacy	References
Reactive skin decontamination lotion	Pretreatment	Topical	In vitro, human skin	18-fold reduction in skin absorption rate, may partially extract SM from the skin reservoir	Chilcott et al. (2002)
Dermabrasion	96 h post	Vapor, skin	Yucatan pigs (miniature, larger white)	Accelerated (≤3 ×) wound healing	Rice et al. (2000)
Debridement, CO_2 laser	6, 24, or 48 h post	Vapor, skin, 15 min	WP	Threefold fewer wounds. Improved histological skin structure	Graham et al. (1997)
Debridement, CO_2 laser	48 h post	Topical, liquid, 2 h	WP	Improved histological skin structure	Graham et al. (2000)
Debridement, xeroform petrolatum	48 h post	Topical, liquid, 2 h	WP	Skin elasticity similar to sham (non-HD-treated) pig skin	Graham et al. (2006)
Debridement, Scarlet Red Ointment	48 h post	Topical, liquid, 2 h	WP	Skin elasticity similar to sham (non-HD-treated) pig skin	Graham et al. (2006)
Debridement, surgical tangential excision	48 h post	Topical, liquid, 2 h	WP	Mild improvement in healing	Graham et al. (2000)
Debridement, surgical tangential excision and skin grafting	48 h post	Topical, liquid, 2 h	WP	Improved histological skin structure	Graham et al. (2000)
Debridement, Versajet	48, 72, and 96 h post	Not specified	WP	No improvement at day 14	Dalton et al. (2008)
Debridement, Compound W	48, 72, and 96 h post	Not specified	WP	No improvement at day 14	Dalton et al. (2008)
Debridement, Collagenase Santyl	48, 72, and 96 h post	Not specified	WP	No improvement at day 14	Dalton et al. (2008)

WP, Weanling pig.

Sodium thiosulfate, a potent antioxidant and scavenger, has been shown to be effective in reducing leukopenia and platelet depression when given systemically in treatment for nitrogen mustard, particularly when given prior to exposure (Owens and Hatiboglu, 1961; Bonadonna and Karnofsky, 1965; McKinley et al., 1982). In the IPPSF model, perfusion with sodium thiosulfate modestly reduced microvesicle formation and attenuated the vascular response (Zhang et al., 1995b). However, it has limited efficacy against skin injury (Vojvodic et al., 1985; Zhang et al., 1995a,b).

Glutathione depletion has been shown to occur in several tissues and cell lines in response to mustard treatment (Omaye et al., 1991; Ray et al., 1995; Kulkarni et al., 2006). Depletion of glutathione by buthionine sulfoximine treatment of isolated human leukocytes increased their sensitivity to SM toxicity (Gross et al., 1993). Given the critical role of glutathione in maintaining the intracellular reducing state of the cell, restoration or pretreatment with glutathione may protect against SM toxicity. Indeed, pretreatment of the basal epidermal keratinocyte cell line SVK14, the upper respiratory tract cell line BEAS-2B, or the lower airway type II epithelial cell line A549 with glutathione was shown to provide resistance to SM toxicity (Smith et al., 1997a; Andrew and Lindsay, 1998; Lindsay and Hambrook, 1998). Similar results were seen with other human cell lines, including G361, SVK14, HaCaT, and NCTC human skin cells (Simpson and Lindsay, 2005). Also, stimulation of glutathione concentration by pretreatment with glutathione itself or the cysteine precursor 10 mM L-oxothiazolidine-4-carboxylate was shown to be protective against SM in vitro (Gross et al., 1993; Amir et al., 1998). However, these early successes did not translate effectively to animal model

FIGURE 38.4 Primary healing phase of the upper body of a 27-year-old male laboratory worker exposed to liquid sulfur mustard over a period of 1 year. The injury was excised and split-skin grafting was performed 14 days after the exposure, and the patient returned to work on day 22 following the injury (Schmidt et al., 2018a). *Reprinted from Schmidt, A., Steinritz, D., Rudolf, K.D., et al., 2018a. Accidental sulfur mustard exposure: a case report. Toxicol. Lett. 293, 62–66, with permission from Elsevier.*

FIGURE 38.5 At approximately 1-year posthealing, the patient described in the previous figure was concerned about the possibility of cancer development, and requested the removal of skin tissue exposed to the SM. The affected areas were excised and covered with split-skin grafts taken from the right thigh (Schmidt et al., 2018a). *Reprinted from Schmidt, A., Steinritz, D., Rudolf, K.D., et al., 2018a. Accidental sulfur mustard exposure: a case report. Toxicol. Lett. 293, 62–66, with permission from Elsevier.*

systems. Reduced glutathione (400 mg/kg) given once before and twice after SM did not protect mice from SM toxicity (Kumar et al., 2001). Continued in vitro efforts have shown the protective effect of glutathione and glutathione-replenishment studies using in vitro models (Balsuweit et al., 2016). Because glutathione would be difficult to administer cutaneously, it is an unlikely therapeutic agent for the skin.

Cysteine is an amino acid with a reduced sulfur group that acts as an antioxidant. Cysteine residues are selectively alkylated in proteins by SM and the bifunctional nature of SM allows chemical cross-linking (Byrne et al., 1996). Early studies with nitrogen mustard in mice demonstrated that pretreatment with cysteine protected against toxicity (Contractor, 1963). However, microvesicle formation and dark basal cell formation were not protected in the IPPSF model (Zhang et al., 1995b). *N*-Acetyl-L-cysteine (NAC) acts both as a scavenger and as an inducer of glutathione synthesis, restoring the normal reducing status of the cell. Because SM lowers intracellular-reduced glutathione, its restoration may contribute to increased tissue survival and repair. In addition, pretreatment with NAC may elevate glutathione levels above normal and offer protection against low concentrations of SM (Atkins et al., 2000). In vitro, pretreatment with NAC protected PBLs from 10 μM SM (Gross et al., 1993). Endothelial cells pretreated with NAC were resistant to loss of cell adherence and rounding following exposure to 250 μM SM (Dabrowska et al., 1996). Liposomes containing NAC increased the viability of HaCaT keratinocytes in an in vitro study if given simultaneously with CEES (Paromov et al., 2008). Although antioxidants have proven to be efficacious if given prior to SM exposure, their ability to ameliorate skin damage or enhance wound repair has not been shown.

Silibinin is the main active flavonone of silybin, an extract of the milk thistle plant (*Silybum marianum*). Silibinin or silybin has been tested in clinical trials as a chemotherapeutic agent (Singh and Agarwal, 2005; Deep and Agarwal, 2010) for hepatitis, diabetic nephropathy, and other indications. The compound has diverse effects, including antiinflammatory, antioxidant, and antimetastatic effects (Gu et al., 2007; Singh and Agarwal, 2009; Deep and Agarwal, 2010). Topical silibinin (1 mg) attenuated CEES-mediated pathology in the skin of SKH-1 mice when applied 30 min post-CEES exposure, including epidermal thickness, apoptosis, induction of proinflammatory genes, lipid peroxidation, and DNA oxidation (Tewari-Singh et al., 2012). It also attenuated NM-mediated injury at 24, 72, and 120 h postexposure as measured by epidermal thickness, dead and denuded epidermis, parakeratosis, and microvesication, and reversed DNA damage as measured by 8-oxodG (Jain et al., 2015).

Ebselen [2-phenyl-1,2-benzisoselenazol-3(2H)-one] is an organo-selenium compound that functions as an antioxidant; it can directly scavenge hydrogen peroxide and peroxynitrite, mimics glutathione peroxidase, and acts as an antiinflammatory agent (Schewe, 1995). Ebselen itself reduced HN2-mediated inflammation at 24 h in the MEVM when applied in three treatments postexposure, with the first starting at 15 min. Several ebselen derivatives have shown efficacy in in vitro studies in skin and lung cell lines (Pino et al., 2013, 2014). In the MEVM, ebselen reduced HN2-induced tissue swelling (Lulla et al., 2014). An analog of ebselen, ebselen oxide (EB-2), reduced HN2-induced increases in wet weight, ear thickness, hyperplasia, vesication, inflammatory cell infiltration, apoptosis, and MMP-9 (Tumu et al., 2018).

AEOL-10150 is a broad-spectrum antioxidant that has been tested as an inhibitor for several chemical agents, including sulfur mustard (Zhang et al., 2018). In the HaCaT epidermal cell line model, AEOL-10150 reversed CEES-induced decreases in DNA synthesis and cell viability (Tewari-Singh et al., 2014a). It also improved skin bifold and epidermal thickness, myeloperoxidase activity, and DNA oxidation in mouse skin (Tewari-Singh et al., 2014b).

38.5.2 Poly(ADP-ribose) polymerase inhibitors

Although PARP inhibitors were one of the first sets of drugs to be investigated for use against vesicant injury, earlier studies did not yield positive results in animal model systems and this line of research was abandoned for many years (Casillas et al., 2000b). Recently, the development of PARP inhibitors with better pharmacologic properties for the treatment of cancers has led to a renewed interest in the potential for PARP inhibitors to treat SM injury. ABT-888, with efficacy against both PARP-1 and PARP-2, was approved as an orphan drug in 2016 by the FDA. In the HaCaT keratinocyte model, ABT-888 protected against CEES and SM-induced cell death and blocked vesicant-mediated depletion of NAD^+/ATP (Debiak et al., 2016; Mangerich et al., 2016). In the MEVM using Kunming mice, ABT-888 reduced edema and epidermal necrosis due to SM when given 30 min prior to SM exposure (Liu et al., 2016). A lingering concern is whether halting apoptosis of damaged cells can lead to carcinogenesis in the future.

38.5.3 Proteolytic inhibitors

Proteases play a critical role in wound repair and remodeling, and therefore are likely important targets for the enhancement of wound repair (Mohan et al., 2002). In particular, damage to the basement membrane by MMPs is thought to be one mechanism responsible for

TABLE 38.2 Summary of the effects of protease inhibitors on SM toxicity.

Therapy	Time of administration	Therapy route	Therapy concentration	Agent route	Species/ system	Efficacy	References
Doxycycline	Cotreatment, then posttreatment	In media	500 μM	In media	HaCaT cells, in vitro	Reduced cellular detachment, but did not prevent apoptosis	Lindsay et al. (2007)
Doxycycline	1 h post	In media	100 μM	In media, 200 μM	HEK keratinocytes, in vitro	Reduction of SM-induced IL-8 production	Nicholson et al. (2004)
Doxycycline	Cotreatment	Topical	90 μM	Topical	In vitro human skin explants	No effect on SM-induced dermal–epidermal separation	Schultz et al. (2004)
GM 1489[a]	Pretreatment 15 min	Topical	20 μL of 25 mM	Liquid	Mouse	Reduced expression of MMP-9 mRNA	Gerecke et al. (2005)
Ilomastat	Pretreatment 15 min	Topical	20 μL of 25 mM	Liquid	Mouse	No effect	Gerecke et al. (2004)
Povidone iodine	15 m and 24 h post	Topical	40 mg 10% povidone iodine	HN2, 0.5 mg	Haired guinea pig	>80% reduction in MMP-2 and MMP-9 activity in skin	Wormser et al. (2002)
Iodine	20 m post	Topical	1% w/v	Liquid, 1.27 mg	Pig	No effect	Margulis et al. (2007)

[a]*GM 1489, N-[(2R)-2,4-methylpentanoyl]-L-tryptophan-(S)-methyl-benzylamide.*

dermal–epidermal separation seen in SM-induced blister formation. This could occur by upregulation of MMP expression, reduced competition for MMPs by adhesion molecules, or both (Mol, 1999; Danne et al., 2001; Shakarjian et al., 2006). MMP-9 expression is upregulated in WP skin (Sabourin et al., 2002) and the MEVM following SM exposure (Chang et al., 2006). Inhibition of proteases might therefore ameliorate damage caused by SM to structural components of the skin (Table 38.2). Explant cultures of SM-treated human skin cotreated with Ilomastat showed no epidermal–dermal separation (Schultz et al., 2004). Sulfur mustard-induced MMP-9 mRNA in the MEVM was partially inhibited by pretreatment with the MMP-9 inhibitor GM 1489 (Gerecke et al., 2005). The antibiotic doxycycline is also an MMP inhibitor that was shown to attenuate SM-induced pulmonary and ocular injury (Guignabert et al., 2005; Horwitz et al., 2014). However, doxycycline does not protect HaCaT viability; cells lose adherence and undergo apoptosis (Lindsay et al., 2007).

Microvesication of human skin in vitro was inhibited by treatment with MMP inhibitors such as Illomastat, but HGP skin had no decrease in microvesication or necrosis following repeated treatments with Ilomastat (Mol and van den Berg, 2006). Mol and Van den Berg suggest that this may be due to lack of delivery of the MMP inhibitor to the site of action. Although MMP inhibitors may reduce the ongoing injury caused by upregulation of MMP-9, most inhibitors have difficulty penetrating the skin. Another study demonstrated that treatment of an ex vivo human skin model with the metalloprotease inhibitor GM6001 blocked microvesication even when given 8 h following HD exposure (Mol et al., 2009). The application of pharmaceutical concepts may aid in the development of better delivery systems that would enhance the efficacy of this class of drugs.

MMP-9 is released by fibroblasts in response to keratinocyte stimulation by sulfur mustard (Ries et al., 2008). Indeed, mustard-stimulated release of MMP-9 only occurred in coculture of human dermal fibroblasts with HaCaT keratinocytes or with culture of human dermal fibroblasts with conditioned media from HD-treated HaCaT cells, suggesting that paracrine signaling is responsible (Ries et al., 2008). Our work showed a dramatic increase in cytokine expression and activation of mediators of inflammation within 24 h after HD exposure, which may contribute to MMP-9 induction (Fig. 38.6) (Gerecke et al., 2009). Together these data suggest that inhibition of fibroblast activation following vesicant exposure may also reduce MMP-9 activation and release.

38.5.4 Steroids, corticosteroids, and glucocorticoids

Steroids have shown some efficacy in reducing inflammation and blister formation in response to SM or genetic blistering diseases such as bullous pemphigoid

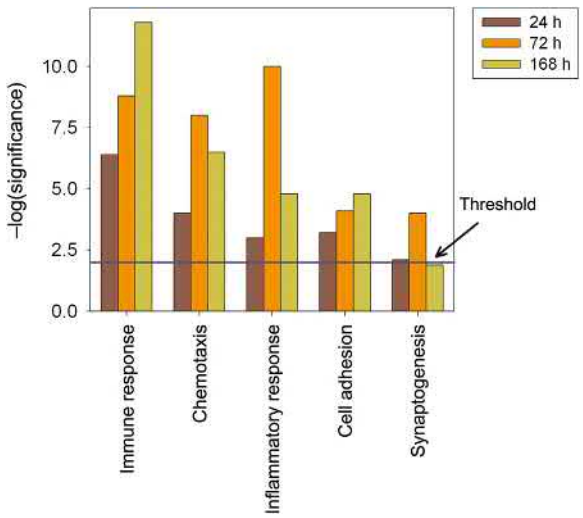

FIGURE 38.6 Results of biological processes sorting for microarray data from three different timepoints after sulfur mustard exposure using the mouse ear vesicant model. The timepoints were 24, 72, and 168 h postexposure. The bars represent positive fold change increases over the carrier solvent alone samples. The immune response genes were within the top three biological processes activated for all the timepoints studied (Gerecke et al., 2009).

(Di Zenzo et al., 2007). Early studies showed that several types of corticosteroids were effective in reducing edema induced by SM (Dannenberg and Vogt, 1982). Glucocorticoids were shown to be effective in reducing edema in the initial phase of injury, but did not affect the overall rate of healing (Vogt et al., 1984). Hydrocortisone given systemically or topically 2 h prior to HD administration resulted in a reduction in ear inflammation in the MEVM (Babin et al., 2000; Casillas et al., 2000b). Steroids given after SM exposure also enhance wound healing in a Yorkshire pig model of SM injury (Reid et al., 2008). Dexamethasone in combination with the nonsteroidal antiinflammatory diclofenac produced more than a 60% reduction in edema in mouse ears treated with SM (Dachir et al., 2004). However, reduction of edema, while important, did not necessarily correlate with a reduction in the progression of injury as seen later in this work. Studies using newer steroids such as clobetasol showed improved healing, lower severity of basal cell necrosis, and less inflammation (Reid et al., 2008). Cotreatment of steroids with nonsteroidal antiinflammatory drugs (NSAIDs) shows greater promise: cotreatment with diclofenac and tacrolimus in the HGP exposed to SM vapor showed less erythema, reduced lesion area, and fewer lesions (Dachir et al., 2008). A similar combination of a steroid (Adexone) and NSAID (Voltaren) applied to mouse ears treated with SM led to reduced inflammation, less edema, reduced area of clinical damage, and reduced damage to epithelial cells (Dachir et al., 2004). Steroids have been used in humans exposed to SM, including a recent accidental exposure (Schmidt et al., 2018a: 62), but they do not appear to affect the progression of the wound or alter the rate of wound healing.

38.5.5 Nonsteroidal antiinflammatory drugs

Several studies have demonstrated that NSAIDs given systemically or topically offer protection against continued SM-mediated toxicity. This suggests that inflammation is a key component of SM-induced injury as it is with other cutaneous injuries, such as those induced by UVA (Yourick et al., 1995). These results suggest that inflammation is involved in the ongoing pathology of SM-induced injury, and that antiinflammatory drugs should be considered as part of a drug cocktail for treatment of SM injury. Early studies with indomethacin in the HGP model showed that oral pretreatment could attenuate erythema and cutaneous injury (Yourick et al., 1995). Partial protection by indomethacin against microvesicle formation was found in the IPPSF model (Zhang et al., 1995b). Significant reductions in SM-induced early edema were found when indomethacin was administered from 24 h prior to exposure to 24 h after exposure (Babin et al., 2000) or when given 20 min post-SM challenge (Kiser et al., 2001). Topical indomethacin given 2 h prior to SM exposure in the MEVM protected against early (24 h) but not late (72 h) edema (Casillas et al., 2000b).

Early studies using the MEVM showed that posttreatment with NSAIDs, particularly in combination with steroids, could diminish SM-induced inflammation at early time points, although later effects were not measured (Dachir et al., 2002). As mentioned above, Voltaren, an NSAID, given in combination with the steroid Adexone, reduced skin injury (Dachir et al., 2004).

38.5.6 Bifunctional compounds

Bifunctional compounds include two active agents tethered chemically to one another. A bifunctional compound containing NSAIDs (such as ibuprofen or diclofenac) tethered to pyridostigmine, an acetylcholinesterase inhibitor, via an 8- or 10-hydrocarbon chain spacer, was somewhat effective against SM dermal toxicity (Amitai et al., 2005). This combination was effective in the MEVM in reducing subepidermal blistering (Amitai et al., 2006), although nothing has been published on these compounds since 2006.

Individually, antiinflammatories and COX-2 inhibitors have been shown to protect against vesicants (Wagner et al., 2019). NDH-4338 (Fig. 38.7), a bifunctional compound consisting of the antiinflammatory molecule indomethacin coupled via an aromatic ester-carbonate linkage to the anticholinergic choline bioisotere 3,3-dimethyl-1-butanol, was tested against NM delivered by cutaneous

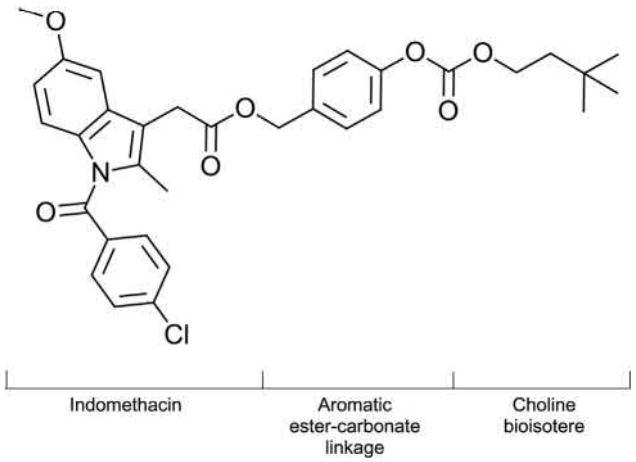

FIGURE 38.7 Chemical structure of the bifunctional anticholinergic NSAID compound NDH-4338. The drug combines two antiinflammatory moieties (indomethacin and a choline bioisotere, 3,3-dimethyl-1-butanol), attached via an aromatic ester-carbonate linkage (Chang et al., 2014). *Reprinted from Chang, Y.C., Wang, J.D., Hahn, R.A., et al., 2014. Therapeutic potential of a non-steroidal bifunctional anti-inflammatory and anti-cholinergic agent against skin injury induced by sulfur mustard. Toxicol. Appl. Pharmacol. 280 (2), 236–244, with permission from Elsevier.*

patch in the CD-1 mouse (Composto et al., 2016). NDH-4338 reduced wound thickness, eschar formation, mast cell degranulation, keratinocyte expression of iNOS and COX-2, and epidermal proliferation markers in CD-1 mice treated with NM. SKH-1 hairless mice treated with SM via a dorsal vapor cup showed that NDH-4338 protected against edema, enhanced reepithelization, reduced COX-2 expression, increased K10 expression in the suprabasal epidermis, reduced expression of K6, and restored basement membrane integrity through laminin-332 expression (Chang et al., 2014). A subsequent study investigating the role of mast cells using the vapor cup model showed that an ointment-based formulation of NDH-4338 reduced mast cell degranulation up to 14 days post-SM exposure (Joseph et al., 2018).

38.5.7 Transient receptor potential ligands

Transient receptor potential cation channels (TRPs) are ion channels that respond to environmental signals such as pain and heat. TRPs have been investigated as potential targets for SM toxicity for well over a decade. Nonmyelinated sensory C-fibers arising from the dorsal route ganglion transmit sensory information from the skin to the central nervous system in response to noxious stimuli, such as pain and heat. These fibers function as dual sensory efferents and release nociceptive and inflammatory neuropeptides such as substance P, peripherally (Szallasi and Blumberg, 1999; Szolcsanyi, 2004). Agents such as capsaicin, the active ingredient in hot peppers, produce analgesia by binding as an agonist to the transient receptor potential V1 channel (TRPV1) (Szolcsanyi, 2004). Capsaicin rapidly produces desensitization and interferes with the release of neuropeptides from sensory fibers (Campbell et al., 1993). Moreover, TRPV1 is expressed on cells in a number of nonneuronal cutaneous tissues, including keratinocytes and mast cells (Li et al., 2007). Capsaicin and its structural analogs, known collectively as vanilloids, have been shown to have antiinflammatory activity, as demonstrated by inhibition of edema, mast cell degranulation, and leukocyte migration (Brand et al., 1990; Bunker et al., 1991). Pretreatment of skin with vanilloids prior to SM exposure was shown to significantly reduce edema formation (Babin et al., 2000, 2003; Casillas et al., 2000b; Sabourin et al., 2003). One such vanilloid, olvanil, is a highly lipophilic analog of capsaicin, and has been shown to reduce SM-induced histological damage and edema as well as cytokine and chemokine mRNA induction (Casillas et al., 2000b; Sabourin et al., 2003). Analogs octyl homovanillamide and heptyl isovanillamide were shown to display similar protective activities against SM (Casbohm et al., 2004).

More recently, TRPA1 was shown to be activated by alkylating agents SM and CEES, inducing increased intracellular calcium; cells lacking TRPA1 did not respond with increased intracellular calcium (Stenger et al., 2015). Furthermore, AP18, an inhibitor of TRPA1, was found to block the effects of vesicants. Follow-on studies showed that TRPA1 antagonists (HC-030031 and A-967079) reduced CEES-induced skin edema, cytokines IL-1beta and CXCL1/KC, and MMP-9 in the MEVM (Achanta et al., 2018). Both TRPV1 and TRPA1 have been implicated in neurogenic inflammatory processes in mouse skin, suggesting that their inhibition might attenuate inflammation induced by vesicants (Horvath et al., 2015).

38.5.8 Cooling

Due to its high vapor pressure, exposure to SM in hot environments can exacerbate exposure. The toxicity of SM also relies on its ability to chemically react with biological molecules within the skin in a temperature-dependent manner. In vitro tests showed that human skin keratinocytes treated with SM and cultured at 25°C had less injury after 24 h than keratinocytes grown at 37°C (Sawyer and Risk, 1999). Similarly, HGPs with skin exposed to SM had less injury after 72 h if treated for 4.5 h postexposure with cold (Sawyer and Risk, 1999). Other studies showed that anesthetized swine skin exposed to mild cooling (15°C) for 2–4 h following SM exposure had significantly less injury progression after 7 days (Sawyer et al., 2002). However, later studies demonstrated that this effect was temporary, slowing the rate of injury progression rather than reducing overall injury. Indeed, tissue and animal studies showed that

temperature-mediated inhibition of injury was reversible upon return of the tissue to normal body temperature (37°C). Sawyer et al. (2002) have suggested that cooling might therefore be used as a temporary measure that "increases the therapeutic window in which other medical countermeasures are useful (Sawyer and Nelson, 2008)." Indeed, later tests with VX poisoning showed similar results, lengthening the time for entry of VX into the bloodstream (Sawyer et al., 2011). Although this work has been largely ignored by the literature, cooling would be inexpensive, effective, and easily applied by first responders.

38.6 Concluding remarks and future directions

Model systems for vesicants have reached a turning point, allowing elucidation of critical molecular pathways in vesicant injury that have allowed the development of therapeutics. NM and CEES have been validated as adequate surrogates for SM, and tremendous progress has been made in characterizing the most popular model systems for mustard, including the MEVM, SKH-1 HM, and WP models. The pharmacological targets remain largely the same as they were 15 years ago: inflammation, oxidative stress, and the TRP channels, with some renewed interest in the PARP and cholinergic pathways. Although early work showed limited success with drugs targeting these pathways, as the drugs in these categories have been refined for other purposes, their efficacy has improved in the vesicant model. Still, no therapeutic countermeasure exists that matches the efficacy of surgical intervention to remove damaged tissue exposed to vesicants, as was again shown with a critical human accidental exposure in Germany that was published in 2018 (Schmidt et al., 2018a: 62). This suggests that some molecular targets are critically and irreversibly damaged by vesicants and do not heal quickly on their own. Debridement and removal of the damaged tissues allows for healing of dermal wounds in a manner consistent with other injuries, rather than the prolonged healing process seen with SM.

Challenges remain for the development of pharmacologic countermeasures. Most of the research on pharmacological countermeasures for vesicants remains focused on the early time points of the healing process, but there is little evidence that targeting these early timepoints impacts the progression of the vesicant wound afterwards. The majority of studies covered in this chapter analyze the efficacy of countermeasures fairly soon after the injury occurred, and early in the healing process. Model systems that accurately model the late stages of vesicant wound healing remain to be characterized, presenting the largest problem going forward for countermeasure research. A second avenue for further research is combining pharmacological and surgical techniques to enhance the rate of wound healing. Finally, a greater focus on the interplay between inflammation and wound repair in vesicant injury is warranted.

Chapter 39

Reproductive toxicity and endocrine disruption of potential chemical warfare agents

Tim J. Evans

Veterinary Medical Diagnostic Laboratory, Department of Veterinary Pathobiology, University of Missouri, Columbia, MO, United States

39.1 Introduction

Since this chapter was originally written for the first edition of this book, the factual information about the effects of potential chemical warfare agents (CWAs) on reproduction has, for the most part, remained unchanged. However, where indicated, the results of recent research has been added for specific toxicants, such as sulfur mustard. Alarmingly, what *has* changed dramatically over the last decade is the ability of information to be communicated or miscommunicated globally. Internet availability, widespread cellular telephone access, and cybersecurity issues have all vastly increased the ability of misinformation, as well as disinformation (i.e., inaccurate information transmitted without malicious intent, versus communication of false information with malicious intentions, respectively), to be possibly manipulated and relayed to large populations of people. It is, therefore, easier than ever for disinformation to be intentionally weaponized, in order to create psychological and/or financial stresses in targeted populations (Forno, 2018).

Reproduction is a critical biological process in all living systems and is required for species survival. The immediate, short-term toxicological concerns regarding chemical warfare and acts of agricultural and industrial terrorism have to do primarily with human and animal incapacitation and mortality. Logically, most of the currently available literature on these aspects of warfare and terrorism focuses on these immediate adverse health effects and their sequelae. However, the entire scope of the effects of these toxic insults can involve the severe emotional and financial distress, as well as the diminished prognosis for long-term survival of exposed human and animal populations, arising from toxicant-induced abortions, congenital defects, and female and/or male infertility. With the advent of online information resources and social media, as well as lapses in cybersecurity, the ability to intentionally distribute nonfactual or misleading information, including that pertaining potential reproductive effects of potential CWAs, can be weaponized to sow fear and confusion in targeted human populations (Forno, 2018). It is therefore more important than ever before that individuals working in human and veterinary medicine, the military, public health, government regulatory agencies, industry and agriculture, as well as public policy makers, be familiar with some of the documented adverse reproductive effects of these types of toxicants on exposed humans and animals. This chapter will review what is currently understood about the potential adverse effects of chemical warfare agents, nuclear fallout, and hazardous industrial and agricultural wastes on human and animal reproductive function. In addition, the rapid intentional distribution of false information about potential CWAs can be viewed as an emerging technological threat.

For the purposes of this chapter, the term "reproduction" will be used primarily in reference to vertebrate species of animals (especially mammals) and will be inclusive of "development" (Fig. 39.1), which is sometimes treated as a separate topic in toxicology texts. This chapter will emphasize what is currently known about the adverse effects of known chemical warfare agents and selected environmental contaminants on male and female reproductive function, as well as xenobiotic-induced effects on the growth, maturation, and sexual differentiation of the embryo and fetus. Endocrine disruption is an

extremely common mechanism of action for xenobiotics associated with impaired reproductive function and will be discussed along with reproductive toxicity in this chapter. Efforts will be made to clarify the currently used terminology related to these topics and to provide the reader with a brief description of proposed mechanisms of action and observed reproductive outcomes associated with selected toxicants which might be relevant to chemical warfare and/or acts of terrorism.

Unfortunately, although there is a relative lack of information documenting long-term, reproductive effects of the types of toxicants covered in this book, space constraints still limit the amount of information which can be presented in this chapter. There are a number of recently published textbooks and book chapters which cover some of these and related subjects in greater detail and provide information which is complementary to what is presented in this chapter (Capen, 2008; Evans, 2017, 2018; Foster and Gray, 2013; Golub, 2006a,b; Gupta, 2006, 2018; Naz, 2005; Rogers, 2013; Romano et al., 2008; Senger, 2012). This is especially true with respect to normal reproductive anatomy and function (Evans, 2018; Evans and Ganjam, 2017; Senger, 2012), and the reader is directed to these publications and the other references cited in this chapter in order to gain additional insight into specific areas of reproductive function and toxicology.

It is important that the reader understand that the areas of toxicology involving the long-term effects of chemical warfare agents and environmental contaminants, reproductive toxicity, in general, and endocrine disruption, in particular, are in continual flux. New data and exceptions to "classical" mechanisms of action are being reported on a regular basis, and there continues to be ongoing debate about the effects of chronic low-level exposures to toxicants available for or arising from military and terrorist activities and various aspects of normal, as well as xenobiotic-induced abnormal reproductive function. Every effort has been made to accurately represent what is currently understood about the topics of discussion in this chapter. Controversial topics or those currently still subject to debate within the scientific community have been noted wherever possible.

39.2 Important definitions and concepts

39.2.1 Chemical warfare agents

For the purposes of this chapter, "chemical warfare agent" (CWA) will be used as a fairly comprehensive term to refer to a diverse group of toxicants commonly discussed within the context of chemical incapacitation for crowd control during riots or death or incapacitation associated with military use or terrorism. The lacrimatory and irritant riot control agents will include α-chlorbenzylidene malonitrile (CS), dibenz (b,f)-1:4 oxazepine (CR), ω-chloroacetophenone (CN), and oleoresin of capsicum (OC pepper spray) (Salem et al., 2008a). The CWAs currently of greatest interest and for which the greatest amount of data have been gathered are arsenicals, chlorine gas, phosgene and phosgene oxime, sulfur mustard, ricin, hydrogen cyanide and cyanide-related compounds, and organophosphate nerve agents (Kikilo et al., 2008; Wismer, 2018).

39.2.2 Environmental contaminants associated with industrial or agricultural terrorism

For the sake of completeness, this chapter will also discuss the adverse reproductive effects of potential toxicants, such as ionizing radiation, pesticides, and other organic environmental contaminants, as well as heavy metals, which are known to adversely affect reproductive function. While all of these potential toxicants have been or are currently being released into the environment in generally low concentrations as a consequence of normal industrial and agricultural activities, the results of accidents, such as those which occurred in Chernobyl, in the former Soviet Union (ionizing radiation), Bhopal, India (methyl isocyanate or MIC), Seveso, Italy and Times Beach, Missouri (dioxins), and Minamata, Japan and Basra, Iraq (methyl mercury), underscore the potential impact that large-scale, industrial or agricultural terrorism-related releases of these contaminants could have on populations of humans and animals. In fact, these

environmental contaminants have the potential to become "low-tech" CWAs in the hands of terrorists and less sophisticated military organizations.

39.2.3 Reproduction

As represented in Fig. 39.1, reproduction in humans and domestic, wild, and laboratory vertebrate animals encompasses the wide range of physiological processes and associated behaviors and anatomical structures involved in the production of the next generation and the survival of a given species of animal (Evans, 2018; Evans and Ganjam, 2017; Senger, 2012). The physiological processes involved in reproduction generally include the following: (1) gametogenesis (production of sperm or ova) and the pre- and peripubertal changes leading up to its onset; (2) release of gametes [i.e., sperm transport and maturation, penile erection and ejaculation of sperm (mammals), copulation between a male and a female of the same species (several vertebrate classes) and ovulation of oocytes]; (3) formation of the zygote (i.e., sperm storage, capacitation, and other processes leading to fertilization, or union, of a single sperm with an egg); (4) embryonic and fetal development during the incubation process in egg-bearing vertebrates or, especially in the case of mammals, during pregnancy (gestation) [i.e., activities related to the initiation and progression of zygote cleavage, blastocyst formation, separation of the germ layers, placentation (mammalian species), neurulation, and organogenesis (including sexual differentiation)]; (5) "birth" of a single or multiple offspring (hatching in oviparous vertebrates); and, finally, in mammalian species, (6) the initiation and maintenance of milk production (lactation) for the postpartum nutrition of offspring (Evans, 2018; Evans and Ganjam, 2017).

39.2.4 Reproductive toxicity

For the purposes of this chapter, "reproductive toxicity" will refer to any manifestations of xenobiotic exposure, including "endocrine disruption" (see discussion below), reflecting adverse effects on any of the physiological processes and associated behaviors and/or anatomical structures involved in animal reproduction or development (Fig. 39.1). This is a fairly broad definition which encompasses developmental toxicity, as well as any toxic effects of postpubertal exposures to xenobiotics on either male or female reproduction. "Developmental toxicity" refers to any adverse effect on the developing organism associated with either preconception parental exposures to toxicants or postconception xenobiotic exposures to the embryo, fetus, or prepubertal offspring, and adverse effects associated with developmental toxicity of xenobiotics might not necessarily be observed until after the affected individuals have reached sexual maturity (Eaton and Gilbert, 2013; Evans, 2018; Hodgson et al., 2000).

39.2.4.1 Teratogenesis

The term "teratogenesis" is derived from the Greek word for monster ("teras") and is a form of developmental toxicity (Rogers, 2013). "Teratogenesis" refers specifically to developmental defects induced by toxicant exposures occurring between conception and birth (Eaton and Gilbert, 2013; Evans, 2018; Hodgson et al., 2000; Rogers, 2013). The types of abnormalities that are typically associated with teratogenesis include embryonic or fetal death; morphological, functional, and/or neurobehavioral abnormalities; and decreased growth rate and/or birth weight (Evans, 2018; Rogers, 2013).

With respect to teratogenesis, there are six basic tenets of teratology, first defined by J.G. Wilson in 1959, which need to be kept in mind whenever gestational exposure to a teratogenic xenobiotic is suspected or when a chemical is being evaluated for its teratogenic potential (Evans, 2018; Wilson, 1977):

1. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which it interacts with environmental factors.
2. Susceptibility to teratogenic agents varies with the developmental stage at the time of exposure.
3. Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis.
4. The final manifestations of abnormal development are death, malformation, growth retardation, functional disorder.
5. The access of adverse environmental influences to developing tissues depends on the nature of the influences (agent).
6. Manifestations of deviant development increase in degree as dosage increases from no effect to the totally lethal level.

39.2.4.2 Mechanisms of reproductive toxicity and teratogenesis

In general, normal reproduction and development require rapidly replicating and differentiating cells undergoing mitosis and, within the gonads, meiosis. There are a wide range of specific mechanisms of action by which xenobiotics can adversely affect reproductive function, including embryonic and fetal development. Many of these mechanisms are the same as those for toxicants affecting other organ systems and essentially involve some sort of toxicant-induced interference with the cell cycle, cellular dysregulation, and alterations in cellular maintenance which, when possible, the body attempts to repair, either

successfully or unsuccessfully (Gregus, 2013). Oxidative damage and interference with normal enzymatic reactions are two common mechanisms by which xenobiotics and, especially, some CWAs (Smith et al., 2008) can cause the dysregulation and altered maintenance of cells within various organs and tissues.

Teratogenesis can be associated with each of the following mechanisms of action: (1) excessive cell death; (2) interference with apoptosis; (3) reduced cellular proliferation rate; (4) failed interactions between cells; (5) impaired morphogenetic movements; (6) reduced synthesis of components essential for growth and development; (7) mechanical disruption; and (8) alterations in pH (Evans, 2018; Hood, 2006; Hood et al., 2002). Some teratogens are capable of more than one mechanism of action, and it is important to keep in mind that the observed developmental abnormalities associated with exposure to any given teratogen will in large part be dependent on the timing of the exposure to that xenobiotic during gestation. Familiarity with the timing of important developmental events in species of interest is critical in the diagnosis and prevention of teratogenesis, as well as the design of experiments investigating the teratogenic potential of different chemicals in animal models (Evans, 2018).

Normal reproduction and development require signaling within and between a variety of diverse organs, and, in sexual reproduction and mammalian pregnancy, critical communication even takes place between distinctly different organisms (i.e., male and female and mother and offspring, respectively) (Evans, 2018). It should be remembered that premature parturition or abortion can be induced by any circumstances which cause fetal or, potentially, maternal stress and initiate the cascade of endocrine and neural signaling events which would normally lead to parturition (Evans, 2018). Any sublethal intoxication or emotionally traumatic event in a pregnant woman or animal has the potential to threaten fetal survival.

The dependence of reproductive function on signaling pathways inclusive of gene transcription makes this physiological process especially prone to adverse effects associated with xenobiotic-induced disruption of or interference with cell-to-cell, organ-to-organ, and/or even animal-to-animal communication. Many of the mechanisms which interfere in some way with physiological signaling activity can be classified as forms of "endocrine disruption" (see discussion below), but there is a great deal of overlap between the various different mechanisms for reproductive toxicity. The level of exposure to a particular toxicant is an important determinant of what toxic effects are observed, and xenobiotics which "disrupt" endocrine pathways can do so without interactions with endogenous receptors, using mechanisms of action which can cause other forms of toxic insult at various dosages.

39.2.4.3 Reproductive toxicants

Any xenobiotic associated with adverse effects on the development of male or female reproductive function can be classified as a "reproductive toxicant" (Evans, 2018; Rogers, 2013). Even chemicals adversely affecting animal well-being have the potential to have a negative impact on development and reproductive function. This chapter will attempt to focus on toxicants which are available for or could arise from military and terrorist activities and specific mechanisms of actions which have a direct effect upon the male and/or female reproductive tract or which target normal embryonic and/or fetal growth and maturation (Evans, 2018).

39.2.4.4 Teratogens

The subclass of reproductive substances capable of inducing teratogenesis is referred to as "teratogens." Some teratogenic chemicals induce their adverse effects "indirectly" on the fetus by altering maternal synthesis of essential nutrients or by other mechanisms which do not require their transport across the placenta. However, many teratogens "directly" affect fetal development by crossing the "placental barrier" and entering the fetal circulation. The passage of nutrients, hormones, and other endogenous, as well as exogenous, substances across the placenta has been traditionally thought of by some references as primarily a function of the intimacy (i.e., number of tissue layers) between the maternal and fetal circulations, especially with respect to maternal immunoglobulins which cross some types of placentation but not others (Evans, 2018). While it is true that placental characteristics, such as thickness, surface area, carrier systems, and lipid-protein characteristics, can influence the passage of xenobiotics across the placenta and that the placenta is generally impermeable to chemicals with molecular weights greater than 1000 Da, most xenobiotics have molecular weights less than 500 Da and cross the placenta by simple diffusion (Foster and Gray, 2013). It is currently thought that a potential teratogen's molecular size, degree of ionization, protein binding, and lipid solubility are the most important determinants of that chemical's ability to move from the maternal circulation across the placenta into the fetal circulation (Evans, 2018; Foster and Gray, 2013; Rozman and Klaassen, 2001). Some toxic xenobiotics can be actively transported by mechanisms intended for structurally similar endogenous molecules (Rozman and Klaassen, 2001), and there is some experimental evidence to suggest that transplacental transport of lead can mimic that of calcium (Evans, 2018; Evans et al., 2003).

39.2.4.5 Endocrine disruption

"Endocrine disruption" is a developing, multidisciplinary area of research, involving aspects of both toxicology and

endocrinology (McLachlan, 2001) and is a potential mechanism of action for many toxicants, especially those affecting reproduction. This term has been defined in a variety of different ways, depending on the circumstances and the intended audience. "Endocrine disruption" can also be defined fairly narrowly with respect to toxicant origin (synthetic versus naturally occurring); source or site of toxicant exposure (exposure from warfare- or terrorism-related activities versus exposure from environmental contamination); xenobiotic mechanism of action (receptor agonism and/or antagonism versus other mechanisms independent of direct interactions between xenobiotics and receptors); and/or the timing of exposure (prenatal versus postnatal exposures) (Evans, 2018; Krimsky, 2000, 2001). However, the definition of "endocrine disruption" used in this and other book chapters previously written by the author (Evans, 2017, 2018) will be fairly "broad" and will encompass the effects of any synthetic or naturally occurring xenobiotic which can affect the endocrine system of exposed individuals (i.e., the balance of normal hormonal functions) and, as a result of exposure, cause physiological alterations (Evans, 2017, 2018; Hodgson et al., 2000; Keith, 1997). Within the broad scope of this definition, reproduction, including prenatal and prepubertal development, certainly would be expected to be one of the physiological functions most profoundly affected by chemicals associated with chemical warfare or environmental contamination capable of endocrine disruption; however, adverse effects on other, "nonreproductive" endocrine systems can also be associated with exposures to xenobiotics (Evans, 2018; Guillette, 2006). Thyroid function, glucocorticoid metabolism, and other endocrine as well as enzymatic factors associated with adipogenesis have recently been shown to be susceptible to interference by several different classes of chemical compounds (Capen, 2008; Cooke and Naz, 2005; Evans, 2017, 2018; Guillette, 2006; Grün and Blumberg, 2006; Newbold et al., 2005, 2006).

39.2.4.6 Mechanisms of endocrine disruption

Although the imitation and/or inhibition of the actions of androgens and, especially, estrogens by xenobiotics is what was first referred to as "endocrine disruption," both the multidisciplinary area of study and mechanism of action generally referred to as "endocrine disruption" have evolved over the years to encompass a wide range of specific mechanisms of action which can ultimately result in adverse effects on invertebrate and/or vertebrate animals (Evans, 2017, 2018; McLachlan, 2001). Endocrine disruption involves many mechanisms of action which can ultimately result in adverse effects on animal species. The mechanisms of action involved in endocrine disruption can include effects which are mediated directly by interactions between the xenobiotic and an endogenous hormone receptor (i.e., the xenobiotic functions as a ligand for an endogenous receptor and a receptor−ligand complex is formed), as well as those adverse effects which alter hormonal functions without direct interactions between the toxicant and an endogenous receptor (Capen, 2008; Evans, 2017, 2018; Keith, 1997). It should also be noted that a given xenobiotic can potentially disrupt the normal balance of hormonal function by more than one mechanism which is independent of direct interactions between the toxicant and an endogenous hormone receptor (Evans, 2017, 2018).

"Classic" endocrine disruption can involve imitation or mimicry of the interactions between cellular receptors and endogenous hormones (i.e., receptor agonism) and/or a blockade or inhibition of the formation of receptor-hormone complexes (i.e., receptor antagonism) (Evans, 2017, 2018; McLachlan, 2001), and both genomic and nongenomic physiological responses can be affected by this mimicry or blockade of endogenous hormone receptor-mediated activity (Evans, 2017, 2018; Thomas and Khan, 2005). Endocrine disruption can also be mediated by the complex interactions between the endogenous aryl hydrocarbon receptor (AhR) and its major agonists, which are xenobiotics belonging to the class of environmental contaminants referred to collectively as "halogenated" or "polyhalogenated aromatic hydrocarbons" (HAHs or PAHs, respectively) (Evans, 2017, 2018; Safe, 2005).

Endocrine disruption. which is independent of interactions between xenobiotics and endogenous hormone receptors, can occur in a variety of different ways, including alterations in the number of hormone receptor sites (up- or downregulation) or direct or indirect hormone modifications which alter hormonal function (Evans, 2017, 2018; Keith, 1997). Xenobiotics can change the rate of synthesis or destruction of endogenous hormones and can alter how hormones are stored, how they are released into and/or transported within the circulation, or even how they are eventually cleared from the body (Capen, 2008; Evans, 2017, 2018; Keith, 1997; Sikka et al., 2005). Any xenobiotic toxic to hormone-producing organs or tissues (e.g., testis and ovary) also has the potential to decrease hormone synthesis and thereby indirectly cause endocrine disruption (Devine and Hoyer, 2005; Evans, 2017, 2018).

In addition to the aforementioned mechanisms of endocrine disruption, there has recently been increasing interest in the association between prenatal exposures to some hormonally active toxicants and the postnatal development of neoplasia (cancer) involving the reproductive tract, as well as the occurrence of transgenerational or vertically transmitted adverse reproductive effects (Crews and McLachlan, 2006). Either "genetic" mutations [i.e.,

alterations in the genotype or deoxyribonucleic acid (DNA) sequence] or "epigenetic" changes, such as DNA methylation of CpG nucleotides in the promoter regions of genes, which are heritable but nongenetic modifications in the properties of a cell (inherited phenotypic alteration without genotypic change) are possible explanations for these phenomena (Crews and McLachlan, 2006; Evans, 2017, 2018; McLachlan, 2001). Patterns of DNA methylation are generally established during development at the gastrulation stage (i.e., lineage-specific pattern in somatic cells) and after sex determination (i.e., germ line-specific lineage pattern in the gonad), and DNA methylation can facilitate "genomic imprinting," which results in the expression of the allele from only one parent (i.e., monoallelic expression) (Anway and Skinner, 2006; McLachlan, 2001).

39.2.4.7 Endocrine-disrupting chemicals, endocrine disruptors, and hormonally active agents

Any reproductive toxicant capable of endocrine disruption can also be considered an "endocrine-disrupting chemical" ("EDC") or an "endocrine disruptor." Another term frequently used with respect to endocrine disruption, especially regarding xenobiotics which interact with endogenous hormone receptors, is "hormonally active agent" or "HAA." In most instances, "endocrine-disrupting chemical," "endocrine disruptor," or "hormonally active agent" can be used interchangeably to discuss the actions of a given xenobiotic (Evans, 2017, 2018).

39.3 The reproductive toxicity of selected toxicants

It should be remembered that the use of CWAs will invariably be associated with wars, acts of terrorism, revolutions, and civil unrest, all of which do not occur in a vacuum and will be concurrent with emotional stress, famine, and other conditions leading to reproductive failure. As a result, information is relatively lacking with respect to specific, adverse reproductive effects, as well as endocrine disruption, related to acute and, particularly, low-level, chronic exposures to many potential CWAs. In addition, much of the information which does exist regarding the long-term reproductive and teratogenic effects of these types of weapons is, unfortunately, somewhat contradictory. While it is possible that exposures to some CWAs might not generally be associated with serious, adverse reproductive effects, the discrepancies between the results of different studies are probably, in part, due to variability in individual responses to specific toxicants and the complexity of analyses of human epidemiological data. In addition, differences in dosing regimens, routes of exposure, and the animal models utilized for in vivo studies can confound comparisons of experimental results. The relative insensitivity of many reproductive endpoints might also contribute to the impression that some chemical weapons do not adversely affect reproductive function.

The embryo and fetus, without a developed blood−brain barrier and with only rudimentary DNA repair mechanisms and hepatic detoxifying and metabolizing capabilities, are especially susceptible, as compared to adults, to the adverse effects of low-level exposures to xenobiotics (Evans, 2017, 2018; Newbold et al., 2006). There has recently been increasing concern within the regulatory, public health, and scientific communities about the effects of prenatal exposures to potential reproductive toxicants, especially those capable of endocrine disruption, on humans and animals. In order to increase our understanding of the long-term, adverse reproductive effects associated with warfare and acts of terrorism, public knowledge of the use of CWAs or awareness of massive releases of reproductive toxicants associated with confirmed acts of terrorism should result in increased surveillance for phenotypic abnormalities in the most susceptible populations of humans and animals exposed during embryonic, fetal, and early postnatal development. Based on these epidemiological observations, carefully designed experiments mimicking "real-life" exposures can be performed in multiple laboratory animal species, using sensitive biomarkers of toxic insult to reproductive development and function, to further elucidate the adverse reproductive effects of xenobiotic exposures likely to be associated with military and/or terrorist activities.

Our relative lack of understanding of the effects of CWAs and other xenobiotics on reproductive function can also be attributed to the complexity of the entire reproductive process and the mechanisms by which it is regulated. It should be evident from Fig. 39.1 that maximum reproductive efficiency, including normal embryonic and fetal development, is dependent on the structural and functional integrity of multiple organs and tissues, as well as various physiological processes and signaling pathways within and (with respect to sexual reproduction and pregnancy) between individuals. Putative reproductive toxicants can affect one or several different steps in the reproductive process, depending on the physiological timing, duration, and level of exposure (Evans, 2018; Foster and Gray, 2013).

In "real life," humans and animals can be exposed to some toxicants both pre- and postnatally. Many organic xenobiotics have the potential to bioaccumulate within exposed individuals, possibly affecting future generations by way of genetic and epigenetic effects. However, reproductive endpoints, such as conception rates and sperm counts, are relatively insensitive, and subtle, toxicant-

induced changes in reproductive efficiency can be overlooked or missed (Evans, 2018).

Much of the evidence for the adverse reproductive effects of selected toxicants will be based on cases involving wildlife exposures to environmental contaminants or on the experimental results of research exposing laboratory animals to large, "pharmacological" doses of potential toxicants. When available, data will be presented from accidental or intentional human and domestic animal exposures to toxicants associated with riot control and chemical warfare or with "environmental catastrophes" where incidences of infertility, abortion, and teratogenesis have been traced over the course of a number of years.

From an epidemiological perspective, it can be extremely challenging to determine the exact cause of reproductive abnormalities in humans and animals. Questions will often remain as to whether the observed poor reproductive outcomes associated with acute exposures to toxicants are due to direct effects of these chemicals on reproductive function or are secondary to toxicant-induced systemic disease and its accompanying stress (e.g., abortions and preterm births in intoxicated, pregnant women or animals). There are multiple factors, including exposures to mixtures of toxicants and other concurrently occurring causes of reproductive failure, which need to be taken into consideration in heterogeneous populations where exposures to toxic agents are not uniform between individuals. This is especially true in instances when there is a significant time interval between exposure to potential toxicants and the observed reproductive outcomes.

39.3.1 The reproductive toxicity of riot control agents

The major lacrimatory and irritant riot control agents include α-chlorbenzylidene malonitrile (CS), dibenz (b,f)-1:4 oxazepine (CR), ω-chloroacetophenone (CN), and oleoresin of capsicum (OC pepper spray) (Salem et al., 2008a). Exposure of pregnant women or animals to these compounds could be expected to be associated with maternal and/or fetal stress, which could potentially lead to the induction of premature parturition (Evans, 2018). Although the riot control agents CS and CN are both alkylating agents, with at least the potential to adversely affect embryonic and fetal development, neither of these chemicals has yet been found to be embryotoxic or teratogenic (Salem et al., 2008a; Sanford, 1976). Limited studies performed with laboratory animals suggest that CR is neither embryotoxic nor teratogenic and that OC, with the possible exception of a slightly reduced crown−rump length, is not associated with any adverse effects on reproductive function (Salem et al., 2008a).

39.3.2 The reproductive toxicity of chemical warfare agents

While it would seem logical that participation in wars would not be conducive to optimal reproductive function, there are conflicting data regarding the short-term and long-term effects of suspected CWA exposure on male and female fertility (Abu-Musa et al., 2008). Additionally, given current global politics and the "War on Terrorism," pertinent information regarding many "newer" potential CWAs is very likely to be unavailable for public review. In order to be as complete as possible, some of the more "historical" and currently available CWAs will be discussed in the context of their primary, immediate, adverse effects on humans and animals. By organizing this discussion in that manner, the potential adverse reproductive effects of "new" CWAs can be anticipated based on the similarities of those toxicants to existing chemical weapons. For simplicity, CWAs will be broadly classified as vesicants (i.e., blistering agents), inhibitors of protein synthesis (e.g., ricin), inhibitors of cellular respiration or "blood agents" (e.g., hydrogen cyanide and cyanide-related compounds), and nerve agents (i.e., organophosphate compounds).

39.3.2.1 Vesicants

39.3.2.1.1 Arsenicals

While arsenicals will be discussed in this chapter with respect to their use in chemical warfare, the metalloid element arsenic, which is classified as a carcinogen, is also a potential environmental contaminant. Arsenicals continue to have important industrial and agricultural uses, and arsenic-containing feed additives, pesticides, and wood preservatives are all still readily available. In general, arsenic binds to sulfhydryl groups, with the activities of thiol-containing enzymes, including those involved in cellular energy production, frequently being adversely affected (Wismer, 2018). Increased capillary permeability is also associated with many acute intoxications involving arsenic.

It is important when discussing the toxicity of arsenicals to distinguish between the effects of organic and inorganic forms of arsenic. Several organic arsenicals, including lewisite [dichloro (2-chlorovinyl) arsine or Agent L], diphenylcyanoarsine, and diphenylchloroarsine, have been used as vesicants and systemic toxicants (Ishii et al., 2004; Wismer, 2018). Like other arsenicals, lewisite has been associated with fetal death in laboratory animals; however, lewisite is reported to not be teratogenic (Wismer, 2018). In contrast, a degradation product of diphenylcyanoarsine and diphenylchloroarsine, diphenylarsinic acid, has recently been associated with abnormal brain development in humans (Ishii et al., 2004).

Inorganic forms of arsenic, particularly arsenite and arsenate, have been associated with neoplasia, estrogenic activity, and testicular and ovarian toxicity, as well congenital neural tube, skeletal, and gonadal abnormalities, in laboratory rodents (Golub, 2006b). Epidemiological evidence in human populations has suggested that acute arsenic exposures with sublethal, maternal toxicity and subchronic exposures to elevated arsenic concentrations in drinking water have both been associated with increased incidences of abortions, stillbirths, and preterm deliveries (Golub, 2006b).

39.3.2.1.2 Chlorine gas

Chlorine (Cl_2) is one of the more commonly produced chemicals in the United States, and chlorine gas is a potent oxidant which is very irritating and, potentially, corrosive (Kikilo et al., 2008; Smith et al., 2008; Wismer, 2018). Chlorine gas is used as a pulmonary and choking agent, and exposure is frequently associated with moderate to severe, painful irritation of the eyes and respiratory tract (Wismer, 2018). Such stressful, sublethal exposures in late-gestational women or animals might be expected to be associated with the induction of premature parturition and, possibly, abortion. Oxidative stress can definitely have adverse effects on reproductive function, but the chronic disease associated with chlorine gas exposure is primarily related to the ocular and respiratory systems (Smith et al., 2008). The limited information available on the reproductive effects of chlorine gas indicates that it is teratogenic (Wismer, 2018).

39.3.2.1.3 Phosgene and phosgene oxime

The most important industrial use of phosgene (Agent CG or carbonyl chloride) is in the production of isocyanates (Kikilo et al., 2008), and MIC exposure is discussed with respect to its accidental release in Bhopal, India. Phosgene is classified as a choking agent, and it acylates sulfhydryl, amine, and hydroxyl groups. Phosgene oxime (Agent CX), a halogenated oxime, is a nonpersistent, chemical blistering agent, which, like phosgene, interacts with sulfhydryl and amine groups (Wismer, 2018). Other than possible adverse reproductive outcomes related to maternal and/or fetal stress or increased dermal absorption of concurrently used CWAs (Wismer, 2018), phosgene oxime is unlikely to have direct adverse effects on reproductive function.

39.3.2.1.4 Sulfur mustard

With respect to sulfur mustard, as well as other vesicants, and even in instances of occupational exposures to pesticides, the genital area, especially the scrotum, is well-recognized as being thin-skinned, with a high degree of cutaneous diffusivity, both characteristics which facilitate enhanced cutaneous absorption of xenobiotics and rapid onset of clinical signs (Lehman-McKeeman, 2013; Panahi et al., 2013). Sulfur mustard [*bis*-(2-chloroethyl) sulfide; mustard gas, Agents HD, H or HS] and analogs, such as 2-chloroethyl ethyl sulfide (CEES), are vesicants which can damage cells by alkylation of macromolecules (i.e., DNA, ribonucleic acid and proteins), oxidative stress, glutathione depletion, and inflammation (Dacre and Goldman, 1996; Smith et al., 2008; Watson and Griffin, 1992; Wismer, 2018). Similar to ionizing radiation and a variety of other radiomimetic alkylating agents, such as busulfan, cyclophosphamide, and nitrogen mustard, sulfur mustard and its analogs can target rapidly dividing cells in multiple organs, including the testes and ovaries, as well as in the developing embryo and fetus (Foster and Gray, 2013; Hurst and Smith, 2008; Rogers, 2013; Wismer, 2018). Consistent with DNA alkylation, as well as, possibly, other mechanisms of action, men exposed to sulfur mustard gas have been reported to have lower sperm counts and testosterone concentrations for several weeks following respiratory exposure. Acute and chronic effects on male fertility have also been reported with cutaneous exposure to sulfur mustard in the genital region, but these results are not consistent between studies (Panahi et al., 2013). Additionally, Iraqi use of mustard gas has been associated with alterations in the infant sex ratio and an increase in some birth defects in children (Arnetz et al., 2013; Azizi et al., 1995; Pour-Jafari, 1994; Wismer, 2018).

However, despite epidemiological and laboratory animal evidence indicating that sulfur mustard is a teratogen and reproductive toxicant in humans and animals (Azizi et al., 1995; Panahi et al., 2013; Pour-Jafari, 1994; Wismer, 2018), contradictory research data involving several different routes of exposure have suggested no adverse, sulfur-mustard-related reproductive effects, especially at levels of exposure not associated with maternal intoxication (Dacre and Goldman, 1996; Watson and Griffin, 1992; Wismer, 2018). While, based on its mechanisms of action, it appears that exposures to sulfur mustard should be associated with several, potential adverse reproductive outcomes, including maternal and/or fetal stress-induced premature parturition, additional mustard gas inhalation experiments should be performed in rodent and nonrodent animal models to confirm this suspicion.

39.3.2.2 Inhibitors of protein synthesis

39.3.2.2.1 Ricin

The seeds of the ubiquitous castor bean plant (*Ricinus communis*) contain high concentrations of a highly toxic, relatively stable, heterodimeric, glycoprotein toxin, ricin, which is a type 2 ribosome-inactivating protein (RIP) (Burrows

and Tyrl, 2001; Millard and LeClaire, 2008; Salem et al., 2008b). The inhibition of protein synthesis by ricin and related type 2 RIPs has been associated with endothelial toxicity, and, depending on the route of exposure, severe gastrointestinal or respiratory disease and death (Millard et al., 2008). While it would be anticipated that acute, sublethal ricin intoxication would be associated with abortion or preterm delivery secondary to maternal and/or fetal stress, ricin has also been shown to have direct adverse effects on reproductive function in female rabbits, causing abortion and inhibition ovulation and implantation in this species (Salhab et al., 1999). Because of the availability of the raw ingredients and the relative ease of its extraction, ricin has the potential to be a "low-tech" alternative for terrorist attacks targeting public water supplies (Salem et al., 2008b). Additional research is needed in order to have a better idea of the adverse reproductive effects which would be anticipated with sublethal and/or chronic exposures to ricin and related toxins (Millard et al., 2008).

39.3.2.3 Inhibitors of cellular respiration ("blood agents")

39.3.2.3.1 Hydrogen cyanide and cyanide-related compounds

With respect to their use in chemical warfare and, most likely, acts of terrorism, hydrogen cyanide [Agent AC, hydrocyanic acid (liquid form) or prussic acid], cyanogen halides and other cyanide-related compounds are frequently described as a "blood agents" (Kikilo et al., 2008; Wismer, 2018). The major mechanism of action associated with acute cyanide intoxication is the formation of a stable complex with the ferric iron (Fe^{3+}) in cytochrome oxidases, resulting in cytotoxic hypoxia from the inhibition of cellular respiration, oxygen utilization, and energy production (Ballantyne and Salem, 2008; Wismer, 2018). As a result of the rapid lethality of this class of compounds, very few studies have been conducted to investigate the adverse reproductive effects of hydrogen cyanide and cyanide-related compounds (e.g., cyanogen halides, cyanides, and nitriles). However, there is evidence to suggest that cyanide exposure in laboratory animals and livestock exposures to plants containing cyanogenic glycosides can be associated with embryonic and fetal death, as well as teratogenesis (Ballantyne et al., 2008; Burrows and Tyrl, 2001; Wismer, 2018). In addition, it would be anticipated that sublethal cyanide-induced hypoxia could cause enough maternal and/or fetal stress to result in abortion or preterm deliveries.

39.3.2.4 Nerve agents

39.3.2.4.1 Organophosphate nerve agents

The development of easily disseminated nerve agents as chemical weapons has been of interest to both military strategists and terrorist organizations because of the ability of these chemicals to rapidly incapacitate and kill opposing forces, as well as civilian populations. The major chemical nerve agents, tabun (Agent GA), sarin (Agent GB), soman (Agent GD), cyclosarin (Agent GF), and Agent VX are extremely toxic, and even very brief exposures to these nerve agents can be lethal (Kikilo et al., 2008; Watson et al., 2006; Wismer, 2018). These chemicals are classified as organophosphorus, organophosphate, or "OP" compounds, and their mechanism of action involves the competitive and irreversible inhibition of acetylcholinesterase (AChE) (Gupta et al., 2018; Watson et al., 2006; Wismer, 2018). Commonly used OP and carbamate pesticides also inhibit AChE, and these chemicals, although generally less potent than those designed for use as CWAs, usually have longer lasting effects and have the potential to be used as "low-tech" chemical weapons.

There have been some discrepancies between the results of various studies evaluating the reproductive toxicity of different OP compounds. While decreased libido has been observed in men following acute exposures to both OP nerve agents and insecticides, this "reproductive" effect is most likely related to the neurobehavioral effects, such as posttraumatic stress disorder, associated with acute exposures to these chemicals (McDonough and Romano, 2008). Some nerve agents have been associated with postimplantation morbidity and mortality in laboratory animals (Wismer, 2018), but rats and rabbits exposed to soman did not apparently experience fetal toxicity or prenatal mortality, even with maternal illness (Wismer, 2018). Similarly, low-level exposures to other nerve agents, as well as some insecticides, have not consistently resulted in impaired fertility and developmental abnormalities (McDonough et al., 2008). However, adverse reproductive effects have recently been reported by several authors in association with OP insecticide exposures (Joshi et al., 2007; Peiris-John and Wickremasinghe, 2008; Sikka and Gurbuz, 2006). Chlorpyrifos exposure has resulted in decreased sperm counts and testosterone concentrations, as well as testicular degeneration, in laboratory animals (Joshi et al., 2007). Similar abnormalities have also been observed in humans following low-level exposures to OP insecticides (Peiris-John and Wickremasinghe, 2008; Sikka and Gurbuz, 2006). It has been reported that OP insecticides can cause disturbances in the feedback loops within the hypothalamic−pituitary−adrenal axis, thereby affecting the release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) (Sikka and Gurbuz, 2006), and some members of this class of pesticides have even been reported to have antiandrogenic activity (Kitamura et al., 2006). In addition, exposures to OP insecticides can also cause oxidative stress, leading to increased apoptosis within the testes (Sikka and Gurbuz, 2006).

As mentioned previously, maternal and/or fetal stress associated with sublethal exposures to OP insecticides could lead to an increased incidence of abortions or preterm births in intoxicated, pregnant women and animals. Because of lower levels of detoxifying enzymes (i.e., paraoxonase), the fetus appears to be more susceptible to OP intoxication than adults, and developmental neurotoxicity and growth retardation have been associated with low-level, prenatal exposures of humans to OP insecticides (Desaiah, 1998; Eskenazi et al., 2008; Peiris-John and Wickremasinghe, 2008). In addition to the maternal and fetal effects, OP insecticides can also have direct toxic effects on the placenta, possibly involving (depending on the species) AChE inhibition within the placental cholinergic system (Pelkonen et al., 2006).

Since the effects of OP insecticides are generally longer lasting and more diverse than those of OP nerve agents, extrapolations between OP insecticides and nerve agents need to take into consideration the toxicokinetic and toxicodynamic differences between these two classes of OP compounds (McDonough et al., 2008). Given their frequent occupational use and the duration of the toxic effects of OP insecticides, it is probably more likely that adverse reproductive outcomes will be investigated and observed with exposures to these compounds than with exposures to nerve agents specifically designed for immediate incapacitation without environmental persistence. Depending on the circumstances, acute or low-level exposures to OP nerve agents might not be associated with overt effects on reproductive function, especially when direct, toxicant-induced effects on reproductive performance are of secondary importance to neurological and/or psychological concerns and the reproductive endpoints being assessed are relatively insensitive. Duration, route, and amount (i.e., dose) of nerve agent exposure, the developmental period during which exposure occurs, and the reproductive endpoints and animal species being evaluated are factors which will need to be taken into consideration in the design of future studies investigating the direct effects of nerve agents on fertility and embryonic and fetal development.

39.3.2.5 The reproductive toxicity environmental contaminants resulting from acts of terrorism

Not all acts of "chemical warfare" are going to necessarily involve weapons specifically designed for that purpose. Especially in instances of terrorism or military attacks involving nongovernmental militias or governments with limited weapons resources, chemical warfare can be "low tech" and make use of toxic chemicals in commercially available products or those hazardous materials present at manufacturing, processing, or storage facilities. Ionizing radiation can be released into the environment through strategic military use of nuclear weapons or from "nuclear accidents" involving municipal power plants, nuclear-powered aircraft carriers and submarines or the explosion of misplaced, misused, or stolen nuclear "weapons of mass destruction." In addition, many potential reproductive toxicants, including pesticides, are routinely used in various manufacturing and agricultural processes. Acts of terrorism or military strikes on industrial or agricultural complexes have the potential to greatly increase the exposure of humans and animals to a large number of different toxicants in the air, water, soil, and food chain.

Depending on the circumstances, both short- and long-term (i.e., immediate and delayed) morbidity and mortality can be observed in "environmental disasters." In these types of catastrophic events, illness and death can be due to the direct effects of toxicants, or they can arise secondarily from other factors associated with the environmental release of xenobiotics. Related conditions, such as famine, can accompany disasters and negatively impact reproductive function in humans and animals. The very real or, in some cases, imagined or exaggerated threats to human and animal welfare from environmental contaminations can be associated with instances of mass fear, panic, and "emotional incapacitation." These psychological stresses can affect reproductive function and, especially, gestational length and fetal survival in humans and animals. Emotional responses are naturally heightened with toxic exposures involving pregnant women and children.

39.3.2.6 Ionizing radiation

Ionizing radiation can target rapidly dividing cells in multiple organs, including the testes and ovaries, as well as the developing embryo and fetus (Cockerham et al., 2008; Foster and Gray, 2013; Rogers, 2013). Exposure of males to ionizing radiation can result in diminished spermatogenesis and testosterone production by the testes, with increased secretion of LH and FSH by the anterior pituitary (Cockerham et al., 2008). Consistent with these effects, Ukrainian workers involved in the cleanup of radioactive materials after the Chernobyl nuclear accident had increased ultramorphological sperm abnormalities (Cockerham et al., 2008; Fischbein et al., 1997). Similar to the radiation-induced endocrine effects observed in the testes, ovarian steroid production is reduced by exposure to ionizing radiation (Cockerham et al., 2008). Depending on the timing and dose of the radiation exposure, ionizing radiation can cause pubertal failure, ovarian failure, or premature menopause in women (Cockerham et al., 2008).

Clusters of Down syndrome in Belarus 9 months following the explosion at the Chernobyl nuclear power

plant suggest a radiosensitive phase of oogenesis in mammals around the time of ovulation and conception (Zatsepin et al., 2007). High radiation exposure in late-gestational women or pregnant animals has the potential to cause abortion or preterm births associated with maternal and/or fetal radiation sickness and stress. Depending on the stage of development and the dose of radiation, exposure of the conceptus, embryo, or fetus to ionizing radiation can result in lethality or morphologic abnormalities (Cockerham et al., 2008), and observations in humans and animals after the Chernobyl incident are consistent with these developmental effects (Østerås et al., 2007; Peterka et al., 2007). In addition, anxiety associated with exposures of pregnant women to ionizing radiation from the Chernobyl nuclear accident reportedly led to increased incidences of induced abortions in several European countries, even in instances where the exposure was minimal (Cordero, 1993).

39.3.2.7 Pesticides and other organic contaminants

Pesticides and other organic contaminants are ubiquitous in both industrial and agricultural settings. Acts of terrorism have the potential to increase the exposure of humans and animals to these types of xenobiotics in the environment by targeting industrial and agricultural complexes. The massive release of pesticides, in particular, has the potential to be a readily available means of inciting fear and inducing morbidity and mortality in humans and animals. In fact, as mentioned previously, carbamate and OP insecticides have the same basic mechanism of action as the previously discussed AChE-inhibiting nerve agents, and MIC, an intermediate in the production of carbamate insecticides, contains a cyanide moiety.

There have been many, well-documented instances of reproductive abnormalities in species of wildlife living in environments contaminated by a wide range of industrial and/or agricultural chemicals (Evans, 2018; Guillette, 2006; Hess and Iguchi, 2002; Jobling and Tyler, 2006; McLachlan, 2001; McLachlan et al., 2006). Wildlife populations are very likely sentinels for exposure to reproductive toxicants because of the contamination of the aquatic habitats in which many of them live and the bioaccumulation of some organic chemicals in predators (Hess and Iguchi, 2002). There is also recent evidence to suggest that domestic animals can act as potential sentinels for human exposure to endocrine disruptors and that hyperthyroidism in cats might be associated with exposure to polybrominated diphenyl ethers (PBDEs) (Dye et al., 2007).

Based on the observations of reproductive toxicity (including endocrine disruption) in wildlife and domestic animals, as well as ongoing concerns about reproductive dysgenesis in human populations and the observed effects of industrial accidents involving MIC and dioxins, there has been increasing interest in the effects of prenatal exposures of humans to suspected endocrine disruptors and other reproductive toxicants. However, when impaired reproductive function is discovered in adults, it is difficult to comment with complete certainty on the relative contributions of pre- versus postnatal exposures to reproductive toxicants. There is a wide array of pesticides and other organic environmental contaminants which have the potential to adversely impact reproductive function. Specific epidemiological or laboratory studies suggesting adverse reproductive effects of exposures to these xenobiotics will be discussed with respect to observed abnormalities in male and female reproductive function, as well as embryonic and fetal development.

39.3.2.7.1 Adverse effects of pesticides and other organic contaminants on male reproductive function

"Androgynization" or a state of indeterminate sexual development encompasses both feminization and demasculinization in males and, similar to the testicular dysgenesis syndrome described in humans, has been observed in populations of various vertebrate populations, including fish, amphibians, reptiles, birds, and mammals (Edwards et al., 2006; Evans, 2018). Adult and immature amphibians exposed to the herbicide atrazine and hatchling, juvenile, and adult male alligators originating from a lake previously contaminated with DDT and other persistent, bioaccumulated pesticides have been reported to exhibit varying patterns of androgynization (Evans, 2018; Hayes et al., 2006; Milnes et al., 2006). Although still somewhat controversial, there is evidence to support the observation that sperm counts in men within some industrialized regions of the world have been decreasing over the last several decades (Jørgensen et al., 2006; Skakkebæk et al., 2006; Swan et al., 2000). The findings of epidemiological studies have suggested a relationship between decreased anogenital distance and prenatal exposures of male infants and phthalates used as plasticizers, as well as a correlation between reduced semen quality in men within certain regions of the United States and the metabolites of several economically important herbicides (Swan et al., 2003a,b, 2005). In addition, a recently completed epidemiological study in Italy has demonstrated a significant relationship between postnatal exposure to 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and abnormal semen and endocrine parameters in men (Mocarelli et al., 2008).

The dicarboximide fungicides, vinclozolin and procymidone, and/or their metabolites inhibit the binding of androgens to nuclear androgen receptors and can demasculinize and feminize the prenatally exposed male fetus or induce important alterations in pre- or peripubertally

exposed offspring (Evans, 2017, 2018; Gray et al., 2006; Monosson et al., 1999). While still subject to debate amongst scientists, vinclozolin has also been reported to be capable of inducing epigenetic modifications which facilitate the occurrence of transgenerational or vertically transmitted reproductive abnormalities (Anway et al., 2005; Anway and Skinner, 2006). Linuron, *p,p′*-DDE, prochloraz, PBDEs, and selected OPs can function as androgen receptor antagonists (Gray et al., 2006; Kitamura et al., 2006), and AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone and disrupt testosterone signal transduction pathways (Jana et al., 1999; Mocarelli et al., 2008; Sikka et al., 2005).

The testes have xenobiotic biotransformation capabilities within both Leydig and Sertoli cells (Thomas and Thomas, 2001). While many toxicants and/or their metabolites are capable of producing relatively nonspecific effects, such as oxidative stress, there are a number of pesticides and other organic compounds which target specific cell populations within the testes. Several toxicants targeting Sertoli cells, including diethylhexyl phthalate and 2,5-hexanedione (a metabolite of *n*-hexane), have age- and species-specific effects (Creasy and Foster, 2002; Foster and Gray, 2013; Thomas and Thomas, 2001). Tri-*o*-cresyl phosphate, an industrial chemical used in lacquers and varnishes and associated with some organophosphate insecticides, inhibits LH-induced steroidogenesis in Leydig cells but, after Leydig cell-mediated conversion to its active metabolite, causes morphological abnormalities in Sertoli cells (Creasy and Foster, 2002; Evans, 2018; Thomas and Thomas, 2001).

As mentioned previously with regards to sulfur mustard, a variety of radiomimetic alkylating agents, including busulfan, cyclophosphamide, and nitrogen mustard, can target rapidly dividing mitotic or meiotic germ cells in the testes. In some instances, xenobiotics can target a specific population of germ cell precursors, such as spermatogonia spermatocytes or round or elongate spermatids (Creasy and Foster, 2002; Evans, 2018; Foster and Gray, 2013). TCDD appears to adversely affect several populations of spermatozoal precursors and alters the sex ratio in favor of female offspring (i.e., decreased viability of y chromosome-bearing sperm) (Foster and Gray, 2013; Ishihara et al., 2007; Mocarelli et al., 2008; Thomas and Thomas, 2001).

39.3.2.7.2 Adverse effects of pesticides and other organic contaminants on female reproductive function

A wide range of agricultural and industrial chemicals have estrogenic and/or antiestrogenic activities (Evans, 2018), and some of the synthetic xenobiotics most commonly discussed with respect to these activities include DDT, polychlorinated biphenyls, and TCDD (McLachlan, 2001). Effluents from industrial and agricultural activities have been shown to have androgenic activities and are associated with the masculinization of female fish (Evans, 2018; Gray et al., 2006; Orlando et al., 2004).

The effects of toxicants on specific cell types within the ovaries are not as well understood as they are in the testes (Thomas and Thomas, 2001). Many female reproductive toxicants do not actually target particular cell lines but, rather, disrupt the endocrine milieu of the tubular genitalia or cause changes in ovarian structures secondary to alterations in the hypothalamic−pituitary−gonadal axis (Yuan and Foley, 2002). Like the testes, the ovaries also have some xenobiotic biotransformation capabilities, and oxidative damage can adversely affect ovarian structure and function (Thomas and Thomas, 2001; Yuan and Foley, 2002). Phthalates and TCDD can delay or decrease ovulations, and, like sulfur mustard and ionizing radiation, some of the alkylating agents reported to adversely affect rapidly dividing germ cells within the testes can also adversely affect primordial follicles within the ovary (Devine and Hoyer, 2005; Thomas and Thomas, 2001). Several PAHs [i.e., BaP, 3-methylcholanthrene (3-MC) and DMBA] and 1,3-butadiene appear to target oocytes in preantral follicles, and DMBA can adversely affect antral follicular development (Devine and Hoyer, 2005; Evans, 2018).

39.3.2.7.3 Adverse effects of pesticides and other organic contaminants on embryonic/fetal development

As has been emphasized previously, the developing fetus undergoing phenotypic sexual differentiation is particularly susceptible to the adverse effects of various agonists and antagonists of estrogen and androgen receptors (Evans, 2017, 2018; Hess and Iguchi, 2002). A large number of xenobiotics, including many pesticides (e.g., carbamate, OP, organochlorine and pyrethroid insecticides) and other potential organic environmental contaminants, have been recognized as potential teratogens in humans and animals (Desaiah and Chang, 1998; Evans, 2017, 2018; Rogers, 2013). Alkylating agents with radiomimetic activity, such as busulfan, cyclophosphamide, and nitrogen mustard, cause teratogenesis by targeting rapidly replicating cells (Rogers, 2013). TCDD has been found to be teratogenic in both laboratory animals exposed experimentally (Aragon et al., 2008; Kransler et al., 2007) and in humans exposed following an accidental release in Seveso, Italy, in 1976 (Alaluusua et al., 2004). Accidental exposure to MIC in Bhopal, India, in 1984 resulted in a significant increase in spontaneous abortions and neonatal

mortality in humans (Varma, 1987; Varma and Mulay, 2006), and these epidemiological data were corroborated by the results of a subsequent rodent experiment (Varma, 1987). In addition, some xenobiotics can cause fetal death and abortion by having direct toxic effects on the placenta, rather than on the fetus itself (Gupta, 2007; Pelkonen et al., 2006).

39.3.2.8 Heavy metals

Heavy metals are routinely used in various manufacturing processes and are contained within many products commonly used by humans. Acts of terrorism have the potential to increase the environmental exposure of humans and animals to heavy metals by targeting industrial complexes and sewage treatment facilities. Because a number of heavy metals have the potential to affect different stages of reproductive function by different mechanisms of action, the adverse effects of metals on male and female reproduction and embryonic and fetal development will be discussed separately.

39.3.2.8.1 Adverse effects of heavy metals on male reproductive function

Excessive cobalt can potentially interfere with normal spermatogenesis, and even generalized hypoxia related to increased blood viscosity which affects the testes (Evans, 2018; Thomas, 1995). Chromium and vanadium have also been associated with adverse reproductive effects, and cis-platinum exposure has been associated with the death of spermatocytes and spermatids, as well as disruption of Sertoli cell tight junctions (Evans, 2018; Thomas, 1995; Thomas and Thomas, 2001). Exposure of male laboratory animals to organotin compounds has been associated with reduced testicular size, alterations in testicular morphology, and impaired spermatogenesis (Ema and Hirose, 2006; Evans, 2018).

Lead and cadmium are ubiquitous heavy metals and have both been associated with testicular toxicity and impaired fertility in a number of species. Divalent lead is known to interact with physiological processes involving calcium and generally has an affinity for sulfhydryl groups (Evans, 2018). Lead is reported to be toxic to germ cells as well as Leydig cells and can suppress anterior pituitary secretion of LH and FSH (Evans, 2018; Thomas and Thomas, 2001). Lead also appears to be able to adversely affect the ability of spermatozoa to fertilize ova; however, this effect, like others associated with lead exposure, appears to be dependent on age and individual variations in susceptibility, adaptation, and reversibility (Evans, 2018; Sokol, 2006). Like lead, cadmium is thought to adversely affect male reproduction by inhibition of spermiation, as well as by interactions with the hypothalamic–pituitary–gonadal axis and adverse effects on the endothelium of the testicular and epididymal vasculature (Akinloye et al., 2006; Creasy and Foster, 2002; Evans, 2018; Thomas, 1995). Cadmium can also alter the junctional complexes between adjacent Sertoli cells and disrupt the integrity of the blood–testis barrier (Akinloye et al., 2006; Evans, 2018; Thomas and Thomas, 2001).

39.3.2.8.2 Adverse effects of heavy metals on female reproductive function

The ovaries do not appear to be as sensitive to the toxic effects of heavy metals as do the testes (Evans, 2018; Thomas, 1995). The neuroendocrine function of the hypothalamic–pituitary–gonadal axis appears to be targeted by lead in the female, as well as in the male (Evans, 2018). Anterior pituitary release of FSH and LH and ovarian steroidogenesis can be inhibited by cadmium (Evans, 2018; Hoyer, 2006; Thomas, 1995). Exposure of female laboratory animals to organotin compounds has been associated with reductions in follicular development and size, as well as the formation of corpora lutea, and it has recently been suggested that tributyltin and cadmium might also have estrogenic activities (Ema and Hirose, 2006; Evans, 2018; Golub, 2006b).

39.3.2.8.3 Adverse effects of heavy metals on embryonic/fetal development

Several heavy metals have been identified as teratogens and possible abortifacients in humans and animals, and the adverse effects of prenatal lead exposure on the developing nervous systems of both human and laboratory animal species have been well documented (Evans et al., 2003; Rice, 1998; Rogers, 2013). Prenatal exposure to organotins has been associated with pregnancy loss and impaired ossification in rodents (Ema and Hirose, 2006). The outcomes of an industrial accident in Japan and misuse of contaminated grain in Basra, Iraq, clearly demonstrated the developmental neurotoxicity of organic mercury (i.e., methyl mercury and related compounds) in humans and animals (Chang et al., 1998; Cordero, 1993; Golub, 2006b). Other heavy metals, including cadmium, have been associated with placental toxicity, as well as developmental neurotoxicity (Gupta, 2007; Hastings and Miller, 1998), and it has been recently reported that cadmium and other metals or metalloids might also have estrogenic effects (Golub, 2006b).

39.4 Conclusion

Reproduction is a critical biological process, required for financially viable livestock production, as well as long-term survival of human and animal populations. Toxicant-induced abortions, congenital defects, and infertility can have devastating effects on humans, domestic animals,

and wildlife species. As a result of the impact of these negative reproductive outcomes, there are growing global concerns about all of the documented potential adverse effects, including those on reproduction, associated with CWAs and other military- or terrorist-related chemical exposures. Adding to these legitimate concerns about the potential adverse health effects of various toxicants being used as weapons of war are the uncertainty, stress, and, panic which can be created by widely and almost instantaneously disseminated, weaponized disinformation. The facts presented in this chapter are intended to familiarize the reader with terminology and concepts pertinent to reproductive toxicity, including endocrine disruption, and to provide an overview of what is currently understood about the adverse reproductive effects of selected, potential CWAs. Additionally, readers need to be keenly aware of emerging, CWA-related issues involving cybersecurity failures and aggressive disinformation campaigns. It is hoped that the information and references provided in this chapter will assist readers in making informed decisions in their interpretation of experimental or epidemiological data concerning potential CWAs. Likewise, this chapter should assist readers in their preparation for future CWA experiments and/or clinical investigations, as well as attempts to weaponize patently false CWA-related information against specific human populations.

Chapter 40

Liver toxicity of chemical warfare agents

Atrayee Banerjee
Senior Toxicologist, Reckitt Benckiser, United States

40.1 Introduction

Xenobiotic-induced liver injury has become the most frequent cause of acute liver failure in humans in the United States and around the world, exceeding all other causes combined (Watkins and Seef, 2006). Owing to its detoxification mechanisms, the liver protects the individual against xenobiotic-induced injury. Liver toxicity caused by chemical warfare agents (CWAs) is a potential area of concern.

Chemical-induced liver injury is encountered in a variety of circumstances. Some natural toxins, such as the peptides of *Amanita phalloides*, the pyrrolizidine alkaloids, the toxin of the cycad nut, and other plant toxins, are hazards posed by the environment. Some mycotoxins are ingested unknowingly because of feed contamination due to climatic conditions that favor fungal growth. Other circumstances of exposure to hepatotoxins include the contamination of a water supply with cyanobacterial toxins, which led to the tragic deaths of 60 patients in a hemodialysis clinic in Brazil in 1996 (Jochimsen et al., 1998).

Research in the last decade has focused on elucidating different mechanisms for chemical-induced liver injury. Investigators have attempted to understand the basis for such hepatic injury. The goal of this chapter is to provide a basic understanding of liver pathophysiology and to introduce the general concepts of liver injury. The chapter also describes some examples of CWAs that can inflict liver damage.

40.2 Structural organization of the liver

The hepatic lobule and hepatic acinus are relatively well-accepted models to describe the structure and functional aspects of the liver. Histologically, the *hepatic lobule* is a hexagonal region of the liver parenchyma around the central vein. Typically, six portal triads, consisting of branches from the portal vein and hepatic artery, as well as bile ductules, border the edge of the lobule. Cords of hepatocytes are arranged radially around the central vein, and blood sinusoids form between them. The hepatic parenchyma is divided into three zones based on proximity to the central vein. The area closest to the central vein is termed *centrilobular*, the area near the portal triads is *periportal*, and the area between the centrilobular and periportal parenchyma is termed *midzonal*.

Alternatively, *hepatic acinus* is defined as the structural and functional unit in the liver based on the hepatic microcirculation. In simple terms, the hepatic acinus is defined as a parenchymal mass organized around the portal triad. Within the acinus, blood drains from the portal area via the sinusoids into the central hepatic vein. The acinus is arbitrarily divided into zone 1, which corresponds to the periportal zone of the hepatic lobule; zone 2, which corresponds to the midzonal parenchyma; and zone 3, which corresponds to the centrilobular zone. The majority of blood supply to the liver is from the portal vein. Approximately 60%−80% of the blood originates from branches of the portal vein and supplies nutrients and toxins from the gastrointestinal tract, while 20%−40% of the blood originates from the hepatic artery, supplying oxygen (Treinen-Moslen and Klaasen, 2001). The blood from the portal vein and hepatic artery is mixed in the penetrating vessels, which then enter the sinusoids. Blood flows sequentially through zone 1, zone 2, and zone 3 before draining via the central vein. Because of this preferential blood circulation, hepatocytes in zone 1 receive blood that is 9%−13% oxygenated, whereas zone 3 is relatively hypoxic—the blood is 4%−5% oxygenated and nutrient-depleted (Treinen-Moslen and Klaasen, 2001).

In addition to hepatic parenchymal cells, which are hepatocytes, hepatocyte stem cells, termed *oval cells*, are reported to be located in the canals of Hering, where bile canaliculi from the hepatic cords converge on bile ductules of the portal triad. It is postulated that new hepatocytes travel down hepatic cords to replace the aging and

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00040-4

damaged hepatocytes from zone 3. Sinusoids lined by specialized endothelium are blood channels located between hepatocyte cords. The endothelial lining of the sinusoids is discontinuous and has fenestrae to facilitate the movement of fluid and molecules less than 259 kDa in size (Watkins et al., 1999; Treinen-Moslen and Klaasen, 2001; Plumlee, 2004). This material enters the space of Disse, which is located between the endothelium and the hepatocytes. Within the space of Disse, hepatocytes contact free and protein-bound molecules, which may be absorbed by diffusion or active transport.

40.2.1 Hepatic functional capacity

The liver contributes to a plethora of functions. Liver filters the blood drained from the gastrointestinal tract via the portal vein for xenobiotics, endotoxins, ammonia, and other bacteria-derived products (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004). The liver is directly involved in glucose homeostasis (Treinen-Moslen and Klaasen, 2001; Piñeiro-Carrero and Piñeiro, 2004); cholesterol synthesis and uptake (Treinen-Moslen and Klaasen, 2001); synthesis of proteins such as clotting factors, albumin, and very-low-density lipoprotein (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004); storage of glycogen, lipids, minerals, and vitamins (Plumlee, 2004); metabolism and excretion of hemoglobin breakdown products (Plumlee, 2004); steroid hormones (Brown, 2001); and drug metabolites.

The hepatic zones have remarkable regiospecificity and metabolic diversity to accommodate the numerous functions of the hepatocytes. In addition to differences in oxygen gradients (zone 3 hepatocytes are oxygen-depleted compared to zone 1 hepatocytes), hepatocytes of zone 3 in particular are rich in drug-metabolizing enzymes. Zone 3 hepatocytes are involved in glycolysis and lipogenesis (Plumlee, 2004), and zone 1 hepatocytes are mitochondria-rich (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004). Functions of zone 1 hepatocytes include bile salt extraction, fatty acid oxidation, gluconeogenesis, and protein synthesis (Treinen-Moslen and Klaasen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). Zone 1 hepatocytes have the highest levels of glutathione (GSH; Treinen-Moslen and Klaasen, 2001).

Bile secretion is a major function of the liver. Bile is composed of bile salts, bilirubin, GSH, phospholipids, cholesterol, proteins, organic anions, metals, and conjugated xenobiotics (Treinen-Moslen and Klaasen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Bile salts and bilirubin enter bile canaliculi via active transport through hepatocyte membranes. Canaliculi are dynamic structures located between hepatocytes and formed by hepatocyte membranes (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004). Energy-dependent transport exists for certain hormones, drugs, and other xenobiotics. These include a group of multiple drug-resistance p-glycoproteins that transport lipophilic cationic drugs, estrogens, phospholipids, and canalicular multiple organic anion transporters involved in the movement of molecules conjugated to GSH, glucuronide, and sulfate. Metal and mineral transport is important for mineral homeostasis and occurs through facilitated diffusion and receptor-mediated endocytosis across the sinusoidal membrane. Lysosomes are involved in storage and export of metals and minerals into canaliculi.

Canaliculi enter canals of Hering in the portal triad and lead to intrahepatic bile ducts, which coalesce to form the hepatic bile duct. The bile duct empties the bile into the gallbladder, which then is released into the duodenum. Bile that is excreted into the small intestine enhances nutrient uptake, protects enterocytes from oxidation, and facilitates the excretion of xenobiotics and endogenous waste in the feces (Treinen-Moslen and Klaasen, 2001).

40.2.2 Hepatic cellular components

In addition to the hepatocytes and the hepatocytic stem cells (oval cells), which are parenchymal in origin, there are four types of nonparenchymal cells present within the liver. The nonparenchymal cells include the endothelial cells lining the sinusoids; bile duct epithelium; Kupffer cells, which are resident macrophages; the *stellate* cells, also called *Ito cells* or *fat-storing cells*; and the pit cells or large granular lymphocytes. In the rat, hepatocytes represent about 60% of the total cell number and 80% of hepatic tissue volume. Nonparenchymal cells in the rat are estimated to constitute about 30% of total cellular population, but comprise only 6%−7% of tissue volume due to their small size relative to hepatocytes (Dahm and Jones, 1996).

Kupffer cells represent 80% of the fixed macrophages in the body. These cells are mostly located within the sinusoidal lumina in close association with endothelial cells. Kupffer cells function as phagocytes, ingesting foreign material which may arrive through the portal circulation (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004), as well as apoptotic or necrotic hepatocytes. Kupffer cells have other immune functions in that they act as antigen-presenting cells and secrete various cytokines. Kupffer cells may store minerals and are also involved in the pathogenesis of a variety of liver diseases induced by toxins such as ethanol (Laskin, 1990; Thurman et al., 1998).

Stellate cells are located within the sinusoids and store fat and vitamin A (Treinen-Moslen and Klaasen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). In the event of liver injury, stellate cells may become activated

to a myofibroblast-like phenotype (Plumlee, 2004; Maddrey, 2005). Activated stellate cells produce collagen and play a role in the pathogenesis of hepatic fibrosis. Pit cells are natural killer cells that have antineoplastic actions (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004). They are also involved in granuloma formation (Plumlee, 2004).

40.3 Factors influencing hepatic toxicity

40.3.1 Preferential hepatic uptake

As mentioned previously, the liver has a dual blood supply. The hepatic artery delivers material from the systemic circulation and the portal blood flow delivers directly from the gastrointestinal system. The portal system is involved in the *first pass effect*, where the nutrients and xenobiotics that are absorbed from the stomach and intestines are filtered through the liver before reaching the systemic circulation (Treinen-Moslen and Klaasen, 2001). The space of Disse allows close contact between circulating plasma, plasma proteins, and hepatocytes, allowing rapid diffusion of lipophilic compounds across the hepatocyte membrane. Some compounds are specifically taken up by sinusoidal transporters, including phalloidin from several species of mushrooms in the genus *Amanita*, microcystin produced by the cyanobacteria *Microcystis aeruginosa*, and bile acids.

Liver cells have the potential to accumulate high levels of metals and vitamins, which can lead to toxic injury. Excessive vitamin A storage in stellate cells acutely leads to the activation and proliferation of these cells (Treinen-Moslen and Klaasen, 2001), while chronic high levels can lead to hepatic fibrosis and portal hypertension, precipitating increased fibrosis (Zimmerman et al., 1999; Piñeiro-Carrero and Piñeiro, 2004; Maddrey, 2005). The liver is also responsible for iron homeostasis. There is a receptor-mediated uptake of iron from the sinusoids and sequestration in storage proteins such as ferritin. High levels of iron cause lipid peroxidation of zone 1 hepatocytes (Treinen-Moslen and Klaasen, 2001). A common example of hepatic accumulation of metals is copper-mediated liver toxicity noted in certain breeds of dogs (e.g., Bedlington terriers, Dobermans, and Dalmatians), where copper is stored within lysosomes of hepatocytes, resulting in progressive accumulation of copper, resulting in liver necrosis (Rolfe and Twedt, 1995).

40.3.2 Xenobiotic metabolic bioactivation

Most xenobiotic agents absorbed by the small intestine are highly lipophilic. Renal excretion is the primary mechanism of xenobiotic removal, but kidney excretion of lipophilic compounds, which are frequently protein-bound in the circulation, is poor (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins et al., 1999). Such lipophilic compounds must be metabolized to increase their water solubility for excretion (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman et al., 1999). Microsomal enzymes within the liver add functional groups or conjugate xenobiotics to water-soluble molecules to facilitate excretion. While these reactions often function in the detoxification of compounds, there is significant potential for toxification (Zimmerman et al., 1999). Examples of phase I reactions include oxidation, reduction, and hydrolysis. Phase I enzymes, which are predominantly located in zone 3 of the hepatic lobule, may produce reactive metabolites.

Many hepatic enzymes are present in the smooth endoplasmic reticulum (ER) of the hepatocyte. When liver tissue is homogenized, the ER breaks down into small vesicles known as *microsomes*; thus, these enzymes are termed *microsomal enzymes*. As a rule, microsomal enzymes require oxygen and reduced nicotinamide adenine dinucleotide (NADPH) to function (Dahm and Jones, 1996; Brown, 2001). Most phase I enzymes contain heme, giving them a red coloration, and they absorb light at a wavelength of 450 nm. Most cytochrome P450s act as mixed-function oxidases. Genes for cytochrome P450s are highly conserved in mammals. There are three gene families, CYP1, CYP2, and CYP3, and more than 36 cytochrome P450 isoenzymes have been identified in animals (Dahm and Jones, 1996; Watkins et al., 1999).

Oxidation is the major phase I reaction produced by the group of cytochrome P450s. Important substrates for CYP450s include steroid hormones and lipid-soluble drugs (Brown, 2001). Oxidative reactions frequently lead to the formation of highly reactive epoxides. These toxic metabolites are usually detoxified rapidly by phase II conjugation or other mechanisms, such as microsomal epoxide hydrolases (Watkins et al., 1999; Piñeiro-Carrero and Piñeiro, 2004).

Noncytochrome P450 enzymes may also be involved in oxidative reactions. One such enzyme is alcohol dehydrogenase, whose substrates include vitamin A, ethanol, and ethylene glycol. Aldehyde dehydrogenase is another enzyme. Most reduction reactions also involve microsomal enzymes, with the exception of ketone reduction. Nitro compounds are reduced to amines, and volatile anesthetics undergo dehalogenation by microsomal enzymes. Hydrolysis reactions are involved in the metabolism of compounds with amide bonds or ester linkages, as in the conversion of aspirin to salicylate (Brown, 2001).

40.3.3 Phase II/conjugation reactions

Phase II enzymes may be cytosolic or microsomal (Dahm and Jones, 1996; Brown, 2001). Phase II enzymes are

predominantly involved in conjugating phase I metabolites or xenobiotics with functional groups. Phase II metabolites are rarely reactive, but there are a few exceptions, such as the glucuronide of the nonsteroidal antiinflammatory drug diclofenac and the GSH conjugate of α-naphthothiourea (ANTU). Phase II enzymes conjugate a polar group to the substrate at a hydroxyl group, carboxyl group, amino group, or sulfhydryl group produced through the actions of phase I microsomal enzymes. Polar molecules that are added to the substrate include glucuronic acid, sulfate derived from sulfuric acid ester, acetate, GSH, methyl groups derived from methionine, and amino acids such as glycine and cysteine. These polar groups significantly increase the water solubility of the substrate, facilitating rapid renal or biliary excretion.

Glucuronidation is the most common phase II reaction in humans, though it is deficient in the neonate (Sturgill and Lambert, 1997; Brown, 2001; Piñeiro-Carrero and Piñeiro, 2004). Substrates for glucuronidation usually include steroid hormones, thyroxin, and bilirubin, as well as many drugs, including salicylates and acetaminophen. Glucuronyl transferases are microsomal enzymes that catalyze the transfer of glucuronide from uridine 5′-diphosphate (UDP; Watkins et al., 1999). UDP may be depleted in patients overdosed with acetaminophen or other drugs that undergo this detoxification pathway. Products of glucuronidation may be excreted in the bile or urine. Those excreted in the bile may undergo hydrolysis in the intestine, which leads to reabsorption of the parent compound in a phenomenon called *enterohepatic cycling* (Brown, 2001). Similar to CYP 450 enzymes, some agents can also induce glucuronyl transferases, such as phenobarbital (Sturgill and Lambert, 1997).

Sulfation is the primary conjugation reaction for substrates with phenol groups or aliphatic alcohols (Sturgill and Lambert, 1997; Brown, 2001). These reactions are catalyzed by sulfotransferases in the cytoplasm. Agents that undergo sulfation include acetaminophen, morphine, ascorbic acid, and endogenous compounds like chondroitin, heparin, and some steroids. The pool of available sulfates may become saturated in drug overdoses.

Drugs with amine and hydrazine groups may be conjugated to acetate (Sturgill and Lambert, 1997). Sulfonamides often undergo acetylation (Brown, 2001). *N*-Acetyltransferase is an enzyme in the cytoplasm involved in acetylation reactions.

GSH and cysteine both have sulfhydryl groups that readily bind many phase I metabolites (Brown, 2001). GSH is a free-radical scavenger that prevents membrane damage from reactive metabolites. These reactions may be spontaneous or catalyzed by GSH peroxidases, which are selenium-dependent enzymes. Because these enzymes are cytosolic, damaged membrane phospholipids must be released by phospholipase A2 for detoxification. GSH is also involved in the reduction and recycling of other antioxidants, such as vitamins E and C (Dahm and Jones, 1996). When oxidized, GSH forms a dimer, which must be reduced by GSH reductases, which are NADPH-dependent enzymes. GSH may be depleted in the acetaminophen-overdosed or fasting person (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004). *N*-Acetylcysteine is frequently used to replenish GSH.

40.3.4 Phase III reactions

In addition to phase I and II biotransformation enzymes, studies suggest the involvement of hepatic transporter systems involved in drug efflux from hepatocytes as a means for the liver to rid itself of foreign chemicals. These are termed *phase III transporter systems*. Several transporter families that mediate uptake of chemicals into liver and excretion of chemicals from liver into blood, bile, or both have been cloned and identified. In general, the organic anion transporting polypeptide family (Oatps), along with organic cation transporter 1 (Oct1) and organic anion transporter 2, mediate the uptake of a large number of xenobiotics from the blood to the liver. Conversely, multidrug resistance proteins (Mdrps), multidrug resistance-associated proteins (Mrps), and breast cancer resistance protein (Bcrps) mediate the efflux of xenobiotics from the liver into bile or blood (Klaassen and Slitt, 2005).

40.3.5 Pathologic manifestations of hepatic injury

40.3.5.1 Hepatic steatosis/fatty liver

Hepatic steatosis is the accumulation of fat droplets within the hepatocytes. Steatosis is usually a common response noted with a variety of liver toxicants and represents a potentially reversible injury to hepatocytes (Treinen-Moslen and Klaasen, 2001). Grossly, the affected liver will be swollen, with rounded edges, friable, and light brown to yellow in color. Compounds that produce prominent steatosis include the antiepileptic drug valproic acid and the antiviral agent fialuridine. Other toxins that may cause hepatic steatosis include aflatoxin and white or yellow phosphorus. Although steatosis has been considered benign and reversible, there are recent reports that suggest the progression of the steatosis stage to steatohepatitis, fibrosis, and cirrhosis (Ramaiah et al., 2004). Recently, there has been a syndrome noted in obese individuals, who are often type 2 diabetics, called nonalcoholic fatty liver disease (NAFLD), where hepatocytes are markedly steatotic and there is a marked inflammatory component (Diehl, 2005). Other disorders that result in fatty livers include hepatotoxic chemicals such

as thioacetamide, ethanol, and carbon tetrachloride. It should be noted, however, that several endocrine abnormalities result in steatosis, thus assigning the cause to a specific etiology should be done with caution.

Steatosis is termed *microvesicular* if the fat droplets are small and do not completely displace the nucleus. Microvesicular steatosis likely indicates a slow lipid accumulation (Bastianello et al., 1987; Plumlee, 2004) and may indicate a deficiency in mitochondrial β-oxidation of fatty acids. It is a relatively severe form of steatosis and has been associated with certain toxins, including aflatoxin in primates and dogs (Bastianello et al., 1987; Zimmerman et al., 1999) and valproic acid in humans (Sturgill and Lambert, 1997; Zimmerman et al., 1999). In contrast, macrovesicular steatosis describes hepatocytes containing large, usually single, fat droplets that displace the hepatocyte nucleus to the periphery of the cytoplasm. Macrovesicular steatosis indicates an imbalance between fatty acid uptake and secretion of very-low-density lipoproteins. This may be due to increased triglyceride mobilization, decreased fatty acid oxidation, decreased synthesis of very-low-density lipoproteins, or other metabolic anomalies (Sturgill and Lambert, 1997; Zimmerman et al., 1999; Treinen-Moslen and Klaasen, 2001; Plumlee, 2004).

40.3.5.2 Steatohepatitis

Steatohepatitis is the accumulation of lipids and the presence of inflammatory cells within hepatic parenchyma. Steatohepatitis is usually the next stage of steatosis if untreated (Lieber, 1994; Bautista, 2002; French, 2003). The inflammatory cells are usually neutrophils and macrophages. Conditions usually associated with steatohepatitis are alcoholic liver disease, NAFLD, and endotoxemia secondary to intestinal disease. Any toxic compounds that cause steatosis can also result in steatohepatitis if the condition is left untreated. Steatohepatitis may progress to fibrosis/cirrhosis and hepatocellular carcinoma if the inciting cause is not removed or treated (Diehl, 2002).

40.3.5.3 Apoptosis versus necrosis

Two forms of cell death are described within hepatocytes: apoptosis and necrosis. As with other organs, apoptosis is often called *programmed cell death* and is a normal physiologic process. Individual cells are affected (Dahm and Jones, 1996), cell death is not associated with inflammation, and normal architecture of the hepatic parenchyma is maintained, allowing regeneration (Treinen-Moslen and Klaasen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Apoptotic cells undergo cell shrinkage and nuclear condensation and pyknosis, but mitochondrial function (Piñeiro-Carrero and Piñeiro, 2004) is maintained and the cell membrane remains intact (Zimmerman et al., 1999). Apoptotic cells are occasionally seen in the centrilobular area but are rapidly phagocytosed by macrophages and other hepatocytes (Plumlee, 2004). Apoptosis may be induced by xenobiotics due to oxidative stress (Piñeiro-Carrero and Piñeiro, 2004), decrease in apoptotic suppressors, or enhanced expression of apoptosis genes (Dahm and Jones, 1996).

Necrosis is the predominant form of cell death in most hepatotoxic insults. The term *necrotic* is used to describe dead and dying cells, which are often identified by homogeneous eosinophilic cytoplasm on hematoxic and eosin-stained liver sections with variable loss of nuclear and cellular detail. Degenerative changes to the hepatocyte may precede necrosis. During necrosis, cells lose osmotic homeostasis and there is swelling of hepatocytes and organelles on an ultrastructural basis (Dahm and Jones, 1996; Treinen-Moslen and Klaasen, 2001), both of which can be observed microscopically. Energy production fails due to loss of calcium homeostasis (Dahm and Jones, 1996; Zimmerman et al., 1999). Eventually, the cell membrane ruptures, and leakage of cell contents occurs.

Necrosis is often initiated by damage to membranes, either the plasma membrane of the cell or the membranes of organelles, particularly mitochondria (Zimmerman et al., 1999). Cell membrane damage is often caused by membrane phospholipid peroxidation. Plasma membrane damage interferes with ion regulation, calcium homeostasis, energy production, and causes a decrease in the ability of that organelle to sequester calcium. Inhibition of protein synthesis is an alternative mechanism that may cause cell necrosis. Toxins that act in this way include phalloidin and related mushroom toxins, which inhibit the action of ribonucleic acid (RNA) polymerase, and therefore mRNA synthesis (Piñeiro-Carrero and Piñeiro, 2004).

40.3.5.4 Hepatic pigment accumulation

Various substances may accumulate within hepatocytes or Kupffer cells. These substances may be visible by microscopy as pigment. Occasionally, these pigments lend a grossly visible tint to the liver. Bile pigment may accumulate in canaliculi and bile ducts, particularly in zone 3, leading to a yellow to green color (Plumlee, 2004; Zimmerman et al., 1999). Iron, in the form of hemosiderin, is stored in the liver as a yellow-brown pigment that may be visualized using Pearl's Prussian blue. Copper may be yellow-brown and is visualized using rhodenase. Lipofuscin may be present within hepatocytes as a senile change. This yellow-brown pigment represents lipid accumulation within lysosomes.

40.3.5.5 Hepatic cholestasis

Cholestasis may be transient or chronic (Treinen-Moslen and Klaasen, 2001) and may be subdivided into

canalicular cholestasis and cholangiodestructive cholestasis. Canalicular cholestasis can be produced by drugs or other chemicals that damage the bile canalicular structure and function. A key component of bile secretion involves several adenosine triphosphate (ATP)-dependent export pumps, such as the canalicular bile salt transporter, that moves bile salts and other transporters that export bile constituents from the hepatocyte cytoplasm to the lumen of the canaliculus. Some of the drugs bind these transporter molecules, resulting in the arrest of bile formation or movement within the lumen of the canalicular system (Klaassen and Slitt, 2005). Secondary bile injury can result if there is cholestasis due to the detergent action of bile salts on the biliary epithelium or hepatocytes in areas of cholestasis. Cholestasis can occur simply as a result of physical obstruction of canaliculi within the liver parenchyma (intrahepatic) or outside the liver (extrahepatic). Causes of cholestasis may include hepatobiliary tumors, endotoxemia, hepatocyte swelling, and intraductal crystals such as calcium salts of plant saponins. Disruption of actin filaments within the hepatocyte may cause cholestasis by preventing the normal pulsatile contractions that move bile through the canalicular system to the bile ducts. Drugs that bind to actin filaments such as phalloidin, those that affect cytoskeletal assembly such as microcystin, and those that affect calcium homeostasis and cellular energy production can generate this type of energy.

Cholangiodestructive cholestasis is caused by bile duct obstruction, which may be intrahepatic or extrahepatic. Bile duct injury may lead to the sloughing of epithelial cells into the lumen, cell edema, and inflammation, which may contribute to obstruction (Treinen-Moslen and Klaasen, 2001; Plumlee, 2004). Chronic lesions associated with cholangiodestructive cholestasis typically include bile duct proliferation and periductular fibrosis. Vanishing bile duct syndrome, characterized by a loss of bile ducts, has been seen in chronic cholestatic disease in humans (Zimmerman et al., 1999; Treinen-Moslen and Klaasen, 2001) and has been produced experimentally in dogs (Uchida et al., 1989).

40.3.5.6 Hepatic fibrosis

Fibrosis usually results from chronic inflammation, which can be the result of continuous exposure to a variety of hepatotoxic chemicals, such as organic arsenicals, vinyl chloride, or high doses of vitamin A (Zimmerman et al., 1999), chronic ethanol ingestion, and NAFLD. Fibrosis usually occurs around the portal area, in the space of Disse, and around the central veins. This results in loss of liver architecture and function. The hepatocytes are replaced with fibrous material, and thus there is hepatocyte loss. Periportal fibrosis may lead to portal hypertension.

40.3.5.7 Cirrhosis

Hepatic cirrhosis is typically the end stage of liver disease. Cirrhosis describes an irreversible change (Treinen-Moslen and Klaasen, 2001) characterized by accumulation of excessive collagen deposition in the form of bridging fibrosis, which disrupts the hepatic architecture. Cirrhosis may be micronodular or macronodular, depending on the amount of fibrosis and tissue regeneration. Liver transplantation is the only solution to restore adequate liver function in human medicine.

40.3.5.8 Pathomechanisms of hepatic injury

Mechanisms of liver injury have been divided into two categories: intrinsic and idiosyncratic. Intrinsic injury may lead to steatosis, necrosis, cholestasis, or a mixed form of damage, often with minimal inflammation (Sturgill and Lambert, 1997). Intrinsic liver injury is a predictable, reproducible, dose-dependent reaction to a toxicant (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman et al., 1999; Piñeiro-Carrero and Piñeiro, 2004). A threshold dose exists for xenobiotics causing intrinsic liver injury. There is commonly a predictable latent period between the time of exposure and clinical evidence of liver injury. This type of liver injury accounts for the vast majority of toxic liver injury and is often caused by reactive products of xenobiotic metabolism, most commonly electrophiles and free radicals. A few drugs cause intrinsic liver injury without bioactivation. An abbreviated summary of mechanisms of intrinsic liver injury is illustrated in Fig. 40.1.

Idiosyncratic responses are, by contrast, unpredictable responses to a drug or other toxicant. They are rare, non-dose-dependent, and often associated with extrahepatic changes (Sturgill and Lambert, 1997; Zimmerman et al., 1999; Piñeiro-Carrero and Piñeiro, 2004; Shenton et al., 2004). Idiosyncratic drug reactions often occur after sensitization, followed by reexposure to a drug. There is a usually a delay of 1−5 weeks (and occasionally several months) between the time of the first dosing and the time that clinical signs become evident, but onset is expedited with rechallenge (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins et al., 1999). Hepatic changes associated with idiosyncratic drug reactions include necrosis, cholestasis, or both; and there is often an inflammatory response involving macrophages and eosinophils. Extrahepatic clinical signs may include pyrexia, rash, and peripheral eosinophilia. Some idiosyncratic drug reactions resemble serum sickness. Some of the mechanisms of liver injury are described in more detail next.

40.3.6 Oxidative stress and free radicals with classic examples

Free radicals are generated within hepatocytes in several ways, such as ionizing radiation, oxidative metabolism by

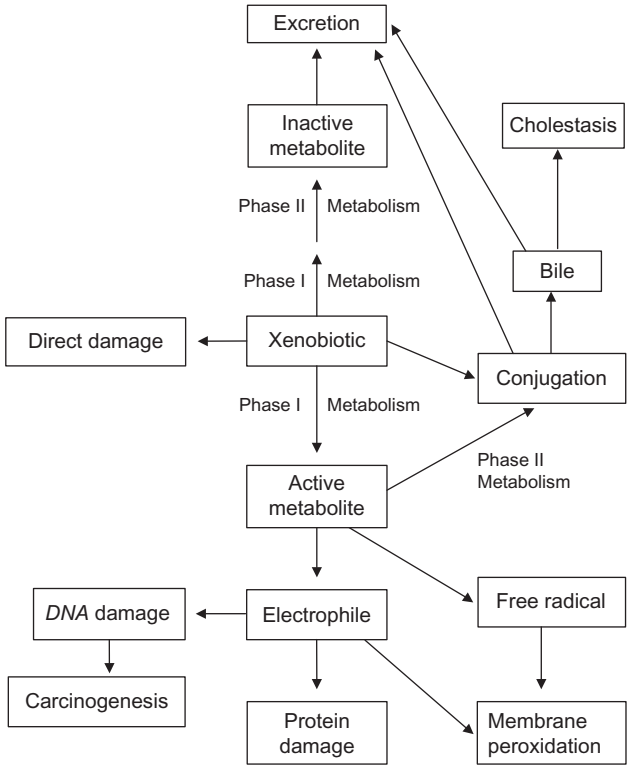

FIGURE 40.1 Multiple metabolic pathways involved in the mediation of hepatic injury for any compound. The liver is central to the metabolism of xenobiotic (and some endogenous) compounds, which produces water-soluble products amenable to urinary or biliary excretion. Some compounds undergo metabolic activation to produce free radicals, electrophiles, or other toxic products that may induce hepatic injury. *Adapted from Gupta, R. (Ed.), 2007. Veterinary Toxicology, first ed. Academic Press, p. 158.*

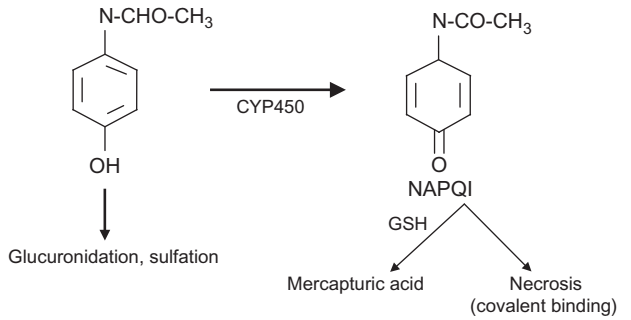

FIGURE 40.2 Metabolism and mechanism of acetaminophen toxicity. Bioactivation of acetaminophen by P450 enzymes results in the formation of the reactive intermediate (NAPQI), which forms covalent protein adducts with GSH, which then is converted to mercapturic acid. When the amount of the reactive metabolite formed exceeds the GSH available for binding, the excess metabolite binds to tissue molecules, resulting in centrilobular hepatic necrosis. *Adapted from Gupta, R. (Ed.), 2007. Veterinary Toxicology, first ed. Academic Press, p. 155.*

cytochrome P450, reduction and oxidation (redox) reactions that occur during normal metabolism, transition metals such as iron and copper, and from nitric oxide generated by a variety of inflammatory cells. The reactive species that are generated result in lipid peroxidation of membranes, oxidative modification of proteins, and lesions within DNA (Crawford, 1999).

Free radicals have unpaired electrons, making them highly reactive. They may be formed by one electron oxidation or reduction reaction, leading to cationic or anionic radicals, respectively (Dahm and Jones, 1996). Alternatively, hemolytic bond scission leads to neutral radical formation. Oxygen free radicals result from metabolic processes, leukocytic respiratory burst, or the effects of ionizing radiation. Hydroxyl radicals, superoxide radicals, and hydrogen peroxide are major reactive oxygen species. The free radical nitric oxide (NO), an important cell-signaling agent released by leukocytes, may react with superoxides to form peroxynitrite.

Free radicals cause peroxidation of phospholipids within the plasma membrane of the cell, as well as the membranes of the mitochondria and ER. The radicals act by removing a proton (H^+) from a methylene carbon within a polyunsaturated fatty acid, forming a lipid free radical. This lipid free radical then may abstract a proton from a neighboring polyunsaturated fatty acid, generating more lipid free radicals. It is estimated that this can occur 4–10 times per initiation. The effects of lipid peroxy radicals on the cell membrane include increased permeability, decreased fluidity, and inactivation of membrane proteins (Dahm and Jones, 1996). Additionally, mitochondrial membranes lose polarity (Watkins et al., 1999).

Lipid peroxy radicals can react with metal ions stored within the hepatocyte, generating more lipid radicals. It is estimated that propagation by this mechanism can occur in 4–10 steps per initiation (Dahm and Jones, 1996). The most frequent mechanism of free-radical production leading to hepatocellular injury involves phase I metabolism of xenobiotics and the cytochrome P450 system. Phase I metabolism may lead to bioactivation of the substrate to a high-energy reactive intermediate molecule in preparation for phase II conjugation reactions. However, in circumstances such as overdosage, phase I products may accumulate. Lesions produced by these compounds are mostly centrilobular because the cytochrome P450s responsible for metabolism are mostly situated in the centrilobular areas of the liver.

The classic examples of this process are cell death resulting from carbon tetrachloride and acetaminophen toxicosis (Fig. 40.2). Acetaminophen has a hydroxyl group that can undergo immediate phase II conjugation reactions. Indeed, at therapeutic doses, 90% of this substrate undergoes glucuronide or sulfate conjugation in humans (Court and Greenblatt, 1997; Sturgill and Lambert, 1997). These are major metabolic pathways in most species, but the glucuronyl transferase deficiency in cats in part explains the sensitivity of felines to this drug.

Acetaminophen in itself is not considered toxic. Cellular injury is caused by the unstable metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI; Fig. 40.2). Under normal conditions in humans, 5% of a dose of acetaminophen is oxidized to NAPQI, which is rapidly neutralized by conjugation with GSH (Sturgill and Lambert, 1997; Maddrey, 2005; Fig. 40.2). Toxic levels of NAPQI may accumulate under certain conditions, as when large amounts of substrate are available for metabolism due to either large ingestions or inadequate glucuronidation.

Metabolism of acetaminophen to NAPQI is increased in individuals who regularly consume alcohol or take medications that induce microsomal enzymes (e.g., antiepileptic therapy). The hepatic pool of GSH becomes overwhelmed and depleted, permitting the accumulation of NAPQI. Possible additional risk factors that lower the threshold for hepatotoxicity have been identified; they include fasting and malnutrition, which deplete GSH reserves (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Treinen-Moslen and Klaasen, 2001; Piñeiro-Carrero and Piñeiro, 2004).

The reaction that produces NAPQI generates superoxide anions as a by-product. Interactions of NAPQI with other cellular molecules also generate reactive oxygen species, leading to oxidative stress on hepatocytes (Dahm and Jones, 1996; Zimmerman et al., 1999). The roles of calcium and Kupffer cell activation have been implicated as contributing factors for acetaminophen-induced liver injury by producing reactive nitrogen species (Treinen-Moslen and Klaasen, 2001).

NAPQI also acts as an electrophile, targeting the mitochondria in particular. This reactive metabolite forms covalent adducts with cellular molecules, particularly proteins with thiol groups. Other targets in addition to mitochondrial proteins include plasma membrane proteins involved in calcium homeostasis and adenine nucleotides (Dahm and Jones, 1996; Sturgill and Lambert, 1997).

40.3.7 Disruption of calcium homeostasis

Calcium ions (Ca^{2+}) are important for the mediation of hepatic injury. Cytosolic-free calcium is maintained at relatively low concentrations compared to the extracellular levels. The majority of intracellular calcium is sequestered within the mitochondria and ER. Membrane-associated calcium and magnesium ATPases are responsible for maintaining the calcium gradient (Farrell et al., 1990). Significant and persistent increases in the intracellular calcium result from nonspecific increases in permeability of the plasma membrane, mitochondrial membranes, and membranes of the smooth ER. Calcium pumps in the mitochondrial membrane require NADPH; thus, depletion of available NADPH can cause the release of calcium from mitochondria (Cullen, 2005).

Elevated cytoplasmic calcium activates a variety of enzymes, with membrane-damaging effects. The major enzymes that are involved in activation by calcium include ATPases, phospholipases, proteases, and endonucleases. Thus, increased calcium causes increased mitochondrial permeability and induction of apoptosis and necrosis. Calcium is required for maintenance and function of the cytoskeleton as well (Dahm and Jones, 1996; Delgado-Coello et al., 2006).

Although cell injury results in increased calcium, which causes a variety of damaging effects, the cause-and-effect relationship of calcium to cell damage is not known. The chemicals that cause liver damage by this mechanism include quinines, peroxides, acetaminophen, iron, and cadmium.

40.3.8 Inhibition of mitochondrial function

Mitochondria function in the process of producing energy, in the form of ATP, for the cell by oxidative phosphorylation. Hepatocytes are highly metabolically active and require a continuous supply of ATP. Hepatocytes active in detoxification or replacement of damaged tissue have even greater ATP requirements (Dahm and Jones, 1996). Compounds that may disrupt mitochondrial oxidative phosphorylation include bile acids and amiodarone.

Mitochondria are also critical to modulation of cell redox status, osmotic regulation, pH control, and cytosolic calcium homeostasis and cell signaling. Mitochondria are important targets for virtually all types of injurious stimuli, including hypoxia and toxins. Mitochondria are targeted by oxidants, electrophiles, lipophilic cations, and weak acids. Damage is often precipitated by increases in cytosolic calcium.

Hepatic injury is frequently accompanied by morphological changes in mitochondria. Mitochondrial changes evident as structural abnormalities include greatly increased size and the development of crystalline inclusions. These changes are usually regarded as pathologic, reflecting either a protective or degenerative response to injury. Mitochondrial damage may result in the formation of high-conductance channels (the so-called mitochondrial permeability transition) in the inner mitochondrial membrane. This is an irreversible change, and because membrane potential is critical for mitochondrial oxidative phosphorylation, it constitutes a death blow to the cell.

Oxidative phosphorylation produces reactive oxygen species (Watkins et al., 1999). These are deactivated by antioxidants present within the mitochondrion. GSH is present within mitochondria as a scavenger for peroxides and electrophiles. Synthesis of GSH requires ATP and takes place outside the mitochondrion. A greater than 90% depletion in GSH reserves decreases the ability of the mitochondrion to detoxify reactive oxygen species

produced by oxidative phosphorylation. GSH *S*-transferase, the enzyme required for recycling of GSH, may become overwhelmed by toxicants and reactive metabolites (Dahm and Jones, 1996).

Xenobiotics may cause cell death by their effects on mitochondrial DNA. Some antiviral dideoxynucleoside analogs can disrupt mitochondrial DNA synthesis through the inhibition of DNA polymerase gammas, leading to depletion of mitochondria and consequent hepatocyte death.

Chemicals that damage mitochondrial structure, enzymes, or DNA synthesis can disrupt beta oxidation of lipids and oxidative energy production within hepatocytes. Prolonged interruption of beta oxidation leads to microvesicular steatosis, which can progress to macrovesicular steatosis. This sequence of events has been noted with both alcoholic and nonalcoholic steatohepatitis. The role of mitochondria has been extensively studied with NAFLD, a major issue in human medicine. Alcoholic steatosis and other forms of hepatic steatosis have been linked to impairment of ATP homeostasis, and mitochondrial abnormalities have been reported in a growing body of literature.

There are several drugs that inhibit beta oxidation of fatty acids in mitochondria leading to lipid accumulation, such as aspirin, valproic acid, and tetracyclines.

40.3.9 Autophagy and endoplasmic reticulum stress

Autophagy is a catabolic process for maintaining cellular homeostasis and integrity of organelles by eliminating cytosolic materials through vacuole-mediated sequestration and subsequent delivery to lysosomes for degradation. Autophagy has emerged as playing a critical role in the regulation of liver physiology and metabolism. During induction of autophagy, cytosolic components are encapsulated in a phagophore, which forms a double-membrane-bound vesicle termed an autophagosome. This newly formed autophagosome fuses with a lysosome, allowing degradation of encapsulated products, whereby molecules and proteins may be recycled to improve cell survival. Further, numerous studies indicate that autophagy plays a role in the pathogenesis of various liver disorders (Cursio et al., 2015). In diabetic mice, autophagy has been closely associated with ER stress during the development of steatohepatitis (Zhang et al., 2015). The expression of ER stress-signaling proteins like CCAAT/enhancer binding protein (C/EBP)-homologous protein (CHOP; a proapoptotic transcription factor) is positively associated with autophagic activity in liver tissues (Zhang et al., 2015). In the literature, ER stress has been indicated as a potent trigger for induction of autophagy (Rashid et al., 2015; Lee et al., 2015), it is possible that acute liver injury may lead to ER stress, which subsequently might activate autophagy.

40.3.10 Disruption of the cytoskeleton

Changes in intracellular calcium homeostasis produced by active metabolites of xenobiotics may cause disruption of the dynamic cytoskeleton. There are a few toxins that cause disruption of the cytoskeleton through mechanisms independent of biotransformation. Microcystin is one of these toxins. Microcystin is produced by the cyanobacterium *M. aeruginosa*. Similar toxins are produced by other species of cyanobacteria. The hepatocyte is the specific target of microcystin, which enters the cell through a bile-acid transporter. Microcystin covalently binds to serine/threonine protein phosphatase, leading to the hyperphosphorylation of cytoskeletal proteins and deformation of the cytoskeleton (Treinen-Moslen and Klaasen, 2001).

Phalloidin and related toxins found in some mushrooms, including *A. phalloides*, act by binding tightly to actin filaments and preventing cytoskeletal disassembly (Treinen-Moslen and Klaasen, 2001).

40.3.10.1 Cholestatic mechanisms

Sinusoidal transporters and canalicular transporters are involved in the movement of bile salts from the sinusoids into the canaliculi. Within the hepatocyte, transcytosis is mediated by cytoskeletal transport mechanisms. Bile is moved within the canaliculi through actions of the hepatocyte cytoskeleton, causing contraction of the canalicular lumina (Treinen-Moslen and Klaasen, 2001). Xenobiotics acting on any of the above systems may influence bile transport and secretion.

Most chemicals that cause cholestasis are excreted in the bile, including the mycotoxin sporodesmin, which concentrates 100-fold in the bile (Treinen-Moslen and Klaasen, 2001). α-Naphthylisothiocyanate (ANIT) is a hepatotoxicant that damages bile duct epithelium and hepatocytes. The drug is used experimentally in rodents as a model of intrahepatic cholestasis. A single dose of ANIT induces acute cholangitis; prolonged exposure causes bile duct hyperplasia and biliary fibrosis. Although the biochemical and histological features of ANIT toxicity are well documented, the mechanism by which ANIT causes liver injury remains uncertain. ANIT does not cause liver damage in vivo until it appears in bile (Jean and Roth, 1995).

This drug is initially detoxified in hepatocytes by conjugation with GSH. ANIT−GSH complexes are secreted into bile, but they are unstable and rapidly dissociate, which exposes biliary cells to high concentrations of the parent compound, which presumably causes direct

cytotoxicity. The reappearance of ANIT in bile also leads to enterohepatic cycling, reuptake of the drugs in the intestine, and repetitive rounds of GSH conjugation and secretion. This not only delays elimination of the drug, but also depletes GSH progressively from hepatocytes and leads to hepatocellular damage. In addition, ANIT is known to cause hepatotoxicity by neutrophil- and platelet-dependent mechanisms (Jean and Roth, 1995).

40.3.10.2 Idiosyncratic reactions

Many idiosyncratic drug reactions are believed to be immune-mediated. Neoantigens may result from adducts formed from the interaction of reactive drug metabolites with cellular proteins. These neoantigens may be processed by Kupffer cells or other antigen-presenting cells, transported to the cell surface, and presented as antigens. A cell- and antibody-mediated immune response may cause severe liver damage. Various drugs are believed to cause immune-mediated idiosyncratic reactions in humans, including halothane, diclofenac, phenytoin, and sulfonamides (Sturgill and Lambert, 1997; Watkins et al., 1999; Zimmerman et al., 1999; Treinen-Moslen and Klaasen, 2001).

Liver injury can be a result of both direct cytotoxicity and antibody-dependent cellular toxicity. Alcoholic liver disease is another example of possible immune-mediated damage. Acetaldehyde, produced by the metabolism of ethanol, forms adducts with hepatic proteins similar to halothane, resulting in higher antibody titers, to which some of the liver damage following ethanol ingestion may be attributed (Ramaiah et al., 2004). However, the role of immune-mediated liver damage following ethanol ingestion is minimal compared to other known mechanisms of alcohol liver damage.

40.4 Biological toxins

Toxins are biomolecules produced by living organisms mainly for defensive purposes. These molecules induce detrimental effects in other organisms, by different routes of exposure (Dorner and Rummel, 2015). Some of these toxins are linked to natural intoxications and are extremely dangerous due to their lethal doses (LD). An $LD_{50} < 25$ mg/kg indicates a very toxic substance, while substances having $LD_{50} > 2000$ mg/kg are not classified as toxic (Malmfors and Teiling, 1983).

Biological agents used for warfare are classified by the Centers for Disease Control and Prevention (CDC) into three categories. Category A consist of factors characterized by high pathogenicity and mortality as well as ease of dissemination (e.g., *Bacillus anthracis*). Category B pathogens are easy to spread, with low morbidity and mortality rates, but require specific monitoring and improved diagnostic capabilities (for example, ricin, abrin). Category C includes emerging pathogens against which the population has little or no immunity, and which could be engineered as a bioweapon (e.g., hantavirus) (Jansen et al., 2014).

40.5 Warfare agents affecting the liver

40.5.1 Fungal and plant toxins

40.5.1.1 Microcystins

The microcystins are hepatotoxic products of freshwater blooms of cyanobacteria of *Microcystis*, *Anabena*, and *Oscillatoria* species (Chen et al., 1993; Luu et al., 1993), with *M. aeruginosa* being the most common. Nearly 60 microcystin cyclic hepatopeptides have been identified, of which microcystin-LR, also known as the *fast death factor*, is the most common, and the toxin of choice to be weaponized (Craig et al., 1993; Rinehart et al., 1994). This toxin has been reported to be responsible for the deaths of wild animals and agricultural livestock (Carmichael, 1988). A potential threat to the health of humans has been recognized in countries where water supplies are contaminated with cyanobacteria (Yu et al., 1989; Gkelis and Zaoutsos, 2014). In 1996, microcystin-LR was also implicated in the death of 50 Brazilian dialysis patients (Jochimsen et al., 1998).

This potent mammalian liver toxin (Carmichael, 1988) acts by altering the hepatocyte cytoskeleton actin filaments, leading to disruption of the structural integrity of the sinusoids. This causes massive necrosis in the liver leading to cell death. The toxic effects of microcystin-LR have been reported due to the presence of 3-amino-9-methoxy-10-phenyl-2,6,8 trimethyl deca,4,6 dienoic acid (ADDA), which is believed to be essential for its functioning. In addition, microcystins are known to be potent and specific inhibitors of catalytic subunits of protein phosphatases 1 and 2A (Cohen and Cohen, 1989; Honkanen et al., 1990; Yoshizawa et al., 1991), and activate the enzyme phosphorylase b. Microcystin administered intraperitoneally in mice caused disruption of bile flow in less than 10 min, and death within a few hours due to hypovolemic shock induced by interstitial hemorrhage following liver necrosis (Carmichael, 1988). Death was also reported within hours of administration of aerosol (LD_{50}, 67 μg/kg body weight) in mice. In humans, microcystin ingestion leads to diarrhea, vomiting, weakness, and pallor, with death occurring in a few hours if a LD is taken.

40.5.1.2 Aflatoxins

Aflatoxins were first isolated more than 40 years ago after the outbreak of disease and deaths in turkeys.

These toxins are produced as secondary metabolites by the fungi *Aspergillus flavus* and *Aspergillus parasiticus* at temperatures between 24°C and 35°C and humidity exceeding 7% (Williams et al., 2004). These fungi are known to infect a variety of crops, such as peanuts, walnuts, pecans, pistachios, and corn.

Aflatoxins are bisfuran polycyclic compounds, and depending on the characteristic blue or green fluorescence produced under ultraviolet light, these compounds are known as aflatoxin B_1, B_2, G_1, and G_2, respectively. Although these compounds have been recognized as potent mutagens and carcinogens, they are still not as toxic as botulinum or ricin. Before the first Gulf War, aflatoxins were not recognized as biological warfare agents; however, they were weaponized by Iraq for missile delivery, and at present, they can be considered as agents of biological warfare (Marshall, 1997; Zilinskas, 1997).

Of the several aflatoxins, aflatoxin B_1 (AFB_1) is the most prevalent and the most potent. AFB_1 is converted to an unstable metabolite (the 8,9-epoxide), is highly electrophilic, and forms covalent adducts with RNA, DNA, and proteins (Roebuck and Maxuitenko, 1994). In addition, aflatoxin M_1, a metabolite of AFB_1, has been found in the milk of cows fed AFB_1.

AFB_1 is acutely toxic in all species tested thus far, with an LD_{50} ranging from 0.5 mg/kg for the duckling to 60 mg/kg for the mouse (Wogan and Bushch, 1973). Acute exposure to AFB_1 has been reported to cause hepatic lesions with edema, biliary proliferation, and parenchymal cell necrosis. In addition, aflatoxin B_1 poisoning has been reported to cause jaundice, rapidly developing ascites, and portal hypertension, with high mortality resulting from massive gastrointestinal bleeding. In children, aflatoxin produces a condition called *Reye syndrome*, resulting in disturbed consciousness, fever, convulsions, and vomiting (Palmgren and Ciegler, 1983).

40.5.1.3 Ricin

Ricin, a potent plant toxin, was discovered by Peter Hermann Stillmark in 1889 (Flexner, 1987) as the first plant lectin. It was extracted from the seeds of castor plants (*Ricinus communis*) and has been considered a CWA since World War I. Although ricin is less toxic than botulinum or anthrax, easy availability and lack of a specific antidote make it a weapon of choice, and it has been included in Schedule 1 of the Chemical Weapons Convention (CWC). To date, more than 750 cases of intoxication in humans have been reported (Rauber and Heard, 1985). Being a ribosome-inactivating protein, a single molecule of ricin reaching the cytosol can kill that cell as a consequence of protein synthesis inhibition (Eiklid et al., 1980). Ricin is also very stable and extremely toxic by several routes of exposure, including ingestion and inhalation; however, compared to oral exposure, inhalation of ricin has been reported to be more harmful. In humans the LD has been reported to be 5−10 μg/kg body weight. Animal studies reveal that ricin is absorbed by the lymphatic and blood vessels with 2 h of ingestion, followed by accumulation in the liver and the spleen.

In addition to pulmonary toxicity, ricin has been reported to be a major hepatotoxicant (Kumar et al., 2003). Studies by Muldoon et al. (1992) reported that humans exposed to ricin experience increased hepatic transaminase and lactate dehydrogenase activities. Furthermore, mice treated with ricin experienced significant oxidative stress, resulting in hepatic GSH depletion and lipid peroxidation (Muldoon and Stohs, 1991). Elevation of lipid peroxidation is reported to originate mainly from the damaged Kupffer cells, which are believed to be the target of this toxin in the liver (Skilleter et al., 1981). The high sensitivity of Kupffer cells has been ascribed to the ability of ricin to bind to the mannose receptors present on these cells (Skilleter et al., 1981; Magnusson and Berg, 1993).

40.5.1.4 Abrin

Abrin, a potent toxin, is extracted from the seeds of the rosary pea (*Abrus precatorius*). Due to its easy availability and preparation, this toxin is an attractive option for weaponizing in poor countries, and thus has also been included in Schedule 1 of the CWC. The mechanism of action of abrin is very similar to that of ricin; however, in mice, abrin is 75 times more toxic than ricin (0.04 μg/kg for abrin is equivalent to 3 μg/kg of ricin). Similar to ricin, inhalation of abrin is found to be more toxic than ingestion. However, abrin ingestion has reported to be toxic to the liver, unlike ricin. At the cellular level, abrin is a potent toxalbumin known to cause cell death by inhibiting protein synthesis (namely type 2 ribosomal inhibitory protein). Further, abrin is also known to induce endothelial cell damage, leading to an increase in cell permeability, fluid and protein leakage, and tissue edema.

40.5.2 Bacterial (anthrax)

Anthrax is a disease caused by the spores of the bacterium *B. anthracis*. It is a recognized biological warfare agent. In the United States, anthrax was deliberately spread through the postal system in 2001 via letters sent to several legislators and other public figures with powder containing anthrax. This resulted in 22 cases of anthrax infection. Inhalation and cutaneous exposure are the main routes of infection. Recent studies have revealed that laboratory animals infected with anthrax have developed

significant liver injury. Studies by Moayeri et al. (2003) reported that mice infected with *B. anthracis* developed extensive liver necrosis and pleural edema. Liver lesions in these animals ranged from small hemorrhagic infarcts to large areas of centrilobular coagulative necrosis. A significant increase in alanine aminotransferase and aspartate aminotransferase was also observed in these animals. Liver dysfunction was also indicated by decreased serum albumin levels in these animals in response to toxin exposure over time.

40.6 Concluding remarks and future directions

In spite of significant advances in human knowledge about the mechanisms of liver damage, scientists seem to have a long way to go before all the mechanisms of toxicity in liver for a given chemical are completely established. However, with the advances in the technologies and techniques, especially the "omics approaches," researchers have been provided with additional tools to obtain breakthroughs in the area of liver toxicity. Clearly, current reports on the number of CWAs targeting the liver are limited, and with further research and case studies, these numbers will continue to grow. With the changing political global climate and the potential for CWAs, target organ toxicities, especially the liver, will likely gain added attention.

Chapter 41

Renal system

Sharon M. Gwaltney-Brant
Veterinary Information Network, Davis, CA, United States

41.1 Introduction

The kidney and urinary system are responsible for the maintenance of homeostasis by regulating the body's fluid and electrolyte balance, eliminating waste products, maintaining acid−base balance, secreting regulatory peptides and hormones, and metabolizing and excreting endogenous compounds and xenobiotics. The kidney receives 20%−25% of cardiac output, putting it at risk for exposure to high levels of bloodborne toxicants. Besides direct exposure to toxic compounds, the kidney can be exposed to toxicants through metabolic activation of xenobiotics by renal tubular epithelial enzyme systems (e.g., cytochrome P450 enzymes). In its excretory capacity, the kidney and urinary tract are exposed to progressively higher levels of toxicants because they are concentrated within the renal/urinary tubules. Loss of renal function because of toxic kidney injury can result in severe systemic derangement and death of the individual; therefore, in theory, toxicants that target the kidney might be considered to be potential agents of chemical or biological warfare. However, if the goal of a chemical warfare agent is to rapidly incapacitate or kill civilians or opposing personnel, then a primary nephrotoxicant would make a poor choice of weapon because of the long delay in clinical effects from the time of exposure. Once renal damage has occurred, it may take many hours or up to a few days before signs of renal insufficiency develop to the point at which the victim is effectively incapacitated. Renal injury occurring subsequent to a chemical or biological attack is generally a matter of collateral damage rather than targeted injury, and many of the chemical agents used in warfare and terrorism have minimal effects on the kidney or urinary system. The renal effects that do develop will be seen in the individuals who survive the acute chemical attack and live long enough for evidence of renal insufficiency to develop.

41.2 Anatomy and physiology

41.2.1 Functional anatomy

In mammals, the kidneys are paired organs that reside ventrolateral to the lumbar vertebrae and musculature. Mammalian kidneys are bean-shaped to horseshoe-shaped with uniform to multilobulated external surfaces, depending on species, and a medial indented hilar region from which the renal artery, renal vein, lymphatics, nerves, and ureter emerge. On sagittal section, the kidney displays two distinct regions, the outer cortex and the inner medulla. The renal cortex corresponds to approximately 80% of total renal mass, and the normal cortex:medulla ratio is 1:2 to 1:3 in most species (Maxie and Newman, 2007). The medulla is divided into ray-shaped sections known as renal pyramids that have their bases at the corticomedullary junction and their apices (papillae) that empty into a renal calyx or pelvis at the hilar area. The number of renal pyramids in the kidney varies with species. Unipyramidal or unipapillate kidneys have a single renal papilla into which renal lobes empty, whereas multipyramidal or multipapillate kidneys have two or more papillae. From the hilar region, urine is channeled to the distal urinary bladder via the ureter, and from the bladder, urine is voided from the body via the ureter.

Renal blood flow originates from the renal arteries, which are direct branches off the aorta. Renal arteries progressively branch to form interlobar arteries, arcuate arteries, interlobular arteries, and afferent arterioles, the latter of which provide blood to the glomerulus. The kidney receives up to 20%−25% of cardiac output, with the cortex receiving the majority (90%) of the blood flow, and the medulla (6%−10%) and papilla (1%−2%) receiving considerably less direct blood flow (Schnellmann and Klaassen, 2008). Thus, bloodborne toxicants are delivered in higher amounts to the cortex, whereas the medulla and papilla are exposed to higher luminal levels of toxicants

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00041-6

that concentrate in the urine. Because of the relative sluggishness of medullary and papillary filtrate transport, these areas are also exposed to intraluminal toxicants for prolonged periods of time.

The functional unit of the kidney is the nephron, which comprises the renal corpuscle (Bowman's capsule and the glomerulus), proximal tubule, loop of Henle, and distal tubule (Fig. 41.1). The number of nephrons per kidney varies with species size, ranging from approximately 10,000 in mice compared with approximately 1,000,000 in humans and 7,000,000 in elephants (Braun et al., 2008). High hydrostatic pressure from afferent arterioles results in ultrafiltration of plasma within the branching and anastomosing capillaries that form the glomerulus. Six- to nine-nanometer fenestrae within the glomerular basement membrane (GBM) form the "sieve" through which the plasma filtrate passes. Filtrate moves through Bowman's capsule and flows into the proximal renal tubule, which has three anatomically and functionally different segments. The S_1 segment is the most proximal segment that consists of the convoluted portion of the proximal tubule, and contains epithelial cells with tall brush borders, well-developed lysosome systems, and numerous basally located mitochondria. The S_2 segment extends from the end of the convoluted tubule to the beginning of the straight segment; its epithelial cells have shorter brush borders, fewer mitochondria, and fewer lysosomes than S_1 cells. The S_3 segment consists of the remaining distal straight segment of the proximal tubule and extends into the outer reaches of the medulla. The S_1 and S_2 segments have higher oxygen consumption, sodium/potassium ATPase activity, and gluconeogenic capacity, whereas the S_3 segment has higher transport capabilities for secretion of certain compounds (e.g., organic acids) and is the primary site for metabolic activation of some toxicants (Castro et al., 2008).

The proximal tubule functions in the passive reabsorption of water and active reabsorption of sodium and potassium (via sodium/potassium ATPase pumps), as well as other solutes, including calcium, phosphorus, bicarbonate, glucose, amino acids, proteins, and various xenobiotics (Rouse and Suki, 1985). Each segment of the proximal tubule has a different range of capacity for reabsorption of various solutes; for instance, the S_1 segment reabsorbs a higher percentage of bicarbonate, glucose, amino acids, and low-molecular-weight proteins, whereas the S_2 segment reabsorbs more calcium and phosphorus. Ultimately, the proximal tubule reabsorbs 60%−90% of solute and water that was filtered through the glomerulus. Excretory functions of the proximal tubule include the active

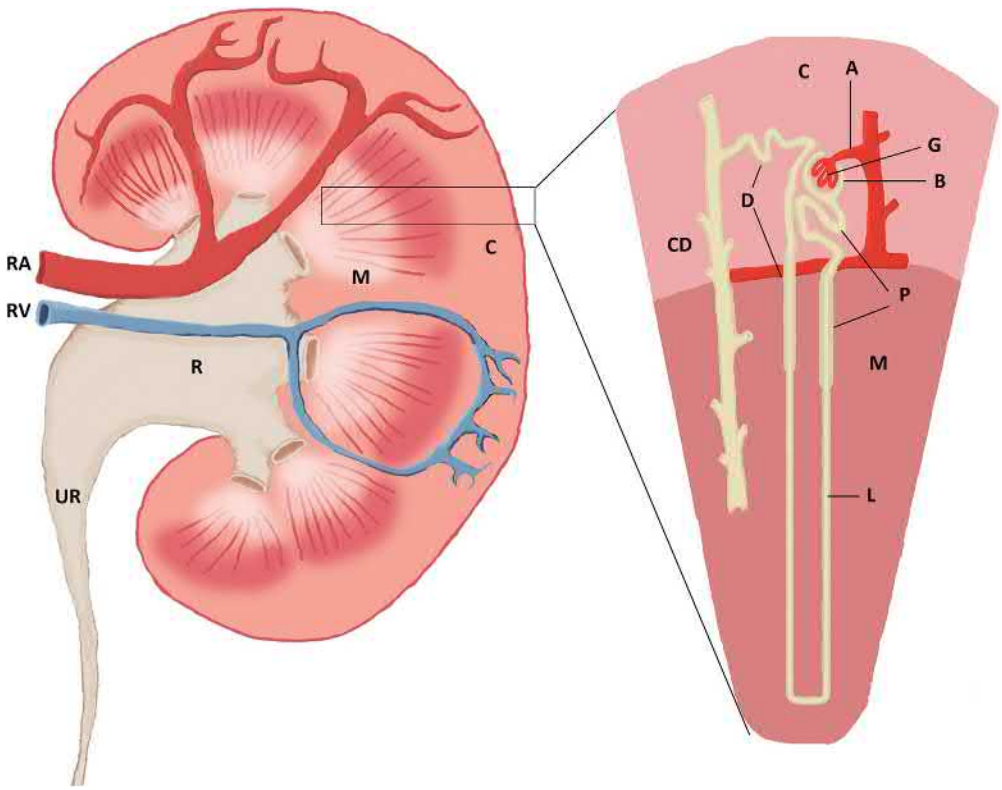

FIGURE 41.1 Diagrammatic view of the kidney showing the relationship of the cortex (C), medulla (M), renal pelvis (R), renal artery (RA), renal vein (RV), and ureter (UR). Enhanced view of microanatomy of the classical nephron. *A*, Afferent arteriole; *B*, Bowman's capsule; *CD*, collecting duct; *D*, distal tubule; *G*, glomerulus; *L*, loop of Henle; *P*, proximal tubule.

secretion of weak organic anions and cations. The absorptive and secretory capacities of the various proximal tubule segments can be induced or inhibited because of pathological or physiological alterations in filtrate composition.

Leaving the proximal tubule, filtrate enters the loop of Henle, which is composed of a thin-walled descending limb and a thick-walled ascending limb that extends to the level of the outer medullary region. Countercurrent exchange mechanisms within the loop result in reabsorption of approximately 20% of filtered water and 25% of filtered sodium and potassium (Schnellmann and Klaassen, 2008). The loop resides largely within the poorly oxygenated renal medulla and contains ATPases with high oxygen demand, making the loop of Henle especially susceptible to hypoxic injury (Brezis et al., 1984). The macula densa sits at the junction of the ascending loop of Henle and the proximal aspect of the distal tubule, in close proximity to the nephron's selfsame afferent arteriole, permitting feedback between macula densa and arteriole. The macula densa "reads" the intratubular solute concentrations and provides feedback to the afferent arteriole, resulting in vasoconstriction or vasodilation that decreases or increases, respectively, the glomerular filtration rate (GFR), thus regulating fluid loss and urine production. The final segment of the distal tubule along with the collecting duct function to reabsorb most of the remaining intraluminal electrolytes and water as needed to regulate the volume and composition of the urine. Collecting ducts progressively intersect and anastomose toward the renal papilla and ultimately empty into the renal calyx, renal pelvis, or ureter, depending on species. Peristaltic action of the ureter propels urine toward the urinary bladder for temporary storage and elimination via the urethra.

In addition to its role in regulation of waste excretion and water/electrolyte balance, the kidney secretes a variety of hormones and regulatory peptides vital for normal systemic homeostasis. Secretion of erythropoietin by renal peritubular interstitial cells promotes red blood cell formation; significant chronic renal disease is often associated with anemia because of decreases in erythropoietin secretion. Renin secreted from the juxtaglomerular cells increases systemic and renal blood pressure and aldosterone release. Prostaglandins and prostacyclin are produced by a variety of renal cells and aid in regulation of renal vascular tone, mesangial contractility, and processing of water and electrolytes by the renal tubules.

41.2.2 Biotransformation

In addition to its other functions, the kidney also plays an important role in xenobiotic metabolism. Renal tubular epithelium contains a variety of biotransformation enzymes including cytochrome P450 monooxygenases, flavin-containing monooxygenases, reductases, hydrolases, UDP-glucuronosyltransferases, sulfotransferases, glutathione-*S*-transferases, cysteine conjugate β-lyase, methylases, and acetylases (Rankin et al., 2005). Although the majority of biotransformation reactions result in inactive metabolites that are then eliminated via the urine, some biotransformation reactions result in the formation of reactive intermediates or metabolites that can cause nephrotoxicity. For example, the blue-green algal toxin cylindrospermopsin requires bioactivation by cytochrome P450 enzymes for it to become genotoxic (Zegura et al., 2011). Biotransforming enzymes are not evenly distributed throughout the kidney, but rather tend to be concentrated in specific sites of the renal tubular epithelium, thereby resulting in a particular pattern of injury depending on which enzyme system was involved in the formation of toxic intermediates.

The cytochrome P450 superfamily is composed of a large number of member enzymes and is divided into four gene families (CYP1, CYP2, CYP3, and CYP4). Individual enzymes (e.g., CYP1E2) are named by family (e.g., CYP1), subfamily (e.g., E), and individual (e.g., 2) designations. This superfamily of enzymes is of major importance in biotransformation of xenobiotics throughout the body and is most prominently expressed in the liver. Cytochrome P405 expression in the kidney is approximately 10% of that of the liver (Cummings et al., 1999). The highest concentrations of P450 in the kidney are in the renal cortex, with smaller amounts in the medulla (Rankin et al., 2005). There is considerable variability in the amount and activity of individual P450 enzymes within the kidney depending on species, age, and gender. Along the nephron, cytochrome P450 expression is highest within the epithelium of the S_2 and S_3 segments of the proximal tubules, so xenobiotics that are bioactivated by P450 to toxic metabolites will preferentially cause damage to those nephron segments first. Flavin-containing monooxygenases catalyze the oxidation of nitrogen-containing, sulfur-containing, phosphorus-containing, selenium-containing, and other nucleophilic heteroatoms-containing compounds in xenobiotics (Cashman and Zhang, 2002). Six isoforms of flavin monooxygenases (FMO1, FMO2, FMO3, FMO4, FMO5, and FMO6) have been identified and the expression of these monooxygenases within tissues varies depending on species, gender, age, and tissue. Glutathione-*S*-transferases catalyze the conjugation of electrophilic sites in xenobiotics with the tripeptide l-γ-glutamyl-l-cysteinylglycine, thus protecting macromolecules from injury from electrophiles (Rankin et al., 2005). Glutathione-*S*-transferase activity is highest in the proximal tubular cells, although distal tubules do express some activity as well.

41.3 Toxic responses of the urinary system

41.3.1 Acute renal failure

Acute renal failure is the sudden decrease in renal function resulting in retention of nitrogenous wastes, and it is a common manifestation of acute nephrotoxic injury (Schnellmann and Klaassen, 2008; Langston, 2010). "Acute kidney injury" (AKI) is the term that has been suggested as most appropriate for use when discussing renal injury, because it encompasses all phases of kidney insult, ranging from minor elevations of serum chemistry renal values to anuric renal failure (Karajala et al., 2010).

The primary manifestation of AKI is decreased GFR resulting in excess accumulation of nitrogenous wastes in the blood (azotemia). Decreased GFR can result from prerenal, renal, or postrenal etiologies. Decreased cardiac output, hypovolemia, and renal vasoconstriction are common prerenal events that can decrease GFR. Postrenal causes of reduced GFR include obstruction of renal tubules or of the lower urinary tract by casts or crystals. Renal tubular injury, glomerular injury, interstitial renal disease (e.g., inflammation, neoplasia), and renal vascular compromise are all primary renal factors that can lead to decreased GFR. In humans, 20%−80% of AKI is attributable to prerenal factors, 10%−45% is attributable to primary renal factors, and postrenal factors cause 5%−15% of AKI (Langston, 2010). Of primary renal factors, ischemia/reperfusion and nephrotoxicosis are thought to be responsible for more than 90% of AKI cases in humans (Schnellmann and Klaassen, 2008).

Damage to kidneys by nephrotoxicants occurs through a variety of different mechanisms, including: direct injury to renal tubular epithelium leading to epithelial cell necrosis with sloughing and obstruction of tubules by cellular debris (tubular casts); detachment of lethally injured cells from the basement membrane resulting in back-leakage of filtrate across the exposed basement membrane and adherence of detached cells to sublethally injured cells still attached to the basement membrane causing lumen obstruction; renal vasoconstriction resulting in hypoxia and ischemic necrosis of renal structures; damage to the glomerular filtration barrier; and impairment of renal healing and repair (Counts et al., 1995). Most nephrotoxic agents cause injury at the level of the renal tubules, and many toxicants will target specific tubule segments.

Clinical effects of AKI generally do not become apparent until GFR is approximately 40% of normal and nitrogenous wastes have accumulated (Khan et al., 2013). Depending on the individual and the dose of toxicant received, this may take several hours to a few days after an acute toxic insult, making nephrotoxicants a poor choice of chemical weapon if the goal is to rapidly disable an opponent. The clinical signs of acute renal injury and/or failure can include polydipsia, nausea or vomiting, lethargy, anorexia, weakness, dehydration, and polyuria/oliguria/anuria. More severe cases may have halitosis, oral ulceration, abdominal (renal) pain, palpably enlarged kidneys, and cardiac arrhythmias. Clinical laboratory abnormalities indicative of AKI include elevations in blood urea nitrogen (BUN) and serum creatinine (azotemia), hyperphosphatemia, hyperkalemia or hypokalemia, and metabolic acidosis. *Uremia* is the term used when azotemia is accompanied by typical clinical signs of AKI. Advanced cases of uremia may present with gastrointestinal ulceration, poorly or nonregenerative anemia, peripheral neuropathy, encephalopathy, metastatic mineralization, and cardiac dysfunction.

The ability of the kidney to heal after an acute toxic insult is dependent on several factors, including the dose and type of toxicant, the amount of functional kidney remaining, the presence and severity of secondary uremic conditions (e.g., soft tissue mineralization), and the degree of medical intervention and supportive care provided during the acute crisis. Mild to moderate renal tubular injury with retention of tubular basement membrane has a reasonable prognosis for tubular regeneration provided that supportive care is administered until tubules have had a chance to recover. In uncomplicated acute tubular injuries, regeneration of epithelial cells generally begins approximately 7−10 days after the renal insult; in mild cases, full recovery of architecture may occur within 2−3 weeks, with longer recovery periods being required for more severe renal injury (Maxie and Newman, 2007). In situations in which nephrons have been fully obstructed by cellular debris or crystals, or if basement membrane integrity is lost, regeneration may be incomplete, resulting in long-term renal insufficiency and/or progression to chronic renal failure (CRF).

41.3.2 Chronic renal failure

The kidneys have a large compensatory capacity to adapt to injury that results in loss of functional renal mass, with potential increases in GFR by 40%−60% in nephrons not directly affected by the insult (Schnellmann and Klaassen, 2008). Biochemical evidence of renal injury generally is not detectable using current renal parameters (i.e., BUN, serum creatinine) until 50%−70% decreases in GFR occur. For these reasons, significant renal injury may occur before any clinically detectable evidence of renal insufficiency develops. CRF is a common result of long-term exposure to toxicants, and many of the alterations found when CRF is finally diagnosed are related to secondary compensatory changes triggered by the initial injury. Toxicant-induced nephron loss causes a decrease

in overall GFR, which triggers an increase in blood flow and pressure to surviving nephrons in an attempt to reestablish normal whole-kidney GFR. Increased glomerular pressure can contribute to degenerative changes such as glomerular sclerosis, tubular atrophy, and interstitial fibrosis, which, in turn, further the progression of renal injury (Brenner et al., 1982). Intraglomerular hypertension results in glomerular hypertrophy, hyaline deposition within glomerular capillary walls, mesangial dysfunction, microaneurysm formation, and thrombosis attributable to endothelial injury (Polzin, 2010). As the glomerulus expands, focal denudation of the GBM occurs, allowing leakage of larger proteins into the glomerular filtrate (proteinuria). Other factors such as cytokines expressed by inflammatory cells, elaboration of reactive oxygen species (ROS), lipid accumulation, increased extracellular matrix deposition, and tubulointerstitial injury contribute to the progression toward CRF (Schnellmann and Klaassen 2008).

Clinical effects associated with CRF include uremia, gastrointestinal disorders (uremic gastritis, uremic enterocolitis), polyuria, polydipsia, nocturia, dehydration, atrial hypertension, peripheral neuropathy, uremic encephalopathy, myopathy, platelet dysfunction, cachexia, and hypokalemia (Polzin, 2010). Edema caused by retention of sodium and water, renal secondary hyperparathyroidism, and anemia caused by decreased erythropoietin synthesis are common manifestations of CRF. Immunosuppression is a potential complication of CRF in humans, and studies of dogs with CRF have shown impaired immunological function as well (Kravola et al., 2010). Patients with CRF may show few outward signs of illness until late in the course of their disease; in some instances, acute decompensation may occur during periods of physical or emotional stress (Hosseininejad and Hosseini, 2008). Lesions of CRF include kidneys that are small and irregular in shape with uneven capsular surfaces. On cut section, pale streaks (fibrosis) may be seen within the interstitium and the parenchyma may be gritty on cutting because of mineralization and/or crystal deposition.

41.3.3 Patterns of toxic injury

Identification of the target site of action of nephrotoxicants can assist in determining the functional impact and potential mechanism of toxicity. Compounds that are directly toxic to cells may cause injury to the glomerulus or the S_1 segment of the proximal tubule as they first enter the nephron. Conversely, direct-acting toxicants may be dilute in the initial ultrafiltrate and may not cause injury until they reach the more distant nephron, where they may reach toxic concentrations as water is gradually reabsorbed and/or the pH changes. Some toxicants require bioactivation to exert their toxic effects and may cause site-specific injury to the segments of the nephron where those bioactivation processes are most active. Fig. 41.2 illustrates the distribution of lesions within the nephron and lower urinary tract that can be induced by chemical warfare agents.

41.3.4 Glomerular injury

The glomerular capillaries are the first component of the nephron to be exposed to bloodborne toxicants. The glomerular cells, matrix, and mesangium are susceptible to toxic injury by several different mechanisms, including direct injury to cellular components, formation of oxygen-derived free radicals, disruption of extracellular substrates (e.g., basement membranes), immune-mediated injury, and disruption of renal hemodynamics (Khan et al., 2013). Direct injury or injury secondary to reactive oxygen intermediates can result in endothelial loss, glomerular podocyte injury, and necrosis of mesangial cells and substrate (mesangiolysis). Further damage could occur secondary to cytokines released by inflammatory cells responding to the site of injury. Alterations in the GBM secondary to cellular injury can result in disruption of the glomerular filtration barrier, leading to proteinuria. Deposition of an immune-mediated reaction to various toxicants (e.g., mercury, gold salts) can result in thickening of the GBM, disrupting the glomerular filtration barrier and leading to membranous glomerulonephropathy.

41.3.5 Proximal tubular injury

Tubular injury is the most common pattern of renal injury induced by toxicants and the proximal tubule is most frequently affected by nephrotoxicants (Schnellmann and Klaassen, 2008). Damage to the proximal tubule may occur because of direct damage from toxicants, metabolic activation of toxicants, ischemia–reperfusion, or physical or chemical disruption of endothelium and/or basement membrane. The S_1 segment is the most vulnerable to injury from toxicants that exert direct injury because the epithelium in this area is exposed to the toxicant first. The proximal convoluted tubule epithelium is actively involved in endocytosis of various compounds that bind to the brush border, sequestering the compounds in phagolysosomes. When this process is overwhelmed by the presence of certain toxicants (e.g., uranyl ion), loss of phagolysosome membrane integrity occurs, resulting in lysosomal leakage and cell injury or necrosis (Khan et al., 2013). This type of injury is most commonly associated with the S_1 and S_2 segments of the proximal tubule. In contrast, the straight segment (S_3) is most susceptible to injury by metabolic activation, transporter-associated accumulation, and ischemia–reperfusion.

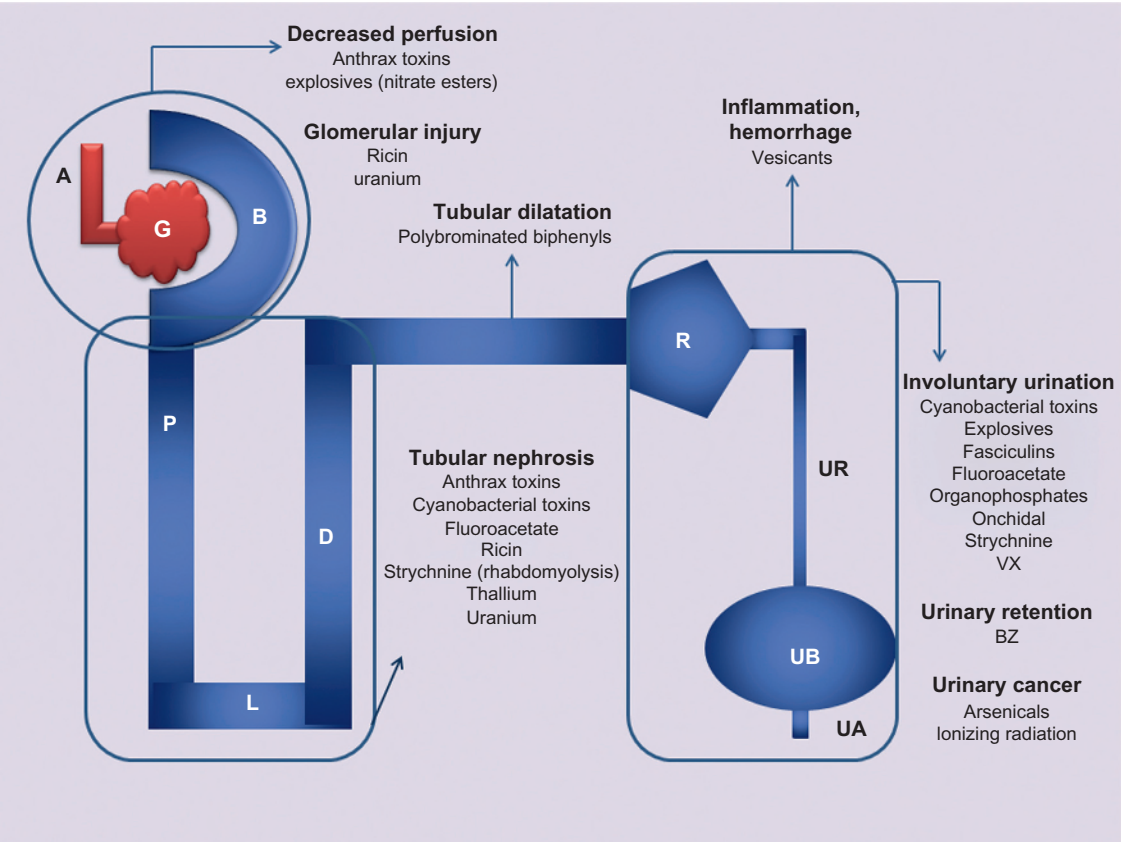

FIGURE 41.2 Cartoon of the nephron and lower urinary tract showing sites of injury caused by various chemical and biological warfare agents. *A*, afferent arteriole; *B*, Bowman's capsule; *C*, collecting ducts; *D*, distal tubule; *G*, glomerulus; *L*, loop of Henle; *P*, proximal tubule; *R*, renal pelvis; *UA*, urethra; *UB*, urinary bladder; *UR*, ureter.

Various metabolic derangements, such as severe acid–base imbalances, induced by toxicants can result in injury to renal tubules. Prolonged muscle activity from tremors or convulsions (e.g., from nerve agents) may result in rhabdomyolysis with myoglobin pigment causing renal tubular damage (Hamilton et al., 1989). Similarly, intravascular hemolysis that occurs during a chemical warfare toxidrome can result in hemoglobinuric nephropathy with resulting renal tubular injury. Decreased cardiac output, hypovolemia, and anemia can result in ischemia of renal tissue and precipitate tubular injury; renal ischemia can also occur secondarily to toxicosis from agents that alter oxygen delivery to tissues (e.g., cyanide).

In humans and dogs, the renal tubules and interstitium are related in such a way that significant injury to one results in a reaction in the other; for this reason, the terms "tubulointerstitial disease" and "chronic interstitial nephritis" are often applied to lesions found in the kidneys of these species (Khan et al., 2013). The latter term acknowledges the fact that, in advanced tubulointerstitial disease, it is difficult to determine which injury came first, that to tubules or to interstitium.

41.3.6 Distal nephron/renal papillary injury

Toxic injury to the distal nephron is relatively uncommon, and injury to this area generally manifests as decreased urine-concentrating ability or as defects in acid secretion resulting in metabolic acidosis (Khan et al., 2013). Injury to the renal papilla is most commonly seen with toxicants that impede blood flow to this normally poorly perfused area. Direct injury to renal papillae from renally excreted irritants (e.g., vesicants such as cantharidin) may also occur.

41.3.7 Lower urinary tract

Toxicants that cause injury to the ureters, urinary bladder, and urethra tend to be those that directly interact with the urothelium (Cohen, 2013). Direct cytotoxicity to urothelium by vesicants such as cantharidin can result in necrosis, ulceration, and hemorrhage. Ionizing radiation and genotoxic chemicals can damage DNA within the regenerative layer of the urothelium, inducing mutations and increasing the potential for development of urinary tumors. Not all toxic effects on the lower urinary tract are

related to cellular injury. Psychotropic or neurotoxic agents can affect neuromuscular control of the bladder, resulting in the involuntary retention or voiding of urine.

41.4 Toxic effects of chemical warfare agents

Very few compounds selected as agents of chemical warfare have significant and direct effects on the urinary system, and any injury to the kidney can be considered an unintended consequence of most chemical weapons. Indirect renal injury can occur because of a variety of effects of chemical weapons, including hemodynamic abnormalities causing decreased renal perfusion (e.g., shock, hypotension), acid–base derangements, interference with normal renal cellular function, or induction of pigmenturia attributable to rhabdomyolysis or hemolysis.

41.4.1 Vesicants

Vesicants are agents that produce chemical burns on body surfaces. Phosgene oxime, an urticariant, is not a true vesicant because it does not produce blisters but is included in this section. Through their action on the skin, respiratory tract, and eyes, these agents tend to incapacitate rather than kill, although systemic involvement and death can occur with severe exposures or because of secondary complications such as bacterial infections, shock, or multiorgan failure.

The biochemical mechanisms of injury from vesicant agents are poorly understood. Mustards [bis-(2-chloroethyl) sulfide] are thought to act as alkylating agents that form highly reactive electrophiles that combine with nucleophilic sites on cellular macromolecules to form stable adducts that interfere with normal function of cells and disrupt the epidermal–dermal junction (Hurst et al., 2008). Once tissue injury has been established, activation of massive local inflammatory response leads to vesicle development. Depletion of glutathione may also contribute to the vesicant injury through loss of protection against oxygen-derived free radicals and lipid peroxidation, resulting in a "snowballing" effect of cellular damage. The biochemical mechanism of action of the arsenical lewisite (*b*-chlorovinyldichloroarsine) may involve interactions with enzymatic sulfhydryl groups, resulting in inhibition of the pyruvate dehydrogenase complex, leading to inactivation of carbohydrate metabolism. As with mustards, depletion of glutathione resulting in increased lipid peroxidation and ROS generation may also play a role in lewisite-mediated cellular injury. Phosgene oxime may act by direct necrotizing effects of chlorine, by enzymatic inactivation of target cells, and/or by activation of macrophages, recruitment of neutrophils, and production of ROS, although the exact mechanism remains obscure (Hurst et al., 2008).

Renal lesions with vesicant exposures are not commonly encountered and, in many cases, may be nonspecific secondary effects attributable to multiorgan failure associated with fatal exposures. Mustards have been reported to cause hemorrhagic nephritis, oliguria, anuria, albuminuria, and casts in mortally injured victims (Papirmeister et al., 1991). Microscopic lesions associated with sulfur mustard victims included calcified and hemoglobin-containing intratubular casts (Alexander, 1947). Although lewisite is an arsenical vesicant, renal lesions typical for inorganic arsenic toxicosis have not been reported in laboratory species or human patients exposed to lewisite (Hurst et al., 2008). No specific renal lesions have been reported with exposure to phosgene oxime. For further details on the toxicology of vesicants/blister agents, readers are referred to Chapter 11, Blister agents.

41.4.2 Nerve agents

Nerve agents classically include the organophosphorus (OP) compounds (e.g., soman, sarin, cyclosarin, tabun, and VX) originally developed as insecticides, but repurposed and refined for use as warfare agents as their extreme toxicity was recognized (Sidell et al., 2008). Although developed and stockpiled for use in Germany during World War II, nerve agents were not used on the battlefield until 50 years later during the Iran–Iraq War. Since then, nerve agents have been used both in battle and in terrorist attacks, such as the 1995 release of sarin on commuter trains in Japan that killed 12 people. Onchidal, an anticholinesterase mollusk toxin, has similar clinical effects to the OP nerve agents and is considered here under the term "nerve agent" (Abramson et al., 1989).

Nerve agents act by binding and inhibiting acetylcholinesterase (AChE), an enzyme that hydrolyzes the neurotransmitter acetylcholine (ACh). The cholinergic system is the only known system to terminate the action of a neurotransmitter via enzymatic cleavage. When anticholinesterase agents such as OPs and onchidal disable AChE, ACh accumulates within the synapse, resulting in continued stimulation of cholinergic pathways and development of the classic nicotinic and muscarinic signs (Anadon et al., 2015). Urinary system signs associated with anticholinesterase poisoning include involuntary urination because of cholinergic stimulation of bladder musculature. Acute renal injury has occasionally been reported after anticholinesterase poisonings and may be attributed to hemodynamic dysfunction leading to shock and hypovolemia during the cholinergic crisis, which, in turn, results in decreased renal perfusion (Bloch-Shilderman

and Levy, 2007). Because the mechanism of anticholinesterase poisoning is biochemical, few characteristic gross lesions occur beyond nonspecific organ congestion and the presence of increased bronchial secretions (Meerdink, 2004). Histopathologic evidence of skeletal muscle necrosis, myocardial hemorrhage and necrosis, and neuronal necrosis within the hippocampus, cerebral cortex, amygdala, and thalamus have been reported after severe OP intoxication (Gupta et al., 1987a,b, 1991, 2013).

41.4.3 Depleted uranium

Depleted uranium (DU) is previously enriched uranium that has had its radioactivity largely spent and, as such, is a very weak alpha and gamma emitter (Gwaltney-Brant, 2013). Lesions produced by DU are thereby related to the metal itself rather than any emitted radiation. Uranium is poorly absorbed orally, and absorption via inhalation requires uranium to be soluble and of small size ($<10\ \mu m$). Once absorbed, uranium is converted to uranyl ion that complexes with citrate, bicarbonate, or plasma proteins and is distributed via the blood, ultimately accumulating in bone and in the proximal tubules of the kidney. In the proximal tubular epithelium, uranyl ion is cleaved from its complex and causes damage to renal tubules and glomeruli, resulting in proteinuria, glucosuria, aminoaciduria, and, with higher exposure levels, acute renal failure. Glomerular lesions include endothelial swelling and necrosis, glomerular sclerosis, and disruption of glomerular fenestrae. Tubular epithelium becomes vacuolated and necrotic, and over time a mosaic of degenerating and regenerating tubules and glomeruli can be seen along with interstitial inflammation and fibrosis. On removal of uranium exposure, tubules and glomeruli may fully regenerate, provided that fibrosis has not developed.

41.4.4 Thallium

Thallium is a heavy metal that has historically been used as a pesticide and as a therapeutic agent; it has also been used illegally as an agent for suicide attempts and intentional poisonings of small groups of people (Thompson, 2015). Thallium is rapidly absorbed via most routes and is widely distributed throughout the body, although the highest levels occur in the skin. Thallium substitutes for potassium in many cellular enzymatic and transport systems, causing widespread disruption of cellular function. Clinically, the classic syndrome of thallium poisoning involves gastroenteritis, polyneuropathy, and alopecia. Renal injury may occur secondarily and is characterized by elevations in BUN and urine protein levels. Histopathological lesions in the kidney include necrosis of epithelium of the loop of Henle, degeneration and necrosis of proximal convoluted tubules, and stromal edema. On electron microscopy, degenerative changes were seen in mitochondria, microvilli, and endoplasmic reticulum (Danilewicz et al., 1979). For further details on thallium toxicosis, see Chapter 20, Thallium.

41.4.5 Ricin

Ricin is a lectin isolated from the seeds of the castor bean plant (*Ricinus communis*) that acts as a ribosome-inactivating protein, enzymatically depurinating adenine residues of 28S ribosomal RNA and irreversibly arresting protein synthesis (Lapadula et al., 2013). The toxicity of ricin has been known for centuries, and more than 750 human cases of intoxication have been reported (Poli et al., 2007). Its potency, worldwide availability, and ease of production have made ricin a biological warfare agent of interest in many countries, but its widespread use as such has not been reported. Ricin has been used as an agent of political assassination, with the most famous incident being the murder of Georgi Markov, a Bulgarian dissident who died a few days after a ricin-impregnated bead was injected into his thigh via a specially modified umbrella (Papaloucas et al., 2008). The fact that the ricin had to be injected into Markov underscores one of the drawbacks in its use as an agent of warfare or terrorism: the toxicity of ricin is largely route-dependent (Poli et al., 2007). Dermal absorption of ricin does not occur to any significant degree; ingestion results primarily in gastrointestinal injury, which is largely survivable if patients receive appropriate therapy. Parenteral administration via injection is not feasible for large-scale use, and efficient inhalational administration requires refinement in manufacturing and delivery methods that make it less desirable as an efficient warfare or terrorism weapon (Schep et al., 2009).

Clinical signs and pathologic lesions in ricin toxicosis are largely route-specific, with ingestion causing primarily gastrointestinal signs (vomiting, diarrhea, abdominal pain) and with inhalation resulting in respiratory signs such as wheezing, pneumonia, and pulmonary edema (Poli et al., 2007). At larger oral or inhaled dosages or with parenteral administration (i.e., injection), more serious systemic effects can develop, including hemorrhagic diarrhea, fever, vascular collapse, hypotension, dehydration, cyanosis, hypovolemic shock, and death after 3 or more days. Liver failure and kidney failure have been reported in human cases with survival beyond several days. Systemic lesions after ricin ingestion by humans include gastrointestinal ulceration and hemorrhage, diffuse nephritis, and necrosis of the liver, spleen, and lymph nodes. Renal lesions associated with ricin toxicosis resemble lesions of hemolytic-uremic syndrome, which is most commonly associated with verocytotoxin-producing *Escherichia coli* (Taylor et al., 1999; Korcheva et al., 2005). In rodents exposed intratracheally to lethal levels of ricin, initial renal injury occurs in the glomerulus, which shows leukocytosis,

accumulation of proinflammatory RNA transcripts, substantial damage to 28S rRNA, and accumulation of fibrin and fibrinogen, resulting in glomerular thrombotic microangiopathy (Wong et al., 2007). Renal tubular degeneration and necrosis develop subsequent to the glomerular injury. Mice exposed to sublethal levels of ricin did not have development of histopathological lesions and 28S rRNA damage within the kidney. In dogs with naturally occurring fatal ricin toxicosis, membranous glomerulonephritis devoid of fibrin deposits and renal tubular degeneration and necrosis have been reported (Roels et al., 2010). For details on ricin toxicosis, see Chapter 28, Ricin.

41.4.6 Anthrax toxins

Anthrax is a zoonotic disease caused by *Bacillus anthracis* that has a long association in human history. Inhalational anthrax, also known as woolsorter's disease because of its association with English woolsorters, is of concern because of its ability to be spread via the aerosol route and its high mortality in humans lacking rapid access to appropriate treatment. A 2001 bioterrorist attack in the United States resulted in the deaths of 5 of 11 individuals who had development of inhalational anthrax. In addition to inhalational anthrax, other forms of anthrax include gastrointestinal anthrax, cutaneous anthrax, and meningitis, with the latter occurring as a complication attributable to bacteremia from any of the other forms of the disease (Purcell et al., 2007).

B. anthracis produces two major toxins, lethal toxin (LT) and edema toxin (ET), which play essential roles in its virulence (Sweeney et al., 2010). As with many bacterial toxins, anthrax toxins are binary in structure, possessing a cell-binding, pore-forming subunit that gains entry into cells, and an enzymatic component that produces the toxic effects. LT is a zinc endopeptidase that cleaves mitogen-activated protein kinases, whereas ET is a potent calmodulin-dependent adenyl cyclase. Although ET is less potent than LT on a molar basis, it produces death more rapidly and is primarily responsible for the renal effects of anthrax (Fioved et al., 2005). ET causes decreased renal perfusion as well as possible direct cytotoxic effects on renal tubular epithelium, leading to increases in BUN and serum creatinine. Histopathologic renal lesions of anthrax include degeneration and necrosis of cortical tubular epithelial cells.

41.4.7 Cyanobacterial toxins

Cyanobacteria produce a variety of toxins, including anatoxins, microcystins, nodularins, and cylindrospermopsin (Patocka et al., 2011; Puschner, 2018). Anatoxin-a and anatoxin-a(s) are not directly nephrotoxic, but their effects on the nervous system (nicotinic and anticholinesterase, respectively) can result in loss of voluntary bladder control and involuntary urination. Microcystins and nodularins are primarily hepatotoxins that cause apoptosis and necrosis of hepatocytes through interference with cytoskeletal structures after acute exposure. Death from acute microcystin toxicosis is attributable to liver failure, with any renal injury generally attributed to terminal multiorgan failure. Chronic administration of microcystins to rats resulted in nephrotoxicity caused by disruption of cytoskeletal structures of the renal tubular cells (Milutinovic et al., 2003). Nodularins have been reported to produce renal lesions after acute exposure (Simola et al., 2012). The lesions were described as radiating streaks of acute tubular necrosis primarily affecting proximal tubular epithelium, with multifocal extensions of necrosis into more distal tubules and collecting ducts. In both microcystin and nodularin toxicosis, decreased renal perfusion may play a role in the renal lesions that develop. Cylindrospermopsin binds to DNA, causing DNA damage, inhibiting protein synthesis, and inducing oxidative damage to cells (Solter and Beasley, 2013). As with microcystins and nodularins, the liver is the primary target of cylindrospermopsin, with renal injury thought to be a combination of direct toxic injury as well as ischemic injury attributable to cardiovascular compromise in terminal stages of toxicosis. Renal lesions include acute degeneration and necrosis of proximal and distal convoluted tubules. In addition to cytotoxicity, cylindrospermopsin can be bioactivated to a genotoxic compound by cytochrome P450 enzymes (Zegura et al., 2011). The genotoxic nature of cylindrospermopsin also makes it a concern as a potential human and animal carcinogen.

41.4.8 Other agents

Many potential agents of chemical warfare have little to no direct injurious effect on the kidney or urinary system, but instead may cause indirect renal injury and/or urinary dysfunction. Nitrate esters used as explosives can cause profound hypotension with the potential to result in renal ischemia secondary to decreased renal perfusion (Gahagan and Wismer, 2012). Metabolic acidosis, proteinuria, glucosuria, and myoglobinuria were reported in a survey of five human cases of cyclonite (C-4) plastic explosive ingestion, and chronic renal insufficiency developed in a dog that recovered from seizures caused by ingestion of cyclonite (Kuccukardali et al., 2003; Fishkin et al., 2008). Chronic or repeated exposure to the riot control agent chloropicrin (PS, nitrochloroform) has been reported to cause kidney injury, but the mechanism or nature of renal injury has not been fully described (Salem et al., 2008). Cattle fed 25 g of polybrominated biphenyls per day for 33–60 days had development of degeneration and necrosis of cells of the collecting ducts and convoluted tubules, whereas those fed

250 mg per day had no development of signs or lesions of toxicosis (Moorhead et al., 1978). Toxic inhalants such as phosgene, chlorine, and hydrogen cyanide do not appear to cause direct injury to the kidney, nor do they appear to cause chronic or long-term renal effects (Tuorinsky and Sciuto, 2008).

Agents that cause neuromuscular dysfunction resulting in fasciculations, tremors, or seizures include compounds such as nerve agents, strychnine, fasciculins, and fluoroacetate. Although none of these have clinically significant direct toxic effect on the kidney, all have the potential to induce involuntary urination during the period of intoxication, and myoglobinuria or hemoglobinuria secondary to severe muscle injury from prolonged tremor or convulsion can cause acute renal tubular degeneration and necrosis. Incapacitants and psychotropic agents such as LSD also can result in loss of voluntary bladder control without causing overt lesions within the urinary system (Ketchum and Salem, 2008). Similarly, agents that produce neuromuscular blockade, paralysis, or unconsciousness, such as tetrodotoxin or botulinum toxin, can cause loss of voluntary bladder control, but cause no direct action on the kidney (Williams et al., 2007; Dembek et al., 2007). Conversely, the antimuscarinic nerve agent 3-quinuclidinyl benzilate (BZ) can cause urinary retention necessitating urethral catheterization to empty the bladder (Barreuto et al., 2006).

41.5 Concluding remarks and future directions

Despite the fact that some nephrotoxic agents (e.g., ethylene glycol) have been used in cases of malicious poisoning of individuals or in cases of suicide, in general, the urinary system makes a poor target for chemical warfare agents whose goal is to rapidly and consistently disable, incapacitate, or kill people on a large scale. Although renal dysfunction can lead to debilitating illness and death of the individual, barriers to the use of nephrotoxins as chemical weapons include delay between exposure and development of clinical signs, difficulty in ensuring delivery of appropriate doses to the targets, and individual variation in response to nephrotoxic agents. Given these barriers, it is not surprising that agents that have been developed to be used for chemical warfare tend to target other organ systems that can accomplish the goal of rapid incapacitation of the opponent more efficiently than primary nephrotoxicants.

Chapter 42

Impact of chemical warfare agents on the immune system

42.1 Introduction

Chemical warfare agents (CWAs) are probably the most brutal agents created by mankind for military operations to kill during war as compared to biological and nuclear warfare. Chemical weapons are inexpensive, relatively easy to manufacture, and can incapacitate people by inducing severe pathophysiological changes in various body systems even with small quantities. A United Nations report from 1969 defines CWAs as "chemical substances, whether gaseous, liquid or solid, which might be employed because of their direct toxic effects on man, animals and plants." However, the Chemical Weapons Convention defines chemical weapons as including not only toxic chemicals but also ammunition and equipment for their dispersal. Toxic chemicals are stated to be "any chemical which, through its chemical effect on living processes, may cause death, temporary loss of performance, or permanent injury to people and animals." Normally, they are highly toxic synthetic chemicals that can be dispersed as a liquid (including aerosols), gas, solid, or adsorbed on to particles to become a powder.

A chemical incident is traditionally defined as an unexpected or uncontrolled release of a chemical from its containment. Chemical incidents may be small or large in scale, and can give rise to multiple primary or secondary chemical casualties and fatalities. Chemical agents have been used in war since time immemorial. The use of CWAs in battlefields reached a peak during World War I and the French were the first to use ethylbromoacetate. This was followed by *o*-dianisidine chlorosulfonate, chloroacetate, chlorine, phosgene, hydrogen cyanide, diphenylchloroarsine, ethyl- and methyldichloroarsine, and sulfur mustard, resulting in nearly 90,000 deaths and over 1.3 million casualties (Eckert, 1991). CWAs were most brutally used by the Germans in the gas chambers for mass genocide of Jews during World War II, and have been used intermittently both in war, as in the Iraq−Iran War, as well as in the terrorist attacks in Japanese subway stations. It is estimated that nearly 100,000 US troops may have been exposed to CWAs during operation Desert Storm (Chauhan et al., 2008).

CWAs have been widely condemned since they were first used on a massive scale during World War I. However, they are still stockpiled and used in many countries as they are cheap and relatively easy to produce, and can cause mass casualties. Although the blood agent CK is extremely volatile and undergoes rapid hydrolysis, the degradation of three types of vesicant CWAs, the sulfur mustards, nitrogen mustards, and lewisite, results in persistent products. For example, sulfonium ion aggregates formed during hydrolysis may be persistent and may retain vesicant properties. The nerve agents include the V agent VX as well as three G agents (tabun, sarin, and soman). VX gives rise to two hydrolysis products of possible concern: EA 4196, which is persistent, and EA 2192, which is highly toxic and is possibly persistent under certain limited conditions (Small, 1984). Thus, their long-term persistence in the body may lead to alterations in the immune system of the exposed population. This chapter describes the immunotoxicity of CWAs and gives an insight into the probable mechanisms of such effects.

42.2 The immune system

Immunotoxicity deals with immune dysfunction resulting from exposure of an organism to a xenobiotic and explores the mechanisms underlying these effects in a biological system. The immune dysfunction may take the

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00042-8

form of immunosuppression or alternatively, exaggerated immune reaction, namely allergy, autoimmunity, or any number of inflammatory-based diseases or pathologies. Immunotoxicity adversely affects the functioning of both local and systemic immune systems, which gets activated on exposure to toxic substances including CWAs. Observations in humans and animal studies have clearly demonstrated that a number of environmental and industrial chemicals can adversely affect the immune system. Immunosuppression may lead to the increased incidence or severity of infectious diseases or cancer, since the immune system's ability to respond adequately to invading agents is suppressed. Toxic agent-induced immunostimulation can cause autoimmune diseases, in which healthy tissue is attacked by an immune system that fails to differentiate self-antigens from foreign antigens. For example, the pesticide dieldrin induces an autoimmune response against red blood cells, resulting in hemolytic anemia.

The immune system is evolved in multicellular organisms to protect them from various pathogens. The immune system is composed of several organs, cells, and noncellular components which act in an interrelated manner to protect the host against foreign organisms and chemical substances. A clear understanding of each of the many players involved will help one appreciate the intricate coordination of the immune system. The immune system participates in the mechanisms responsible for the maintenance of homeostasis and an altered immune system reflects the adverse changes in both internal and external microenvironments. The immune system protects organisms against pathogens or other innocuous substances like pollens, chemicals, indoor molds, potential food allergens, and environmental agents, and acts as layered defenses of increasing specificity. Most simply, physical barriers (e.g., skin) prevent pathogens and xenobiotics from entering the organism. If they breach these barriers, the innate immune system provides an immediate but nonspecific response. However, if pathogens successfully evade the innate response, there is a third layer of protection, that is, the adaptive immune system, which is activated by the innate response. Here, the immune system adapts during an infection to improve its recognition of the pathogen and its response is then retained after the pathogen or xenobiotic has been eliminated. This immunological memory allows the adaptive immune system to respond faster, with a stronger attack each time the same insult is encountered (Kindt et al., 2007).

The immune system protects organisms from infection with layered defenses of increasing specificity. The layered defense includes mechanical, chemical, and biological barriers which protect organisms from toxic substances. Skin, a mechanical barrier, acts as the first line of defense against infection. In the lungs, coughing and sneezing mechanically eject pathogens and other irritants from the respiratory tract, while mucus secreted by the respiratory and gastrointestinal tract traps and entangles microorganisms and other toxins (Boyton and Openshaw, 2002). Chemical barriers also protect against infection. The skin and respiratory tract secrete antimicrobial peptides such as the β-defensins. Enzymes such as lysozyme and phospholipase A2 in saliva, tears, and breast milk are also antibacterials (Moreau et al., 2001). In the stomach, gastric acid and proteases serve as powerful chemical defenses against ingested pathogens.

There are two interconnected systems of defense mechanisms: innate and adaptive immunity. These two systems collaborate to protect the body against foreign invaders.

42.2.1 The innate immune system

Innate immunity includes built-in molecular and cellular mechanisms that are encoded in the germline and are evolutionarily more primitive, aimed at preventing infection or quickly eliminating common invaders, in a nonspecific manner. This means that the cells of the innate system recognize, and respond in a generic way, but do not confer long-lasting or protective immunity to the host. The innate immune response was initially dismissed by immunologists as it was thought to provide a temporary holding of the situation until a more effective and specific adaptive immune response develops. However, it has now become clear that it plays an important role as a dominant system of host defense in most organisms (Litman et al., 2005). The major function of the innate immune system is to recruit immune cells to sites of infection and inflammation. Inflammation is one of the first responses of the immune system to infection or irritation through the production of cytokines. These cytokines released by injured cells serve to establish a physical barrier against the spread of infection. Several chemical factors are produced during inflammation, for example, histamine, bradykinin, serotonin, leukotrienes, and prostaglandins, which sensitize pain receptors, cause vasodilation of the blood vessels, and attract phagocytes.

The inflammatory response during innate immunity is characterized by the redness, heat, swelling, pain, and possible dysfunction of the organs or tissues involved. The fluid exudate contains the mediators for four proteolytic enzyme cascades: the complement system, the coagulation system, the fibrinolytic system, and the kinin system. The exudate is carried by lymphatics to lymphoid tissue, where the product of foreign organisms can initiate an immune response. The activation of the complement cascade helps to identify the invading substance, activate

cells, and promote clearance of dead cells by specialized white blood cells (WBCs). The cascade is composed of nine major components, designated C1−C9, which are plasma proteins synthesized in the liver, primarily by hepatocytes. These proteins work together to trigger the recruitment of inflammatory cells. One of the main events is the splitting of the C3, which gives rise to various peptides. One of them, C3a (anaphylatoxin), can stimulate mast cells to secrete chemical mediators and another, C3b (opsonin), can attach to the surface of a foreign body and facilitates its ingestion by WBCs. C5 is a powerful chemotactic of white cells and causes release of mediators from mast cells. Later components from C5 to C9 assemble in a sequence at the surface of bacteria/xenobiotics and lead to their lyses, ridding the body of neutralized antigen−antibody complexes. The main events of this system can also be directly initiated by the principal enzymes of the coagulation and fibrinolytic cascade, thrombin and plasmin, and by enzymes released from WBCs. Further, an innate immune system leads to the activation of an adaptive immune system.

42.2.2 The adaptive immune system

A second form of immunity, known as adaptive immunity, is much more attuned to subtle molecular differences. The adaptive immune system is composed of highly specialized, systemic cells and processes that eliminate pathogenic challenges and provide the ability to recognize and mount stronger attacks each time the same pathogen is encountered. Antigen specificity requires the recognition of specific "nonself" antigens during a process called antigen presentation. The ability to mount these immune responses is maintained in the body by "memory cells." The response is slow to develop, but is much more antigen specific. The cells of the adaptive immune system are special types of leukocytes, B cells and T cells, which constitute about 20%−40% of WBCs. The peripheral blood contains 20%−50% of circulating lymphocytes and the rest move within the lymphatic system (Kindt et al., 2007). B cells and T cells are derived from the same pluripotential hematopoietic stem cells (HSCs) in the bone marrow, and are indistinguishable from one another until after they are activated. B cells play a large role in the *humoral immune response*, whereas T cells are intimately involved in *cell-mediated immune responses*. B cells derive their name from the bursa of Fabricius, an organ unique to birds, where the cells were first found to develop. However, in nearly all other vertebrates, B cells (and T cells) are produced by stem cells in the bone marrow (Kindt et al., 2007). T cells are named after thymus where they develop and through which they pass. In humans, approximately 1%−2% of the lymphocyte pool recirculates each hour to optimize the opportunities for antigen-specific lymphocytes to find their specific antigen within the secondary lymphoid tissues. Both B cells and T cells carry receptor molecules that recognize specific targets.

Naive T cells continually recirculate between the blood and lymph systems. During recirculation, naive T cells reside in secondary lymphoid tissues such as lymph nodes. If a naive cell does not encounter antigen in a lymph node, it exits through the efferent lymphatics, ultimately draining into the thoracic duct and rejoining the blood. It is estimated that each naive T cell recirculates from the blood to the lymph nodes and back again every 12−24 h. Because only about 1 in 10^5 naive T cells is specific for any given antigen, this large-scale recirculation increases the chances that a naive T cell will encounter the appropriate antigen. T cells express a unique antigen-binding molecule, the T-cell receptor (TCR), on their membrane. There are two well-defined subpopulations of T cell: T helper (T_H) and T cytotoxic (T_C) cells. They can be distinguished from one another by the presence of either CD4 or CD8 membrane glycoproteins on their surfaces. T cells displaying CD4 generally function as T_H cells whereas those displaying CD8 function as T_C cells. T cells recognize a "nonself" target, such as a pathogen, only after antigens have been processed and presented in combination with a "self" receptor called a major histocompatibility complex (MHC) molecule. T_C cells only recognize antigens coupled to class I MHC molecules, while T_H cells only recognize antigens coupled to class II MHC molecules. Naive T_H cells are activated only by dendritic cells, whereas memory T_H cells can be activated by macrophages, dendritic cells, and B cells (Thokchom et al., 2017).

B cells are the major cells involved in the creation of antibodies that circulate in blood plasma and lymph, known as humoral immunity. The function of a B cell is to secrete antibodies capable of binding to any organism or molecule that poses a threat to the host. Like the T-cell receptor, B cells express a unique B-cell receptor (BCR), in this case an immobilized antibody molecule. The BCR recognizes and binds to only one particular antigen. A critical difference between B cells and T cells is how each cell "sees" an antigen. T cells recognize their cognate antigen in a processed form—as a peptide in the context of an MHC molecule—while B cells recognize antigens in their native form. Once a B cell encounters its cognate (or specific) antigen and receives additional signals from a helper T cell, it further differentiates into an effector cell, known as a plasma cell.

A single plasma cell is capable of secreting antibody molecules actively from a few hundred to more than a thousand molecules of antibody per second and they are

responsible for humoral immunity. Antibodies (or immunoglobulin, Ig) are large Y-shaped proteins used by the immune system to identify and neutralize foreign objects. In mammals there are five types of antibody: IgA, IgD, IgE, IgG, and IgM. Differing in biological properties, each has evolved to handle different kinds of antigens. These antibodies bind to antigens, making them easier targets for phagocytes, and trigger the complement cascade. About 10% of plasma cells will survive to become long-lived antigen-specific memory B cells (Lu and Kacew, 2002). The memory B cells circulates through the lymphoid organs and remain poised for subsequent stimulation and respond quickly if the same foreign body reinfects the host and prepares the immune system for future challenges.

Although immunotoxicology is a relatively new field, a considerable amount of data has accumulated during the past few years on immunotoxicity of certain xenobiotics. The majority of the research thus far carried out has been on environmental contaminants. Thus, from the defense point of view considerable work is required to investigate the immunotoxicity of several chemicals and some bacterial and fungal toxins which may be potential CWAs. Furthermore, there are several chemicals used in the defense industry to which defense industrial workers may be constantly exposed. These chemicals, following low-level exposure to humans and animals, may cause immunological alterations. Thus studies on such chemicals are being conducted to understand the potential risks of such exposure on the host's defense as well as the cellular and molecular mechanism of such immunomodulatory action. A number of animal models have been developed and validated to detect the chemical-induced direct immunotoxicity.

42.3 Targets of immunotoxicity

42.3.1 Effects on precursor stem cells

All functionally specialized, mature blood cells (red blood cells, granulocytes, macrophages, dendritic cells, and lymphocytes) arise from a single cell type, the HSC. The process by which HSCs differentiate into mature blood cells is called hematopoiesis. Two primary lymphoid organs are responsible for the development of stem cells into mature immune cells: the bone marrow, where HSCs reside and give rise to all cell types; and the thymus, where T cells complete their maturation. All leukocyte lineages originate from these stem cells, but once distinct subsets of leukocytes are established, their dependence on replenishment from the bone marrow differs vastly. The turnover of neutrophils is very rapid, that is, more than 10^8 neutrophils enter and leave the circulation in a normal adult daily so there is dependence on new formation in the bone marrow. In contrast, macrophages are long-lived and have little dependence on new formation of precursor cells. The adaptive immune system, comprising antigen-specific T and B lymphocytes, is almost completely established around puberty and is therefore essentially bone marrow independent in the adult.

As a consequence of their high proliferation rate, stem cells in the bone marrow are likely to be extremely vulnerable to cytostatic drugs and chemicals like CWAs. Lineages like neutrophils with rapid turnover will be most vulnerable and will be affected first by such treatments/exposures. After prolonged exposure, macrophages and T or B cells of the adaptive immune system are also suppressed. Recognizing immunomodulation mechanisms produced by CWAs is a platform for identifying the best therapeutic and management approaches to check deleterious effects on the biological system.

42.3.2 Effects on maturation of lymphocytes

The thymus is a primary lymphoid organ where T cells mature. T-cell development is not complete until the cells undergo selection in the thymus. T lymphocytes mature in the thymus by a very complex selection process that takes place under the influence of the thymic microenvironment and ultimately generates an antigen-specific, host-tolerant population of mature T cells. This process involves cellular proliferation, gene rearrangement, apoptotic cell death, receptor up- and downregulation and antigen-presentation processes, and is very vulnerable to a number of chemicals. Drugs may target different stages of T-cell differentiation like naive T cells, proliferating and differentiating thymocytes, antigen-presenting thymic epithelial cells and dendritic cells, cell death processes, etc. (Vos et al., 1999). The CWA may cause a depletion of peripheral T cells, particularly after prolonged treatment and during early stages of life when thymus activity is high and important in establishing a mature T-cell population. In addition, suppression of T cells may result in suppression of the adaptive immune system by affecting the maturation of B cells and thus antibody level.

42.3.3 Effects on initiation of immune responses

In response to the attacking pathogen, B and T lymphocytes generate antibodies and effector T cells that specifically recognize and neutralize or eliminate the invaders. The innate and adaptive immune systems act together to eliminate invading pathogens. Ideally, T cells tailor the responses to neutralize invaders with minimal damage to the host. The recognition of autoantigens is maintained by

the two distinct signals that govern lymphocyte activation. One is the specific recognition of antigen via clonally distributed antigen receptors and the other is antigen-nonspecific costimulation or "help" and involves interactions of various adhesive and signaling molecules expressed in response to tissue damage, linking initiation of immune responses to situations of acute "danger" for the host (Vos et al., 1999). This helps to aim immune responses at potentially dangerous microorganisms (nonself), while minimizing deleterious reactions to the host (self). Xenobiotics, however, can interfere with the initiation of immune responses if they act as antigens, by forming haptens or by releasing previously hidden self-antigens. They may also trigger an inflammatory response, or disturb T–B-cell cooperation.

CWAs with large molecular weight can function as antigens and become targets of specific immune responses themselves. This is particularly relevant for foreign protein pharmaceuticals, as these can activate both T and B lymphocytes. The resulting immune responses may lead to formation of antibodies, and induce specific memory which can lead to allergic responses to the drug. Immunotoxic effects may occur after repeated treatment with the same CWA. However, low-molecular-weight CWAs cannot function as antigens, because they are too small to be detected by T cells. Reactive chemicals that bind to proteins, however, can function as haptens and become immunogenic if epitopes derived from them prime T cells, which in turn provide costimulation for hapten-specific B cells. This effect is responsible for allergic responses to many new (neo) epitopes formed by chemical haptens.

Modification of autoantigens can also lead to autoimmune responses to unmodified self-epitopes. Haptenated autoantigens can be recognized and internalized by antigen-presenting cells. These cells subsequently present a mixture of neo- and self-epitopes complexed to distinct class II major histocompatibility (MHC-II) molecules on their surface and neospecific T cells. Th cells provide signals for the B cell. This leads to production of either antihapten or antiself antibodies depending on the exact specificity of the B cell. Moreover, once these B cells are activated, they can stimulate autoreactive Th cells recognizing unmodified self-epitopes. This process is called epitope (determinant) spreading and causes the diversification of adaptive immune responses. For example, injection of mercury salts initially induces a response directed only to unidentified chemically created neoepitopes, but after 3–4 weeks includes reactivity to unmodified self-epitopes. Thus the allergic response may gradually culminate as autoimmune responses reflecting the relative antigenicity of the neo- and self-epitopes involved (Lu and Kacew, 2002).

42.3.4 Induction of inflammation and noncognate T–B cooperation

Exposure to the CWAs is associated with an immune and inflammatory pathway mediating the release of proinflammatory cytokines like tumor necrosis factor α (TNFα), interleukin-1 (IL-1), IL-6, and attracts inflammatory cells like granulocytes and macrophages. Cytokines produced during this inflammatory response activate antigen-presenting cells and accumulation of tissue debris. The epitopes of antigens on debris provide costimulation for Th cells, which lead to the initiation of an adaptive immune response. Reactive xenobiotics may also stimulate adaptive immune responses by disturbing the normal cooperation of Th and B cells. Normally, B cells receive stimulation from Th cells that recognize (epitopes of) the same antigen. However, when Th cells respond to nonself-epitopes on B cells, such B cells may be noncognately stimulated by the Th cell. This occurs during graft-versus-host responses following bone marrow transplantation, when Th cells of the host recognize nonself-epitopes on B cells of the graft and vice versa. Drug/chemical-related lupus is characterized by a similar spectrum of autoantibodies which leads to T- and B-cell activation and results in production of autoantibodies to distinct autoantigens like DNA, nucleoli, nuclear proteins, erythrocytes, and basal membranes.

42.4 Exposition of autoantigens and interference with co-stimulatory signals

Co-stimulatory molecules expressed on the surface of various cells play a decisive role in the initiation and sustenance of immunity. Self-tolerance involves specific recognition of autoantigen leading to selective inactivation of autoreactive lymphocytes at birth, but tolerance is not established for (epitopes of) autoantigens that are normally not available for immune recognition. Pharmaceuticals can expose such sequestered epitopes by disrupting barriers between the antigen and the immune system (i.e., blood–brain barrier, blood–testis barrier, cell membranes). Tissue damage, cell death, and protein denaturation induced by chemicals can largely increase the chances of such (epitopes of) autoantigens for immune recognition. Antigen recognition followed by costimulation of signaling molecules leads to activation of lymphocytes and initiation of immune responses. Many xenobiotics have the inherent capacity to induce or inhibit this costimulation due to their intrinsic adjuvant activity. An array of co-stimulatory molecules is displayed on the surface of APCs and T cells. The level of the expression of the co-stimulatory molecules may play an important role during the course of acute disease and its remission

or relapse. Hence, modulation of these molecules may help to develop immunotherapeutic strategies (Khan et al., 2012).

42.5 Regulation of the immune response

The immune response elicited in response to a foreign pathogen or allergen is the result of a complex interplay of cytokines produced by macrophages, dendritic cells, mast cells, granulocytes, and lymphocytes. Immunotoxic chemicals can lead to either immunosuppression or immune exaggeration, that is, hypersensitivity and autoimmunity. Hypersensitivity is an immune response that damages the body's own tissues. Hypersensitivity reactions require a presensitized (immune) state of the host. They are divided into four classes (types I–IV) based on the mechanisms involved and the time course of the hypersensitive reaction. Type I hypersensitivity is an immediate or anaphylactic reaction, often associated with allergy. Symptoms can range from mild discomfort to death. Type I hypersensitivity is mediated by IgE released from mast cells and basophils. Type II hypersensitivity occurs when antibodies bind to antigens on the patient's own cells, marking them for destruction. This is also called antibody-dependent (or cytotoxic) hypersensitivity, and is mediated by IgG and IgM antibodies. Immune complexes (aggregations of antigens, complement proteins, and IgG and IgM antibodies) deposited in various tissues trigger type III hypersensitivity reactions. Type IV hypersensitivity (also known as cell-mediated or delayed-type hypersensitivity) usually takes between 2 and 3 days to develop. Type IV reactions are involved in many autoimmune and infectious diseases, but may also involve contact dermatitis (poison ivy). These reactions are mediated by T cells, monocytes, and macrophages. Actual development of clinical symptoms is influenced by the route and duration of exposure, the dosage of the pharmaceutical, and by immunogenetic (MHC haplotype, Th1-type vs Th2-type responders) and pharmacogenetic (acetylator phenotype, sulfoxidizer, Ah receptor, etc.) predisposition of the exposed individual. Moreover, atopic individuals that tend to mount Th2 immune responses are more susceptible to anaphylaxis triggered by an IgE response to chemical haptens than typical Th1 responders.

The dysregulation of the immune system can be characterized in several ways. Immune dysregulation can also be in the form of immune suppression and both innate and adaptive arms of the immune systems play crucial roles. A wide variety of physiological, pharmacological, and environmental factors can exert a negative influence on the immune system and sometimes result in immunotoxicity. Experimental data have shown that emotional and environmental stressors influence the functioning of the immune system and this is reflected in the various markers of specific immunity (Ray et al., 1991; Koner et al., 1998). Such experimental stressors consistently suppressed both humoral and cell-mediated immune (CMI) responses in experimental animals. Both antibody-forming cell counts and antibody titer were lowered and a neuroendocrine–immune axis concept was proposed. Similar attenuations in CMI responses were also seen after such stressors and DTH responses, leukocyte/macrophage migration indices, and also cytokine profiles (both Th1 and Th2 dependent). Further analysis of the mechanisms involved indicated that CNS-mediated changes could have contributed to this immunotoxicity. Depletion or antagonism of brain dopamine aggravated emotional stress-induced immune suppression, whereas psychoactive drugs like benzodiazepines and opioids prevented this response (Ray et al., 1992; Puri et al., 1994). In another set of experiments, rats exposed to several environmental pollutants like DDT showed graded degrees of immune suppression and immunotoxicity, when the exposure lasted for a reasonably long period of time. Gradual accumulation in the various body tissues resulted in a variety of untoward effects in the immune system, which was particularly susceptible to such xenobiotic-induced damage (Banerjee et al., 1996; Koner et al., 1998). Both humoral and CMI responses were affected, depending on the quantum and duration of exposure to these xenobiotics. Further, a combination of emotional stress and xenobiotic exposure had additive effects on the immunotoxicity parameters studied (Banerjee et al., 1997). Recent studies revealed that such emotional stress and xenobiotic-induced immunotoxicity was accompanied by derangements in oxidative stress parameters, such as enhancements in MDA levels and lowering of GSH/SOD levels in the blood (Koner et al., 1997; Ray and Gulati, 2007; Gulati et al., 2007; Ray et al., 2015; Thakur et al., 2017).

42.6 Immunotoxicity of chemical warfare agents

Xenobiotic-induced hypersensitivity reactions and autoimmune disorders are a major concern, whereas some of CWAs result in immunosuppression. Very few studies have been conducted to explore the immunomodulation and immunotoxic potential of CWAs, and there is little evidence that these drugs are associated with such undesirable, immunologically significant effects. The reason may be due to confounding factors such as stress, nutritional status, lifestyle, comedication, and genetics (Vos et al., 1999). Few conventional compounds have been shown to induce unexpected enhancement of immune competence. In particular, impaired activity of the first line of defense of the natural immune system can have

disastrous consequences. These are generally not influenced by the genetic predisposition of the exposed individual, but on actual outbreak of infections and the general immune status prior to exposition. This explains why immunosuppressive xenobiotics are most likely to have clinical consequences in immunocompromised individuals such as young children, the elderly, and can be aggravated further by stressful situations. Thus, the conduct of immunotoxicity studies on such CWAs is important to understand the mechanisms underlying these effects in a biological system.

There are thousands of toxic substances, but only a few are considered CWAs based on their characteristics, such as high toxicity, rapid action, and persistency. The exposure to CWA, depending on the type of agent and duration of exposure can result in immunodepressed conditions on the one hand, to allergic and autoimmune diseases on the other. CWAs can be classified in many different ways. Chemical warfare (CW) agents may be encountered as solids, liquids, or gases. Volatile substances may mainly contaminate the air and persistent substances, which are nonvolatile, mainly cover surfaces. Some agents, for example, sulfur mustard, may appear as solids under North European winter conditions (freezing point 14.4°C), as a liquid at a wide range of temperatures (boiling point 219°C), or as a vapor evaporating from the liquid phase. CW agents may also be encountered as mixtures or solutions of one agent in another, or of an agent in a solvent. The mixing of lewisite with sulfur mustard has been undertaken to lower the vapor pressure and freezing point of the mustard and hence to increase its persistence, without reducing the effective CW payload of weapon systems.

CWAs mainly used against people may also be divided into lethal and incapacitating categories. A substance is classified as an incapacitating agent if less than 1/100th of the lethal dose causes incapacitation, for example, through nausea or visual problems. The limit between lethal and incapacitating substances is not absolute but refers to a statistical average. CWAs are generally classified according to their principal target organs.

1. *Nerve agents.* These agents are extremely toxic compounds that work by interfering with the nervous system, and include soman, sarin, cyclosarin, tabun, and VX.
2. *Blister agents/vesicants.* These compounds severely blister the eyes, respiratory tract, and skin on exposure, and include nitrogen mustard, sulfur mustard, lewisite, etc.
3. *Choking agents.* These agents cause severe irritation, primarily affecting the respiratory tract, and include phosgene, ammonia, methyl bromide, methyl isocyanate, etc.
4. *Blood agents.* These agents are absorbed into the blood and interfere with the oxygen-carrying capacity, for example, arsine, cyanides, carbon monoxide, etc.

42.6.1 Nerve agents

Terroristic attacks in Japan in 1994 and 1995 (Ohtomi et al., 1996) proved that nerve agents are highly toxic organophosphorus compounds (OPs) and deadliest of CWAs, which represent potential threats to both military and civilian populations. These agents have both chemical names as well as two-letter NATO codes. These are categorized as G series agents: GA (tabun), GB (sarin), GD (soman), GF (cyclosarin), and V series agents: VE, VG, VM, and VX, the letter "G" representing the country of origin "Germany" and the letter "V" possibly denoting "venomous." Their initial effects occur within 1−10 min of exposure, followed by death within 15−30 min for sarin, soman, and VX, and within 30−60 min for tabun.

On the basis of scientific literature published on health effects of exposure to OP nerve agents and insecticide nerve agents in humans and animal studies, their short- and long-term effects are compiled. Four distinct health effects are identified: acute cholinergic toxicity; OP-induced delayed neuropathy (OPIDN); subtle long-term neuropsychological and neurophysiological effects; and a reversible muscular weakness called "intermediate syndrome." Each effect has data suggesting threshold exposure levels below which it is unlikely to be clinically detectable. High-level exposure results in definitive cholinergic poisoning; intermediate-level threshold cholinergic effects include miosis, rhinorrhea, or clinically measurable depression of cholinesterase; and low-level exposure results in no immediate clinical signs or symptoms. However, in combat settings, such as Iraq and Afghanistan, mild traumatic brain injury (mTBI) has been reported with lower level exposures or subclinical exposure (Gregory et al., 2014). Mohamed et al. (2016) reviewed that exposure to sarin in animal models resulted in neurotoxicity that approximates human mTBI in subclinical exposure. Animal studies show that low-level blast pressure waves are transmitted to the brain, thus causing behavioral, biochemical, pathological, and physiological effects on the nervous system. Further, Gregory et al. (2014) concluded that low-level blasts have long-term effects on the nervous system. Threshold exposure levels for known long-term effects of OP nerve agent are above intermediate-level exposure (Brown and Brix, 1998).

Sarin (GB, O-isopropyl methylphosphonofluoridate) is a potent OP nerve agent that irreversibly inhibits AChE. The ease and low cost of production make sarin gas a tool of mass destruction in the hands of terrorist groups and rogue nations. While people in the immediate vicinity of

a sarin attack may receive neurotoxic doses, people remote from the vicinity are likely to receive subclinical exposures. The subsequent build-up of acetylcholine (ACh) in the CNS causes seizures and respiratory arrest and at peripheral autonomic synapses causes "cholinergic crisis" due to accumulation of ACh. At high doses, exposure to sarin can cause tremors, seizures, and hypothermia. More seriously, accumulation of ACh at neuromuscular junctions (NMJs) also can cause paralysis and ultimately peripherally mediated respiratory arrest which can lead to death. Apart from its primary action on the cholinergic system, sarin can cause other indirect effects such as activation of several neurotransmitters including gamma-amino-butyric acid (GABA) and the alteration of other signaling systems such as ion channels, cell adhesion molecules, and inflammatory regulators. Moreover, sarin exposure is associated with toxic and immunotoxic effects (Mohamed et al., 2016). Subclinical doses of sarin cause subtle changes in the brain, and subclinical exposure to sarin has been proposed as an etiology to the Gulf War syndrome. Gulf War illness (GWI) is a chronic multisymptom disorder affecting veterans of the 1990−91 Gulf War. GWI was linked with exposure to chemicals including the nerve gas prophylactic drug pyridostigmine bromide (PB) and pesticides (DEET, permethrin). Veterans with GWI exhibited prolonged, low-level systemic inflammation. Anca et al. (2018) assessed the effects of GWI-related chemicals on macrophage infiltration and its subsequent influence on hepatic cholestasis using Sprague-Dawley rats. Exposure to GWI-related chemicals alone increased IL-6, CD11b + F4/80 − macrophages and developed worse liver pathology due to sustained low-level inflammation of the liver when compared to animals without GWI.

The wide use of cholinesterase inhibitors in various spheres of human life and the risk of acute and chronic intoxications associated with this process prompted investigation of the role of acetylcholinesterase (AChE) and nonspecific esterases in the immunotropic effects of these chemicals. They irreversibly bind to AChE that normally catalyzes the hydrolysis of ACh at the cholinergic synapses and NMJs. The inhibition of degradation results in accumulation of ACh in the cholinergic synapses, causes the overstimulation of peripheral as well as central cholinergic nervous systems, and is clinically manifested as acute cholinergic crisis (diarrhea, sweating, salivation, miosis, convulsions, respiratory failure, and/or death) (Marrs, 1993; Taylor, 2006).

Exposures to seizure-inducing chemical threat agents such as OP cholinesterase inhibitor, diisopropylphosphorofluoridate (DFP), and the GABA receptor inhibitor, tetramethylenedisulfotetramine (TETS), also caused convulsions and long-term neurological sequelae in survivors, and represent a major public health concern (Isaac et al., 2016). The toxic organic compound, TETS, is used as an effective rodenticide, unfortunately, human poisoning by this substance occurs commonly. Every year, the largest number of poisonings is reported in China and dozens of poisonings happen annually in the United States. TETS is one of the most hazardous pesticides and also a possible CWA with no known antidote (Patocka et al., 2018).

Phosphine (PH3) inhalation is characterized by a steep probit slope of 11, ranking it among CW nerve agents such as sarin, which has a probit slope in the 9.4−13.2 range. It is another toxidrome-spanning chemical that is widely used as an insecticide and rodenticide. Exposure to PH3 can cause a host of target organ and systemic effects, such as oxidative stress, cardiopulmonary toxicity, seizure-like activity, and overall metabolic disturbance, altogether leading to death (Benjamin et al., 2017).

42.6.1.1 Immunotoxicity of nerve agents

Low doses of sarin are shown to be highly immunosuppressive and reduce glucocorticoid production (Kalra et al., 2002). The effects of sarin exposure on the immune system are attenuated by ganglionic blockers and decreased glucocorticoid level may be a biomarker for cholinergic toxicity. In addition, nerve agents cause the activation of multiple noncholinergic neurotransmitter systems in the central nervous system (CNS), thus resulting in mutagenic, stressogenic, immunotoxic, hepatotoxic, membrane, and hematotoxic effects (Bajgar, 1992). The CNS and the immune system communicate bidirectionally, and cholinergic agents modulate the immune system. The ability of OP compounds to induce an alteration of the immune system was primarily demonstrated in animals or humans exposed to OP insecticides (OPIs). The results provide evidence that, especially neutrophil function, natural killer cell, cytotoxic T-cell, and humoral immune functions, and spontaneous as well as mitogen-induced lymphocyte proliferation, are altered in animals or humans exposed to OP compounds (Li et al., 2002; Newcombe and Esa, 1992). In addition, a decreased number of cells in the spleen and thymus (Ladics et al., 1994), an inhibition of chemotaxis in neutrophils, inhibition of monocyte accessory functions, or inhibition of interleukin-2 production (Casale et al., 1993; Pruett and Chambers, 1988) were reported following exposure to OPs, at relatively high toxic doses.

Lee et al. (1979) were the first to demonstrate that lymphocyte proliferation was decreased in the presence of OPs. Although most of the studies described the results of OPI exposure, there are studies about the immunotoxic effects of highly toxic nerve agents and their byproducts. Marked impairment in neutrophil chemotaxis and neutrophil adhesion and a reduction in the natural killer cell and

cytotoxic T-cell function were observed in workers exposed to OPIs and byproducts of sarin (Newcombe and Esa, 1992; Li et al., 2002). Kant et al. (1991) documented a decrease in the weight of thymus, an important immune organ in severely affected soman survivors, but other tests of immune function did not show differences between control and soman-exposed rats. Samnaliev et al. (1996) described a decrease in the number of plaque-forming cells in soman-exposed rats after the administration of sheep red blood cells (SRBCs) as an antigen. However, Johnson et al. (2002) demonstrated that OP-induced modulation of immune functions can involve not only their suppression but also their activation. Similar activation of some immune functions involving an "acute phase response," such as an increase in the synthesis of acute phase proteins, increase in release of histamine from basophile leukocytes, and activation of macrophages were observed following exposure to soman (Sevaljevic et al., 1992; Newball et al., 1986). Although most of the studies dealt with exposure to high doses, Kassa et al. (2004) confirmed that not only symptomatic but also asymptomatic doses of nerve agent sarin were able to modify various immune functions. The proportion of T lymphocytes was found to be decreased, while the B-cell levels were raised. However, sarin significantly suppressed nonspecific in vitro stimulated proliferation of both T and B cells, which suggests that it can also block the normal immune response to infection. Immunosuppression may result from direct action of ACh upon the immune system or it may be secondary to the toxic chemical stress associated with cholinergic poisoning (Pruett et al., 1992). Further, immunomodulation at low levels seems to be very complex and it is suggested that there are probably other protein targets very sensitive to some anticholinesterases, including nerve agents. However, the function of these protein targets is not yet known (Ray, 1998). Some immune functions are probably stimulated due to the development of "acute phase response" generally characterized for inflammatory reaction of OP-exposed organisms (Sevaljevic et al., 1989, 1992). Other immune functions are suppressed due to the immunotoxicity of OP compounds. Although these findings are difficult to extrapolate directly to low-level exposures to nerve agents, they indicate that subtle alteration of the immune system could also occur in humans at exposure levels which do not cause any clinical manifestation. Postintoxication immunodeficiency can promote infectious complications and diseases.

AChE has been shown to be located on the plasma membrane of T lymphocytes, while B cells are esterase negative (Szelenyi et al., 1982). Thus, AChE inhibition by toxic agents in sublethal doses may play an important role in immunodeficiency following exposure to nerve gases. Zabrodskii et al. (2003) showed inhibition of AChE in T cells and the decrease in the number of esterase-positive T lymphocytes (and, to a certain extent, in monocytes and macrophages) directly correlated with suppression of T-cell-dependent antibody production and to the degree of DTH reduction, on exposure to dimethyl dichlorovinyl phosphate, sarin, VX, lewisite, tetraethyl lead, and dichloroethane. This presumably involves the loss of some functions by T lymphocytes (e.g., by Th1 cells), which leads to attenuation of T-dependent immune reactions. Thus, the anticholinesterase effect of lewisite, TEL, and DCE may be one of the important mechanisms in the formation of T-cell-mediated immunodeficiency. A study showed that malathion (an analog of VX) in acute noncholinergic doses enhanced the humoral immune response to SRBCs, and macrophage function, and also caused mast cell degranulation. When effects of acute administration of malathion were observed in mast cell-deficient mice, the humoral activation was not observed, thus suggesting that the mast cells contribute to the increases in macrophage function and humoral immunity observed in normal mice (Rodgers et al., 1996).

The effects of subchronic doses of malathion exposure on humoral and CMI responses were studied in male albino mice, rats, and rabbits using SRBCs, tetanus toxoid and ovalbumin as antigens. Malathion resulted in (1) attenuation in antigen-induced antibody response, (2) suppression of PFC, and (3) marked inhibition of LMI and MMI factors. Subchronic malathion exposure induced differential degrees of humoral and CMI suppression in these experimental animals. However, both cellular and humoral immune responses were decreased in a dose−time-dependent pattern and a consistent trend was observed. Banerjee et al. (1998) reported that the threshold level of malathion for inducing immune suppression varies on the basis of species of animals, type of antigen used, and the method of immunological assay. In another study, rats were administered with malathion alone and in combination with bradykinin potentiating factor (BPF), and effects were compared to a vehicle group on immune parameters. The results showed that the concentration of total globulin, total immunoglobulins, IgG, IgM, circulatory immune complexes, total number of RBC and platelets, and hemoglobin concentrations decreased significantly in malathion-exposed animals. The results suggested that exposure to malathion has negative effects on immune function that were mediated through alteration of cytokines, antioxidants, and direct damage of BM. Also, BPF can ameliorate both physiological and morphological changes (Ahmed, 2012). In another human study involving malathion-poisoned subjects, high levels of malathion were associated with significant enhancements of IL-2, IL-4, and TNF-α levels in blood, whereas no significant changes in immunoglobulin levels were seen. This study thus showed altered levels of cytokines in the

blood of malathion-exposed subjects (Seth et al., 2008). Kassa et al. (2001) showed that rats exposed once or repeatedly to three various low concentrations of sarin for 60 min in an inhalation chamber induced immunotoxicity. Nonconvulsive concentrations of sarin caused subtle suppression of spontaneous, as well as lipopolysaccharide-stimulated, proliferation of spleen lymphocytes and the bactericidal activity of peritoneal macrophages.

Hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) is a well-known explosive compound causing neurotoxicity. In an experimental study by Youping et al. (2014), miRNA and mRNA were used as novel biomarkers to study the molecular mechanisms for RDX-induced neurological disorder and neurotoxicity. In their study, it was found that immune and inflammation response genes are highly enriched in differentially expressed mRNAs after exposure to RDX. Interestingly, the immune and inflammation response genes connected network indicated that RDX could first modulate miRNA expression and then trigger an immune and inflammation gene network. For instance, miR-98 could target IL10, which then upregulates TNF, which induces the expression of the transcription factor HSF1, to carry out immune functions. Their findings on RDX-regulated immune and inflammation responses could contribute to RDX-induced neurotoxicity.

42.6.2 Blister or vesicant agents

Blister agents act on skin and other epithelial tissues and severely blister the eyes, respiratory tract, and internal organs, and also destroy different substances within cells of living tissue. The symptoms are variable depending upon the compound and the sensitivity of the individual. Acute mortality is low; however, they can incapacitate the enemy and overload the already burdened healthcare services during war time. Some of these agents are SM (sulfur mustard), HN (nitrogen mustard), L (lewisite), and CX (phosgene oximine).

Sulfur mustard was the most widely used CWA in the Iran–Iraq War, resulting in over 100,000 chemical casualties between 1980 and 1988. It acts as an alkylating agent with long-term toxic effects on several body organs, mainly the skin, eyes, and respiratory system. The extent of tissue injury depends on the duration and intensity of exposure. When absorbed in large amounts, SM can damage rapidly proliferating cells of bone marrow and may cause severe suppression of the immune system. In the pulmonary system, epithelial cells and macrophages are the primary layer of cells that can be exposed to SM. Following SM exposure, intense cellular and molecular modifications occur in the normal cells of lung. During several days after exposure, innate immunity induces an adaptive immune system with proinflammatory mediators. If the apoptosis and necrosis rate increase, cell contents are released into the extracellular matrix (ECM), and immune cells are activated. Epithelial cell detachment, cell death, fibrosis, DNA repair system activation, tissue repair induction, and systemic signaling have been reported after SM exposure (Imani et al., 2015).

42.6.2.1 Immunotoxicity of blister agents

Several lines of investigation have provided evidence that SM causes immunosuppression in humans. The earliest evidence came from clinical observations of humans directly exposed to sulfur mustard during World War I, who showed significant changes (quantitative and qualitative) in the circulating elements of the immune system. Stewart (1918) studied 10 fatal cases of mustard poisoning and observed striking depression of bone marrow production of WBCs. Among the sulfur mustard casualties during the Iran–Iraq conflict, leukopenia was accompanied by total bone marrow aplasia and extensive losses of myeloid stem cells, and proved an association between suppression of immunologic functions and an increased incidence of infectious disease (Eisenmenger et al., 1991).

SM was widely used during the Iran–Iraq conflict and there are many reports of the influence of SM on the respiratory, gastrointestinal, and endocrine systems, as well as the immune system (Balali-Mood and Farhoodi, 1990; Emad and Razaian, 1997; Sasser et al., 1996; Budiansky, 1984). The influence of SM on the immune system has been the subject of many researches since 1919 (Krumbhaar and Krumbhaar, 1919). Early investigations on SM casualties during the Iran–Iraq War showed decreased immunoresponsiveness, expressed as leukopenia, lymphopenia, and neutropenia, as well as hypoplasia and atrophy of the bone marrow (Tabarestani et al., 1990; Balali-Mood et al., 1991). Chronic exposure to SM has been associated with the impairment of NK cells among workers of poison gas factories in Japan (Yokogama, 1993). Similarly, cell-mediated immunity was found to be suppressed following mustard gas exposure (Zandieh et al., 1990).

Leukopenia is the first manifestation to appear within the first few days postexposure. Thrombocytopenia and anemia followed later if the patients survived (WBC counts of some patients dropped to less than 1000 per cm^3). Although most of these patients suffered skin burns, clinicians reported cases that had minor skin lesions and yet developed leukopenia. Bone marrow biopsies revealed hypocellular marrow and cellular atrophy involving all elements. Studies on the status of immunocompetent cells in the blood of patients exposed to sulfur mustard showed that T-cell and monocyte counts dropped in 54% and 65% of the patients, respectively, from day 1 and up to the seventh week postexposure (Hassan and Ebtekar, 2002). The majority of the patients showed increased

levels of IgG and IgM during the first week, but the percentage decreased over the next 6 months. The percentage of patients with increased levels of C3, C4, and CH50 was somewhat higher than of healthy controls during the first week and up to the sixth month (Tabarestani et al., 1990) and remained higher 3 years postexposure, especially in the severely affected group. Eight years after exposure there was a significant increase in the number of atypical leukocytes (such as myelocytes). The severely affected group presented with significantly lower CD56 NK, as well as CD4 and CD8 counts, compared with healthy controls (Yokogama, 1993). However, Hassan and Ebtekar (2002) reported that there was no major difference between the severely affected patients and healthy controls concerning CD19 B cells, CD14 monocytes, and CD15 granulocytes. The moderately and mildly affected patients did not significantly differ in their leukocyte subset counts from the control group 8 years after exposure (Mahmoudi et al., 2005). Follow-up studies on the clinical conditions of exposed Iranian victims still show that they suffer from three major problems: recurrent infection, septicemia and death, respiratory difficulties and lung fibrosis, as well as a high incidence of malignancies, septicemia, and death. Hassan and Ebtekar (2002) suggested that patients with moderate clinical manifestations may be experiencing a shift from Th1 to Th2 cytokine patterns since leukocyte cultures from this patient group showed a decrease in IFN-γ levels.

When absorbed in large amounts, SM can damage rapidly proliferating cells of bone marrow and may cause severe suppression of the immune system (Sasser et al., 1996). Moreover, this alkylating agent has been reported to produce short- and long-term suppression of antibody production in both animals and humans. It also affects complement system factors C3 and C4. Incidences of acute myelocytic and lymphocytic leukemia are reported to be 18 and 12 times higher in patients exposed to SM, in comparison with the normal group, respectively (Zakeripanah, 1991). reported that exposure to SM could result in the impairment of human immune function, especially in the number of B and T lymphocytes. Hence, SM is still a potential threat to the world and effective therapeutic measures must be taken for the relief of the victims of this incapacitating agent. Ghotbi and Hassan (2002) showed that the percentage of NK cells, playing an important role in cellular immunity, was significantly lower in severe patients than in the control group. Studies on animal models have shown that alkylating agents such as SM mainly affect B cells, which is why hypogammaglobulinemia is one of the main features in animal models, whereas studies on human cases, following treatment with cytotoxic drugs, suggest that low-dose exposure to alkylating agents impairs cellular immunity and high-dose exposure to such agents impairs both cellular and humoral responses (Marzban, 1989; Malaekeh et al., 1991). There are reports suggesting that sulfur mustard can produce toxicity through the formation of reactive electrophobic intermediates, which in turn covalently modify nucleophilic groups in biomolecules such as DNA, RNA, and protein (Malaekeh et al., 1991). As a result, these agents are particularly toxic to rapidly proliferating cells including neoplastic, lymphoid, and bone marrow cells. Mahmoudi et al. (2005) reported higher IgM levels after 16−20 years of exposure to SM, compared to the control group. A significant decrease in the number of NK cells in severely affected patients is probably due to the destructive effect of this alkylating agent on NK cell precursors in bone marrow. However, activity of NK cells was found to be noticeably above normal, which possibly compensates for the reduction in the number of these cells.

Korkmaz et al. (2006) explained the toxicodynamics of sulfur mustards in three steps: (1) binding to cell surface receptors; (2) activation of ROS and RNS leading to peroxynitrite ($OONO^-$) production, and (3) $OONO^-$-induced damage to lipids, proteins, and DNA, leading to polyadenosine diphosphate ribose (PARP) activation. This could provide a lead for devising strategies for protection against/treatment of mustard toxicity.

A study has been conducted to evaluate the incidence of immunocompetence, among survivors of the chemical bombardment of Halabja in the Kurdistan region of Iraq. The result revealed that there was a deficiency in antibody-mediated immunity. There were significant differences between the exposed and the control samples with respect to total leukocytes, neutrophil count, lymphocyte count, IgG, and IgA. The immunological reactions were more closely related to the effects of mustard gas, which appeared to be long-lasting. They concluded that long-term effects were produced by CWAs on victims who have survived in Halabja and, in particular, on their immune system at both antibody- and cell-mediated levels. This study confirmed the immunosuppressive property of mustard compounds, and indicates increased vulnerability of the exposed individuals to secondary opportunistic or pyogenic bacterial infections due to injuries which occurred frequently among chemical survivors in Halabja (Hama et al., 2008).

In another study, Kumar et al. (2015) showed that topical application of nitrogen mustard (NM), an analog of sulfur mustard (SM), on mice caused an increased in the expression of inflammatory mediators, microvesication, and apoptotic cell death. Further, NM also induced the activation of MAPKs/ERK1/2, JNK1/2, and p38 as well as that of Akt together with the activation of transcription factor AP1. NM exposure caused a very strong and time-dependent increase in COX-2 and iNOS levels in NM-exposed skin tissue compared to vehicle control. NM

exposure caused a 21-fold induction in iNOS levels at 24 h postexposure, which decreased thereafter at 72 and 120 h postexposure. The expression of TNF-α, a cytokine involved in inflammation, apoptosis, and immune system development also increased in a biphasic manner, where a time-dependent increase compared to control was observed up to 24 h, followed by a decline at 72 h and again an increase at 120 h post-NM exposure. Gelatinases, especially MMPs that could come from infiltrating neutrophils, have the ability to degrade basement membrane components and interrupt the epidermal−dermal junction. These also play an important role in vesicant-related inflammatory and immune responses.

Liemin et al. (2015) conducted a study to show that toxicity resulting from topical mustard exposure is mediated in part by initiating exaggerated host innate immune responses. They used an experimental model of skin exposure to NM and observed the activation of inflammatory dermal macrophages that exacerbate local tissue damage in an inducible nitric oxide synthase (iNOS)-dependent manner. Intervention with a single dose of 25-hydroxyvitamin D3 [25(OH)D] suppressed macrophage-mediated iNOS production, resulting in mitigation of local skin destruction, enhanced tissue repair, protection from marrow depletion, and rescue from severe precipitous wasting. These protective effects were confirmed using pharmacological inhibitors of iNOS. The study proposed the role of the host innate immune system in exacerbating injury following exposure to NM and supported the translation of 25(OH)D in therapeutic use against these chemical agents.

In another study, Alessandro et al. (2015) reported persistent pulmonary injury progressing to fibrosis, accompanied by a macrophage inflammatory response following NM exposure. The appearance of M1 and M2 macrophages in the lung correlated with NM-induced acute injury and the development of fibrosis, suggesting a potential role of these macrophage subpopulations in the pathogenic response to NM. Thus their study demonstrated that proinflammatory/cytotoxic (M1) and antiinflammatory/profibrotic (M2) macrophages accumulate sequentially in the lung after nitrogen mustard exposure. Therefore, for clinical relevance, their study suggested that targeting these macrophage subsets may be useful as a novel therapeutic strategy against NMt-induced lung injury. Lewisite (LEW) is a potent arsenical vesicating CWA used as a terrorist weapon. Ocular tissue is exquisitely sensitive to LEW and exposure can cause devastating corneal lesions. Tewari-Singh et al. (2017) evaluated the pathophysiology of the corneal injury in rabbits following LEW vapor exposure and analyzed the expression of COX-2 (an inducible enzyme expressed in mononuclear phagocytes and neutrophils that is involved in proinflammatory prostaglandin synthesis) and changes in other inflammatory cytokines via cytokine array. Interestingly, LEW exposure caused an increase in the number of blood vessels and inflammatory cells. LEW also caused an increase in the expression levels of COX-2, IL-8, MMP-9, and VEGF, indicating their involvement in LEW-induced inflammation, vesication, and neovascularization.

In conclusion, the results suggest that exposure to blister agents causes a higher risk of opportunistic infections, septicemia, and death following severe suppression of the immune system, especially in the case of lesions and blisters produced by these agents. As alkylating agents, they form covalent linkages with biologically important molecules, resulting in disruption of cell function, especially cell division. As a result, these agents are particularly toxic to rapidly proliferating cells, including neoplastic, lymphoid, and bone marrow cells. However, there is still a paucity of information regarding the long-term immunosuppressive properties of alkylating agents in the setting of battlefield exposure to this agent.

42.6.3 Choking agents

Choking agents, such as phosgene (CG), diphosgene (DP), chlorine, and chloropicrin (PS), act on the pulmonary system causing severe irritation and swelling of the nose, throat, and lungs. These inhalational agents damage the respiratory tract and cause severe pulmonary edema in about 4 h, leading to death. The effects are variable, rapid, or delayed depending on the specific agent (Gift et al., 2008).

Phosgene was first used as a chemical weapon in World War I by Germany and later as an offensive capability by French, American, and British forces. In this conflict, phosgene was often combined with chlorine in liquid-filled shells, so it was difficult to state the number of casualties and deaths attributable solely to phosgene. In military publications, it has been referred to as a choking agent, pulmonary agent, or irritant gas. Since World War I, phosgene has rarely been used by traditional militaries, but the extremist cult Aum Shinrikyo used this agent in an attack against the Japanese journalist Shouko Egawa in 1994. Nowadays, phosgene is primarily used in the polyurethane industry for the production of polymeric isocyanates. Phosgene is also used in the polycarbonate industry and in the manufacture of carbamates and related pesticides, dyes, pharmaceuticals, and isocyanates. Suspected sources of atmospheric phosgene are fugitive emissions, thermal decomposition of chlorinated hydrocarbons, and photooxidation of chloroethylenes. Individuals are most likely to be exposed to phosgene in the workplace during its manufacture, handling, and use. Phosgene is extremely toxic by acute (short-term) inhalation exposure. Severe respiratory effects, including pulmonary edema, pulmonary emphysema, and death have been reported in

humans. Severe ocular irritation and dermal burns may result following eye or skin exposure. Chronic inhalation exposure to phosgene has been shown to result in some tolerance to the acute effects noted in humans, but may also cause irreversible pulmonary changes of emphysema and fibrosis (US Department of Health and Human Services, 1993).

Primarily because of phosgene's early use as a war gas, many exposure studies have been performed over the past 100 years to examine the effects and mode of action of phosgene following a single, acute (less than 24 h) exposure. Many studies have examined the effects of acute phosgene exposure in animals but the human data are limited to case studies following accidental exposures. Most studies were performed in rodents and dogs, with exposure concentrations ranging between 0.5 and 40 ppm (2−160 mg/m^3) and duration intervals ranging from 5 min to 8 h. Acute exposure studies in animals suggest that rodent species may be more susceptible to the edematous effects of phosgene acute exposure than larger species with lower respiratory volumes per body weight such as dogs and humans (Pauluhn, 2006; Pauluhn et al., 2007). Pauluhn et al. (2007) reported that acute phosgene exposure results in increased lung lavage protein, phospholipid content, enzyme levels, number of inflammatory cells, and lethality (LC_{50}). Rats seem to be able to survive approximately threefold higher levels of lung edema than humans (100- vs 30-fold), thus rat responses in short- and long-term assays may still be relevant to humans, even if it is ultimately shown that rats produce higher levels of edema following acute phosgene exposure.

42.6.3.1 Immunotoxicity of choking agents

Acute exposure to phosgene has been shown to result in immunosuppression in animals, as evidenced by an increased susceptibility to in vivo bacterial and tumor cell infections and viral infection as well as decreased in vitro virus-killing and T-cell response (Ehrlich and Burleson, 1991). Selgrade et al. (1989) reported that a single 4-h exposure to phosgene concentrations as low as 0.025 ppm significantly enhanced mortality due to streptococcal infection in mice. Later, Selgrade et al. (1995) administered *Streptococcus zooepidemicus* bacteria via an aerosol spray to the lungs of male Fischer-344 rats immediately after phosgene exposure and measured the subsequent clearance of bacteria. They showed that all phosgene concentrations from 0.1 to 0.5 ppm impaired resistance to bacterial infection and that the immune response is modulated by phosgene exposure. After 4 weeks following exposure, bacterial resistance as well as immune response returned to normal. Yang et al. (1995) also reported a decrease in bacterial clearance in the lungs at 24 h after infection following a single 6-h exposure to phosgene. Yang et al. (1995) also found that if the bacteria are administered 18 h after single phosgene exposures rather than immediately, the clearance is normal, which indicates that recovery from the toxic effect of phosgene is rapid. When inhaled, phosgene either is rapidly hydrolyzed to HCl and CO_2 and exhaled (Schneider and Diller, 1989) or penetrates deep into the lungs and is eliminated by rapid reactions with nucleophilic constituents of the alveolar region (Pauluhn et al., 2007).

As phosgene is electrophilic, it reacts with a wide variety of nucleophiles, including primary and secondary amines, hydroxy groups, and thiols. In addition, it also reacts with macromolecules, such as enzymes, proteins, or other polar phospholipids, resulting in a marked depletion of glutathione (Sciuto et al., 1996) and forms covalent adducts that can interfere with molecular functions. Phosgene interacts with biological molecules through two primary reactions: hydrolysis to hydrochloric acid and acylation reactions. Although the hydrolysis reaction does not contribute much to its clinical effects, the acylation reaction is mainly responsible for the irritant effects on mucous membranes. The acylation reactions occur between highly electrophilic carbon molecules in phosgene and amino, hydroxyl, and sulfhydryl groups on biological molecules. These reactions can result in membrane structural changes, protein denaturation, and depletion of lung glutathione. Acylation reactions with phosphatidylcholine are particularly important as it is a major constituent of pulmonary surfactant and lung tissue membranes. Exposure to phosgene has been shown to increases the alveolar leukotrienes, which are thought to be important mediators of phosgene toxicity to the alveolar−capillary interface. Phosgene exposure also increases lipid peroxidation and free radical formation. These processes may lead to increased arachidonic acid release and leukotriene production. Proinflammatory cytokines, such as interleukin-6, are also found to be substantially higher 4−8 h after phosgene exposure. In addition, studies have shown that postexposure phosphodiesterase activity increases, leading to decreased levels of cyclic AMP. Normal cAMP levels are believed to be important for maintenance of tight junctions between pulmonary endothelial cells and thus for prevention of vascular leakage into the interstitium. Oxygenation and ventilation both suffer, and breathing is dramatically increased.

Schneider and Diller (1989) reported that inhalation of phosgene at high concentrations results in a sequence of events, including an initial bioprotective phase, a symptom-free latent period, and a terminal phase characterized by pulmonary edema. The first is an immediate irritant reaction, likely caused by the hydrolysis of phosgene to hydrochloric acid on mucous membranes, which results in conjunctivitis, lacrimation, and oropharyngeal burning sensations. This symptom complex occurs only in

the presence of high-concentration (>3–4 ppm) exposures but does not have any prognostic value for the timing and severity of later respiratory symptoms. The most important finding to identify during this stage is a laryngeal irritant reaction causing laryngospasm, which may lead to sudden death. The irritant symptoms last only a few minutes and then resolve as long as further exposure to phosgene ceases. The second phase, when clinical signs and symptoms are generally lacking, may last for several hours after phosgene exposure. The duration of the latent phase is an extremely important prognostic factor for the severity of the ensuing pulmonary edema. Patients with a latent phase of less than 4 h have a poor prognosis. Increased physical activity may shorten the duration of the latent phase and worsen the overall clinical course. Unfortunately, there are no reliable physical examination findings during the latent phase to predict its duration. However, histologic examination reveals the beginnings of an edematous swelling, with exudation of blood plasma into the pulmonary interstitium and alveoli. This may result in damage to the alveolar type I cells and a rise in hematocrit. The length of this phase varies inversely with the inhaled dose. The third clinical phase peaks approximately 24 h after an acute exposure and if lethality does not occur, recedes over the next 3–5 days. In the third clinical phase of phosgene toxicity, the accumulating fluid in the lung results in edema. Oxygenation and ventilation both suffer, and the breathing is dramatically increased. Often, positive end expiratory pressure (PEEP) is required to stent open alveoli that would otherwise collapse and result in significant ventilation/perfusion (*V*/*Q*) mismatch. This hyperventilation causes the protein-rich fluid to take on a frothy consistency. A severe edema may result in an increased concentration of hemoglobin in the blood and congestion of the alveolar capillaries.

Increased levels of protein in bronchoalveolar lavage have been shown to be among the most sensitive endpoints characterizing the early, acute effects of phosgene exposure, and are rapidly reduced after the cessation of exposure (Sciuto, 1998; Sciuto et al., 2003). With continuous, chronic, low-level phosgene exposure, there may be transition of edema to persistent cellular inflammation, leading to the synthesis of abnormal type I collagen and pulmonary fibrosis. An increased synthesis of type I relative to type III collagen can lead to chronic fibrosis. Surfactant lipids are important for maintaining alveolar stability and for preventing pulmonary edema. Pauluhn et al. (2007) reported that the induction of surfactant abnormalities following phosgene exposures is a key pathophysiological event leading to pulmonary edema and chronic cellular inflammation, leading to the stimulation of fibroblasts and the synthesis of "abnormal" collagen in pulmonary fibrosis. Ehrlich and Burleson (1991) demonstrated an enhanced and prolonged viral infection using an influenza virus infectivity model in rats on days 3 and 4 following exposure to the toxicant gas phosgene. There are limited studies, in both humans and experimental animals, to evaluate immunotoxicity of chronic low-level environmental exposures to phosgene. The lack of studies examining the effects in humans or laboratory animals from chronic exposure to phosgene is a concern and the sequelae of effects leading to phosgene-induced pulmonary fibrosis is not well understood.

In a study, phosgene toxicity has been shown to stimulate the production of additional mediators of vasoconstriction (e.g., leukotrienes C4, D4, and E4) and suppress mediators of vasodilation (e.g., prostaglandins and cAMP), all of which can occur via ETA/ETB coupled signal transduction. Liberated arachidonic acid is then metabolized by lipoxygenase-producing leukotrines C4, D4, and E4. The release of these cysteinyl leukotrienes (LTC4, LTD4, and LTE4) leads to cellular contraction by stimulating the release of intracellular Ca^{2+} stores. Metabolism of AA can also result in the production of prostaglandins through cyclooxygenase activity, which in turn can stimulate cAMP synthesis inducing vasodilatation. These findings are in agreement with this proposed mechanism of phosgene toxicity, as there is no evidence of altered cyclooxygenase activity and levels of cAMP are diminished following phosgene exposure (Wesley et al., 2016).

Piotr et al. (2015), recently reported that phosgene exposure via an industrial or warfare release produces severe acute lung injury (ALI) with high mortality, characterized by massive pulmonary edema, disruption of epithelial tight junctions, surfactant dysfunction, and oxidative stress. There are no targeted treatments for phosgene-induced ALI. Nitric oxide synthase 2 (NOS-2) is upregulated in the lungs after phosgene exposure. They demonstrated that NOS-2 expression in lung epithelium exacerbates inhaled endotoxin-induced ALI in mice, mediated partially through downregulation of surfactant protein B expression. Therefore, they further conducted a selective NOS-2 inhibitor delivered to the lung epithelium by inhalation that mitigated phosgene-induced ALI. Inhaled phosgene produced increased lung NOS-2 expression at 24 h. Administration of aerosolized 1400W, a selective NOS-2 inhibitor, via inhalation significantly attenuated phosgene-induced ALI and preserved epithelial barrier integrity. They also demonstrated for the first time that NOS-2-derived nitric oxide downregulates the tight junction protein, that is, zonula occludens 1 expression at the transcriptional level in human lung epithelial cells, providing a novel target for ameliorating vascular leak in ALI. Their data demonstrated that lung NOS-2 plays a critical role in the development of phosgene-induced ALI and suggested that aerosolized NOS-2 inhibitors offer a novel therapeutic strategy for its treatment.

42.6.4 Blood agents

Blood agents like arsine, cyanide, and carbon monoxide are rapidly absorbed into the blood, affect its oxygen-carrying capacity, and produce seizures, respiratory failure, and cardiac arrest. Hydrogen cyanide has been known as a potent toxicant for over 200 years. It was used as a CWA during World War I by France. Although it is highly volatile (and was later considered "militarily useless" because of its volatility), no deaths from its military use during World War I were ever reported. After World War II, the importance of hydrogen cyanide as a CWA diminished rapidly, primarily as a result of the rise of nerve agents. Although reduced in importance, there are some reports of hydrogen cyanide being used as a war gas by Vietnamese forces in Thailand territories and during the Iran−Iraq War in the 1980s (Sidell, 1992). Hydrogen cyanide can be detoxified rapidly by humans. It is very volatile and massive amounts of the gas are needed for it to be effective as a CWA.

Cyanide is primarily an environmental contaminant of industrial processes. It is used in the metal-processing industry for electroplating, heat treating, and metal polishing and can be found in waste waters from many mining operations that use cyanide compounds in the extraction of metals, such as gold and silver, from ore. The acute toxicity of cyanide has been well documented in humans and experimental animals. Symptoms of toxicity in humans include headache, breathlessness, weakness, palpitations, nausea, giddiness, and tremors (Gupta et al., 1979). Depending on the degree of intoxication, symptoms may include "metallic" taste, anxiety and/or confusion, headache, vertigo, hyperpnea followed by dyspnea, convulsions, cyanosis, respiratory arrest, bradycardia, and cardiac arrest. Death results from respiratory arrest. Onset is usually rapid. Effects on inhalation of lethal amounts may be observed within 15 s, with death occurring in less than 10 min. Hydrogen cyanide should be suspected in terrorist incidents involving prompt fatalities, especially when the characteristic symptoms of nerve agent intoxication are absent. Chronic exposure to low-level cyanide can result in neuropathies, goiter, and diabetes. Cyanide and derivatives prevent the cells of the body from using oxygen. Cyanide acts by binding to mitochondrial cytochrome oxidase, blocking electron transport, thus inhibiting enzymes in the cytochrome oxidase chain and in turn blocking oxygen use in metabolizing cells and preventing the use of oxygen in cellular metabolism. These chemicals are highly toxic to cells and in high doses may result in death. Cyanide is more harmful to the heart and brain as these organs require large amounts of oxygen.

42.6.4.1 Immunotoxicity of blood agents

There are very few reports on immunotoxicity of blood agents; however, acrylonitrile (vinyl cyanide, VCN), an environmental pollutant which is metabolized to cyanide, has been shown to be an animal and human carcinogen, particularly for the gastrointestinal tract (Mostafa et al., 1999; National Toxicology Program Technical Report Series, 2001). Earlier, Hamada et al. (1998) evaluated the systemic and/or local immunotoxic potential of VCN and demonstrated that VCN induces immunosuppression as evident by a decrease in the plaque-forming cell response to SRBCs, a marked depletion of spleen lymphocyte subsets, as well as bacterial translocation of the normal flora leading to brachial lymph node abscess. These results suggested that VCN has a profound immunosuppressive effect which could be a contributing factor in its gastrointestinal tract carcinogenicity.

Acute exposure to high levels of hydrogen sulfide (H_2S) is life threatening while long-term exposure to ambient levels of H_2S elicits human health effects. In a study by Saeedi et al. (2015), they studied the harmful effects of long-term exposure to low levels of H_2S on human blood cells. In their study, adult workers from Iran who were occupationally exposed from a natural gas processing plants to 0−90 ppb H_2S for 1−30 years were studied. A control group of males who were not in contact with H_2S was also studied. For all participants, hematological profile including total hemoglobin and red blood cell count, sulfhemoglobin and methemoglobin levels were measured. The methemoglobin and sulfhemoglobin levels were significantly higher among workers who were exposed to sulfur compounds than the control group. There was a major difference particularly in sulfhemoglobinemia level among exposed groups. Thus, they have concluded that long-term exposure to even low levels of H_2S in workplaces exhibited both physiological and toxicological roles which may have potential harmful effects on human health.

42.7 Concluding remarks and future directions

CW was on a massive scale during World War I. Chemical weapons are cheap, can cause mass casualties, and are relatively easy to produce, even by developing nations. They were used most recently by Iraq during the Iran−Iraq War, as well as in terrorist attacks. The health effects of chemical weapons on society makes them ideal for terrorism, as shown by the release of nerve gas in the Tokyo subway system by members of the Aum Shinrikyo in 1995. The immune system could be extremely vulnerable to these CWA. As the field of immunotoxicology is developing rapidly, this chapter reviews the impact of CWA on various aspects of the immune system.

The immune response is associated with rapidly multiplying cells and the synthesis of regulatory/effector

molecules and the immune system works as an amplifier for this integrated information network. Immunologic tissue damage can result from activation of the cellular and biochemical systems of the host. The interactions of an antigen with a specific antibody or with effector lymphocytes trigger the sequence of humoral and cellular events to produce the pathophysiologic effects that lead to tissue injury or disease. Stem cells often appear to be sensitive targets for therapeutic and environmental toxicants, most likely because of their rapid proliferation. Certain chemical exposures and doses that do not affect other organs can result in immune dysfunction. Xenobiotics that are toxic to the myelocytes of the bone marrow can cause profound immunosuppression due to loss of stem cells. Humans are now under sustained and increasing pressure from xenobiotic exposure. Xenobiotics can stimulate the immune system as antigens by provoking a substantial immune response. Even mild disturbances of this network could result in detrimental health effects. The influence of the xenobiotics on the immune system could be either suppressive or enhancing. The former leads to immunosuppression with consequent increased susceptibility to infection and cancer. The latter is associated with the development of an autoimmune reactivity such as delayed hypersensitivity, atopy, systemic or organ-specific immunopathology, and granuloma formation. It is likely that the overall immunosuppressive effects of xenobiotics are caused by interference with cellular proliferation and differentiation, downregulation of cytokine signaling, and enhanced apoptosis of immune cells. In contrast, autoimmune reactions are induced by abnormal activation of immune cells followed by dysregulated production of cytokines resulting in harmful inflammatory response (Gulati et al., 2016).

Xenobiotics can act as immunogens to stimulate the production of specific immunoglobulins as a part of an immune response. Specific immunoglobulins might be used as markers of exposure to specific xenobiotics. Attempts must be made to conduct basic research to address the cellular and molecular mechanisms of the immunomodulatory action of various xenobiotics. The newly emerging technologies such as genomics, proteomics, and bioinformatics will certainly be helpful to investigate the interactions between the immune system and xenobiotics in their full complexities. Toxic compounds may be antigenic or act as haptens and can evoke an antibody response. If these antibodies bind to the determinant on the parent molecule which is responsible for causing toxicity, then it can lead to biological inactivation of the parent molecule and thereby prevent toxicity. This may constitute an immunological antidote approach to neutralize the toxicity of certain compounds. Thus, passive administration of the antibodies may be used to prevent the toxic effects of the specific compound, and this approach may be useful in biological or CW to protect against the toxicity of known chemicals or toxins. The antibodies can also be used to protect industrial workers against the toxic effects of known chemicals or gases during accidental exposure. Although this assumption seems logical, it will involve elaborate and time-consuming research to identify the site of the parent molecule responsible for causing toxicity, to chemically link the molecule with a large protein molecule which should be immunogenic but not toxic, and to screen various antibodies raised for their capacity to neutralize or prevent the toxicity of the compound.

As CWAs are a threat to mankind, they have been widely condemned since their first use on a massive scale during World War I. In 1993, the United States signed the Chemical Weapons Treaty, which required the destruction of all chemical weapon agents, dispersal systems, and production facilities by April 2012. The US destroyed 45% of its stockpile of chemical weapons by 2007. As of 2012, stockpiles have been eliminated at seven of the nine chemical weapons depots and 89.75% of the 1997 stockpile had been destroyed by the treaty deadline of April 2012 and the rest was to be destroyed by 2017. The most recent arms control agreement in International Law, the *Convention of the Prohibition of the Development, Production, Stockpiling and Use of Chemical Weapons and on their Destruction*, or the Chemical Weapons Convention, outlaws the production, stockpiling, and use of chemical weapons. It is administered by the Organisation for the Prohibition of Chemical Weapons (OPCW), an intergovernmental organization based in The Hague. However, in early 2007, multiple terrorist bombings had been reported in Iraq using chlorine gas and these attacks wounded or sickened more than 350 people. Thus, in view of the current global scenario, it appears that use of CWAs may continue in different types of warfare as these agents are not only inexpensive but easy to disseminate with the help of unsophisticated devices. Hence the medical profession should assemble on a common platform through globally recognized organizations like the WHO and put in efforts to monitor, research, and study the scientific and medical aspects of CWAs in the interest of humans. There should be updating of guidelines on the prevention and management of CWA-induced insults to reduce morbidity and mortality. Nations worldwide should ensure that adequate supplies of antidotes (wherever available), protective equipment, and decontamination devices are available in adequate quantities and at all times.

The impact of CWAs on the immune system is enormous and CWA exposed individuals are prone to immune system-mediated diseases. Such immunological disorders are growing at epidemic proportions, which requires the development of aggressive and innovative treatment

approaches to cope with such maladies. Developing vaccines, by recognizing the molecular patterns on some xenobiotics, can be a viable approach to tackle the issue and could be the most critical challenge for the research community. In future, more research findings with better data showing the mechanisms of nonimmunologically mediated sensitization, including identification of the cells and mediators involved, is highly recommended. Furthermore, one of the great therapeutic opportunities for the survivors of war is organ transplantation. However, immune system-mediated graft rejection remains the single greatest barrier to widespread use of this approach. In this chapter, the various mechanisms of CWA-induced immunotoxicity are discussed. The effects on different cell types and interference with immune responses, ultimately leading to immunotoxicity as well as sensitizing capacity, are also highlighted. Thus, the need of the hour is a multisectorial approach involving health, defense, agriculture, and environmental specialists, with clearly defined roles of each, for establishing and maintaining effective, robust, and sustainable strategies to counter this threatening situation. Further, physicians and scientists trained in immunotoxicology and environmental health research are needed in the private and academic sectors to help develop expertise in this area. Understanding and perception of risks associated with CWA exposure, especially as related to the immune system, should be fostered through various mechanisms, including the mass media.

Chapter 43

Health effects of nuclear weapons and releases of radioactive materials

Roger O. McClellan
Toxicology and Human Health Risk Analysis, Albuquerque, NM, United States

43.1 Introduction

Humankind and conflict between individuals, that is, warfare, very likely share a common evolution. In the 9th century, the nature of warfare was changed forever when the Chinese invented gun powder. Gun powder could be used to propel projectiles that killed people. Over the centuries a wide range of chemicals were discovered that were increasingly effective in releasing explosive energy. These reactions could be controlled to produce weapons that injured and killed people with projectiles and, yet later, with blast waves. In World War I, the use of explosive weapons was joined by the use of weapons that released chemicals that caused immediate injury and death. Most of the chapters in this textbook are concerned with chemical weapons. This chapter addresses the effect of nuclear weapons and releases of radioactivity. A separate chapter on nuclear weapons and the health effects of blast and ionizing radiation is appropriate in view of their tremendous impact on international politics over the past three-quarters of a century from the end of World War II to the present time.

Warfare, war, and weapons are words that automatically evoke fear and concern. In a similar fashion, the use of the words atomic, nuclear, radiation, and radioactivity, also evoke fear and concern. These words are frequently joined together as in nuclear or atomic weapons or releases of radioactive materials from a nuclear reactor or some other kind of nuclear accident. The fear that these words evoke is grounded in the wide recognition that exposure to ionizing radiation can cause acute injury to living creatures and, with sufficient levels of exposure, cause death in days or weeks. With lower levels of radiation exposure and dose, deaths occur later. At even lower radiation doses, deaths will shorten lifespan with deaths occurring late in life primarily related to an increased incidence of cancers. To provide context, it is important to recognize that cancers are a frequent cause of death, especially late in life, in all mammalian populations. Nonetheless, the word cancer evokes fear and concern.

Concern for the health effects of accidental releases of radioactivity, such as occurred on April 26, 1986, in the reactor accident in Chernobyl, Ukraine and on March 11, 2011, in the Fukushima tsunami incident, led to the evacuation of large populations, thus, adding Chernobyl, Fukushima, and evacuation to the list of words evoking fear. Visual images such as that of a mushroom cloud from a nuclear explosion will also evoke fears.

The level of fear associated with the word radiation is so great that even when radiation is used in a beneficial manner, such as a medical diagnostic procedure or to treat diseases, including treatment of cancer, patients may have concern that potential adverse effects may be greater than the benefits of the radiation-based medical procedure. In some situations, patients may even personally question the advisability of having recommended medical procedures performed that are identified as involving radiation.

The power of the words, atomic, nuclear, radiation, and radioactivity, is such that they are sometimes purposefully used to create fear and concern. I submit that opponents of the use of nuclear reactors to generate electrical power have sometimes used these words to create concern for the use of nuclear reactors. Indeed, in some instances opponents of nuclear-generated electrical power have purposefully equated nuclear reactors with nuclear weapons, although they are vastly different potential sources of radiation exposure. In some circumstances, the intent of some individuals is to arouse fear and concern even in the absence of any radiation exposure or with radiation exposures that are unlikely to produce adverse health effects. It is apparent that fear alone, in the absence

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00043-X

of physical harm, is a potent weapon. I am sure this fact is well known to terrorists.

In recent years, increased use has been made of the phrase—weapons of mass destruction. This includes nuclear weapons. Indeed, nuclear weapons are widely regarded as the premier weapon system for causing massive destruction and numerous casualties and deaths, as occurred with the bombings of Hiroshima and Nagasaki, Japan, with nuclear bombs. This destructive capability relates to four components of an explosion of a nuclear weapon: (1) blast or overpressure, (2) thermal radiation, (3) direct ionizing radiation, and (4) residual radioactivity that may be transported meteorologically downwind of the site of the nuclear explosion. It is remarkable that concern for nuclear weapons most frequently focuses on the health effects of direct exposure to ionizing radiation from weapons and residual radioactivity. This chapter appropriately notes the substantial health effects of blast and thermal radiation releases in causing massive injuries and mortality.

This chapter starts with some basic concepts and definitions, and then proceeds with a historical review of key events and activities related to the development of our current extensive knowledge of ionizing radiation and its health effects. This will include the period from Wilhelm Conrad Roentgen's discovery in 1895 of X-rays to 1940, an era which was dominated by the increasing use of radiation in medicine. The second era, beginning in 1940, is anchored by the discovery of new elements such as plutonium, and the development and detonation of the first nuclear weapons. Over the last three-quarters of a century, from 1945 to the present, there has been a marked expansion of the use of radiation in medicine, the development and use of nuclear reactors globally to generate electricity, the use of nuclear reactors to power naval vessels, and the development and stockpiling of enhanced nuclear weapons by many nations.

The development of new applications of nuclear radiation in society was accompanied by substantial research on its adverse health effects. This new science was used to inform judgments on standards and regulations to limit occupational and environmental exposures to radiation and radioactivity. Over the past century no potentially hazardous agent has been more extensively studied than ionizing radiation. In my opinion, our level of scientific knowledge of the short- and long-term health effects of exposure to ionizing radiation from external sources or internally deposited radionuclides exceeds our knowledge of the hazardous properties of any other agent or class of agents used by society. Radiation standards and regulations used around the world to limit the exposure of workers and the public are based on a huge body of scientific knowledge.

43.2 Conceptual framework

Hazard and risk are two other words used frequently in this chapter and elsewhere in this textbook. Unfortunately, hazard and risk have frequently been used interchangeably over the past 50 years, especially in the United States, although they have come to have distinctly different definitions. A hazard is any agent or circumstance that has the potential for causing damage, harm, or adverse health effects to someone or something. Hazard is a French word that was probably borrowed from Arabic "az-zahr" meaning "the dice" or "one of the dice." In conventional practice an agent may be classified as hazardous or of causing a specific hazard, such as cancer, without reference to any particular exposure. In contrast, risk is defined as the probability of a particular kind of harm, such as death or occurrence of cancer, from a particular exposure circumstance.

A conceptual background for this chapter is provided in Figs. 43.1–43.3. The risk characterization paradigm

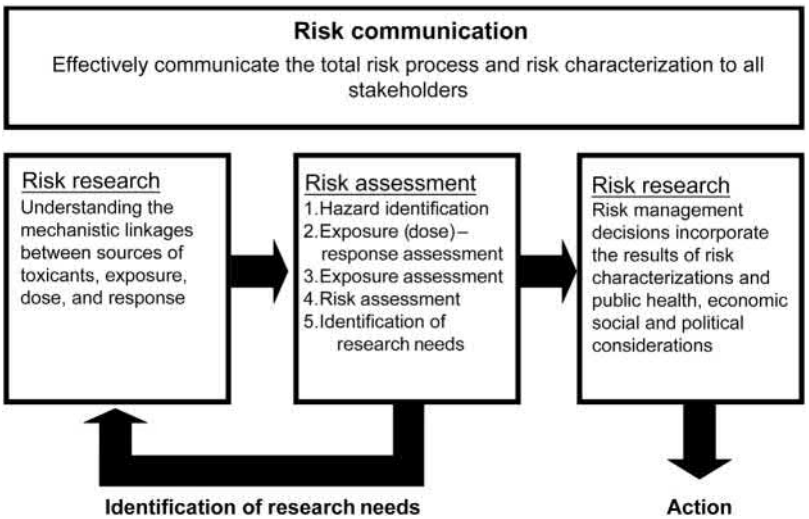

FIGURE 43.1 The risk paradigm that is widely used around the world.

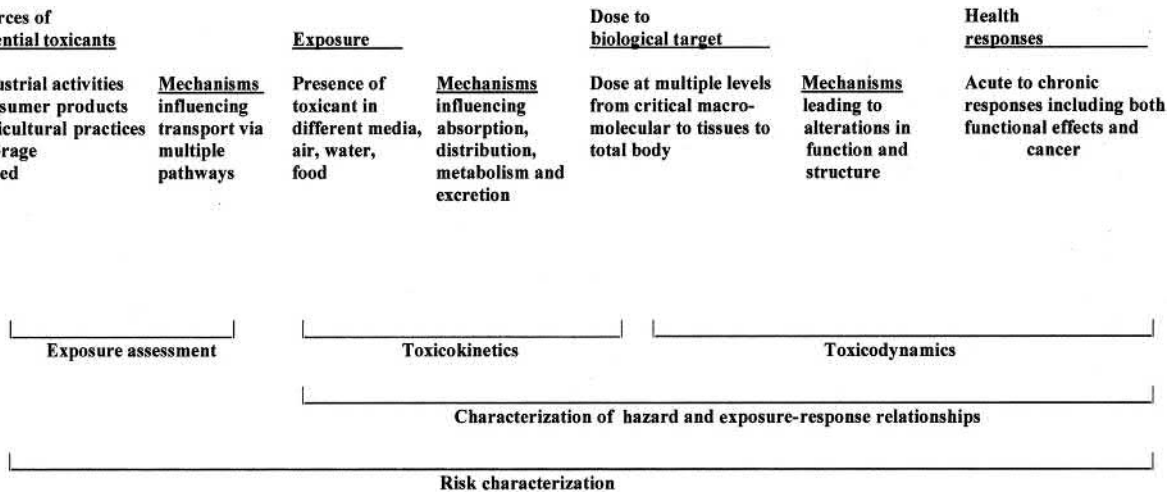

FIGURE 43.2 An expanded risk characterization paradigm.

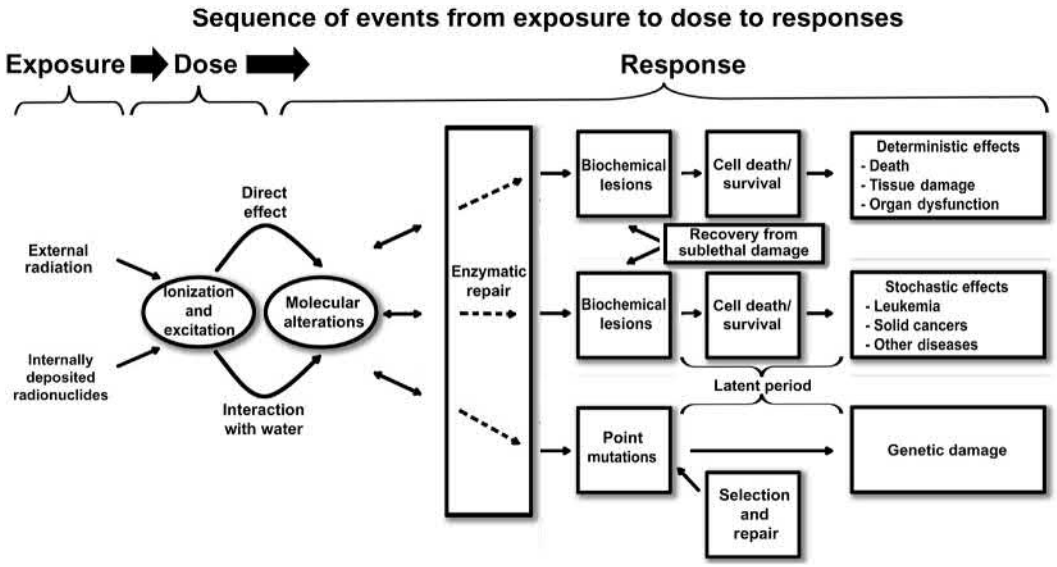

FIGURE 43.3 Conceptual framework linking events from exposure to external sources or internally deposited radioactivity to dose to biological responses. *Adapted from Bushong, S.C., 2017. Radiological Science for Technologists: Physics, Biology and Protection. eleventh ed. 688 pgs, St. Louis, MO: Elsevier/Mosby.*

shown in Fig. 43.1 can be used for all kinds of potentially hazardous agents; it is not unique to radiation. Indeed, I postulate that research on the health effects of ionizing radiation has been a major contributor to the development of the risk paradigm (McClellan, 1999, 2014, 2019).

An expanded risk characterization paradigm is shown in Fig. 43.2, extending from sources of potential toxicants such as ionizing radiation and radioactive materials to health responses. In the world of chemicals, exposure and dose are frequently used interchangeably, which is inappropriate. With ionizing radiation and radioactive materials, the distinction between exposure and dose is well known and clearly illustrated in Fig. 43.2. Additional detail is provided in Fig. 43.3. In recent decades, increased attention has appropriately been given to mechanisms or modes of action of toxicants. This concept has been ingrained in the radiation sciences since soon after the harmful effects of ionizing radiation were discovered. It is often not fully appreciated that mechanistic considerations relate both to the linkage (1) between exposures and dose, that is, toxicokinetics, and (2) between dose and health response, that is, toxicodynamics. I have used toxicokinetics and toxicodynamics deliberately, rather than pharmacokinetics or pharmacodynamics, as I believe these latter terms should be used only for pharmaceuticals.

We all live, play, and work in a world of hazardous agents and circumstances that if not properly controlled can produce health effects over and above those occurring from natural circumstances. Moreover, endogenous events in the absence of external factors such as exposure to radiation or chemicals can cause cancer. To state the obvious, birth is ultimately followed by death and the questions are when death will occur and from what causes. The disease processes and diseases that occur in life are rarely unique to any agent, including radiation.

It is important to recognize that exposure to different agents may cause the same kinds of disease. For diseases occurring soon after exposure to a hazardous agent, the causative nature of the radiation—effect relationship may be circumstantial and quite clear. Identifying a causal linkage between exposure to a hazardous agent and a disease, such as cancer occurring late in life, becomes much more challenging. Indeed, many diseases, such as cancers, are multifactorial in their origin. Thus, a critical issue for many situations is the extent to which there is an excess of disease associated with exposure to a specific agent or circumstance, such as ionizing radiation, relative to a background incidence occurring naturally and unknown etiology.

43.3 Nomenclature

Some key definitions are provided in Table 43.1 for words and phrases regularly used in radiation science and used throughout this chapter.

A concise summary of key units used in radiation science and radiation protection schemes is provided in Table 43.2. The earliest units, shown as old units in the table, are sometimes referred to as conventional units. These have been superseded by the newer International System of Units first developed and used in Europe and more slowly accepted in the United States. In general, when referencing previously published research findings, I will use the units used by the original authors. The reader should be mindful that different prefixes are used,

TABLE 43.1 Key definitions in radiation science and the effects of radiation on health.

Alpha particles	A charged particle consisting of two protons and two neutrons bound together into a particle identical to a helium-4 nucleus
Beta particles	A charged particle of very small mass emitted spontaneously from the nuclei of certain radioactive elements. Physically, a beta particle is identical to an electron moving at high velocity
Blast wave	A rapid change in atmospheric pressure followed by negative pressure. It travels faster than sound
Elements	One of the distinct, basic varieties of matter occurring in nature
Fission	Electromagnetic radiation of variable energy originating in atomic nuclei. Physically, X-rays and gamma-rays are identical.
	The process whereby the nucleus of a particular heavy element following absorption of a neutron splits into two nuclei of lighter elements with release of substantial energy. Controlled and sustained fission occurs in a nuclear reactor. Fission of Pu^{239} and U^{235} is a key component of the detonation of nuclear weapons
Fusion	The process whereby the nuclei of lighter elements, especially those of hydrogen (deuterium and tritium), combine to form the nucleus of heavier elements with the release of substantial energy. A thermonuclear weapon involves fission followed by fusion
Gamma-rays	Electromagnetic radiation of variable energy originating in atomic nuclei. Physically, X-rays and gamma-rays are identical
Isotopes	Forms of the same element having identical chemical properties but differing in atomic mass (due to different numbers of neutrons in their respective nuclei) and nuclear properties (radioactivity)
Nuclide	An atomic species of an element distinguished by the composition of its nucleus, that is, the number of protons and neutrons
Radioactive half-Life	The time required for the activity of a given radionuclide to decrease to half its initial value due to radioactive decay
Radionuclide or radioisotope	An isotope or nuclide that is unstable and will spontaneously decay by emission of alpha or beta particles
Thermal radiation	Steep thermal gradient of energy released in a nuclear explosion
Transmutation	Conversion of one chemical element into another electro-magnetic radiation of variable energy produced by slowing down fast electrons. X-rays can penetrate the body and be absorbed or pass through the body
X-rays	

TABLE 43.2 International units for radiation and radioactivity compared to old units.

International Units	Describes	Old units
Becquerel (Bq)	Radioactivity, the spontaneous decay of atomic nuclei 1 Bq = 1 disintegration/second	Curie = 3.7
		$X10^{10}$ Bq
Gray (Gy)	Dose to tissue 1 Gy = energy uptake of 1 joule/kilogram	Rad = 10 mGy
Sievert (Sv)	Effective dose,[a] dose normalized to effects of gamma radiation by applying a radiation weighting factor (WR) based on the relative biological effectiveness (RBE) of the radiation of interest, to the absorbed dose in an organ or tissue to derive the equivalent dose. The effective dose is usually expressed as millisievert (mSv) 1 mSv = 10^{-3} Sv	Rem[b] = 10 mSv

[a] *Allows conversion of dose from gamma, beta, or alpha radiation to a standard unit.*
[b] *Rem, originally based on Roentgen Equivalent Man.*

such as with Curies or Becquerels, to span many orders of magnitude from micro to milli levels of the base unit. I submit that sometimes authors express the potency of radiation exposure using micro or milli levels of the base unit to exaggerate the apparent potency of the exposure.

43.4 Sources of radiation dose

In considering the potential exposure from any specific incident, it is important to recognize that we all live in a sea of radiation from both natural sources and human activity (Table 43.3). It may be noted that about half of the radiation dose for a member of the US public comes from background and about half from anthropogenic sources. It is important to recognize that radiation exposures are readily measurable. Likewise, the radioactive content of samples is readily measurable. It is important to emphasize that the mere measurement of radiation exposures or the radioactive content of a sample does not directly equate to a health risk.

43.5 Key early events in radiation science

Key early events in the field of radiation science, including those resulting in evidence of radiation-induced health effects, have been well documented. Book chapters I authored provide a succinct review of the subject (McClellan, 2014, 2019). Thus, for this chapter, I will only provide a summary of some of the key events relevant to considering the health effects of nuclear weapons and potential releases of radioactive materials.

Wilhelm Conrad Roentgen, in 1895, discovered a new kind of ray emitted by a gas discharge tube that could blacken photographic film. Because the rays represented the unknown, he called them X-rays. X-rays were soon used diagnostically in medicine and therapeutically to treat cancer. Both diagnostic and therapeutic applications of radiation are an integral part of the practice of modern medicine.

In 1896, Antoine Henri Becquerel discovered radiation emissions from uranium compounds. In 1898, Pierre and Marie Curie isolated polonium and radium from pitchblende ore containing uranium and its decay products. They coined the term radioactivity to describe these materials and to distinguish them from radiation emissions.

The pitchblende ore and uranium from many of these early experiments came from mines in Schneeberg and Joachimstal in the Erz Mountains of Central Europe. As early as the 1400s, it was known that miners in this district frequently developed a chronic respiratory malady. In 1879, the German investigators Härtung and Hesse showed that a majority of the deaths of these miners were due to lung cancer. In the 1940s, this experience would unfortunately be repeated with observation of an excess of lung cancer in uranium miners, especially those who also smoked, working on the western slope of the Rocky Mountains in the United States. One of the benchmark effects of exposure to ionizing radiation was established—alpha particle irradiation of the bronchial epithelium causes an excess of lung cancer.

In the early 1900s, it was discovered that trace quantities of radium and thorium salts could be mixed with phosphors which resulted in phosphorescence. Soon, young women were employed to paint luminous watch and instrument dials. They tipped the fine brushes on their lips and subsequently ingested radium and thorium. Many of these women died from acute injury to their bones and hematopoietic tissues. Others survived this acute injury only to die later from cancer. A recent book, *The Radium Girls*, provides vivid descriptions of working conditions and health outcomes in that time period (Moore, 2016). Thus, another benchmark effect of ionizing radiation was established—alpha particle irradiation of the skeleton and bone marrow causes bone cancer and leukemia.

TABLE 43.3 Relative contribution of different radiation sources to the average radiation dose received by the US public for 2006.

Background	Millisieverts (mSv)	Percent
• Space radiation	0.31	5
• Internal radionuclides	0.31	5
• Terrestrial dose	0.19	3
• Radon and thoron	2.29	37
Background	3.10	
Anthropogenic		
• Computer tomography (CT)	1.49	24
• Nuclear medicine	0.74	12
• Interventional fluoroscopy	0.43	7
• Conventional radiography/fluoroscopy	0.31	5
• Consumer products	0.12	2
• Occupational	<0.1	<0.1
• Industrial	<0.1	<0.1
Anthropogenic	3.10	

Source: Data from National Council on Radiation Protection and Measurements (NCRP) Report 160, Ionizing Radiation Exposure of the Population of the United States (2009).

By the 1920s, it was apparent that exposure to high doses of X-rays or gamma rays could cause acute injury to multiple tissues and with sufficiently high doses with extended periods of observation, an excess of cancer was observed, a third benchmark situation for radiation-induced disease.

On the eve of World War II, Paul S. Henshaw, on the staff of the only recently created US National Cancer Institute, published a seminal paper that summarized the then current knowledge on radiation effects. It identified multiple effects that could be grouped as shown in Fig. 43.4. Most significantly, it postulated that two fundamentally different dose–response relationships were operative for radiation-induced effects (Fig. 43.5).

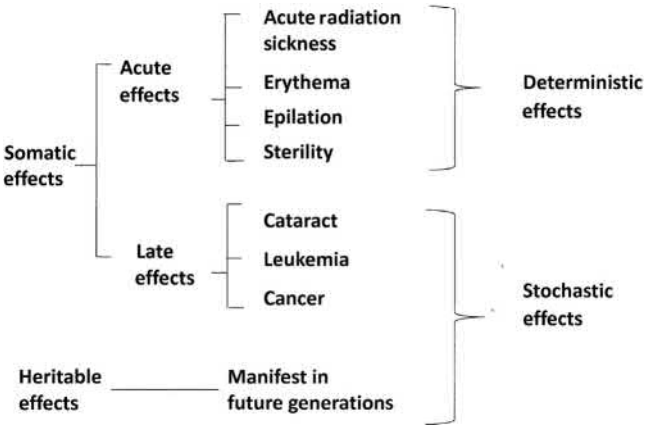

FIGURE 43.4 Major health effects of exposure to ionizing radiation.

43.6 Historical overview of radiation protection standards

Very soon after the discovery of radiation and radioactivity and recognition that radiation could cause harmful effects, action was taken to develop guidance to limit adverse health effects in people using radiation and radioactivity. I have discussed these activities in some detail in a book chapter (McClellan, 2014). To provide context for this chapter, I will briefly review those activities here.

The first radiation protection activities were voluntary and involved defining levels of exposure to X-rays that could or would not harm the skin; in short, the identification of a threshold dose for producing erythema. In 1902, Rollins proposed a specific tolerance dose—"if a photographic plate is not fogged in 7 min the radiation is not of harmful intensity." This represented the first association of an exposure or dose metric with a health outcome. It also represented a joining of the physical sciences with medical science and practice. This was an era in which

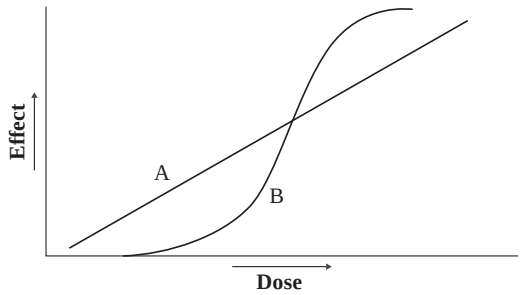

FIGURE 43.5 Schematic rendering of two fundamentally different dose–response relationships for radiation. A—a linear nonthreshold relationship (stochastic) and B—threshold (deterministic) relationship. *Adapted from Henshaw, P.S., 1941. Biologic significance of the tolerance dose in x-ray and radium protection. J. Natl. Cancer Inst. 1, 789–805.*

the disciplines of medical physics and radiological physics were developing with individuals in these disciplines applying their expertise to medical issues. The British took a lead role in developing radiation protection guidance, and in 1925 radiologists and medical physicists convened at the First International Congress of Radiology in London. A second congress followed in 1928 in Stockholm. The radiation protection programs that originated at those meetings evolved into what is now known as the International Commission on Radiological Protection (ICRP) that continues today as a self-governing entity.

An employee of the US National Bureau of Standards, Lauriston Taylor, attended the 1928 Stockholm Congress. He brought back to the United States the radiation protection criteria that had been agreed to at the Stockholm Congress. Taylor soon organized a US Advisory Committee on X-ray and Radium Protection under the auspices of the US Bureau of Standards. This would evolve into the National Council on Radiation Protection and Measurements (NCRP), an independent nonprofit entity that operates under a US Congressional Charter given in 1964. It is governed by a self-elected Council of 60 individuals. The author served on the NCRP Council from 1971 to 2001 and is now a Distinguished Emeritus Member.

The ICRP and the NCRP have both issued numerous reports on radiation protection matters. These reports, in turn, have provided guidance to government agencies, both international and national, for the development of government-authorized standards, regulations, and guidance. It is also appropriate to note three other organizations that have influenced radiation protection guidance. One of these is the United Nations Scientific Committee on Effects of Atomic Radiation (UNSCEAR) that periodically issues reports on various aspects of the health effects of radiation. A second is the International Atomic Energy Agency (IAEA) that operates at the interface of science and policy. The third entity is the US National Academies of Science, Engineering and Medicine (NASEM) subunit, the National Research Council (NRC), that has sponsored various committees such as the Committee on Biological Effects of Ionizing Radiation (BIER). The BEIR reports have had a substantial influence on US government policy and standards dealing with radiation matters.

43.7 Discovery of fission changed the world

Let me turn to the events that triggered a second era in the radiation sciences. In December 1938, German chemists Otto Hahn and Fritz Strassmann sent a manuscript to Natnwissenschaften (Hahn and Strassmann, 1939) reporting they had detected the much lighter element, barium, after bombarding uranium with neutrons. They shared these results by mail with Lisa Meitner, who had lost her German citizenship because of her Jewish lineage and moved to Sweden. Her nephew, Otto Frisch, was visiting with her over the holidays at the end of 1938. Meitner and Frisch (1939) correctly interpreted the findings as nuclear fission, a splitting of the atom. Frisch, who had shifted his interests to biology, proposed calling the process fission as an analogy to binary fission in biological cells and the resulting fission products were called daughter products. The discovery of fission was key to the subsequent development of atomic or nuclear bombs that first used fission and later fission followed by fusion. Nuclear fission was soon verified by an American scientist, Phillip H. Abelson (1939), working at the University of California-Berkeley.

In December 1940, Glenn Seaborg and his colleagues used the cyclotron invented and built by Ernest Lawrence at the University of California-Berkeley, to produce a new element, plutonium, and soon thereafter nine other new elements. It was quickly determined that ^{239}Pu could fission and, thus, it was postulated it could be used to fuel a nuclear bomb. It was already recognized that naturally occurring ^{235}U could be used to fuel an atomic bomb.

In the buildup to World War II, the United States created the Office of Scientific Research and Development to coordinate research aligned with national defense. One of the projects it sponsored was Enrico Fermi's research to demonstrate that a self-sustaining chain reaction of nuclear fission in natural uranium could be produced and the uranium transmutated to higher atomic number elements such as Pu. On December 2, 1942, Fermi and his team, working at the University of Chicago, demonstrated that a sustained chain reaction yielding neutrons could be produced in a uranium pile with carbon black moderation with the reaction stopped by introducing a neutron-absorbing material such as boron.

43.8 The Manhattan Project

In early 1943, the responsibilities of the Office of Scientific Research and Development were transferred to the US Army Corp of Engineers with a new secret entity created, the Manhattan Project. It was headed by Major Andrew Groves, who would soon be promoted to General. A review of the details of the Manhattan Project is beyond the scope of this chapter. Suffice it to note that (1) a new laboratory was created at Los Alamos, NM, to design and build nuclear bombs, (2) new facilities were constructed at Hanford, WA, including water-cooled graphite-moderated reactors to produce ^{239}Pu from uranium and specialized separation facilities to separate ^{239}Pu from the residual uranium and fission products, and (3) new facilities were constructed at Oak Ridge, TN, to produce ^{235}U. Basic research and development activities continued at the University of California-Berkeley and University of Chicago and other institutions were engaged to meet specific needs.

Safety was of paramount concern at all the sites and was heightened by the construction and use of facilities never built before, such as nuclear reactors, specialized chemical separations facilities, and the handling of newly discovered elements such as Pu. Glenn Seaborg told me that when he isolated weighable quantities of Pu he was aware of the experience of the radium dial painters developing bone cancer. He shipped an aliquot of the ^{239}Pu to his colleague, Joe Hamilton, at the University of California-Berkeley, to investigate the toxicity of the new material. A new field of science was initiated.

43.9 The tolerance dose

Each of the Manhattan Project sites faced unique radiation protection issues. Hence, it is not surprising that each of the sites developed specific guidance to protect its workers and the public. The document for the Hanford site was developed beginning in the fall of 1943 by Seymour Cantril, a physician oncologist, knowledgeable of using radiation in cancer therapy, and Herbert M. Parker, a British-trained medical physicist experienced in the use of radiation in cancer therapy. In developing the document, Cantril and Parker drew heavily on the guidance of the ICRP and the US Advisory Committee on X-ray and Radiation Protection, which would later become the NCRP. They also made use of the Henshaw (1941) paper, including the phrase "the tolerance dose," which he used in the title of his paper. Their goal was to release the document before start-up of the first Hanford reactor and the first processing of irradiated fuel. However, publication of the document entitled "The Tolerance Dose" was delayed due to security concerns; it was published on January 5, 1944 (Cantril and Parker, 1945). Key excerpts from the document are quoted below.

"In reviewing the subject of tolerance dose, it is most striking that animal experimental evidence has played practically no part in arriving at present day levels. In summary, there are only three tolerance levels, which have been established and accepted as a working basis for occupational exposure.

0.1 r per day for external X and gamma radiation
-1×10^{-14} curie/cc for radon in the air of working rooms
0.1 μg of radium as the maximum allowable amount deposited in the body of a radium dial painter

Each of these levels has been established by adding a safety factor to the amount, which has been known to produce lasting injury to persons so exposed. It is of interest also to note that in each case the factor does not exceed 10, and is more likely considerably less than 10. Human misfortune rather than animal experimentation were the basis for these levels."

The emphasis on the use of human data, when they are available, as noted in 1945, continues to the present time. Data from experiments with laboratory animals designed and conducted in a purposeful manner have a supporting role. The same may be noted for observations from the use of in vitro systems.

43.10 The first nuclear weapons

On September 26, 1944, the 100-B reactor at Hanford went critical under the watchful eye of Enrico Fermi and was soon producing grams and then kilograms of Pu-239. The 100-B reactor was a 36-foot cube of carbon with transverse channels to hold the uranium fuel slugs and cool the reactor with purified cold Columbia River water. In December 1944, green irradiated nuclear fuel rods were processed at Hanford using the methods developed by Glenn Seaborg and colleagues at the University of Chicago. This was accomplished in large canyon-like buildings about 800 ft in length. Workers called them the "Queen Marys." The first shipment of Pu-239 for use in a bomb was sent from Hanford to Los Alamos in early 1945. Soon the Oak Ridge facility was shipping kilogram quantities of U-235 to Los Alamos.

The bomb design and fabrication activities at Los Alamos came to a crescendo in the summer of 1945. On July 16, 1945, at the Trinity Site in central New Mexico, the first atomic bomb with Pu-239 as the fissile material was tested on a tower under the watchful eye of Robert Oppenheimer, who came from the University of California at Berkeley, to head the bomb design and fabrication team at Los Alamos. On viewing the nuclear explosion, Oppenheimer was reported to have quoted a passage from Bhagavad Gita: "If the radiance of a thousand suns were to burst at once into the sky, that would

be like the splendor of the Mighty One.... I am become death, the shatter of worlds." The world would never be the same!

It is noteworthy that downwind of the Trinity detonation, some cattle, sheep, and burros were grazing. Within weeks, the backs of some of the dark-skinned Hereford cattle and burros were showing white spots, a result of beta burns from radioactive fallout particles. Soon the US government bought some of the cattle and burros and shipped them to Los Alamos and Oak Ridge for observation. This is probably the first government indemnification program related to nuclear activities. It is not known if any observations of whole-body radioactivity were made on the Los Alamos officials who likely enjoyed steaks from the slaughtered cows. It would be a few years before the first whole-body counter to measure body burdens of radioactivity would be developed. It is known that the burros enjoyed long lives in Tennessee and when necropsied decades later by the late Clarence Lushbaugh were found to be free of cancer, an unexpected finding.

On August 6, 1945, a previously untested U-235 fueled bomb, called "Little Boy" was detonated over Hiroshima, Japan. On August 9, 1945, a Pu-239 fueled bomb, called "Fat Man," similar to the device tested at the Trinity Site, was detonated over Nagasaki, Japan. Within a very short period of time Japan surrendered, ending World War II.

It is noteworthy that shortly after the atomic bombs were dropped on the Japanese cities the workers at Hanford were informed of the role of Hanford and workers were thanked for their special efforts with letters from the US Secretary of War and the President of DuPont, the prime contractor at Hanford. Special note was made of the unique facilities and safe work practices. As an aside, DuPont had been selected as the prime contractor at Hanford based on its unique experience designing, constructing, and operating facilities producing chemical explosives.

43.11 Post-World War II nuclear weapons development and testing

After World War II, the United States continued to develop, manufacture, and test nuclear weapons. On July 1 and 25, 1946, the US detonated nuclear fission bombs in "Operation Crossroads" conducted at Bikini Atoll in the Pacific.

On January 1, 1947, the activities of the Manhattan Project were shifted to a newly created civilian agency, the US Atomic Energy Commission. Ostensibly, this was a shift from military to civilian control of nuclear weapons and nuclear energy. The history of the AEC has been reviewed in depth by Hewlett and Anderson (1962) and Hewlett and Duncan (1969). In 1974, the AEC activities related to commercial reactor development were transferred to a newly created entity, the US Nuclear Regulatory Commission. Other AEC activities were continued under the Energy Research and Development Administration (ERDA). In 1977, ERDA became the US Department of Energy.

As World War II came to a close, the Union of Soviet Socialist Republics (USSR) accelerated its effects to develop atomic bombs. This included development of ^{239}Pu-producing facilities at Mayak, Russia, that were very similar to those developed at Hanford. On August 29, 1949, the USSR detonated a "Fat Man" type, ^{239}Pu-fueled bomb. The nuclear arms race was on and accelerating!

Soon other nations joined the race, which continues to the present time with large stockpiles created of both fission and fusion bombs with potential for delivery by aircraft, naval vessels from silos, or from ground-based mobile units. These are frequently referred to as the nuclear triad. Nuclear testing activities by the United States continued in the South Pacific. Later tests were also conducted at a special test site in Nevada. There were both surface and underground detonations. By early 1962, the US had conducted about 1000 tests of nuclear weapons. The United Kingdom conducted nuclear tests in Australia, the French in North Africa and the Pacific, the USSR in north central Asia, and later, India would conduct underground nuclear tests on the Indian subcontinent, China would detonate multiple devices in northern China, and North Korea would conduct underground tests.

After a brief tacit moratorium on testing in 1958–61, the USSR resumed testing. The United States followed suit with a series of 31 tests (Operation Dominic) in 1962 in the South Pacific. Those 31 tests had a total yield of 38.1 megatons. On May 6, 1962, a nuclear-powered submarine, the USS Ethan Allen, as a part of Operation Dominic in a test code named Frigate Bird, fired a nuclear warhead-armed Polaris ballistic missile from its location south of Hawaii toward Johnston Island in the South Pacific. The reentry vehicle traveled 1200 miles in 12.5 min. The fission/fusion weapon, 18 in. in diameter, 46.6 in. long, and weighing 717 pounds was detonated in the air at 11,000 ft, releasing about 600 kt of energy. For comparison, the atomic bomb dropped on Hiroshima was estimated to have released 16 kt of energy. I encourage readers to view on the internet videos of the detonation taken from a submarine located about 30 km from the detonation. The explosion was awesome! It should be noted that many nuclear devices and missile delivery systems have been tested independently. Frigate Bird is the only test of an integrated system from launch to detonation. A crew member on the Ethan Allen related: "the detonation was right on target in the old pickle barrel just as planned."

The Frigate Bird weapon had a yield to weight ratio of 1.84 kt/kg. It has been reported that some nuclear weapons have yield to weight ratios on the order of 5.0 kt/kg. It is apparent that weapons with enormous destructive power can be delivered to targets anywhere in the world. It is difficult for me to envision a "small nuclear weapon" that will not have a devastating impact on a substantial area around a target.

The use of nuclear systems extended into space in the 1960s. The US initiated a program to develop Space Nuclear Auxiliary Power (SNAP) systems. This included the use of nuclear reactors and radionuclides to generate electrical power. ^{238}Pu was quickly identified as the radionuclide thermal source of choice. The configuration of the ^{238}Pu fuel was changed after one SNAP device (9A) failed to achieve orbit and burned up over Africa. These radionuclide- fueled SNAP units are still being used. The Soviet effort using nuclear reactors to generate electrical power was apparently discontinued after one failed and burned up over Canada.

43.12 Contemporary nuclear activities

In mid-2019, it became apparent that Russia was developing and testing a nuclear-powered missile that could carry a nuclear weapon. The program became public when an accident releasing radioactivity occurred. The US had conducted a similar program centered at Los Alamos in the 1960s and 1970s. However, that program was discontinued before a nuclear-propelled rocket was fully developed and tested.

Public media reports indicate that Iran is continuing to pursue the development of ^{235}U-fueled nuclear weapons and North Korea has continued to develop and test ^{239}Pu-fueled nuclear weapons. What was once called a nuclear arms race is now best described as an on-going nuclear weapons political brawl!

In addition to the existence of stockpiles of nuclear weapons containing ^{239}Pu and ^{235}U, substantial quantities of fission products and uranium from reprocessing of spent fuel from nuclear reactors exists. In addition, in the United States there are substantial amounts of spent irradiated fuel assemblies that have not been processed and are in interim storage. This situation exists because in the administration of President Jimmy Carter a decision was made that the United States would discontinue the reprocessing of spent nuclear fuel.

It is also noteworthy that a number of nuclear-powered naval vessels have been built over the decades. The concept of using a nuclear reactor to propel submarines was first advanced by Phillip Abelson (Abelson and Abelson, 2007) and soon embraced by Admiral Rickover. Some have also been deactivated. In accord with international agreements, the decommissioned nuclear reactors containing spent nuclear fuel are stored above ground so they are readily visible for observation from space for accountability purposes. A discerning eye can observe many of these units above ground at Hanford in what I call "Admiral Rickover's Graveyard" in homage to the individual who provided leadership for decades for the US Nuclear Navy. Earlier I made reference to the nuclear-powered submarine, the USS Ethan Allen. It was launched on November 22, 1960, and commissioned on August 8, 1961. In the 1980s, in accord with international agreements, its Polaris missile-launching capabilities were deactivated. It was decommissioned at Bremerton, WA, on March 31, 1983, and recycling was completed on July 30, 1999. A part of its hull containing reactor components is now visible at Hanford, WA.

43.13 Blast and thermal effects of nuclear weapons

As I have already noted, the detonation of a nuclear weapon results in release of extraordinary amounts of energy in four forms: (1) thermal energy, (2) blast wave, (3) direct emissions of ionizing radiation as gamma rays and neutrons, and (4) radioactive elements that can be transported downwind of the explosion. It is very fortunate that only two nuclear weapons have been used in war, that is, the bombings of Hiroshima and Nagasaki, Japan, which resulted in thousands of deaths. As will be discussed later, some of the populations of those cities who survived the bombing have been studied extensively. These studies are on-going with support from the governments of Japan and the United States. A description of those activities, *Song Among the Ruins*, was authored by one of the major scientific participants, W.J. Schull (1990).

Since the bombings of Hiroshima and Nagasaki, numerous nuclear weapons have been exploded for test purposes. Several of the nuclear weapons tests resulted in inadvertent exposure of very small populations that have been studied (Conrad et al., 1980). The vast majority of nuclear weapons tested yielded large amounts of physical measurements on the destructive effectiveness of the weapons—it is huge! Radioactive materials formed in the nuclear explosions have been injected into the atmosphere, transported around the world, and studied extensively. A discussion of the results of that research is beyond the scope of this chapter.

This section focuses on the effects of the blast waves produced by nuclear explosions and the direct thermal radiation emissions. Few scientists today are knowledgeable of these effects, even scientists who have spent a career in the radiation field. Ignoring these devastating effects will not make them go away; they are a reality for nuclear weapons!

As one might surmise, a substantial amount of the literature on the effects of nuclear weapons is classified and, thus, not available to the public. However, a nonclassified document, *The Effects of Nuclear Weapons*, was compiled and edited by Samuel Glasstone and Philip J. Dolan (1977). Although the document was published over four decades ago, I have been informed by experts on this specialized subject that the basic concepts presented in 1977 are still highly relevant. It is appropriate to note that the first edition of the nuclear weapons effects document was published in 1950 when the explosive yields of the fission bombs available at that time were equivalent to some thousands of tons (i.e., kilotons) of TNT. By 1957, when a second edition was released, thermonuclear (fusion) weapons had been developed and tested with energy yields in the range of millions of tons (i.e., megatons) of TNT. To provide perspective, a kiloton explosion releases 10^{12} calories of explosive energy. This is equivalent to 3.97×10^9 British Thermal Units of energy.

For the purposes of this chapter it is sufficient to note that the energy yield of every nuclear weapon is specific to that weapon. Moreover, the distribution of any population relative to the nuclear detonation will determine the relative impacts of thermal, blast, direct radiation, and radionuclide releases on exposed populations.

The 1977 Edition of *The Effects of Nuclear Weapons* (Glasstone and Dolan, 1977) contained as a supplement a circular slide rule—"Nuclear Bomb Effects Computer"—that was developed by the Lovelace Biomedical and Environmental Research Institute personnel based on data in the document. The "slide rule computer" can be used to calculate a number of parameters for different nuclear weapons yields; thermal radiation, blast parameters, reflected overpressures, translational velocities for man, initial radiation exposures, and early fallout dose-rates. I strongly suspect that this rudimentary computer has been updated and improved by many governments around the world using contemporary computer technology.

The values of the various physical yield parameters and their related health impacts that are calculated for even low-yield nuclear weapons are staggering! Suffice it to note, all of the individuals near the epicenter of a nuclear weapons explosion, even of low yield, will be killed by thermal radiation, blast pressure, direct radiation, or a combination of these components. A critical issue becomes at what distance from the epicenter will there be any survivors with injuries amendable to treatment, using modern medical procedures. In evaluating the potential effectiveness of such treatment it is important to recognize that the number of immediate casualties could number in the tens of thousands dependent upon the target. The number of survivors with life-threatening injuries could number in the tens of thousands and higher. Thus, it is unlikely that the heroic medical procedures used in modern medical centers to effectively treat a few patients with thermal burns or blast injury will be available to treat large numbers of patients with blast or thermal radiation injuries.

It is important to recognize that blast injuries are not unique to nuclear weapons, explosive devices of all kinds produce blast waves that kill people. This includes improvised explosive devices (IEDs) that have accounted for about 75% of all US military casualties in Iraq and Afghanistan (Belmont et al., 2010). A recent Institute of Medicine Report (IOM) entitled "Gulf War and Health, Vol. 9, Long-Term Effects of Blast Exposures" (National Academies Press, 2014) provides an excellent review of blast effects. The contents of the 2014 report builds on material on the blast effects of blast waves reviewed in an earlier IOM report, "Gulf War and Health, Vol. 7, Long Term Consequences of Traumatic Brain Injury" (National Academies Press, 2009). These reports focused on the effects of relatively small IEDs with explosive yields of a few pounds of TNT to 500 pounds of explosives in the trunk of a sedan to 10,000 pounds in a small box van to 60,000 pounds in a semitrailer. The lethal air blast range from a 500-pound IED is estimated to extend to 100 ft and increases to 600 ft for a 60,000 lbs IED. The reports cover a range of effects from acute deaths to delayed effects observed in survivors.

I strongly encourage individuals interested in blast effects to read and study the 1977 report of Glasstone and Dolan as well as the IOM reports. However, I want to emphasize that the focus in the IOM reports on blast effects from relatively small IEDs and the limited number of individuals in harm's way need to be kept in mind in extending these results to even low-yield nuclear weapons. The destructive potential of nuclear weapons is substantial!

The IOM reports selectively review the experimental data developed under experimental conditions in studies with many mammalian species. Much of this early data was developed under the direction of Clayton S. White of the Lovelace Medical Center in Albuquerque, NM (Bowen et al., 1968a,b; White et al., 1970; Martinez and Stuhmiller, 1999). Those studies conducted at the Nevada test site and using blast tubes demonstrated that the primary blast effects were observed in the thorax and abdomen. Clemedson and Criborn (1955), in a classic post-World War II paper, postulated that these effects resulted from the shock waves' kinetic energy.

A key finding of the Lovelace research was the observation of substantial differences in blast tolerance (24-h survival) among the 12 species studied (Bowen et al., 1968a; Richmond et al., 1967, 1968) (Fig. 43.6). Body size-dependent differences in blast tolerance have been explained on the basis of lung density. The lung density of larger species (humans, monkeys, cats, and dogs) is only about one-half that of smaller species such as

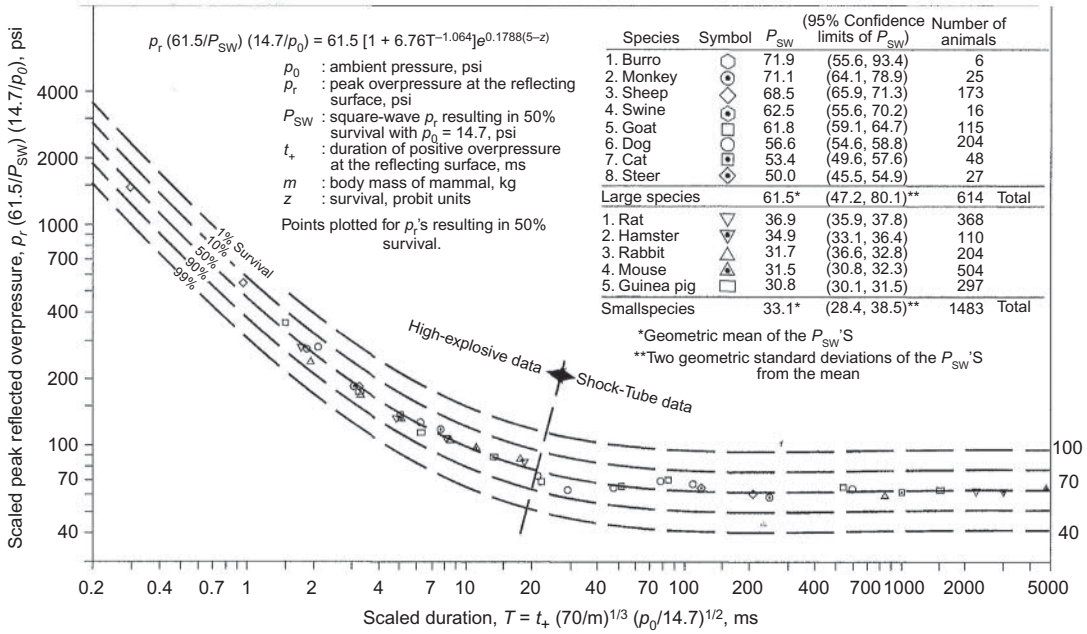

FIGURE 43.6 Survival curves (24-h) applicable to sharp-rising blast waves typical of a nuclear explosion, derived from analysis of data from 12 mammalian species (excluding guinea pigs) (Bowen et al., 1968b).

mice, rats, guinea pigs, hamsters, and rabbits. In contrast, the lung volumes relative to body mass in smaller species were three times greater than in the large species (White et al., 1965).

Despite these documented species differences, many recent studies of blast injury have used mice and sophisticated molecular and cellular approaches. The findings are interesting. However, I question the relevance of some of these findings to the human situation. I urge future investigators to take the time to review literature on blast effects developed over half a century ago using larger species before initiating new research on blast effects using rodent species. The appropriate animal model is as important as using sophisticated methodology. In my opinion, the study of blast effects is a situation where in vitro techniques cannot substitute for whole-animal studies.

43.14 Exposures to radioactive materials and radiation dose

The complex nature of the pathways of exposure for ionizing radiation and radioactive materials is illustrated in Fig. 43.7. To avoid giving undue emphasis to the direct effect of ionizing radiation from explosion of a nuclear weapon, that type of exposure is not illustrated in Fig. 43.7. As will be discussed later, the explosion of a nuclear weapon directly releases fission fragments, beta particles, gamma-rays, and neutrons that can expose individuals. The exposure and associated delivered radiation dose will depend on the individual's distance from the

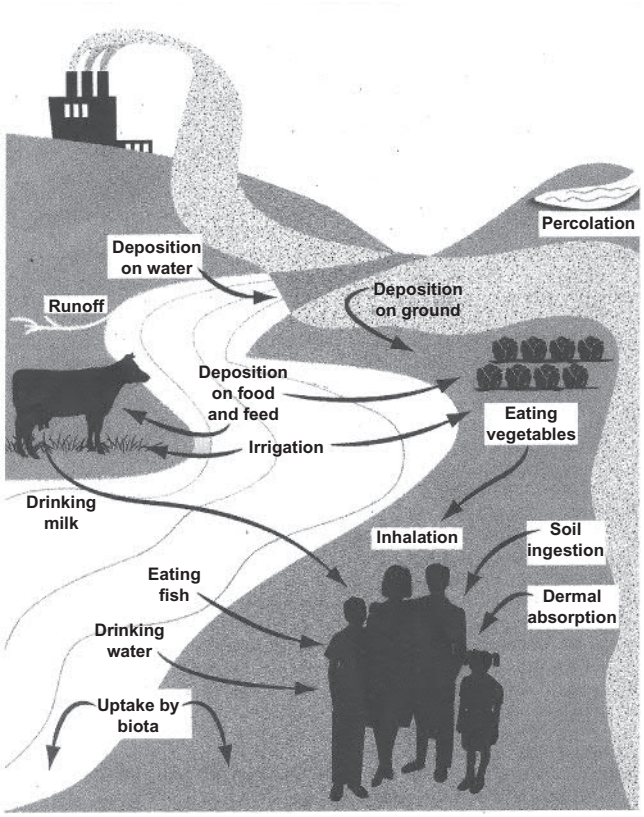

FIGURE 43.7 Schematic representation of pathways for radioativity to reach humans. *Adapted from Paustenbach (2001).*

nuclear explosion and other factors, most notably shielding. Airborne radioactivity, that is, fission products, from a nuclear explosion, a nuclear reactor accident, or other releases of radioactive materials may serve as a source of external exposure. However, intake of radioactivity typically results in the most substantial radiation dose to populations downwind of the nuclear explosion.

One of the most important pathways for exposure of human populations to radionuclides from a variety of accidental releases involves intake of contaminated pasture, grass, or hay by dairy cows, resulting in contaminated milk and ingestion of that milk by humans. As will be discussed later, recognition of the role of this pathway and actions to block it are critically important in limiting population exposures for many kinds of releases of radioactive material. An enormous array of different radionuclides is constantly being produced in a nuclear reactor by fission of the uranium or plutonium fuel or to a lesser extent by neutron activation. A similar array is produced instantaneously in a nuclear fission or fission–fusion weapon. Most of these radionuclides and their radioactive decay products have very short physical half-lives, measured in seconds or minutes, that limit human exposures.

Three radionuclides released in the fission of uranium and ^{239}Pu have decay characteristics (half-lives and emissions) and biological characteristics that are of special concern. Radioiodine, ^{131}I, decays with a physical half-life of 8.05 days and, like stable iodine, is readily adsorbed when ingested and concentrates in the thyroid. Radiostrontium, principally ^{90}Sr with a physical half-life of 28.0 years, behaves like its alkaline earth analogy, calcium, and is readily absorbed when ingested in a soluble form and concentrates in the skeleton. It decays to short-lived ^{90}Y with beta emissions. The beta emissions of ^{90}Sr and ^{90}Y irradiate the skeleton and bone marrow. The alkali metal, ^{137}Cs, behaves like its analog, potassium, and when ingested or inhaled rapidly distributes throughout the body with gamma and beta emissions serving as a source of whole-body irradiation.

Of these three radionuclides, ^{131}I is most important for down-wind exposure of populations to radioactive fallout from detonation of a nuclear weapon, releases from a nuclear reactor accident, or reprocessing of "green" irradiated fuel. Fig. 43.8 relates key data from a study in which ^{131}I was fed to dairy cows to simulate what might occur following a nuclear detonation, a reactor accident, or a nuclear fuel reprocessing release. The amount of radioactivity intake each day is reduced as a result of the 8.05 day physical half- life of ^{131}I. As may be noted, there is a buildup of ^{131}I in the thyroid of the cows and continuous secretion of ^{131}I in the cow's milk. In this study, volunteers drank aliquots of the contaminated milk and buildup of ^{131}I in the thyroid of the volunteers occurred. As an aside, the radiation dose to the thyroid of the volunteers was less than that associated with a chest radiograph given in the early 1960s. The data contained in the figure provides a sound scientific basis for avoiding the processing and consumption of milk from dairy cows after any release of radioactivity until assurance can be given that the levels observed will not result in ^{131}I intakes that exceed dose limits. This kind of prudent action was carried out quite effectively following the Fukushima incident. Unfortunately, this practice was not uniformly followed in areas downwind of the Chernobyl reactor accident. Indeed, people in many areas downwind of Chernobyl were not informed for some time of the occurrence of an accident releasing substantial amounts of radioactivity, including ^{131}I.

The significance of radionuclide contamination in ruminants. In: Physiology of Digestion in the Ruminant, pp. 131–143. Washington, DC: Butterworth (Bustad et al., 1965).*

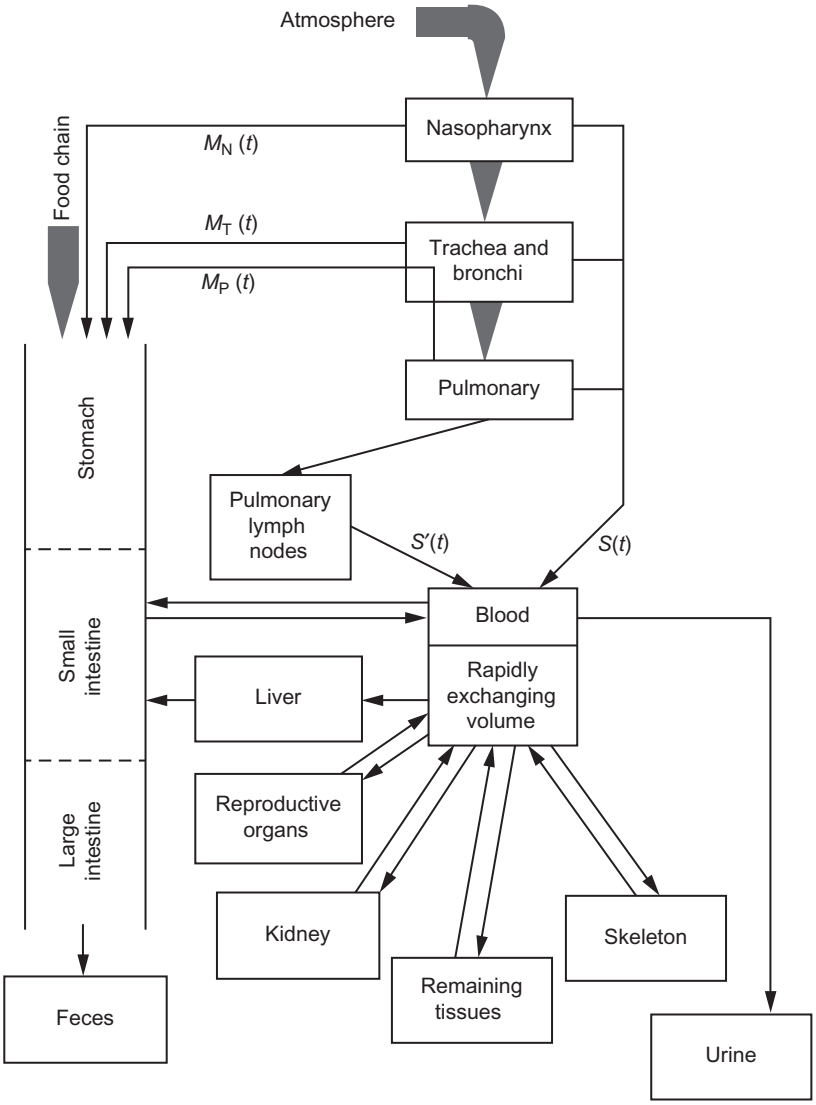

FIGURE 43.9 General model used to simulate organ distribution and retention patterns for inhalation, ingestion, or injection of radioactive elements. Clearance of material from the respiratory tract is considered to involve competing mechanical clearance pathways with material reaching the gastroingestinal tract, $M(t)$ or lymph nodes and dissolution with absorption into blood, $S(t)$. Both rates may be time-varying functions dependent upon the physical-chemical characerristics of the inhaled material. Other transfer rates are considered to be first-order unless better information is available for specific radionuclides and chemical forms (Cuddihy et al., 1976).

As an aside, if radionuclides are inhaled the retention kinetics will be determined by the vector with which the radionuclide is associated. For example, if the aerosol is a soluble chloride, such as $SrCl_2$, the ^{90}Sr will readily reach the bloodstream and be transported to the skeleton. In contrast, if the vector is relatively insoluble fused aluminosilicate particles (FAPs), the ^{90}Sr-FAP will be retained for an extended time in the pulmonary region and irradiate the lung. A general model used for describing the fate and radiation dose for internally deposited radionuclides is shown in Fig. 43.9.

43.15 Radiation-induced health effects

43.15.1 Sources of information on radiation effects

There are multiple sources of information on the health effects of exposure to radiation. As Cantril and Parker (1945) noted at the time they wrote their now classic document, *The Tolerance Dose*, studies of "human misfortune" are a major source of information on radiation effects. In retrospect, each of those pieces of human information with documented adverse effects represents a failure to adequately control past activities and limit radiation exposures. Post World War II, substantial effort were expended conducting epidemiological information on exposed human populations. Key human populations studied following external exposures to X- or gamma radiation are shown in Table 43.4. Key human populations studied following intake of radioactivity are shown in Table 43.5. The quality of those studies was heavily influenced by the quality of dosimetry, epidemiological methodology, and statistical considerations (NCRP, 2018). These considerations will be discussed in detail later in the chapter when the use of linear nonthreshold models is considered.

Soon after the USAEC was created, the agency recognized there were critical voids in knowledge of radiation effects that could be best addressed with lifespan studies in multiple species, including rodents and dogs. A review of this extensive research is beyond the scope of this chapter. Thus, I will focus on the dog studies that have provided useful information in complementing the results of epidemiological studies. These are shown in Table 43.6.

As already noted, the principal product of the Hanford site was ^{239}Pu. Thus, when a biological research program was initiated there, one of the major research efforts focused on the health effects of ^{239}Pu. The inhalation route of exposure was used since this was considered a likely route of accidental occupational exposures. Later, studies with ^{238}Pu were initiated as concern arose for its use as a thermal source in SNAP devices.

The University of Utah program focused on the critical issue of estimating the cancer health hazards of alpha particle-emitting ^{239}Pu building on earlier data from the radium dial painters who ingested ^{226}Ra,

TABLE 43.6 Major lifespan studies with internally deposited radionuclides in Beagle dogs with multiple exposure levels and lifespan observation.

Laboratory	Radionuclides	Route of administration
Hanford	$Pu^{238}PuO_2$, $Ra^{239}O_2$, Pu^{239}, nitrate	Inhalation of polydisperse aerosols
University of Utah	Ra^{226}, Ra^{228}, Th^{228}, Pu^{239}, Am^{241}, Sr^{90}	Single intravenous injection
UC Davis	Ra^{226}	Multiple intravenous injections
	Sr^{90}	Chronic ingestion
Lovelace	Y^{90}, Y^{91}, Ce^{144} and Sr^{90} Chloride	Inhalation of polydisperse aerosol
	$Cs^{137}Cl_2$	Intravenous injection
	Y^{90}, Y^{91}, Ce^{144} and Sr^{90} in fused aluminosilicate particle	Inhalation of polydisperse aerosols

^{228}Ra, and ^{230Th}, all of which had alpha particle emissions. Intravenous injections were used to administer the radionuclides. Dogs were used instead of rats because the distribution of administered Pu in dogs (i.e., liver to skeleton ratios) was similar to that found in humans. Rats were not viewed as a good model for humans. As increased concern developed in the 1950s for the effects of nuclear weapons testing and fallout ^{90}Sr, a beta particle-emitting radionuclide on children, a decision was made to enlarge the Utah program to include dogs given single injections of ^{90}Sr.

Yet later a decision was made to create a new program at the University of California-Davis in which dogs were fed ^{90}Sr. Female dogs were mated, ingested ^{90}Sr, and nursed their pups exposing them to ^{90}Sr via their dam's milk. The pups ingested ^{90}Sr until they were 540 days old. Other dogs received six injections of ^{226}Ra to link the University of California-Davis results to the radium dial painters and the Utah studies. All the dogs were followed for their lifespan.

The Lovelace Fission Product Inhalation Program, later renamed the Inhalation Toxicology Research Institute, was initiated in 1960 in response to increasing concern over the potential for a catastrophic nuclear reactor accident. An AEC Report (WASH-740) prepared by Brookhaven National Laboratory (BNL, 1957), highlighted deficiencies in the information available to estimate the hazards of airborne releases of gamma ray- and beta particle-emitting fission product radionuclides in the event of a catastrophic reactor accident. Later the Lovelace program was expanded to include research on inhaled ^{239}Pu as the potential for use of ^{239}Pu as a breeder reactor fuel was being evaluated. Likewise, ^{238}Pu was added to the Lovelace Program as it became the preferred fuel for SNAP devices. A unique feature of the Lovelace Program was the use of monodisperse particles of ^{238}Pu and ^{239}Pu.

The results of the Beagle studies have been reported in hundreds of peer-reviewed publications. In this chapter I will selectively summarize some of the results focusing on cancer induction. These studies are reviewed in greater detail in McClellan (2014, 2019).

It is important to note that all of the studies conducted in Beagles involved the conduct of toxicokinetic studies linked to the lifespan studies (Fig. 43.9). Thus, it was possible to provide an estimated radiation dose pattern for multiple potential target organs for each individual dog. Each dog was followed closely throughout its life and at death, detailed necropsies were conducted, and causes of death identified. Thus, a vast array of data were available for evaluation of radiation–dose response relationships. Indeed, the data were made available publicly and have been used by scientists around the world. The data, as well as some tissues, from the Lovelace studies are held in a repository at Northwestern University.

Two critical questions were addressed by the dog studies: (1) what is the relative effectiveness of alpha- versus beta-irradiation? and (2) how does dose protraction influence the effectiveness of the internally delivered radiation dose? It is important to recognize that the number of dogs studied in the various studies was not sufficient based on statistical limitations to address the nagging question of whether dose–response relationships at low doses were or were not linear.

43.15.1.1 Overview of key biological mechanisms

Let us now turn our attention to adverse health outcomes resulting from radiation exposures. Before addressing specific health outcomes it is appropriate to emphasize that exposure–dose–health response relationships for ionizing radiation are strongly influenced by the quality of the radiation and by both dose rate and total dose as a

function of time. Both fractionation and protraction of the delivery of the radiation dose will reduce the health impact per unit of delivered radiation dose. The influence of these factors is schematically illustrated in Fig. 43.10. The panel on the left illustrates the situation for most external exposures. The time interval for exposure and delivered dose coincide. This is the situation for external radiation from detonation of a nuclear weapon or a single treatment session for a cancer patient receiving external beam therapy. The panel on the right illustrates the situation for intake of radioactive material. The intake via inhalation or ingestion may be brief. The delivered radiation dose to various tissues from ingestion or inhalation of radionuclides will be protracted and the radiation dose pattern dependent on the distribution of the radioactive material in the body determined by biological processes and the physical half-life of the radionuclide.

As an aside, one of the first radiation effects studies I conducted compared the effects of ^{131}I and X-irradiation on the sheep thyroid (McClellan et al., 1963). The radiation dose pattern from the X-irradiation was analogous to that shown in the left panel of Fig. 43.10, while the ^{131}I yielded protracted beta-irradiation was analogous to the pattern shown on the right. The X-irradiation was substantially more effective than the protracted dose from ^{131}I in producing early injury to the thyroid.

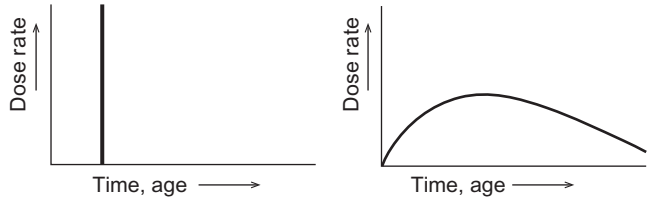

FIGURE 43.10 External brief radiation exposures and resulting tissue dose occur simultaneously while the intake of radioactivity results in a protracted tissue dose.

The effects of radiation on living things begin with interactions at the molecular and cellular levels (recall Fig. 43.3). The interactions begin with ionization or excitation of orbital electrons and results in the deposition of energy in cells. The ionizations can directly affect biological molecules, principally DNA. In addition, there may be indirect action of radiation mediated by free radicals that can diffuse far enough to reach other target molecules. This is noteworthy since the body is about 80% water. When atoms are ionized, their chemical binding characteristic changes. The ionization may result in breakage of molecules or relocation of atoms within molecules. These changes, in turn, can alter cell function, including causing cell death or mutations in surviving cells. Ionization of water or biological molecules is an initial step in the complex processes illustrated in Fig. 43.3. Many of these processes are described in the 100 most-cited papers published in the *Radiation Research Journal*. The textbooks by Bushong (2017), Hall and Giaccia (2012), Mettler and Upton (2008), and Turner (2007) all provide in-depth coverage of the vast literature on mechanisms of action of ionizing radiation.

Ionization in cells results in cell death, mutations, and other alterations in cell function. Cell killing and functional alterations in surviving cells can alter organ function and with sufficiently high radiation doses lead to death of those exposed individuals. The most common form of cell death from radiation is mitotic death. The irradiated cells die as they attempt to divide because of the severe damage to their chromosomes. This is the basis of the effectiveness of radiation in treating cancer. An example of the survival of cells related to delivered dose of X-rays is shown in Fig. 43.11. Irradiation of cells produces mutational changes as illustrated in Fig. 43.12. Later, experiments conducted by Brooks (2012) demonstrated the relative biological effectiveness of beta/gamma irradiation versus alpha particles and alpha particles plus

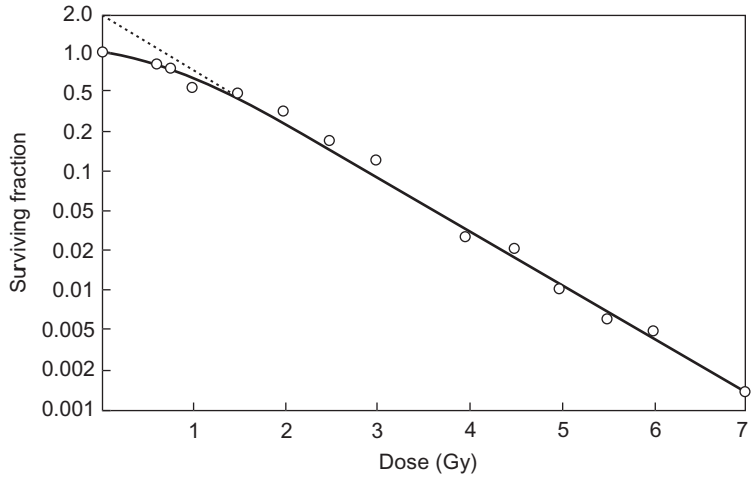

FIGURE 43.11 Survival curve for HeLa cells in culture exposed to X-rays (Puck and Markus, 1956).

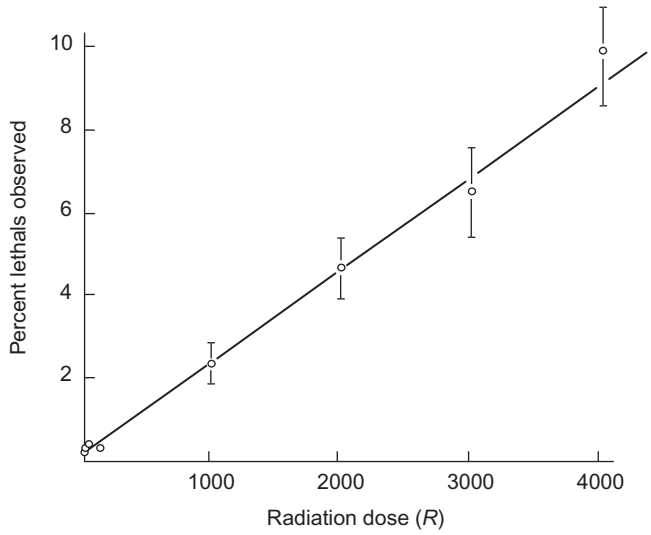

FIGURE 43.12 Dose–response relationship for induction of mutations in X-irradiated *Drosophila*. Note the substantial radiation doses studied. *Adapted from Oliver, C.P., 1930. The effect of varying the duration of x-ray treatment upon the frequency of mutation. Science 71:44-46 (Oliver, 1930).*

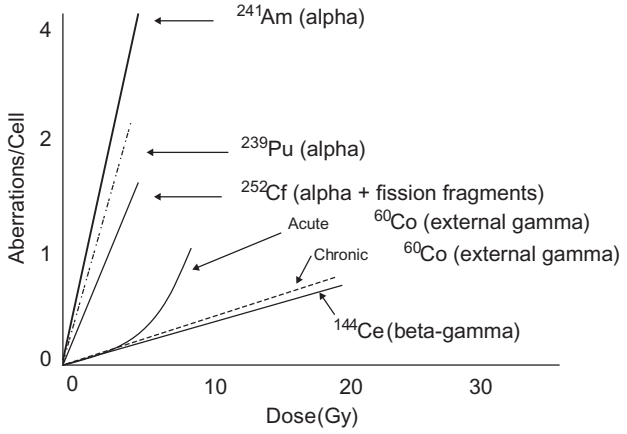

FIGURE 43.13 Dose–response relationship for in vivo induction of chromosome aberrations in liver cells of Chinese hamsters by high LET (alpha particles from $Am^{241,}$ ^{239}Pu, and Cf^{252}) and low LET (CO^{60} gamma rays and Ce^{144}-Pr^{144} beta particles) (Brooks, 2012).

fission fragments (Fig. 43.13). The figure also illustrates the sparing effect, that is, reduced mutations, when ^{60}Co external radiation is protracted.

The postulated role of cell killing and induction of transformations in causing leukemia is illustrated in Fig. 43.14. The critical interplay between cell survival and mutational events and subsequent cell transformation in the induction of cancer was explicitly incorporated in the now classic model developed by Moolgavkar and Venzon (1979). See also Moolgavkar and Knudson (1981), Moolgavkar (1986), Moolgavkar et al. (1988, 1999), and Dewanji et al. (1989).

43.15.2 Acute radiation syndrome and early effects

The acute effects of external radiation, including lethality, have been studied in many different species including humans. Mettler and Upton (2008) estimated the acute radiation dose required to kill 50% of individuals within 60 days. For 10 nonhuman species, in the absence of medical intervention, the LD_{50} (60 days) ranged from 3–5 to 4.0 Gy air or surface dose, corresponding to midline tissue doses of about 2.7 Gy. The range of values is remarkably narrow considering the studies were done at different times with different radiation sources and with subjects maintained under different environmental conditions, diets, and microbial flora.

Early literature on acute effects referred in a generic manner to early deaths being due to multiple acute radiation syndromes, including the nervous, gastrointestinal, or hematopoietic systems. More recent literature uses the term acute radiation sickness (ARS) (Mettler and Upton, 2008). The word acute relates to deaths occurring within a few months of exposure to external radiation or a protracted dose over several months received from intake of a substantial amount of radioactive material. The use of syndrome or sickness refers to the injury occurring in neurovascular, gastrointestinal, hematopoietic, and cutaneous tissues that cause death at various absorbed radiation doses.

Many thousands of individuals died of ARS following the bombings of Hiroshima and Nagasaki, Japan. As discussed earlier, these individuals were also impacted by the blast wave and thermal radiation. These were the individuals who had been exposed to blast and thermal radiation at levels that did not produce immediate lethality.

To give a clear picture of radiation effects alone, it is most appropriate to turn to a unique data set developed by the International Atomic Energy Agency (IAEA) (1998) for evaluating early injury from radiation. This is a registry that includes about 400 cases of which about 100 died of ARS. The other 300 individuals survived despite having some signs and symptoms of ARS. Tables 43.7–43.9 provide useful summaries of the radiation dose-related signs and symptoms of ARS for humans.

As I noted in an earlier review of biomarkers of exposure and effects of ionizing radiation (McClellan, 2019), the biomarkers most extensively studied represent good old-fashioned, tried and proven medical practices used in the diagnosis and treatment of diseases. Since radiation-induced effects were first observed a century ago there has been a search for new biomarkers of radiation-induced effects, a search for "special biomarkers." That research effort was rejuvenated following the September 11, 2001, disaster in New York City as concern was renewed over potential terrorist events, including devices

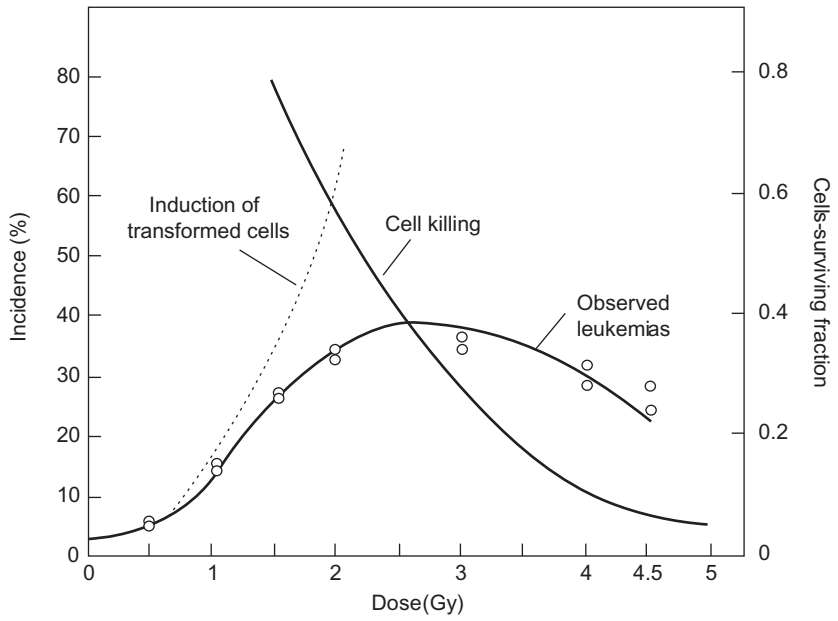

FIGURE 43.14 The postulated role of cell killing and induction of cell killing in producing leukemia in irradiated mice (Gray, 1965).

resulting in radiation exposure. Some of the most recent research findings were reviewed in Ray et al. (2014).

Let me now transition from the health effects of brief external radiation exposures from external sources to the effects of internally deposited radionuclides. At the outset, I note that there are limited data from human studies on the acute effects of internally deposited radionuclides. This is the case because it is difficult to create situations in which the intake of radioactive materials is sufficient to result in radiation doses that will result in acute radiation-induced effects. I have underlined this statement to give emphasis to this point for any policy makers or potential terrorists reading this chapter.

There is one case in which a postulated single intake of radioactive material resulted in an acute death of a human and was a purposeful poisoning with ^{210}Po. Another case involved the accidental treatment of a patient with an erroneously high dose of a radio- therapeutic agent, ^{198}Au.

43.16 Early radiation effects from internally deposited radionuclides

In the absence of human experience with internally deposited radionuclides and acute injury, it is useful to examine the data from studies with laboratory animals (Table 43.6). In my view the most relevant data for describing the acute effects of internally deposited radionuclides are from studies conducted by Lovelace scientists. In the studies, Beagles were exposed briefly (on the order of an hour) to graded concentrations of various fission product radionuclides. It was originally planned to use inhalation exposures for all the studies. This included giving dogs ^{137}CsCl by inhalation, however, a few calculations indicated the exposure conditions could pose a hazard to the personnel conducting the inhalation exposures. Thus, recognizing that inhaled ^{137}CsCl and intravenously injected ^{137}CsCl are distributed in the same manner in the body, resulting in a similar radiation dose pattern, animals were exposed by intravenous injection.

Using different radionuclides with varying physical half-lives, the radiation dose patterns realized in the several studies were quite different (Table 43.10). With large intakes of the fission product radionuclides, the resulting radiation doses to hematopoietic tissues were sufficient to cause lethality in weeks to a few months from hematopoietic injury. As illustrated in Fig. 43.15, the protracted radiation dose from injected ^{137}CsCl or inhaled $^{91}YCl_3$, $^{90}SrCl_2$, or $^{144}CeCl_3$ was about one-fourth as effective as a brief exposure to 1 MeV X-rays in producing the acute bone marrow syndrome in dogs.

Studies were also conducted in which Beagles briefly inhaled ^{90}Y-, ^{91}Y-, ^{144}Ce-, or ^{90}Sr-infused aluminosilicate particles (FAPs). In these studies, the FAPs served as a particulate matter vehicle. The difference in radiation dose pattern for the different beta particle-emitting radionuclides was determined by differences in their physical half-lives. These exposures resulted in protracted radiation doses to the respiratory tract. At the highest doses to the lungs, in excess of 30 Gy, pneumonitis developed producing death within about 500 days of the initial intake of the radioactive aerosol (Fig. 43.16). For comparative purposes, human data are shown for pneumonitis induction by brief exposure to X-rays. The protracted low-LET irradiation in the dogs is substantially less effective in

TABLE 43.7 Prodromal phase of acute radiation sickness (ARS).

Degree of ARS and approximate dose of Acute WBE (Gy)					
Symptoms and medical response	**Mild (1–2 Gy)**	**Moderate (2–4 Gy)**	**Severe (4–6 Gy)**	**Very Severe (6–8 Gy)**	**Lethal[a] (>8 Gy)**
Vomiting onset	2 h after exposure or later	1–2 h after exposure	Earlier than 1 h after exposure	Earlier than 30 min after exposure	Earlier than 10 min after exposure
% of incidence	10–50	70–90	100	100	100
Diarrhea	None	None	Mild	Heavy	Heavy
Onset	–	–	3–8 h	1–3 h	Within min or 1 h

inducing injury than less protracted irradiation. The more extended or protracted the delivery of the radiation dose, the larger the integrated dose required to produce equivalent effects. Dose rate and dose protraction are very important!

It is important to note that the cumulative radiation doses required to produce radiation-induced effects from intake of radioactive materials are on the order of 10 Gy and higher for hematopoietic injury and 50 Gy and higher for pneumonitis. The air concentrations of radioactive materials and exposure durations required to produce these radiation doses are very substantial!

It is also important to recognize that special effort was taken to produce the experimental highly respirable aerosols used in the research described above. The aerosols had an activity median aerodynamic diameter on the order of 1–2 μm, a size selected to minimize nasopharyngeal deposition and maximize pulmonary deposition. Most crude devices that might be used to create radioactive aerosols to purposefully harm people will produce larger particles that are not as readily respired and deposited in the respiratory tract.

In closing this section, let me briefly address the issue of potential treatments to reduce radiation doses from internally deposited radionuclides. The US Centers for Disease Control and Prevention maintain a website on radiation emergencies (CDC, 2019). It provides general guidance for dealing with radiation emergencies. This includes the use of stable iodine to minimize the uptake and radiation dose of ^{131}I (recall Fig. 43.8). This topic is also covered in detail in a special report by the World Health Organization (WHO, 1999).

In my opinion, there are no other treatments that can realistically be used to treat populations numbering in the

thousands to either reduce their radiation dose or treat radiation-induced injury after a nuclear detonation.

43.16.1 Radiation-induced cancer in humans from acute exposures

At this juncture, it is appropriate to discuss the late-occurring effects of radiation exposure. In my opinion, the most relevant data set for detailed analysis are the Japanese A-bomb survivors. This population was originally assembled under the auspices of the Atomic Bomb Casualty Commission (ABCC), now reconstituted as the Radiation Effects Research Foundation (RERF). This research has been supported over the decades by the governments of Japan and the United States. There are three ABCC/RERF cohorts. The Life Span Study (LSS) cohort includes 120,321 individuals; 82,214 in Hiroshima and 38,107 in Nagasaki. A second cohort includes about 3300 individuals who received their exposure in utero as a result of their mother's whole-body exposure. Information from this cohort has provided valuable insights into the incidence of malformations, growth retardation, microcephaly, and mental retardation related to radiation exposure. A third cohort consists of 77,000 children born to the survivors of the atomic bombings. Observation of this latter cohort has provided valuable data for assessing heritable effects (Neel et al., 1990; Satoh et al., 1996). Grant et al. (2015) reported on the risk of death among children of atomic bomb survivors.

The first report on mortality in the LSS cohort was published by Beebe et al. (1962). With each report the duration of follow-up is increased. The 14th report in this

series was published by Ozasa et al. (2012, 2013). A recent paper by Grant et al. (2015) reviews follow-up from 1958 through 2009.

The basic dose-related characteristics of the LSS population are shown in Table 43.11. It is of interest to note that of the 86,601 individuals enrolled in the cohort in 1950, a total of 46,614 individuals (53.8%) had died by 2003, with 39,987 (46.2%) surviving. A total of 10,929 had died with solid cancers with an estimated 527 cancer deaths attributed to radiation exposure using statistical methods. None of these 527 radiation-attributable cases carried a sign "Caused by Cancer." Most people, including many scientists, reviewing these data are surprised at the relatively few cancers attributed to radiation exposure. Many people, including scientists, consider radiation to be a super carcinogen. In fact, radiation is not a very effective carcinogen. Look at the data!

A detailed presentation of the array of specific causes of death is given in Fig. 43.17.

Note the data are shown as excess relative risk (ERR) per Gy. Many experimentalists will not be familiar with the analytical approach using baseline risk and estimated ERR to describe effects. Most experimentalists customarily present absolute incidence values for controls and toxicant-exposed groups. Indeed, many rat bioassays are truncated at 2 years. This has traditionally been done to make it easier to distinguish toxicant-induced cancers from spontaneous cancers in controls with all animals entered in an experiment at 6–12 weeks of age and observed for 2 years. The low incidence of cancers observed in controls by about 2 years of death presumably makes it easier to detect an increase in cancer related to the toxicant exposure, the presence of a cancer hazard. Unfortunately, in my opinion, this well-intentioned approach is now outdated. It was useful in identifying agents that pose a significant carcinogenic hazard to rodents as a harbinger of carcinogenic hazards to humans. Unfortunately, this approach is not very useful in helping understand cancer induction late in life when low exposures (doses of toxic agents) may cause small increases in cancer risk on top of substantial spontaneous incidence. Small increases in cancer associated with administration of toxicants may very likely involve the same mechanisms operative in producing the background incidence of cancers.

The influence of radiation dose on induction of solid cancers in the LSS cohort is shown graphically in Fig. 43.18. Note the arithmetic horizontal scale. In this presentation, it appears there is a linear relationship between radiation dose and ERR. The same data analyzed by a different team of investigators are presented in Fig. 43.19. Note that a logarithmic scale is used in this figure. With the latter mode of presentation, it appears that a threshold exists in the radiation dose–ERR relationship.

Recall the issue of alternative dose–response relationships raised by Henshaw (1941) and illustrated earlier in Fig. 43.5. The debate over the choice of radiation dose–response relationship models continues three-quarters of a century after the debate was framed. Edward

FIGURE 43.17 Estimates of excess relative risk (ERR) per Gy and 95% CI for major causes of death. [a]ERR was estimated using the linear dose model, in which city, sex, age at exposure, and attained age were included in the background rates, but not allowing radiation effect modification by those factors. [b]Confidence interval. Horizontal bars show 95% confidence intervals. [c]The size of plots for site-specific cancers was proportional to the number of cases. [d]ERR (95% CI) of leukemia was 3.1 (1.8, 4.3) at 1 Gy and 0.15 (-0.01, 031) at 0.1 Gy based on a linear-quadratic model with 318 cases (not displayed in the figure). [e]The lower limit of 95% CI was lower than zero, but not specified by calculation (1950−2003) (Ozasa et al., 2012).

Calabrese has published extensively on radiation hormesis and its implications for risk assessment (Calabrese and Baldwin, 2000, 2003; Calabrese, Baldwin and Holland, 1999; Calabreese, 2011). He has also raised questions concerning ethical issues surrounding the early radiation assessments concerning effects at low doses (Calabrese, 2011).

A strength of the ABCC/RERF data set is that the individuals were all exposed in the same manner, a single brief exposure to external radiation. Thus, the use of the

data is most relevant to evaluating the effects of acute radiation doses and setting standards to limit such exposures.

43.16.1.1 Radiation-induced cancer from internally deposited radionuclides

This naturally leads to a question as to the availability of data on chronic exposures to radiation, including chronic exposures from internally deposited radionuclides. As noted earlier, some human data on this topic are available (Table 43.5). However, there are challenges involved in interpreting each of them.

In my opinion, the results of the dog studies are particularly useful in understanding the adverse effects of chronic irradiation from internally deposited radionuclides. A comparison of the effectiveness of protracted beta irradiation of the lung in producing lung cancer is shown in Table 43.12. Recall from Table 43.10 that ^{90}Y in FAP delivered 90% of its total dose in 8 days, whereas ^{90}Sr in FAP delivered 90% of its total dose in 5.5 years. The longer protraction of dose delivery for ^{90}Sr in FAP resulted in it being only 0.22% as effective as ^{90}Y in producing cancer. The two radionuclides, ^{91}Y and ^{144}Ce, with intermediate physical half-lives, had potency values intermediate between those for ^{90}Y in FAP and ^{90}Sr in FAP.

These data are shown in a schematic presentation in Fig. 43.20. In addition, this figure illustrates the greater effectiveness of chronic alpha irradiation of the lung from ^{239}Pu oxide compared to chronic beta irradiation in inducing lung cancer. The comparative effectiveness of alpha irradiation of bone from ^{226}Ra, ^{228}R, ^{241}Am, ^{238}Pu, and ^{239}Pu compared to beta irradiation from ^{90}Sr in inducing bone cancer is also evident in Fig. 43.20. The comparative potency of several different alpha particle emitters versus beta irradiation from ^{90}Sr in inducing bone cancer is evident from the results shown in Table 43.13. Of the various alpha emitters, the volume-seeking ^{226}Ra and ^{238}Ra are less effective than the bone surface-seeking Pu.

The comparative effectiveness for Pu inhaled in several forms in inducing lung cancer is shown in Table 43.14. ^{239}Pu nitrate was more effective in inducing lung cancer than the other forms of Pu. This is postulated to be related to the ^{239}Pu nitrate distributing more uniformly in the lung and being more effective in damaging lung cells than particulate Pu oxide. The results from the Lovelace studies with inhaled monodisperse particles are of special interest. The smaller the particles, the greater the total number of particles inhaled with equal total quantities of radioactivity. Thus, for equal radioactivity, more 0.75-μm particles will be deposited than 1.5-μm particles and even fewer 3.0-μm particles. For induction of

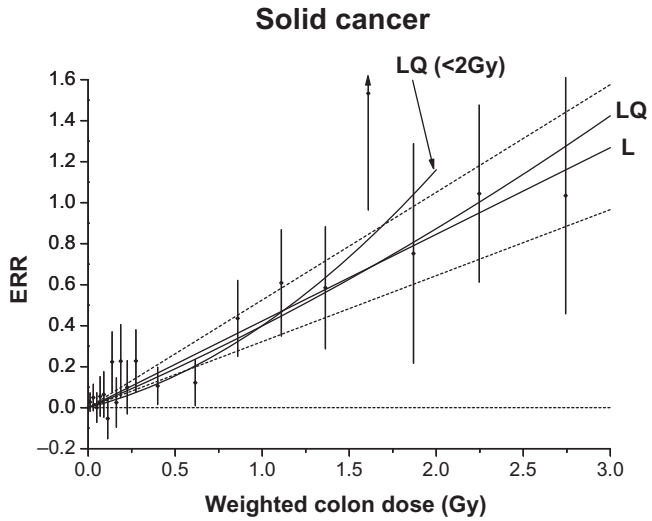

FIGURE 43.18 Excess relative risk (ERR) for all solid cancers in relation to radiation exposure. The black circles represent ERR and the bars are the 95% confidence intervals for the dose categories together with trend estimates based on linear (L) with 95% confidence intervals (dotted lines) and linear quadratic (L-Q) models using the full dose range and LQ model for data restricted to dose < 2 Gy (Ozasa et al., 2012).

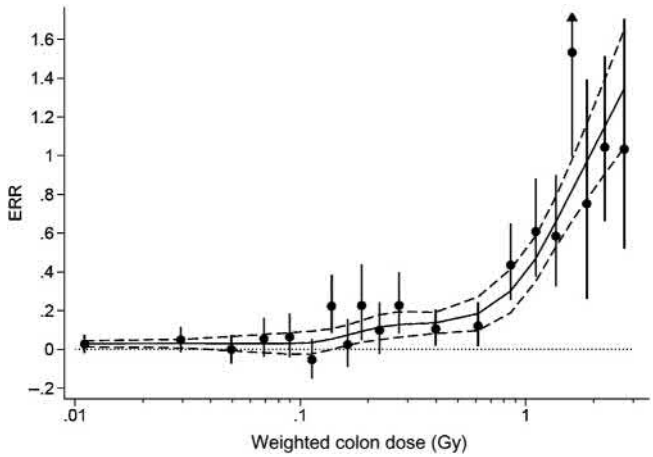

FIGURE 43.19 Excess relative risk (ERR) for all solid cancers in atomic bomb survivors in relation to radiation exposure. The black circles and error bars represent ERR and 95% CIs for the dose categories. Data from Ozasa et al. (2013). Solid line—fit to the ERR data using a multiple linear regression in which weighted log colon dose was entered into the model using a restricted cubic spline transformation with five knots. Regression weights were equal to the inverse of the variance of the point estimates. Dashed lines are 95% CI of the fit. Figure from performing analysis equivalent to Doss et al. (2012) with the corrected data in Ozasa et al. (2013). Figure provided by Brian L. Egleston. (Doss, 2013).

TABLE 43.12 Summary of relative carcinogenic and dosimetric ratios from four beta-emitting radionuclides inhaled in fused aluminosilicate particles and inducing lung cancer.

Nuclide	Emission type	Organ	Laboratory	Potency ratio
^{90}Y	β	Lung	Lovelace ITRI	1.0
^{91}Y	β	Lung	Lovelace ITRI	0.51
^{144}Ce	β	Lung	Lovelace ITRI	0.27
^{90}Sr	β	Lung	Lovelace ITRI	0.22

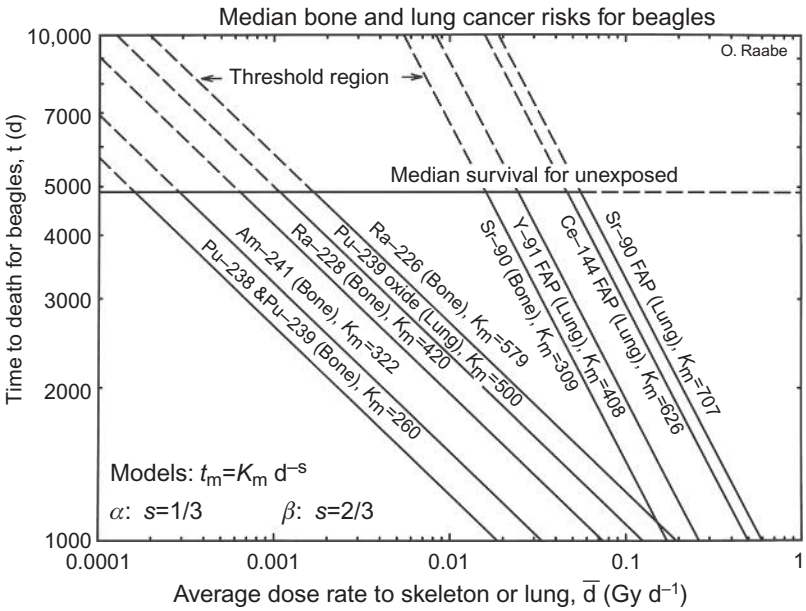

FIGURE 43.20 Illustration of bone sarcoma and lung carcinoma risk functions for Beagles demonstrating similar target organ average-dose-rate/time/response patterns with lifespan virtual thresholds at low dose-rates. The positions of the lines vary because of inherent differences in irradiation of the target cells by the different radionuclides and forms. Data were selected from lifetime laboratory studies of internally deposited radionuclides in Beagles including skeletal deposits of ^{90}Sr after exposure by ingestion at Davis and by injection at Utah, lung deposits of inhaled ^{144}Ce-, ^{91}Y-, and ^{90}Sr-infused aluminosilicate particles (FAP) at ITRI, lung deposits of inhaled $^{239}PuO_2$ at PNL, skeletal deposits of injected ^{226}Ra at Davis and Utah, inhaled $^{238}PuO_2$ at ITRI, and skeletal deposits of injected ^{226}RA and ^{241}Am at Utah (Raabe, 2010).

lung cancer, the 0.75-μm particles were more effective than the 1.5-μm particles, with the 3.0-μm particles least effective. From these summary results, it is apparent that radiation quality (beta versus alpha irradiation), dose protraction, and total dose are very important for cancer causation in the lung or skeleton.

It is appropriate to ask whether the results from the dog studies are relevant to estimating human hazards. The lifespan studies in Beagles were initiated in part because it was thought the dogs would serve as effective surrogates for human populations. At that time, it was not anticipated that human data would become available from worker populations. This proved to be the case in the United States and Britain. The protection goals in the US or British workers were always zero exposure with no intake of ^{239}Pu. The maximum body burden among US and British workers was 3.2 Bq (Wiggs et al., 1994; Voelz et al., 1997; Omar et al., 1998; Brown et al., 2004; Wing et al., 2004). No excess risk of lung, liver, or skeletal cancer was observed. The situation would prove quite different in the case of Russian workers.

With a brief recess in the Cold War in the early 21st century, there was increased scientific cooperation between the United States and the USSR in some areas. One of the areas of cooperation related to access to health data on key populations. One of these populations was the workers at the Mayak Production Association (MPA) facility in Russia which produced and handled large quantities of ^{239}Pu. Sokolnikov et al. (2008), Tokarskaya et al. (2002, 2006), and Gilbert et al. (2013) have reported on MPA workers. This population included 354 cases of lung cancers, 40 cases of liver cancers, and 11 cases of bone cancer. Five of the bone cancers were in controls and six in exposed workers. The small number of bone cancers was a surprise since for decades it was assumed that if an increase in cancers were to be observed in Pu workers, it would be bone cancer. Recall the radium dial painter experience.

With positive data available from ^{239}Pu workers, an obvious question was how these findings in workers compared to those in dogs that had been exposed to ^{239}Pu. To address this issue, Wilson et al. (2010) analyzed a pooled set of data for dogs that were exposed to ^{238}Pu or ^{239}Pu at either Hanford or Lovelace. The lung cancer mortalities for the MPA workers (354 cases) and the dogs (231 cases) are shown in Fig. 43.21. It is important to note that the worker data were analyzed taking account of their smoking history. Many of the MPA workers were heavy smokers. The dogs did not smoke. The similarity of the results for lung cancer in MPA workers and dogs is striking. Indeed, the MPA worker data clearly validate the use of the dog model used at Hanford and Lovelace to produce data relevant to humans for hazard/risk assessment purposes.

The liver cancer mortality rates for MPA workers (14 controls, 26 exposed) and dogs (7 controls and 39

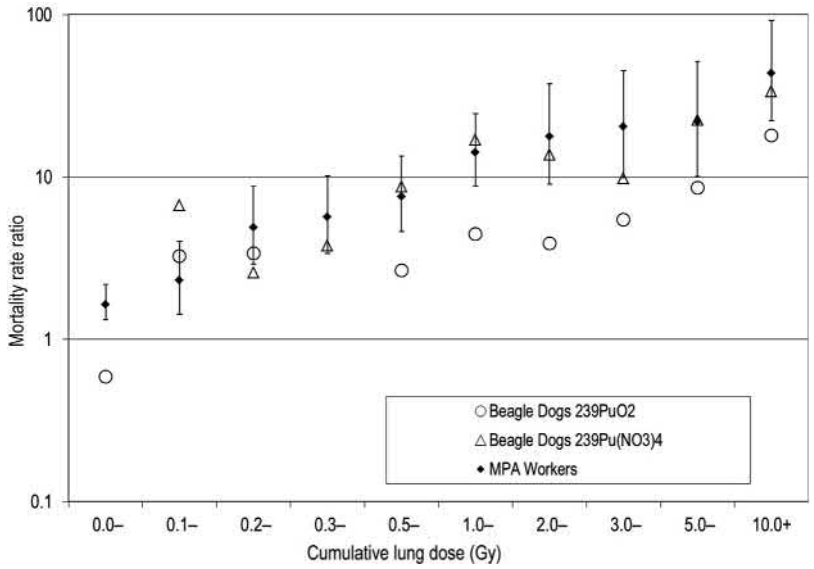

FIGURE 43.21 Lung cancer mortality rate ratio (with 95% confidence intervals) for Mayak Production Association Workers with known plutonium exposure plotted with rate ratios in Beagle dogs exposed by inhalation to plutonium by level of cumulative lung dose (Wilson et al., 2010).

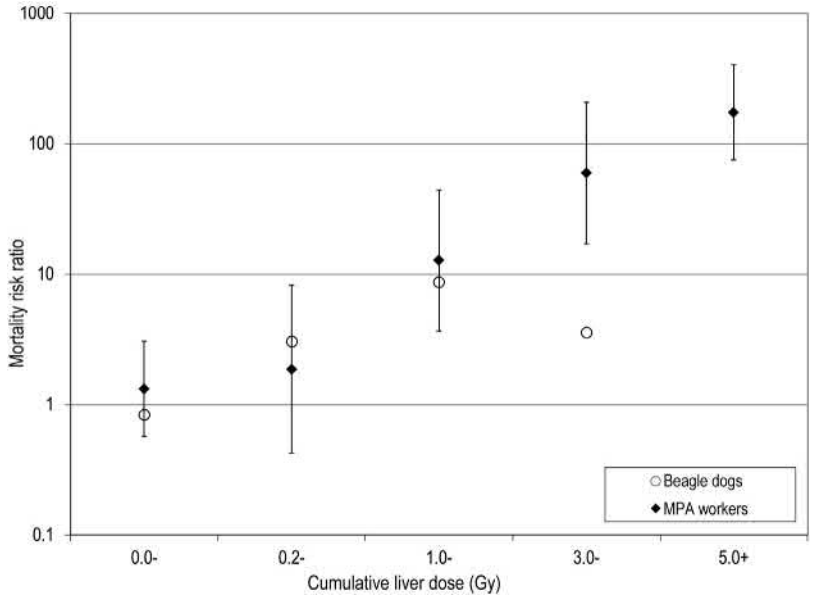

FIGURE 43.22 Liver cancer mortality rate ratios (with 95% confidence intervals) for Mayak Production Association Workers with known plutonium exposure plotted against rate ratios in Beagle dogs exposed to plutonium by level of cumulative liver dose (Wilson et al., 2010).

exposed) are shown in Fig. 43.22. Again, the similarity in the radiation dose–response relationships for workers and dogs is remarkable, especially for liver cases below 3.0 Gy. The lower dose groups included essentially all of the cases in dogs and 14 of 26 cases in workers. Twelve of the liver cancer cases were observed in workers with liver doses of over 3.0 Gy. A key factor to consider in evaluating the liver cancer cases is the important role of alcohol consumption as a confounder in causing liver cancer as pointed out by the Russian investigators (Tokarskaya et al., 2006). The Russian workers at Mayak consumed large quantities of alcohol. The dogs did not consume alcohol.

43.17 Linear nonthreshold models

In a recent report, the National Council on Radiation Protection and measurements (NCRP) evaluated the use of the linear-nonthreshold (LNT) model for radiation protection purposes (NCRP, 2018). In a sense, they addressed the fundamental issue on choice of radiation dose–response relationships posed by Henshaw (1941). The NCRP evaluated 29 different sets of data (Table 43.15). Each of the data sets was independently evaluated with regard to dosimetry, epidemiology, and statistical methods used with a score of 1–3 assigned to each method and then an aggregate score of 1–4 was

TABLE 43.15 Ratings of the quality of cancer studies reviewed with regard to dosimetry, epidemiological statistical methodology, and their aggregate degree of support for the LNT model.

Study (or groups of studies)[a]	Dosimetry[b]	Epidemiology[b]	Statistics[b]	Support for LNT model[c]

[a] *A representative recent publication is listed for each study. Others are found in the text.*
[b] *Judged quality of the dosimetry, epidemiology and statistics scores: 1 = weak-to-moderate, 2 = moderate, 2.5 = moderate-strong, 3 = strong.*
[c] *Ratings of the support for LNT: 1 = essentially no support (null or negative; or unreliable and inconclusive), 2 = weak-to-moderate support, 3 = moderate support, 4 = strong support. Study ratings were based on reported solid cancer (or close surrogates) risk unless noted otherwise.*
[d] *Studies excluded: ecological studies of risks around nuclear sites (no dosimetry and extremely low exposures); the 15-Country worker study and other studies that overlap with the more recent INWORKS; the MPS is not yet completed, but published components of it are included separately; studies of genetic effects (since no human heritable risks have been shown); studies of tissue reactions (because these are generally not believed to be LNT).*
[e] *The dosimetry used in the Preston et al. (2016) study of breast cancer, based on the Simon et al. (2014) dosimetry, is significantly improved and would be rated "2" compared to the dosimetry that was used in other published epidemiologic analyses of this cohort. However, since little other epidemiology has been published using the new dosimetry, for the purposes of this Commentary, these studies are limited in their support for LNT.*
[f] *Considered "weak" support or "inconclusive" primarily because of weaknesses in the epidemiology, dosimetry or statistical risk modeling. The other studies scored as 1 (no support) had reasonable methodologies but provided little or no support for the LNT model because their risk coefficients were essentially zero or negative.*
[g] *Fallout studies were included as a group (they mostly had little or poor dosimetry and many were studies of aggregates rather than individuals, however, the Hanford ^{131}I fallout study was of better quality, so was identified separately).*

given in aggregate to each data set with regard to support of the LNT model. The NCRP report concludes "that no alternative dose–response relationship appears more pragmatic or prudent for radiation protection purposes than the LNT model." I fully concur with this scientific assessment and the resulting policy choice.

In my opinion, much of the LNT debate results from a failure on the part of some scientists, policy makers, and the public at large to understand how standards and regulations are developed. Scientists may overreach and argue science, especially scientific information they have personally developed, is crucial in the standard setting process. They argue for science-based standards. In some cases they may even argue that the scientific information translates into specific numerical standards different than current standards. I also argue for science-based standards and regulations, but reach a different conclusion.

In my opinion, it should be recognized that science informs policy judgments or decisions that are at the core of setting standards. Very few standards for any hazardous agents are actually set based on the use of specific data sets to arrive at specific risk target doses, that is, less than one extra cancer over a lifetime for a population of 10,000 individuals. Rather, numerical radiation protection standards intended to limit occupational or environmental exposures were initially set based on scientific judgment. The methods used have evolved over time. Many early standards were set by practitioners in a field. More recently, in the United States and many other countries, legislation has assigned standard setting responsibility to government agencies. At the same time, the process has increasingly called for greater involvement of the public. This approach places a premium on scientists learning to communicate more effectively with the public on matters that are at the interface of science and public policy. The legislative framework used in the United States for setting standards assigns the ultimate responsibility to a responsible government administrator, for example, the Administrator of the US Environmental Protection Agency or the Nuclear Regulatory Commission. I have previously reviewed a similar situation for the setting of national ambient air quality standards (McClellan, 1999).

43.18 Current radiation protection guidance

The recommended dose limits of the ICRP and NCRP at the time this chapter was written are shown in Table 43.16. Both the ICRP and NCRP systems make use of weighting factors to take account of the relative biological effectiveness of different types of radiation (Table 43.17). They also use tissue-weighting factors (Table 43.18).

TABLE 43.16 Recommended dose limits for ionizing radiation (mSv in a year).

Type of limit	ICRP	NCRP
A. *Occupational exposure* Stochastic effects Effective dose limit (cumulative)	20 mSv/yr averaged over 5 years, not to exceed 50 mSv in any one year	10 mSv × age
Annual	50 mSv/yr	50 mSvr/yr
Deterministic effects Dose equivalent limits for tissues and organs (annual) Lens of eye	150 mSv/yr	150 mSv/yr
Skin, hands, and feet	500 mSv/yr	500 mSv/yr
B. *Embryo/fetus exposure* Effective dose limit after pregnancy is declared	0.5 mSv/month	Total of 1 mSv to abdomen surface
C. *Public exposure (annual)* Effective dose limit, continuous or frequent exposure	No distinction between frequent and infrequent—1 mSv/yr	1 mSv/yr
Effective dose limits, infrequent exposure		5 mSv/yr
Dose equivalent limits Lens of eye	15 mSv/yr	15 mSv/yr
Skin and extremities	50 mSv/yr	50 mSv/yr
D. *Negligible individual dose (annual)*	No statement	0.01 mSv/yr

Both the NCRP and ICRP systems use a dose and dose rate effectiveness factor (DDREF) as an intermediate step to estimating total detriment from cancer and heritable stochastic effects of radiation. The ICRP recommends a DDREF of 2.0. The National Academies Biological Effects of Ionizing Radiation (BEIR) Committee has recommended a DDREF of 1.5 (BEIR VII, 2007). The DDREF as currently used combines both dose and dose rate. In my opinion, DDREF should be separated into two separate factors: a dose effectiveness factor (DEF) and a dose rate effectiveness factor (DREF). In my opinion, the information reviewed earlier would support a DREF of about 4.0. Brooks et al. (2009) have stated a similar view for internally deposited radionuclide exposure.

The ICRP framework for dose constraints reference levels is shown in Table 43.19 (ICRP, 2007; Wrixon, 2008). The detriment-adjusted nominal risk coefficients used for stochastic effects after exposure to radiation at low dose rates are shown in Table 43.20 (NCRP, 2007; Wrixon, 2008).

Both the ICRP and NCRP operate with an overarching goal to achieve radiation doses "as low as reasonably achievable." The standards are not intended to provide a license to allow exposure circumstances and radiation doses at the level of the standard.

Before concluding the consideration of radiation protection guidance, let me emphasize that this guidance has been developed to protect both workers and the public by controlling potential radiation exposures. This guidance also provides a useful context when considering and dealing with accidental releases such as a nuclear reactor or nuclear fuel reprocessing accident. However, an abundance of "common sense" needs to be exercised in dealing with accidents. For example, overzealous actions including evacuation of large populations to limit radiation exposures may result in greater loss of life from other causes such as traffic accidents than the estimated lives saved if the focus is inappropriately limited to radiation effects. In addition, the psychological stress associated with evacuations should not be discounted.

TABLE 43.19 Framework for dose constraints and reference levels.

Bands of effective dose, mSv (acute or annual)	Characteristics	Requirements	Examples
20 – 100	Controlled by action on exposure pathway	Consider reducing doses	Reference level for radiological emergency
1 – 20	Controlled by action or source or exposure pathway	For planned exposure situations, individual dose assessment and training	Constraints for occupational exposure. Constraints for comforters and carers of patients treated with radiopharmaceuticals. Reference level for radon in dwellings
< 1	Controlled by action on source	Periodic checks on exposure pathways	Constraints for public exposures in planned situations

43.19 Summary

It is my opinion that our collective knowledge of the health effects of exposure to ionizing radiation from external sources or internally deposited materials exceeds that existing for any other single potentially hazardous agent or class of agents. Further, it is my professional opinion that the high level of knowledge of radiation effects today strongly supports current radiation protection standards. Despite that high level of knowledge, there are few potential hazards that evoke more fear and concern than potential radiation exposures. I submit that in some situations the level of fear and concern is irrational and severely inhibits public discourse on anything to do with radiation or nuclear activities. This includes consideration of the use of nuclear reactors versus fossil-fueled power plants or solar or wind to generate electrical power.

The health effects of explosion of a nuclear weapon are directly evident from the bombing of Hiroshima and Nagasaki, Japan, with weapons that had yields on the order of 20 kt. The effects were devastating, with hundreds of thousands of people killed from the blast overpressure, thermal radiation, and direct ionizing radiation. A cohort of survivors enrolled in 1950 is still being followed with the primary effect observed being a small increase in radiation attributable to cancer deaths over and above the substantial background incidence of cancer. Nuclear weapons are now in the hands of about a dozen countries and other nations are attempting to develop nuclear weapons. On the order of several thousand weapons have been tested, with yields extending up to the megaton range. Political efforts to control the spread of nuclear weapons have been a dominant international political issue for the past three-quarters of a century and must be continued!

The threat of terrorists using nuclear weapons is a continuing concern. A more realistic concern is for rogue nations to use nuclear weapons in the face of uncertainty

as to how other nations will respond. There will be no winners in a war that involves nuclear weapons! Concerns continue for terrorists attempting to create and use weapons that disperse radioactivity. The threats of such usage continue to generate fear. In my opinion, the potential for such devices to injure substantial numbers of individuals is quite low. However, the efforts to clean up contamination from use of any radioactivity-dispersing devices could be substantial and would certainly create additional fear and confusion. Terrorism of any kind must be curbed!

43.20 Personal perspective

My life and professional career have been profoundly impacted by the events I have just discussed. In 1943, my parents joined the work force that would ultimately total about 50,000 workers constructing the Hanford, WA complex. At the time they were recruited, it was known as the "Hanford Engineering Works." It would ultimately become the Hanford Atomic Products Operation. In the summer of 1944, I joined my parents living in Richland, WA, just south of the Hanford complex. I was underage for radiation work, I started the third grade. Coincidently, Cantril and Parker (1945) who would become my mentors were writing a radiation protection plan for Hanford. Growing up in a very technocratic community I was influenced by many engineers and scientists employed at Hanford who were my neighbors. As a high school student I participated in experiments on ^{131}I effects in sheep. Later as a university student I spent three summers as an intern at Hanford conducting research on ^{65}Zn, ^{131}I, ^{239}Pu, and other radionuclides. After receiving my Doctor of Veterinary Medicine degree from Washington State University in 1960, I joined the staff of the Hanford Laboratories, which were headed by Herbert M. Parker and conducted research on numerous radionuclides in laboratory and domestic animals working with Leo K. Bustad. Phillip Abelson would also become a mentor.

I spent 1965–66 in a term assignment with the US Atomic Energy Commission's (AEC) Division of Biology and Medicine. I was fortunate to have Paul S. Henshaw, the author of the 1941 classic radiation effects paper, as my office mate. Glenn Seaborg was at the helm of the AEC as Chair of the five-person Commission. He was influential in encouraging me to accept a position in September 1966 with the Lovelace Medical Center in Albuquerque, NM, providing leadership for a new research program. That program focused on developing an improved scientific basis for understanding the potential health effects of a catastrophic nuclear reactor accident such as ultimately occurred on April 26, 1986, in Chernobyl, Ukraine.

For over four decades the Lovelace research program was a major contributor to the world's literature on the health effects of inhaled fission product radionuclides and plutonium. In the mid-1970s, the Lovelace program diversified and used its substantial expertise in aerosol science and inhalation toxicology to address the health consequences of airborne emissions from hydrocarbon-fueled energy technologies such as diesel engines. Later, starting in 1988, I provided leadership for the Chemical Industry Institute of Toxicology (CIIT) in Research Triangle Park, NC, a research laboratory focused on the mechanisms of actions of chemical agents. While at CIIT and continuing to the present, I have maintained a keen interest in understanding the human health risks of radiation exposure.

43.21 Dedication

This chapter is dedicated to my parents, my teachers, and fellow students in the Richland, WA, schools and the many colleagues who I have had the pleasure of working with for over 60 years in the radiation field. In 1943, my parents made a bold move from Minnesota to the state of Washington to become a part of the Hanford Engineering Works, which would later become known as the Hanford Atomic Products Operation. They did not know what products were to be produced nor could they have possibly envisioned the impact the key product, plutonium, would have on the world. They viewed the association with the Hanford site as an adventure and opportunity. They had interesting jobs that had impact. My father was a chemical process operator. As a youngster, I knew he must do some unusual kind of work because periodically there was a gray box on our front porch containing bottles to collect his urine—my introduction to bioassay systems. Later, I learned he worked in the plant that separated ^{239}Pu from irradiated fuel. My mother was a secretary to the principal in multiple schools. Later, I would appreciate that this position is critical to the success of any organization; those individuals are de facto chief operating officers.

My siblings and I were fortunate that the Richland schools had exceptional teachers and demanding curricula. We had fellow students who were quite accomplished. They and their parents came from all over the United States. In high school, our sports teams after 1945 were known as the "Bombers" and there was a large mural of a Bomber on the side of the high school. Our logo was a mushroom cloud. In 1954, I graduated from Richland Columbia High School. Not surprising, the graduates followed a multitude of career paths. Some followed in the footsteps of their parents and immediately went to work on the Hanford site. Others joined the military. Many went to college and, some like myself, followed career paths related to nuclear activities.

One of my classmates, David Koeppen, had a little different background. His father had a ranch close to Richland. I had the good fortune to work on the Koeppen Ranch in 1953 and learned the value of hard physical

work. David and I were good friends. In the fall of 1954, David joined the US Navy and quickly rose to the rank of Chief Petty Officer. He traveled around the world under the sea on nuclear submarines. As I was finishing this book chapter, I attended the 65th reunion of the Columbia High School Class of 1954. I had a wonderful visit with David as we connected the dots on what we had both done during the last 65 years. During that visit I learned that while I was busy studying the health effects of radiation, David had a remarkable career that involved up close contact with nuclear activities. Most of his 20 years in the US Navy were spent on nuclear-powered submarines. He was frequently berthed and worked close to a nuclear reactor! Moreover, the submarines he crewed were armed with ballistic missiles topped with nuclear war heads. During our visit I learned that one of the highlights of his career occurred when he served on the nuclear-powered submarine, the USS Ethan Allen, from October 1, 1960, to October 18, 1968. He was on board the submarine on May 6, 1962, south of Hawaii when it participated in Operation Dominic—Frigate Bird. It fired a Polaris ballistic missile with a nuclear war head that traveled 1200 miles in 12.5 min and on reentry at about 11,000 ft detonated near Johnston Island in the South Pacific. David noted with justifiable pride: "We put that war head right in the old pickle barrel as planned." Ironically, in the 1980s, I would serve on an advisory committee guiding cleanup of the Pacific islands impacted by nuclear weapons testing. We were two classmates whose paths were different, yet so close at times! I am saddened to note that after the reunion David flew his private plane toward his home in southern Idaho, crashed in the mountains of Oregon, and was killed. I salute his distinguished service to our nation and will forever treasure our friendship.

In closing this dedication, I wish to also note my appreciation to the many colleagues that I worked with over the decades to expand the world's knowledge of the health effects of radiation and radionuclides. Our research had two hallmarks. It was purpose driven, directed at addressing uncertainties in our scientific ability to address human risks of exposure to radionuclides. It was research that could not have been conducted without teamwork from individuals that had complementary talents and were willing to work together to achieve important goals. It was a pleasure to be a part of that team and learn from and be mentored by many of my team mates.

44.1 Introduction

Traumatic brain injury (TBI) is a sporadic mechanical impact to the head that leads to acute or chronic impairments in neurological function. It is the most common cause of death in North America in individuals between ages 1 and 45 years (Rutland-Brown et al., 2006; Rosenfeld et al., 2012), accounting for 30.5% of all injury-related deaths. There are approximately 1.7 million cases of TBI annually in the United States, leading to 1.4 million emergency department (ED) visits, 275,000 hospitalizations, and 52,000 deaths. Costs of TBI, including direct medical expenses and indirect costs related to loss of productivity, amount to an estimated $76.5 billion each year.

TBI occurs most commonly to children aged 0−4 years, adolescents aged 15−19 years, and adults older than 65 years. Unfortunately, the prevalence of TBIs has increased in recent years, rising by 58% (from 520 to 820 per 100,000) between 2001 and 2010. In that same period, the number of TBI-related deaths decreased by 8%, likely due to better understanding of how to manage TBIs. The injury mechanisms of TBI-related deaths varies between age groups (cdc.gov, 2019). In persons 0−4 years old, TBI-related deaths often occur as a result of child abuse. In young children to young adults, TBI-related deaths are usually caused by motor vehicle accidents. In middle to late adulthood, self-inflicted TBIs are the major cause of death. In the elderly, falls account for the majority of deaths by TBI. TBI-related death rates are highest in adults older than 75 years, and males are more likely to die from TBI than females across all age groups (Faul et al., 2010).

This chapter summarizes our understanding of the cellular and molecular mechanisms that account for neurological abnormalities observed after TBI. The points of this work can be summarized as follows:

- TBI includes both primary and secondary injuries.
- Immediate care after TBI shares the same principles as advanced life support.
- A team of healthcare specialists work with the patient and family to facilitate recovery post-TBI.
- Primary injuries lead to necrosis and apoptosis.
- Secondary injuries lead to apoptosis or alterations in synaptic function.
- Several pathological changes suggest that TBI is a risk factor for other neurological diseases.

44.2 Traumatic brain injury mouse models

Our understanding of the cellular and molecular changes that occur after TBI have been advanced through the use of animal models of TBI (Fig. 44.1). In general, animal models of TBI deliver mechanical forces to the brain or skull in a controlled manner in order to replicate known neuropathology, rather than the physical parameters of injury. Accordingly, many of the outcomes in animal models mimic those observed in human TBI, such as concussion, contusion/hemorrhage, and *diffuse axonal injury (DAI)*. As with any experimental model, however, there is a trade-off between reproducibility and physiological relevance. A brief description of commonly used animal models of TBI follows. Readers interested in further details about different animal models of TBI should read the work by Xiong et al. (2013).

Highly reproducible models include fluid percussion injury and controlled cortical impact. In *fluid percussion injury*, a pressure pulse is sent through a fluid reservoir

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00044-1

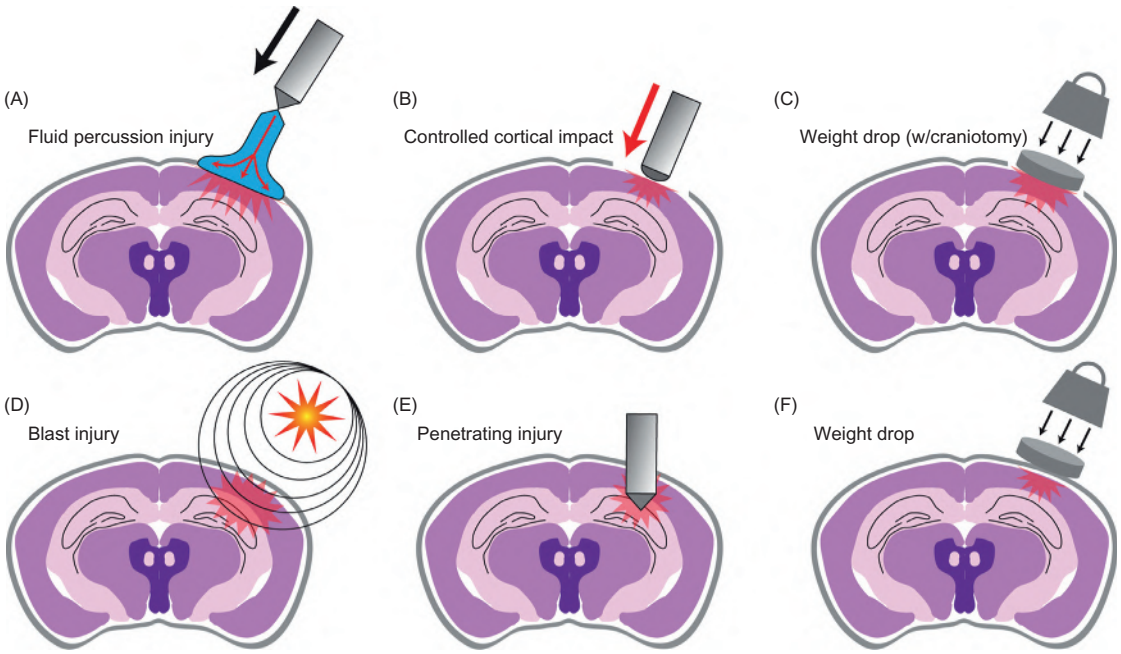

FIGURE 44.1 Mouse models of TBI. (A) Fluid percussion injury uses a saline-filled reservoir resting on the dura to reliably transfer energy from a piston onto the brain. (B) Controlled cortical impact uses a pneumatic piston or electromagnetic actuator to drive a rod directly onto the skull or dura. (C & F) Weight drop models apply force by dropping weights from set heights. Compared to fluid percussion injury and controlled cortical impact, weight drop models are relatively inexpensive to implement but produce more variable injuries. (D) Blast injuries use pressurized air waves to delivery energy to brain tissue. Due to the spread of blast waves, peripheral tissues are also prone to damage. (E) Penetrating injuries drive small probes into the brain parenchyma. These models uniquely simulate the effects of penetrating injuries, while all other models simulate closed head injuries.

placed on the exposed dura. This pressure pulse displaces the brain to generate focal and diffuse injuries. *Controlled cortical impact* drives a rigid object directly onto the exposed dura. Both of these are open models of TBI, requiring removal of a portion of the skull (craniotomy). This decreases variability of the injury but reduces the physiological relevance to closed TBI.

More biomechanically relevant models include blast injuries, penetration injuries, weight-drop, and repeated mild injuries. *Blast injuries* deliver a pressurized gas wave to the head. Because this model uses a pressure wave that is difficult to focus, the animal's body must be protected using a Kevlar jacket. Blast injuries are excellent models of TBIs suffered as a result of improvised explosive devices, which are the primary cause of head injuries in modern military conflicts (see Chapter 45: Neurological effects and mechanisms of blast overpressure injury). *Penetrating injuries* drive a projectile into the brain with high energy to mimic TBIs that occur from gunshot wounds. In *weight-drop models*, a free-falling weight is dropped on the exposed skull. In some weight-drop models, a craniotomy is performed to increase reproducibility.

Repeated mild injury models are of particular interest because they mimic injuries that occur in contact sports. In addition, mild TBIs account for between 70% and 90% of all TBIs, although this figure is likely to be an underestimate due to the difficulty in diagnosing mild injuries. Repeated injuries have been delivered using fluid percussion, blast, and weight-drop models. Although more characterization is needed, repeated mild injury models suggest that even mild TBIs can produce rapid, disastrous effects (Fehily and Fitzgerald, 2017). Areas with repeat injuries show exacerbated neuropathology, including reactive gliosis, myelin degeneration, axonal damage, tau phosphorylation, blood–brain barrier (BBB) permeabilization, and reduced cerebral blood flow. Repeated mild injuries also worsen behavioral symptoms, such as learning impairments and behaviors suggestive of anxiety and depression. These findings are consistent with data from athletes and active military personnel showing that repeated head injuries worsens the severity of neurological symptoms.

44.3 Clinical manifestations and management of traumatic brain injury

44.3.1 Classifying traumatic brain injury using the Glasgow Coma Scale

TBI is a heterogeneous entity. The severity of TBI can be classified according to various injury scoring systems, with each carrying different impacts on prognosis and treatment. The most commonly used scoring system is the

TABLE 44.1 Using the GCS to assess head injury severity.

Behavior	Response	Score
Eye opening	Open and blinking spontaneously	4
	Open to verbal stimuli	3
	Open to painful stimuli	2
	No response	1
Verbal	Aware of self, time, and location	5
	Slight confusion	4
	Inappropriate replies	3
	Incomprehensible replies	2
	No reply	1
Motor	Follows commands	6
	Appropriate purposeful withdrawal from pain	5
	Normal flexion in response to pain	4
	Abnormal flexion in response to pain	3
	Extension in response to pain	2
	No response	1

Classification: Coma: 3. Severe head injury: 4–8. Moderate head injury: 9–12. Mild head injury: 13–15.

Glasgow Coma Scale (GCS) at initial presentation (Vos et al., 2002; Moppett, 2007) (Table 44.1). A GCS score of 13–15 is considered mild injury, 9–12 is moderate, and 8 or less represents severe TBI. The initial severity of TBI has prognostic value regarding the long-term outcome of the injury (Thornhill et al., 2000). Although the majority of TBI cases are mild (>75%) (Faul et al., 2010), the minority of patients presenting with moderate or severe TBI have a very poor prognosis, with mortality rates as high as 55%. Of all patients with a post-TBI GCS of 12 or less, 2% die within the first hour and 8% die within the first 6 h (Peek-Asa et al., 2001).

Although the GCS excels as a universal tool for TBI classification because of its simplicity, reproducibility, and prognostic power, its use may sometimes be limited by clinical confounders, such as anesthesia, sedation, paralysis, and coexisting intoxication. These confounding factors are especially prominent in patients with a low GCS score (Stocchetti et al., 2004). Hence, CT-based scoring systems are sometimes used by neurotrauma centers for a more objective classification on TBI. These include the Marshall scale, which has been shown to be accurate in predicting risks of increased *intracranial pressure (ICP)* but lacks reproducibility in cases of multiple brain injuries (Marshall et al., 1992), and the Rotterdam scale, which was developed more recently to overcome the limitations of the Marshall scale but still lacks validation in large populations (Maas et al., 2005).

44.3.2 Coma recovery scale to track meaningful changes with severe traumatic brain injury

Severe TBI is often described as a disorder of consciousness. After a severe injury, there can be a disruption of awareness of one's self and the surrounding environment, the inability to interact with others, and disorders of consciousness. Disorders of consciousness include coma, vegetative state, and minimally conscious state. Disorders of consciousness can be assessed using the *Coma Recovery Scale-revised* (*CRS-R*, Table 44.2). The CRS-R consists of 23 items with six subscales of sensory-evoked behaviors that are arranged in a hierarchy from absent to reflexive behaviors to cognitive mediated behaviors (Giacino et al., 2004). A maximum score of 23 indicates cognitive mediated behaviors and normal consciousness, whereas lower scores indicate absent of reflexive behaviors and a disturbance in consciousness (Giacino et al., 2004). The CRS-R can be used to assist with differential diagnosis, prognostic assessment, and treatment planning in individuals with disorders of consciousness.

TABLE 44.2 Using the CRS-R to track meaningful changes with severe TBI.

Behavior	Response	Score
Auditory	Consistent movement to command	4
	Reproducible movement to command	3
	Localization to sound	2
	Auditory startle	1
	None	0

	Unarousable	0

44.3.3 Intracranial pressure

TBI is often associated with brain edema, which increases ICP. It is important to note that there are two types of brain edema: cytotoxic brain edema and vasogenic brain edema. Cytotoxic brain edema is caused by disturbances in the osmotic balance of neural cells, such that increased water influx leads to necrosis, as observed in cases of excitotoxicity. Vasogenic brain edema involves disruption of BBB integrity. The BBB is a series of tight junctions between vascular epithelial cells. These tight junctions are dynamic structures that are maintained by the astrocytic endfoot processes that line the vascular epithelium. In pathological states (such as TBI), the tight junctions between epithelial cells are replaced by porous structures that allow the entry of large macromolecules (and their accompanying solvent) into the brain.

To understand the relationship between ICP and brain herniation, it is important to conceptualize the cranium as a rigid vault packed with three major components: brain

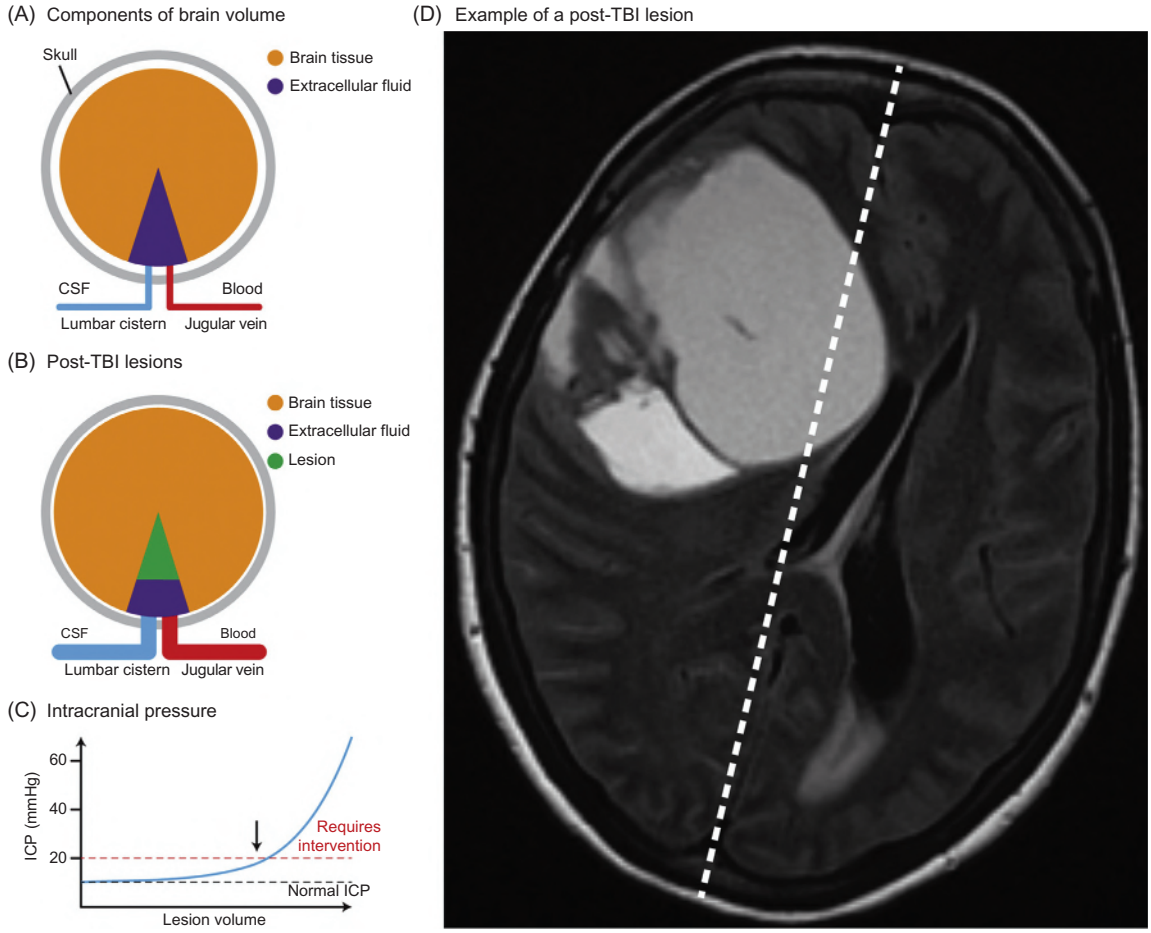

FIGURE 44.2 Regulation of brain volume is critical for maintaining safe ICP. (A) Brain tissue and the extracellular fluid (comprising blood and CSF) contribute to normal brain volume. (B) Brain lesions that occur after TBI increase intracranial volume. (C) An initial increase in intracranial volume only leads to a minimal increase in ICP because of a compensatory outward flow of CSF and blood. Once this protective mechanism has been exhausted (arrow), ICP begins to increase with a steep slope. (D) Magnetic resonance imaging (MRI) showing midline shift of brain contents secondary to a decompensated increase in intracranial volume (in this case by a growing tumor). Loss of sulci/gyri prominence and asymmetric compression of ventricles are seen. White line depicts the expected midline of the brain.

tissue (~80%), blood (~8%), and CSF (~12%). The physical law of compliance governs the relationship between ICP and the volume of these three components: an increase in pressure leads to a decrease in volume. Blood and CSF, both being fluids, are much more easily displaced than the solid brain parenchyma. Hence, when intracranial volume increases (e.g., due to acute intracranial bleeding), CSF and blood are the first components to be "pushed out" of the cranial vault. CSF drains from the cranium into the communicating subarachnoid space in the spinal column, whereas venous blood drains back to the heart. The flexibility of CSF and blood volume within the cranium creates a compensatory "cushion," such that increases in intracranial volume do not lead to elevated ICP initially. This "cushioning" effect lasts for as long as there is blood or CSF to be displaced. However, when intracranial volume expands beyond a certain level, this compensatory mechanism becomes exhausted. ICP will now begin to increase steeply with further volume expansion (Fig. 44.2), and brain tissue now becomes the only other element left to be compressed by the increased ICP. Such compressive forces can lead to herniation of the brain across various weak points in the brain or across the tentorium. Brain herniation manifests with a wide variety of clinical signs and symptoms, depending on the area of the brain being compressed. The most dreaded complication is brain stem compression, which leads to suppression of many neurological functions important for survival, such as regulation of respiration and circulation. Other ominous signs suggestive of impending herniation include unilaterally or bilaterally fixed and dilated pupil(s), decorticate or decerebrate posturing, and the Cushing triad (bradycardia, hypertension, and respiratory depression).

Because a TBI that increases ICP is likely to have a poor outcome, it was thought that preventing edema

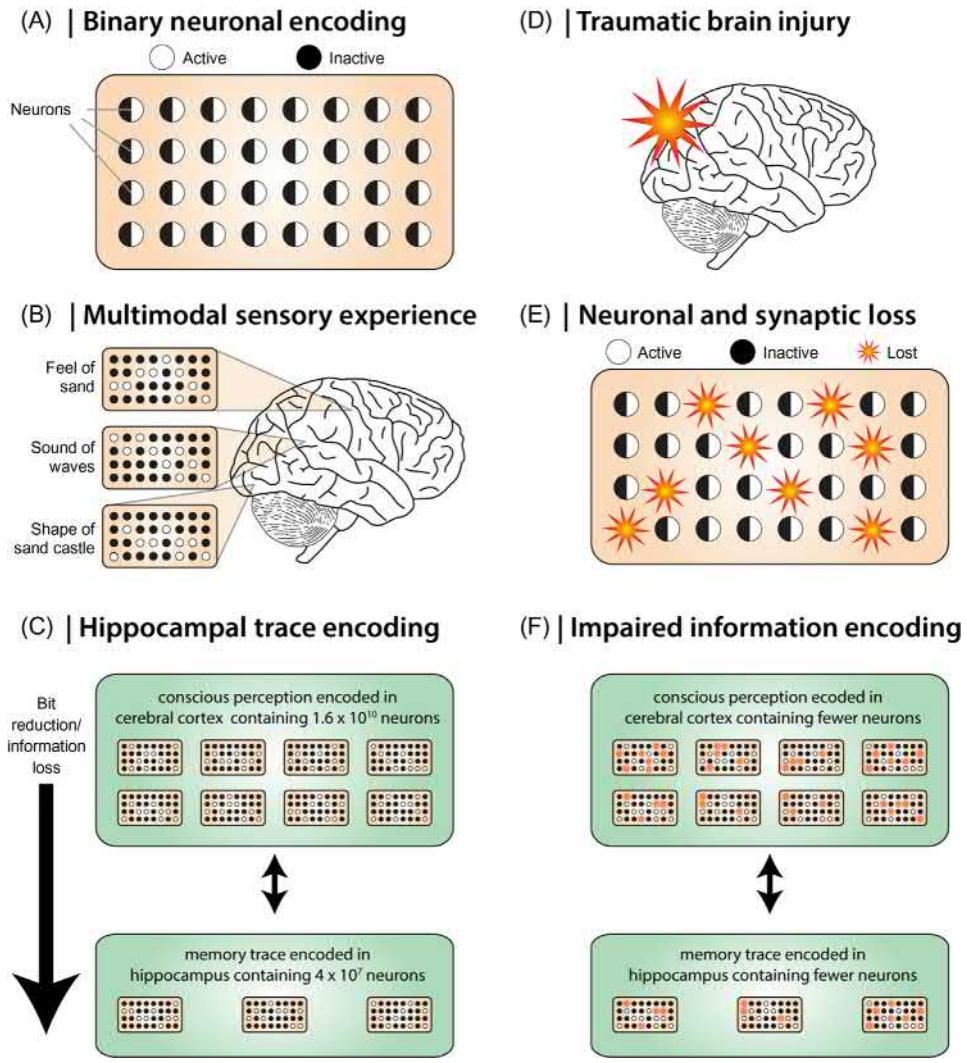

FIGURE 44.3 Cortical and hippocampal networks integrate sensory information. (A) The brain is often thought of as a computer. The binary code used by the brain is the activity or inactivity of specific neurons. Even a simple network of 30 neurons can encode more than 100 million (2^{30}) different information states. (B) Different patterns of neuronal activity in distinct brain regions encode a variety of sensory information. (C) Extensive interconnections between the cortex and hippocampus via the entorhinal cortex allow the encoding of memory traces. Because there are fewer neurons and synapses in the hippocampus than in the cortex, information is lost during the encoding of memory traces, which may explain why memories are not as vivid as primary sensory experience. (D, E) The loss of neurons that occurs after a TBI reduces the amount of information we can encode. In fact, DAI may also sever connections between brain regions. (F) The loss of neurons and synapses impairs information encoding, storage, and retrieval, causing memory, cognitive, sensory, and motor deficits.

would have therapeutic benefits. However, antiedematous therapy (e.g., steroids, superoxide dismutase, calcium antagonists, and inhibitors of bradykinin and glutamate receptors) has not proved effective in clinical trials conducted after TBI (Unterberg et al., 2004). This suggests that management of functional impairments associated with TBI will require targeting more upstream changes in cell signaling pathways. In line with this, intracranial lesions do not always lead to increased ICP, and increased ICP does not always equate with increased risk of herniation. In certain conditions, such as pseudotumor cerebri, ICP can be chronically elevated but well-compensated with decreased ventricular size and intracranial CSF volume. Hence, patients with pseudotumor cerebri are not at significantly increased risk for brain herniation. Neuroimaging can be helpful in assessing the degree of intracranial distortion from elevated ICP. Concerning radiological findings suggestive of decompensated ICP elevation include loss of gray/white distinction, loss of sulci/gyri prominence, asymmetrical compression or enlargement of ventricular space, mass effect (distortion of size or position of normal brain structures), and midline shift (Fig. 44.3). These findings should prompt immediate medical or surgical therapy.

44.3.4 Primary and secondary brain injury

TBI is often divided into two distinct but related phases: primary brain injury and secondary injury (Werner and Engelhard, 2007; Greve and Zink, 2009). Clinically, primary brain injury often requires surgical attention, whereas secondary injury is managed in the intensive care setting, where the prevention and treatment of these secondary insults become the major focus of neurotrauma intensivists.

Primary brain injury occurs at the time of the initial mechanical impact to the skull. The transfer of external mechanical forces to intracranial contents can lead to intra-axial damage and/or extra-axial injuries. *Intra-axial damage* involves the brain parenchyma. Focal cerebral contusions occur most commonly after TBI. Injuries involving abrupt acceleration/deceleration result in direct resonant impact of the brain with the base of the skull. Hence, the basal, frontal, and temporal areas are especially susceptible to contusion due to their anatomical distribution in relation to the bony areas of the cranial vault. In addition, shearing forces during mechanical impact can cause DAI. Patients with DAI often present with profound coma without elevated ICP, and often have a very poor prognosis. The cellular and molecular outcomes of intra-axial damages are described in greater details in other sections of this chapter.

Extra-axial damage involves non-brain cranial structures. Penetrating trauma, blast waves, or direct impact can result in skull fracture and rupture of intracranial vessels. Depending on the location of the impacting force, different types of hematomas may result.

1. *Epidural hematoma (EDH)*. Direct impact to the lateral surfaces of the head may cause rupture of the middle meningeal arteries embedded within the dura, forming an EDH. EDHs usually appear as a well-demarcated, biconvex lens-shaped density on CT scan. Bleeding in EDH is usually from a high-pressure arterial source, but is initially tamponaded by the tightly tethered dura. However, as the hematoma expands and strips the dura from the skull, it gradually creates an intense headache. Classically, patients with EDH are described as having a lucid period right after injury, when bleeding is still contained and tamponaded by the dura. This lucid period is followed by sudden loss of consciousness, when expansion of hematoma becomes large enough to cause a significant increase in ICP and compression or herniation of brain tissue.
2. *Subdural hematoma (SDH)*. Impact to the frontal regions, as well as shearing forces from linear or rotational acceleration/deceleration, can tear the subdural bridging veins and result in SDH. On CT, SDHs appear as poorly demarcated crescent-shaped densities. Unlike EDH, SDH occurs between the dura and the arachnoid layers. Hence, SDH lacks the additional layer of "protection" offered by the rigid dura. Clinically, patients with SDH present with gradually increasing confusion and headaches. Acute SDH has a high mortality rate and often requires prompt surgical evacuation.
3. *Subarachnoid hemorrhage (SAH)*. SAH refers to bleeding that occurs in the subarachnoid space, which is between the arachnoid and pia mater and is normally filled with cerebrospinal fluid (CSF). The majority ($>85\%$) of SAHs occur in patients with a preexisting intracerebral vascular lesion, most commonly an aneurysm (van Gijn and Rinkel, 2001), which serves as a functional weak point that is susceptible to rupture when intravascular pressure is elevated. However, in the setting of trauma, sufficient external forces could lead to rupture of intracerebral vessels without preexisting vascular abnormalities. Radiologic clues for traumatic SAH include localized bleeding in the superficial sulci, adjacent skull fracture, cerebral contusion, as well as external evidence of traumatic injury (Rinkel et al., 1993). Clinical suspicion for SAH should be high for patients reporting sudden, severe headaches (often described as "thunderclap" headache or "the worst headache of my life"). In these cases, emergent CT of the head should be obtained. If CT fails to identify intracranial bleeding but clinical suspicion for SAH remains high, then a lumbar puncture must be performed to look for blood in the CSF.

Intracranial bleeding after TBI can be further exacerbated by *coagulopathies*, which develop in up to one-third of TBI patients (Zehtabchi et al., 2008; Allard et al., 2009; Wafaisade et al., 2010). Coagulopathies may result either from underlying anticoagulation medications (e.g., warfarin, clopidogrel) or from TBI-induced platelet dysfunction, release of systemic tissue factor, and activation of endogenous anticoagulation pathways (Maegele, 2013).

Secondary injuries of TBI result from cellular perturbations caused by primary injury. Secondary injury can happen at any later time point after the initial impact. Although the primary injury of TBI is a major predictor of outcome, secondary insults can contribute to further worsening of prognosis (McHugh et al., 2007). The mechanisms of secondary injury include neurotransmitter-mediated excitotoxicity, free-radical injury to cell membranes, electrolyte imbalances, mitochondrial dysfunction, inflammatory responses, apoptosis, secondary ischemia from vasospasm, focal microvascular occlusion, and vascular injury (Werner and Engelhard, 2007). These events can lead to cerebral edema and further increases in ICP. The detailed molecular mechanisms of these events are described later in this chapter.

Individuals who have a severe brain injury, defined as a GCS <8, are at risk for developing a secondary complication called *paroxysmal sympathetic hyperactivity*, more commonly referred to as *brainstorming*. A brainstorming episode is thought to be an exaggerated stress response due to increased sympathetic nervous system activity. Symptoms can include posturing, dystonia, hypertension, tachycardia, pupillary dilation, diaphoresis, hyperthermia, and tachypnea (Kishner et al., 2006; Thorley et al., 2001;

Baguley et al., 2004). Immediate treatment of symptoms with mediations and environmental modifications must be administered to avoid the long-term effects of these episodes.

A critical aspect in post-TBI intensive care management is the avoidance of these secondary brain insults, which would otherwise be well tolerated but can exacerbate neuronal injury in cells made vulnerable by the initial TBI. Of particular importance is the prevention of hypotension and hypoxia (which decrease substrate delivery of oxygen and glucose to injured brain), fever and seizures (which may further increase metabolic demand), and hyperglycemia (which may exacerbate ongoing injury mechanisms), as discussed in the following sections.

TBI management focuses on stabilization of primary injury and prevention of secondary injury. Prolonged hospital stays due to increased risk for deep vein thrombosis, muscular contractures, spasticity, pressure sores, generalized muscle weakness, and overall impaired functional mobility must be addressed early on in medical care. TBI patients have limited opportunities for mobility in early recovery and are at risk for developing these difficult secondary complications. Below, we discuss management strategies during the early resuscitation period, postresuscitation intensive care therapeutic goals, and long-term rehabilitation. It is important to remember that at any period after TBI, the main goal is to avoid hypoxia and hypotension, the two most critical factors in predicting post-TBI outcome (Manley et al., 2001; Brain Trauma Foundation, 2007a; McHugh et al., 2007). The presence of prehospital hypoxia (PaO_2 <60 mmHg) and hypotension (systolic pressure <90 mmHg) is strongly associated with a poorer outcome (odds ratio $= 1.7-2.6$ and $2.1-3.4$, respectively) (McHugh et al., 2007).

44.3.5 Immediate care

For TBI patients and patients on advanced life support (ALS), the primary focus is on securing airway, breathing, and circulation (i.e., the ABCs of ALS). This may require intubation to maintain adequate oxygenation and fluid resuscitation or use of pressors to maintain perfusion pressure. The patient's heart rate, blood pressure, respiratory rate, and temperature should be continuously monitored. Neurological examination should be performed to assess the GCS score, and should be reassessed at regular intervals. A secondary survey should be performed to assess other extracranial injuries. All patients with TBI should be assumed to have an unstable cervical spine, and precautions should be applied to stabilize the spine (e.g., using a C-collar, "log-roll" precautions) to avoid cervical spinal cord or brain stem impingement during movements of the head. Blood should be sent to check for complete blood count, glucose, electrolytes, blood gases, and pH, as well as toxicology screen. As soon as the patient is stabilized, CT scan of the head should be obtained. CT can reveal skull fractures, intra-axial or extra-axial hemorrhages, significant brain contusions, and edema, which can guide downstream treatment strategies. If initial neurological examination or imaging shows findings suggestive of decompensated ICP elevation and impending herniation (Fig. 44.2), then emergent treatment should be started immediately, including head elevation, maneuvers to improve venous drainage, and osmotic therapy.

44.3.6 Surgical management

Timing and indications for surgical intervention after TBI are based on neurological status and radiological findings. Intracranial bleeding causing significant midline shift should be evacuated surgically regardless of hematoma size. In the absence of midline shift, surgical evacuation of hematomas is recommended if the blood volume is large, or if the patient has a GCS less than 8. For penetrating injuries and skull fractures, surgery for superficial debridement and repair of dural tears and CSF leaks are often recommended. However, debridement of deeper tissues and aggressive extraction of intracranial foreign bodies and bone fragments have not been shown to improve outcome or prevent delayed infection, as long as prophylactic broad-spectrum antibiotics are administered in the setting of penetrating injuries. Occasionally, decompressive craniectomy (removal of a substantial portion of the skull) is performed in conjunction with hematoma evacuation to help decrease ICP. However, the efficacy of decompressive craniectomy in outcome improvement is still controversial, and ongoing clinical trials are under way to determine the benefits versus risks of this technique (Jiang et al., 2005; Cooper et al., 2011; Ho et al., 2011; Servadei, 2011).

44.3.7 Targeted therapies to prevent secondary injury

After the initial resuscitation phase, TBI patients are monitored in the intensive care unit (ICU), where the major goal of care is to maintain cerebral and systemic perfusion, to correct electrolyte and coagulation abnormalities, and to minimize secondary insults.

44.4 Maintenance of adequate cerebral perfusion improves outcome after traumatic brain injury

Adequate *cerebral perfusion pressure (CPP)* is essential to prevent cerebral ischemia or toxic pooling of inflammatory mediators. Optimal CPP after TBI is between 50

and 70 mmHg, with 60 mmHg being the target (Elf et al., 2005; Jaeger et al., 2010). CPP is equal to mean arterial pressure (MAP) minus ICP (CPP = MAP − ICP). Because CPP cannot be readily measured, MAP and ICP are used as surrogate measures. Goal CPP should be achieved first by reducing ICP, then optimizing MAP.

Patients with TBI should be positioned strategically to minimize ICP elevation. The head of the bed should be elevated to 30°. The neck should be in a neutral position without external compression to ensure adequate venous drainage from the brain to the heart. ICP monitoring is invasive, requiring surgical insertion of a ventricular catheter, but it is indicated in severe TBI (Brain Trauma Foundation, 2007b). Ventricular catheters are both diagnostic and therapeutic, allowing drainage of CSF if ICP is too high. In general, CSF drainage is recommended if ICP increases to more than 20 mmHg (Chesnut et al., 2012). If CSF drainage alone is inadequate, then osmotic therapy with hyperosmolar agents (mannitol or hypertonic saline) should be considered. These hyperosmolar agents create an osmotic gradient that draws water across the BBB, thereby decreasing interstitial volume in the brain. Caution should be applied when using these agents, because they invariably trigger diuresis and may lead to an acute decrease in MAP.

MAP can be maintained with fluid infusion and the use of vasopressors. Normal saline is the fluid of choice to maintain euvolemia. Use of albumin is associated with a twofold increase in mortality and should be avoided (Chesnut et al., 2012). Infusion of excessive volume should also be avoided, because hypervolemia may cause further ICP elevations by raising central venous pressure and impeding venous return from the brain. In addition, hypertension may exacerbate intracranial hemorrhage.

44.4.1 Other targeted therapies

Many pharmacologic agents and therapeutic strategies have been tested in clinical trials for management of secondary insults after TBI. Unfortunately, no specific neuroprotective agent or strategy has been shown to improve outcome (Maas et al., 2008).

Hyperglycemia or hypoglycemia should be avoided. Hyperglycemia is associated with poor outcome after TBI and should be avoided. However, aggressive treatment of hyperglycemia with insulin infusions has the risk of iatrogenic hypoglycemia, which also leads to adverse outcomes. Glucose control remains a controversial issue in TBI and other critical care arenas. There is a lack of consensus on the exact range of target glucose levels. In general, it is recommended to avoid extremes of hyperglycemia or hypoglycemia.

Normothermia should be maintained. Prehospital hypothermia is strongly associated with poorer outcome after TBI (McHugh et al., 2007). However, hyperthermia has been postulated to exacerbate secondary inflammatory insults. There is no clear evidence, however, that hyperthermia leads to worsened neurological damage or outcome (Childs, 2008). Despite many clinical trials, neither therapeutic hypothermia nor antipyretic treatments have been shown to correlate with improved mortality or morbidity (Henderson et al., 2003; Sydenham et al., 2009). Hypothermia could potentially lead to coagulopathies, metabolic derangements, and increased infections, and is thus not recommended as routine practice.

Early use of antiepileptics may improve outcome. *Posttraumatic seizures (PTS)* may develop in up to 20% of patients with TBI (Temkin et al., 1990). Seizures increase cerebral blood flow and metabolic demand, which increases ICP and aggravates secondary brain injury (Vespa et al., 2007). Thus, early antiepileptic therapy is recommended, which can reduce the rate of early PTS, but does not prevent later development of PTS (Temkin, 2001).

Glucocorticoids may worsen outcome. Steroids were considered in the treatment of TBI due to postulated potential in reducing inflammation and edema. However, a large clinical trial showed that use of methylprednisolone in early TBI is associated with increased mortality without benefits (Roberts et al., 2004; Edwards et al., 2005). Thus, the use of glucocorticoids is not recommended.

44.4.2 Opportunities for rehabilitation and recovery posttraumatic brain injury

TBIs can produce lifelong impairments, and intensive rehabilitation is often warranted for recovery. Once an individual is considered medically stable, they may qualify for intense acute inpatient rehabilitation. To qualify for this type of rehabilitation, an individual must be able to tolerate intense therapy for a minimum of 3 h/day, 5 days/week. Each individual is assigned a healthcare team consisting of a medical doctor, case manager, nurse, neuropsychologist, physical therapist, occupational therapist, and speech therapist that are all trained in TBI management. Physical, cognitive, and psychosocial impairments are evaluated and treated by the healthcare team. Interventions such as activities of daily living, functional mobility tasks, communication, and memory activities are all used to promote recovery. The healthcare team establishes goals with the emphasis on returning the individuals back to life before injury.

TBI is often described as a silent epidemic that leaves individuals with lingering cognitive and psychosocial deficits throughout the individual's life span (Uhl et al., 2013). Family training is often required to help adapt to a

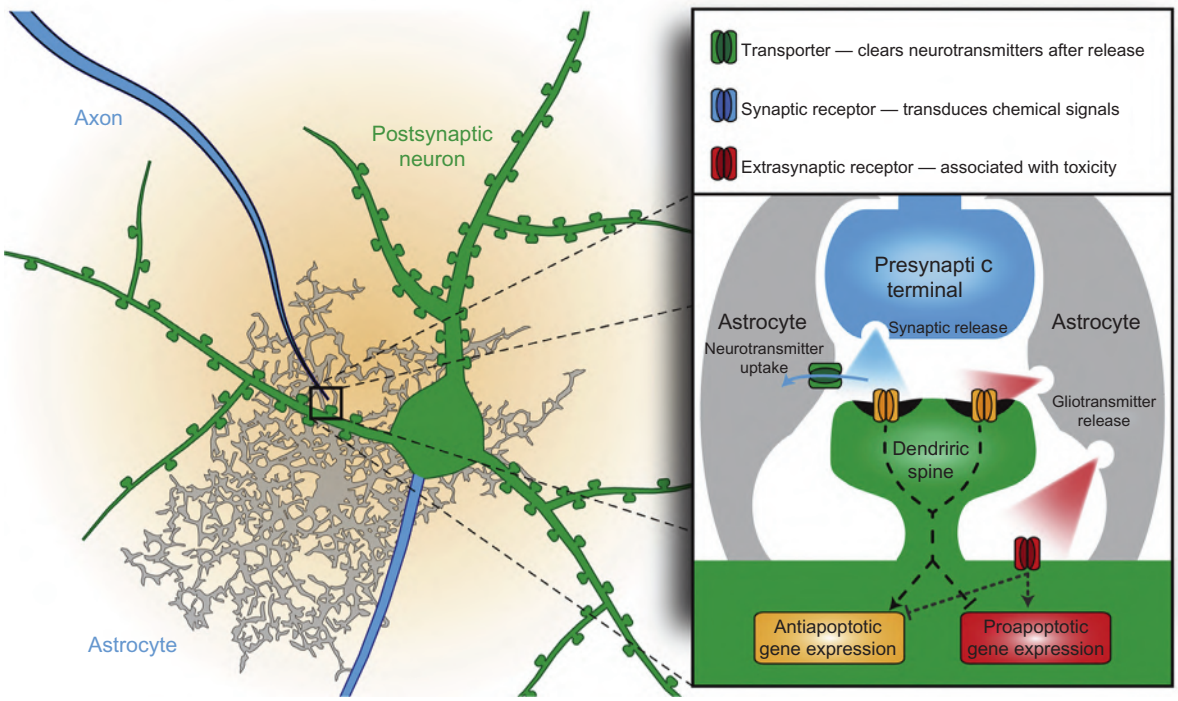

FIGURE 44.4 The synapse is a tripartite structure. Many synapses consist of three components: (1) a presynaptic site; (2) a postsynaptic site; and (3) a glial element. Presynaptic sites typically occur on axons and release neurotransmitters in an activity-dependent manner. Neurotransmitters bind to receptors on the postsynaptic site and elicit a cellular response. The activity of neurotransmitters is regulated by astrocytic processes, which express transporter proteins to uptake neurotransmitters such as glutamate. There is also emerging evidence that astrocytes may release neuroactive compounds (called "gliotransmitters") in an activity-dependent manner (called "gliotransmission"). Because of their peripheral location at the synapse, gliotransmitters from astrocytes tend to activate presynaptic and extrasynaptic receptors. Hyperactivation of extrasynaptic NMDA receptors (NMDARs) can lead to apoptotic cell death.

new way of life after injury. The healthcare team will work closely with family members, suggest modifications, and teach new strategies to help ease the transition back home.

44.5 Cognitive impairments

Memories are stored in our synapses, the connections between neurons. Our ability to form, recall, and lose memories requires the formation, maintenance, and loss of specific synapses. In general, we consider episodic memories to be stored in two broad areas: the hippocampus (for short-term memories) and the cerebral cortex (for working and long-term memories). Memories are required for us to build our seamless conscious experiences, in which we perceive senses, plan actions, and experience emotions through the activity of a vast network of synaptic connections within and between the cortex and hippocampus (Fig. 44.3). As such, the loss of neurons and synapses is attributable to the cognitive decline observed in many pathological states, including TBI. In fact, impaired short-term memory and attention are characteristic of the majority of TBIs (Faul et al., 2010). As discussed above, the superficial location of the cerebral cortex makes it particularly vulnerable to TBI.

44.5.1 Neuronal loss

Neurons are polarized cells with a number of extensive projections. In general, neurons receive information at their *dendrites* or cell body and transmit information along their *axons* (Fig. 44.4). Although a vast oversimplification, it is generally true that a greater number of neurons and synapses can allow a greater diversity of information to be encoded. Thus, the loss of neurons disrupts information processing and accounts for the behavioral changes observed in several neurodegenerative disorders (e.g., Alzheimer's disease, Parkinson's disease, and Huntington's disease).

Cell death can occur through a variety of mechanisms, such as necrosis, autophagy, apoptosis, and necroptosis. Of these, necrosis and apoptosis are highly relevant to TBI. *Necrosis* is uncontrolled cell death caused by acute disruption of the plasmalemma. In TBI, necrosis can occur through shearing forces that rip apart axons or osmotic imbalance due to hyperactive ionic conductances that occur during excitotoxicity. Conversely, *apoptosis* is

a form of programmed cell death and is controlled by a variety of intracellular signaling cascades. Briefly, apoptosis occurs when contents in the intermembrane space of the mitochondria leak into the cytoplasm. Notable examples include cytochrome c, Smac/DIABLO, and Omi/Htra2, which lead to the activation of *caspases*—cysteine proteases that cleave a variety of intracellular contents. Through autoproteolytic activation, caspases create a positive feedback loop of proteolysis that inevitably leads to cell death. Accordingly, the cell contains the Bcl-2 family of proteins, which regulate mitochondrial permeability and caspase activity. A detailed description of apoptosis and its regulation by Bcl-2 proteins is beyond the scope of this chapter. Readers interested in additional details about the regulatory role of Bcl-2 proteins in apoptosis should read the work by Youle and Strasser (2008).

The loss of neurons through necrotic and apoptotic pathways may explain some of the cognitive impairment that occurs after TBI. Markers of necrosis and apoptosis are detectable in human cases and animal models of TBI. In controlled cortical contusion rat TBI models, cortical and hippocampal degeneration is evident within hours of injury, and the magnitude of degeneration is related to TBI severity (Sutton et al., 1993). Hippocampal neuron loss is relevant to memory impairments and a feature of the majority of severe TBI cases. A postmortem analysis by Kotapka et al. (1992) demonstrates how extensive this loss can be—most patients with severe, fatal TBI lose more than two-thirds of their neurons in region CA1 (Kotapka et al., 1992). The loss of neurons in the hippocampus after TBI correlates with cognitive impairments in human patients and rodent TBI models (Hicks et al., 1993; Bigler et al., 1997; Tate and Bigler, 2000).

44.5.2 Synapse loss

In addition to neuronal loss, more subtle alterations in neuronal and synaptic function are observed after TBI. Because these changes do not involve stark cell loss, they are potentially reversible. Before discussing alterations, it is important to give an overview of synaptic structure and function. Synapses can be either electrical or chemical. We focus on chemical synapses (called synapses for the rest of the chapter) because they are, by far, the most common type of synapse. Synapses are incredibly small structures, with a diameter of 300 ± 150 nm and a gap of only 20 ± 2.8 nm (Ribrault et al., 2011). By and large, synapses comprise three parts: a presynaptic site, a postsynaptic site, and a glial element (Fig. 44.4).

Presynaptic sites are typically found along axons and are the site of neurotransmitter release. *Postsynaptic sites* are typically found on dendrites and cell bodies. The postsynaptic site contains a high density of neurotransmitter receptors that bind neurotransmitters and transduce the signal into a cellular response. Postsynaptic sites that occur at *dendritic spines* are very plastic to allow the storage of new information (i.e., memory formation). Finally, the *glial element* is an astrocytic projection that is involved in buffering the concentration of ions and neurotransmitters in the extracellular space. Astrocytic projections play an important role in preventing neurotransmitters from leaking outside the synapse or building up to toxic levels—preventing astrocytic uptake of the excitatory neurotransmitter glutamate leads to lethal, convulsive seizures.

All three of these synaptic elements are affected by TBI (Fig. 44.5). Presynaptic sites are destroyed by DAI, in which rotational forces cause a shearing of axons. DAI can be measured in vivo using *diffusion tensor imaging (DTI)*. Loss of white matter (i.e., axons) scales with TBI severity—moderate-to-severe TBI patients have obvious, global white matter damage, whereas mild TBI patients have more subtle alterations. Axonal damage measured by DTI also correlates with cognitive impairments (Kraus et al., 2007). Postsynaptic alterations are also obvious after TBI. In controlled cortical impact mouse TBI models, dendritic spine density is reduced in the cortex and hippocampus within days of the injury (Gao et al., 2011; Winston et al., 2013). The loss of dendritic spines reduces the number of postsynaptic sites, thus reducing neuronal excitability and restricting release from the presynaptic site. Thus, TBI can compromise synaptic function at presynaptic and postsynaptic sites in the absence of stark neuronal loss. Finally, glial elements are disrupted after TBI. One of the most reliable alterations is, in fact, reactive gliosis. In reactive gliosis, microglia and astrocytes alter their morphologies in order to quarantine damaged areas of the nervous system and recruit macrophages to remove cell debris. Pronounced reactive gliosis may be damaging to neurons due to glutamate excitotoxicity (see below).

It is not clear whether glial damage occurs before, after, or simultaneously with neuronal damage. However, it is likely that both cell types experience acute injury simultaneously, but neurons are more vulnerable to damage. Consistent with this notion, markers of neuronal injury are detected earlier than markers of glial injury in the CSF of children after TBI (Berger et al., 2002).

The brain is a dynamic organ, and dendritic spines are perhaps the most dynamic structures in the brain, showing the ability to rapidly retract and grow in an experience-dependent manner (Schubert and Dotti, 2007). In a unilateral fluid percussion injury rat TBI model, the excitatory synapse marker PSD95 is downregulated in the cortex and hippocampus (Campbell et al., 2012a). In harmony with this PDS95 reduction, the density of dendritic spines, particularly in the cortex, decreases acutely (<24 h) after

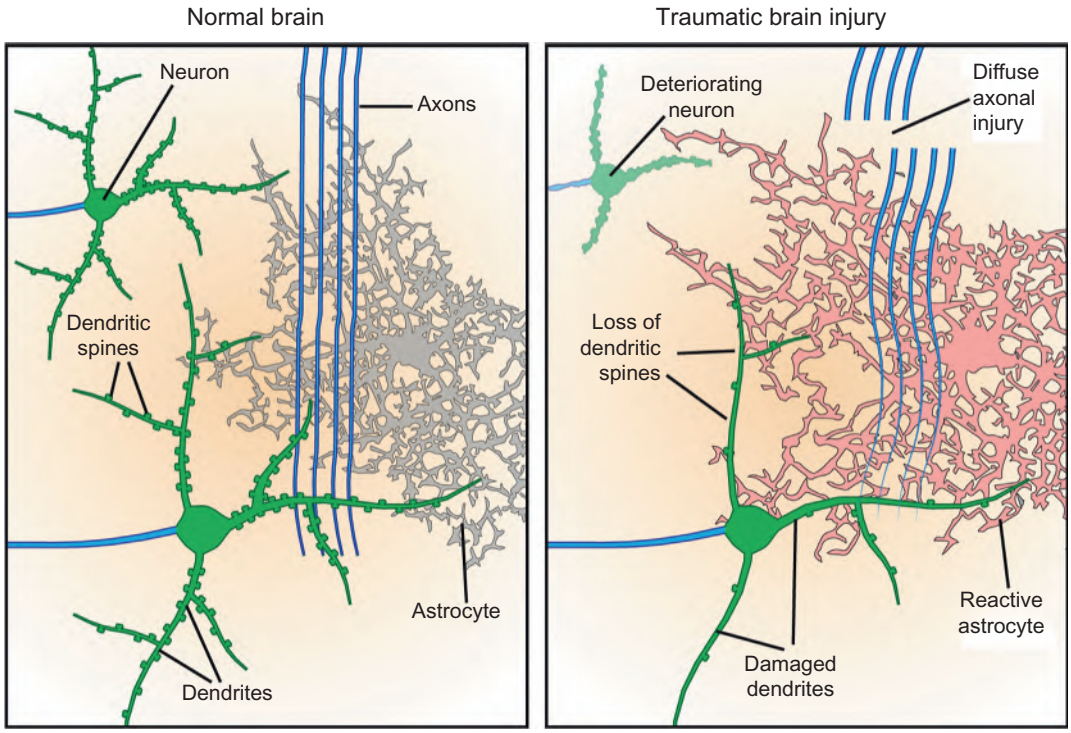

FIGURE 44.5 Traumatic brain injury causes cell death, synapse loss, axon damage, and astrocyte reactivity.

fluid percussion injury (Campbell et al., 2012b). However, after 1 week, the density of dendritic spines recovers. Interestingly, hippocampal neurons have a higher density of dendritic spines 1 week after TBI compared with controls. The significance of this is not clear, although the authors speculate that elevated spine density in the hippocampus may explain the epileptogenic activity reported after TBI.

44.5.3 Seizures

Seizures occur in many cases of brain injury, including stroke, neoplasm, neurodegenerative diseases, infection, and all types of traumatic injuries. The risk of PTS increases with the severity of TBI. The 30-year cumulative incidence of PTS is 2% for mild TBI, 4% for moderate TBI, and >15% for severe TBI (Annegers et al., 1998). This figure can rise much higher. For example, over 50% of Vietnam veterans with penetrating head injuries suffered posttraumatic seizures (Salazar et al., 1985).

There are likely to be several mechanisms of seizure induction following TBI (Fig. 44.6). Brain swelling or mass lesions (i.e., hematoma or neoplasm) increase intracranial pressure and can deform the membranes of neurons. Physical deformation of neurons leads to delayed depolarization, making them more excitable. Neurons may also express different ion channels and transporters following injury, leading to an increase in excitability. A notable example is the sodium-potassium-chloride cotransporter (NKCC1), which imports one Na^+, one K^+, and two Cl^- to help establish appropriate ionic concentrations across the membrane. Following TBI, NKCC1 is expressed at higher levels. Elevated NKCC1 increases intracellular Cl^- levels, which decreases the inhibitory effects of GABA and increases the excitability of neurons.

Additionally, TBI can lead to an inflammatory response that can directly and indirectly stimulate neurons. Neurons are stimulated by a variety of proinflammatory cytokines that are released following nervous system injury. Proinflammatory cytokines also trigger reactive gliosis, in which microglia and astrocytes undergo morphological and functional changes in order to respond to injury. Reactive microglia can release (1) proinflammatory cytokines, which amplify inflammation, and (2) glutamate, which may lead to excitotoxicity (discussed below). Reactive astrocytes may also contribute to glutamate excitotoxicity through glutamate release or reduced uptake—there are inconsistent data of glutamate transporter function in reactive astrocytes. Glutamate toxicity may also be caused by glutamate released by T cells that invade the nervous system during the inflammatory response. In addition to proinflammatory cytokines and glutamate, neurons are also stimulated by an increase in extracellular K^+. Extracellular K^+ levels are tightly regulated by astrocytes, and impaired K^+ buffering by reactive astrocytes leads to epileptiform activity.

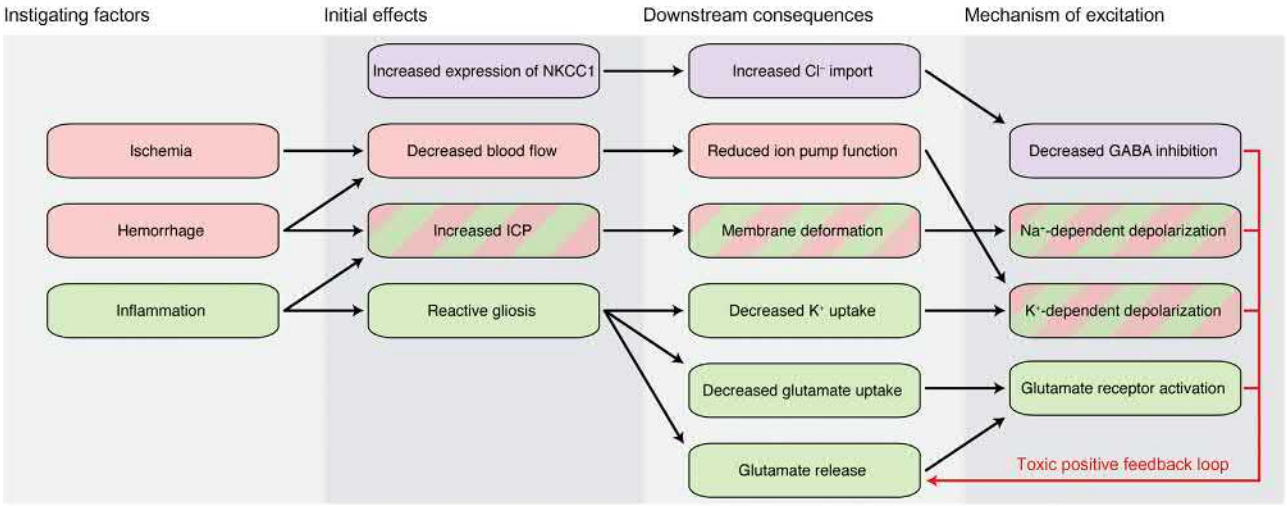

FIGURE 44.6 **Potential mechanisms of seizure induction.** TBIs can damage nervous (green) and vascular (red) tissues. Damage to any tissue produces an inflammatory response, which can cause brain swelling and reactive gliosis. Vascular effects include hemorrhage, which can create hematomas and increase ICP, and ischemia, which decreases blood flow to nervous tissue. Ischemia may be caused by increased ICP or vasospasm following injury. Neurons may also respond to injury by altering gene expression. One example includes an increase in the sodium, potassium, chloride cotransporter NKCC1 (purple). Alterations in gene expression, blood flow, ICP, and glial function increase neuron excitability through a variety of mechanisms. A few selected mechanisms are shown above. Hyperactive neurons can create a toxic feedback loop through the release of glutamate (signified by the red arrow), which drives another wave of neuronal activity.

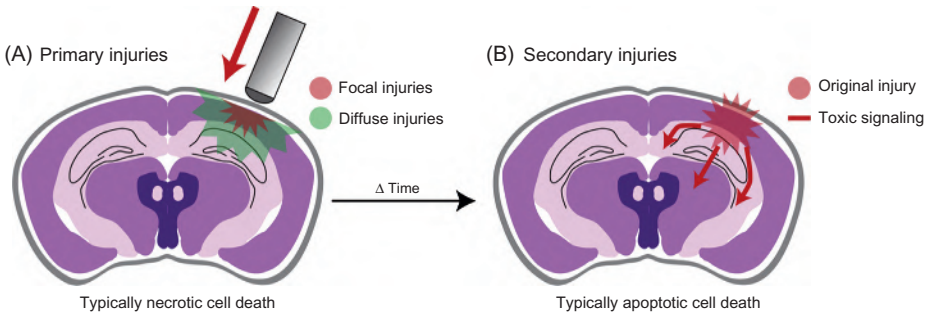

FIGURE 44.7 **TBI comprises several types of injury.** (A) Primary injuries result from the physical forces of the TBI. Focal damage is caused by contact forces that drive the brain into the skull, whereas diffuse damage is caused by inertial forces (linear and rotational acceleration of the head that shear axons). (B) Over time, secondary injuries emerge due to aberrant cellular signaling cascades that emanate from the initial site of damage.

44.6 Cellular mechanisms of primary and secondary injuries

Neurological injuries that result from a TBI are classified as focal versus diffuse and primary versus secondary (Fig. 44.7). Focal injuries occur in confined areas of the brain and are caused by contact forces to the head. Diffuse injuries occur over more widespread brain regions and are caused by inertial forces to the head. Primary and secondary injuries are distinguished based on their cause—primary injuries are caused directly by a TBI, whereas secondary injuries result from downstream effects of the original TBI. As a result, primary injuries occur immediately following the TBI and are associated with necrotic cell death. Secondary injuries may take hours to weeks to manifest and are generally attributable to apoptotic cell death. The physical and cellular basis for these injuries is discussed.

44.6.1 Necrosis

The mechanical force of a TBI causes immediate injury due to contact and inertial forces. Contact forces are the forces that prevent the head from moving after impact, which drives the brain into the skull. Even in the absence of skull fracture, movement along naturally occurring ridges and protuberances of the skull causes focal injuries to the cerebral cortex. Inertial forces are the linear and rotational accelerations of the head. Inertial forces cause axonal shearing, particularly at the junction of gray and

white matter, which have different densities. This accounts for the diffuse nature of injuries that result from inertial forces. The primary injuries caused by contact and inertial forces are not likely to be treatable due to the limited regenerative capabilities of the central nervous system (CNS). Instead, these injuries must be prevented through the use of protective equipment.

The DAI that occurs during primary injury impairs the propagation of signals from the cell body of neurons to presynaptic terminals. White matter tracts are particularly susceptible to shearing forces incurred during a TBI. DAI is only confirmed by microscopic analysis, although there are many in vivo imaging and detection methods that are used to assess axonal integrity. DTI is an MRI variant that measures the diffusivity of water molecules. In white matter, water is unable to diffuse freely and is restricted in certain directions. This directional restriction of diffusion is termed anisotropy. By measuring the fractional anisotropy of different brain regions, white matter maps can be created to trace bundles of axons. DTI can readily detect DAI in moderate-to-severe TBI patients, whereas mild TBI patients show some subtle alterations (Inglese et al., 2005; Kraus et al., 2007). Using in vivo microdialysis in patients with mild TBI (Glasgow Coma Score = 9), Petzold et al. (2011) monitored axonal injury by detecting neurofilament heavy chain, an intermediate filament found in axons. Extracellular levels of neurofilament heavy chain show two phases of elevation: a pronounced, immediate elevation and a delayed, longer lived elevation (Petzold et al., 2011). Presumably, these phases reflect primary and secondary neuronal loss: the marked, early elevation is likely due to axonal shearing, which spills out the intra-axonal contents, whereas the later elevation is due to neuronal loss through secondary injuries.

Axons in the CNS may be particularly vulnerable to rotational and translational forces due to the high compaction of myelin. Myelin is a lipid-rich substance that wraps around 0.3- to 2-mm-long segments of axons. The purpose of myelin is twofold: myelin insulates the axon to speed the conduction of action potentials and myelin reduces metabolic demand by decreasing the number of ions that move across the membrane during an action potential. Myelin in the peripheral nervous system (PNS) is moderately compact, providing some cushioning to allow peripheral nerves to withstand compression forces. PNS myelin is synthesized by Schwann cells, which produce an extracellular matrix (ECM) that contains proteins that support axonal regeneration, such as laminin-2 (Chen and Strickland, 2003)—this explains the minimal regenerative properties of the PNS. Myelin in the CNS, however, is highly compacted to allow a greater density of synapses. However, this comes at the cost of providing minimal cushioning in the event of compression forces. CNS myelin is synthesized by oligodendrocytes, which also secrete little to no ECM. As a result, when axons are severed, the myelin sheath does not have the appropriate growth signals to allow regeneration. In fact, CNS myelin contains factors that may actually prevent axonal regeneration (Huang et al., 2005). This lack of regenerative abilities in the CNS highlights the importance of preventing TBIs through the use of proper protective equipment.

44.6.2 Apoptosis

Hours or days after the primary injury, secondary injuries develop. Secondary injury is caused by the release of substances that alter synaptic function, blood flow, ionic and neurotransmitter homeostasis, metabolic function, and inflammatory signaling pathways. This section focuses on mechanisms of neuronal loss by secondary injuries; mechanisms of synaptic alterations are discussed in the next section.

As discussed, apoptosis is a highly regulated form of programmed cell death that culminates in the activation of caspases. Caspase 3 activation is detectable in the vicinity of cerebral contusions (Petzold et al., 2011), highlighting the importance of maintaining the integrity of the BBB. Disruption of the BBB is associated with TBI and a variety of neurodegenerative disorders (Fig. 44.2 and Chapter 48: Blood–brain barrier damage and dysfunction by chemical toxicity). A variety of other proapoptotic markers are detectable in the CSF of infants and children after severe TBI, including cytochrome c, caspase 1, and Fas. The increase in proapoptotic markers was greater in girls; however, the cause of this gender difference is not clear (Satchell and Lai, 2005).

The expression of prosurvival and proapoptotic genes in cortical neurons was measured using antisense mRNA (aRNA) amplification in individual cortical neurons with fragmented DNA (a sign of cellular damage). After 12 h, prosurvival genes (e.g., neurotrophins, TrkB, and superoxide dismutase) are downregulated in injured neurons. After 24 h, the levels of many prosurvival gene expressions return to normal, although by this time the proapoptotic genes caspase-2 and bax are upregulated. The study by O'Dell et al. (2000) shows that genetic alterations occur rapidly after TBI and compromise cell health.

If apoptotic pathways are activated after TBI and play a role in the ensuing impairments, then apoptosis inhibitors should offer some therapeutic benefits. Continuous administration of the calpain inhibitor AK295 15 min after injury rescues motor deficits in a fluid percussion injury TBI rat model. However, only marginal improvements were observed in memory function (Saatman et al., 1996). Along these lines, inhibiting formation of the mitochondrial permeability transition pore with cyclosporine A has therapeutic benefits in a variety of TBI models, although utility in human TBI patients has yet to be demonstrated (Okonkwo et al., 1999; Sullivan et al., 2000;

Mazzeo et al., 2009). Taken together, these data show a clear connection between TBI and activation of apoptotic pathways.

44.6.2.1 Glutamate dysregulation and excitotoxicity

The principal excitatory neurotransmitter in the CNS is glutamate. There are two classes of ionotropic glutamate receptors—NMDA and non-NMDA receptors. Non-NMDA receptors desensitize rapidly and show no voltage gating. NMDA receptors (NMDARs), however, desensitize slowly and are only active when the cell is depolarized enough to remove a Mg^{2+} ion that blocks the ion channel. Glutamate levels are tightly regulated by glutamate transporters expressed in neurons and astrocytes.

Persistent glutamatergic activity leads to excitotoxicity through two routes: necrosis and apoptosis (Fig. 44.8). In both routes, persistent glutamatergic input depolarizes the cell and allows hyperactivation of NMDA receptors, which desensitize much more slowly than non-NMDA receptors and thus allow more ions to enter the cell. Acutely, as sodium and calcium rush in through ionotropic glutamate receptors, they make the cell hyperosmotic. Acute swelling can lead to rapid necrotic cell loss. Alternatively, if the cell successfully reestablishes ionic imbalance across its membrane, it will deplete its ATP stores. To replenish ATP, mitochondrial activity increases, which elevates the production of free radicals (termed reactive oxygen species, ROS) that lead to oxidative stress. Both oxidative stress and sustained Ca^{2+} elevations can induce cell death by activating apoptotic proteases through formation of mitochondrial transition pores that allow the efflux of proapoptotic signaling molecules.

Nilsson et al. (1990) used microdialysis to measure changes in a variety of energy-related metabolites and neurotransmitters in a weight-drop rat TBI model. Two hours after TBI, extracellular glutamate levels increase in relation to TBI severity; mild TBI increases glutamate eightfold, whereas severe TBI increases glutamate 13-fold. Increases in glutamate coincide with higher levels of lactate, the end product of glycolysis (Nilsson et al., 1990). Because astrocytes display higher levels of anaerobic metabolism than neurons, these data suggest that after TBI, neuronal activity is upregulated, which leads to increased glutamate uptake and glycolytic activity in astrocytes in an attempt to buffer this excess glutamate. As discussed, increased levels of glutamate will eventually lead to intracellular calcium increases, which can lead to apoptosis or more subtle alterations in cellular/synaptic function. Readers interested in additional details about the role of glutamate excitotoxicity in TBI should read the work by Arundine and Tymianski (2004).

Because glutamate is a ubiquitous, excitatory neurotransmitter with potentially toxic consequences, the extracellular level of glutamate is tightly regulated. After presynaptic release, glutamate is rapidly taken up by astrocytes. As discussed, astrocyte processes surround

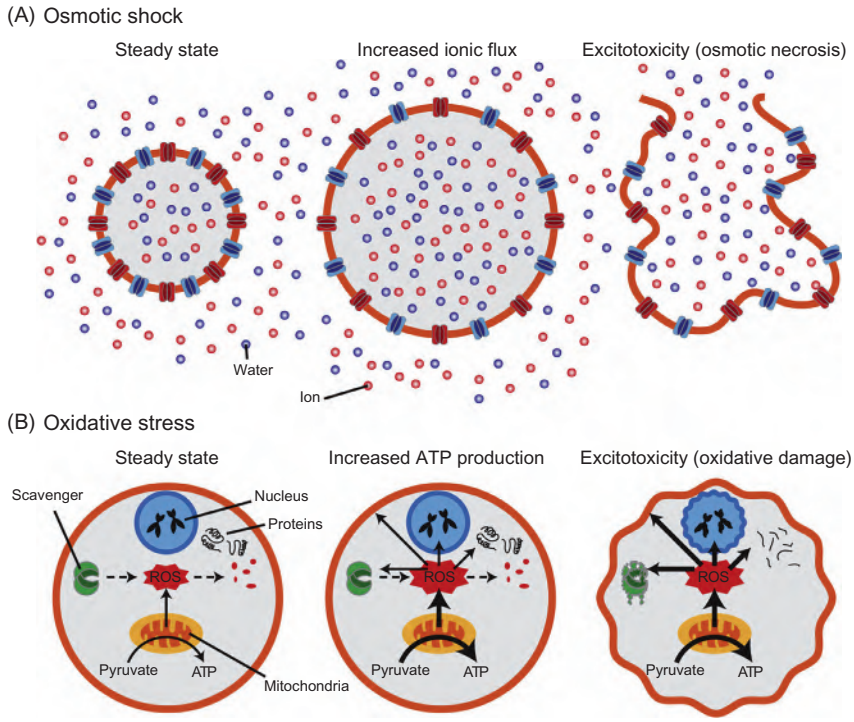

FIGURE 44.8 Excitotoxicity occurs through two routes. Excitotoxicity is caused by excessive glutamatergic signaling. (A) Continuous ionic flux increases the osmolarity of the cell. In extreme cases, this will drive enough water into the cell to cause osmotic necrosis. (B) If the cells survive the massive influx of ions, then ionic imbalance is reestablished in an ATP-dependent manner through a variety of ion pumps. As more ATP is generated through the TCA cycle and oxidative phosphorylation, ROS are produced. High rates of ATP production will produce toxic levels of ROS that cannot be scavenged by intracellular reducing agents [e.g., ROS, glutathione, and nicotinamide adenine dinucleotide phosphate (NADPH)]. ROS oxidize a variety of macromolecules to damage the DNA, proteins, and membranes of the cell. Ultimately, this oxidative damage results in apoptosis.

many synapses and play a role in buffering neurotransmitter levels. In the case of glutamatergic transmission, astrocytes regulate extracellular glutamate levels through high-affinity excitatory amino acid transporters (EAATs 1 and 2). For many years, astrocytes were viewed as morphologically simple cells due to their visualization using antibodies against the intermediate filament glial fibrillary acidic protein (GFAP). It is now clear that GFAP occupies a mere 10% of astrocytic volume and that astrocytes extend numerous tortuous processes to sample nearly all of their occupied volume, with essentially no overlap between adjacent astrocytes (Halassa et al., 2007). However, neighboring astrocytes are coupled to one another via gap junctions to create an extensive network with greater buffering capacity and potentially unappreciated signaling capabilities. Readers interested in additional details about astrocytic network functions should read the work by Giaume et al. (2010).

After injury, astrocytes and microglia undergo reactive gliosis, which is characterized by cellular hypertrophy and, in extreme cases, reentry into the cell cycle. Reactive gliosis is one of the most reliable markers of neurological damage and occurs within days of TBI. Although reactive gliosis is generally thought of as neuroprotective, cellular hypertrophy may lead to glutamate release from reactive microglia and astrocytes. Additionally, the epileptiform activity that occurs following TBI will cause neurons to release high levels of glutamate and increase metabolic demands. Because glutamate uptake is driven by ionic gradients that are established in an ATP-dependent manner, depletion of energy stores and reduced metabolic support will necessarily reduce glutamate uptake by neurons and astrocytes. Because of their peripheral location at synapses, glutamate released from astrocytes may be particularly toxic due to the activation of extrasynaptic NMDA receptors.

NMDA receptors are found at and away from the synapse. In general, synaptic NMDA receptors are considered neuroprotective, whereas activation of extrasynaptic NMDARs leads to apoptosis (Fig. 44.4). This may be a homeostatic adaptation that eliminates leaky synapses (i.e., those that allow glutamate to escape and active extrasynaptic NMDARs). The details of synaptic versus extrasynaptic NMDA receptor signaling are still not clear, although it does appear that these two pathways have opposing functions on prosurvival, CREB-dependent gene expression and prodeath, FOXO-dependent gene expression. Readers interested in additional details about the cytotoxic effects of extrasynaptic NMDA receptors should read the work by Hardingham and Bading (2010).

44.6.2.2 Oxidative stress

A commonly reported event that occurs after TBI is an increase in ROS from mitochondria. ROS are highly reactive free radicals (e.g., superoxide and hydroxyl radicals) that damage a range of macromolecules, including lipids, proteins, and DNA. Thus, cells maintain reducing conditions through production of NADPH and glutathione, which work with superoxide dismutase to neutralize ROS. Elevated levels of ROS are indicative of cellular stress and will eventually lead to cell death if left unchecked.

Bayir et al. (2002) published a comprehensive analysis of antioxidant reserve and oxidative damage after TBI. Early on, 1 day after TBI, CSF samples from children and infants with severe TBI show higher levels of the oxidative stress marker F2-isoprostane. F2-isoprostane levels normalized after day 2. However, levels of the antioxidant ascorbate are reduced immediately after TBI (day 1) and continue to decline afterward (up to day 7). Glutathione, an important reducing agent, levels show a biphasic response to TBI: glutathione is elevated immediately after TBI and declines after 5 days (Bayir et al., 2002).

A variety of antioxidant compounds have been used to scavenge ROS in rodent TBI models and human TBI patients (Dohi et al., 2006; Hall et al., 2010). Some ROS scavengers produce positive impacts on survival and neurological outcomes in larger phase III clinical trials (Marklund et al., 2001; Hall et al., 2010). Despite this, ROS scavengers are not currently used as a therapeutic option to treat TBI.

44.6.2.3 Cell-cycle reentry

Neurons are *postmitotic* cells; thus, they no longer undergo cell division. This loss of reproductive capabilities is attributable to their complex cellular morphology. To undergo cell division, neurons must retract their intricate dendritic and axonal arbors—an impossible task. Neurons that reenter the cell cycle invariably fail to complete the task and die. Because of this, neurons actively suppress cell-cycle reentry. This suppression is removed in several neurodegenerative disorders, including TBI.

Cyclin-dependent kinase inhibitors, such as flavopiridol, prevent cell-cycle progression. In a lateral fluid percussion injury rat model of TBI, the expression of genes associated with DNA injury and cell-cycle progression are upregulated. These genetic alterations appear to play a causative role in neuronal cell death, because intracerebroventricular injection of the cell-cycle inhibitor flavopiridol reduces neuron loss. Flavopiridol also reduces the activation of astrocytes and microglia, although it is unclear whether cell-cycle reentry occurs in neurons, glia, or both, or whether neuronal dysfunction and glial dysfunction synergize during TBI (Di Giovanni et al., 2005).

44.7 Potential mechanisms of synaptic impairment

Synapses are maintained in part through neurotrophic signaling. Neurotrophins are a class of proteins that activate receptor tyrosine kinases (Trk receptors) to regulate the growth and maintenance of synapses. Cell growth is stimulated by neurotrophins through their activation of Rho GTPases, a diverse family of proteins that (in general) positively regulate the stability and growth of actin filaments and microtubules. Through their positive impact on cytoskeletal organization, neurotrophins induce the outgrowth of dendrites and axons in a variety of neurons. The importance of neurotrophic support on synaptic maintenance is illustrated in mice that lack brain-derived neurotrophic factor (BDNF), a neurotrophin implicated in learning and memory. BDNF knockout mice develop normal dendritic arbors but fail to maintain them (Gorski et al., 2003). Because dendrites are important postsynaptic sites, this reduction in dendritic arborization reduces the number of possible synaptic contacts.

As discussed, neurotrophic expression is downregulated in neurons with DNA fragmentation after TBI (O'Dell et al., 2000). However, whole-brain analysis shows upregulation of neurotrophins within the same time frame in a controlled cortical impact TBI rat model (Oyesiku et al., 1999). Another study using in situ hybridization shows that some neurotrophins increase after mild TBI (e.g., BDNF), whereas others (e.g., NT-3) decrease (Hicks et al., 1999). These data suggest that nondamaged neurons and glia upregulate their expression of neurotrophins to offset the decreased expression in injured neurons. However, upregulation of neurotrophins may be deleterious as high levels of neurotrophins activate the low-affinity $p75^{NTR}$, which is linked to proapoptotic and synapse-degenerating signaling pathways.

The loss in postsynaptic sites is regulated by enzymes that control the polymerization state of actin. Work by Campbell et al. (2012a) provides mechanistic insights into the postsynaptic alterations that occur in a fluid percussion injury rat TBI model. Within 18 h after injury, PSD95 levels in the cortex and hippocampus decline, indicating the loss or shrinkage of postsynaptic sites. Reduction of PSD95 is preceded by an increase in the activity of cofilin—an actin-severing enzyme. When cofilin is activated, it breaks apart actin filaments and causes the shrinkage of dendritic spines (i.e., excitatory postsynaptic sites). Normally, cofilin is held in an inactive state through phosphorylation of Ser3, which disallows interactions between cofilin and actin. However, TBI increases the activation of the protein phosphatase calcineurin, which dephosphorylates and activates cofilin. Because calcineurin activity is regulated by calcium−calmodulin, these results suggest that calcium dysregulation after TBI may cause the loss of excitatory synapses through cofilin-dependent actin depolymerization.

44.8 Pathological hallmarks of Alzheimer's disease in traumatic brain injury

44.8.1 Alzheimer's disease: Aβ and tau

Alzheimer disease (AD) is a progressive dementia that is classically characterized by amyloid plaques, tau neurofibrillary tangles, and brain atrophy. Amyloid plaques are extracellular aggregates composed mostly of aggregated forms of Aβ. Although plaques are easily detected postmortem, cognitively normal elderly individuals can have high levels of plaques (Buckner et al., 2005). Additionally, a population of Japanese AD patients with a specific mutation in Aβ (E22Δ) exhibited dementia in the absence of plaques (Tomiyama et al., 2008). Therefore, many experts in the field have moved away from the amyloid cascade hypothesis proposed by Hardy and Higgins (1992) and instead believe the soluble oligomer hypothesis, in which diffusible Aβ oligomers (AβOs) attach at or near synapses and alter synaptic function (Hardy and Higgins, 1992; Wilcox et al., 2011). A similar movement has occurred with regard to the microtubule-associated protein tau: soluble tau oligomers are viewed as more toxic than insoluble tau neurofibrillary tangles. Finally, it is absolutely critical to remember that the best correlate with dementia severity is not brain atrophy, but rather synapse loss (Terry et al., 1991). Thus, although most view AD as being typified by plaques, tangles, and atrophy, these are antiquated views.

Aβ is derived by proteolytic processing of the amyloid precursor protein (APP) by a group of proteases called *secretases* to produce a number of soluble peptides with diverse cellular functions. Aβ is produced when APP is cleaved outside the membrane by *β-secretase* (now identified as BACE-1) and within the membrane by *γ-secretase*. The strongest support for a causative role for Aβ in AD progression comes from human genetics. There are several mutations and duplications in APP and γ-secretase that can lead to heritable familial AD (FAD). FAD-association mutations can increase Aβ production (Swedish, Flemish), promote Aβ polymerization into toxic forms (Osaka and Arctic), or shift the metabolism of APP to produce more Aβ that is 42 amino acids long (Florida, London), two amino acids longer than normal and far more prone to polymerization. It is important to note that one mutation exists that actually decreases the risk of development of AD (Icelandic) by disrupting Aβ production (Jonsson et al., 2012).

Based on studies using tau knockout mice, it appears that Aβ induces synaptic loss and eventually cell death by

structural and functional modifications to tau. Normally, tau is localized in axons, where it binds to and stabilizes microtubules. However, when tau is phosphorylated, it leaves the microtubule and activates a protein phosphatase 1 (PP1) through its phosphatase activating domain (PAD). PAD likely acts as an autoregulatory mechanism to limit the time that tau spends away from the microtubule and to prevent tau from becoming hyperphosphorylated—tau hyperphosphorylation is associated with AD progression. In fact, when tau is hyperphosphorylated in AD, it no longer interacts with axonal microtubules and translocates to the cell body and dendrites.

Tau is phosphorylated by a number of kinases, but glycogen synthase kinase 3β (GSK3β) appears to be highly relevant to AD. AβOs indirectly activate GSK3β, thus causing tau phosphorylation. Phosphorylated tau activates PP1 through its PAD. PP1 dephosphorylates both tau and GSK3β, which keep the kinase active and inevitably lead to tau hyperphosphorylation. The functional consequence of tau hyperphosphorylation is "synaptic starving," in which impaired axonal transport disrupts the delivery of critical proteins and energetic substrates to the synapse, eventually leading to synapse loss (Mandelkow et al., 2003). Alterations in intracellular trafficking are likely due to prolonged GSK3β activation (Kanaan et al., 2011). GSK3β phosphorylates the motor protein kinesin, which delivers vesicular cargo to presynaptic and postsynaptic sites. Phosphorylation by GSK3β causes kinesin to dump its cargo, which, in the case of chronic GSK3β activation, can lead to depletion of synaptic components. Thus, the tau−PP1−GSK3β-positive feedback, which may be initiated by Aβ, inevitably leads to tau pathology and synaptic dysfunction.

44.8.2 Aβ in traumatic brain injury

Amyloid pathology is observed in rodent TBI models and human TBI patients. In fact, diffuse amyloid plaques are present in the brains of professional boxers with TBI at levels comparable with those observed in AD patients (Roberts et al., 1990). APP, BACE-1, presenilin (a component of γ-secretase), and Aβ accumulate in the terminal portion of severed axons after TBI (Chen et al., 2004). By concentrating APP and the secretases together, Aβ production is favored. Increased Aβ production leads to oligomer formation and eventually synaptic dysfunction and loss. Accordingly, Aβ accumulation increases with repetitive head injury and correlates with injury severity (Uryu et al., 2002; Tran et al., 2011). However, attenuating Aβ production with a γ-secretase inhibitor does not prevent the loss of dendritic spines after a controlled cortical impact TBI (Winston et al., 2013). This suggests that although TBI may promote the onset of AD pathology, acute synaptic damage occurs through alternative routes. It is likely that elevated Aβ levels may play a role in the chronic effects of TBI on synaptic structure and function, although this is purely speculative.

44.8.3 Tau in traumatic brain injury

Because TBIs increase Aβ burden, and because Aβ acts upstream of tau, TBIs also induce tau pathology. Brains from TBI and AD patients show tau hyperphosphorylation at the same amino acid residues (Schmidt et al., 2001), and both occur in cortical pyramidal cells, albeit in different subpopulations (Hof et al., 1992). Neurofibrillary tangles are found in TBI patients years after a single TBI (Johnson et al., 2012). As expected, axonal transport appears to be impaired in mouse models of TBI (Säljö et al., 2000).

Tau pathology appears in a delayed fashion after TBI. A single mild TBI does not increase tau pathology after 3 weeks in hTau mice, which express human tau isoforms. Instead, multiple TBIs are required to observe tau pathology, although astrocyte reactivity is apparent 3 weeks after a single TBI (Ojo et al., 2013). Because of the axonal localization of tau, one likely cause of tau pathology in TBI is DAI, which occurs when delicate axons are torn apart during rapid head acceleration (Elson and Ward, 1994). However, based on the time required for tau pathology to become apparent, it is likely that increased Aβ production drives tau hyperphosphorylation through alterations in intracellular signaling.

44.9 Concluding remarks and future directions

TBI is a multifactorial and sporadic neurodegenerative syndrome that is caused by contact and inertial forces that lead to primary injuries that are focal or diffuse, respectively. Early primary injuries cause necrotic cell loss. The surviving cells have compromised cellular function or support, leading to secondary injuries. Secondary injuries lead to aberrant cell signaling, impaired synaptic function, and apoptotic cell death. The mechanisms of apoptotic cell death have multiple factors and include glutamate excitotoxicity, oxidative damage, and reduced neurotrophic support. In the absence of marked cell loss, synaptic loss is also observed after TBI. Synaptic impairments are the result of impaired neurotransmitter homeostasis, which leads to aberrant calcium signaling. Pathological overlaps between TBI and AD also contribute to the loss of synapses and neurons.

Chapter 45

Neurological effects and mechanisms of blast overpressure injury

Jason Pitt
Department of Physical Therapy, University of Evansville, Evansville, IN, United States

45.1 Introduction

Traumatic brain injury (TBI) is a major cause of disability in civilian and military populations. In civilians, TBIs are usually caused by unintentional falls, especially in elderly persons. On the other hand, military personnel are more likely to experience TBI from blast or explosive injuries, as blast injuries account for the majority of casualties during active combat. For example, blast injuries accounted for 236 of the 269 casualties treated at a US Army echelon II medical facility between October 1, 2003 and June 30, 2004 during Operation Iraqi Freedom, with 111 of those 236 blast injuries involving the head or multiple body areas (Murray et al., 2005). This has led to *blast TBI (bTBI)* being deemed the "signature injury" of the Iraq and Afghanistan conflicts.

The incidence of probable TBI in deployed military personnel is estimated to be between 11−23% (Lindquist et al., 2017). This estimate far exceeds the reported incidence of 0.33% for diagnosed TBIs in soldiers deployed to Afghanistan and Iraq between September 11, 2001 and September 30, 2007 (Wojcik et al., 2010). Regardless of the actual incidence rate for TBI, it is clear that a large number of military personnel suffer from TBI. Between January 1, 2000 and March 31, 2018, 383,947 US military service members were diagnosed with a TBI (Defense and Veterans Brain Injury Center, 2019). The majority of TBIs were classified as mild (82%), followed by moderate (10%), penetrating (1.4%), and severe (1.1%). TBIs were most frequently reported in members of the Army (58% of all TBIs).

Blast or explosive injury is the most common cause of head injury in veterans, particularly those with high combat exposure. In Iraq and Afghanistan veterans, bTBIs accounted for over 60% of all TBIs (Wojcik et al., 2010). The cause of bTBIs is most commonly *improvised explosive devices (IEDs)*. Based on the medical records of soldiers who suffered blast injuries during Operation Iraqi Freedom (from March 2004 to February 2007), IEDs accounted for nearly 70% of all injuries, followed by mortars (8%), rocket-propelled grenades (5%), and landmines (5%), with the remaining 12% left unclassified (Dougherty et al., 2011). The increased use of IEDs has been attributed to the higher overall instance of TBI and bTBI in Iraq compared to Afghanistan.

45.2 Blast waves and mechanisms of injury

Classically, TBI has been divided into two groups: (1) *penetrating TBI (pTBI)* and (2) *closed TBI (cTBI)*. pTBI involves a foreign object penetrating the skull and entering the brain parenchyma, causing physical damage to nerve cells, fiber tracts, and blood vessels. In addition to physical damage from the foreign object, the subsequent hemorrhage, edema, and cerebrospinal fluid (CSF) leakage amplifies nerve cell loss in pTBI. cTBI involves sudden head acceleration that leads to brain deformation within the intact cranium. Contact between the brain and skull can lead to physical trauma to nervous tissue. In addition, head rotation produces shearing forces that sever fiber tracts. Depending on the severity of the cTBI, hemorrhage may or may not occur.

bTBIs are complex and can include elements of both pTBI and cTBI depending on the types of injuries (see Table 45.1 and Fig. 45.1). For example, pTBI may be caused by secondary blast injuries in which shrapnel penetrates the skull. cTBI may be caused by the blast wave itself (primary) or when blunt objects strike the head (secondary or tertiary). It is important to note that although primary injuries likely represent the unique

TABLE 45.1 Blast injuries types.

Type of injury	Cause of injury
Primary	Direct interaction between blast pressure wave and organs
Secondary	Impact of physical objects propelled by blast pressure wave
Tertiary	Impact with physical objects when victims are flung by blast pressure wave
Quaternary	Burns or toxic fume inhalation

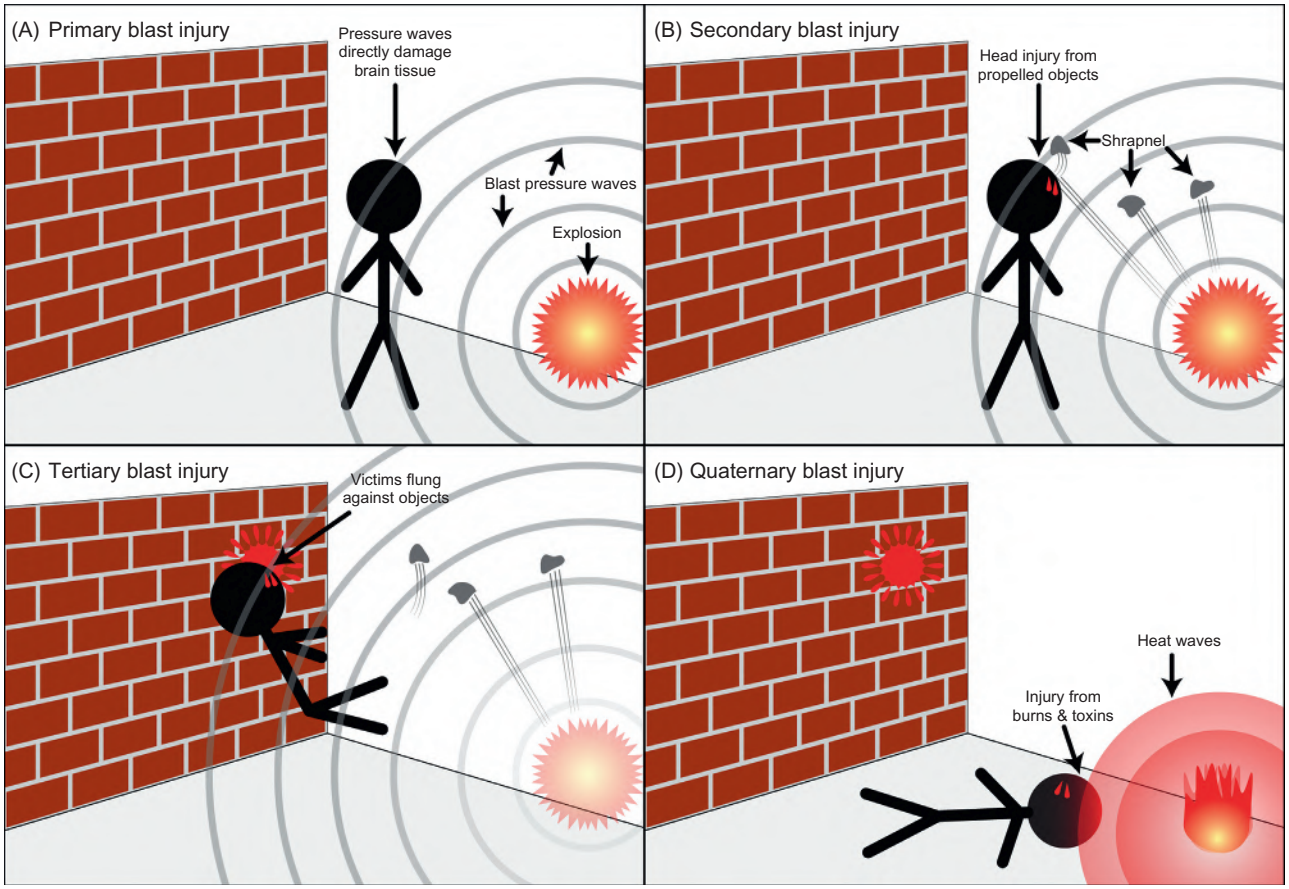

FIGURE 45.1 Explosive devices cause multiple types of injuries. (A) Primary injuries are caused by tissue deformation from blast pressure waves. (B) Secondary injuries are caused by shrapnel and other objects propelled by blast pressure waves. (C) Tertiary injuries are caused when victims are flung against objects, such as a wall, by blast pressure waves. (D) Quaternary injuries arise from heat and toxic fumes produced by the explosion.

aspect of blast TBI, primary injuries almost never occur in isolation. Adding to the complexity of bTBIs is the fact that blast pressure waves affect other bodily regions besides the head, leading to peripheral effects that may amplify brain damage.

45.2.1 Pressure waves

Explosive devices employ violent chemical reactions to transfer energy into the surrounding medium (i.e., air). This energy transfer compresses air molecules, increasing air pressure and temperature to produce *pressure waves*. Pressure waves travel through the air at supersonic speeds that exceed the characteristic wave speed of air, leading to compression of pressure waves to form *shock waves* that include a sharp high-pressure phase followed by a negative pressure phase (see Fig. 45.2). This characteristic change in air pressure (P) over time (t) is described by the Friedland equation: $P(t) = P_s * e^{-t/t^*}\left(1 - (t/t^*)\right)$, where $P(t)$ is the air pressure at any given time, P_s is the

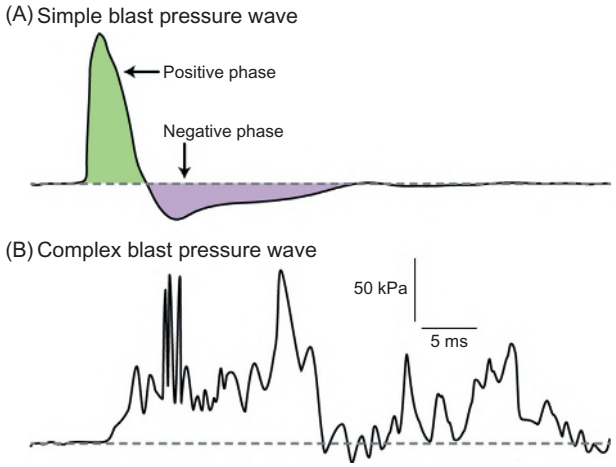

FIGURE 45.2 **Pressure waves compress to form shock waves.** (A) The idealized pressure waveform over time exhibits a sharp peak of positive pressure followed by a negative pressure phase. (B) Pressure waves reflecting off solid surfaces create complex blast waves.

peak pressure, and t^* is the time at which air pressure becomes negative. The behavior of spherical shock waves is an open field and well characterized, with the peak pressure change decaying nonlinearly as a function of distance (d). Idealized decay based on spheric expansion is equal to the cube of distance, while empirical measurements estimate the decay of open field overpressure waves to be $P_s = d^{-1.2}$ (Reed, 1972).

The behavior of pressure waves in enclosed spaces is more complicated and varies on a case-by-case basis. Pressure waves reflected off solid surfaces—such as walls, ceilings, or the skull—can merge to form a *complex wave field*. This can expose victims to multiple amplified pressure waves. This, along with the closer proximity to the explosion, likely explains the roughly sixfold increase in mortality reported for blast injuries sustained in buses compared to open-air bombings (Leibovici et al., 1996). Furthermore, different numbers of casualties were reported during the March 11, 2004, bombings of commuter trains in Madrid, Spain. The two trains with open doors had far fewer casualties (29 and 17 deaths) than the two trains with closed doors (64 and 67 deaths) (Turégano-Fuentes et al., 2008). The Madrid bombings presumably all occurred with similar distances to the explosive device, providing strong evidence that exposure to complex blast waves is associated with higher mortality than open-field blasts.

45.2.2 Mechanism of primary injury

The transduction of pressure into the brain could occur through two possible routes: direct transcranial propagation or indirect propagation through bodily fluids (e.g., blood or CSF). The prevailing view favors transcranial propagation of pressure waves. Only ~3% of the pressure delivered to the abdomen makes it to the brain (Säljö et al., 2008). However, in rat models, protection of the abdomen and thorax with a Kevlar vest reduces mortality and axonal injury (Long et al., 2009). These findings could be explained by species differences in vasculature or differences in the blast models used. It may also be the case that peripheral injury exacerbates TBI through effects on cardiopulmonary function, which may explain the increased stroke risk reported in TBI patients (Burke et al., 2013).

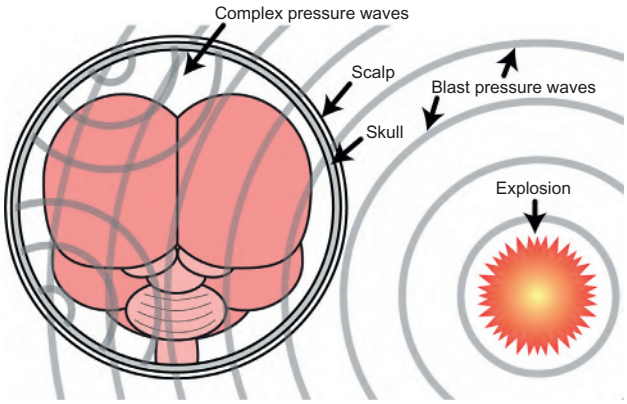

FIGURE 45.3 Pressure waves rebound off the skull to produce complex pressure waves.

Primary injuries from pressure waves are caused by physical tissue deformation. Pressure waves move the particles in the medium they pass through. When pressure waves encounter tissue or pockets of fluid or air within tissues, they cause movement. Blasts waves, particularly at close range, deliver nonuniform energy to tissues that they encounter, thus creating nonuniform tissue movement and deformation. Nonuniform movement of the brain generates shearing forces that can sever axons. Blast waves may rebound off the skull or protective helmet, creating complex wave fields and exacerbating injury (Fig. 45.3). Air-filled organs, such as the lungs, are particularly susceptible to high-pressure waves. In fact, the most common fatal primary blast injury is *blast lung* (i.e., pulmonary barotrauma). The consequences of blast injury are discussed further in the next section.

45.3 Clinical features of traumatic brain injury

All types of TBIs share many of the same clinical features. In fact, patients suffering bTBI and cTBI have nearly identical abnormalities on neuropsychological tests (Mac Donald et al., 2014). Currently, there is no strong evidence that bTBI produces distinct changes in cognition compared to other TBI mechanisms. As such, I will

TABLE 45.2 TBI severity.

Severity	Loss of consciousness	Posttraumatic amnesia	Neuroimaging	Glasgow rating
Mild	<0.5 h	<1 h	Normal	13–15
Moderate	0.5–24 h	1–7 days	May be abnormal[a]	9–12
Severe	>24 h	>7 days	Abnormal	4–8

[a]*Abnormal neuroimaging includes signs of intracranial bleeding, skull fractures, brain swelling, diffuse axonal injury, or brain atrophy.*

TABLE 45.3 Using the GCS to assess head injury severity.

Behavior	Response	Score
Eye opening	Open and blinking spontaneously	4
	Open to verbal stimuli	3
	Open to painful stimuli	2
	No response	1
Verbal	Aware of self, time, and location	5
	Slight confusion	4
	Inappropriate replies	3
	Incomprehensible replies	2

	No response	1

Classification:
Coma: 3.
Severe head injury: 4–8.
Moderate head injury: 9–12.
Mild head injury: 13–15.

briefly describe the common clinical features of TBI as these are covered further in Chapter 44, Clinical and cellular aspects of traumatic brain injury.

45.3.1 Common clinical features of traumatic brain injury

TBIs can produce clinical features as mild as transient confusion or as severe as coma. TBIs are classified into one of three categories based on neurological signs and neuroimaging data: mild TBI, moderate TBI, and severe TBI (see Table 45.2). Mild TBI is characterized by: (1) loss of consciousness <30 min, (2) posttraumatic amnesia <1 h, and (3) normal neuroimaging (e.g., no contusion, hematoma, or skull fractures). *Moderate TBI* is characterized by: (1) loss of consciousness between 0.5–24 h, (2) posttraumatic amnesia between 1–7 days, and (3) neuroimaging that may or may not be normal. *Severe TBI* is characterized by: (1) loss of consciousness >24 h, (2) posttraumatic amnesia >7 days, and (3) abnormal neuroimaging. These classifications are made almost exclusively based on subjective neurobehavioral exams, such as the *Glasgow Coma Scale (GCS)* (Table 45.3). Neuroimaging data (e.g., CT or MRI) are only occasionally used for diagnostic purposes.

TABLE 45.4 Clinical symptoms of traumatic brain injury.

Type	Symptoms	Notes
Sensory	Headache	Common. May persist or worsen in moderate or severe TBI
	Neck pain	–
	Dizziness	Common. May persist in moderate or severe TBI
	Nausea or vomiting	Common and brief. May persist or worsen in moderate or severe TBI
	Ringing in the ears	–
	Blurred vision	–
	Sensitivity to light or sound	–
	Numbness in limbs	More common in moderate or severe TBI
	A bad taste in the mouth	–
Motor	Reflexes	May be slow. Absent or abnormal reflexes may occur in moderate or severe TBI
	Dilated pupils	More common in moderate or severe TBI. May occur in one or both eyes
	Slurred speech	More common in moderate or severe TBI
	Weakness in limbs	More common in moderate or severe TBI
	Loss of coordination	More common in moderate or severe TBI
Cognitive	Confusion and difficulty concentrating	More common in moderate or severe TBI
	Memory loss	May be transient. More common in moderate or severe TBI
	Agitation	More common in moderate or severe TBI
	Loss of consciousness	Typically brief. Lasts for minutes to hours in moderate or severe TBI
	Seizures	More common in moderate or severe TBI
	Sleep abnormalities	Fatigue is more common with mild TBI. Difficulty waking from sleep may occur in moderate or severe TBI

Common symptoms of mild TBI include headache, fatigue, sleep disturbances, sensory abnormalities, dizziness, mood disturbances, confusion, inability to concentrate, amnesia, and seizures (see Table 45.4). Because mild TBIs are transient and may produce subtle impairments that arise after the initial injury, they may go undiagnosed. This is especially true in combat scenarios where nonlife-threatening injuries may be examined less thoroughly or dismissed. Undiagnosed TBIs may place victims at increased risk of additional TBIs, as they are less likely to be removed from combat. This is especially problematic, as the ill effects of nonlethal head injuries appear dose-dependent. Veterans with multiple head injuries are more likely to experience PTSD (relative risk = 1.56−3.21), depression (relative risk = 1.06−1.85), suicidal ideation (relative risk = 1.07−3.10), and pain (relative risk = 1.08−1.66) than veterans with a single head injury (Lindquist et al., 2017). Furthermore, multiple head injuries slows the recovery from TBI.

More severe forms of brain injury may lead to seizures. Seizures occur in >20% of patients with moderate to severe TBI within the first week following injury (Vespa et al., 1999). Seizures occur following a variety of brain injuries, including stroke, neoplasm, neurodegenerative diseases, infection, and all types of traumatic injuries. This suggests a common underlying pathological mechanism in all states of injury. Likely candidates include neuroinflammation and reactive gliosis, which may increase neuronal excitability through physical deformation of the membrane or increased extracellular concentrations of K^+ or glutamate (see Chapter 44: Clinical and cellular aspects of traumatic brain injury).

TBIs increase the risk of dementia or long-term cognitive dysfunction. Moderate and severe TBI are well-known risk factors for dementia, increasing the risk between two- and fourfold. The relationship between mild TBI and dementia is not yet clear, especially in cases with no loss of consciousness (Ramalho and Castillo, 2015).

Repeated head injuries can create a condition called *chronic traumatic encephalopathy (CTE)*, which is a sporadic tauopathy that causes dementia in patients with a history of head trauma. bTBI has been linked to CTE and mouse models exhibit characteristic alterations in tau structure. However, it remains unknown whether bTBI presents any elevated risk of dementia compared to other forms of head injury.

45.3.2 Distinct clinical features of blast traumatic brain injury

45.3.2.1 Blast lung

bTBI typically involves injury to additional areas beyond the head. Bodily injury is far more common in bTBI than pTBI and cTBI due to the mechanism of injury. A projectile or blunt object that strikes the head may completely spare the rest of the body from injury. On the other hand, blast pressure waves spread to potentially injure any unprotected area of the body. Consistent with this, blast lung is the most common fatal primary blast injury. Signs of blast lung include apnea, bradycardia, hypotension, chest pain, and hemoptysis. These signs usually occur immediately after blast injury, although they may take as long as 48 h to emerge. Damage to lung vasculature is visible by chest X-ray as a characteristic butterfly pattern.

45.3.2.2 Hearing loss, tinnitus, and visual impairments

The ears are another air-filled organ susceptible to blast injury. Accordingly, hearing loss and tinnitus are more common in soldiers suffering from bTBI compared to other forms of TBI (Lew et al., 2007). The most common injury to the middle ear from pressure waves is tympanic membrane rupture. Rupture of the tympanic membrane is associated with the loss of consciousness following bTBI (Xydakis et al., 2007). As such, one should suspect bTBI in victims of blast injury with hearing loss.

In addition to hearing loss, visual impairments can occur following bTBI. These can occur from damage to the eye, ocular nerve, or visual cortices. The likelihood of suffering an ocular or visual disorder increases with the severity of bTBI (Dougherty et al., 2011).

45.3.2.3 Postconcussive syndrome and posttraumatic stress disorder

Mild blast exposure can create a collection of symptoms referred to as *postconcussive syndrome (PCS)*, shell shock, or blast concussion. The symptoms of PCS overlap considerably with mild TBI listed in the previous section, and PCS can be caused by any head injury. One important aspect of PCS is the fact that it can be triggered years after injury, much like *posttraumatic stress disorder (PTSD)*. In fact, PTSD shares many features with PCS, and PTSD symptoms are more common in soldiers with blast injuries (Sayer et al., 2008). PTSD symptoms correlate better with PCS symptoms than injury mechanism (i.e., blast vs. nonblast), suggesting an important emotional component of PCS. While PCS and PTSD can mimic one another, PCS is suspected when physical and somatic symptoms are present. The relationship between blast severity and PCS is unclear, although additional head injuries slow recovery from PCS.

45.4 Human neuropathology of blast traumatic brain injury

As with clinical features, the neuropathological hallmarks of bTBI are similar to those seen with pTBI and cTBI. The lack of distinct neuropathological consequences in bTBI compared to other forms of TBI may be due to our extremely limited data from humans. Alternatively, the considerable overlap between the neuropathology of different forms of TBI may simply reflect the fact that they all involve brain tissue damage. Regardless of the injury mechanism, tissue damage triggers an inflammatory response, reactive gliosis, and alterations in neuronal function. In this section, I will outline neuropathological features of TBI and highlight any unique aspects of bTBI. A brief discussion of the clinical management of blast TBI is provided. For further details on clinical management of TBI, see Chapter 44, Clinical and cellular aspects of traumatic brain injury.

45.4.1 Neuropathological features of blast traumatic brain injury

Blast injuries cause a variety of neurological effects, ranging from extremely mild to fatal (Hicks et al., 2010). A range of neuropathologies can be observed in cases of bTBI, including edema, contusion, hematoma, hemorrhage, blood−brain barrier (BBB) disruption, diffuse axonal injury, and cortical atrophy. None of these are unique to bTBI, although they appear to emerge with different time courses in bTBI. Brain swelling occurs within hours of injury, leading to dangerous increases in *intracranial pressure*, which may compress neural and vascular tissues, leading to brain herniation or ischemia (Ling et al., 2009). This rapid swelling appears to occur more commonly in bTBI than other TBIs. Swelling from blast injuries is treated by military neurosurgeons with decompressive craniectomies more commonly than for other types of TBIs.

Another characteristic feature of bTBI is vasospasm. *Vasospasm* is the sudden contraction of arterial walls,

which may lead to ischemia. Cerebral vasospasms are commonly caused by *subarachnoid hemorrhage (SAH)*, although traumatic vasospasm can occur in the absence of hemorrhage and appears to be unique in terms of temporal course and pathophysiology (Kramer et al., 2013). The peak incidence of vasospasm following sporadic SAH is 5−14 days, compared to 5−7 days for traumatic SAH. Traumatic vasospasm in the absence of SAH peaks around 1.25 days.

The *BBB* is a collection of tight junctions and transporter proteins in the cerebral vasculature that acts as a diffusion barrier to restrict entry into the central nervous system. The BBB maintains the integrity of the interstitial fluid, and leakage at the BBB can allow the invasion of neuroactive compounds (e.g., neurotransmitters) or peripheral cells (e.g., immune cells). BBB permeabilization occurs in a host of neurological conditions, including tumor growth, neurodegenerative conditions, and TBI. Increased BBB permeability has been reported in blast and nonblast TBI patients (Korn et al., 2005; McKee and Robinson, 2014). BBB permeabilization may be exacerbated by neuroinflammation that occurs following injury.

Mild bTBI patients have a greater degree of cortical atrophy in the frontal lobes than nonblast TBI patients, leading to a corresponding decrease in executive function (Clark et al., 2018; Eierud et al., 2019). The degree of cortical thinning is related to PTSD, depression, and postconcussive symptoms (Michael et al., 2015). Additional areas of cortical thinning include inferior temporal and insular regions. However, it should be noted that cortical thickness varies considerably within groups and cortical thickness preinjury is unknown in these studies. As such, long-term follow-up will be important in bTBI victims to determine whether cortical atrophy rates are any different following bTBI.

Another site of injury in bTBI patients is the cerebellum. Cerebellar white matter injury has been reported in a small sample of military personnel with mild TBI following exposure to a single blast (Mac Donald et al., 2013). Exposure to repeated blasts negatively correlates with glucose uptake measured by fluorodeoxyglucose-positron emission tomography in the cerebellum of patients with mild TBI, indicating cerebellar hypoactivity (Meabon et al., 2016). The cerebellum has well-established roles in motor output coordination, language, and working memory function. As such, damage to the cerebellum may contribute to a variety of impairments that occur following bTBI.

In addition to damaging specific brain regions, TBIs cause diffuse axonal injury, in which a subset of axons are severed due to shearing forces on axons. Diffuse axonal injury causes widespread changes in the functional connectivity between different brain regions by severing the axons of projection neurons that interconnect brain regions, which may explain the changes in cognition, memory, perception, and motor function that occur following TBI. *Functional connectivity* refers to the degree to which the activities of two regions correlate with one another, reflecting their ability to function as a part of a larger network to carry out complicated tasks that require multiple brain regions (e.g., memory). Alterations in functional connectivity have been reported in a variety of cortical and subcortical structures and appear to be heterogeneous between patients. As such, there is no bTBI signature for altered functional connectivity.

45.4.2 Clinical management

The severity of blast injuries can be reduced with protective head and body equipment. This, along with advances in medical care, has led to the lowest kill:wounded ratio for soldiers in modern history, with fewer than 1 in 10 wounded dying. This high survival rate necessitates improved acute and long-term clinical care for TBI patients. Fortunately, the majority of TBI cases are mild and full recovery is expected to occur within 3 months following injury for 85% of victims—the other 15% develop PCS. Unfortunately, only about half of the patients with a single mild TBI are free of cognitive impairments after 3 months (Meabon et al., 2016). Patients with multiple head injuries have a poorer prognosis and an increased risk of long-term neurological defects (e.g., dementia).

Blast injuries are complex and often involve injuries to multiple body systems. The clinical management of TBI on the battlefield involves first controlling bleeding and ensuring proper airway and circulatory function. Next, the level of head injury is assessed using the GCS (see Table 45.3). Higher levels of injury necessitate more immediate evacuation and elevation of the level of care.

Once off the battlefield, more detailed assessments of injury and further treatments can be performed. CT scans can help identify intracranial hemorrhage, skull fractures, or pronounced increases in ICP. As discussed above, swelling is a common feature of the acute phase of blast TBI. Swelling is managed with intravenous hypertonic saline, mild hypothermia, and decompressive craniectomy. Although decompressive craniectomies can effectively treat elevated ICP, complications arise in greater than half of all cases and are more likely in patients who are older or have more severe injuries (Moon and Hyun, 2017). Potential complications of decompressive craniectomy include infection, CSF accumulation, hematoma expansion, and syndrome of the trephined (i.e., severe headache, dizziness, irritability, seizures, pain or discomfort at the surgical site, and psychiatric symptoms).

45.5 Animal models of blast traumatic brain injury

A variety of animal models exist for the different types of TBI (Xiong et al., 2013). bTBI can involve multiple types of injuries to a variety of body systems, as well as a host of physical parameters that may be impossible to replicate in the lab (e.g., complex wave fields). Add to this the sparsity of human data, and it becomes difficult to validate animal models of blast TBI. That said, mouse models of TBI all show signs of brain damage. As in any experimental approach, models with a greater degree of control over injury parameters have reduced physiological relevance, while models that aim to reproduce the conditions of blast injury may exhibit more variable degrees of injury.

The most commonly used animal models of TBI include fluid percussion, controlled cortical impact (CCI), weight drop injury (WPI) models, and blast overpressure injury (BOI) models. *Fluid percussion injury (FPI)*, *CCI*, and many *WDI* models are open models, meaning they involve a craniotomy in order to open a window in the skull and expose the cerebrum to external forces that displace and deform brain tissue. In FPI, the external force is generated when a pendulum is dropped to strike a reservoir of fluid, creating a fluid pressure pulse that is delivered to the dura. In CCI, the external force is generated by a pneumatic or electromagnetic device that drives a rigid impactor onto the dura. In WDIs, small weights are dropped from varying heights onto the exposed dura (open models) or skull (closed models). Open models reliably delivery mechanical energy to the cerebrum, allowing them to reproduce secondary injuries of bTBI with less variability than closed models. FPI, CCI, and WDI produce many of the neuropathological hallmarks of TBI, including intracranial hemorrhage, edema, axonal injury, BBB dysfunction, and gray matter atrophy. However, craniotomies are not benign and likely influence the results from these models.

BOI models use pressurized gas or miniature explosives to deliver blast pressure waves ranging from 20 to 350 kPa to the animal. Pressure waves can be generated using blast tubes, which contain a reservoir of air and a long tube to direct the blast separated by a diaphragm—diaphragm thickness determines blast pressure. Air is pumped into the reservoir until the diaphragm ruptures, producing a blast pressure wave that travels out of the blast tube. Alternatively, small explosives can be discharged at specified distances from anesthetized animals in order to deliver blast pressure waves. Experimental blast pressure waves reproduce the idealized pressure waveform (i.e., sharp peak of positive pressure followed by a negative pressure phase) and can be confined to the head with the use of Kevlar vests.

BOI is a more relevant model for bTBI than FPI, CCI, or WDI for two reasons. First, BOI does not require craniotomy and is thus a true closed TBI model. Second, the use of gas pressure waves accurately reproduces the physical parameters of primary blast injuries—other TBI models only reproduce secondary injuries, which are not specific to bTBI. For these reasons, I will focus my discussion on data from BOI models.

Animal models of bTBI reproduce many of the neuropathological hallmarks of human TBI, including vasospasm, edema, contusion, axonal injury, hemorrhage, reactive gliosis, and neuroinflammation. The neuropathological effects of BOI depend on the amplitude of the blast pressure wave (Long et al., 2009). Each experimental set-up must be calibrated in order to determine the lethal dose of blast pressure, so the absolute values of blast pressure waves may not translate well between different studies. At lower blast pressures, neuropathology may be absent. At moderate blast pressures, diffuse axonal injury occurs in the absence of overt cell loss. Subtle impacts on the vasculature can occur at moderate blast pressures, such as increased BBB permeability (Readnower et al., 2010). At higher blast pressures, more obvious neuropathologies emerge, including cortical degeneration, necrosis, inflammation, reactive gliosis, and hemorrhage.

The behavioral effects of BOI include reduced motor function, impaired sensorimotor reflexes, and learning and memory deficits as measured by maze navigation and novel object recognition. An important negative outcome of TBI in humans is the onset of mood disturbances. Mood disturbances can be detected in nonhuman animals by measuring a variety of anxiety-related behaviors, which typically involve hiding behaviors (e.g., avoiding well-lit areas or the center of an enclosure). Anxiety-related behaviors can be elicited by multiple exposures to extremely mild blast pressures, consistent with reports from veterans who suffered bTBIs. Remarkably, the learning and mood abnormalities that occur in BOI can be reversed by the mGluR2/3 antagonist BCI-838 in a dose-dependent manner (Perez-Garcia et al., 2018). These data suggest that elevated glutamate signaling may play a role in the PTSD symptoms associated with bTBI. Indeed, glutamate is elevated in the CSF of patients with head injuries (Yamamoto et al., 1999).

BOI has detrimental impacts on cardiopulmonary function, including acute apnea, bradycardia, and hypotension (Long et al., 2009). These likely contribute to the increased mortality rates observed following blasts, as encasing the body in a Kevlar vest reduced the cardiopulmonary effects and mortality of blast pressure waves. Whether this is a strength or weakness of the model depends on the experimental set-up and research question. Although the peripheral effects of blasts may increase injury variability, they also increase physiological relevance.

45.6 Biomarkers of blast injury

Given the subtle and transient nature of neurological deficits that occur following mild TBI, diagnosis can be challenging. This is especially true on the battlefield, where medical care providers may lack the time or resources necessary to assess mild TBIs. One appealing option is to use fluid biomarkers to assess the level of injury (Zetterberg and Blennow, 2016). Fluid biomarkers are molecules (i.e., proteins or RNAs) that can be measured in biological fluids such as serum or CSF.

I will discuss fluid biomarkers for TBI in general for two reasons. First, there is considerable overlap in the neuropathology and clinical symptoms that occur in blast and nonblast TBI. In other words, bTBI is clinically indistinguishable from other forms of TBI. Second, there is limited information of bTBI-specific biomarkers and little expectation for there to be unique biomarkers for blast injury. Markers of neuron death, reactive gliosis, demyelination, and neuroinflammation will appear regardless of injury mechanism. For example, elevated CSF levels of the microtubule-associated protein tau are found in patients with TBI, dementia (including Alzheimer's disease, Parkinson's disease, vascular dementia), stroke, brain tumor, infection, and hydrocephalus (de Bont et al., 2008; Franz et al., 2003; Hu et al., 2017; Kaerst et al., 2013; McKhann et al., 2011). From this, it seems that current fluid biomarkers are more likely to be useful for screening the level of injury, rather than determining the underlying cause of injury. Because the clinical utility of fluid biomarkers has not yet been determined, this section will merely survey the broad categories of biomarkers currently identified in TBI patients and mouse models.

45.6.1 Serum and cerebrospinal fluid protein biomarkers

Serum and CSF are commonly used biological fluids for obtaining biomarkers, and they each have their own advantages. Serum is easier to sample than CSF, while CSF has a smaller volume than serum, has lower protease activity than serum, and more directly contacts nervous tissue. Because of serum's greater volume (i.e., dilution), potential proteolytic degradation, and lack of free diffusion with interstitial fluid in the brain, serum biomarkers may be less sensitive to subtle or mild nervous system injury than CSF biomarkers.

Obtaining a sample of CSF is more difficult than obtaining a blood sample and, rarely, can produce adverse effects such as headache. CSF is usually sampled by lumbar puncture, although CSF can also be obtained through intracranial catheters in cases of severe TBI. Lumbar and intracranial CSF have different protein compositions, so it is important to note the source of CSF when interpreting these data.

45.6.1.1 Biomarkers of neuronal injury

Several different types of serum protein biomarkers have been identified in TBI (Agoston and Elsayed, 2012). The first class of protein biomarkers is those related to neuron death. When neurons die, their intracellular proteins are no longer confined by the plasma membrane. Neuronal intracellular proteins must also cross the BBB, which is presumably damaged, in order to enter the blood. The following proteins have been detected in TBI patients and animal models: neuron-specific enolase (NSE), tau, neurofilament heavy subunit, secretagogin, ubiquitin C-terminal hydrolase (UCH)-L1, α2 spectrin, and spectrin breakdown products.

NSE is among the most commonly studied biomarkers for TBI. Serum and CSF levels of NSE are elevated following severe TBIs and have been observed in BOI models (Pleines et al., 2001; Svetlov et al., 2010). Higher levels of serum and CSF NSE may be an indicator of poor prognosis (Böhmer et al., 2011; Žurek and Fedora, 2012). However, serum NSE is not sensitive enough to detect mild TBI, as mild TBI patients with and without intracranial lesions can only be distinguished based on serum NSE with a sensitivity of 56% and a specificity of 77% (Wolf et al., 2013). Despite its name, NSE is also highly expressed in erythrocytes, making it possible for hemolysis to contaminate serum samples.

45.6.1.2 Biomarkers of glial injury

The second class of protein biomarkers is those related to glial cell damage. As with neurons, the detection of intracellular proteins in extracellular fluids is a marker of cell death. Biomarkers of glial injury include S100β, glial fibrillary acidic protein (GFAP), and myelin basic protein (MBP). S100β and GFAP are commonly used markers of reactive astrocytes. MBP is a marker of demyelination and oligodendrocyte damage.

Elevated serum and CSF levels of S100β, GFAP, and MBP have been reported in TBI patients and BOI models (Böhmer et al., 2011; Gyorgy et al., 2011; Svetlov et al., 2010; Žurek and Fedora, 2012). Glial markers of injury may also have prognostic value, as CSF S100β and serum GFAP levels are significantly higher in nonsurvivors than survivors of severe TBI. Compared to S100β and GFAP, MBP levels rise later (>72 h) and remain elevated for longer (up to 2 weeks).

45.6.1.3 Biomarkers of inflammation

The final class of protein biomarkers is those related to inflammation. Biomarkers of inflammation include proinflammatory cytokines such as tumor necrosis factor (TNF) α, interleukins (ILs), and interferons (IFNs). Proinflammatory cytokines are released from glia following injury to stimulate reactive gliosis and recruit immune

cells to the site of injury. As such, elevated serum and CSF levels are expected to occur following injury. Indeed, elevated serum and CSF levels of proinflammatory cytokines have been reported in TBI patients (Woodcock and Morganti-Kossmann, 2013). The level of proinflammatory cytokines has prognostic value. For example, in severe TBI patients, elevated serum IL and TNFα levels correlate with increased ICP and decreased cerebral perfusion (Stein et al., 2011).

Neuroinflammation appears to be an early component of TBI, rising within minutes following injury. In animal models of bTBI, serum TNFα levels peaked earlier than tau or GFAP levels (Liu et al., 2014). Inhibition of TNFα synthesis prevents neuron loss and reactive gliosis in a WDI mouse model of TBI (Baratz et al., 2015). These data are consistent with cytokine measurements from postmortem human brain tissue, showing elevated TNFα, IL-6, and IFN-γ levels within minutes following TBI (Frugier et al., 2010). Taken together, these data suggest that neuroinflammation is an early instigating factor in neurotrauma.

45.6.1.4 MicroRNA biomarkers

There is considerable enthusiasm for the use of microRNA (miRNA) biomarkers in a variety of diseases. miRNAs are short, noncoding RNAs that shape the gene expression profile in cells by interacting with 3′ untranslated regions in messenger RNAs. miRNAs are important gene expression regulators in neurons and are implicated in the induction of neural cell fate, development of neural circuits, and maintenance of neuron function. In fact, roughly 70% of all known miRNAs are expressed in the brain (Adlakha and Saini, 2014).

miRNAs are secreted from cells into biological fluids and are surprisingly stable. Hundreds of secreted miRNAs have been identified as potential biomarkers for TBI, although only a small fraction of these miRNA biomarkers have been reported in multiple studies. miR-21, miR-16, and let-7i are of particular interest as TBI biomarkers due to their ability to differentiate between mild and severe TBI. It should be noted that miRNA levels can be highly variable between samples due to the exponential nature of polymerase chain reaction and the lack of appropriate normalization techniques. Because of this, miRNAs are currently more relevant in the laboratory than the clinic. For an in-depth discussion of miRNA biomarkers, readers are directed to recent reviews (Atif and Hicks, 2019; Di Pietro et al., 2018).

45.7 Concluding remarks and future directions

Blast injuries are often considered a signature injury for soldiers in active combat zones. Modern combat helmets and interceptor body armor vests improve survival after blast injuries, which necessitates the advancement of medical care for blast TBI patients. Civilian populations are not spared from blast injury, however, as explosive devices are commonly used during terrorist attacks.

Diagnosing bTBI may be difficult in many cases since the majority of bTBIs are mild and produce transient symptoms. Currently, fluid biomarkers are better suited to detect severe TBIs. The development of a biomarker signature for mild TBI may be especially useful on the battlefield, where time and resources are limited. This will require better normalization methods for protein and miRNA biomarkers. For example, NSE concentrations should be compared with free hemoglobin levels in order to estimate potential contamination by erythrocyte NSE in serum and CSF samples. Finally, the temporal sequence of biomarkers should be correlated with different levels of injury.

Currently, it is not clear to what degree bTBI is distinct from pTBI or cTBI. A large degree of overlap is expected between different types of TBIs in terms of pathophysiology, clinical symptoms, and fluid biomarkers. However, only two clear distinguishing features of bTBI have emerged so far. First, blast injuries may be accompanied by severe psychological distress that can create or exacerbate neurological symptoms of bTBI. This is likely due to the fact that bTBIs are typically acquired in military conflicts and terrorist attacks. Better diagnostic tools that discriminate between PTSD and bTBI are needed. The other key feature of bTBI is the peripheral injuries that occur due to the nature of blast pressure waves, which spread in spherical manner to affect the entire body. Animal models of blast TBI should account for the effect of primary blast injuries on the brain and body.

Chapter 46

Genomics and proteomics in brain complexity in relation to chemically induced posttraumatic stress disorder

Gopala Krishna and Mayur Krishna
Expert Consultants, Ellicott City, MD, United States

46.1 Introduction

Posttraumatic stress disorder (PTSD) is an anxiety disorder rooted in an extremely traumatic experience, usually one that threatens severe injury or death. PTSD is characterized by symptoms in three primary domains: (1) reminders of the exposure (flashbacks, intrusive thoughts, and nightmares); (2) activation (hyperarousal, insomnia, agitation, irritability, impulsivity and anger); and (3) deactivation (numbing, avoidance, withdrawal, confusion, derealization, dissociation, and depression). Signs and symptoms can last beyond 1 month (even though such periods can occur long after the original traumatic exposure) and therefore reflect a persistent, abnormal adaptation of neurobiological systems to the stress of witnessed trauma. According to the World Health Organization (WHO), mental disorders account for 4 out of 10 of the leading causes of disability in developed countries, and epidemiological data suggest that 7.8% of people will experience PTSD in their lifetimes (Kessler et al., 1995; Roth et al., 2011; Gelernter and Sun, 2019). Clinical studies have shown a high prevalence of PTSD in war veterans, especially in those who suffered from chemical warfare. Based on symptom severity and persistence, PTSD is generally categorized into three types: acute, chronic, and delayed onset. In acute PTSD, symptoms normally last less than 3 months. In chronic PTSD, symptoms may last 3 months or more. In delayed onset of PTSD, symptoms first appear at least 6 months after the traumatic event. The estimated lifetime prevalence of PTSD is ~8% in the US population, with women (10.4%) twice as likely as men (5%) to experience PTSD. According to the same report, the prevalence ranges from 3% to 58% in high-risk groups, such as combat veterans and victims of violent crimes such as rape, sexual molestation, physical attack, and violence.

Current diagnostics for PTSD rely on subjective measures and patient recall, making it difficult to accurately diagnose the condition or differentiate its symptoms from those of depression or anxiety. The exact causes of PTSD and the long-term changes in the body, especially the brain, due to PTSD remain unknown. Identifying specific areas of the brain whose key functions are altered in association with a specific disorder is key to understanding the fundamental causes and sustaining factors of disease pathology. Recent advances in brain imaging technologies have allowed scientists to analyze the brains of patients afflicted with a variety of neurological disorders. Whole-brain imaging studies offered valuable information about the permanent changes and long-term effects of PTSD in the brain (Brown et al., 2014; Hull, 2002). However, some of these key brain areas are also involved in a number of closely associated brain disorders such as anxiety and depression (Kroes et al., 2011); and distinguishing subtle morphological changes between these closely related neurological disorders through brain imaging is extremely challenging. Additionally, whole-brain imaging studies can only provide a snapshot of the current morphological status, requiring the development of advanced methodologies that can predict the predisposition of an individual, mainly the alterations in genetic makeup, which serve as molecular signatures of PTSD. High-throughput genomics and proteomics approaches have been widely applied for identifying biomarkers for many diseases as well as characterizing the molecular toxicology of chemical agents (Gupta, 2014).

There are many questions that are relevant while trying to characterize the molecular fingerprint of a complex

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00046-5

disease like PTSD. Determine whether there are changes in gene expression—that is, can the activity or output of particular genes—associated with the onset of PTSD after exposure to traumatic events or some environmental factors such as toxic chemical exposure affect the way our genes behave, the RNA they make, ultimately resulting in the alteration of the body's production of various proteins and hormones. Do those changes contribute to the development of PTSD? Can we identify specific variants in the genetic architecture involved in alterations in gene expression and associated with PTSD? Answers to these questions will help researchers understand what happens with our genes and the proteins they make and related basic biology as we are exposed to trauma and toxic environments. This, in turn, could educate new intervention efforts, including medication treatments that offset biological factors leading to PTSD's development. In this chapter, we briefly discuss the outcomes of current research in the anatomical changes in the brain, genomic factors leading to PTSD development, and recent advances in genomics, transcriptomics, and proteomics to understand PTSD at the molecular level, and develop early diagnostic tools and specific pharmacotherapy.

46.2 The effect of posttraumatic stress disorder on different regions of brain

Earlier brain imaging studies have identified a few key brain regions in which patients with PTSD appear to have altered stress response structure and function. The neurobiological systems regulating stress response pathways and the network of brain regions known to regulate fear and emotive behavior also seem to have a role in PTSD. Investigations to identify neurobiological markers for PTSD originally presumed that abnormalities were acquired as a consequence of traumatic experience. However, certain abnormalities in a patient with PTSD could simply represent preexisting conditions or functionally dormant pathology, which arise through trauma exposure and hence are detected thereafter upon investigation. Patients with PTSD showed drastic changes in the hippocampus and amygdala as well as cortical regions including the anterior cingulate, insula, and orbitofrontal region (Bremner et al., 2008; Shin et al., 2006). All these areas form a neural circuit mediating, among other functions, adaptation to stress and fear conditioning and changes in these circuits are considered directly related to the development of PTSD (Rauch et al., 2006).

46.3 The hypothalamic–pituitary–adrenal axis

The "headquarters" of the mammalian neuroendocrine stress response system is the hypothalamic–pituitary–adrenal (HPA) axis and, as such, it has been the main target for investigation in PTSD patients. Briefly, the HPA axis is made up of endocrine hypothalamic components, including the anterior pituitary and the adrenal glands as effector organs. Upon exposure to stress, neurons in the hypothalamic paraventricular nucleus secrete corticotropin-releasing hormone from nerve terminals in the median eminence into the hypothalamo-hypophyseal portal circulation, which stimulates the production and release of adrenocorticotropin (ACTH) from the anterior pituitary. ACTH in turn stimulates the release of glucocorticoids from the adrenal cortex. Prolonged glucocorticoid exposure has adversarial effects on hippocampal neurons, involving a reduction in dendritic branching, loss of dendritic spines, and impairment of neurogenesis (Fuchs and Gould, 2000).

Cortisol, secreted in the adrenal cortex in response to stress, is an informative biomarker that can be used to differentiate PTSD from normal patients. Outcome from a simulation study supported the hypothesis proposed by Yehuda and colleagues that high stress intensity and strong negative feedback loop may cause a hypersensitive neuroendocrine axis that results in hypocortisolemia in PTSD (Sriram et al., 2012; Yehuda et al., 1993). Also, low-dose dexamethasone suppression testing suggests that hypocortisolism in PTSD occurs due to increased negative feedback sensitivity of the HPA axis (Wingenfeld et al., 2007). In summary, these studies suggest that decreased availability of cortisol, due to irregular regulation of the HPA axis, may lead to abnormal stress reactivity and fear processing.

46.4 Hippocampus

Reduced hippocampal volume is a well-known hallmark feature of PTSD. Initial magnetic resonance imaging (MRI) studies determined smaller hippocampal volumes in Vietnam veterans with PTSD and patients with abuse-related PTSD compared with controls (Bremner et al., 1997). Therefore, the severity of trauma and memory impairments was related to the decrease in hippocampal volumes. However, reduced hippocampal volume has not been observed in children with PTSD (De Bellis et al., 1999). Additionally, proton magnetic resonance spectroscopy investigations further observed a reduction of the levels of *N*-acetyl aspartate (NAA), a marker of neuronal integrity, in the hippocampus of adult patients with PTSD (Villarreal et al., 2002). Hippocampal volume reduction in PTSD likely reflects a neurotoxic effect of repeated exposure to stress-increased glucocorticoid levels or glucocorticoid sensitivity, though decreased hippocampal volumes might also be a preexisting vulnerability factor for developing PTSD (van der Werff et al., 2013).

Convincing evidence suggested that smaller hippocampal volume in trauma-exposed persons resulted in them being diagnosed with more severe, unremitting PTSD (Gilbertson et al., 2002). In fact, early life stressors can affect hippocampal volume and predispose for the disorder (Yehuda et al., 2010). However, at this stage how trauma, per se, affects hippocampal volumetric (as well as other histopathological) measures, is not well understood. Intriguingly, functional neuroimaging studies have also shown deficits in hippocampal activation during a verbal declarative memory tasks in PTSD patients (Bremner et al., 2003). Both hippocampal atrophy and of functional deficits SSRIs notably, likely due to an increase of neurotrophic factors and neurogenesis (Nestler et al., 2002).

46.5 Amygdala

Investigators have suggested the idea that aberrant stress response and an enhanced amygdala-induced augmentation of emotional memories in PTSD subjects may be underpinned by abnormal amygdala functioning (Elzinga and Bremner, 2002) due to its functional role in mediating both stress responses and emotional learning. However, no clear evidence for structural alterations of the amygdala has been found in PTSD patients. Functional imaging studies have revealed amygdala hyperresponsiveness in PTSD subjects when stressful scripts (Hendler et al., 2003; Shin et al., 2004), cues, and/or trauma reminders were presented (Shin et al., 2006). On the other hand, PTSD patients show increased amygdala responses even to general emotional stimuli that were not trauma-associated (Shin et al., 2006) or subliminally threatening cues (Bryant et al., 2008; Hendler et al., 2003). Amygdala hyperactivity seems to be related with specific genetic traits (Hariri et al., 2002; Kilpatrick et al., 2007), hence it may likely have a role in developing PTSD. In fact, several investigations have found a positive relationship between activation of the amygdala and PTSD symptom severity (Shin et al., 2004).

PTSD patients show a hyperactive amygdala as a consequence of trauma and throughout the course of the disorder, hence reducing the activity of the amygdala could potentially prevent onset of the disorder or be therapeutic for those individuals who have already developed psychopathology. That led to the hypothesis that noradrenergic activity could promote amygdala-dependent fear memories. Indeed, researchers have speculated that adrenergic receptor antagonists could potentially reduce the severity of PTSD symptoms as adrenergic receptor modulators, such as prazosin (α1 receptor antagonist) (Raskind et al., 2007), clonidine (α2 receptor agonist) (Boehnlein and Kinzie, 2007; Strawn and Geracioti, 2008), and propranolol (β receptor antagonist) (Brunet et al., 2011; Pitman, 2011), have shown promising results as components of therapy for PTSD.

46.6 Cortex

The prefrontal cortex (PFC), and particularly the medial PFC, is highly involved in the extinction of fear memories (Sherin and Nemeroff, 2011) and in general in the inhibitory control of inappropriate cognitive and emotional responses that are mediated, in part, by the amygdala (Elzinga and Bremner, 2002). Given this large inhibitory role of the PFC over the amygdala, researchers have speculated that impaired PFC functioning may trigger amygdala hyperactivity and hence exacerbate emotional responsiveness. Actually, individuals with PTSD exhibit smaller volumes of the PFC, its major subregions, and specifically anterior cingulate cortex (ACC) (Woodward et al., 2006; Yamasue et al., 2003). Therefore, PTSD symptom severity could likely be related to these volumetric reductions (Zoladz and Diamond, 2013). Moreover, shape abnormalities (Corbo et al., 2005) as well as a decrease in NAA levels in the ACC (De Bellis et al., 2000) have also been reported.

However, recent evidence has suggested that volume loss in the PFC and ACC could also be a consequence of PTSD rather than a preexisting risk factor (Kasai et al., 2008). Functional imaging studies have demonstrated a reduced activity of the medial PFC in PTSD patients in response to stimuli, such as trauma scripts (Britton et al., 2005; Shin et al., 2004), combat pictures and sounds (Bremner et al., 1999), trauma-unrelated negative narratives (Lanius et al., 2003), fearful faces (Shin et al., 2005), and impaired performance on PFC-dependent tasks (Koenen et al., 2001). Finally, PTSD patients show impaired abilities to extinguish fear (Peri et al., 2000) and reduced activities of PFC regions during extinction trials (Bremner et al., 2005).

These individuals exhibited a reduced activity of PFC, or a complete failure to activate PFC brain regions during the presentation of trauma-associated stimuli (Britton et al., 2005; Shin et al., 2004), hence, it is likely that a reduced activation of PFC along with amygdala hyperactivity could lead to the development of the intrusive emotional thoughts and memories often experienced by PTSD patients. A reduced PFC activity could lead to greater governance of behavior by more primitive brain areas, such as the amygdala, impairing brain processes involved in adaptation, behavioral flexibility, and cognition. As for the volume decrease, it is still unclear whether the reduced PFC inhibition of lower brain areas, such as the amygdala, is a result of the disorder or a preexisting condition for developing PTSD. Investigations of twin brothers who were discordant for PTSD (Gilbertson et al., 2006) supported the hypothesis that reduced PFC

functioning is both a preexisting condition and a risk factor for the development of PTSD. Moreover, animal and clinical studies mainly suggest a complex interaction among early life stress (Karssen et al., 2007; Lyons et al., 2010), gene−environment influences (Garrido, 2011), and the well-described adverse effects of stress on PFC functioning in adulthood (Arnsten, 2009), which could interact to influence PTSD susceptibility and posttrauma expression. SSRI treatment has been shown to restore medial prefrontal cortical activation patterns (Shin et al., 2006).

Though the above findings using brain imaging studies advance our understanding of PTSD pathology, they fall short of identifying predispositions to the disease. The significant progress in genetics and genomics has generated approaches that screen full genome and genetic networks rather than individual genes. The recent move toward the "omics" fields, including genomics and proteomics, offers enormous opportunity to analyze genes, RNA transcripts, and protein expression patterns in diseased and normal tissues. Such approaches have equipped us with many advantages and made access to thousands of new molecular targets for disease screening and drug discovery. In the following pages we discuss the genomic and proteomic methods that are currently used to understand the molecular-level players in PTSD.

46.7 Understanding posttraumatic stress disorder: the genomics and proteomics way

The central dogma of biology coined by Francis Crick proposed that an organism's genetic information encoded in its DNA molecules is transcribed into RNA molecules (transcriptome), which are then translated to proteins (proteome) that facilitate particular biological functions. In addition to the transfer of information from genome to proteome, proteome functions are regulated by epigenetic mechanisms such as posttranslational modifications and regulation via noncoding RNAs (ncRNAs). The development of advanced techniques over past two decades has allowed the scientific community to take a closer look at the genome, transcriptome, and proteome of any tissue or organ, and proved to be invaluable in studying complex tissues such as the brain. Monitoring the specific activity of a genome by measuring mRNA expression levels of large gene sets can identify molecular profiles correlated to disease states, which may then be developed as diagnostic tools.

The human brain is one of the most complex biological structures, which consists of approximately 100 billion neurons and a nearly equal number of nonneuronal cells (Azevedo et al., 2009). Neurons that perform a specific function are assembled into circuits and the neurons within each circuit talk to each other through unique connections called synapses. Anomalies that affect communication within neural circuits lead to neurological disorders and affect regular brain functions (Geula, 1998). For over a century, researchers have tried to understand human brain functions using simple animal models such as worms, flies, snails, mice, and rats. Over the past two decades, molecular genetics studies have enabled a common conceptual framework for the development and basic function of the nervous system. However, because many debilitating human disorders are genetically complex and phenotypic screens are difficult to perform, large-scale genomic approaches to discover genes that are uniquely expressed in brain circuits and regions that control complex behaviors are becoming highly significant.

A comprehensive picture of the genomic factors underlying an individual's susceptibility to complex diseases is essential to understanding diseases like PTSD where it is often difficult to make an absolute clinical diagnosis. One such study showed that a single-nucleotide polymorphism (SNP) of the gene Oprl1 is associated with PTSD symptoms in humans and an altered expression of this gene in the amygdala of mouse models led to alterations in fear processing that may lead to PTSD development (Andero et al., 2013). Another study of adult civilians with PTSD has shown that individuals with a history of childhood abuse have very discrete and profound changes in gene activity patterns, compared to adults with PTSD but no history of child abuse (Mehta et al., 2013). The outcome of both these studies provide us the evidence that susceptibility to developing PTSD may be coded in one's DNA; and the exposure to traumatic events may act as the trigger to PTSD onset. In addition, scores of recent studies on epigenetic mechanisms account that it is not just DNA that carries all the information for a specific phenotypic outcome, and specific alterations in epigenetic signatures such as DNA methylation were more frequent in the PTSD group that suffered child abuse (Mehta et al., 2013). The above study also found that the PTSD with child abuse group demonstrated more changes in genes linked with nervous system development and regulation of the immune system, while the PTSD patient group with no child abuse history showed more changes in genes linked with apoptosis (cell death) and regulation of growth rate. Though the symptoms in both the PTSD groups were the same, these findings showed that the specific affected biological pathways might lead to different mechanisms of PTSD symptom formation within the brain. These studies provide ample evidence that PTSD is associated with distinct molecular fingerprints and identifying the key genetic factors for PTSD etiology will not only improve our understanding of the underlying pathophysiology, but may also lead to new avenues for preventing and treating this distressing

disease at an early stage. In recent years, these approaches have been strengthened by the data-driven advancements in science and technology (Duncan et al., 2018; Nievergelt et al., 2018; Sumner, 2017).

46.8 Applications of genomic and transcriptomics methods

Transcriptomics and gene expression profiling methods analyze the expression of thousands of genes simultaneously in a single biological sample by quantifying the levels of individual mRNA transcripts. Some of the earlier methods used for the identification of genes in different parts of brain include differential display, representational difference analysis, serial analysis of gene expression, and massively parallel signature sequencing. These techniques are relatively expensive and laborious, which led to the search for high-throughput screening techniques that can capture dynamic gene expression changes and perform large-scale gene expression profiling in complex neuronal systems.

Microarrays hold the promise of becoming a revolutionary tool for large-scale analyses of genome sequences and gene expression (Noordewier and Warren, 2001; Young, 2000). The most commonly used formats are the oligonucleotide microarray (Fodor et al., 1993) and the cDNA microarray (Schena et al., 1995). Over the years, microarray technology advanced to support maximum coverage of the transcriptome. The successful applications of microarray technology offer a robust and unbiased approach to acquire global gene expression patterns in the whole brain, specific tissue, or a single neuron. cDNA arrays are often used in RNA expression analyses, while oligonucleotide arrays are used for sequence analyses. Oligonucleotide arrays offer a number of advantages over cDNA microarrays such as increased specificity of hybridization, which is key to SNPs (LaForge et al., 2000), mutational analysis (Hacia, 1999), identification of splice forms, and alternatively polyadenylated transcripts (Hu et al., 2001). Microarrays have been extensively used to study expression profiles of complex neuropsychiatric disorders using both animal models (Lin et al., 2012) and RNA from postmortem human brain tissue (Lehrmann et al., 2003). Thus microarrays can be effectively applied toward robust screening of a large number of genes, which are altered with PTSD onset.

Validation of microarray results is often performed by another sensitive technique, such as qualitative real-time PCR (qRT-PCR). qRT-PCR uses fluorescence detection of the PCR product by combining a thermal cycler with a fluorescent spectrophotometer (Higuchi et al., 1993). qRT-PCR reaction can be performed in two different formats. In the first case the double-stranded DNA generated is detected by the binding of a fluorescent dye such as SYBR green I that intercalates only to the double-stranded DNA (Ponchel et al., 2003). The second format uses a fluorescent reporter molecule that is released due to the exonuclease activity of the DNA polymerase enzyme. qRT-PCR is widely used as a robust method for quantitative gene expression analysis (Gibson et al., 1996). Apart from qRT-PCR, another widely used approach to validate gene expression in transcriptomics is in situ hybridization. Fluorescence in situ hybridization (FISH) was developed in the 1980s, and rapidly became a powerful technique (Langer-Safer et al., 1982). Using FISH, a small RNA fragment of the mRNA transcript to be tested is fluorescently labeled and used for hybridization in fixed samples. The probe binds to the complementary sequences within the sense transcript, which can be visualized by fluorescence microscopy. FISH can identify whole chromosomes, centromeres, telomeres, specific regions or genes, or aberrations in interphase tumor nuclei, and can be effectively used to identify novel mRNA transcripts, the levels of specific genes expressed, and their cellular localization. Using this technique, a genome-wide three-dimensional map of the entire human brain is constructed that details where each gene is "turned on or off."

Very often, however, the molecular characterization of clinical samples is complicated and limited by the available amount of samples. Strategies to overcome this problem include amplification of the starting material or of the signal to be detected, or miniaturization of the method. Novel means are also required to measure gene expression with allele-specific and splice-variant-specific profiles. Such technologies promise to be a further big step from bench to bedside. Though microarrays are still widely used, an increasing number of studies now use direct sequencing of transcripts by high-throughput sequencing technologies (RNA-Seq), also known as "next-generation" or "deep" sequencing (Wang et al., 2009). Unlike microarrays, RNA-Seq is not limited to detecting transcripts that correspond to existing genomic sequences and has significantly low, if any, background signal. In addition, RNA-Seq does not have an upper limit for quantification, offering a large dynamic range of expression levels over which transcripts can be detected. Most commonly used techniques to analyze genetic and genomic variants are shown in Fig. 46.1.

SNP genotyping is an advanced genotyping method that measures SNPs between genomes. In an SNP, a single base pair is mutated at a specific locus, leading to malfunction of the specific gene product and a disease phenotype. Over 1 million SNPs are currently reported to be present within the human genome (Sachidanandam et al., 2001). Even though very small numbers of SNPs cause changes in gene function or expression, it is critical

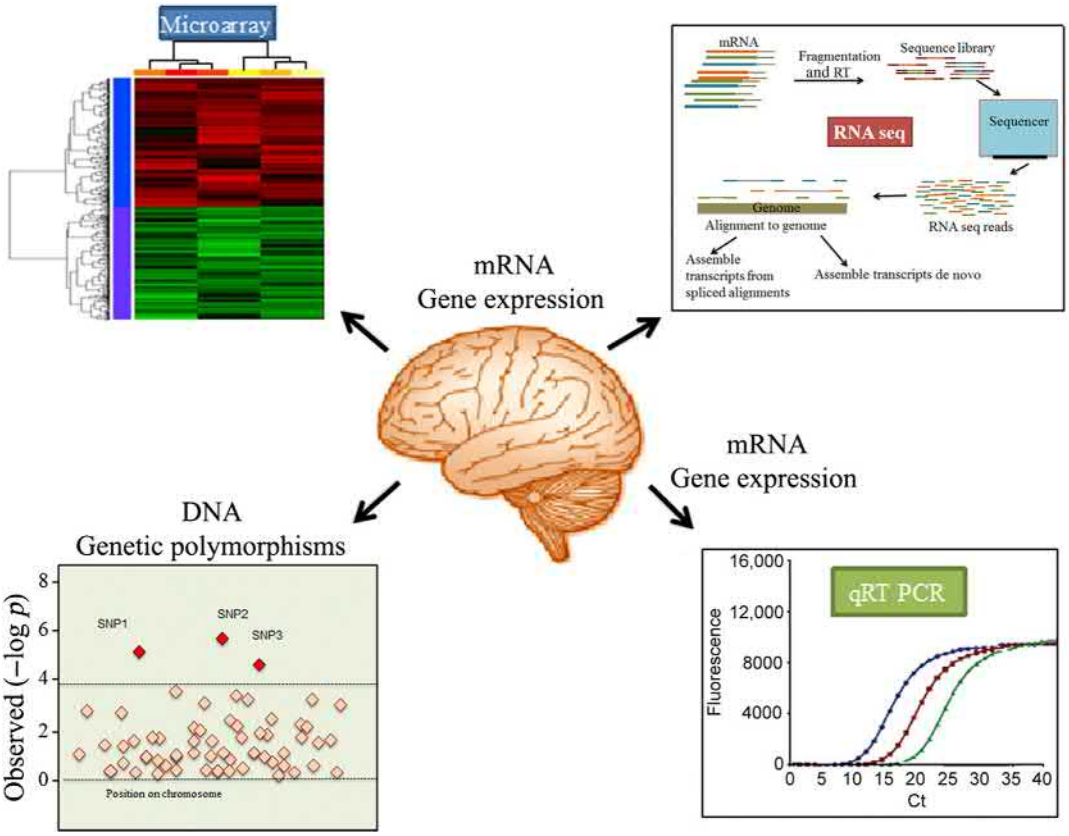

FIGURE 46.1 The most commonly used techniques to identify the genomic and transcriptomic changes associated with specific diseases. In microarray, RNA-seq, and qRT-PCR, mRNA isolated from samples is characterized to observe any changes in gene expression. In single-nucleotide polymorphisms (SNPs), DNA is used to identify a single base pair mutation at a specific *locus* on the chromosome.

to identify SNPs as they are implicated in a number of diseases. There are multiple platforms to perform SNP genotyping and multiple studies have shown specific SNPs are associated with PTSD. A genome-wide SNP association analysis in 1578 European Americans (EAs), 300 of whom suffered from PTSD, and 2766 African Americans, 444 of whom had PTSD using Illumina Omni1-Quad microarray found novel common risk alleles for PTSD (Xie et al., 2013). This study yielded close to 90,000 SNPs and found a new susceptibility gene for PTSD called Tolloid-Like 1 gene. A similar genome-wide association study (GWAS) from a cohort of veterans reported a SNP (rs8042149) located in the retinoid-related orphan receptor alpha gene (RORA) associated with PTSD susceptibility (Logue et al., 2013). RORA has been implicated in prior GWASs of psychiatric disorders and is known to have an important role in neuroprotection and other behaviorally relevant processes. This study represents an important step toward identifying the genetic underpinnings of PTSD.

Another well-studied example is the FK506 binding protein 5 (FKBP5), a glucocorticoid receptor cochaperone regulator (Mehta et al., 2011) that has reduced expression levels in PTSD (Yehuda et al., 2009). In a cross-sectional study on childhood abuse, four specific SNPs of the FKBP5 gene were found to be predictors of adult PTSD symptoms (Binder et al., 2008). These four SNPs were identified as rs3800373, rs9296158, rs1360780, and rs9470080 from a study done on European Americans and African Americans who were originally screened for lifetime PTSD (Xie et al., 2010). All four SNPs showed a similar linking pattern (Shinozaki et al., 2011), which supported a genetic as well as environmental basis for childhood abuse and the subsequent onset of PTSD in adulthood.

In another study the peripheral expression levels of FKBP5 gene expression and volumes of specific brain structures such as the hippocampus, amygdala, and medial orbitofrontal cortex in 39 patients with PTSD were compared before and after cognitive behavioral therapy. Microarray and qRT-PCR analysis have found that there was a significant increase in FKBP5 expression and hippocampal volume in patients with PTSD. Another study in the similar line on Pituitary Adenylate Cyclase—Activating Polypeptide (PACAP)—PAC1 receptor was found to be involved in abnormal stress responses

underlying PTSD in a sex-specific manner in heavily traumatized individuals (Ressler et al., 2011). Analyzing the levels of PACAP in the blood and extensive SNP genotyping of PACAP and PAC1 genes showed a single SNP within PAC1 gene (rs2267735) that predicts PTSD diagnosis and symptoms in females only. The study also found that methylation of the PAC gene in peripheral blood is associated with PTSD.

46.9 Role of noncoding RNAs and epigenetics in posttraumatic stress disorder

Earlier, SNPs associated with a number of genes were described as genomic indicators of PTSD vulnerability. Recent studies provide evidence that epigenetic mechanisms and ncRNAs are also involved in the development of PTSD, increasing the molecular complexity to a further level. An initial animal model study examining DNA methylation of the brain-derived neurotrophic factor (BDNF) gene in rat models of PTSD found a significant increase in BDNF DNA methylation in the dorsal hippocampus, the highest increase in the dorsal CA1 subregion, and a significant methylation decrease in the ventral hippocampus (CA3) following the stress regimen (Roth et al., 2011). Meanwhile, this study found no change in BDNF DNA methylation in the medial PFC or basolateral amygdala. Interestingly, the mRNA levels of BDNF were decreased in both the dorsal and ventral CA1, providing key evidence that traumatic stress can induce CNS gene methylation and alter gene expression in key brain areas leading to the pathophysiology of PTSD.

A recent study on African Americans involved in the Grady trauma project has found that DNA demethylation altered the transcription of FKBP5, leading to long-term dysregulation of the stress hormone system for stress regulation associated with PTSD (Klengel et al., 2013). It has been reported that PTSD patients who faced significant abuse in childhood displayed more changes in gene expression associated with central nervous system development and immune system regulation, whereas those without a history of childhood abuse displayed more changes in gene expression associated with cell death and growth rate regulation. Specific alterations in the DNA methylation profile were up to 12-fold higher in PTSD patients with a history of childhood abuse (Mehta et al., 2013). In a similar study, gene expression profiles in DLPFC Brodmann area of 46 postmortem patients with or without PTSD have been investigated using human mitochondria-focused cDNA microarrays (hMitChip3) (Su et al., 2008). A total of 119 genes were found differentially expressed between the control and PTSD patients and the majority of genes altered in PTSD samples belonged to the neuronal function-survival networks. Similarly, a recent study using bold sera from US military service members evaluated temporal changes in DNA methylation in select promoter regions of immune system-related genes between PTSD diagnosis, pre- and postdiagnosis, and in control patients. This study found reduced mC levels at the promoter regions of a long ncRNA H19 and interleukin-18 (IL18) in those who did not develop PTSD after deployment, while those who did develop PTSD had increased levels of IL18 (Rusiecki et al., 2013).

MicroRNAs (miRNA) have recently emerged as epigenetic modulators of gene expression in psychiatric diseases like schizophrenia and depression (Miller and Wahlestedt, 2010). miRNAs are short, single-stranded RNA sequences that regulate gene expression by binding to the regulatory regions of mRNA and preventing translation, representing another mechanism of regulating gene expression besides up- or downregulation of transcription (Fabian et al., 2010). In a recent study reporting the connection between miRNAs and PTSD, miRNA profiles of the PFCs from fluoxetine-treated and control wildtype C57BL/6N mice were dissected 74 days after they were subjected to either a single traumatic electric footshock or a mock treatment (Schmidt et al., 2013). Fluoxetine is an antidepressant effectively used both in PTSD patients and in mice suffering from a PTSD-like syndrome. Using miRBase 18.0 screening and qPCR validation, the study found five miRNAs, including one (mmu-miR-1971) showing a significant reduction in fluoxetine-treated shocked mice.

The relevance of the noncoding genome to human disease has mainly been studied in the context of miRNA expression and function. However, it is still a start for us to recognize the nature and extent of the involvement of other ncRNAs in disease. A GWAS of PTSD was conducted using a primarily African American sample set of women from the Detroit Neighborhood Health Study that included 94 PTSD cases and 319 controls exposed to at least one traumatic event as well as an independent cohort of primarily European American women from the Nurses Health Study II (NHSII) which was composed of 578 PTSD cases and 1963 controls (Su et al., 2008). More than 700,000 markers were screened using Illumina HumanOmniExpress BeadChip. The results found a genome-wide significant association of one marker mapping to a novel RNA gene, lincRNA AC068718.1. The study also performed pathway analysis to obtain a protein functional interaction network, and found pathways related to telomere maintenance and immune function. This study demonstrated the emerging evidence that ncRNAs may play a crucial role in shaping the landscape of gene regulation with putative pathological effects that lead to phenotypic differences.

46.10 Toxic chemical exposure and human diseases

Scores of studies point to the influence of an individual's genetic information and social conditions in the development of PTSD. However, it is also important to address the role of other external factors such as brain cell damage and nervous system damage caused by chemical exposure. It has been reported that residents from regions of high-intensity warfare and chemical weapons during the 1980–88 Iran–Iraq War significantly had higher risks of meeting criteria for lifetime and current PTSD compared with the residents of high-intensity warfare alone (Hashemian et al., 2006). Currently, PTSD development following trauma or exposure to chemical war agents (CWAs) is poorly understood. Although every individual with PTSD has been exposed to a traumatic event, studies show that the majority of people who experience trauma do not develop PTSD. It is intriguing why some people remain resilient; some experience short-term difficulties; and others develop a chronic problem such as PTSD.

According to the Research Advisory Committee report on "Scientific Progress in Understanding Gulf War Veterans' Illnesses: Report and Recommendations," almost 30% of the veterans from the Gulf War were disabled by chronic symptoms such as severe headaches, memory problems, confusion, dizziness, blurred vision, and tremors (http://www.va.gov/RAC-GWVI/Gulf_War_Illnesses_links.asp). Notably, Gulf War veterans have developed ALS at twice the rate of veterans who did not serve in the Gulf War. Based on the research data collected, the committee identified the nerve gases sarin and pyridostigmine bromide, and multiple pesticides as potential factors in the development of neurological disorders. More research is needed to better understand the veterans' vulnerability to PTSD after exposure to CWAs, especially to consider why only a small portion of the veterans who experienced childhood abuse developed the symptoms.

46.11 Genomic applications: understanding the relationship between posttraumatic stress disorder and chemical toxicity

The development of modern genomic analysis techniques offers an unparalleled opportunity to investigate neurological diseases such as PTSD due to CWA and other toxic chemical exposure. CWAs like organophosphate (OP) insecticides and nerve gases are capable of changing neuronal activity primarily via cholinergic pathways. These CWAs bind irreversibly to acetylcholinesterase (AChE), an important regulator of the neurotransmitter acetylcholine (ACh) that leads to lasting changes in neuronal activity. Studies in rodent brains have shown that the exposure could affect brain regions critical for attention, anxiety, and addiction. Nerve agents affect central and peripheral nervous systems, and cardiovascular, respiratory, gastrointestinal, and metabolic systems. Most importantly, they cause behavioral and psychological changes in humans, leading to memory loss and depression. One of the nerve agents used in previous wars, sarin (GB), is suspected to be one of the key factors responsible for Gulf war syndrome.

Animal models have greatly aided our understanding of the effects of CWAs on the cellular functions, molecular pathways, organ functions, and gene expression changes that are conserved in humans. Earlier studies on rats showed that sarin usually induces neurotoxicity by affecting the mRNA expression of alpha tubulin in the CNS. The study used northern blot to look at the differential expression of alpha tubulin mRNA in different regions of rat brain. Another similar study found that there is a differential distribution of AChE mRNA expression following exposure to sarin (Damodaran, 2009). These studies clearly showed that exposure to sarin causes gene expression changes in the CNS that may lead to neurotoxicity as well as behavioral and psychological changes. Another study looked at sarin-induced global gene expression pattern changes at different time points after exposure by microarray (Damodaran et al., 2006; Damodaran, 2009). Analysis of gene expressions at an early time point (15 min; $0.5 \times LD_{50}$) and a later time point (3 months; $1 \times LD_{50}$) identified specific gene expression changes to each time point and seven genes that were consistently altered in both time points (Ania-9, Arrb-1, CX-3C, Gabab-1d, Nos-2a, Nrxn-1b, and PDE2). Further genome-wide study in the rat brain at another early time point (2 h: $0.5 \times LD_{50}$) following sarin exposure showed 46 genes were significantly altered in comparison to the control animals. Most of these 46 genes belong to ion channels, calcium channels, and binding protein families. The study also found many genes are involved in the pathogenesis of sarin-induced pathology and OP-induced delayed neurotoxicity. These studies indicate that exposure to sarin can lead to neurodegeneration at a later time and result in neuropathological alterations. Pachiappan and colleagues applied single (3 and 24 h) or repeated (2×24 h) doses of sarin (5 μg/mL) on human neuronal cells (SH-SY5Y) to identify altered gene expressions (Pachiappan et al., 2009). Microarray analysis identified over 200 genes that were significantly altered following sarin administration in this study. The study also found repeated doses over 48 h persistently downregulated genes linked to neurodegenerative mechanisms indicating the adverse effect of sarin exposure for prolonged time.

O-Ethyl-*S*-2-diisopropylaminoethyl methylphosphonothiolate (VX), another member of the OP compounds family, used in chemical warfare, is a very potent nerve agent. A recent microarray study using cultured human neural cells (hN2) exposed to 0.1 or 10 μM of VX for 1 h has reported changes in gene expressions after 6, 24, and 72 h (Gao et al., 2013). The altered genes were subjected to functional pathway analysis and many of them were found to be involved in pathways related to nervous system development and function. Advancement in genomics may also shed light on some other poorly understood toxic effects of nerve agents. It has been reported that civilians exposed to industrial OPs, such as pesticides, have a higher incidence of Parkinson's disease (Hatcher et al., 2008; Manthripragada et al., 2010), though it is not clear whether nerve agents lead to similar neurodegenerative effects. There are many relevant questions in conjunction with neurological disorders and the use of CWAs. Some questions to be asked are whether long-term regional differences seen in the brain after nerve agent exposure also reflected in large-scale gene expression changes. Can we correlate changes in gene expression profiles with altered behavioral patterns? And does neuroinflammation, one of the acute effects of nerve agents (Chapman et al., 2006; Svensson et al., 2001; Williams et al., 2003) diminish across time? Genomics analysis of subjects exposed to CWAs may provide us ample information to answer these questions and provide additional information as we approach an understanding of the spectrum of chronic effects of nerve agent exposure.

Microarrays are still highly useful to characterize changes in gene expression due to a toxicant of interest, identify up- or downregulated genes, map regulatory pathways modulated by the toxicant, and, in the case of CWAs, identify potential therapeutic targets in these pathways (Hamadeh et al., 2002; Thomas et al., 2001). Nevertheless, RNA-seq offers high technical reproducibility and large dynamic range compared to microarray, and can be used effectively to identify differential gene expression to understand complex disorders like PTSD. Recent efforts such as the consortium called STRONG STAR Consortium to Alleviate PTSD (STRONG STAR-CAP) led by the University of Texas Health Science Center at San Antonio are employing next-generation sequencing and mass spectrometry to research PTSD and its treatment. The enormous potential of RNA-Seq offers an invaluable resource to investigate the transcriptomic profile of the brain in different layers. A similar recent study showed a transcriptomic analysis of distinct regions of the Alzheimer's disease (AD) brain using Illumina RNA-Seq analysis to examine gene expression levels, splicing isoforms, and alternative transcript start sites from the total brain, frontal, and temporal lobe of healthy and AD postmortem tissue, which found a significant representation of genes associated with neuronal cytological structure and synapse function.

46.12 Proteomics

High-throughput genomic and transcriptomics approaches are indispensable to understanding the molecular map of complex diseases. However, their application is limited by the fact that they can only assess gene expression changes. Translation of mRNA into protein is a highly regulated and complex mechanism and modulated at different levels. Effects due to changes in protein expression, modification, or function can lead to development of diseases and only be inferred from analysis of protein expression profiling. The proteome was initially defined as the complete complement of proteins that are expressed by a genome, then it was denoted as "the total set of expressed proteins by a cell, tissue or organism at a given time under a determined condition" by Wilkins et al. (1996). To assess protein expression status, different proteomics techniques need to be utilized.

Proteomics is widely applied in biological sciences to study protein expression, posttranslational modification, protein−protein interactions, and protein−nucleic acid interactions. It gives us a new platform for studying complex biological functions involving large numbers and networks of proteins (Husi and Grant, 2001; Martins-de-Souza et al., 2011). Since Patrick O'Farrell first presented two-dimensional gel electrophoresis (2DE) in 1975, proteomics has given rise to a new scientific approach for comparative global proteome analyses, especially when combined with mass spectrometry (MS) for protein identification. As a result of the development of in-gel digestion protocols and related optimizations (Shevchenko et al., 1996), the resolution power of 2DE can lead to the separation of more than 2000 protein spots on large-format gels. So far 2DE, followed by MS, is the most used proteomic technique in studies of psychiatric disorders (Ditzen et al., 2006; Kromer et al., 2005). Typically, mass spectrometers have three main features: an ionization source (e.g., matrix-assisted laser desorption/ionization and electrospray ionization), a mass analyzer (e.g., time of flight and quadrupole) and a detector (Bayes and Grant, 2009), that measures the mass-to-charge (m/z) ratio of ionized particles. The 2DE-MS approach provides direct information on intact proteins and protein isoforms. Fig. 46.2 depicts the main techniques currently used in proteomics methodology for PTSD diagnosis.

Link et al. (1999) launched shotgun proteomics in 1999, which increased the capacity for proteome characterization. Shotgun-MS was originally designed as a

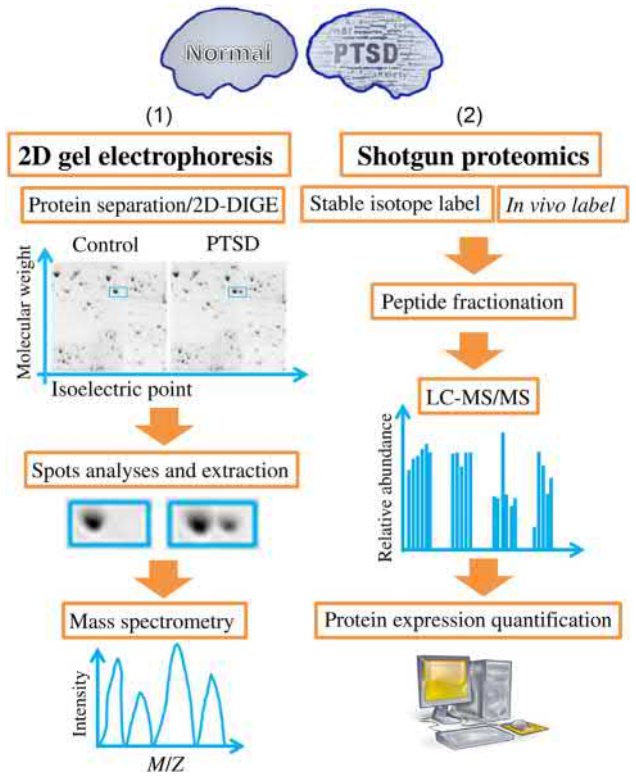

FIGURE 46.2 Major techniques used in proteomics methodology for PTSD diagnosis: (1) two-dimensional gel electrophoresis for proteomics, 2D-DIGE: proteomes mixed in gel; (2) shotgun proteomics methodology.

nongel/MS-direct approach, which was regarded as a more sensitive and reproducible proteome representation compared with 2DE proteomics. Shotgun-MS includes shotgun-MS, liquid chromatography-tandem MS (LC-MS/MS), and multidimensional protein identification technology (MudPIT). Basically, this approach involves digesting the whole proteome of interest using specific enzymes and subsequently identifying the resulting peptides by MS, while proteome quantification and sample comparison rely on a label-free MS methodology or stable isotope labeling. Mass spectrometric (MS) analysis is capable of identifying small modifications, like point mutations, phosphorylation, and glycosylation; it can also detect the primary structure of proteins and peptides, for example, amino acid sequences (Davidsson et al., 2003). Based on its applications, proteomics includes (1) expression proteomics, which studies protein expression profiles; (2) comparative proteomics, which compares physiological and diseased states; (3) Structural proteomics for structure investigations; and (4) functional proteomics, which studies the interactions between molecules. Due to the high levels of accuracy and ultrasensitivity features, proteomics has become a preeminent tool in many areas, especially in neuroscience (Tyers and Mann, 2003).

46.13 Neuroproteomics: proteomics applications in neuroscience

"Neuroproteomics" is the study of the proteomes of the nervous system (Bayes and Grant, 2009) and is of great importance in functional studies. Bayes and Grant (2009) have reviewed four major categories of neuroproteomics, including: (1) expression neuroproteomics, which refers to the qualitative and quantitative cataloging or profiling of neuroproteome; (2) functional neuroproteomics, which addresses functional properties of individual proteins as well as their organization into substructures, complexes, and networks; (3) clinical neuroproteomics, which includes the identification of biomarkers and disease mechanisms for neurological, neurodegenerative, and psychiatric diseases which also benefit drug discovery; and (4) neuroproteomic informatics, which handles analyzing proteomic data sets using computational tools and databases. A typical example of a proteomic approach to study the effect of complex neurological diseases is the shotgun analysis of *postmortem* dorsolateral PFC brain tissue from major depression disorder (MDD) patients (Martins-de-Souza et al., 2012). Gel electrophoresis followed by shotgun data-independent label-free liquid chromatography-mass spectrometry led to identification of distinct proteome fingerprints between MDD and control subjects. Another study to tackle the proteomic profile of anxiety disorder applied a quantitative proteomic approach where metabolic labeling of an HAB/LAB mouse model with stable isotopes was used to identify a large number of proteins in a high-throughput manner (Zhang et al., 2011). Differentially expressed proteins were subjected to pathway discovery analyses that suggested several biological processes and pathways to be affected in the genetic predisposition to extremes in trait anxiety. Though these studies did not draw any connection between the proteins and pathways connected with PTSD, they may trail blaze similar efforts toward proteomic research.

46.14 Proteomics approaches to understand natural and chemical toxicity-induced posttraumatic stress disorder

Despite the enormous medical and economic consequences of traumatic injury to the CNS, relatively little work has been directed toward elucidating the proteomic profile of posttraumatic psychopathology due to the complexity of the molecular mechanisms of the disease. Some of these proteins may serve as diagnostic and prognostic markers to assess the severity of tissue damage. Studies of proteomic biomarkers of PTSD risk have been in play

for a long time; yet they are limited by many technical issues such as optimizing sample collection time frame and the variation in the timing between the traumatic incident and the biological sample collection. Despite these limitations, the initial research provided key insights into the biological mechanisms underlying PTSD vulnerability. A key observation from initial proteomics studies was the high concentrations of inflammatory proteins and, together, these studies indicated increased concentrations of inflammatory cytokines related to the risk for PTSD onset (Gill et al., 2008, 2010). Proteomics makes it possible to identify molecular mechanisms and molecular targets for PTSD through large-scale screening of patients and a validated animal model for protein expression profile analysis. In a recent study, large-scale proteomic approach and mass spectrometry with the use of human proteomic databases were employed to identify the differential serum proteomic profile in combat-related PTSD subjects and healthy controls (Dragica Kozaric-Kovačic et al., 2010). The study found more than 100 proteins expressed differently between individuals with PTSD and healthy controls. These results indicated the direction for a larger analysis of this type in people with PTSD. This pilot study offers a good basis for further proteomic research, which could help in better diagnosis and treatment of PTSD, as well as clarification of its etiology.

Sulfur mustard [SM, bis-(2-chloroethyl) sulfide], a potent alkylating agent and one of the chemical reagents used in chemical warfare, is indicated in PTSD development. A quantitative proteomic approach using stable isotope labeling combined with immobilized metal affinity chromatography tested the effect of SM in a human keratinocyte cell culture model. The study found large-scale protein phosphorylation changes resulting from SM exposure and characterized over 2300 phosphorylation sites, many of which showed altered levels in response to SM treatment. The study also found new proteins that are associated with SM toxicity (Everley and Dillman, 2010). Global organizations, including governmental agencies, have taken an interest and invested in finding data-driven solutions in the field (Koenen, 2019). Further, there is an enormous effort from the pharmaceutical industry to find new drugs to relieve pain and eventually to cure such a complex disease (Melville, 2017).

46.15 Concluding remarks and future directions

It is clear that PTSD is not a monolithic simple disorder, which can be characterized by unique and consistent mental and biological traits, as the development of this disorder results from complex interactions among numerous factors. Genetic background as well as environmental factors may contribute to whether one is sensitive to complex circumstances such as trauma exposure, leading to PTSD development. Recent research studies provided solid evidence that specific DNA functions can be modified by such exposure through epigenetic pathways, resulting in alterations in gene expression leading to the pathological phenotype. In this chapter, we have provided a comprehensive picture of the technological advances in genotyping, expression profiling, and proteomics that offer exciting and promising advances in understanding the basis of PTSD as well as improved diagnosis and therapy. Additionally, short- and long-term exposure to toxic chemicals, such as OP nerve agents and insecticides, and other chemical warfare agents contribute toward PTSD onset. The combination of genomic and proteomic information will allow early and more accurate prediction of individuals' susceptibility to chemical exposure-related trauma, development of PTSD, and disease progression. Though significant discoveries have been made, there is clearly substantial promise and potential remaining to be fully realized through increasing the use of and further development of -omic technologies. Governmental organizations and the pharmaceutical industry have taken an enormous interest in accelerating effort in this field to enable a difference to be made in that "waiting" PTSD patient, sooner.

Acknowledgment

We sincerely thank all those who have tirelessly contributed and continue to contribute to this field of science and technology, collectively termed the "Global Village," to counter PTSD, particularly, warfare-related PTSD.

Chapter 47

Excitotoxicity, oxidative stress, and neuronal injury

Snjezana Zaja-Milatovic[1] and Ramesh C. Gupta[2]

[1]*PAREXEL International, Billerica, MA, United States,* [2]*Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, KY, United States*

47.1 Introduction

Exposure to anticholinesterase (anti-AChE) agents, organophosphates (OPs), and carbamates (CMs) in the form of insecticides and chemical warfare agents (CWAs) affects or threatens much of the world's population. The widespread use and easy accessibility to more than 100 different OPs used as insecticides worldwide result in a huge number of intoxications and several hundred thousand fatalities annually (Gunnell and Eddleston, 2003). Other derivatives of phosphoric acid, nerve agents used in warfare, are considered the most toxic compounds of all chemical weapons. The devastating effects of these agents were demonstrated during the Iraqi conflict with Iranian troops and Kurdish civilians, as well as a terrorist attack on the Tokyo subway train system that occurred in 1995, resulting in over 5500 casualties (Nozaki et al., 1995; Nagao et al., 1997). Terrorist attacks involving warfare nerve agents, weapons of mass destruction, or other industrial chemicals present worldwide security threats and health concerns. Therefore, anti-AChE agents represent a significant potential threat not only to the military, but also to the general civilian population.

Pharmacologically, all these compounds are acetylcholinesterase (AChE) inhibitors. Their acute symptoms are attributed to accumulation of acetylcholine (ACh), thus exhibiting cholinergic toxicity. Phosphorylation of the esteratic site of the enzyme diminishes its capacity to catalyze endogenous substrate ACh (Taylor et al., 1990). Most OP compounds combine with AChE only at the esteratic sites, and the stability of the bond depends upon the structure of the compound that is attached. OP compounds containing larger alkyl groups may hinder cleavage, leaving the phosphorylated AChE inactivated almost indefinitely. As a result, normal activity recurs only upon the synthesis of a new enzyme. This process is known as *aging*, and its time course varies depending on the nerve agent. Consequently, the hydrolysis of ACh is prevented, leading to accumulation of ACh in the synaptic cleft and overstimulation, followed by the desensitization of muscarinic and nicotinic ACh receptors.

The constantly activated nicotinic cholinergic receptors generate involuntary skeletal muscle contraction, followed by complete depolarization block, the clinical manifestation of which is flaccid paralysis. In a manner similar to the events in the peripheral nervous system (PNS), the accumulation of ACh in central nervous system (CNS) nerve endings causes anxiety, disorientation, and general convulsions, followed by loss of consciousness and respiratory arrest. Anti-AChE agent-induced ACh accumulation at the muscarinic sites also enhances the activity of various secretory glands, leading to excessive salivation, lacrimation, bronchorrhea, diarrhea, and sweating. The severity of poisoning by nerve agents varies from minor cases (mild dyspnea, blurred vision, and glandular hypersecretion) to more severe poisoning, which is characterized by severe dyspnea, skeletal muscle fasciculation, convulsions, and unconsciousness, which occurs soon after an intense exposure of only a few minutes (Goldfrank et al., 1982; Weinbroum, 2005). Thus, depending upon the degree of AChE inhibition, cholinergic stimulation may also lead to respiratory failure, coma, and death.

Convulsions are a major sign of OP nerve agent poisoning (Misulis et al., 1987). OP-induced seizures rapidly progress to status epilepticus (SE), which leads to profound structural brain damage (Lemercier et al., 1983; McLeod, 1985). Excitotoxic levels of glutamate following soman exposure are thought to be involved in the

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00047-7

dendritic and synaptic damage as an early toxicological response that leads to neuronal dysfunction and memory impairment (Carpentier et al., 1991). Anti-AChE exposure is also associated with oxidative stress, synaptic architecture dysfunction, and cellular deterioration in the brain, especially in the hippocampus (Johnson et al., 2008; Zaja-Milatovic et al., 2009; Milatovic et al., 2010).

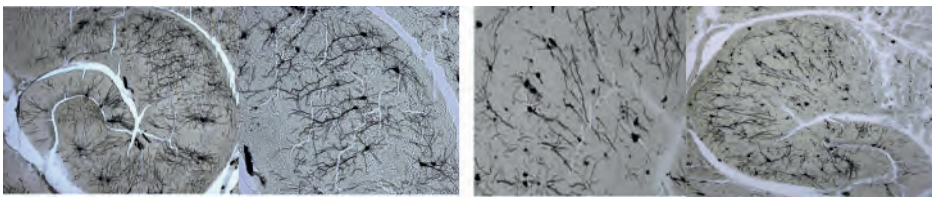
47.2 Excitotoxicity and oxidative injury

The most consistent pathological findings in acute experiments with anti-AChE agents include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially damaged), dorsal thalamus, and cerebral cortex. It has been shown that soman-induced seizures produce an increase in extracellular glutamate in the pyriform cortex (Wade et al., 1987) and the cornu ammonis (CA) region of the hippocampus (Lallement et al., 1992), followed by activation of *N*-methyl-D-aspartate (NMDA) glutamate receptors in the CA1 region. Moreover, glutamate stimulates the continuous release of ACh (Anderson et al., 1994), contributing to further excitatory stimulation, prolongation of the seizures, and neurodegeneration in vulnerable brain regions (Wade et al., 1987; Lallement et al., 1991, 1992). This excitotoxic injury caused by increased levels of glutamate also causes cognitive dysfunction (Phillips et al., 1998; O'Dell et al., 2000; Faden et al., 2001). Increased synaptic glutamate concentrations following OP exposure also alter glutamate receptor expression (Piehl et al., 1995; Cebers et al., 2001) and perturb NMDA receptor subunit distribution, thus changing the overall physiology of the receptor and the functionality of the hippocampus (Cebers et al., 1999).

Although seizures can induce neuronal death, they may also have nonlethal pathophysiological effects on neuronal structure and function. Dendritic spines represent the structural sites of contact for the majority of excitatory, glutamatergic synaptic inputs into neurons, and they are strongly implicated in mechanisms of synaptic plasticity and learning. NMDA and other glutamate receptor subtypes are clustered in dendritic spines (Rao and Craig, 1997; O'Brien et al., 1998), which serve as integrative units in synaptic circuitry and participate in synaptic plasticity (Yuste and Denk, 1995). The accumulation of glutamate receptor clusters in spines is governed by excitatory synaptic activity and increases when activity is suppressed (Rao and Craig, 1997; O'Brien et al., 1998). Conversely, excitotoxicity produces a rapid and profound loss of dendritic spines in cultured neurons (Halpain et al., 1998), mimicking the loss in dendritic spine synapses in neurological conditions, including epilepsy, aging, and schizophrenia (Jeffrey et al., 1997; Jiang et al., 1998). This suggests that receptor localization at synapses might be critical to excitotoxicity and govern neuronal vulnerability to excitotoxicity.

Earlier studies investigating the role of glutamate receptors in mediating seizure-induced brain damage showed that kainic acid (KA)-induced epilepsy damaged limbic structures in rats (Ben-Ari et al., 1980). Kainate is a rigid analog of glutamate, the principal excitatory neurotransmitter in the CNS, and it is a very potent stimulant of a subset of the ligand-gated ion channel, called KA receptors (Milatovic et al., 2005b). Activation of the KA subtype of ionotropic glutamate receptors results in sustained epileptic activity in the hippocampus, followed by a selective pattern of neuropathology that is similar to human temporal lobe epilepsy (Schwob et al., 1980; Ben-Ari and Cossart, 2000). Kainate administration and intense seizure activity associated with SE are sufficient to induce oxidative stress, degeneration of hippocampal CA neurons, and hyperexcitability of surviving hippocampal CA neurons (Ben-Ari, 2001; Dong et al., 2003; Zaja-Milatovic et al., 2008) (Fig. 47.1).

The hypothesis concerning OP-induced neuronal oxidative injury is that overstimulation of glutamatergic receptors results in sustained epileptic activity in the hippocampus and neuropathologic changes predominantly in the pyramidal neurons. Cell damage is thought to result from intense transient influx of calcium, leading to mitochondrial functional impairment characterized by activation of the permeability transition pores in the inner mitochondrial membrane, cytochrome c-release, depletion of adenosine triphosphate (ATP), and simultaneous formation of reactive oxygen species (ROS)



Saline exposure Kainic acid exposure

FIGURE 47.1 Photomicrographs of mouse hippocampi with pyramidal neurons from the CA1 hippocampal area of brains 1 h after saline (control) and kainic acid (KA, 1 nmol/5 μL, ICV) injections. Treatment with KA induced degeneration of the hippocampal dendritic system and a decrease in the total length of the dendrite and spine density of hippocampal pyramidal neurons.

(Cadenas and Davies, 2000; Patel, 2002; Nicholls et al., 2003). In addition, an increase in cytoplasmic calcium ions triggers intracellular cascades through stimulation of enzymes, including proteases, phospholipase A_2, and nitric oxide synthase (NOS), which also leads to increased levels of free radical species and oxidative stress (Lafon-Cazal et al., 1993; Farooqui et al., 2001). Since free radicals are direct inhibitors of the mitochondrial respiratory chain, ROS generation perpetuates a reinforcing cycle, leading to extensive lipid peroxidation and oxidative cell damage (Cadenas and Davies, 2000; Cock et al., 2002). Previous studies have supported a role of oxidative stress and excessive generation of ROS and reactive nitrogen species (RNS) in anti-AChE-induced neurotoxicity (Dettbarn et al., 2001; Gupta et al., 2001a,b, 2007; Milatovic et al., 2005a; Zaja-Milatovic et al., 2009).

Two radicals that play predominant roles as initiators of lipid peroxidation are the hydroxyl radical (OH^-) and the peroxynitrite radical ($OONO^-$). The superoxide anion radical (O_2^-), which is generated during the electron transport process in mitochondria, is involved in the generation of both OH^- and $OONO^-$. Superoxide dismutase (MnSOD and Cu/ZnSOD) converts O_2 to hydrogen peroxide (H_2O_2), which is then converted to OH^- via the Fenton reaction, catalyzed by Fe^{2+}, Cu^+, or Mn^{2+}. $OONO^-$ is generated from the interaction of NO with O_2^-. A major stimulus for NO production is the elevation of intracellular Ca^{2+}, which binds to calmodulin, resulting in the activation of NOS. Peroxynitrite is a powerful oxidant exhibiting a wide array of tissue-damaging effects, including lipid peroxidation, inactivation of enzymes and ion channels via protein oxidation and nitration, and inhibition of mitochondrial respiration (Virag et al., 2003). Peroxynitrite, which dissipates during oxidation (Wang et al., 2003), has also been found to induce nitration as well as oxidation of adenine, guanine, and xantine nucleosides (Sodum and Fiala, 2001). Low concentrations of peroxynitrite trigger apoptotic death, whereas higher concentrations induce necrosis with cellular energetics [ATP and nicotinamide adenine dinucleotide (NAD)] serving as a switch between the models of cell death. ROS and RNS produced under oxidative stress are known to damage cellular biomolecules including lipids, sugars, proteins, and polynucleotides and to initiate detrimental effects (Negre-Salvayre et al., 2010; Roberts et al., 2010; Marrocco et al., 2017; Cheignon et al., 2018). Together, ROS- and RNS-damaged biomolecules may induce a variety of cellular responses through the generation of secondary metabolic reactive species (Fig. 47.2).

Thus, increased ROS and RNS production has been directly linked to oxidation of proteins, deoxyribonucleic acid (DNA), and lipids, which may cause injury or induce a variety of cellular responses through the generation of secondary metabolic reactive species (Fig. 47.2).

47.3 Lipid peroxidation and in vivo markers of oxidative damage

Due to a high concentration of substrate polyunsaturated fatty acids (PUFAs) in cells, lipid peroxidation is a major outcome of free radical-mediated injury (Montine et al., 2002a,b). A critical aspect of lipid peroxidation is that it will continue until the oxidizable substrate is consumed or termination occurs, making it fundamentally different from many other forms of free radical injury, in that the self-sustaining nature of the process may entail extensive tissue damage (Porter et al., 1995). Decreased membrane fluidity following lipid peroxidation makes it easier for phospholipids to exchange between the two halves of the bilayer, increase the leakiness of the membrane to substances that do not normally cross it other than through specific channels (e.g., K^+ and Ca^{2+}), and damage membrane proteins, inactivating receptors, enzymes, and ion channels (Halliwell and Gutteridge, 2006; Halliwell, 2007). Increases in Ca^{2+} induced by oxidative stress can activate phospholipase A_2, which releases arachidonic acid (AA) from membrane phospholipids. The free AA can then both undergo lipid peroxidation (Farooqui et al., 2001) and act as a substrate for eicosanoid synthesis (Milatovic et al., 2011a). Increased prostaglandin (PG) synthesis is immediately linked to lipid peroxidation because low levels of peroxides accelerate cyclooxygenase (COX) action on PUFAs (Smith, 2005). Phospholipase A_2 can also cleave oxidized AA residue from membranes.

The use of reactive products of lipid peroxidation as in vivo biomarkers is limited because of their chemical instability and rapid and extensive metabolism (Gutteridge and Halliwell, 1990; Moore and Roberts, 1998). For these reasons, other more stable lipid products of oxidative damage have generated intense interest in recent years as in vivo markers of oxidative damage. These compounds include the F_2-isoprostanes (F_2-IsoPs), F_4-neuroprostanes (F_4-NeuroPs), and isofurans (IsoFs) (Morrow et al., 1990; Fessel et al., 2002; Milatovic and Aschner, 2009; Janicka et al., 2010; Milatovic et al., 2011b; Milne, 2017; Van't Erve et al., 2017).

F_2-IsoPs are PG-like compounds that are produced by a non-COX free radical-catalyzed mechanism involving the peroxidation of AA. Formation of these compounds initially involves the generation of four positional peroxyl radical isomers of arachidonate, which undergo endocyclization to PGE_2-like compounds. These intermediates are reduced to form four F_2-IsoP regioisomers, each of which can consist of eight racemic diastereomers (Morrow et al., 1990; Milne et al., 2015). In contrast to COX-derived PGs, nonenzymatic generation of F_2-IsoPs favors the formation of compounds in which the stereochemistry of the side chains is oriented *cis* in relation to

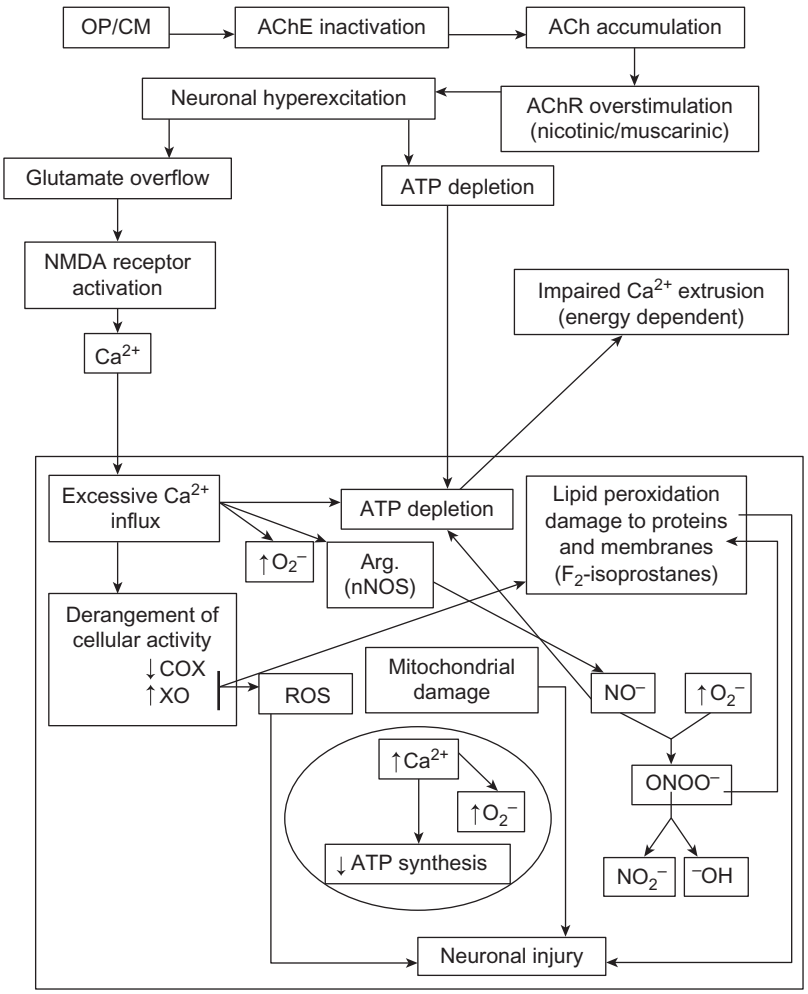


FIGURE 47.2 A schematic diagram showing possible mechanisms involved in an anti-AChE-induced neuronal injury or death by excessive production of ROS/RNS, leading to lipid peroxidation.

the prostane ring. A second important difference between F_2-IsoPs and PGs is that F_2-IsoPs are formed primarily in situ, esterified to phospholipids, and subsequently released by phospholipases (Gao et al., 2006), whereas PGs are generated only from free AA (Morrow et al., 1990; Milatovic et al., 2011a; Milne et al., 2015).

The measurement of F_2-IsoPs is a method that has been extensively replicated as an efficient means of quantifying free radical damage in in vivo models associated with neurodegenerative diseases, including Alzheimer's disease (Montine et al., 1999; Milne et al., 2015), inflammation (Milatovic et al., 2003), metal toxicity (Milatovic et al., 2009, 2011c), excitotoxicity (Milatovic et al., 2005b; Zaja-Milatovic et al., 2008, 2009), cancer, and genetic disorders (Milne et al., 2015). Since AAs present throughout the brain and in different cells in the brain at roughly equal concentrations, F_2-IsoPs reflects damage to brain tissue, but not necessarily to neurons.

Similar studies of lipid peroxidation products have been performed for other substrate lipids. Of particular interest are oxidation products of docosahexaenoic acid (DHA), which have been termed F_4-NeuroPs (Roberts et al., 1998). In contrast to AA, which is evenly distributed in all cell types in all tissues, DHA is highly concentrated in neuronal membranes (Salem et al., 1986; Montine et al., 2004). Thus, determination of F_4-NeuroPs permits the specific quantification of oxidative damage to neuronal membranes in vivo (Montine et al., 2004; Milatovic and Aschner, 2009). In fact, to our knowledge, F_4-NeuroPs are the only quantitative in vivo marker of oxidative damage that is selective for neurons.

Another F_2-IsoPs analog may be formed by peroxidation of eicosapentaenoic acid (EPA, C20:5, $\omega-3$) that leads to the production of F_3-IsoPs. Levels of F_3-IsoPs can significantly exceed those of F_2-IsoPs generated from AA, perhaps because EPA contains more double bonds and is therefore more easily oxidizable (Gao et al., 2006). It has also been shown that in the presence of increased oxygen tension in the microenvironment in which lipid peroxidation occurs, an additional oxygen insertion step

may take place (Fessel et al., 2002; Milatovic and Aschner, 2009). This step diverts the IsoP pathway to form tetrahydrofuran ring-containing compounds termed IsoFs, which are functional markers of lipid peroxidation under conditions of increased oxygen tension. (Milne et al., 2015). Thus, measurements of IsoFs represent a much more robust indicator of hyperoxia-induced lung injury than measurements of F_2-IsoPs. Like IsoPs, IsoFs are chemically and metabolically stable, so they are well suited to act as in vivo biomarkers of oxidative damage (Milne et al., 2015; Van't Erve et al., 2017).

The enzymatic and free radical peroxidation of PUFAs which contains at least three double bonds, like AA and DHA, could lead to malondialdehyde (MDA). This product can be generated by thromboxane synthase, but a report from the Biomarkers of Oxidative Stress Study (BOSS) showed that peripheral levels of MDA derive primarily from nonenzymatic peroxidative degradation of unsaturated lipids (Kadiiska et al., 2005). MDA-TBA adducts, produced in reaction of MDA with thiobarbituric acid (TBA) are used to spectrophotometrically measure the levels of oxidative stress and consequent lipid peroxidation (Spickett et al., 2010; Fang et al., 2017). 4-Hydroxy-2-nonenal (HNE) is also a reactive aldehyde arising from peroxidation of ω6 fatty acid (Uchida, 2003; Guéraud et al., 2010; Barrera et al., 2018). HNE is formed under various conditions like auto-oxidation and stimulated microsomal lipid peroxidation (Neely et al., 2005). MDA and HNE can covalently modify proteins and alter their functions (Butterfield et al., 2006). In addition to protein modification, these lipid peroxidation products can interfere with the synthesis of DNA and ribonucleic acid (RNA), alter cell metabolism and signaling, and mediate brain-induced oxidative damage. Several studies suggest that MDA and HNE can promote the degeneration of cholinergic neurons, Aβ aggregation, and amyloidogenesis (Pedersen et al., 1999; Butterfield et al., 2006).

ROS and RON can react with the DNA molecule and induce purine or pyrimidine base or sugar lesions, nitration and deaminations of purines, and DNA−DNA or DNA−protein cross-links (Dizdaroglu et al., 2002). These processes lead to mutations and impaired transcriptional and posttranscriptional processes and compromise protein synthesis (Colurso et al., 2003). The most investigated DNA adduct, 8-hydroxy-2′-deoxyguanosine (8-OHdG), can be evaluated by multiple techniques including GC-MS, HPLC, LC-MS, immunoassay, and capillary electrophoresis (Lovell and Markesbery, 2007; Fang et al., 2017).

In addition, DNA damage, oxidative phosphorylation, and altered cell metabolism may lead to apoptosis and promote neuronal death (Fishel et al., 2007; Becker and Bonni, 2004). ROS and RNS can also attack amino acids, leading to the protein oxidation and formation of carbonyl derivatives (Stadtman and Levine, 2003; Davies, 2016). Oxidation of protein also leads to protein fragmentation and protein cross-linking. In addition, peroxynitrite and a hydroxyl radical can react with tyrosine and form other indexes of protein oxidation, 3-nitrotyrosine and ortho-tyrosine, respectively. These protein products are relatively stable, with sensitive assays available for their detections (Chakravarti and Chakravarti, 2007; Davies, 2016).

47.4 Anti-AChE-induced seizures, oxidative injury, and neurodegeneration

Lipid peroxidation, mitochondrial dysfunction, reduced neuronal energy levels, and reduced cytochrome c-oxidase (COx) activity support the contention that anti-AChEs, such as diisopropylfluorophosphate (DFP) and carbofuran (CF), cause neuronal injury by excessive formation of ROS (Yang and Dettbarn, 1998; Milatovic et al., 2000a,b, 2001, 2005a; Gupta et al., 2001a,b). Additionally, our studies showed that seizure-induced cerebral oxidative damage in adult animals is accompanied by alterations in integrity of the hippocampal CA1 dendritic system (Gupta et al., 2007; Zaja-Milatovic et al., 2008, 2009; Milatovic et al., 2010).

A single injection of DFP [1.5 mg/kg, subcutaneously (s.c.)] or another AChE inhibitor, CF (1.5 mg/kg, s.c.), produces toxic signs in rats, including salivation, tremors, "wet dog" shakes, fasciculations, and mild to moderate seizures with rearing and rolling over, with progression to severe seizures within 7−15 min (Milatovic et al., 2006; Gupta et al., 2007; Zaja-Milatovic et al., 2009). Signs of maximal intensity such as severe muscle fasciculations, seizures, and convulsions develop within 15−30 min and last for more than 2 h before tapering off. By 24 h, animals are free of toxic signs. The observed signs are typical of anti-AChE toxicity and reveal the involvement of both the CNS and the PNS (Gupta et al., 2001a,b; Milatovic et al., 2005a). Analysis of brains from saline-treated control rats revealed regional variability in brain AChE activity (cortex, 222.0 ± 10.7; amygdala, 529.2 ± 10.29; and hippocampus 301.2 ± 9.5 μmol/g wet weight). A single acute dose of DFP (1.5 mg/kg, s.c.) suppressed AChE activity to less than 20% in all brain regions, compared to the controls, at 60 min following the exposure. Similarly, 60 min after a single acute dose of CF (1.5 mg/kg, s.c.), AChE was markedly depressed (% remaining activity: cortex, $10.02\% \pm 1.04\%$; amygdala, $18.18\% \pm 1.48\%$; and hippocampus, $12.75\% \pm 0.74\%$) (Gupta et al., 2007). At the time of high AChE inhibition and resultant severe seizure activity, significant increase in biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) were seen in the brains of DFP- and CF-exposed animals. While twofold elevations are

seen in F_2-IsoPs levels, F_4-NeuroPs levels are more than fivefold higher than those of controls (Fig. 47.3). The results confirm the presence of oxidative damage in the cerebrum as a novel aspect of anti-AChE toxicity. The selective increase in F_4-NeuroPs indicates that neurons are specifically targeted by this mechanism.

DFP exposure also caused marked elevation in brain citrulline levels, which indicates NO/NOS activity (Gupta et al., 2001b, 2007). Control levels of citrulline are similar in the hippocampus (247.90 ± 4.10 nmol/g) and the amygdala (293.20 ± 6.90 nmol/g) (Gupta et al., 2007). Within 5 min of CF injection, the citrulline levels were elevated more than twofold in the investigated brain areas. Within 15 min of CF treatment, the levels of citrulline were significantly higher in both brain regions and were maximally elevated at 30 min postinjection (three- to fourfold). They remained elevated up to 60 min, but returned to control levels when measured 24 h later (Fig. 47.4). A similar response was seen following DFP exposure.

Many reports provide evidence that NO impairs mitochondrial/cellular respiration and other functions by inhibiting the activities of several key enzymes, particularly COx, thereby causing ATP depletion (Yang and Dettbarn, 1998; Dettbarn et al., 2001; Gupta et al., 2001a,b; Milatovic et al., 2001). Results from our experiments also showed that 1 h after DFP (1.5 mg/kg, s.c.) or CF (1.5 mg/kg, s.c.) treatment, the levels of ATP and PCr were significantly reduced in the hippocampus and amygdala (Fig. 47.5). With either DFP or CF treatment, the reduction in ATP and PCr levels was similar in the amygdala and hippocampus. During the course of these excitatory processes, a high rate of ATP consumption, coupled with the inhibition of oxidative phosphorylation, compromises the cell's ability to maintain its energy levels, and excessive amounts of ROS and RNS may be generated. Thus, the combination of impaired synthesis of ATP with its greater utilization during brain hyperactivity appears to result in a significant depletion of ATP. Three days after anti-AChE treatment, significant recovery of ATP and PCr is observed in discrete brain regions (Fig. 47.5). The rapid decrease in energy metabolites at the onset of seizures indicates early onset of mitochondrial dysfunction, in turn further increasing ROS production and neuronal injury.

An important question that emerged from previous studies is whether brain hyperactivity, such as seizures, first generates increases in ROS and then causes a decrease in high-energy phosphates (HEPs). The findings revealed that within 5−15 min after CF injection (the time required for onset and development of clinical signs), NO levels increased more than fivefold to sixfold in the cortex and more than twofold to threefold in the amygdala and hippocampus. The maximum increase in NO occurred at 30 min postinjection in all three brain regions. The data also revealed that the maximum decline in HEPs occurred 1 h after CF injection. This agrees with our previous data showing that a rapid and significant increase in NO precedes increases in lipid peroxidation, mitochondrial dysfunction, and loss of energy metabolites, as well as a reduction in COx activity and an increase in xanthine oxidase (Dettbarn et al., 2006). Therefore, the findings suggest that in the case of CF, the increase in ROS preceded the decrease in HEPs.

Seizures, convulsions, and CNS lesions are typical results of systemic application of sublethal doses of anti-

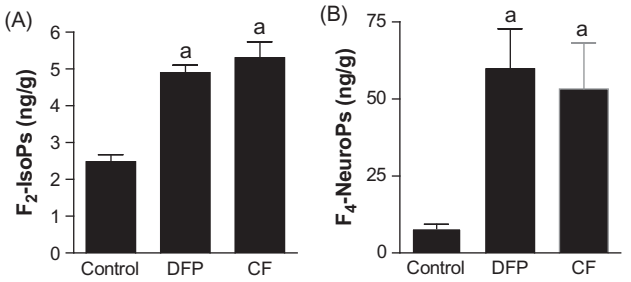

FIGURE 47.3 Effect of DFP (1.5 mg/kg, s.c.) and CF (1.5 mg/kg, s.c.) on F_2-IsoPs (A) and F_4-NeuroPs (B) levels in rat brain. Values are mean ± SEM ($n = 4-6$). [a]Significant difference between controls and DFP- or CF-treated rats ($P < .05$).

Rats were sacrificed 1 h or 3 days after CF or DFP injection. Values of ATP and PCr are presented as mean ± SEM ($n = 4-6$). [a]Significant difference between values from controls and DFP- or CF-treated rats ($P < .05$).

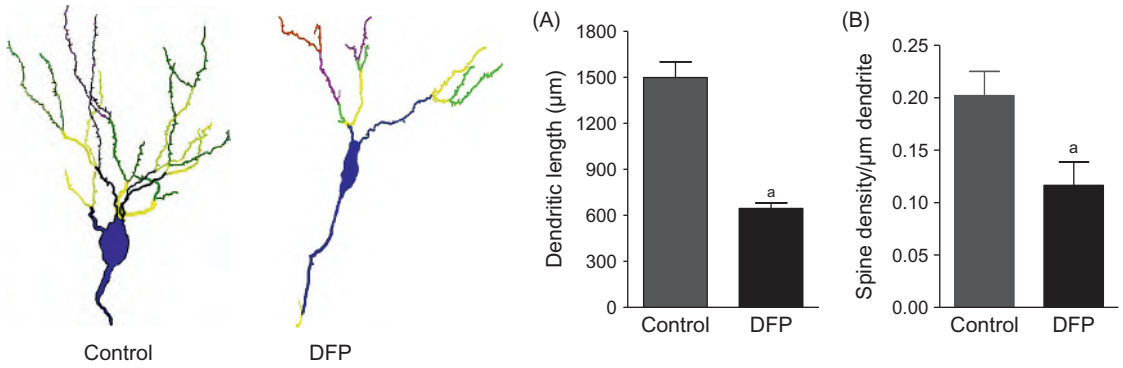

FIGURE 47.6 Morphology and quantitative determination of dendritic length (A) and spine density (B) of hippocampal pyramidal neurons from the CA1 sector of rats treated with saline (control) or DFP (1.5 mg/kg, s.c.) and sacrificed 1 h after the treatment. A total of 4–6 Golgi-impregnated dorsal hippocampal CA1 neurons were selected and spines counted by using the Neurolucida system. [a]Significant difference between controls and DFP-treated rats ($P < .05$). Treatment with DFP induced degeneration of the hippocampal dendritic system and decrease in the total length of the dendrite and spine density of hippocampal pyramidal neurons. Tracing and counting are done using the Neurolucida system at 100 × magnification under oil immersion (MicroBrightField, VT).

AChE agents (Sparenborg et al., 1992). The most consistent pathological findings in acute experiments include degeneration and cell death in the pyriform cortex, amygdala, hippocampus (where the CA1 region is preferentially destroyed), dorsal thalamus, and cerebral cortex. The early morphological changes in AChEI-induced SE include dendritic swelling of pyramidal neurons in the CA1 region of the hippocampus (Carpentier et al., 1991). Therefore, we have investigated whether seizure-induced cerebral oxidative damage in adult rats is accompanied by alterations in the integrity of the hippocampal CA1 dendritic system. Our results showed that anti-AChE induced early increases in biomarkers of global free radical damage (F_2-IsoPs) and the selective peroxidation biomarker of neuronal membranes (F_4-NeuroPs) was accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area (Zaja-Milatovic et al., 2009). Anti-AChE-induced brain hyperactivity targeted the dendritic system with profound degeneration of spines and regression of dendrites, as evaluated by Golgi impregnation and Neurolucida-assisted morphometry (Fig. 47.6).

Rats injected with DFP show a significant decrease in total dendritic length and spine density compared to pyramidal neurons from the hippocampal CA1 area of control rats (Fig. 47.6). Taken together with the biochemical data presented previously, our results suggest that oxidative damage that selectively targets cerebral neurons is a hitherto-unrecognized aspect of anti-AChE toxicity. Results also revealed that anti-AChE exposure is associated with oxidative and nitrosative stress, alteration in energy metabolism, and consequent degeneration of pyramidal neurons from the CA1 hippocampal region of rat brain. Ultimately, the additive or synergistic mechanisms of cellular disruption caused by anti-AChE agents lead to cellular dysfunction and neurodegeneration.

47.5 Oxidative damage and dendritic degeneration following KA-induced excitotoxicity

Since excessive presynaptic release of glutamate and activation of NMDA and non-NMDA receptors have a

significant role in anti-AChE-induced neurotoxicity, we have investigated the role of glutamatergic excitation, oxidative injury, and neurodegeneration in the model of KA excitotoxicity. We have used intracerebroventricular (ICV) injection of KA, which is known as an experimental model for the investigation of cerebral vulnerability, particularly during acute brain disorders and SE (Schwob et al., 1980; Ben-Ari and Cossart, 2000). The study was designed to investigate whether F_2-IsoPs and F_4-NeuroPs formation correlated with the vulnerability of pyramidal neurons in the CA1 hippocampal area following KA-induced excitotoxicity. Our results showed that ICV KA-induced early increase in biomarkers of oxidative damage, F_2-IsoPs, and F_4-NeuroPs were accompanied by dendritic degeneration of pyramidal neurons in the CA1 hippocampal area.

Time-course changes in biomarkers of oxidative damage in the rat model of anti-AChE-induced seizures showed that the highest increase in F_2-IsoPs was evaluated 1 h after the injection of anti-AChE agent or 40 min after the beginning of seizure symptoms (Gupta et al., 2007). In the model of KA-induced excitotoxicity the earliest time point evaluated was 30 min since seizures start immediately after the ICV KA injection. Elevated levels of these in vivo markers of oxidative damage are in agreement with our previous findings (Montine et al., 2002c; Milatovic et al., 2005b; Gupta et al., 2007), as well as those of others (Patel et al., 2001), and indicate that KA injection leads to profound cerebral and neuronal oxidative damage in mice.

Our results also showed that the transient rise in F_2-IsoPs and F_4-NeuroPs is accompanied by rapid evolution of dendritic abnormalities, which becomes apparent due to a significant decrease in dendritic length and spine density of pyramidal neurons as early as 30 min post-KA injection. However, the recovery in both oxidative damage biomarkers at 60 min after the injection was not paralleled by the rescue of damaged neurons from the CA1 hippocampal area. Extended seizure activity (60 min) induced the same level of dendritic length and spine density decrease when compared to 30 min following KA injection (Table 47.1). Together, these data suggest that both oxidative stress and neurodegeneration occur as an early response to seizures, but they do not determine whether oxidative stress is a cause or an effect of seizure-induced CA1 cell damage. Neuronal damage processes triggered by sustained seizure activity may occur as a continuum, last longer than formation of oxidative lipids, and, although not evident by the markers, may already be in progress when the peak increases in F_2-IsoPs and F_4-NeuroPs occur. Thus, we investigated dynamic changes in lipid peroxidation and dendritic structures immediately after seizures occur, but future studies over the longer period should be able to determine the long-term course of these spine and dendritic changes. It is very likely that the spine loss seen in our study is the initial phase of more chronic spine loss and progressive neurodegeneration reported in other studies (Muller et al., 1993; Jiang et al., 1998; Zeng et al., 2007).

In vivo data have also established that KA induced a significant increase (more than twofold) in citrulline concentrations 30 min following the injection (Zaja-Milatovic et al., 2008). Although we did not determine whether increased citrulline originated from a combination of NOS isozymes or one in particular, our data agree with the results from the models of anti-AChE toxicity and activated innate immunity (Milatovic et al., 2003, 2004; Gupta et al., 2007) and indicate that a subset of NOS activity also contributes to cerebral oxidative damage in the model of KA-induced excitotoxicity.

47.6 Suppression of seizure-induced oxidative injury and neurodegeneration

47.6.1 Antioxidants

Antioxidants [e.g., vitamins, glutathione (GSH), selenium, zinc, creatine, and arginine] and antioxidant enzymes (e.g., superoxide dismutase, catalase, GSH reductase, and GSH peroxidase) exert synergistic actions in scavenging free radicals. A large body of literature (e.g., Fang et al., 2002) supports the notion that antioxidants play an

TABLE 47.1 Cerebral concentrations of F_2-IsoPs and F_4-NeuroPs and dendritic degeneration of hippocampal pyramidal neurons following KA-induced seizures in mice.

	F_2-IsoPs (ng/g)	F_4-NeuroPs (ng/g)	Dendritic length (μm)	Spine density (number/100 μm dendrite)
Control	3.07 ± 0.05	13.89 ± 0.58	1032.10 ± 61.41	16.45 ± 0.55
KA 30 min	4.81 ± 0.19[a]	34.27 ± 2.71[a]	363.44 ± 20.78[a]	8.81 ± 0.55[a]

important role in preventing many human diseases (e.g., cancer, atherosclerosis, stroke, rheumatoid arthritis, and neurodegeneration). Vitamin E has been recognized as one of the most important antioxidants. Vitamin E inhibits ROS-inducing generation of lipid peroxyl radicals, thereby protecting cells from peroxidation of PUFAs in membrane phospholipids, from oxidative damage of cellular proteins and DNA, and from membrane degeneration (Topinka et al., 1989; Azlina et al., 2018; Simioni et al., 2018). Vitamin E mainly acts as a chain-breaking antioxidant and radical scavenger, protecting cell membranes against oxidative damage (Van Acker et al., 1993). In addition, vitamin E regulates ROS production (Chow et al., 1999), maintains oxidative phosphorylation in mitochondria, and accelerates restitution of high-energy metabolites (Punz et al., 1998). Decreased levels of vitamin E in response to hyperoxia or treatment with convulsants reported in studies (Onodera et al., 2003; Mori et al., 2004; Rauca et al., 2004) suggest that vitamin E in the brain is consumed to prevent oxidative damage. Vitamin E also prevented metasystox (OP insecticide)-induced changes in lipase activity and lipid peroxidation in the brain and spinal cord of rats (Tayyaba and Hasan, 1985).

A synthetic spin-trapping agent such as phenyl-*N*-*tert*-butylnitrone (PBN) is also capable of scavenging many types of free radicals. This compound is widely used to trap ROS in a variety of physical, chemical, and biological studies using electron paramagnetic resonance spectrometry. PBN is known to be concentrated in the mitochondria, where it reacts with ROS and forms stable adducts, and thereby maintains normal levels of energy metabolites. Numerous in vitro and in vivo experiments have shown the beneficial effects of PBN on the prevention of neuronal degeneration. Protective effects are described in experimental models of brain ischemia/reperfusion (Carney and Floyd, 1991; Fetcher et al., 1997; Gido et al., 1997), excitotoxicity (Lancelot et al., 1997; Milatovic et al., 2002), inhibition of NOS induction (Miyajima and Kotake, 1995), and in different models of seizures (He et al., 1997; Thomas et al., 1997). Additional findings also corroborate that PBN effectively prevents neurodegeneration in Parkinson's disease (Sack et al., 1996; Frederiksson et al., 1997), Alzheimer's disease, and anti-AChE neurotoxicity (Sack et al., 1996; Gupta et al., 2001a,b). Thus, PBN has been proven to rescue neurons in multiple experimental injury models. Other pharmacological properties of spin-trapping agents have been described that could influence the outcome of oxidant injury. These have been described for PBN as reversible Ca^{2+} channel blockade in vascular muscle, causing vasodilatation (Anderson et al., 1993); direct effect on striatal function, including inhibition of excitation−contraction coupling; and induction of hypothermia (Pazos et al., 1999).

Previous studies have shown that antioxidant pretreatment suppressed DFP- or CF-induced alterations in HEP, their metabolites, and citrulline levels, supporting the possibility that increased generation of ROS/RNS contributes to the depletion of energy phosphates (Gupta et al., 2001a,b). PBN or vitamin E treatment alone did not alter the levels of HEPs, their major metabolites, or citrulline in any of the brain regions. Vitamin E pretreatment suppressed the depletion of HEP and their metabolites and increased citrulline levels without preventing seizures (Gupta et al., 2001a). The protective efficacy provided by vitamin E against DFP- or CF-induced changes in energy metabolites was of varying degrees in different brain regions and could partly be due to pharmacokinetic variables involved in attaining different levels of vitamin E in different brain regions. However, PBN pretreatment 1 h before the anti-AChE agent protected mitochondria and maintained the cellular level of high-energy metabolites, but it also prevented DFP- or CF-induced convulsions and seizures (Gupta et al., 2001a,b). This could primarily be due to a protective interaction of PBN with AChE, sufficient to protect a critical fraction of AChE against phosphorylation by DFP or carbamylation by CF (Zivin et al., 1999; Milatovic et al., 2000a,b). We have also shown that AChE inhibitor-induced increases in NO (citrulline) were significantly prevented by PBN and by vitamin E (Gupta et al., 2001a). There is evidence that suggests that PBN inhibits the induction of inducible NOS (iNOS) by reducing the expression of iNOS protein (decrease in mRNA expression), thus preventing the overproduction of NO (Miyajima and Kotake, 1997).

The efficacy of the spin-trapping agent PBN and the antioxidant vitamin E was tested to suppress the increase in NO and lipid peroxidation and prevent neurodegeneration of pyramidal neurons in the CA1 hippocampal area in the model of KA-induced excitotoxicity (Zaja-Milatovic et al., 2008). Vitamin E or PBN alone did not alter basal citrulline and F_4-NeuroPs levels or dendritic arborization. However, vitamin E and PBN suppressed KA-induced increases in citrulline and cerebral and neuronal markers of oxidative damage, F_2-IsoPs and F_4-NeuroPs, respectively (Figs. 47.7 and 47.8).

Importantly, vitamin E and PBN completely suppressed both reduction in dendrite length and reduction in spine density of pyramidal neurons from the CA hippocampal area from KA-exposed mice (Fig. 47.9).

A close concordance was found between these results, showing that protection of the cerebrum from neuronal oxidative damage also protected hippocampal CA1 pyramidal neurons from dendritic degeneration. These agents did not alter kainate-induced seizure severity, indicating that the protective effect of vitamin E and PBN is most likely mediated by scavenging ROS and preventing lipid peroxidation and consequent neuronal damage, not by a

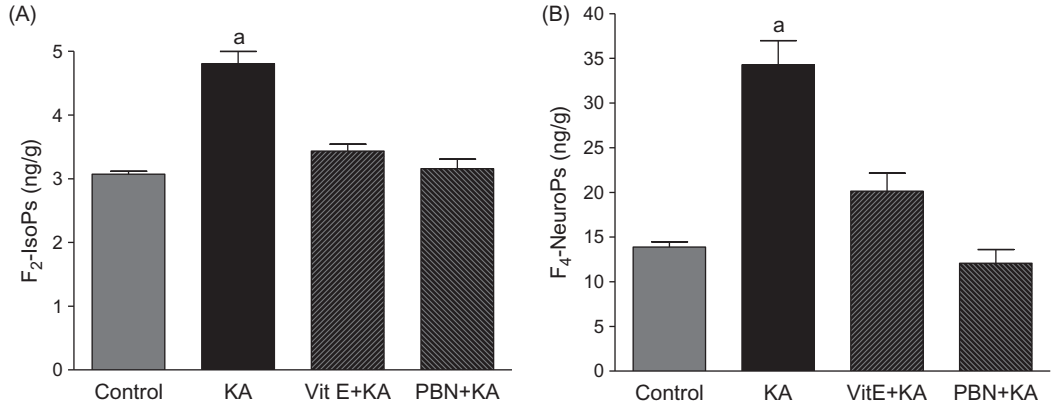

FIGURE 47.7 Ipsilateral cerebral F_2-IsoPs (A) and F_4-NeuroPs (B) concentrations following ICV KA with or without vitamin E (Vit E) or PBN pretreatment. Brains from mice exposed to KA were collected 30 min postinjection ($n \geq 5$ for each group). One-way ANOVA had $P < .0001$ with Bonferroni's multiple comparison tests significant for KA versus control, vitamin E + KA or PBN + KA treatment.

specific effect on seizures per se. Furthermore, since antioxidants minimize lipid peroxidation following an increase in α-tocopherol and PBN, then a parallel reduction in neuronal damage provides strong evidence that oxidative stress and lipid peroxidation in a causal way mediate seizure and the corresponding injury. One limitation to the potential therapeutic application of this type of substance is that, to be effective, the drugs need to be administered prophylactically before the onset of seizures. Future research should address the efficacy of these agents in preventing seizure-induced oxidative and dendritic changes and potentially reducing resultant neurocognitive deficits when they are administered at higher concentrations, either during or possibly even after seizures.

47.6.2 *N*-methyl-D-aspartate receptor antagonist (memantine)

As excitotoxicity-induced neuronal damage in the model of anti-AChE-induced seizures is explained by the excessive release of glutamate that activates both NMDA and non-NMDA postsynaptic receptors, antagonism of the excitotoxicity mechanism may protect the CNS from the deleterious effects of anti-AChE agents. Several NMDA receptor antagonists have been shown to exert anticonvulsant effects against nerve agent-induced seizures when administered either as a pretreatment or after the seizure has been initiated, usually terminating the convulsions after an initial period of epileptical activity (Shih, 1990; Sparenborg et al., 1992). NMDA receptor antagonists do not modify the events responsible for the early phase of the seizure, but they block the subsequent recruitment of glutamate receptor activation, and hence the maintenance of seizure activity and irreversible functional and structural brain damage.

Among promising candidates as antidotes against CNS intoxication by OP nerve agents, memantine has been shown to pose both antiexcitotoxic and antiepileptic properties. Memantine is an uncompetitive NMDA receptor antagonist, clinically used for the treatment of Alzheimer's disease, Parkinson's disease, and spasticity, in the absence of serious side effects (Lipton, 2005; Ozsuer et al., 2005; Wang and Redd, 2017; Folch et al., 2018). From a series of rat in vivo experiments, it is evident that preadministration of memantine significantly protects AChE activity from inhibition caused by AChE inhibitors, including OP and CM insecticides and OP nerve agents (Gupta and Kadel, 1990; Gupta and Dettbarn, 1992; McLean et al., 1992; Gupta and Dekundy, 2005). By now, it has been well established that memantine exerts various pharmacological effects by multiple pharmacological mechanisms: (1) blockage of

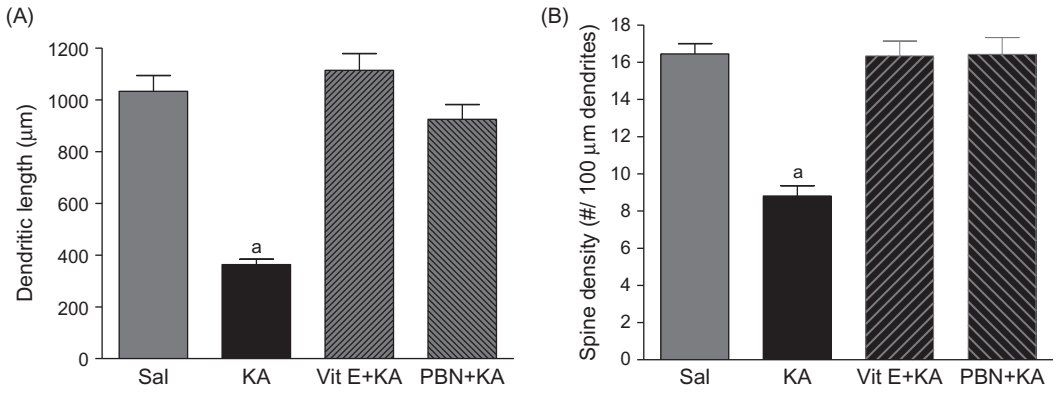

FIGURE 47.9 Dendritic length (A) and spine density (B) of pyramidal neurons from the CA1 hippocampal area of mice following ICV KA with or without vitamin E or PBN pretreatment. Brains from mice exposed to KA were collected 30 min postinjection ($n \geq 5$ for each group). One-way ANOVA had $P < .001$ with Bonferroni's multiple comparison tests significant for KA versus control, vitamin E + KA or PBN + KA treatment.

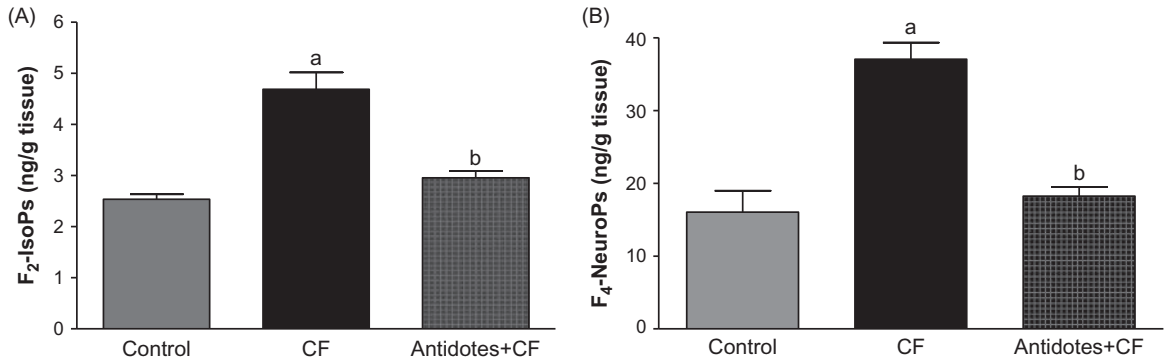

FIGURE 47.10 Cerebral F_2-IsoPs (A) and F_4-NeuroPs (B) concentrations following CF (1.5 mg/kg, s.c.) with or without antidote pretreatment (memantine, 18 mg/kg, and atropine, 16 mg/kg, given prophylactically, 60 and 15 min, respectively, before CF administration). Brains from rats exposed to CF were collected 60 min postinjection ($n \geq 5$ for each group). One-way ANOVA had $P < .0001$ with Bonferroni's multiple comparison tests significant for CF versus control (a), and for CF versus antidote + CF (b).

nicotinic ACh receptor-ion channel complex (Masuo et al., 1986), (2) reduced reflex excitability of both flexors and extensors (Wand et al., 1977), (3) prevention of neural hyperexcitability (McLean et al., 1992), (4) central muscle relaxation (Grossman and Jurna, 1997), and (5) prevention of AChE inhibitor-mediated energy loss from muscle cells (Milatovic et al., 2005a). Memantine is also able to prevent the pathogenic calcium influx caused by continuous mild activation by low-level glutamate. On the other hand, memantine allows the physiological activation of the NMDA channels by high concentrations of glutamate, a phenomenon necessary for synaptic plasticity underlying normal learning and memory (Parsons et al., 1999).

Previous studies have also demonstrated that memantine treatment significantly reduces lipid peroxidation (Fig. 47.10) and alterations in citrulline and HEP levels in muscles and brain of rats intoxicated with CF (Milatovic et al., 2005a; Gupta et al., 2007; Zaja-Milatovic et al., 2009).

No significant alterations in biomarkers of neuronal damage, citrulline, HEP, and their metabolite levels were seen in any of the brain regions receiving memantine and atropine. In addition, memantine and atropine exposure did not induce any alteration in neuronal morphometry, but when given as pretreatment, it did provide protection against CF-induced morphometric changes in hippocampal neurons (Fig. 47.11). Memantine, in combination with atropine, completely suppressed the reduction in both dendrite length and in spine density of pyramidal neurons from the CA1 hippocampal area from CF-exposed rats (Fig. 47.11).

In conclusion, the data demonstrated that synergistic mechanisms of cellular disruption caused by anti-AChE agents led to cellular dysfunction and neurodegeneration. It has also been demonstrated that preventing CF-induced neuronal hyperactivity by pretreatment with memantine and atropine blocks pathways associated with oxidative damage in rat brain. The documented ability of memantine therapy to reduce free radical generation and lipid

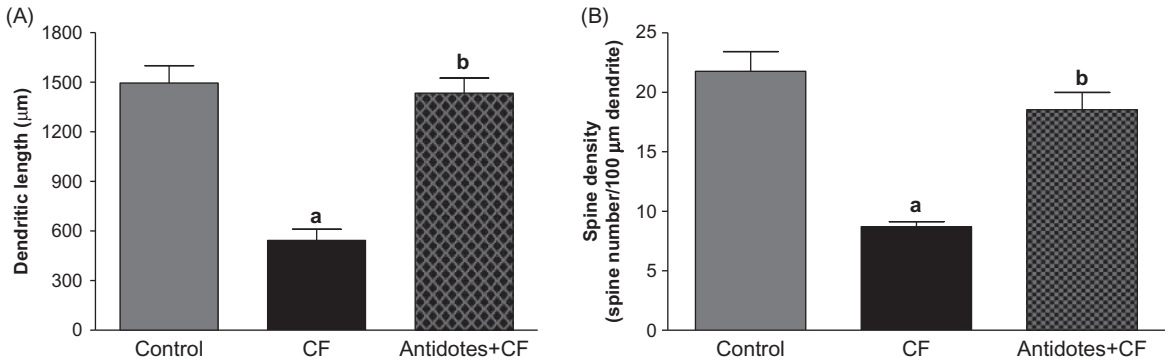

FIGURE 47.11 Dendritic length (A) and spine density (B) of pyramidal neurons from the CA1 hippocampal area of mice following CF (1.5 mg/kg, s.c.) with or without antidote pretreatment (memantine, 18 mg/kg and atropine, 16 mg/kg given prophylactically, 60 and 15 min, respectively, before CF administration). Brains from rats exposed to CF were collected 60 min postinjection ($n \geq 5$ for each group). peroxidation, prevent HEPs, and attenuate the morphological injury provides further support for the role of ROS and RNS in anti-AChE-induced seizures.

47.7 Concluding remarks and future directions

Exposure to OP nerve agents induces seizures, rapidly progressing to SE and profound structural brain damage. The progression of events includes initial high cholinergic activity followed by activation of glutamatergic neurons as a result of release of glutamate. Moreover, glutamate stimulates the continuous release of ACh, contributing to further excitatory stimulation, prolongation of the seizures, and excitotoxic neurodegeneration in vulnerable brain areas. The ensuing neuronal damage is thought to result from intense transient influx of calcium, which leads to mitochondrial functional impairment, cytochrome c-inactivation, depletion of ATP, simultaneous formation of free radical species, and oxidative stress. Therefore, control of excitotoxicity and oxidative stress, better understanding of the mechanisms of noncholinergic-mediated activities, and pathways that protect or promote neuronal survival are essential for the development of efficacious treatments and preventive therapies associated with OP exposures.

We have explored mechanisms associated with OP-induced neurotoxicity by probing their effects on oxidative stress and associated dendritic degeneration of pyramidal neurons in the CA1 hippocampal area. We have also investigated different pathways to attenuate biomarkers of oxidative damage associated with anti-AChE exposure and the extent to which such attenuation is accompanied by rescue from neurodegeneration. Results from our studies suggest that vitamin E, PBN, and memantine efficiently suppress oxidative injury. Future studies should be directed at deciphering the mechanisms of protection, addressing the ability of these agents to attenuate OP neurotoxicity via radical scavenging, AChE inhibition, suppression of neuroinflammation, glutamate antagonism, or any combination of these. Additional studies should also determine whether a combination of these treatments improves the therapeutic index against OP poisoning (compared to administration of each alone). Complementary studies should also investigate not only the prophylactic, but also the therapeutic effects of these neuroprotectants. Successful identification of safe and effective neuroprotectants that suppress noncholinergic activities associated with anti-AChE exposure will provide new pharmacological modalities to protect and treat both the acute and delayed effects of nerve agent poisoning.

Chapter 48

Blood–brain barrier damage and dysfunction by chemical toxicity

Ramesh C. Gupta[1], Jason Pitt[2] and Snjezana Zaja-Milatovic[3]

[1]*Toxicology Department, Breathitt Veterinary Center, Murray State University, Hopkinsville, KY, United States,* [2]*Department of Physical Therapy, University of Evansville, Evansville, IN, United States,* [3]*PAREXEL International, Alexandria, VA, United States*

48.1 Introduction

Direct evidence for the existence of the blood–brain barrier (BBB) came at the dawn of the 20th century from the observations of Nobel Laureate Paul Ehrlich. When he injected colored dyes, including trypan blue, into the bloodstream, they leaked out of capillaries in most regions of the body to stain the surrounding tissue, but the brain and spinal cord remained unstained. Further support for the existence of the BBB came from the work of the Russian neurophysiologist Lina Stern in 1921, who called this barrier a "hematoencephalic" barrier. Since then, doubts have been cast over the actual existence of the BBB, until the emergence of electron microscopic data demonstrating the presence of the tight junctions between the endothelial cells that form brain capillaries (Abbott et al., 2010; Palmer, 2010). The BBB is formed and maintained through a dynamic interaction between cerebral and endothelial cells constituting the anatomical basis of the BBB and other neighboring cells, such as astroglia, pericytes, perivascular microglia, and neurons (Deli et al., 2005). The cross-talk between these cells endows endothelial cells with a unique BBB phenotype comprising not only the morphological barrier of endothelial tight junctions, but also the enzymatic and metabolic barriers, as well as the uptake and efflux transport systems (Abbott et al., 2010).

The term BBB describes a series of mechanisms that control the internal environment of the brain (Saunders et al., 2008). Stability of this environment is essential for normal brain development and function. Underlying the cellular mechanisms that determine the brain's internal environment is a fundamental physical barrier at the level of intercellular tight junctions between cells forming the interface between blood and brain (BBB) and in the choroid plexuses (blood–cerebrospinal fluid barrier, BCSFB). These tight junctions severely attenuate or occlude movement of chemicals and proteins through intercellular spaces between endothelial cells in the BBB and epithelial cells in the choroid plexus BCSFB.

The BBB formed by the endothelium of cerebral blood vessels is one of the three main barrier sites protecting the central nervous system (CNS). The barrier is not a rigid structure, but rather a dynamic interface with a range of interrelated functions, resulting from extremely effective tight junctions, transendothelial transport systems, enzymes, and regulations of leukocyte permeation, which thereby generates the physical, transport, enzymatic, and immune regulatory functions of the BBB (Abbott and Friedman, 2012). In addition, recent studies have revealed important stages, cell types, and signaling pathways involved in BBB development. Several enzymes (monoamine oxidase, epoxy hydrolase, endopeptidases, acetylcholinesterase, DOPA decarboxylase, γ-glutamyl transpeptidase) are known to be present in endothelial cells and are important elements of the BBB phenotype constituting the so-called metabolic barrier, and they participate in the regulation of brain penetration of drugs (Fenstermacher and Neuwelt, 1989; Pardridge, 2002). The role of the BBB as a metabolic barrier was further ascertained by the presence of mitochondria in cerebral endothelial cells (Fenstermacher and Neuwelt, 1989). Thus, the BBB may be considered a physical as well as a metabolic barrier.

Because the involvement of brain barriers is apparent in neurodegenerative diseases, neurotrauma, chemical-induced neurotoxicity, and delivery of drugs of use and abuse, renewed interest in this area of research has emerged (Neuwelt et al., 2008; Palmer, 2010).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00048-9

In physiological conditions, the BBB regulates the exchange of nutrients, waste, and immune cells between the blood and the nervous tissue of the CNS and is the most important component preserving CNS homeostasis and neuronal function (Abbott et al., 2010). Dysfunctional brain barrier mechanisms contribute to the pathology of neurological conditions, ranging from trauma to neurodegenerative diseases, and provide obstacles for successful delivery of potentially beneficial pharmaceutical agents (Saunders et al., 2008; Palmer, 2010; Erickson and Banks, 2013). Interestingly, modulations in the BBB can be the cause and/or consequence of non-CNS diseases, such as diabetes, chronic inflammatory pain, and obesity, but they are not discussed in this chapter because of chapter size constraints. This chapter describes, in brief, the structure and function of the BBB and modulations of its components and permeability by chemical warfare agents (CWAs) and other toxicants, Gulf War illness (GWI), stress, blasts, excitotoxicity, and neurodegenerative diseases.

48.2 Structure and function of the BBB

The brain develops and functions within a strictly controlled environment resulting from the coordinated action of different cellular interfaces located between the blood and the extracellular fluids (interstitial fluid and the cerebrospinal fluid) of the brain (Strazielle and Ghersi-Egea, 2013). The barrier between the blood and the brain or spinal cord parenchyma proper, referred to as the BBB, is formed by the endothelium of the cerebral microvessels. Several layers exist between the blood and brain: capillary endothelial cells, a basement membrane consisting of type IV collagen, fibronectin and laminin that completely cover the capillaries, pericytes embedded in the basement membrane, and glia/astrocytes that surround the basement membrane (Fig. 48.1). Each of these layers could potentially restrict the movement of solutes (Hawkins et al., 2006; Alvarez et al., 2013).

de Boer et al. (1998) described that the BBB has narrow tight junctions, has no intercellular clefts, has minor pinocytotic activity, is not fenestrated, has a continuous basement membrane, contains many mitochondria, and has high electrical resistance (1500−2000 $\Omega \times cm^2$). Next to the microvascular endothelial cells, pericytes, microglia, and neurons influence the functionality of the BBB, and there are also leukocytes (lymphocytes and monocytes) and, in the surrounding larger vessels, perivascular macrophages and mast cells. In addition to endothelial and epithelial cells, astrocytes and pericytes are involved in structure, functions, and regulation of brain barriers (Abbott et al., 2010; Armulik et al., 2010; Daneman et al., 2010; Wilhelm et al., 2011; Mizee et al., 2013).

The BBB is to be distinguished from a second barrier component located between the blood and the ventricular CSF, and thus is called the blood−CSF barrier (BCSFB). The BCSFB interface is formed by the tight epithelium of the choroid plexuses, which are specialized structures projecting in all four ventricles of the brain and are responsible for the active secretion of CSF. The BBB develops a large surface area of exchange between the blood and the neutrophil, with an average of 100 cm^2/g of brain tissue in the adult mammal. In a 1-month-old rat, the apical surface area in contact with CSF has been estimated to be 75 cm^2 and close to the surface area developed by the BBB (Keep and Jones, 1990).

BBB tightness is maintained by various intercellular junctions, such as tight junctions, adherence junctions, gap junctions, and syndesmos, from which the tight junctions seem to be the most important ones in restricting passive hydrophilic transport. The BBB presents more possibilities for the transport of small molecules (molecular weight 400−600 Da) compared with large ones, keeps the composition of electrolytes constant in the interstitial fluid of the brain, and prevents the passage of water-soluble drugs and proteins from the blood to the brain.

The BBB closely regulates the exchange of molecules in and out of the brain parenchyma to maintain its optimal homeostasis for a chemical environment that allows adequate brain functioning (de Vries et al., 2012). The ionic stability, neurochemical environment, and normal functioning of the brain are crucially dependent on the integrity of the brain barrier systems (Saunders et al., 2008). Without this stability, complex functions performed by the brain would be impossible. Saunders et al. (2008) further emphasized that dysfunction of brain barrier mechanisms in a variety of pathologies is more than a disruption of the normal (tight junction) diffusion restraint and that such dysfunction might be a part of the disease process, rather than a consequence. Erickson and Banks (2013) described that the BBB dysfunction is a cause as well as a consequence of neurological diseases, such as Alzheimer disease (AD).

48.3 In vivo and in vitro models to study the BBB

The movement of compounds from the circulating blood into the brain is strictly regulated by the brain capillary endothelial cells, which constitute the BBB. The importance of the BBB is not only in the passage of toxicants but also in therapeutic drugs and antidotes. Brain capillary endothelial cells are connected to each other by continuous tight junctions and have a low number of pinocytotic vesicles. Several proteins (such as P-glycoproteins) and enzymes (such as monoamine oxidase, DOPA

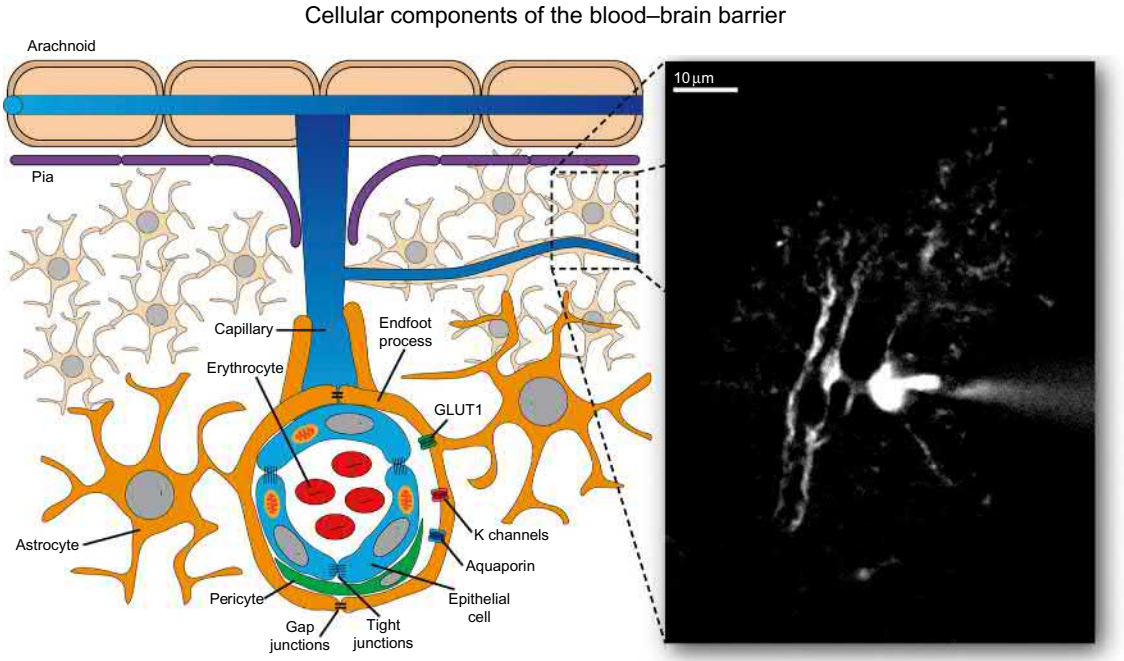

FIGURE 48.1 The BBB is a multicellular interface.
The brain is a highly vascularized organ; blood vessels in the arachnoid space enter the brain and form a network of highly branched capillaries. Vascular epithelial cells are linked together through tight and adherens junctions. These intercellular junctions restrict the entry of bloodborne molecules from entering the CNS and form the BBB. Interactions between the epithelial cells are maintained by astrocytes, a type of glial cell that surrounds more than 99% of the vascular epithelium. Astrocytes ensheath blood vessels with specialized processes called endfoot processes, which express a variety of transporter proteins to maintain osmotic balance and uptake glucose from the blood. This intimate relationship between astrocytes and the vasculature is illustrated in the inset figure, which shows an astrocyte in an acute brain slice filled with a fluorescent dye. The patch pipette and blood vessel are visible to the right and left of the astrocyte, respectively. The buffering capacity of astrocytes is dramatically improved through a series of gap junctions between neighboring astrocytes.

decarboxylase, acetylcholinesterase, and others) are expressed by brain endothelial cells and constitute the so-called metabolic barrier. Because of these characteristics, the BBB limits or impairs the delivery of certain drugs to the CNS. Therefore, to understand the crossing of compounds of various classes, drugs, and antidotes, various in vivo and in vitro models have been developed.

48.3.1 In vivo model

Birngruber et al. (2013) reported a cerebral open-flow microperfusion as a new membrane-free technique for measuring substance transport across the intact BBB in Sprague-Dawley rats. This in vivo technique is based on a probe that is inserted into the brain, thereby rupturing the BBB. The BBB is usually reestablished within 15 days, which then allows sampling of interstitial brain fluid under physiological conditions. This technique allows monitoring of BBB permeability, which can be useful for measuring pharmacokinetics across the BBB and pharmacodynamics in the brain. Using tracers, such as Evans blue (EB), horseradish peroxidase, and [^{131}I]albumin, breakdown of the BBB in humans and experimental animals has been studied under many conditions, such as hypoglycemia, hypertension, seizures/convulsions, and inflammation (Öztaş and Couraud, 1996).

48.3.2 In vitro models

In vitro reconstituted models of the BBB from different mammalian species have been used since the late 1970s. However, their comparison is difficult because of the different species and methods used for isolation, culture, coculture, and characterization of the models. Lundquist et al. (2002) confirmed that the epithelial cells might not represent a valid and reliable in vitro BBB model, because results obtained on epithelial monolayers correlated poorly with in vivo BBB permeability values. Bowman et al. (1983) introduced the first in vitro BBB filter model. The insert was made of nylon mesh and polycarbonate tubing, and bovine brain endothelial cells were seated on it for studying the effect of calcium-free medium and osmotic shock on sucrose flux. Since then, a variety of chambers and inserts from different materials and with diverse pore size have become commercially available. Garberg et al. (2005) used an in vitro model for

BBB permeability based on the use of a continuous cell line and to investigate the specificity of this model. These authors developed a coculture procedure that mimics the in vivo situation by culturing brain capillary endothelial cells on one side of a filter and astrocytes on the other. Under these conditions, endothelial cells retain all the endothelial cell markers and characteristics of the BBB, including tight junctions and enzyme activities (γ-glutamyl transpeptidase and monoamine oxidase). Raub (1996) identified the signaling pathways involved in the barrier-enhancing effects of C6 glioma cells, suggesting that the action is not mediated through cAMP, but rather by protein kinase C (PKC) activation via phospholipase D, independent of intracellular calcium increase.

Deli et al. (2005) presented permeability data from various in vitro BBB models by measuring transendothelial electrical resistance (TEER) and by calculation of permeability coefficients for paracellular or transendothelial tracers. These authors summarized the results of primary cultures of cerebral microvascular endothelial cells or immortalized cell lines from bovine, human, porcine, and rodent origins. This also described the effect of coculture with astroglia, neurons, mesenchymal cells, blood cells, and conditioned media, as well as the physiological influence of serum components, hormones, growth factors, lipids, and lipoproteins on the BBB function.

The strong correlation between in vivo (Oldenhorf method) and in vitro (coculture) drug transport, the relative ease with which such cocultures can be produced in large quantities, and the reproducibility of the system provide evidence for an efficient system for the screening of drugs that are active in the CNS (Dehouck et al., 1997). These authors suggested that the coculture method is a useful system for investigating passive diffusion, carrier-mediated transport, and P-glycoprotein (Pgp)-dependent drug transport. The in vitro permeabilities of propranolol and cyclosporine A were parallel with indications from in vivo extraction, showing that transporters and Pgp are expressed in the coculture system. For further details, readers are referred to the work by Deli et al. (2005), who reviewed various in vitro models covering bovine, human, porcine, and rodent brain endothelial cell-based systems. Bovine systems provide a high yield of brain endothelial cells sufficient for pharmacological screening, and they are widely used in basic as well as in applied research. Mouse brain yields the least endothelial cells compared with other species.

Some examples of the modulators of BBB permeability in in vitro models are: both cAMP elevator peptide hormone adrenomedulin and calcitonin gene-related peptide decrease paracellular permeability; a glucocorticoid hormone, hydrocortisone, improves the barrier properties; insulin exerts a tightening effect on tight junctions; and catecholamines (adrenaline and noradrenaline) increase the sodium fluorescein flux.

In essence, in vitro models have been widely used in pharmacological research for screening drugs and drug candidate molecules for either modifying BBB permeability or investigating brain penetration (Deli et al., 2005; Wilhelm et al., 2011). This area of research is very important for permeability screening during drug development in the pharmaceutical industry.

48.4 Gender differences in the BBB

For more than three decades, evidence has suggested that the BBB differs in males and females in terms of morphology, metabolism, and permeability. Interest arose from previous studies suggesting that women had higher cerebral blood flow than men, and the differences were more pronounced in the frontal regions (Mathew et al., 1986). Follow-up studies further confirmed the finding of higher cerebral blood flow in females as compared with males (Rodriguez et al., 1988).

In animal studies, although Saija et al. (1990) found no substantial difference in the permeability of the BBB between male and female rats, fluorescein penetrated to a greater extent in the brains of females as compared with males, but only into those regions that reside outside the BBB. Öztaş (1998) investigated the gender effects on BBB permeability during bicuculline-induced seizures in female and male rats and found the extravasation of EB-stained albumin in a more pronounced manner in the brains of females as compared with males. In a similar study, Öztaş and Couraud (1996) noted that disruption of BBB permeability during pentylenetetrazol-induced seizures was asymmetric between the right and left hemispheres in female rats but not in male rats. Interestingly, ovariectomy decreased BBB permeability during seizures, suggesting the involvement of estrogen because endothelial cells have been shown to contain estrogen receptors (Colburn and Buonassivi, 1978).

Furthermore, the distribution of serotonin is different in the brain and cerebral endothelial cells of males and females (Fischette et al., 1983), and serotonin is an important modulator of BBB permeability (Sharma and Dey, 1986). The sex hormone-related differences in the serotonin and other neurotransmitter levels in endothelial cells may cause different responses under pathological conditions. Öztaş (1998) hypothesized that if BBB permeability can increase more easily in females, then this increased breakdown may result in higher incidences of neurodegenerative diseases, such as AD and multiple sclerosis (MS) in women.

48.5 The BBB in young and adult brains

The structure and function of the BBB substantially differ in young and adult brains. In general, the BBB is immature in fetuses and newborns. This may be partly because of the fact that the blood vessels in the immature brain are more fragile than in the adult. Astrocytes in the developing brain are also responsible for the induction of tight junctions in the cerebral endothelial cells as well as other features of brain barrier mechanisms (Janzer and Raff, 1987; Saunders and Habgood, 1999). Saunders et al. (1999) provided evidence that barriers to proteins at blood–brain and blood–CSF interfaces (tight junctions) are present from very early in development.

Immunocytochemical and permeability findings revealed that proteins are largely excluded from extracellular space in the developing brain. In addition to tight junctions present at the BBB and BCSFB, the immature brain also has a mixture of other junctions present at the outer CSF–brain barrier (plate junctions, strap junctions, and wafer junctions). These barriers are not present in the adult (Saunders et al., 1999). It was suggested that both the functional and morphological properties of the BBB develop progressively from the onset of intraneural vascularization. However, the morphological characteristics of the BBB do not fully develop until the neonatal period. Because the BBB in fetal and early neonatal life is not fully developed, it allows for the diffusion of bloodborne macromolecules and toxins that are normally excluded from the mature CNS. Apparently, the fetus and neonate are at greater risk for brain injury from toxicants, such as CWAs, metals, pesticides, and other environmental contaminants.

48.6 Transport of molecules across the BBB

Brain capillary endothelial cells form the BBB. They are connected by extensive tight junctions and are polarized into luminal (blood-facing) and abluminal (brain-facing) plasma membrane domains (Hawkins et al., 2006). A pivotal function of the endothelial cells is to express transporters at the BBB and regulate the selective transport and metabolism of substances from blood to brain (Daneman et al., 2010). These transporters may be utilized to target specific molecules for delivery into the brain for therapeutic purposes. Fig. 48.2 depicts various transport mechanisms for amino acids, glucose, proteins, and other molecules.

There are two major pathways for molecules and cells to cross the BBB: the paracellular (junctional) route and the transendothelial route (Deli et al., 2005). One of the hallmarks of the BBB phenotype is the restrictive paracellular pathway, which is regulated by interendothelial tight junctions. Tight junctions not only restrict paracellular flux but also maintain the polarity of enzymes and receptors on luminal and abluminal membrane domains. The most important integral tight junction proteins include occludin, claudin-1, claudin-5, and junctional adhesion molecules. Daneman et al. (2010) identified several tight junction molecules whose expression was found at the BBB, including marveld2, cingulin-like-1, and pard3, that might play a crucial role in the formation of BBB tight junctions.

It is established that the brain environment signals brain endothelial cells to form the BBB, but the identity of these signals is unknown. Paracellular permeability is regulated by diverse signaling cascades (Krizbai and Deli, 2003). Among many signaling pathways, some are noteworthy, such as Wnt/β-catenin signaling (Leibner et al., 2008; Daneman et al., 2010), sonic hedgehog (Shh) signaling (Alvarez et al., 2011), intracellular stabilization signals mediated VE-cadherin (Rudini et al., 2008; Taddei et al., 2008), and retinoic acid signaling (Mizee et al., 2013). Daneman et al. (2010) generated a comprehensive data set describing the transcriptome of the BBB, which will provide a valuable resource for understanding the development and function of this crucial barrier, as well as its role in modulating CNS function.

The transendothelial pathways also exist at the brain microvasculature. In contrast to peripheral endothelium, the rate of pinocytosis is minimal, and free membrane diffusion applies mainly to small lipophilic molecules, for example, ethanol or nicotine (Pardridge, 2002). Daneman et al. (2010) utilized ingenuity pathway analysis (IPA) software to analyze the CNS endothelial enriched transcripts to identify signaling pathways that are enriched at the BBB or in peripheral endothelial cells. Various transport systems are present at the BBB to transport compounds in and out of the brain (de Boer et al., 1998). Active transport systems can be divided into three groups. First is carrier-mediated bidirectional transport, which is responsible for nutrient uptake in the brain. These transporters include glucose transporter GLUT-1, monocarboxylic acid transporter MCT1, large neutral amino acid transporter LAT1, or sodium-coupled nucleoside transporter CNT2 (and others). Second is efflux transport, which is unidirectional and delivers metabolites and xenobiotics from the brain to blood. Third is receptor-mediated transport by endocytosis and transcytosis, which is important for the brain supply of peptides and proteins, such as low-density lipoproteins, transferrin, leptin, and insulin (Pardridge, 2002). Bidirectional transporters include glucose transporter (GLUT-1), monocarboxylic acid transporter (MCT1), large neutral amino acid transporter (LAT1), or sodium-coupled nucleoside transporter (CNT2) (and others) (Pardridge, 2002). Pgp and MRP-1 multidrug resistance proteins, brain multidrug resistance

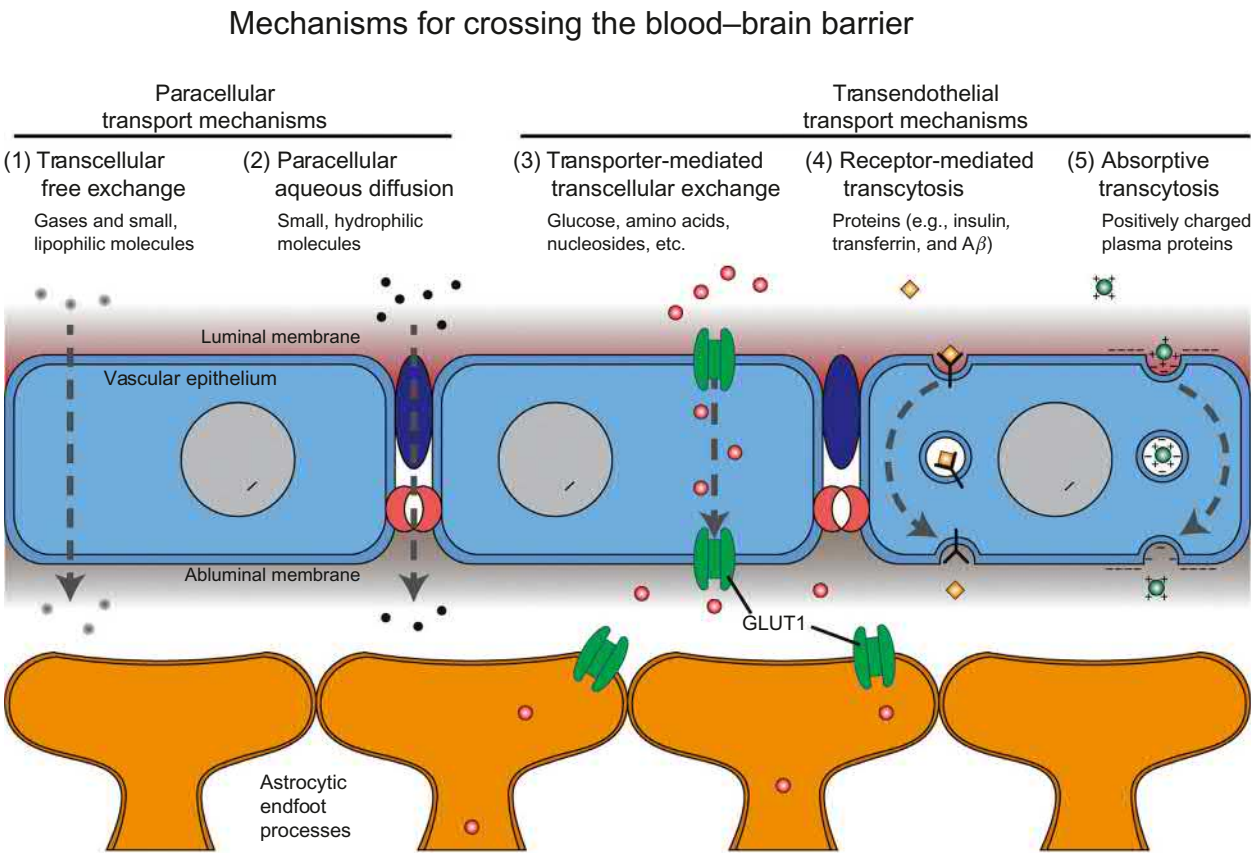

FIGURE 48.2 Transport across the BBB occurs through a variety of mechanisms.
Gases and small lipophilic molecules enter and exit the CNS freely through transcellular exchange. Very small hydrophilic molecules are able to permeate the tight junctions (dark blue ovals) and adherens junctions (salmon crescents) between vascular epithelial cells that restrict the entry of larger molecules into the CNS. Instead, larger hydrophilic molecules are transported through transmembrane pores, receptor-mediated transcytosis, or absorptive transcytosis. After crossing the BBB, solutes are then transported through the astrocytic endfoot processes and shuttled to neurons.

proteins (ABCG2/BCRP), or organic anion-transporting polypeptide (OATP2) belong to the rapidly growing group of efflux transporters at the BBB (de Boer et al., 2003; Chan et al., 2013). Additionally, ABCC1 and ABCC4 are expressed in the cerebral endothelium as efflux transporters (Wilhelm et al., 2011).

A number of cellular and molecular factors can influence transport of molecules across the BBB. For most solutes and macromolecules, permeability is largely dependent on their lipophilicity. Hydrophilic solutes and macromolecules are believed to cross the barrier through specific carrier mechanisms or facilitated diffusion (Aschner and Slicker, 1998). Some of these carriers are symmetrically distributed both on the luminal and abluminal membranes of the endothelial cells, whereas others have an asymmetric distribution. For example, the carriers for the essential neutral amino acids, which are required in the brain for neurotransmitter synthesis, are localized on both luminal and abluminal membranes. In contrast, the carrier for the amino acid glycine appears to be located only on the abluminal membrane. The function of this asymmetric distribution is to remove glycine from the CNS and to keep its concentration low in the brain. The polar distribution of proteins maintains amino acid homeostasis in the brain. The existence of two facilitative transporters for neutral amino acid on both membranes provides the brain with access to essential amino acids. It is now well-established that the BBB participates in the active regulation of the amino acid content of the brain. These comprise various amino acid transport systems (System L1, System ASC, System A, acidic amino acid transporter, peptide transporter) (Begley, 1995). In addition to these transporters, Pgp is one of the transporters of great interest (Wilhelm et al., 2011; Chan et al., 2013).

Daneman et al. (2010) and Geier et al. (2013) stated that the transporters and neuroprotective function of the BBB present major challenges for therapeutic drug delivery to the CNS. Critical to this function, BBB membrane transporters include the ATP-binding cassette (ABC) transporters, which limit drug penetration across the BBB, and the less studied solute carrier (SLC) transporters. These authors demonstrated expression of profiling of

359 SLC transporters and immunoassays in microvessels at the human BBB. In some situations, to be more effective, osmotic opening of the BBB has been used clinically to enhance entry of water-soluble drugs from the blood into the brain. Daneman et al. (2010) also asserted that IPA software can be used to identify metabolic pathways enriched at the BBB or in peripheral endothelial cells. Glycolysis/gluconeogenesis and amino acid metabolism are enriched at the BBB, suggesting that brain endothelial cells may be intimately involved in the production of energy metabolites and amino acids for neurons, a function that has been thought to be uniquely served by astrocytes (Bélanger et al., 2011).

48.7 Effects of toxic agents on the BBB

Breakdown of the BBB in humans and experimental animals in various conditions (stress, hypertension, convulsions, seizures, ischemia, hypoglycemia, inflammation) has been well-documented. The BBB is incapable of preventing the exchange of toxins/toxicants from the blood to the brain when its integrity (structure, function, or permeability) is compromised by chemicals or their toxicity.

48.7.1 Anticholinesterase organophosphate nerve agents

Drewes and Singh (1985) reported that the cerebral transendothelial carrier-mediated transport of glucose and amino acids was not affected in mongrel dogs poisoned by soman, an irreversible acetylcholinesterase (AChE) inhibitor. Carpentier et al. (1990) investigated acute changes in BBB permeability to proteins using EB-labeled serum albumin and plasmatic gamma-immunoglobulin G (IgG) as indicators in rats. An increased BBB permeability to the EB–albumin complex was macroscopically observed in two-thirds of the convulsive rats intoxicated by 85 μg/kg of soman. Soman produced seizures and reversible BBB opening to a greatest extent after 30–60 min of paroxysmal electroencephalographic (EEG) discharges when signs of cerebral hyperactivity (epileptic EEG pattern, hyperoxia) were also at their height. Topographically, the protein leakage was bilateral and restricted to anatomically defined brain structures, some of which were sites of parenchymal edema and neuronal damage. Vascular damage occurred approximately when toxic symptoms began to reduce and was nearly concomitant to the highest level of brain oxygenation and to the maximal intensity of seizures. Interestingly, the first signs of increased BBB permeability were shown to precede the onset of edema. Carpentier et al. (1990) detected the BBB opening in the amygdaloid complex and in some cortical regions (cingulum, entorhinal, and piriform complex). The thalamus was the most frequently and intensely affected structure, and the hippocampus remained free of exudated immunoreactive IgG.

Observations from various studies suggest that soman-induced brain alterations are predominantly related to seizures or brain hyperactivity or to a direct cytotoxic action of soman or acetylcholine (ACh) itself, or because of ChE inhibition (McDonough et al., 1987).

Domer et al. (1983) found increased permeability of the BBB by systemic administration of ACh. Of course, brain hyperactivity alone appears inadequate to be responsible for the BBB opening. Obviously, the short duration of the transient protein leakage (Carpentier et al., 1990) contrasted with the well-known long-lasting brain AChE inhibition induced by soman (Petrali et al., 1985). Several other anti-ChE compounds, such as physostigmine and paraoxon, are also known to produce the BBB opening for macromolecules that was seizure-dependent, reversible, and unrelated to brain ChE inhibition. Ashani and Catravas (1981) observed that in soman-intoxicated rats, induced damage to BBB integrity was significantly reduced, despite a high degree of AChE and BChE inhibition, and protected from seizures by nembutal or atropine. In essence, endothelial AChE or BChE plays no role in BBB opening, although it may function as an "enzymatic barrier" to ACh.

Although the exact mechanism is unknown, various contributing factors, such as increased electrical activity, oxidative/nitrosative stress, decreased energy supply and store, deleterious action of excitatory amino acids, enhanced calcium intrusion, and brain edema, seemed to play significant roles in the brain damage (Misulis et al., 1987; Carpentier et al., 1990; Solberg and Belkin, 1997; Gupta et al., 2001a,b; Zaja-Milatovic et al., 2009; Prager et al., 2013; Milatovic et al., 2019). Other mechanisms in soman-induced damage to BBB integrity may be related to vasoactive substances (ACh, amines, amino acids, peptides, free radicals, and steroid hormones of the pituitary adrenal axis) and vasogenic events (acidosis, increased blood flow, and hypertension).

OP nerve agents, which are small lipophilic molecules, can easily penetrate the BBB by free diffusion and thereby inhibit AChE in the CNS (Mercey et al., 2012). Increased BBB permeability by OP nerve agents or other ChE inhibitors may lead to their enhanced entry into the brain, resulting in greater AChE inhibition and possibly resulting in subsequent maintenance of seizures and aggravation of their pathological consequences, such as edema and neuronal loss in certain brain structures. Evidently, increased BBB permeability may facilitate the entry of an antidote (oxime class) to the brain, which otherwise has limited access because of the BBB.

48.7.2 Oxime reactivators of AChE inhibited by OPs and the BBB

AChE-reactivating oximes can be categorized into four groups: charged or noncharged and one-ring or two-ring compounds (Worek and Thiermann, 2013; Esposito et al., 2014). Commonly used AChE reactivators (2-PAM, MMB-4, and HI-6) against OP nerve agents/pesticide-induced AChE inhibition are permanently charged cationic compounds that do not appreciably cross the BBB (Melchers et al., 1994; Cassel et al., 1997; Mercey et al., 2012; Esposito et al., 2014). These oximes reactivate AChE in peripheral sites, but they are not effective in the CNS and, consequently, they provide little or no protection against the neurological/neurotoxic effects of OP nerve agents. However, BBB-penetrating uncharged oximes, such as monoisonitrosoacetone (MINA), diacetylmonoxime (DAM), and dihydropyridine 2-pralidoxime (pro-2-PAM), act centrally and abrogate brain OP-induced seizure activity. But these compounds have a much lower propensity for reactivation of ChEs in peripheral tissues and blood compared with 2-PAM and other quaternary oximes, and they are too toxic for use (Skovira et al., 2010; Demar et al., 2010).

Okuno et al. (2008) examined the BBB penetration of novel PAM-type oximes (alkylPAMs) using brain microdialysis with LC-MS/MS. Findings revealed that 4-[(hydroxyimino) methyl]-1-octylpyridinium bromide (4-PAO) may be effective for the reactivation of inhibited ChE in the brain; however, its toxicity was greater than that of 2-PAM. Recently, Okolotowicz et al. (2014) reported that uncharged amidine-oxime reactivator, (*z*)-*N*-((*E*)-1-(dimethylamino)-2-(hydroxyimino)ethylidine) butan-1-aminium chloride, is more lipophilic, chemically and metabolically stable, nontoxic, and can penetrate the BBB in animals and protect from the toxicity of nerve agents. Chambers et al. (2013) and Pringle et al (2018) evaluated phenoxyalkyl pyridinium oximes that are more lipophilic than currently approved oximes against OP nerve agent surrogates. Being more lipophilic, these oximes may penetrate the BBB easily and thereby reactivate the OP-inhibited AChE. Furthermore, Esposito et al. (2014) developed QSAR models to understand and improve physicochemical properties for the reactivation of OP-inactivated AChE, and these novel oximes may have easy access to cross the BBB as well.

Other strategies to deliver oximes across the BBB may include facilitative transport where sugar-oxime conjugates could be transferred by glucose transporters (Mercey et al., 2012; Bhonsle et al., 2013). Bhonsle et al. (2013) developed and validated molecular models for AChE reactivation by sugar oximes, which appear to be relatively nontoxic with a guinea pig LD_{50} of 1590 mg/kg. It is demonstrated that sugar oximes are relatively better reactivators of AChE inhibited by OPs compared with monoamine quaternary pralidoxime derivatives.

In OP nerve agent poisoning, a combination of AChE-reactivating oximes provides better therapeutic efficacy compared with an individual oxime (Kassa et al., 2010, 2011a,b). Also, oximes (pralidoxime, trimedoxime, obidoxime, HI-6, HLo-7) provide greater neuroprotection against OP nerve agents when given in combination with an antimuscarinic drug (e.g., atropine sulfate) and an anticonvulsant drug (e.g., diazepam). In such scenarios, oximes alone or in combination, with and without atropine sulfate/diazepam, need to be evaluated at the BBB for their mechanisms of transport.

Karasova et al. (2010) evaluated 30 AChE-reactivating oximes for BBB penetration using an in vitro model. Findings revealed that monoquaternary AChE reactivators were able to penetrate the BBB, and their molecular structure and molecular weight appeared to be the influencing factors for passive transport. Regarding the transport of bisquaternary oximes, the connecting linker plays a key role in penetrating the BBB, for example, short linkers tend to facilitate penetration. Furthermore, the location of the oxime group on the pyridine ring influences passive transport into the brain. The optimum position of the oxime group was found to be at position four (i.e., para).

In essence, novel oxime reactivators (alone or in combination) that are capable of crossing the BBB and efficiently reactivating ChEs within the CNS are of great interest for protection of military personnel and civilians from nerve agents and OP pesticides.

48.7.3 NMDAR antagonist memantine and the BBB

Currently, an *N*-methyl-D-aspartate (NMDA) receptor (NMDAR) antagonist memantine is widely used as a neuroprotectant in neurodegenerative diseases, but is more commonly used in moderate to severe AD. In a series of experimental studies, memantine has also been shown to protect animals from seizures, lethality, AChE inhibition, oxidative/nitrosative stress, high-energy phosphate depletion, cytotoxicity, and morphological alterations in the dendritic system of the brain against OP nerve agents or their surrogates (McLean et al., 1992; Gupta et al., 2007; Zaja-Milatovic et al., 2009; Stojiljković et al., 2019). To protect or reverse OP-induced effects in the brain, memantine has to cross the BBB. Yet, the exact mechanism by which memantine crosses the BBB remains unknown. Mehta et al. (2013) identified the putative transporter involved in memantine disposition in the brain in mice. The findings implicate the involvement of an organic cation transporter regulated by proton antiport mechanisms

in the transport of memantine across the mouse BBB, possibly the organic cation/carnitine transporter, OCTN1. Furthermore, memantine brain uptake was markedly reduced by various cationic transporter inhibitors (such as amantadine, quinine, tetraethylammonium, choline, and carnitine), suggesting the need for further investigation in patients using memantine and other medications (multidrug regimens). In the case of OP nerve agent poisonings, memantine is given in combination with atropine sulfate, which does not easily penetrate the BBB, and the interaction of memantine and atropine sulfate needs to be investigated at the BBB. Recently, memantine was also given in combination with HI-6 and diazepam in addition to atropine (Stojiljković et al., 2019), suggesting crossing of these antidotes through the BBB.

48.7.4 Drugs of abuse-induced BBB damage

Currently, a large number of drugs of abuse are consumed by civilians as well as military personnel around the world. Among these illicit drugs, cocaine, morphine, and amphetamines [methamphetamine (METH), amphetamine, and methcathinone] are most commonly used (Milatovic et al., 2019). Because of its small size and lipophilicity, METH readily crosses the BBB by nonspecific diffusion. METH can induce BBB dysfunction in rodents, particularly in the limbic region including the hippocampus (Bowyer and Ali, 2006; Martins et al., 2017). Recently, Multani et al. (2019) described BBB disruption using protein tracers, such as EB, iodine, and albumin immunohistochemistry of IgG1 in the cortex, hippocampus, thalamus, hypothalamus, cerebellum, and amygdala, and METH-induced neurotoxicity. The appearance of albumin immunoreactivity in the neuropil and leakage of serum albumin into the brain tissue had been observed as a consequence of METH-induced BBB breakdown, further leading to neuronal damage, myelin degeneration, reactive astrocytosis in the parietal and occipital cortices, extensive degeneration of pyramidal cells, and activation of microglia in the amygdala and hippocampus of rats (Sharma et al., 2007). It is suggested that, in addition to direct damage of monoaminergic nerve terminals, the deregulation of the BBB in these areas potentially contributes to widespread METH-induced neurotoxicity. METH directly damages dopaminergic and serotonergic nerve terminals, but also causes BBB dysfunction, which is thought to contribute to its neurotoxicity (Silva et al., 2010). Martins et al. (2013) provided mechanistic evidence that BBB breakdown was attributable to endothelial nitric oxide synthase (eNOS) activation and enhanced transcytosis. The neurotoxic effects of METH-induced BBB damage have been linked to hyperthermia, because METH causes dose-dependent temperature increases. Antioxidant H-290/51 pretreatment prevented hyperthermia, neuronal damage, myelin degradation, glial response, and leakage of serum albumin into brain tissue, establishing the role of free radicals in BBB damage and oxidative stress in METH neurotoxicity (Milatovic et al., 2019).

ElAli et al. (2012) reported that repeated administration of low-dose METH induces a transient parenchymal stress response, reflected by JNK1/2 and p38 MAPK activation, accompanied by the induction of proinflammatory cell adhesion molecules ICAM-1 and VCAM-1 in cerebral microvessels. Although tight junction proteins occludin and claudin-5 were expressed at high levels, a differential regulation of ABC transporters was observed after METH administration. The luminal ABCB1, which carries its substrates from the vessel into the blood, was upregulated, whereas the abluminal ABCC1, which carries its substrates from the vessel into the brain (Kilic et al., 2008), was downregulated in brain capillary cells (ElAli et al., 2012). These studies confirmed that METH modifies the structure of the BBB. JNK signaling has been shown to be involved in BBB breakdown associated with cerebral ischemia and subarachnoid hemorrhage. Urrutia et al. (2013) demonstrated that METH-induced changes in BBB integrity were attributable to JNK1/2-mediated activation of MMP-9 and laminin degradation. These effects were observed after acute exposure to METH at doses comparable with those used by consumers, for example, doses ingested typically in the range of 50–500 mg.

48.7.5 Metals

Metals, such as manganese (Mn), lead (Pb), and mercury (Hg), are transported on endogenous carriers, which otherwise function in the transport of essential macromolecules (Aschner and Slicker, 1998; Song et al., 2014). Mn binds readily to transferrin without displacing iron (Fe) in plasma. Brain areas (pallidum, thalamic nuclei, and substantia nigra) with high Mn levels differ from those with high levels of transferrin receptors (nucleus accumbens and caudate putamen), suggesting that perhaps these sites may accumulate Mn through neuronal transport. Like Fe, Mn-loaded transferrin is taken up by receptor-mediated endocytosis at the luminal membrane of brain capillaries.

Pb can enter the CNS by more than one mechanism. The transport of Pb may occur either via the exchange of $PbCO_3$ with an anion or via exchange of an anion–ternary complex of $PbCO_3$ with another anion. Kinetic studies with ^{203}Pb continuously infused intravenously into adult rats revealed that ^{203}Pb uptake into different brain regions was linear with time up to 4 h after infusion (Bradbury and Deane, 1993). In the absence of organic ligands for Pb, the metal readily entered the CNS. However, the presence of albumin, l-cysteine, or EDTA during the vascular

perfusion completely abolished the measurable uptake of ^{203}Pb. It was also suggested that Pb may passively enter the CNS in the form of $PbOH^+$.

It is well-established that Pb accumulates in the choroid plexus of humans as well as animals, suggesting that the choroid plexus is a primary target for Pb-induced neurotoxicity. Behl et al. (2009) demonstrated that exposure to Pb results in a significantly increased accumulation of intracellular amyloid-β ($A\beta_{1-40}$) in rat choroid plexus tissues in vivo and in immortalized choroidal epithelial Z310 cells in vitro. Several mechanisms may lead to an increased Aβ level at the BCSFB: a diminished expulsion of Aβ molecules from the plexus cells to the extracellular milieu; an increased uptake of Aβ from the CSF, blood, or both; an increased synthesis of Aβ; and/or a reduced metabolism or degradation of Aβ. Pb-induced inhibition of the production of LRP1 (a key intracellular Aβ transport protein in the choroid plexus) may be responsible for the accumulation of Aβ, and may be a major risk factor for AD.

Developing fetuses and neonates are most sensitive to methyl mercury (MeHg)-induced neurotoxicity, because MeHg is more readily transported across the immature BBB and because of its inhibitory effects on cell division. Aschner et al. (1990) demonstrated that MeHg conjugated to cysteine is transported across the BBB via the neutral amino acid transport L-system. It was reported that the structural similarity of the l-cysteine−MeHg conjugate with the structure of methionine suggested that, because of the broad specificity of the L-system, it should transport cysteine−MeHg conjugates efficiently across the BBB.

Copper (Cu) and Fe are trace minerals that are essential for normal brain function. They play important roles as catalysts, gene expression regulators, and second messengers. Monnot et al. (2011) and McCarthy and Kosman (2015) investigated how BBB and BCSFB regulated Cu transport and how Fe levels altered brain Cu homeostasis. The findings demonstrate that both the BBB and BCSFB contribute to maintaining a stable Cu homeostasis in the brain and CSF. Cu appears to enter the brain primarily via the BBB and is subsequently removed from the CSF by the BCSFB. Fe deficiency has a more profound effect on brain Cu levels than Fe overload. Fe deficiency increases Cu transport at the brain barriers and prompts Cu overload in the CNS. The BCSFB plays a key role in removing excess Cu from the CSF.

48.8 Bacterial toxin-induced BBB damage

Bacteria, their cell wall components, and their toxins can induce severe damage and dysfunction to the BBB (Deli et al., 2005). Lipopolysaccharide (LPS) is the primary endotoxin involved in inflammatory processes, sepsis, and multiorgan failure caused by Gram-negative bacteria like *Escherichia coli* (*E. coli*) or *Haemophilus influenzae*. LPS has been found to affect the CNS and damage the BBB by either direct or indirect means (Wispelwey et al., 1988; Shukla et al., 1996; Banks et al., 2015). Wispelwey et al. (1988) reviewed several studies dealing with LPS-induced damage to the BBB. In one study, intracarotid injections of *E. coli* LPS in rabbits caused diffuse breakdown of the BBB. In a second study, intracarotid LPS injections in rabbits were followed by an injection of colloidal Fe 4 h later. Electron microscopy of the brains of the LPS-treated animals revealed a large quantity of Fe within the endothelial cells, basement membrane, and glial process; however, in the saline controls, the Fe remained confined to the vascular lumen. In a third study, microscopic evaluation of brains from cats that had received intracisternal injection of *E. coli* LPS revealed evidence of profound inflammatory cell infiltration and microcirculatory impairment in both meningeal and cortical microvessels. Free radicals and nitric oxide (NO) appear to play a role in the LPS-induced increase in BBB permeability because stimulation with LPS not only produces superoxide radicals, but also enhances NO production. Minami et al. (1998) investigated the roles of NO and prostaglandins (PGs) in the development of damage to the BBB induced by LPS using NOS and cyclooxygenase (COX) inhibitors. These authors concluded that both the NO produced by NOS (especially by iNOS) and the PGs produced by COX participate in the LPS-induced increase of BBB permeability. In in vitro BBB models, LPS induced a concentration-dependent and time-dependent increase in monolayer permeability (de Vries et al., 1996; Gaillard et al., 2003). Interestingly, glial cells protected cerebral endothelial cells from LPS-mediated injury in a coculture model.

Pertussis toxin, a virulence factor of *Bordetella pertussis*, severely compromises the integrity of brain endothelial monolayers in a dose-dependent and time-dependent manner and is possibly mediated by the PKC pathway (Brückener et al., 2003).

Meningitis-causing bacteria interact with brain endothelium and can cross the BBB as live bacteria either transcellularly or paracellularly and subsequently multiply inside the CNS (Kim, 2008). *Bacillus anthracis*, the etiologic agent of anthrax, has been shown to penetrate the BBB in vivo, and expression of the anthrax toxins was essential for this transmigration (van Sorge et al., 2008). Anthrax toxins are known to cause BBB disruption, invasion, trafficking, and the development of meningitis during live bacterial infection (Ebrahimi et al., 2011).

48.9 GWI and the BBB

After the first Persian Gulf War, many soldiers reported a variety of symptoms designated as Gulf War illness

(GWI). The long-term symptoms include chronic fatigue, musculoskeletal pain, and cognitive–psychological disturbances, such as memory loss, confusion, inability to concentrate, mood swings, irritability, and somnolence. Among several factors, the use of pyridostigmine bromide (PB) pills, given to protect troops from the effects of AChE-inhibiting OP nerve agents (such as sarin, soman, tabun), and pesticides used during deployment, is highly likely (Amourette et al., 2009). PB is a reversible AChE-inhibiting carbamate that has been recommended by most military health services for prophylaxis against intoxication with irreversible AChE-inhibiting nerve agents. The toxic signs associated with PB are due to overstimulation of nicotinic and muscarinic receptors in the peripheral nervous system (PNS). Because of its quaternary amine structure, PB has limited access to the CNS. Therefore, no effects on the CNS are described at doses currently recommended, unless BBB permeability is compromised.

Stress can disrupt the BBB and thereby can increase the neurotoxicity induced by chemicals in many cerebral areas (Sharma and Dey, 1986). Therefore, involvement of stress during PB treatment may allow PB to enter the brain and produce inhibition of brain AChE activity. It has been hypothesized that combat stress combined with PB treatment may have induced central penetration of PB, leading successively to the following: brain AChE inhibition; stimulation of muscarinic ACh receptors; rapid induction of c-fos oncogene; and selective regulatory effects on the long-lasting activities of genes involved in ACh metabolism (Amourette et al., 2009). Experimental studies have shown an increase in BBB permeability and inhibition of brain AChE activity after exposure to a combination of stress and PB (Friedman et al., 1996). At high doses, PB crosses the BBB in the hypothalamus to induce cholinergic and noncholinergic changes in nonstressed mice (Ropp et al., 2008). It is also suggested that the neurological symptoms of GWI are linked to neurodegeneration in some discrete brain areas, as clearly demonstrated in rats subjected to daily restraint stress and combined exposure to a repellent (*N,N*-diethyl-*m*-toluamide; DEET), an insecticide (permethrin), and PB (Abdel-Rehman et al., 2004).

48.10 Effects of blasts on the BBB

In several military conflicts, the incidence of explosive blast-induced traumatic brain injury (TBI) has been increased substantially. BBB disruption associated with TBI results in brain edema and increased cerebrovascular permeability, both of which affect morbidity and mortality in patients with head injury (Ling et al., 2009; Hue et al., 2013; Shetty et al., 2014). Brain edema after TBI is thought to be initiated by BBB rupture, permitting the influx of protein-rich exudate through compromised endothelial tight junctions that may lead to delayed neuronal dysfunction and degeneration (Shlosberg et al., 2010). In TBI, elevation of glutamate results in neuronal death primarily because of NMDAR-mediated excitotoxicity (Zhou and Sheng, 2013). Hue et al. (2013), using an in vitro model, reported the impact of primary blast on the BBB. By multiple measures, the barrier function of an in vitro BBB model was disrupted after exposure to a range of controlled blast loading conditions. Transendothelial electrical resistance (TEER) decreased acutely in a dose-dependent manner that was most strongly correlated with impulse, as opposed to peak overpressure or duration. Significantly increased hydraulic conductivity and solute permeability after injury further confirmed acute alterations in BBB function. Compromised zonula occludens-1 (ZO-1) immunostaining identified a structural basis for BBB breakdown. After blast exposure, TEER remained significantly decreased 2 days after injury, followed by spontaneous recovery to preinjury control levels by day 3. A study conducted on breachers (a military and law enforcement population that is routinely and repeatedly exposed to low-level blasts) showed changes in serum brain biomarker levels (ubiquitin C-terminal hydrolase-L1, αII-spectrin breakdown product, and glial fibrillary acidic protein), neurocognitive performance, and self-reported symptoms, suggesting brain injury and possibly damage to the BBB (Tate et al., 2013).

48.11 Excitotoxicity, stress, and the BBB

Glutamate excitotoxicity has been linked to chronic neurodegenerative disorders, including AD, amyotrophic lateral sclerosis (ALS), MS, and Parkinson disease (PD), as well as in ischemia and TBI (Deli et al., 2005; Marmiroli and Cavaletti, 2012; Gupta and Gupta, 2019). Škultétyová et al. (1998) reported a stress-induced increase in BBB permeability in control and monosodium glutamate-treated rats. Glutamate administration in neonatal rats causes reversible changes in BBB permeability and known neurotoxic lesions. These investigators evaluated whether glutamate repeatedly administered to neonatal rats influences properties of the developing BBB with consequences on adult BBB function. In control rats, 30 min of immobilization stress resulted in increased endogenous albumin extravasation in the hypothalamus, hippocampus, brainstem, and cerebellum, but not in the cortex and striatum. Basal levels of albumin in adult glutamate-treated rats (4 mg monosodium glutamate/g body weight, intraperitoneal, five times during neonatal period) were significantly lower in the hypothalamus compared with that in controls. Stress-induced increase in albumin levels was lower in the brainstem, higher in the hypothalamus, and similar in other brain regions in

glutamate-treated rats in comparison with controls. In conclusion, short-lasting immobilization stress increased BBB permeability in some, but not all, brain regions. Glutamate treatment of neonatal rats resulted in low basal albumin levels in the hypothalamus but did not exert a pronounced influence on adult BBB function. BBB vulnerability in glutamate-treated rats during stress exposure was increased in the hypothalamus and decreased in the brainstem.

In in vitro studies, although no permeability change was found in the case of basolateral application on a bovine coculture (Gaillard et al., 1996), apical glutamate treatment increased the flux of 70 kDa FITC-dextran (Collard et al., 2002) and decreased TEER (Sharp et al., 2003) in human brain endothelial monolayers. These findings support that brain endothelial cells express functional glutamate receptors (Krizbai et al., 1998; Sharp et al., 2003).

48.12 Brain barriers and CNS diseases

Involvement of brain interfaces, such as BBB and BCSFB, has been implicated in various neurodegenerative diseases, such as AD (Deane and Zlokovic, 2007; Zisper et al., 2007; Agyare et al., 2013; Burgmans et al., 2013; Srinivasan et al., 2016), PD (Shaltiel-Karyo et al., 2013), motor neuron disease (Garbuzova-Davis et al., 2007), Huntington's disease (Drouin-Ouellet et al., 2015), and MS (Minagar and Alexander, 2003; van Horssen et al., 2007; Basivireddy et al., 2013). Modulation of the BBB permeability has also been reported in stroke, TBI, epilepsy (Abbott and Friedman, 2012; de Vries et al., 2012; Hue et al., 2013), autism, schizophrenia and other psychiatric disorders (Shalev et al., 2009; Palmer, 2010), GWI (Amourette et al., 2009), and edema, hypoxic-reoxygenation, or ischemic conditions (Deli et al., 2005; Kaur and Ling, 2008).

Impaired cognitive function and short-term memory are characteristic clinical features of AD. Underlying pathological features of this disease include neuronal and synaptic loss in the cerebral cortex as well as amyloid-β (Aβ)-containing diffuse and neuritic plaques (senile plaques), intraneuronal neurofibrillary tangles, and cerebral amyloid angiopathy (Zisper et al., 2007; Agyare et al., 2013). A prevailing hypothesis in the AD field was the amyloid cascade hypothesis that Aβ deposition in the CNS initiates a cascade of molecular events that cause neurodegeneration, leading to AD onset and progression. However, because of poor correlation between insoluble amyloid and cognitive impairment, increased in vitro toxicity of Aβ in the presence of antifibrillogenic agents and the synaptic localization of soluble oligomeric polymers, many experts now support the soluble Aβ oligomer cascade hypothesis (reviewed in Wilcox et al., 2011). Amyloid plaques may instead act as Aβ sinks, plaques that are surrounded by a halo of oligomers, which then attach to synapses and eventually cause synapse loss (Koffie et al., 2009). The loss of synapses is highly relevant to cognitive impairments, and is the best correlate with AD dementia severity (Terry et al., 1991).

Zisper et al. (2007) provided evidence that in advanced AD, plasma proteins like prothrombin can be found within the microvessel wall and surrounding neuropil, and that leakage of the BBB may be more common in patients with at least one APOE4 allele. Agyare et al. (2013) demonstrated that DutchAβ40 shows preferential accumulation in the BBB endothelial cells because of its inefficient blood-to-brain transcytosis. Consequently, DutchAβ40 establishes a permeation barrier in the BBB endothelium, prevents its own clearance from the brain, and promotes the formation of amyloid deposits in the cerebral microvessels. Burgmans et al. (2013) presented ample evidence for interplay between Aβ and BBB function in AD and reiterated that accumulation of the Aβ and disruption of the BBB can initiate cerebral microangiopathy, which has frequently been associated with vascular dementia. Although Aβ and BBB dysfunction have both been associated with AD and vascular dementia, respectively, they coexist in most demented patients. In fact, increasing evidence suggests that Aβ and BBB disruption may interact and facilitate each other in their effect on neurodegeneration. Erickson and Banks (2013) published a review of BBB dysfunction as a cause and consequence of AD. Paganetti et al. (2014) demonstrated that oral treatment with pirenzepine dose-dependently reduced brain Aβ level by its enhanced clearance in AβPPS1, $hA\beta PP_{st}$, and AβPP/PS1 transgenic mice by selective inhibition of muscarinic ACh receptors on endothelial cells of brain microvessels at the BBB.

It appears that the BBB does not play a major role in the etiology of PD, but its disruption may be beneficial in drug development. The neuropathological hallmarks of PD are progressive loss of dopaminergic neurons in the substantia nigra pars compacta accompanied by inclusions termed Lewy bodies and dystrophic Lewy neuritis in surviving neurons. The main constituent of the Lewy bodies is the α-synuclein protein. The etiology of these proteins is thought to involve major conformational changes leading to their misfolding, followed by production of β-sheet structures that have a strong tendency to aggregate into small oligomers and protofibrils that elongate into mature fibrils (Leong et al., 2009). One of the main obstacles in drug development is the inability of most drugs to pass across the BBB into the CNS. Mannitol, a nonmetabolized FDA-approved osmotic diuretic mediator, can also be used to open the BBB by producing osmotic shrinkage of the endothelial cells and mechanical separation of the tight junctions that form the BBB. Shaltiel-Karyo et al. (2013)

demonstrated that mannitol interferes with α-synuclein aggregation without exerting adverse effects, and suggested that mannitol administration in combination with other drugs could be a promising novel approach for treating PD or other brain-related diseases.

In neurologic disorders such as MS, epilepsy, capillary cerebral amyloid angiopathy, and AD, a profound dysfunction of the BBB is apparent (de Vries et al., 2012; Gupta and Gupta, 2019). In stroke and TBI, acute BBB dysfunction causes vasogenic edema with the danger of transtentorial herniation, and the effects of chronic BBB impairment are involved in neuroinflammatory disorders, such as MS, AD, and epilepsy (de Vries et al., 2012). Studies have led to the belief that BBB disruption represents an early event in MS lesion formation, preceding the massive infiltration of leukocytes (mainly T lymphocytes and monocyte-derived macrophages), leading to myelin degradation and nervous tissue destruction (Minagar and Alexander, 2003). In vitro and in vivo animal studies and patient tissue studies showed a significant involvement of the disruption of BBB integrity and function in MS pathology. Alterations not only involved the modulations of the tight junction but also included a reduced expression of the efflux pumps and the ABC transporters (Kooij et al., 2011).

48.13 Melatonin and the BBB

CWAs are known to generate excess free radicals and cause excitotoxicity and neuroinflammation. Melatonin (*N*-acetyl-5-methoxytryptamine), being an indirect antioxidant and free radical scavenger, can modulate and control oxidative stress. Melatonin is also involved in vasomotor control and adrenal function. It possesses antiexcitatory actions, regulates immune function and energy metabolism, and exerts antiinflammatory properties (Jumnongprakhon et al., 2016). Melatonin is highly lipophilic and, consequently, easily crosses cell membranes, including the BBB. Considering all these properties, melatonin could be an excellent and suitable candidate molecule to prevent CWA-induced tissue damage (Pita et al., 2013).

48.14 Concluding remarks and future directions

The CNS is composed of various interfaces, such as the BBB, the BCSFB, and the blood–spinal cord barrier (BSCB). Brain capillary endothelial cells form tight junctions and are referred to as the BBB. Currently, there are many in vivo and in vitro models to understand the mechanistic aspects of BBB functionality and permeability. Under physiological conditions, brain barriers protect the brain from pathogens, toxins, toxicants, proteins, and neurotransmitters. Disruption of the normal function of the BBB to circulating solutes and toxicants is usually the result of widened interendothelial junctions and/or alterations in one of the transporters localized within the BBB. Structure and function of the BBB and its permeability can be modulated by CWAs, toxins/toxicants, adverse conditions, and induced pathological conditions. Disruption of the BBB can also be the cause and/or consequence of neurodegenerative diseases, such as AD and MS. In future studies, novel in vitro and in vivo methods need to be developed to screen the compounds with properties of easy access to the BBB and those that can be used as therapeutic agents against CWAs.

Acknowledgment

The authors thank Ms. Robin B. Doss for her technical assistance in the preparation of this chapter.

Chapter 49

The effects of organophosphates in the early stages of human skeletal muscle regeneration

Tomaz Mars[1,*], Katarina Mis[1,*], Maja Katalinic[2], Katarina Pegan[1], Zoran Grubic[1] and Sergej Pirkmajer[1]

[1]*Laboratory for Molecular Neurobiology, Institute of Pathophysiology, Faculty of Medicine, University of Ljubljana, Ljubljana, Slovenia,* [2]*Institute for Medical Research and Occupational Health, Zagreb, Croatia*

49.1 Introduction

Organophosphate (OP) poisoning may result in myopathy (Wecker et al., 1978; Preusser, 1967; Karalliedde et al., 2006; Abdollahi and Karami-Mohajeri, 2012) which is—when it occurs—one of the most serious chronic consequences of such poisoning. The final outcome of this condition depends on the one hand on the extent of muscle damage, and on the other on the efficiency of muscle regeneration. The first stage of OP poisoning leads to muscular hyperactivity and a combination of factors, including mechanical stress, Ca^{2+} overload, and alterations in oxidative processes in the muscle fibers (Mense et al., 2003; Karalliedde et al., 2006; Abdollahi and Karami-Mohajeri, 2012) leads to destruction of the muscle tissue. During sustained seizures and fasciculations, the flow of oxygen through the muscle is greatly increased at a time when the demand for ATP is greater than its rate of generation. Under such conditions, production of reactive oxygen species is greatly increased and exceeds the protective capacity of the cellular defense system so that their damaging effects result in muscle injury, including necrosis of muscle fibers (Ariens et al., 1969; Abdollahi and Karami-Mohajeri, 2012; Gupta et al., 2002; Dettbarn et al., 2001, 2006).

Necrosis, the extent of which depends on the level of muscle activity, is followed by infiltration with inflammatory cells, clearing the debris, and regeneration of muscle fibers (Ariens et al., 1969; Robertson et al., 1993; Cantini and Carraro, 1995; McLennan, 1996). Skeletal muscle has the capacity to alleviate its damage by quite efficient regeneration which, however, might be affected by the conditions imposed by OP poisoning. Therefore, it is important to know whether OPs interfere in any way with the mechanisms involved in the process of muscle regeneration. This aspect of OP poisoning has not been examined in detail in human muscle. Here we provide evidence that the mechanisms underlying early stages of human muscle regeneration are affected by OPs.

OP poisoning is a complex condition with various primary and secondary effects. Increased acetylcholine (ACh) concentration in the cholinergic synapses attributable to acetylcholinesterase (AChE) inhibition leads to altered signaling in these synapses, causing various pathological effects, including fasciculations, diarrhea, failure of respiratory muscles, excessive bronchosecretion, and cardiac arrhythmias (Abou-Donia et al., 2016; Alahakoon et al., 2018; Chhabria and Bhalla, 2016). Hypoxia that develops as a combination of impaired exchange of gases in the lungs and bradycardia is an especially threatening complication. Especially with high OP intake, typically found with suicide attempts (Alahakoon et al., 2018), poisoning is often complicated by respiratory failure combined with metabolic and respiratory acidosis (Emerson et al., 1999; Abou-Donia et al., 2016). These patients must be treated in intensive care units and often require mechanical ventilation (Alahakoon et al., 2018). Critically ill patients frequently develop skeletal muscle dysfunction (Bolton, 2005; de Letter et al., 2001; Friedrich et al., 2015) that often persists even after hospital discharge.

* Tomaz Mars and Katarina Mis contributed equally to the work.

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00049-0

There is now substantial evidence that inhibition of AChE is not the exclusive mechanism underlying a wide variety of adverse consequences of OP exposure described previously (Terry, 2012). It is known that cholinesterases (ChEs) are not the only targets of OPs and that various intracellular mechanisms are modified because of direct or indirect OP actions (Terry, 2012; Lima et al., 2013; Jett and Lein, 2006). For instance, DNA microarray analysis of MCF-7 cells treated with OP diazinon disclosed overwhelming modulation (upregulation or downregulation) of a wide range of genes (Mankame et al., 2006). Although still poorly understood, such noncholinergic OP actions might directly or indirectly modify functioning of the complex intracellular mechanisms and importantly contribute to the effects of OP poisoning. Indeed, a recent RNA-seq study in salmon fed chlorpyrifos-methyl in doses that are below the threshold for systemic toxicity due to AChE inhibition leads to marked alterations in the brain and liver transcriptome (Olsvik et al., 2019). Similarly, a marked effect on transcriptome was observed in cultured thyrocytes treated with chlorpyrifos (Porreca et al., 2016).

Skeletal muscle injury always activates the regeneration process (Bischoff, 1979) and insufficient muscle regeneration might directly contribute to the above-mentioned myopathies (Prelovsek et al., 2006). Muscle regeneration shares its basic features with embryonic myogenesis, although it also differs from it in some respects (Yin et al., 2013; Bentzinger et al., 2012; Charge and Rudnicki, 2004; Feige et al., 2018; Dumont et al., 2015). The regeneration process starts from the dormant mononucleated satellite cells located between the basal lamina and cell membrane of the adult skeletal muscle fiber (Mauro, 1961; Katz, 1961). One of the key steps in the process of muscle regeneration is myoblast proliferation, which decisively determines the mass of regenerated muscle tissue. Our investigations into the effects of OPs on muscle regeneration were therefore focused on these early precursors of muscle fibers.

Recently, we identified the neuropathy target esterase-related enzyme (NRE, PPLA7) as a novel OP target in human skeletal muscle. NRE is highly homologous to the neuronal neuropathy target esterase (NTE), which was originally identified as a target enzyme for highly toxic OPs that cause delayed paralyzing syndrome (Richardson et al., 2013). If targeted by OPs in vivo, NRE might be involved in OP poisoning-related myopathy.

All experiments were performed in the in vitro model in which the process of human muscle regeneration is genuinely reproduced. We describe various OP influences on the early precursors of muscle development and discuss their potential effects on muscle regeneration. Because AChE is the most thoroughly characterized target of OPs, we also approached the question of its role and expression in the cultured human (mononuclear) myoblasts. Diisopropylphosphorofluoridate (DFP) was used throughout our studies.

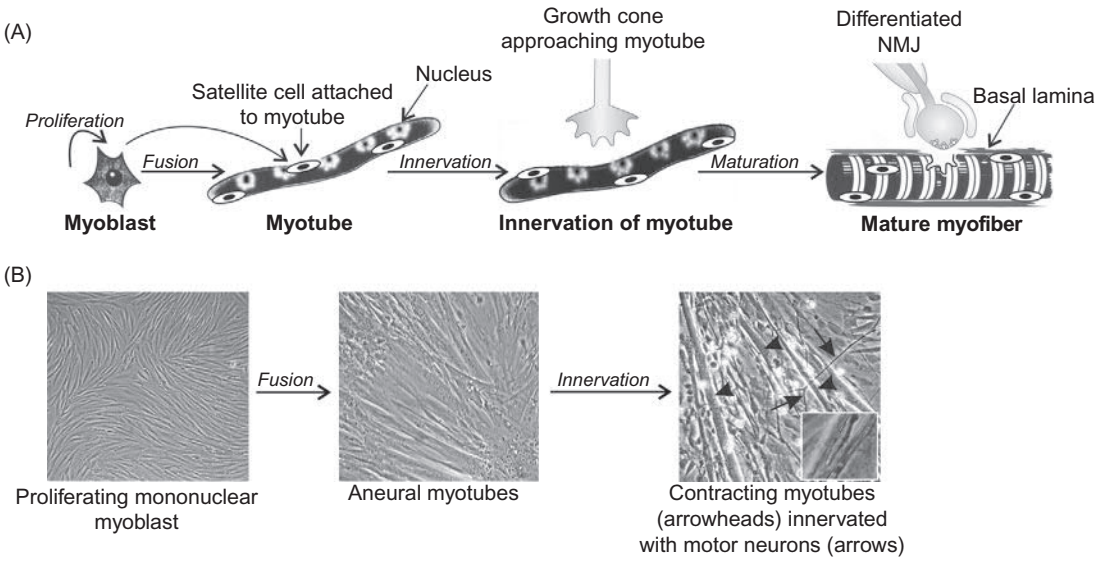

FIGURE 49.1 (A) Schematic presentation of the stages of muscle development. (B) Reproduction of these stages under in vitro conditions. (A) Stages of muscle development from mononuclear myoblast to the mature innervated myofiber. Nuclei, which are still centrally located in myotubes, move to the periphery in the mature fiber as a result of the synthesis of contractile elements in the sarcoplasm. Mature fibers contract and exhibit cross-striations. Only mononuclear myoblasts still have the capacity to divide and proliferate. Some of them do not fuse and become entrapped as mononuclear satellite cells under the basal lamina of the mature fiber. (B) Reproduction of this process in the experimental model of the in vitro innervated human muscle; axons are labeled by arrows and functionally innervated myotubes by arrowheads. Cross-striations could be seen in the innervated myotubes at higher magnification (insert).

49.2 Regeneration process in human skeletal muscle

The process of human muscle regeneration in many respects follows the process of embryonic development of skeletal muscle (Fig. 49.1A). The earliest myogenic precursors in this development are mononuclear myoblasts (Feige et al., 2018; Dumont et al., 2015; Yin et al., 2013; Charge and Rudnicki, 2004; Bentzinger et al., 2012). These still mononucleated, but already committed, cells proliferate several times to reach sufficient density before they fuse into multinucleated myotubes. Once formed, myotubes enter into a long-term and complex process of muscle differentiation that results in development of fully functional mature myofiber. An important step in the transition from myotube to myofiber is its innervation and formation of the complex structure of the neuromuscular junction (NMJ) (Emerson et al., 2004; Witzemann et al., 2013). All these steps are repeated during the postnatal regeneration process, except that adult mononuclear myoblasts are derived from the satellite cells. These primordial cells failed to enter the developmental and differentiation process during embryonic myogenesis, but retained the capacity to enter the myogenic process and self-renewal when activated by the muscle damage (Collins, 2006). As such, they serve as mononuclear muscle precursors of muscle fibers formed de novo during muscle regeneration (Fig. 49.1A).

All stages of muscle regeneration can be reproduced in the experimental model of the in vitro innervated human muscle (Fig. 49.1B). This system was first described in the 1980s (Kobayashi and Askanas, 1985; Askanas et al., 1987) and was further characterized in studies in various laboratories, including ours (Mis et al., 2017). In this experimental model, satellite cells are released by trypsinization from small pieces of adult human muscle routinely removed at orthopedic operations (Dolinar et al., 2018; Lojk et al., 2015). The experiments using human muscle cells were approved by the National Medical Ethics Committee of the Ministry of Health of the Republic of Slovenia (permit numbers 63/01/99, 71/05/12 and 0120-698/2017/4) and were conducted in accordance with the Declaration of Helsinki and Good Laboratory Practice regulations. Satellite cells released by trypsinization are the source of mononucleated myoblasts that then proliferate and, at a certain density, start to fuse and form multinucleated myotubes. To establish innervation, an explant of the rat embryonic spinal cord is placed on a monolayer of muscle cells (Mis et al., 2017). After 6–10 days of coculture, motor neurons functionally innervate myotubes, which then start contracting. Such cocultures are long-lived and contract for up to 6 months. The morphology of the NMJs closely resembles the NMJ in vivo (Askanas et al., 1987). Also, glial cells in the embryonic spinal cord explant recapitulate temporally regulated developmental steps observed in vivo (Mars et al., 2001). For details of preparation and various applications of the aneural and in vitro innervated model, see our recent review on this topic (Mis et al., 2017) and previous studies (Grubic et al., 1995; Mars et al., 2003; Jevsek et al., 2004; Pegan et al., 2010; Lojk et al., 2015, 2017; Rezonja et al., 2013, 2014; Mis et al., 2013; Gros et al., 2014; Dolinar et al., 2018).

49.3 Noncholinergic effects of DFP in regenerating human skeletal muscle

49.3.1 The effect of DFP on IL-6 secretion from myoblasts and myotubes

Cultured human myoblasts and myotubes used in our experiments constitutively secrete interleukin-6 (IL-6) (Prelovsek et al., 2006; Pirkmajer et al., 2010; Gros et al., 2014). IL-6 is a major cytokine released from the skeletal muscle during exercise as well as inflammation (Pal et al., 2014; Pedersen and Febbraio, 2012; Pedersen and Febbraio, 2008; Pedersen, 2019). We found that IL-6 secretion from cultured skeletal muscle cells is stimulated by the major proinflammatory agents, such as tumor necrosis factor (TNF-α) and endotoxin lipopolysaccharide, and suppressed by dexamethasone (Prelovsek et al., 2006; Pirkmajer et al., 2010). Because IL-6 promotes myoblast proliferation (Austin et al., 1992; Austin and Burgess, 1991; Cantini et al., 1995; de Letter et al., 2001; Baeza-Raja and Munoz-Canoves, 2004; Serrano et al., 2008), it is assumed that the physiological meaning of myoblast IL-6 secretion under such conditions is promotion of muscle regeneration, so that the myopathy attributable to septic conditions is, at least to some extent, compensated by muscle regeneration.

Critical illness is often complicated by so-called critical illness polyneuropathy (CIP) and myopathy (CIM) (Friedrich et al., 2015). As already mentioned, OP poisoning resulting in severe hypoxia often causes critical illness. Although the incidence of CIP/CIM in OP poisoning has not been established, it possibly overlaps with the so-called intermediary syndrome, which develops 24–96 h after OP poisoning and is characterized by muscle weakness (Hulse et al., 2014). Nevertheless, it can be expected that development of CIM is even more likely in the setting of OP poisoning because OPs directly lead to development of myopathy (Dettbarn et al., 2006), which includes necrosis of muscle fibers (De Reuck and Willems, 1975). IL-6 is thought to play an important role in CIM, although its precise function has not been established (Friedrich et al., 2015). It is therefore important to find out whether the OP intoxication affects IL-6 signaling and, consequently, muscle regeneration. The effects

of OP on IL-6 secretion from human myoblasts can be expected because it has already been reported that OPs drastically interfere with cytokine signaling in the mouse immune system (Alluwaimi and Hussein, 2007).

We show that IL-6 secretion from human myoblasts is significantly inhibited by DFP (Fig. 49.2). IL-6 secretion was decreased by 50% in myoblasts, which might significantly reduce the efficiency of the muscle regeneration process in damaged muscle. The mechanism underlying this effect of DFP remains to be established and is probably complex. In our culture medium, DFP is hydrolyzed quickly and becomes practically inactive in less than 1 h (Worek et al., 2004). Despite rapid hydrolysis, DFP-induced intracellular alterations may persist beyond the period during which DFP is still active. In our recent study, we observed a 53% decrease in IL-6 secretion from human myoblasts after treatment with 10^{-5} M tabun (Katalinic et al., 2013). Our experiments are in accordance with the study of Zabrodskii et al. (2012), who demonstrated reduced concentrations of blood IL-6 in rats exposed to 30 days of sublethal doses of sarin and methylparathion (Zabrodskii et al., 2012). Also, chlorpyrifos-oxon, a metabolite of chlorpyrifos, reduced IL-6 mRNA levels in mouse cortex and hippocampus (Locker et al., 2017). In contrast, DFP treatment in mice increased expression and/or secretion of TNF-α and/or IL-6 in the brain (Liang et al., 2018; Locker et al., 2017). In another mouse model, DFP increased IL-1β and IL-6 mRNA levels in the hippocampus, while TNF-α mRNA was not increased (Li et al., 2015). Taken together, these results indicate that the extent and pattern of cytokine response may vary across brain regions, cell types, and/or experimental approaches (Li et al., 2015; Locker et al., 2017; Liang et al., 2018).

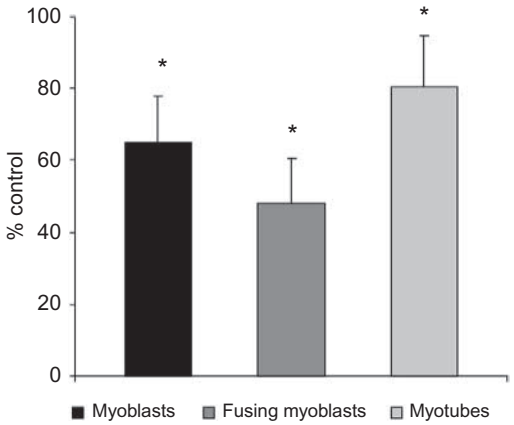

FIGURE 49.2 IL-6 secretion from myoblasts, fusing myoblasts, and myotubes. Cultured human myoblasts, fusing myoblasts, and myotubes were exposed to DFP (10^{-5} M). Concentration of IL-6 (expressed per 100,000 nuclei) was determined 24 h later with ELISA (Endogen, Rockford, IL). *Significant difference (Student t test, $P < .05$; $n = 3$) between control and treated cultures was observed at all stages studied, but was most prominent in the myoblasts.

49.3.2 Heat shock proteins in human myoblasts and myotubes after treatment with DFP

One of the most prominent cellular responses to stress is a rapid upregulation of heat shock proteins (Hsp), a family of highly conserved proteins that exert cytoprotective effects attributable to their chaperone functions in protein folding and protein degradation (Welch, 1992; Morimoto, 1993; Kregel, 2002; Kiang and Tsokos, 1998; Rosenzweig et al., 2019). Various physical, chemical, and biological environmental stress factors including xenobiotics can induce this response (Wu and Tanguay, 2006). Because OP pesticides are among inducers of the Hsp response in vivo and in vitro (Bagchi et al., 1996), we tested whether DFP actions include Hsp-mediated stress response in myogenic precursors. We measured the expression of Hsp27 and Hsp70, which are typically induced by various stress factors. The expression of stress factor Hsp27, but not of Hsp70, was slightly but significantly increased in DFP-treated human myoblasts (Fig. 49.3), which is consistent with the reported selectivity of Hsp induction in various tissues (Wu and Tanguay, 2006).

We observed the DFP-stimulated increase in Hsp70 expression in myotubes, which indicates that the Hsp response to DFP becomes more prominent during the myotube stage (Fig. 49.3). This pattern of effects is the opposite to the observed decrease in IL-6 secretion (Fig. 49.2), indicating that Hsp-mediated stress response does not promote IL-6 secretion. An increase in Hsp70 was also demonstrated in several organs of common carp exposed to chlorpyrifos (Xing et al., 2013), suggesting a

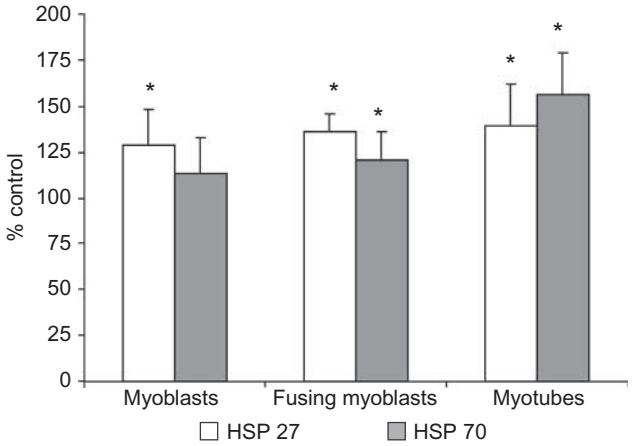

FIGURE 49.3 The effects of DFP on the Hsp27 and Hsp70 levels in myoblast, myoblasts in fusion, and myotube cultures. Levels of Hsp27 and Hsp70 were determined 24 h after addition of DFP (10^{-5} M). They were quantitated by western blot with Chemi Genius BioImaging System (Syngen, Cambridge, United Kingdom). *Significant difference (Student t test, $P < .05$; $n = 4$) between control and DFP-treated cultures was observed in all determinations except for Hsp70 in myoblasts.

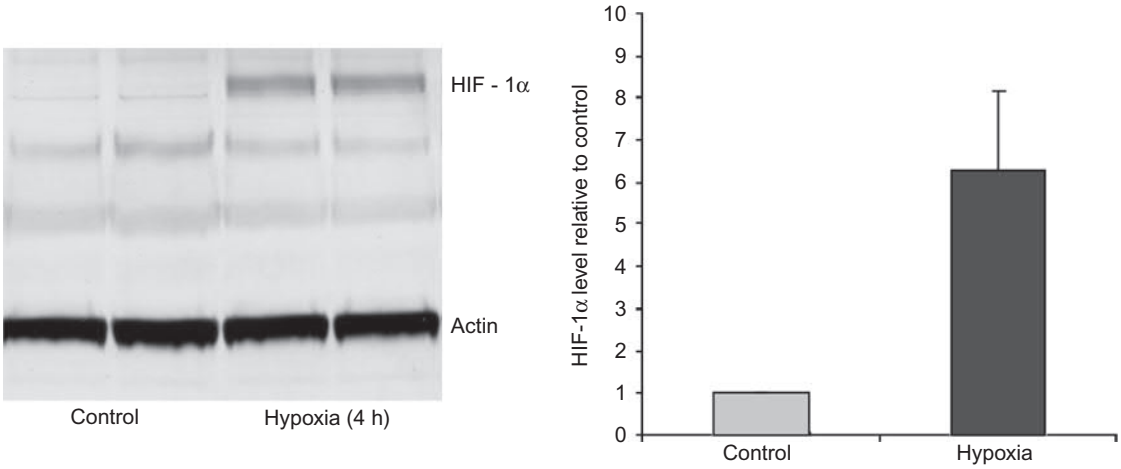

FIGURE 49.4 The effect of acute hypoxia on HIF-1α expression in human myoblasts. Human myoblasts were exposed to 1% O_2 for 4 h. A representative western blot is shown on the left. Relative expression level of HIF-1α (three independent experiments) is shown on the right (arbitrary units, control = 1) (Student *t* test, $P = .004$). Quantification was performed with Chemi Genius BioImaging System (Syngen, Cambridge, United Kingdom).

conservative mechanism unrelated to specific species, tissue, or OP. From the standpoint of muscle regeneration, it remains to be investigated whether the observed Hsp response to DFP in any way protects the proliferative potential of myoblasts that may be hampered by a DFP-induced decrease in IL-6 secretion. These results are again indicative of the wide spectrum of effects that OPs induce on the muscle tissue.

49.3.3 Response of human myoblasts to hypoxia

Severe OP poisoning may result in respiratory failure with arterial oxygen partial pressures less than 50−60 mmHg (6.65−7.99 kPa) (Tsao et al., 1990; Suzuki et al., 1997). In such circumstances, peripheral tissues, including skeletal muscle, become extremely hypoxic, which might have important effects on the myogenic precursors during regeneration. Central to the cellular response to hypoxia is hypoxia-inducible factor-1 (HIF-1), a heterodimeric transcription factor consisting of oxygen-regulated α-subunit (HIF-1α) and oxygen-independent β-subunit (HIF-1β) (Samanta and Semenza, 2017; Semenza and Wang, 1992; Semenza et al., 1991a, b). HIF-1α, which is normally almost undetectable because of its continuous degradation in the ubiquitin−proteasome pathway, rapidly accumulates in hypoxia and translocates to the nucleus, where it dimerizes with HIF-1β to form a functional transcription factor that controls the expression of hundreds of genes related to cellular adaptation to hypoxia (Samanta and Semenza, 2017; Semenza, 2007b).

Through its effects on gene expression, HIF-1α not only increases oxygen delivery to hypoxic tissues by stimulating erythropoiesis and angiogenesis, but also promotes cell survival by redirecting cellular energy metabolism toward glycolysis (Semenza, 2007a; Seagroves et al., 2001). Because of its central role in the hypoxic response, we tested whether such an adaptation also takes place in human myoblasts in vitro. We exposed human myoblasts to acute hypoxia (1% O_2 for 4 h) and found markedly increased HIF-1α levels compared with normoxic control (Fig. 49.4). This and our other results (Pirkmajer et al., 2010; Lojk et al., 2015) suggest that human myoblasts respond to hypoxia in a fashion similar to that of other cell types.

Myoblast proliferation is accompanied by apoptosis, which reduces the number of myogenic precursors and therefore affects the final outcome of the regeneration process. To determine if hypoxia affects muscle regeneration by altering the extent of myoblast apoptosis, the apoptotic markers were followed in human myoblasts under hypoxic conditions. We found that the activity of effector caspases in myoblasts remained unaltered during 48 h exposure to 1% oxygen, suggesting low susceptibility to hypoxia-induced apoptosis (Fig. 49.5A). Consistent with this notion, hypoxia did not lead to marked necrosis of myoblasts as assessed by measuring the activity of lactate dehydrogenase in the supernatant (Fig. 49.5B).

49.3.4 The effects of DFP on the NRE activity in human myoblasts

OP poisoning may lead to delayed polyneuropathy, which is thought to result from inhibition of neuropathy target esterase (NTE) (Glynn, 2006; Richardson et al., 2013; Johnson, 1969a,b). NTE-related esterase (NRE, PNPLA7), a *trans*-membrane serine esterase linked to the endoplasmic reticulum, has been identified as a member of the patatin domain-containing enzymes family (Kienesberger et al., 2008). Several isoforms of NRE

were detected in different stages of skeletal muscle regeneration in vitro (Fig. 49.6A). Notably, the 150 kDa isoform was markedly upregulated on fusion of myoblasts into myotubes, suggesting NRE might have a role in differentiation of myogenic precursors. NRE activity was decreased in human myoblasts exposed to DFP (Fig. 49.6B). Taken together, these results indicate that OPs may impair myogenesis via NRE inhibition. Inhibition of NRE may represent a novel mechanism underlying OP poisoning-related myopathy.

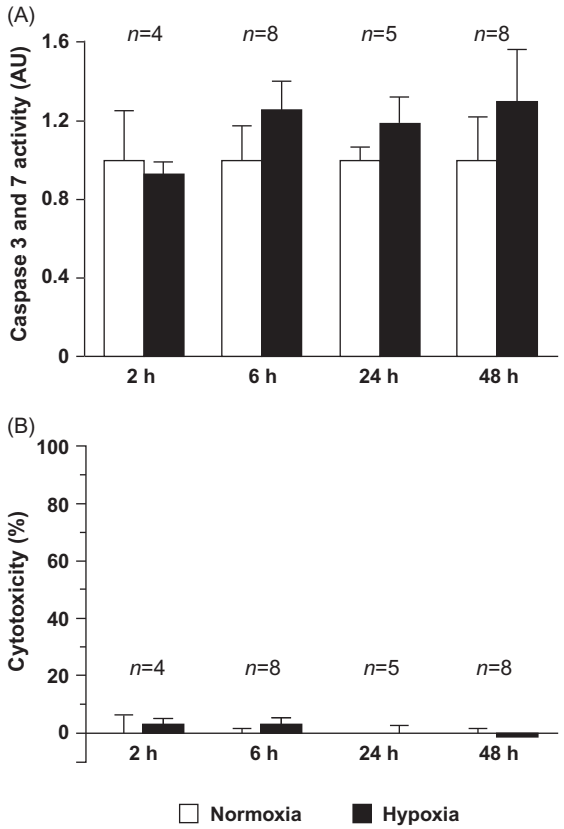

FIGURE 49.5 The effect of hypoxia on viability of human myoblasts. Cells were exposed to hypoxia (1% O_2) from 2 to 48 h as indicated. (A) Apoptosis and (B) cytotoxicity were estimated by measuring activity of caspases (3 and 7) and activity of lactate dehydrogenase, respectively. Results are means ± SD.

49.4 Expression and role of AChE in human myoblasts

Most of the contractile and synaptic muscle proteins cannot be detected before formation of myotubes. Conversely, AChE is already expressed in the myoblast stage (Tennyson et al., 1971; Grubic et al., 1995). Although its function in this earliest stage of muscle ontogenesis is not known, it is most likely noncholinergic or noncatalytic because other components of the cholinergic system are not present in myoblasts (Meshorer and Soreq, 2006). However, some studies suggested that skeletal muscle cells might be the source of ACh or a related cholinergic agent, whose function might be to stimulate nicotinic AChR in an autocrine and paracrine manner (Bandi et al., 2005; Hamann et al., 1995). Thus, the catalytic role of AChE in myoblasts and/or myotubes cannot be excluded. To further explore the role of AChE in myoblasts, we followed various functional parameters in human myoblasts after selective elimination of AChE expression by siRNA.

49.4.1 Recovery of AChE mRNA expression and AChE activity after gene silencing of AChE and after exposure to DFP

De novo AChE synthesis importantly contributes to the recovery of AChE activity after OP poisoning (Grubic et al., 1981). In order to find out whether OPs influence this synthesis at the mRNA level, and if they induce any morphological or functional changes of human myoblasts,

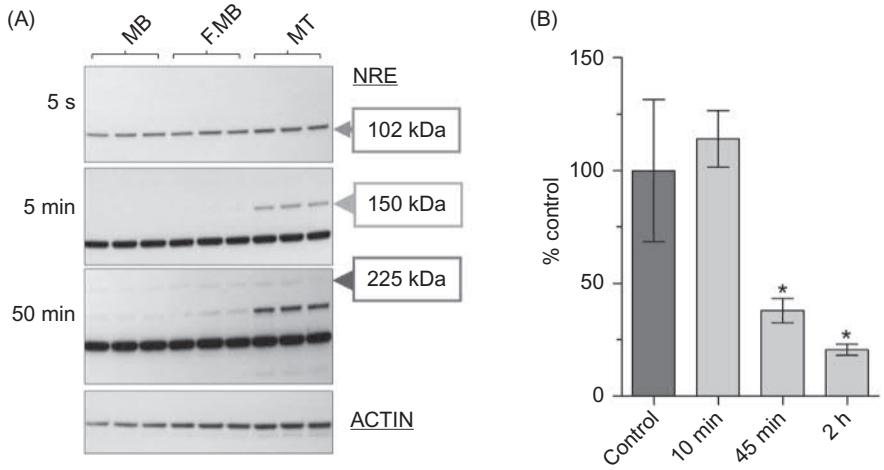

FIGURE 49.6 (A) Expression of NRE in cultured human skeletal muscle cells. (B) Inhibition of NRE by DFP. (A) Expression of NRE in cultured human myoblasts (MB), fusing myoblasts (F.MB), and myotubes (MT). Several immunoreactive bands were detected with the anti-NRE antibody at 102, 150, and 225 kDa (note different times of film exposure) with a significant increase of 150 kDa isoform between fusing myoblasts and myotubes. (B) Time-dependent inhibition of NRE-specific esterase activity by DFP. Myoblasts were exposed to 10^{-5} M DFP for 10, 45, and 120 min. NRE-specific esterase activity was measured in myoblast homogenates using *p*-nitrophenyl valerate as a substrate. Data shown represent means ± SE ($n = 4–6$). *$P \leq .05$ vs. control.

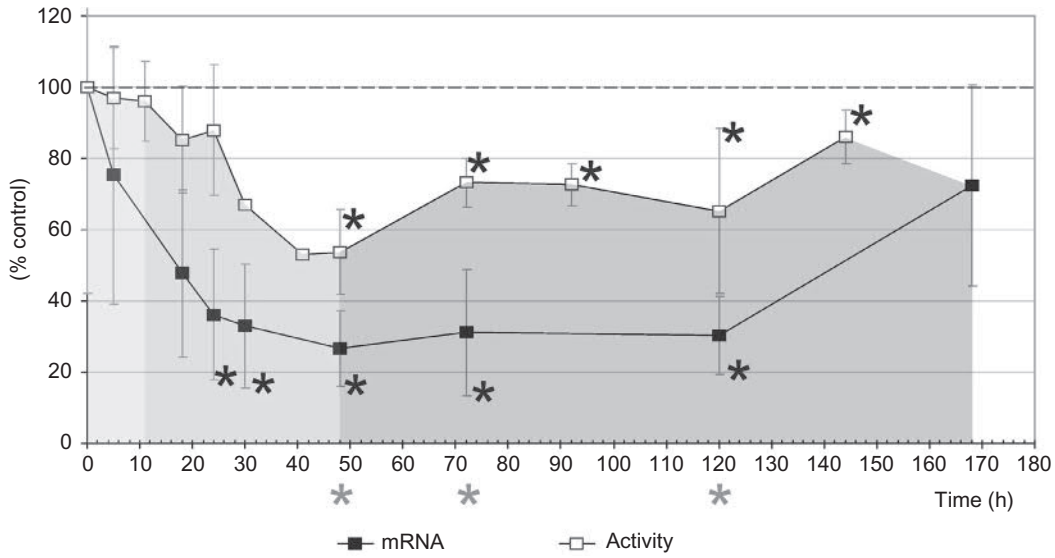

FIGURE 49.7 Relative changes of AChE-T mRNA and AChE activity in lysates of human myoblasts during the first week after siRNA application. Cultures of control and treated myoblasts were prepared from the satellite cells of the same donor and were processed in parallel. Gene silencing was achieved by lipofection of siRNA (Dharmacon); for details see Mis et al. (2006). Q-PCR with TaqMan chemistry was used for mRNA measurements. AChE mRNA levels were standardized to GAPDH mRNA. AChE activity levels determined by Ellman technique were expressed per 10,000 cells, the number of which was determined on the basis of Hoechst 33258 nuclear staining. Each point represents the mean (± SD) of three to seven measurements, and in each of which we determined the AChE-T mRNA or AChE activity ratio between control and siRNA-treated levels (% control). *The statistically significant (Student *t* test, $P < .05$) differences relative to the starting point. The statistically significant (Student *t* test, $P < .05$) percent differences between AChE activity and mRNA levels at the same time point are indicated by * under the *x*-axis. Three shades of gray correspond to the three stages discussed in the text.

we explored the recovery of AChE mRNA and AChE activity after gene silencing of AChE or after DFP exposure. AChE level (determined on the basis of its catalytic activity) decreased to approximately 50% of control after siRNA treatment (Fig. 49.7). No functional or morphological changes in myoblast cultures could be detected in comparison with controls. Addition of DFP to siRNA-treated myoblasts, which blocked practically all AChE catalytic activity, also resulted in no morphological changes in myoblast cultures. This observation suggests that complete loss of AChE catalytic activity exerts no visible effect in human myoblasts.

We then followed and compared the levels of AChE mRNA and AChE activity in siRNA-treated myoblasts and estimated the relationship between AChE expression at the mRNA and mature protein level. Because AChE is polymorphic and alternative splicing of primary transcript gives rise to three AChE mRNA species, tailed (T), hydrophobic (H), and read-through (R), which encode differently targeted AChE catalytic subunits (Massoulie, 2002), we followed these mRNA species separately in these experiments.

Three stages could be distinguished during a 170-h (approximately 7-day) period, during which we followed AChE activity:AChE mRNA ratio in the siRNA-treated myoblasts. During the first 10 h after siRNA treatment, AChE mRNA already decreased to approximately 60% of control level, whereas AChE activity remained practically unchanged. During the second stage (hours 10−50), AChE mRNA decreased to approximately 30% of control. AChE activity followed this decline and reached its lowest level of approximately 50% of control 50 h after siRNA treatment. From hour 50 onward, a new (more or less) constant relationship between AChE and its mRNA is established (Fig. 49.7).

Of the three mRNA species, AChE-H and AChE-T mRNA followed practically the same pattern of expression after siRNA treatment of human myoblasts, whereas AChE-R mRNA behaved in a completely different and less reproducible manner (Fig. 49.8). In comparison with the other two mRNA species, which decreased to approximately 20% of control after siRNA treatment, AChE-R mRNA never decreased to less than 50% of control. It quickly recovered and then increased so that 7 days after siRNA treatment, its level was almost 1.5 times higher than that in controls. After approximately 150 h, but not earlier, we also observed similar overshoot for AChE-H, but never for AChE-T. All three AChE mRNA species could be detected at all developmental stages. Patterns of their expression were developmental stage-dependent, but AChE-T was the predominant species in all stages.

At present, we have no explanation for the different expression pattern of R-mRNA species in comparison with the other two. Increased AChE-R mRNA levels have

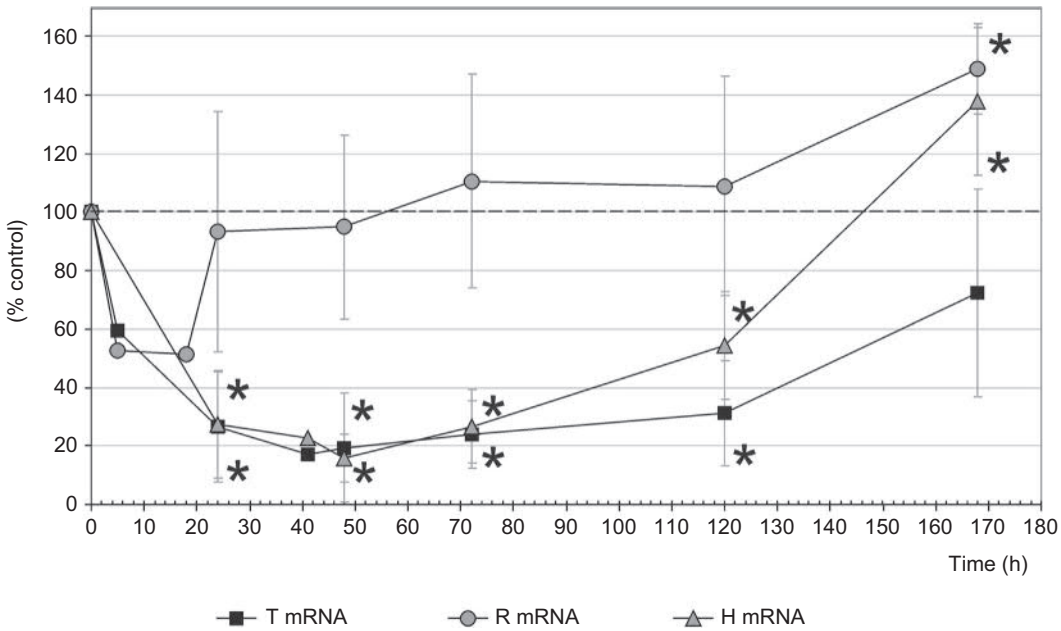

FIGURE 49.8 Relative changes of AChE-H, AChE-R, and AChE-T mRNAs in human myoblasts during the first week after siRNA application. Q-PCR with TaqMan chemistry was used for mRNA measurements. AChE mRNA levels were standardized to GAPDH mRNA. Each point represents the mean (± SD) of five separate siRNA experiments. In absolute terms, the levels of AChE-T mRNA were approximately 50 times higher than the levels of H and R. The differences vs. starting point (*) were statistically significant (Student *t* test, $P < .05$).

been reported in mouse brain after exposure to stress (Nijholt et al., 2004). However, under in vivo conditions, external factors not present in vitro could be responsible for changed expression of this mRNA. There have been several reports from the Soreq group in which AChE-R variant was specifically induced by various stressors (Cohen et al., 2003; Evron et al., 2007; Ofek et al., 2007; Grisaru et al., 2006; Shapira-Lichter et al., 2008; Shaltiel et al., 2013). However, we do not know whether our results obtained in an artificial environment in which systemic stress response is absent are related to these findings. In any case, R-species represent only a very small fraction of AChE mRNA, and it is not known whether it is translated. It might belong to the nontranslational RNAs, the role of which has recently been reported in various biological systems. No significant changes in the levels of any of the three AChE mRNA species could be observed at any of the developmental stages of human muscle after treatment with DFP, suggesting that OPs have no direct influence on AChE expression at the mRNA level in human muscle during the regeneration process.

49.4.2 The role of AChE in myoblast apoptosis

One of the frequently reported noncholinergic AChE functions is its participation in apoptosis. AChE was shown to be involved in regulation of apoptosis in different types of cells, including hematopoietic cells (Soreq et al., 1994), cultured smooth muscle cells, fibroblasts, endothelial cells and various cancer cells (Zhang et al., 2002), human neuroblastoma cells (Yang et al., 2002), and cultured human myoblasts (Pegan et al., 2010). Direct stimulation of apoptosis by AChE was noted in some cases (Toiber et al., 2008), but increased AChE expression per se is not necessarily sufficient to directly trigger apoptosis. Thus, AChE most likely promotes apoptosis primarily in conjunction with other apoptotic stimuli (Zhang and Greenberg, 2012), such as staurosporine (Pegan et al., 2010).

AChE may promote apoptosis by hydrolyzing ACh, which would tend to decrease prosurvival cholinergic signaling via nicotinic AChR and/or muscarinic AChR (Wessler and Kirkpatrick, 2008). Consistent with this notion, AChE inhibitors tacrine and physostigmine decreased apoptosis of fibroblasts (Zhang et al., 2002). In contrast, AChE inhibitors did not prevent apoptosis of Jurkat cells (Huang et al., 2005). Further, the C-terminal fragment of AChE (Day and Greenfield, 2004) as well as AChE that lacks cholinesterase activity both promote apoptosis (Du et al., 2015), indicating that the catalytic and proapoptotic activity are likely two separate functions of AChE. As for the molecular mechanism underlying these effects, there is evidence that AChE participates in apoptosome formation (Park et al., 2004, 2008) and that the AChE-T splice variant possesses DNase activity (Du et al., 2015). Inhibitors of AChE or mutations of the catalytic triad residues (S234A, E365A, and H478A) abolish

cholinesterase activity but not DNase activity of AChE (Du et al., 2015). Thus, pharmacological inhibitors of AChE may reduce apoptosis via conformational changes, which subsequently suppress proapoptotic activity of AChE, and not by inhibiting cholinesterase activity per se (Toiber et al., 2008). Taken together, while more detailed characterization of molecular mechanisms is clearly required, current evidence supports involvement of AChE in modulation of apoptosis (Zhang and Greenberg, 2012; Campoy et al., 2016).

AChE is expressed in proliferating myoblasts (Grubic et al., 1995), although these cells are deficient in most other components of the cholinergic system. To investigate if early AChE expression in myoblasts reflects its role in the development of the apoptotic apparatus, we followed the effect of siRNA-mediated AChE silencing on the apoptotic markers after staurosporine-induced apoptosis in cultured human myoblasts. We found that siRNA-mediated silencing of AChE in primary human myoblasts reduced staurosporine-induced activity of the initiator caspase 9 and the executioner caspase 3/7 (Pegan et al., 2010). AChE silencing reduced the fraction of apoptotic myoblasts as assessed with annexin V/propidium-iodide and 3,3-dihexyloxacarbocyanine iodide [DiOC6 (3)] staining, which confirmed AChE involvement in apoptosis of myoblasts (Pegan et al., 2010). In most cells which play no role in cholinergic transmission AChE is expressed only once these cells enter apoptosis (Zhang et al., 2002). In contrast, AChE is prominently expressed (Grubic et al., 1995) and active in proliferating myoblasts (Figs. 49.7 and 49.8) as well as in mature myofibers. Involvement of AChE in termination of neuromuscular transmission as well as apoptosis of myogenic precursors suggests these biological functions might be regulated by maintenance of different AChE pools. To regulate apoptosis, AChE should be localized in cytoplasm or nucleus, which is indeed the case in cultured myoblasts (Grubic et al., 1995). We may therefore speculate that in the apoptotic myoblasts AChE is diverted from the secretory route by which it is normally delivered to the extracellular space, to nucleus, cytoplasm, or other subcellular compartments, where it modulates apoptotic pathways. For instance, AChE may translocate into the nuclei of apoptotic cells and contribute to DNA degradation (Du et al., 2015).

49.5 Concluding remarks and future directions

Myopathies are a typical consequence of OP poisoning (Dettbarn et al., 2001, 2006). They might be additionally complicated by reduced efficiency of muscle regeneration. Our findings demonstrate that various intracellular mechanisms are influenced by exposure of precursors of muscle regeneration to DFP. Our experiments revealed reduced IL-6 secretion after DFP treatment, which might hamper myoblast proliferation and the efficiency of muscle regeneration. Increased levels of Hsps in DFP-treated myoblasts suggest that cellular response to stress is induced after DFP treatment. The increased level of HIF-1α after exposure to hypoxia shows that adaptation mechanisms against hypoxia are also organized during the early stages of muscle regeneration, while the apoptotic mechanisms in myoblasts apparently remained unchanged. We also demonstrated the role of AChE in apoptosis. As it has been demonstrated that AChE mutants lacking catalytic activity still participate in apoptosis it is possible that conformational changes of AChE induced by OP binding rather than inhibition of its catalytic activity are responsible for the OP effects on apoptosis. Whether such mechanisms affect muscle regeneration remains to be established.

50.1 Introduction and background

Since the mid-20th century (Ellenbroek and Youn, 2016; Shimoyama et al., 2016), the rat, *Rattus norvegicus*, has remained one of the most popular species for laboratory studies. The central nervous system disturbances, renal and intestinal diseases, proteomics and metabolomics, sports medicine, effects of toxic and pharmacological preparations and nutraceuticals, are some of the scientific areas in which use of rats is indispensable (Barker-Haliski et al., 2017; Ellenbroek and Youn, 2016; Korf et al., 2017; Mindukshev et al., 2017; Singh et al., 2017; Sobolev et al., 2017; Ukolov et al., 2017). In toxicology, particularly in studying the action mechanisms of organophosphate (OP) toxic agents and in developing novel antidotal therapies, a major biochemical feature of rats that has to be considered is the presence of carboxylesterase (CE) activity in blood plasma. Mammalian carboxylesterases (EC 3.1.1.1) belong to a multigene superfamily with wide substrate specificity, being able to catalyze hydrolysis of esters, thioesters, amide-containing xenobiotics, and endogenous compounds, including fatty acid esters (Barker-Haliski et al., 2017; Hatfield et al., 2016). In contrast to rodents and lagomorphs, blood plasma of humans, monkeys, and hollow-horned artiodactyls does not contain CE (Lian et al., 2018). However, esterase activity is intrinsic to human serum albumin, the catalytic characteristics of which are far removed from those of rat and bovine serum albumins (Goncharov et al., 2015, 2017b; Li et al., 2005). Suppression of CE activity in rodent blood plasma can greatly increase the adequacy of experimental models in studying the action mechanisms of, and for developing novel antidotes against, highly toxic OPs such as soman, sarin, tabun, and paraoxon (Goncharov et al., 2017a; Maxwell et al., 1987; Maxwell, 1992). For these purposes, ES1 knockout mice (ES1−/−) are often used (Duysen et al., 2012). Knockout rats, however, have not yet been bred due to the complex and expensive technology involved. Use of specific CE inhibitors is a simpler and more reasonable approach, but has only been applied on a very limited scale. Consequently, the dynamics of long-term effects of acute OP poisoning against the background of suppressed rat plasma CE activity remained virtually unstudied. Moreover, even without preliminary suppression of CE activity, the consequences of acute OP poisoning have generally been studied over limited time intervals and using a limited list of indices (Duysen et al., 2011). Previously, we explored the dynamics of CE activity and some other biochemical and hematological blood indices at different times, from 3 h to 6 weeks, after acute soman or VX poisoning (Garnyuk et al., 2012; Flannery et al., 2016). The peculiarity of that series of experiments was injection of OP twice with a dose of $0.4LD_{50}$ at a 1-h interval. The first injection was aimed at partially suppressing rat plasma CE to allow the second injection to predominantly affect cholinesterases (ChE) in blood and synapses. A disadvantage of this model is the low selectivity of highly toxic OPs towards CE, especially considering that VX does not interact with CE at all (Maxwell, 1992). The aim of our recent studies was to carry out a comparative biochemical analysis of experimental models for investigating the long-term effects of acute OP poisoning with paraoxon (POX) and one of the selective CE inhibitors, 2-(*o*-crezyl)-4H-1:3:2-benzodioxaphosphorin-2-oxide (CBDP) (Shmurak et al., 2012).

Handbook of Toxicology of Chemical Warfare Agents. DOI: https://doi.org/10.1016/B978-0-12-819090-6.00050-7

50.2 Experimental procedures

Toxicological and biochemical studies were carried out on male outbred Wistar rats, *R. norvegicus*, weighing 200 − 240 g. Animals were kept in a vivarium at 20°C − 22°C, humidity ≤ 50%, and air exchange volumes (outdraught: inflow) of 8:10, under 12 h/12 h day/night light regime, in standard plastic cages with dust-free rat litter (PFLANZENFASER REHOFIX MK. 3500). Animals were given ad libitum access to water and standard lab chow pellets. Intact animals (negative control) received no injections and were kept in separate cages holding four rats each. Animals of a positive control were injected subcutaneously (s.c.) with a physiological solution instead of POX and kept in the same cage as their poisoned counterparts: a single positive control rat per three experimental ones. POX was injected to the withers' region (100 μL/100 g body weight) twice at a 1 h interval (POX2x, doses 0.45 + $0.6LD_{50}$), and in an hour after CBDP at a dose $0.6LD_{50}$ (CBPOX group). CBDP was injected intraperitoneally (i.p.) in the amount of 3.3 mg/kg. The indices were measure at 3, 24, and 72 h and at 1, 2, 4, 6, and 12 weeks after exposure. No less than six animals were taken for each time point.

Heparinized (50 IU/mL) blood was obtained after decapitation and centrifuged for 4 min at 1500 g. The plasma obtained was stored at −70°C until use. The following 27 biochemical markers were measured: whole-blood acetylcholinesterase (AChE), plasma cholinesterases (ChE), butyrylcholinesterase (BChE), plasma carboxylesterase (CE), paraoxonase 1 (PON1), alanine transaminase (ALT), albumin, total protein, glucose, D-3-hydroxybutyrate (3HB, beta-oxybutyric acid), triglycerides (TG), free fatty acids (FFA), glycerol, cholesterol, bile acids, high-density lipoproteins (HDL), low-density lipoproteins (LDL), lipase, iron, inorganic phosphate, alkaline phosphatase (ALP), urea, creatinine, calcium (Ca), uric acid (UA), amylase, and orosomucoid (alpha-1-acid glycoprotein, AAG).

Whole-blood AChE and plasma ChE activities were assayed by the Ellman method in its microplate modification (Prokofieva et al., 2010, 2012). Absorption was measured at 412 nm on a microplate spectrophotometer ThermoMultiscan FC (USA). Blood plasma biochemical analyses were carried out after defrosting on an automated biochemical analyzer Sapphire 400 (Japan) using commercial kits according to the manufacturer's recommendations. CE and PON1 activities were determined by nitrophenol output during paraoxon hydrolysis, according to Phuntuwate et al. (2005).

Software packages SciPy, NumPy, Pandas (McKinney, 2010; Pérez and Granger, 2007; Van Der Walt et al., 2011), Matplotlib, Seaborn, and Scikit-Posthocs (Hunter, 2007) were used, as well as the Kruskal-Wallis nonparametric test followed by the Conover test with Benjamini-Hochberg *p*-value corrections (Benjamini, and Hochberg, 1995). Data are presented as means ± SEM.

50.3 Toxicological data

The following basic POX toxicometric indices were established for male rats after a single s.c. injection: $LD_{16} = 241$, $LD_{50} = 250$, $LD_{84} = 259$ μg/kg. In a series of individual experiments we selected equitoxic POX and CBDP doses at 110 and 3.3 μg/kg, respectively. The objective was to select a CBDP dose that would not inhibit whole-blood AChE. It was established that 1 h after injection of POX (110 μg/kg) or CBDP (4 mg/kg) whole-blood AChE activity decreased more than twofold, while CBDP at 3.3 mg/kg and below did not inhibit AChE and BChE activities at all. After injections of POX (110 μg/kg + X) or CBDP + POX, repeated twice at a 1 h interval, the second POX dose required to achieve LD_{50} was established to be 165 μg/kg, that is, CBDP injection increased rat sensitivity to POX by approximately one third. This finding disagrees with other authors' data (Maxwell, 1992), which indicate that preliminary injection of rats with CBDP (2 mg/kg) increases sensitivity to POX twofold. The different method of CBDP injection, subcutaneous in previous experiments (Maxwell, 1992) or intraperitoneal in our hands, is the likely main cause of the differences in doses and the degree of sensitivity increase. A double POX poisoning of rats at doses of 110 and 150 μg/kg (0.45 and $0.6LD_{50}$; POX2x group) or POX injection at a dose of 150 μg/kg at 1 h after CBDP injection at a dose of 3.3 mg/kg (CBPOX group), did not lead to death of animals but induced clinical manifestations of cholinergic crisis, which is typical of the effect of nerve agents with the subsequent development of delayed pathologies. The latter is of great theoretical and practical value because the mechanisms underlying the development of consequences of acute poisoning are not yet clear.

50.4 Biochemical data

50.4.1 Cholinesterases

Among the above biochemical indices suitable for diagnostic purposes within the first hours and days after OP poisoning, the most sensitive is whole-blood AChE activity, which declined by almost an order of magnitude in both experimental groups by 3 h after poisoning (Fig. 50.1). It was 2 − 2.5-fold and 1.5 − 2-fold lower than in the control after 1 and 3 days, respectively, being restored within a week up to the negative control level but still remaining 20% − 30% lower than the positive

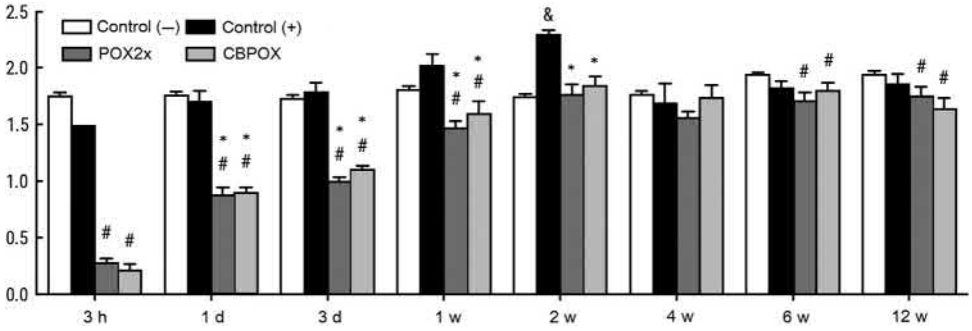

FIGURE 50.1 Activity dynamics of whole-blood acetylcholinesterase in control and experimental groups. *X*-axis (in this and other figures): time after poisoning, *Y*-axis: AChE activity (μmol/min/g Hb). Notes to Figs. 50.1 – 50.9: *, significant differences between experimental and positive control groups; #, significant differences between experimental and negative control groups; $, significant differences between experimental groups; &, significant differences between positive and negative control groups.

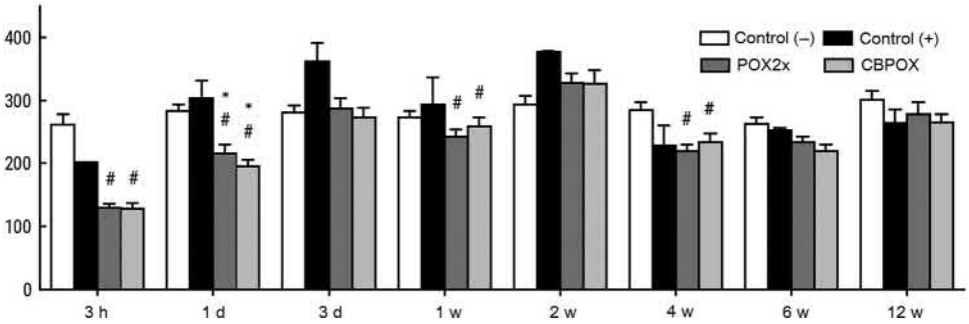

FIGURE 50.2 Activity dynamics of blood plasma butyrylcholinesterase in control and experimental groups. *Y*-axis: BChE activity (IU/L).

control level, which was slightly increased in activity compared to the negative control. The obtained data may indicate the influence of psychic stress in the positive control animals on the whole-blood AChE level. In this regard, it is worth mentioning a positive correlation described in the literature between human plasma ChE activities and human age, body mass index (BMI), stress level, inflammatory processes, and neurodegenerative diseases (Das, 2007; Dong et al., 2017; Reale et al., 2018; Shields et al., 2017; Sklan et al., 2004; Thayer and Sternberg, 2010). A complete restoration of AChE activity was registered at 2 weeks after poisoning, although increased AChE activity was still detected in the positive control group. This dynamic of AChE in the poisoned animals is more comparable with the changes we revealed after rat poisoning with soman (60% restoration in a week) than those with the V-type (VX) compound (complete restoration in a week) (Shmurak et al., 2012).

Both the amount and activity of plasma or serum BChE in rats are about 20-fold lower than in humans, and after OP poisoning the decrease was relatively low compared to that seen for AChE and restored completely by day 3 (Fig. 50.2). Total activity of rat plasma ChE was also decreased by twofold at 3 h after poisoning, but completely restored by the end of week 1; this could be explained by a higher rat plasma level of AChE compared to that of BChE (Goncharov et al., 2017a; Kurdyukov et al., 2012).

50.4.2 Carboxylesterase

Plasma CE activity decreased by three- and fourfold in POX2x and CBPOX groups, respectively (Fig. 50.3). Relative to the negative control, activity was restored by day 3, but in the positive control group it had increased by 15% – 20% in both the 1- and 3-day samples. Later, a steady trend was observed toward increasing level of CE activity in the positive control, POX2x and CBPOX groups, especially in 2-, 4-, and 6-week samples, reverting to the normal level in the 3-month sample. Differences were significant for each of the two experimental groups relative to the negative control after 2 weeks, but after 4 weeks a significant difference was only revealed for the POX2x group; after 6 weeks statistically significant deviations from the negative control were observed not only for experimental groups but also for the positive control group (Fig. 50.3). A foremost explanation of these findings could be that CE is one of the acute-phase proteins; to prove or reject this, one should study expression of the respective ES1 gene. An alternative explanation

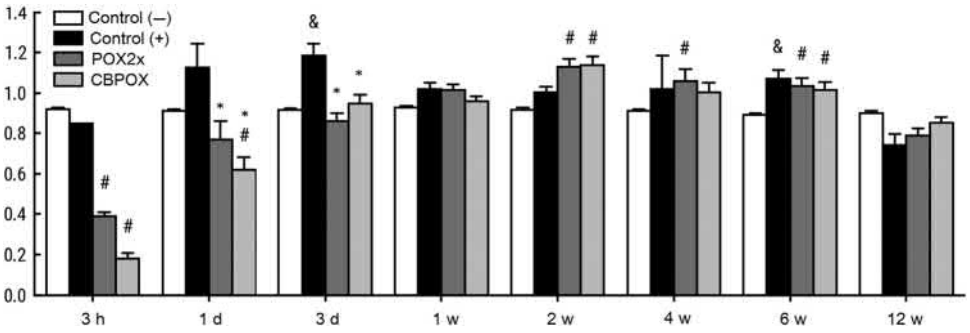

FIGURE 50.3 Activity dynamics of blood plasma carboxylesterase in control and experimental groups. *Y*-axis: CE activity (μmol NPA/min/mL).

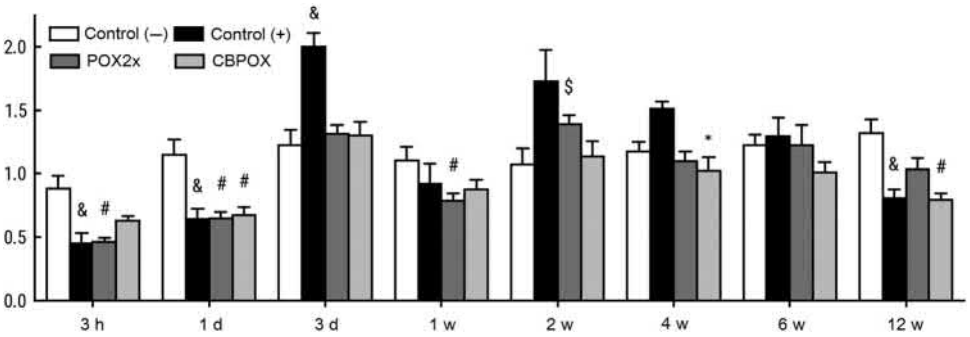

FIGURE 50.4 Activity dynamics of blood plasma level of triglycerides in control and experimental groups. *Y*-axis: TG concentration (mmol/L).

could be an affliction of the vascular endothelium and/or liver, where CES1 gene-encoded CE abounds along with the known tissue-specific markers (Orcholski et al., 2017). PON1 exhibited increased activity in 3-day, 2- and 4-week samples, and decreased activity 6 weeks after the poisoning, but only compared to the negative control group since measurements in the positive control group showed considerable deviations from the background activity unidirectional with those of the experimental groups. PON1 is a component of HDL, the level of which was increased in the intoxicated animals in 3-h and 1-day samples relative to the negative control, and decreased in both control groups by 3 days and 3 months after the poisoning. Moreover, the experimental groups exhibited an increased LDL level in the 3-month sample ($P < .01$).

50.4.3 Carbohydrate and fat metabolism

The indices of carbohydrate and fat metabolism were found to change at different time points after the poisoning, not only in experimental groups but also in the positive control group, with phasic changes evident for some indices. For example, at 3 h and 1 day, the TG levels were decreased almost twofold in three of the groups relative to intact animals; by day 3, it was restored in the poisoned animals, and exceeded the initial level 1.5 − 2-fold in the positive control group; then, the TG level showed some decrease by week 1 followed by an increase by week 2 and almost complete restoration by week 4 after poisoning (Fig. 50.4). The FFA levels also underwent phasic changes, which were most pronounced in the CBPOX group: an increase in 3 h, a decrease in 1 and 3 days, restoration in 1 week, a repeated decrease in 2 weeks, and the final restoration 4 weeks after the poisoning. Phasic changes in the glycerol levels were more pronounced in the CBPOX and, strange as it may seem, the positive control groups: an increase in 3 h and decrease in 1 day, then again, an increase in 3 days and decrease in 1 week, and the final return to initial level in 2 weeks. However, the 3HB dynamics was only demonstrated by the groups of poisoned animals: a three- to fourfold increase after 3 h, decrease down to the control level in 1 day, the second increase two- to threefold in 3 days, the second return to control level in 1 week, and yet another increase in 6 weeks, but only in the CBPOX group. Since 3HB is the most specific indicator of ketosis, compared to acetone and acetoacetate, it is reasonable to assume that CBPOX animals (to a greater extent than POX2x ones) are characterized by impaired glucose utilization, increased gluconeogenesis from proteins and fatty acids, reduced muscle mass, and increased risk of developing the metabolic syndrome. In 3 h after the poisoning, α-amylase increased almost equally in the POX2x and CBPOX groups (by 20% − 30%), however, its activity tended to increase more explicitly in the CBPOX group, indicating greater pancreatic damage in the toxicogenic phase.

Phasic changes in the cholesterol level in the positive control group were nearly identical to those in the POX2x group, with some differences: the maximum for the positive control fell on the first day, while that for the POX2x group was on the third day; and the amplitude of fluctuations in the POX2x group was more pronounced, within a minimum of a week after the poisoning. The levels of cholesterol in these groups came to the level of the negative control in just 4 weeks. The dynamics of cholesterol phasic changes in the CBPOX group was not as explicit, though it should be mentioned that the maximum fell on the third hour and the minimum on the sixth week after the poisoning ($P < .05$)! A decreased cholesterol level is known to be as harmful for an organism as an elevated one, being a risk factor for hemorrhagic stroke and unfavorable outcome of cardiac infarction and ischemic stroke (Iso et al., 1989; Markaki et al., 2014; Suzuki et al., 2011; Vauthey et al., 2000; Zhao et al., 2016; Zhou et al., 2016); moreover, a very low cholesterol level can promote the development of neurodegenerative diseases (Ferris et al., 2017; Fukui et al., 2015). The revealed metabolic disorders do not rule out that OP poisoning can lead to a delayed development of the hypometabolic status, which may manifest itself as neurodegenerative disorders, such as Alzheimer's disease (Landin et al., 1993).

50.4.4 Liver and kidney damage

The signs of liver damage were manifested most distinctly in the CBPOX group: a twofold increase in the ALT level in 3 h and 1 day after the poisoning (Fig. 50.5). In the POX2x group, changes were less pronounced: ALT increased by 20% − 30% at 3 h and twofold at 1 day. A complete reduction of the ALT level in POX2x and CBPOX groups occurred in a week, but in 4 weeks the ALT level had increased again by 10% − 20% in the poisoned animals (Fig. 50.5). Albumin and total protein were reduced insignificantly (by 5% − 10%) in 3 h, but a positive acute-phase protein AAG (orosomucoid) was increased almost threefold at 1 day after the poisoning (Fig. 50.6), reflecting a development of inflammatory processes. It should be pointed out that later the AAG level tended to increase relative to the negative control not only in the intoxicated rats, but also in the positive control group. Moreover, at some time points (1 and 2 weeks) this AAG increase in the positive control group was even more pronounced than that in the poisoned rats, reverting to the normal level in 3 months.

Kidney damage is indicated by the creatinine, urea, and uric acid biochemical indices. In the CBPOX group, the creatinine level was elevated by 35% − 40% at 3 h ($P < .05$) relative to both controls, while the urea level was increased by 20% − 30% at 1 and 2 weeks ($P < .05$), and relative to the negative control only. Previously, we detected very similar elevations of the creatinine level at 4 and 6 weeks after soman poisoning, and of the urea level at 4 and 6 weeks after poisoning with RVX and soman, respectively (Shmurak et al., 2012). Uric acid was one of the few indices for which the level changed significantly in our experiments exclusively in the POX2x group, by 20% − 40% at 1 day and 1 week. Since up to 80% of UA are excreted by the kidneys, this index provides additional evidence of kidney damage after acute OP poisoning. Besides, we detected an almost synchronous elevation in the levels of calcium ions and inorganic phosphate, as well as of ALP activity in rats of the CBPOX group in 3 h after the poisoning (Figs. 50.7 and 50.8). A simultaneous elevation in calcium and phosphate levels indicates intensified catabolic processes in tissues, including those under ketoacidosis, and renal dysfunction (Marshall et al., 2016). Considering increased creatinine, urea, and UA in blood plasma and increased glycosaminoglycans in urine (Sobolev et al., 2017), we view kidney damage as an integral component of cholinergic crisis consequences. Of particular note is a decrease in ALP activity that occurred 3 months after the poisoning for the three groups relative to the negative control, alongside an increase in the calcium levels in the same groups (Fig. 50.9). A combination of these characters may indicate hypomineralization of skeletal bones and even a development of the epileptic status (Buchet et al., 2013), as supported by the data from neurophysiological and

toxicological studies (Deshpande et al., 2016a,b). In addition, a reduced ALP hydrolytic activity relative to ATP, a physiological P2X7 receptor agonist, determines enhanced activation of these receptors and, as a result, decreased axonal growth rate (Sebastián-Serrano et al., 2014).

50.5 Concluding remarks and future directions

An important outcome of this study is the detection of statistically significant changes in a numerous number of biochemical indices in the positive control rats, which were permanently associated with the poisoned rats, relative to the negative control rats that were kept in isolated cages. Maximal differences were established in the dynamics of fat metabolism: a decreased TG level at 3 and 24 h was, nonetheless, elevated by 1.5 − 2-fold at 3 days and 2 weeks after the poisoning (Fig. 50.4). Elevation of cholesterol by 20% was evident in 1 day, while a reduction to the negative control level occurred in 4 weeks. However, the FFA level, being reduced in the positive control rats in 1 day after the poisoning by about 20%, later did not undergo any considerable changes relative to the negative control group.

We noted an increase in the AAG and a decrease in the albumin levels in the positive control rats 3 h after the poisoning. Interestingly, in these rats, maximally elevated BChE and AChE whole-blood levels also fell on the second week (Figs. 50.1 and 50.2). Blood plasma and hence whole blood in rats and mice, in contrast to human blood plasma, contains an appreciable amount of AChE [ca. 200 μg/L (Li et al., 2005)], with the plasma BChE level in rats being lower than that of AChE. As mentioned above and in a number of publications, plasma BChE and AChE were shown to be markers of low-level inflammatory processes (Das, 2007). It is also worth noting that there is a correlation between increased BChE activity, TG level, and decreased insulin sensitivity in patients with type 2 diabetes mellitus (Abbott et al., 1993). Our present data suggest a considerable metabolic impairment in the positive control rats that occurs within 2 weeks after the poisoning, evidently due to the stressful conditions. An analogous phenomenon has been reported in a study by Flannery et al. (2016), namely the development of neuroinflammatory processes in the CNS and the attenuation of cognitive functions in rats after acute OP poisoning; notably, these pathologies were expressed more or less equally in animals both with maximal and minimal manifestations of intoxication. Large-scale changes in the positive control rats relative to the negative controls are presented here for the first time. It appears that the state of anxiety and stress in rats is powerful enough to generate an additive or synergic effect with regard to numerous physiological and biochemical indices. This phenomenon deserves focused investigation in the future.

Chapter 51

Alternative animal toxicity testing of chemical warfare agents

Gopala Krishna[1], Saryu Goel[2] and Mayur Krishna[1]
[1]Expert Consultants, Ellicott City, MD, United States, [2]Expert Consultants, Leesburg, VA, United States

51.1 Introduction

Chemical warfare agents have been in existence for centuries. They are substances which have toxic properties used to kill, injure, or incapacitate humans. Broadly, they are categorized into two groups: chemical or biological.

1. Chemical warfare agents use poisons that kill, injure, or incapacitate. These can be gases or liquids and are more commonly dispersed as aerosols.
2. Biological warfare agents use living organisms such as bacteria (e.g., *Bacillus anthracis*, the causative agent of anthrax) or viruses (e.g., Variolae, the virus that causes smallpox).

Further, these warfare agents have been subdivided into multiple classes in the public domain. These include choking gases and lung irritants, blister agents (vesicants), blood agents, nerve agents, incapacitants and psychoactive chemicals, harassing or riot-control agents, vomiting agents, herbicides, Napalm, and obscurant smoke and masking agents. The main routes of entry of these substances include inhalation, ingestion, injection, and absorption.

The US Food and Drug Administration (FDA), in collaboration with the US Department of Defense (DOD), continues to support the US military and the nation's counterterrorism efforts. The FDA has helped make critical medical products available for combat readiness so that armed forces are better equipped for combat. It has helped US Special Forces obtain medical products for airborne hospitals used in evacuating battlefield casualties. The FDA has provided consultation and review to help make investigational and licensed medical products such as vaccines and drugs available to combat forces. In developing such warfare agents for counterterrorism, extensive testing for their efficacy and safety is required, especially in animals and humans. A schematic diagram showing the effects of warfare agents and use of the 3Rs concept is shown in Fig. 51.1. The agreement on Mutual Acceptance of Data (MAD; www.oecd.org/chemicalsafety/testing/mutualacceptanceofdata-mad.htm) eliminated the need for duplication of tests in each country before approval or banning of a substance within Organization for Economic Co-operation and Development (OECD) countries, thus reducing animal use.

It is noted that animal testing is highly controversial and has become an emotional issue in recent years (Krishna, 2010; SOT, 2013a,b). Keeping the focus of this chapter in mind, the testing of chemical warfare agents in humans is not practical and is considered unethical, especially at toxic doses. To address this issue, it is important to understand and recognize the growing impact of alternatives to animal and/or human testing. These methods include in vitro toxicity, metabolism, and efficacy/potency testing in a variety of scenarios.

Anadon et al. (2013) highlighted the value of in vitro testing in science. They stated that there is a correlation between toxicological data from in vivo animal studies and in vitro assays. They proposed an integrated in vitro testing strategy by taking into consideration the following: exposure modeling of chemical agents for in vitro testing; data gathering, sharing and read-across for testing a class of chemical; a battery of tests to assemble a broad spectrum of data on different mechanisms of action to predict toxic effects; applicability of the test and the integrated in vitro testing strategies and flexibility to adjust the integrated in vitro testing strategies to test substances (Goldberg and Frazier, 1989; Hartung, 2011; Hartung et al., 2013). However, they emphasize validating in vitro

FIGURE 51.1 Alternative concept of warfare testing.

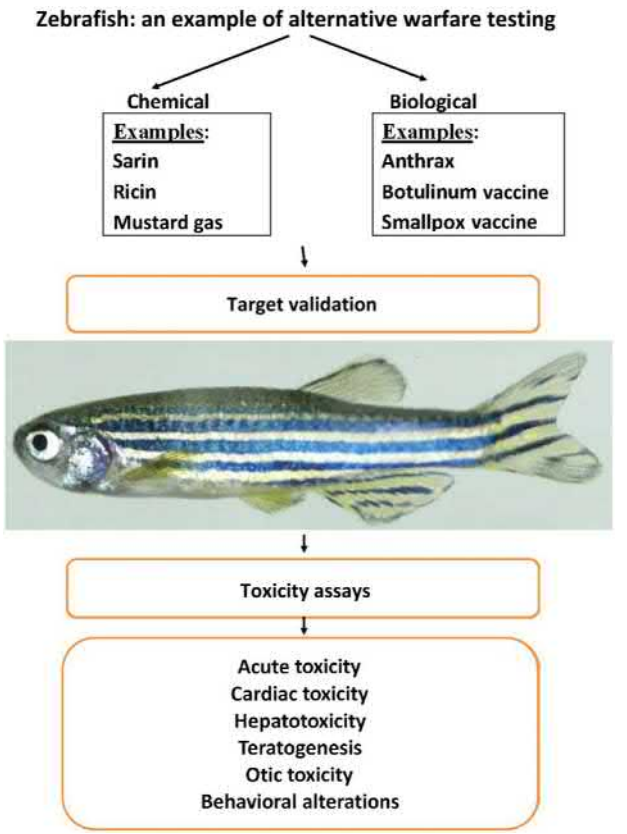

FIGURE 51.2 Zebrafish as an alternative animal model in warfare testing.

systems to ensure reliability and suitability for humans, thus, the data can be invaluable and effective. Schechtman (2002) reviewed the implementation of the 3Rs (refinement, reduction, and replacement) and validation and regulatory acceptance considerations for alternative toxicological test methods and suggested pros and cons of in vitro testing.

Animal testing is an essential part of basic research, especially in inventing and developing effective chemical warfare. Animal testing is defined as the use of nonhumans, such as vertebrate and nonvertebrate animals or organisms, in scientific experimentation in search of answers for the good of mankind and the pursuit of basic knowledge (Krishna et al., 2014). Vertebrate animals ranging from zebrafish to nonhuman primates are commonly used worldwide. However, their use is heavily regulated. An example of a zebrafish testing strategy is shown in Fig. 51.2. More recently, the zebrafish has been identified as an important vertebrate model for studying the development of embryos and pathogenesis of human diseases (Lieschke and Currie, 2007). When compared with mammalian models, experimental results show that zebrafish embryos exhibit similar responses to test agents (Hill et al., 2005). This suggests that the zebrafish model can be used as a bridge between in vitro and in vivo models in the toxicity screening process.

Similarly, invertebrates such as fruit flies (*Drosophila*) and earthworms are also commonly used in research, where applicable, but their use is excluded from the regulations. Around the globe, animal testing is conducted under strict regulatory guidelines which set fundamental standards for the humane use of animals for training, experimentation, biological testing, or other related purposes. These regulations and guidelines require minimizing harm to animals through the 3Rs: reduction, refinement, and replacement, as initially described by Russell and Burch (1959), searching for alternatives including consideration for hierarchical use of species and in vitro methods.

In this chapter, a brief history of chemical warfare use in humans, their classification, use of alternative methods of animal testing, in particular, in vitro toxicology tests, structure–activity relationships, the use of 3Rs including the "Animal Rule" (FDA 2009, 2010) and "human-on-a-chip" to possibly test warfare agents are described.

51.2 Brief history of chemical warfare use

- Poisonous agents have been used as tools of war for thousands of years, even as early as 600 BCE, for example, poisoned arrows, boiling tar, arsenic smoke, and noxious fumes, etc. (www.opcw.org/about-chemical-weapons/history-of-cw-use/).
- In the 1900s, modern chemical warfare began on the battlefields of World War I. Chlorine and phosgene gases were released from canisters on the battlefield and dispersed by wind. The first large-scale attack with chlorine gas occurred on April 22, 1915, at Ypres in Belgium.
- The use of several different types of chemical weapons, including mustard gas (yperite), resulted in 90,000 deaths and over one million casualties during the war. Those injured in chemical warfare suffered from the effects for the rest of their lives; thus the events at Ypres during World War I scarred a generation. By the end of World War I, 124,000 metric tons of chemical agent had been expended. The means of delivery for chemical agents evolved over the first half of the 20th century, increasing these weapons' already frightening capacity to kill and maim through the development of chemical munitions in the form of artillery shells, mortar projectiles, aerial bombs, spray tanks, and landmines.
- After witnessing the effects of such weapons in World War I, it appeared that few countries wanted to be the first to introduce even deadlier chemical weapons onto the World War II battlefields. However, preparations were made by many countries to retaliate in kind should chemical weapons be used in warfare. Chemical weapons were deployed on a large scale in almost all theaters in World Wars I and II, leaving behind a legacy of old and abandoned chemical weapons, which still present a problem for many countries.
- During the Cold War, the United States and the Soviet Union both maintained enormous stockpiles of chemical weapons, amounting to tens of thousands of metric tons. The amount of chemical weapons held by these two countries was enough to destroy much of the human and animal life on Earth.
- Iraq used chemical weapons in Iran during the war in the 1980s, and Iraq also used mustard gas and nerve agents against Kurdish residents of Halabja, in northern Iraq, in 1988.
- The two most recent examples of the use of chemical weapons are the sarin poisoning incident in Matsumoto, a Japanese residential community, in 1994, and the sarin attack on the Tokyo subway in 1995, both perpetrated by the Aum Shinrikyo doomsday cult. These two attacks refocused international attention on the potential use of chemical weapons by terrorists, and on the dangers posed by these chemical weapons.
- The devastating impact chemical weapons have had in the past, and the potential for the use of modern—even more deadly—chemical agents not only by states at war but in other violent conflicts and by nonstate actors, provide the imperative for an international effort to uphold the ban on such weapons and to work toward the complete, global elimination of chemical weapons.

51.3 Top five chemical warfare agents

It has been reported that sarin, ricin, mustard gas, agent 15, and chlorine gas are the top chemical warfare agents (www.livescience.com/39332-5-chemical-warfare-agents.html).

1. *Sarin* is a deadly toxic organophosphate compound with no color, taste, or odor. Though it is produced as a liquid, its low evaporation point allows it to turn into a gas quickly when exposed to the environment. Sarin, also known as GB by military personnel, was originally developed as a pesticide in Germany in 1938, but since then, it has been classified by many national governments as a chemical nerve agent. Nerve agents are the most toxic and fast-acting chemical warfare agents in the world. People exposed to large amounts of sarin quickly lose control over their bodily functions, and, if not treated immediately, can fall into a coma or succumb to respiratory failure.
2. *Ricin* is derived from a common plant, the castor bean (*Ricinus communis*), native to the Mediterranean and Middle East and cultivated elsewhere as an ornamental plant. It is also the source of castor oil, which has many uses in medicine, food, and industry. Ricin is also a highly potent toxin that can kill a person in amounts as small as a few grains of sand.
3. *Mustard gas*, or sulfur mustard ($(Cl\text{-}CH_2CH_2)2S$, is a chemical agent that causes severe burning of the skin, eyes, and respiratory tract. It can be absorbed into the body through inhalation, ingestion, or by contact with the skin or eyes. First used during World War I, the gas is effective at incapacitating its victims en masse. Sulfur mustard is generally colorless in its gaseous state, though it may have a faint yellow or green tint. It is easily recognized by its trademark "mustardy" odor, though some compare its smell to that of garlic, horseradish, or sulfur.
4. *Agent 15* is also called compound 3-quinuclidinyl benzilate, BZ or "Buzz." It is a powerful chemical warfare agent. As one of the most potent psychoactive chemical agents, only a small amount of BZ is needed to produce complete incapacitation. When used as an aerosol, BZ is absorbed through the respiratory system (it has no odor). It can also be absorbed through the

skin or the digestive system. It takes about an hour for BZ to take effect, and the symptoms of exposure include confusion, tremors, stupor, hallucinations, and coma, which can last for more than 2 days. Use of BZ was suspected in the Bosnian conflict in 1995. Similarly, in January 2013, Syrian government troops may have used Agent 15 on rebels.

5. *Chlorine gas* is another chemical agent with a history of use going over 100 years. During World War I, chlorine gas, sometimes known as bertholite, was used by the German army during the Second Battle of Ypres in Belgium. Because chlorine can be pressurized and cooled into a liquid, it can be easily shipped and stored in tanks. When released as a gas, chlorine stays close to the ground and spreads quickly, making it an ideal agent for warfare or terrorism. Though it is used less often today (because more lethal agents exist), chlorine is easy to manufacture and disguise, since it has many other civilian uses such as water sanitation. In 2007, chlorine gas bombs were used to kill dozens of people during the conflict in Iraq.

Toxicology of these warfare agents and many more have been elegantly described elsewhere in this book. Table 51.1 lists a variety of warfare agents. The focus of this chapter is alternatives to animal testing of such warfare agents. The tests mentioned and the strategies described might have to be optimized to suit such a test setting, depending on the type of warfare agent, whether it is liquid, solid, aerosol, or even a biological agent.

TABLE 51.1 Listing of multiple categories of chemical warfare agents.

Blood agents		
Name	**CAS number**	
Arsine	7784-42-1	
Cyanogen chloride	506-77-4	
Hydrogen cyanide	74-90-8	
Vomiting agents		
Name	**CAS number**	**Chemical name**
Adamsite	578-94-9	(10-Chloro-5,10-dihydrophenarsazine)
Diphenylchloroarsine	712-48-1	
Diphenylcyanoarsine	23525-22-6	
Nerve agents		
Name	**CAS number**	**Chemical name**
Cyclohexyl sarin	329-99-7	Cyclohexylmethylphosphonofluoridate
GE	1189-87-3	Phosphonofluoridic acid, ethyl-, 1-methylethyl ester
Sarin	107-44-8	Phosphonofluoridic acid, methyl-, 1-methylethyl ester
Soman	96-64-0	Phosphonofluoridic acid, methyl-, 1,2,2-trimethylpropyl ester
Tabun	77-81-6	Phosphoramidocyanidic acid, dimethyl-, ethyl ester
VE	1189-87-3	Phosphonofluoridic acid, ethyl-, 1-methylethyl ester
Amiton	78-53-5	Phosphorothioic acid, *S*-[2-(diethylamino)ethyl] *O*,*O*-diethyl ester
GV (also GP)	141102-74-1	Phosphoramidofluoridic acid, dimethyl-, 2-(dimethylamino)ethyl ester
VM	21770-86-5	Phosphonothioic acid, methyl-, *S*-[2-(diethylamino)ethyl] *O*-ethyl ester
VX	50782-69-9	Phosphonothioic acid, methyl-, *S*-[2-[bis(1-methylethyl)amino]ethyl] *O*-ethyl ester
Blister agents		
Name	**CAS number**	**Chemical name**
Mustard gas	505-60-2	Bis(2-chloroethyl) sulfide
Nitrogen mustard	0538-07-08	Bis(2-chloroethyl)ethylamine

(*Continued*)

TABLE 51.1 (Continued)

Blister agents

Name	CAS number	Chemical name
Nitrogen mustard	51-75-2	Bis(2-chloroethyl)methylamine
Nitrogen mustard	555-77-1	Tris(2-chloroethyl)amine
Phosgene oxime	1794-86-1	
2-Chloroethyl ethyl sulfide	0693-07-02	
Sesqui mustard	3563-36-8	1,2-Bis(2-chloroethylthio)ethane
Ethyldichloroarsine	598-14-1	
Lewisite	541-25-3	2-Chlorovinyldichloroarsine
Lewisite-2	40334-69-8	Bis(2-chlorovinyl)chloroarsine
Lewisite-3	40334-70-1	Arsine, tris(2-chloroethenyl)-
Methyldichloroarsine	593-89-5	Arsonous dichloride, methyl-
Mustard/lewisite		
Phenyldichloroarsine	696-28-6	Arsonous dichloride, phenyl-

Riot control/tear agents

Name	CAS number	Chemical name
Bromobenzylcyanide	16532-79-9	4-Bromophenylacetonitrile
Chloroacetophenone	532-27-4	
Chloropicrin	1976-06-02	
CNB		10% CN, 45% benzene, 45% carbon tetrachloride
Fentanyl	437-38-7	Propanamide, *N*-phenyl-*N*-[1-(2-phenylethyl)-4-piperidinyl]-
CNC		30% CN in chloroform
CNS		23% CN, 38% chloropicrin, 38.4% chloroform
Dibenz-(b,f)-1,4-oxazepine	0257-07-08	
O-Chlorobenzylidenemalononitrile	2698-41-1	CS1, CS2, CSX all have CS as agent

Pulmonary (choking) agents

Name	CAS number	Chemical name
Ammonia	7664-41-7	
Chlorine	7782-50-5	
Hydrogen chloride	7647-01-0	
Phosgene	75-44-5	
Diphosgene	503-38-8	Trichloroacetyl chloride
Titanium tetrachloride	7550-45-0	
Nitric oxide	10102-43-9	
Perflurorisobutylene	382-21-8	1,1,3,3,3-Pentafluoro-2-(trifluoromethyl)-1-propene
Red phosphorous	7723-14-0	
Sulfur trioxide-chlorosulfonic acid		(Smoke mixture)
Sulfur trioxide	7446-11-9	
Chlorosulfonic acid	7790-94-5	
Zinc oxide	1314-13-2	

(*Continued*)

TABLE 51.1 (Continued)

Pulmonary (choking) agents		
Name	**CAS number**	**Chemical name**
Agent 15 (similar to BZ)		
3-Quinuclidinyl benzilate	6581-06-2	3-Quinuclidinyl benzilate
Delta-9-THC	33086-25-8	Delta-9-tetrahydrocannabinol
China White	79704-88-4	alpha-Methylfentanyl
Fentanyl	437-38-7	Propanamide, *N*-phenyl-*N*-[1-(2-phenylethyl)-4-piperidinyl]-
LSD	50-37-3	D-Lysergic acid *N*,*N*-diethylamide
Phenothiazine	92-84-2	Phenothiazine
Thorazine	50-53-3	Chlorpromazine

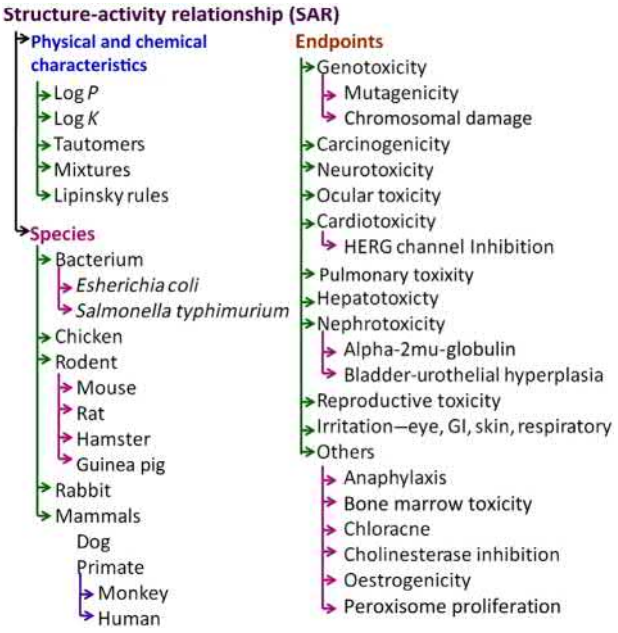

FIGURE 51.3 In silico endpoints commonly used to achieve 3Rs.

51.4 The concept of 3Rs

The concept 3Rs is further explained by the National Center for the Replacement, Reduction and Refinement of animals in research (NC3R, 2013; http://eslav-eclam.org/other-associations/nc3rs). These are a widely accepted ethical framework for conducting scientific experiments using animals humanely. These include:

- *Replacement*: Use methods that avoid or replace the use of animals defined as "protected" under the Animals (Scientific Procedures) Act 1986, amended 2012 (ASPA) in an area where they would otherwise have been used. "Protected" animals are all living vertebrates (other than man), including some immature forms, and cephalopods (e.g., octopus, squid, cuttlefish). This can be:
  - Absolute replacements—those which do not involve animals at any point;
  - Relative replacements—those which avoid or replace the use of "protected" animals.
  - Examples include:
    - Computer modeling, such as Lhasa (2014) (Fig. 51.3);
    - Human volunteers, for example, for noninvasive imaging studies;
    - Invertebrates, such as *Drosophila* (fruit fly) and nematode worms;
    - Immature forms of vertebrates: mammal, bird, and reptile embryos, up to the last third of their gestation or incubation period, larval forms of amphibians and fish, until the stage where they become capable of independent feeding, cephalopods until the point at which they hatch;
    - In vitro methodologies, utilizing established human or animal cell lines, animal cells, tissues, and organs from animals killed by a humane method, abattoir material from the meat industry (Figs. 51.4 and 51.5).
- *Reduction*: Use methods which minimize animal use and enable researchers to obtain comparable levels of information from fewer animals or to obtain more information from the same number of animals, thereby further reducing future use of animals.
  - Examples include:
    - Sharing data and resources, such as the MAD agreement;
    - Improved experimental design and statistical analysis;

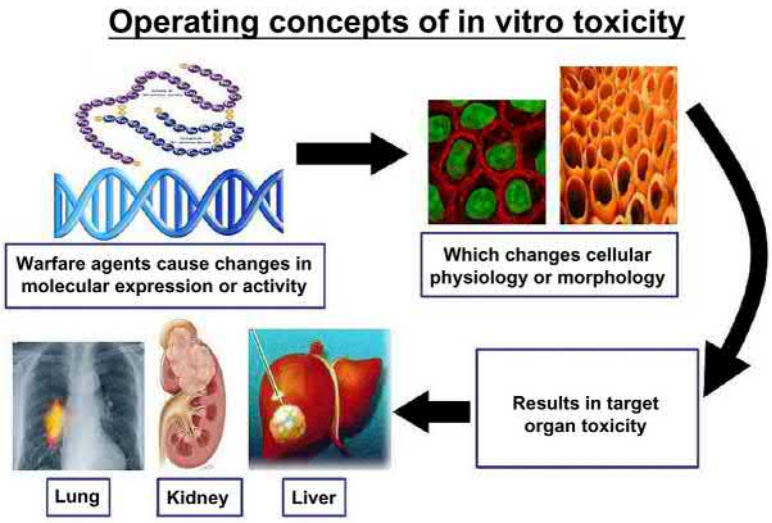

FIGURE 51.4 Warfare agents cause changes at the molecular level (DNA or protein), which are expressed at the cellular level, which in turn result in target organ toxicity (e.g., liver, kidney), which can be studied and extrapolated to whole animal or humans based on in vitro studies.

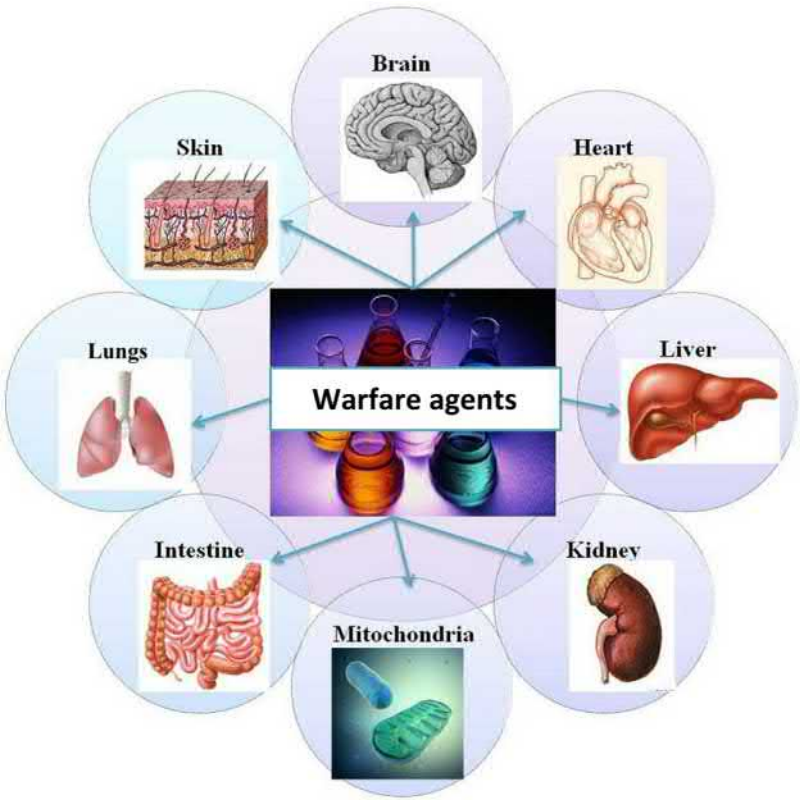

FIGURE 51.5 Warfare agents interact with various cells, organelles, and organ systems to produce their toxicological effects. These effects can now be studied using various in silico or in vitro tools minimizing the use of animal testing.

– Integrated genotoxicity testing using fewer animals and collecting most information. The concept of integrating toxicity assessment, where with fewer animals a variety of relevant toxicity data can be collected and evaluated (Krishna et al., 1994, 1995a,b, 1998, 2000; Fig. 51.6). As an example, an integrated in vivo genotoxicity testing philosophy and a practical approach, as applied to pharmaceuticals, is currently practiced and recommended by the International Conference on Harmonization (ICH) guidance (ICH, 2006). In this case, a rodent (primarily rat) micronucleus assay is integrated with routine 2- to 4-week repeat dose toxicity and toxicokinetic studies. This approach has several advantages: (1) it utilizes the general principles of toxicology that govern the overall toxicity

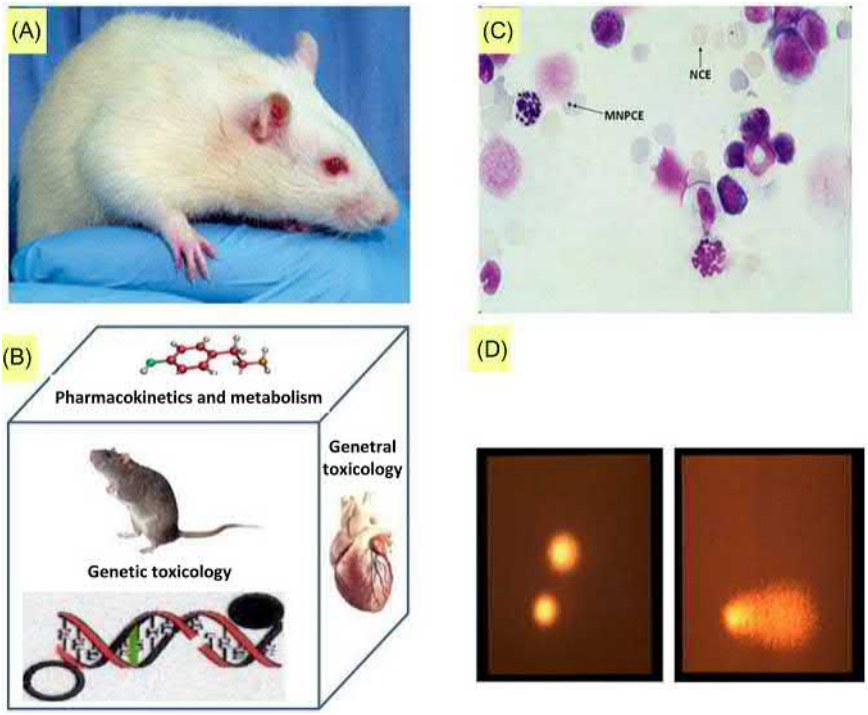

FIGURE 51.6 Integrated in vivo genotoxicity of warfare agents can be evaluated using samples obtained during the general toxicity study: (A) samples are obtained from the animal (e.g., rat), (B) the test agent is exposed to in vivo biochemical processes, including metabolism and opportunity to interact with the DNA, thereby providing an intact animal with homeostatic assessment of the genotoxic potential of test agent, and (C) the blood sample/bone marrow is obtained and stained to detect for the presence of micronuclei in polychromatic erythrocytes (PCE); if positive, then the test agent is considered as clastogenic. (D) Cells, particularly from the liver, are processed and tested for DNA strand breaks in the COMET assay. The breaks in the DNA are observed as a comet-shaped migration of DNA from the nucleus of the cell following gel electrophoresis in treated compared to intact round nucleus suggesting unaffected DNA (control).

profile of a test substance; (2) factors such as the dose and/or route of test agent administration, metabolism, principles of toxicokinetics, and saturation of defense mechanisms are considered in evaluating genotoxicity; (3) it uses the concept of administering multiple tolerable doses aiding in achieving steady-state plasma test agent levels, which is more relevant for risk assessment compared to high acute doses; and (4) it helps minimize the amount of test agent, number of animals used, and other resources. This integration approach can be extended to other toxicology studies and other relevant genotoxicity endpoints may be assessed. Based on experience reported in the literature, integrating micronucleus assessment in routine toxicology testing is promising and should be utilized when practical. A number of genotoxicity endpoints can be easily evaluated in peripheral blood lymphocytes of exposed subjects by genetic monitoring.

- Modern imaging techniques
  - Noninvasive, whole-body imaging of small animals using techniques such as X-ray, CT, SPECT, PET, and MRI, is helping to reduce the number of animals used in basic research and testing of chemical warfare agents. Fig. 51.7 illustrates such an example. The same animal can be imaged multiple times in order to monitor visually, often in real time, the progression or regression of infection or disease. This avoids the need to sequentially sacrifice animals at different time points, allowing significant reductions in the number of animals used per study.
- *Refinement*: Use improvements to scientific procedures and husbandry which minimizes actual or potential pain, suffering, distress, or lasting harm and/or improves animal welfare in situations where the use of animals is unavoidable. Refinement applies to the lifetime experience of the animal. There is evidence that refinement not only benefits animals, but can also improve the quality of research findings. Fig. 51.8 shows a unique refinement of housing of mice.
  - Examples include:
    - Noninvasive techniques;
    - Appropriate anesthetic and analgesic regimens for pain relief;
    - Training animals to voluntarily cooperate with procedures (e.g., blood sampling) so that they have greater control over the procedure and are less stressed;
    - Accommodation and environmental enrichment which meets the animals' physical and behavioral needs (e.g., providing opportunities for nesting for rodents).

51.5 International cooperation on alternative test methods

In 2009, the United States, Canada, Japan, and the EU signed a memorandum of cooperation that could reduce

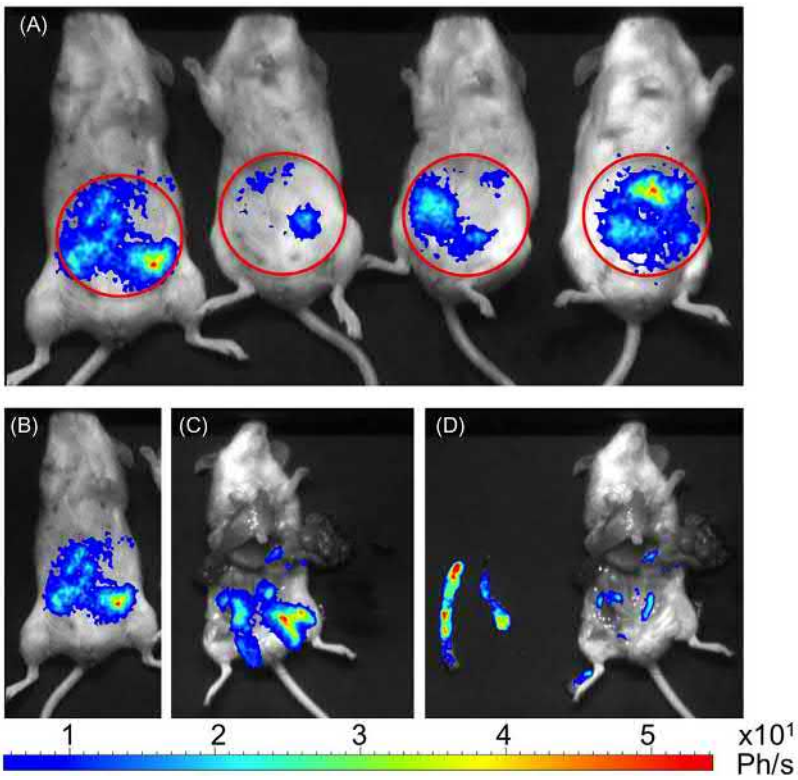

FIGURE 51.7 Localization of bioluminescent parasites in intraabdominal mesenteric fat in infected mice. Infection was monitored by bioluminescence imaging (BI) technique. On day 40 postinfection (A), mice showed intraperitoneal parasites localized by BI. One representative mouse (B) was dissected and the adipose tissue localization was verified in situ by BI (C) and confirmed after removing the adipose tissue and reimaging (D).

FIGURE 51.8 The "mouse house" is a refinement using a transparent, red, plastic house, which enables the mice to perform natural behaviors such as nesting, hiding, and climbing, which is important for their welfare. The house appears dark to the mice, yet the transparent walls allows the scientist to make observations without disturbance (www.scanbur.com).

the number of animals required for consumer product safety testing worldwide (International Cooperation on Alternative Test Methods [ICATM]; http://ntp.niehs.nih.gov/?objectid = 62A650A4-DD4B-D0A8-C26C7AE0A57F82E8). A similar approach can be used for evaluating chemical warfare agents. The agreement is hoped to yield globally coordinated scientific recommendations on alternative toxicity testing methods that should speed their adoption in each of these countries, thus reducing the number of animals needed for safety testing. A flowchart of this is shown in Fig. 51.9.

ICH: The International Conference on Harmonization of Technical Requirements for Registration of Pharmaceuticals for Human Use;

OECD: The Organization for Economic Cooperation and Development has a Test Guideline program that deals with chemicals;

ICCR: The International Cooperation on Cosmetics Regulation (ICCR) is an international group of cosmetic regulatory authorities from the United States (FDA), Japan (Ministry of Health, Labor, and Welfare), the EU (EC, DG Enterprise), and Canada (Health Canada). This multilateral framework maintains the highest level of global consumer protection, while minimizing barriers to international trade.

The alternative toxicology methods listed and suggested may be used for chemical warfare agents, as applicable. Nonanimal methods for toxicity testing currently being used are listed in Table 51.2. This was initially compiled by an organization called AltTox (2013), but was modified to serve the purposes of this chapter. These methods are also used by organizations such as Registration, Evaluation, Authorization and Restriction of Chemicals (REACH, 2013).

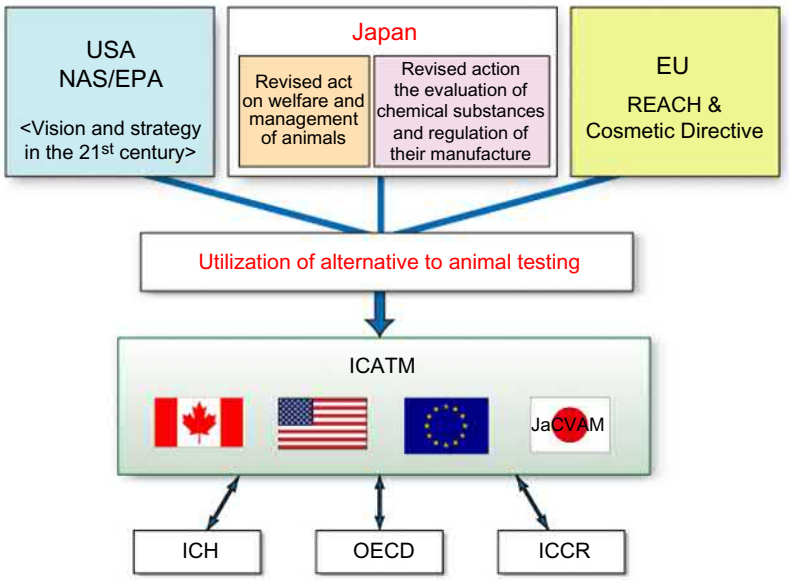

FIGURE 51.9 International Cooperation on Alternative Test Methods (ICATM).

TABLE 51.2 Alternative test methods and testing strategies for chemical warfare agents.

Endpoint	Method name	Test type
Acute mammalian toxicity (oral)	Acute toxic class method	In vivo
	Fixed dose procedure	In vivo
	Up-and-down procedure	In vivo
	Normal human keratinocyte neutral red uptake (NHK NRU) assay	In vitro
	Balb/c 3T3 neutral red uptake assay	In vitro
Acute mammalian toxicity (hematotoxicity)	Colony forming unit-granulocyte/macrophage assay for acute neutropenia in humans	In vitro
Acute mammalian toxicity (inhalation)	Acute toxic class method	In vivo
Acute toxicity testing of pesticides	Guidance for waiving or bridging of mammalian acute toxicity tests for pesticides (acute oral, dermal, inhalation; primary eye and dermal; dermal sensitization)	In vivo
Biologics and vaccines	Enzyme-linked immunosorbent assay (ELISA) for swine erysipelas vaccines batch potency testing	In vitro
	ELISA for human tetanus vaccines batch potency testing	In vitro
	Toxin binding inhibition test for human tetanus vaccines batch potency testing	In vitro
	Batch potency testing of erythropoietin concentrated solution	In vivo
	Deletion of target-animal safety test for batch safety testing of veterinary vaccines after consistency in 10 consecutive batches	NA
	ELISA for in vitro batch potency testing of *Leptospira* veterinary vaccines	In vitro
	Use of humane endpoints in animal testing of veterinary biologics, including rabies vaccines	In vivo
	Veterinary vaccine potency assays: exemptions from standard requirements tests; master reference qualification and requalification	NA
	Cell-based assay for stability and potency of botulinum neurotoxin type A products	In vitro
